Many software tools can be developed to assist with the management of data for a clinical trial. Examples include programs to generate reports on the progress of a study (e.g. accrual, eligibility rates, adverse events, etc.), programs to request missing or overdue data, programs to monitor the performance of participating sites, and programs for the use of the data manager to help with the data processing. The latter could include programs that allow easy inspection of data in the database, or programs that generate status reports of the data for a study. If scheduling software is not available at all sites, the statistical center could also generate patient calendars by computer to assist the institutions with scheduling visits and forms submission.

Distributed Computing

The model described so far is one where paper forms are completed at the institutions and sent to the statistical center where the data are entered into a computer. It is also possible to distribute all or part of the computing system to the participating sites. Again, the extent of distribution depends on the resources available, both in terms of computing capabilities and personnel support. The most common component of a system to be distributed to the sites is data entry, and this has been used successfully in several clinical trials. However, it may not be the best choice for all trials, and careful consideration should be given to the advantages and disadvantages within the context of a specific trial. The main aspects to consider, prior to deciding, are the volume and frequency of data to be collected, the number and stability of participating sites, the likelihood of frequent changes to the protocol or forms, the resources available at the sites and the statistical center, and the need for ready accessibility to data at the sites and the statistical center.

Volume

It is important to have accurate estimates of the volume of data to be collected at each site. Once the volume exceeds the capacity of the available hardware and personnel, the data will get backlogged and the system will be ineffective. If the volume and frequency of data exceed that which can be handled by a single person, then consideration will need to be given to either multiple PCs at the site or a computer environment with a multiuser operating system. There also need to be adequate personnel to deal with the volume of data entry.

Number of Sites

If the number of sites entering patients on the trial is large and subject to fluctuation over the life of the study, it is difficult to build and maintain a distributed system, and the costs may be prohibitively high. If hardware is purchased as part of the trial budget, as sites drop out and new ones join, the hardware needs to be transferred from one site to the other. Staff training to use the system also requires a substantial investment of time and effort. Distributed systems are more advisable in an environment where there are a relatively small number of sites which are likely to be participating throughout the life of a trial. In some environments (e.g. the cancer clinical trial cooperative groups), the large number of trials active at any point in time also makes distributed systems less viable.

Changes to Protocols and CRFs

If the protocol or forms are likely to change frequently during a study, the maintenance burden for a distributed system can be high, as it is essential

that any new software be installed simultaneously at all sites on the day of implementing the change. This requires rapid development and testing of the changes at the statistical center, and the ability to ensure that the new version of the software is implemented at each site. It is important that the changes should not be introduced until the software is ready, otherwise the data collection will be suspended pending introduction of the new software, and this could cause problems. The distributed system is more suited to an environment where there are unlikely to be major changes while the study is in progress.

Resources

Maintaining a distributed system is likely to require more resources than a paper-based system. Before deciding to implement a distributed system, it is important to ensure that there are sufficient resources for purchase and maintenance of hardware and any commercial software being used. Software development staff must be readily available at the statistical center and it is essential that there is ongoing user support to answer questions and deal with problems at the institutional sites. Without this kind of support, the sites are likely to get frustrated with the system. User manuals are also important, and need to be updated quickly as changes are made.

Accessibility to Data

While data entry is the most common function to be distributed, it is possible to pass responsibility for other aspects of a trial to the local site. The site can be responsible for maintaining their own trial database and for quality control of all data entered. In this model, it is important to set rules for the use of data in the local database so that an investigator does not release data prematurely. Because the data will be transferred eventually to the central trial database so that a full analysis can be done, it is important to decide which database is the official database, as changes are likely to be made to the data in both locations. It may also be necessary to define rules for concurrency of the two databases.

If it is important for the local sites to have immediate access to all their data, a distributed system may be the better choice. Examples of this are the use of a dynamic randomization balancing scheme that depends on data available only at the site, or where treatment decisions are based on recent data. It is possible to implement this kind of system in the central model, but it requires rapid transmission of data to the central database and the ability to access the database from the local sites. If there is a need to have data available rapidly on the central system, then distributed data entry may be the optimal solution.

Other Solutions

Optical scanning technology is not yet accurate enough to be a viable option for most clinical trials, although for small trials where all data can be recorded by marking special areas on the forms, it can be used. Error rates for character scanning are still higher than acceptable for a trial.

There is an increasing use of facsimile (fax) machines for submitting clinical trials data and several commercial software packages are now available for implementing this type of system. This provides a hybrid system with data being recorded on paper CRFs at the institution and then sent by fax to the statistical center. Software at the statistical center allows the data manager to review the CRFs and do quality control on-line. Images of the forms can be stored and, if necessary, retrieved and printed.

While a distributed system may seem appealing and, in this time of expanding network communications, the most logical model to use, it is essential that a detailed resource requirement analysis be done prior to deciding on such a system. Distributed systems are most effective in an environment where there are a small number of sites, a limited number of trials, and there is the likelihood that there will be few changes to protocol design or forms during the course of the study. Inadequate resources for personnel or equipment are likely to cause serious problems.

Summary

Good data management is essential to any clinical trial, no matter how large or small. It is important that extensive planning be done and all necessary systems be in place before a trial is activated. Both the CRAs at the participating sites and the data managers at the statistical center play an important role in all stages of the trial, including protocol development, forms design, system testing and implementation,

and in the collection of complete, consistent and objective data.

Data Mining, Software Packages for

Data Mining and Biostatistics

The term **data mining**, often used in conjunction with Knowledge Discovery in Databases (KDD), refers to the identification – within a typically large database – of new, valid, and interesting patterns. The focus in data mining shifts away from that of statistical significance, since many effects might turn out to be significant solely because of the magnitude of the sample size. The techniques of data mining borrow from both traditional statistics and computer science, and include methods such as **exploratory data analysis** tools (suitable for large data sets) and predictive modeling tools such as **regression** analysis, **neural nets**, and decision trees (*see* **Computer-aided Diagnosis**). Exploratory methods include, for example, **cluster** and **principal component analyses**, as well as methods that amount to a combination of dimensionality reduction and clustering such as Kohonen maps (which are in fact a special case of a neural net). Techniques such as market basket or association analysis, in which association rules are identified ("those who buy cheese tend to also buy crackers", for example), are also widespread.

While data mining has become most popular in the context of, for example, database marketing, most of the methods under the data mining umbrella have been widely applied in biostatistics. We detail below which main applications have arisen recently.

Data Mining Techniques Commonly used in Biostatistics

Data mining is frequently mentioned in the context of pharmacovigilance. Reference [17] gives the results of a literature search on data mining, signal generation, knowledge discovery in relation to the detection of adverse drug events (ADE) or pharmacovigilance. Among the methods mentioned are predictive methods such as tree classifiers (*see* **Tree-structured Statistical Methods**) and regression models, and market basket analysis, also referred to as link analysis or association analysis. This latter method consists in identifying rules of the form "if x then y", such as, for example, "if drug A is taken, then event B is observed". Reference [15] presents a Bayesian data mining technique (**empirical Bayes**) to detect ADEs and provide details of the **algorithm**. Reference [3] also proposes Bayesian methods for pharmacovigilance signal detection.

Another major area where data mining is applied is the analysis of microarray data. Microarray data consist essentially of **gene expression** levels (one gene per row) for different samples (one sample per column). The Microarray Core Facility website at Dana Farber [10] describes some of the analysis techniques, mostly clustering, used in this context (to find similar gene expression patterns, for example). Hierarchical and K-means (nonhierarchical) clustering methods are described, as well as the Kohonen map algorithm, which in a nutshell, performs a reduction of dimensionality together with a clustering and produces most commonly a two-dimensional map where clusters can be visualized. These methods are also covered in the book [2] on data analysis tools for DNA microarrays.

We also note the application of principal component analysis to gene expression mapping problems [9]. Reference [14] discusses analysis, prediction and discovery in protein data, and [8] discusses association rules in the context of protein sequence patterns.

In the context of genetics, [7] discusses how the results of a market basket analysis, which can be cumbersome because of the large number of rules identified, can be made more useful to the scientist. Reference [13] describes how CART, Multiple Adaptive Regression Splines (MARS), Random Forests and MCMC (**Markov Chain Monte Carlo**) algorithms can be used, notably to help identify **interactions** in predictors of diseases.

We also mention an application of CART to the modeling of the occurrence of bad glycemic control in a diabetes data warehouse [1], and an application of neural nets to the prediction of **infant mortality** in India [16]. Exploratory **factor analysis** was used by [12] to summarize potential predictors of preterm birth in obstetrical patients. Reference [11] uses empirical Bayesian data mining in the detection of vaccine adverse event detection. Reference [5] applies text mining to the tracking of outbreaks of diseases.

We finally refer the reader to a presentation [6], which summarizes methods commonly used in mining health-related data.

A few Software Packages for Data Mining

In a recent article [4], the authors reviewed five software packages for data mining, in alphabetical order, Clementine (SPSS), Ghostminer, Quadstone, SAS Enterprise Miner, and XLMiner. We refer the reader to [4] for details and report here only a few features of particular interest to biostatisticians.

Clementine is a self-standing SPSS package; it can be run independently of SPSS. It covers all the standard data mining procedures and is relatively easy to install and to use. Ghostminer is a self-standing package with some advantages, as well as strong restrictions (see [4]). Ghostminer is easy to install and to use, and comes with a very good documentation, but is likely to be too restricted for the needs of most biostatisticians. Quadstone is a powerful self-standing package that can deal with very large data sets, but which uses methods that may not be standard to many biostatisticians. For example, there is no obvious way to perform a traditional **logistic regression** analysis in Quadstone. Quadstone comes with good documentation and is relatively easy to use once installed, but is very difficult to install (the installation is meant to be performed by an expert). SAS Enterprise Miner runs in conjunction with SAS, and acts as a special module with its own user interface. It is the most complete of all the reviewed packages, and is relatively easy to use. XLMiner is an Excel add-on (the student version was reviewed in [4]; a professional version is now available) with good capability to perform the most common data mining procedures, such as decision trees, logistic regression, and market basket analysis, for example. File sizes are of course restrained to the allowed Excel maximum. XLMiner is very easy to install and to use.

Most data mining packages, including the ones reviewed in [4], tend to target applications such as in database marketing, where focus is often on the *lift* a model can provide. In a nutshell, this means the following. Suppose an analyst is modeling who is likely to respond to an offer. A model is expected to provide a formula, or algorithm, to score the file, that is to assign a score to each observation as to the estimated probability of response. One then sorts the file from the most likely to the least likely to respond and divides the file into, for example, 10 deciles. The first decile should have a higher response rate (percent of responders) if the model is working well. The ratio of a decile's response rate to the overall response rate is often referred to as the *lift*. SAS Enterprise Miner, as well as Clementine and XLMiner provide lift charts.

Because most readers who use SAS might be familiar with the traditional SAS user interface, we reproduce here (Figure 1) a snapshot of an Enterprise Miner diagram, to give an idea of the different user interface.

We also reproduce typical market basket analysis output from SAS Enterprise Miner (Figure 2). The analysis was performed on the Bookbinders Club Case dataset from the Direct Marketing Educational Foundation.

The first rule indicates that people who bought children and art books also tended to buy geography books.

As for Kohonen maps, we refer the reader to the excellent packages provided by the Neural Networks Research Team at the Helsinki University of Technology (`http://www.cis.hut.fi/research/software.shtml`). Freely accessible libraries for the package R provide – among other tools, many of which will be familiar to readers – functions for decision trees, and some forms of the MARS algorithm, as well as functions that are more specialized to, for example, genetics (see `http://finzi.psych.`

DOMINIQUE HAUGHTON

Data Mining

Data mining is a new discipline, which has sprung up at the confluence of several other disciplines, stimulated chiefly by the growth of large **databases**. The basic motivating stimulus behind data mining is that these large databases contain information which is of value to the database owners, but this information is concealed within the mass of uninteresting data and has to be discovered. That is, one is seeking surprising, novel, or unexpected information and the aim is to extract this information. This means that the subject is closely allied to **exploratory data analysis**. However, issues arising from the sizes of the databases, as well as ideas and tools imported from other areas, mean that there is more to data mining than merely exploratory data analysis.

Perhaps, the main economic stimulus to the development of data mining tools and techniques has come from the commercial world: the promise of money to be made from data processing innovations is a familiar one, and huge commercial databases are now rapidly growing in size, as well as in number. However, there is also substantial scientific and medical interest: philosophers of science have remarked that advances and innovation often occur when a mismatch between the data and the predictions of a theory occurs, and nowadays to detect such mismatches often requires extensive analysis of large data sets. Examples of areas of scientific applications of data mining include astronomy [3] and molecular biology [8]. Genomics, proteomics, microarray data analysis, and bioinformatics, in general, are areas that are making extensive use of data mining tools (*see* **Bioinformatics**; **Genetic Markers**; **DNA Sequences**; **Gene Expression Analysis**).

Apart from the sizes of the data sets, one of the distinguishing features of data mining is that the data to which it is applied are often *secondary*. That is, the data will typically have been collected to answer some other question, or perhaps secondarily in the course of pursuing some other issue (medical records will have been collected for monitoring and treating patients, but can subsequently be analyzed *en masse* in the search for previously unsuspected relationships and causes of disease). Of course, there is no reason – apart from the expense of collecting large data sets – why data should not be collected specifically to answer a particular question, but then the analysis is a more standard statistical one.

The excitement of data mining is also partly a consequence of this secondary nature: it suggests that there is valuable information concealed within the data one already has, simply waiting for someone to tease it out. Unfortunately, the "simply" part of this exercise is rather misleading. Indeed, if it was simple, it would doubtless already have been done. One of the problems is that large data sets necessarily have a great deal of structure in them, but this structure has three major sources in addition to the target one of "important, *real*, undiscovered structure". These three sources are data contamination, chance occurrences of data, and structure which is already known to the database owner (or, if not explicitly articulated as known, sufficiently obvious once it has been pointed out to be of no genuine interest or value – such as the fact that married people come in pairs). The first and second of these are sufficiently important to warrant some discussion.

It is probably not too much of an exaggeration to say that all data sets are contaminated or distorted in some way, though with small data sets this may be difficult to detect. With large data sets, it means that the data miner may triumphantly return an unusual pattern which is simply an artifact of data collection, recording, or other inadequacies. Brunskill [1] describes errors that occurred in the coding of **birth weights**: 14 oz recorded as 14 lb, birth weights of one pound (1 lb) being read as 11 lb, and misplaced decimal points - for example, 510 gms recorded as 5100 gms. Note that all of these errors yield over-reporting of birth weights. A data mining exercise might therefore report an unusual excess of high birth weights (indeed, we might hope that a successful analysis *would* report this), but an excess that was of no real interest. Indeed, it seems that this may have happened [2, 7]. Digit preference is another cause of such curiosities, and is only detectable in large data sets. Wright and Bray [9] describe this occurring in measurements of nuchal translucency thickness, and Hand et al. [5] describe it in blood pressure measurements.

In statistics, one is often able to cope with data inadequacies by extending the model to cope with them. Thus, for example, distorted sampling may be allowed for by including a model for the case selection process (*see* **Selection Bias**), and incomplete vectors of measurements may be handled via

the **EM algorithm** (*see* **Missing Data**). However, such strategies can only be adopted if one has some awareness (and understanding) of the data contamination mechanism. In data mining, with secondary data, this is often not the case. Often, such problems are ignored – with obvious potential for misleading conclusions.

Statistics tackles the possibility of spurious (chance) patterns arising in the data using tools which estimate the probability of such structures arising by chance, merely as a consequence of random variation; that is, with **hypothesis** and significance tests. Unfortunately, with large data sets, and large sets of possible patterns being sought, the opportunity for the discovery of apparent structures is clearly great. This means that the statistical approach cannot be readily applied. Instead, data miners simply define score functions (for the "interestingness" or "unusualness" of a pattern), without any probability interpretation, and pass those patterns that show the largest such scores over to an expert for evaluation. This description reveals the *process* nature of data mining. Data mining is not a "one-off" exercise, to be done and finished with. Rather, it is an ongoing process: one examines a data set, identifies features of possible interest, discusses them with an expert, goes back to the data in the light of these discussions, and so on.

The score functions may be the same as the criteria used in statistical model fitting, without the probabilistic interpretation, or there may be other criteria. An illustration of the differences in perspective is given by **regression** analysis. A statistician may find the maximum likelihood estimates of the parameters, assuming a normal error distribution. In contrast, a data miner may adopt the sum of squared residuals as a score function to use in choosing the parameters (*see* **Least Squares**). Since **maximizing the likelihood** based on a **normal error distribution** leads to the sum of squares criterion, these two approaches yield the same result – but they start from different positions. The statistician has a formal model in mind, while the data miner is simply aiming to find a good description of the data. Of course, the distinction is not a rigid one – there is overlap between the two perspectives.

This example does show how central the concept of modeling is to the statistician. In contrast, data miners tend to place much more emphasis on **algorithms**. Given the essential role of computers in data mining, this algorithmic emphasis is perhaps not surprising. Moreover, when data sets are very large, the popular statistical algorithms may become impracticable (tools that make repeated passes through the data, for example, may be out of the question with a billion data points). Computers are, of course, also important for statistics, but many statistical techniques can be applied on small data sets without computers – many were originally developed that way. One consequence of the stress on algorithms is that it may be difficult to describe exactly what model is being fit to the data. This can have adverse consequences. For example, cluster analysis is widely used in data mining, but without careful thought about the nature of the procedure, it can be difficult to be clear about what sort of "clusters" are being found. Thus, compact structures may be appropriate in some situations (e.g. to produce compact summarizing descriptions, with the clusters being represented by "central" points), while in others, elongated shapes may be desirable, in which neighboring points in the same cluster are similar but distant ones are not. Without an awareness of the type of structure that the method reveals, inappropriate conclusions could be drawn: a species could be incorrectly partitioned on a dimension in which it has substantial variability (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**; **Cluster Analysis, Variables**).

In the above, we have used phrases such as "model", "structure", and "pattern" without defining them. Hand et al. [4] define a model as a large scale summary of a set of data (i.e. as the standard statistical notion of a model), and a pattern as a small scale, local structure. A Box–Jenkins decomposition of a **time series** (*see* **ARMA and ARIMA Models**) is a model, whereas a conjunction of values, which occasionally repeats itself (e.g. a petit mal seizure in an EEG trace), is a pattern (*see* **Clinical Signals**). Models are the staples of statistics, but patterns are something with which it has generally not been concerned (there seem to be three main exceptions: the study of scan statistics, of spatial disease clusters (*see* **Clustering**), and of **outliers**, all concerned with local anomalies). An examination of the data mining literature shows that both models and patterns are important, but narrow views of data mining sometimes fail to recognize the diversity of the tools used. Thus, for example, it is sometimes claimed that data mining is merely the application of

recursive partitioning methods (e.g. tree classifiers; *see* **Tree-structured Statistical Methods**), but this is a parody of the breadth of the field. Likewise, the viewpoint sometimes proposed in the econometric literature, that data mining is merely an elaborate and extensive form of model search (*see* **Model, Choice of**), fails to recognize the various other kinds of data mining activities that go on.

A large number of different kinds of tools are used in data mining – reflecting the eclecticism of its origins. Some recent ones in pattern detection, culled from the data mining literature with no particular objective other than to indicate the diversity of different kinds of methods are: tools for characterizing, identifying, and locating patterns in multivariate response data; tools for detecting and identifying patterns in two dimensional displays (such as fingerprints); identifying sudden changes over time (as in patient monitoring); and identifying logical combinations of values that differ between groups. Some examples of important tools in model building in data mining (again chosen with no particular aim other than to illustrate the range of such methods) include: recursive partitioning, cluster analysis, regression modeling, segmentation of time series into a small number of segment types, techniques for condensing huge (tens of billions of data points) data sets into manageable summaries, and collaborative filtering, in which transactions are processed as they arrive, so that future transactions may be treated in a more appropriate manner.

Much statistical theory is aimed at producing valid inferences from a sample to some population (real or notional) from which the sample has been drawn. This might be so that one can make comparative statements about the populations, or for forecasting, or for other reasons. These methods are also appropriate in data mining, provided one has a sample and that it has been drawn in a probabilistic way (so that one knows the probability of each object appearing in the sample). Going further than this, in many data mining applications one has available data on the entire population (for example, all chemical molecules in a particular class) and then, in model building data mining applications, analyzing a sample from the data set may be a sensible way to proceed. In contrast, however, in a pattern detection exercise, it will typically be necessary to analyze the entire data set: if one is seeking those data points that are anomalous, there is no alternative to examining every data point.

It is clear that data mining will be of increasing importance as time progresses. However, the importance should not conceal the difficulties. Finding unsuspected structures in large data sets and identifying those that are due to phenomena of genuine interest and not merely arising from data contamination or due to chance is by no means a trivial exercise. Issues of theory, of data management, and of practice all arise. General descriptions of data mining include those of Fayyad et al. [4] and Hand, Mannila, and Smyth [6].

Data Monitoring Committees

The randomized controlled clinical trial (*see* **Clinical Trials, Overview**) has become a standard as a research method during the past four decades to evaluate the risk–benefit ratio of novel or existing interventions or therapies. The results of a new or existing intervention are compared with a standard or a control, using clinically relevant outcome measures such as survival, morbidity, or quality of life. Most interventions or therapies should be evaluated by this rigorous comparative methodology before being widely accepted or used in practice. Such evaluation is often required for regulatory approval, especially for drugs and biologics.

For some trials the outcome of the disease or the risks of the therapy may be irreversible. Several issues in the design and conduct of a clinical trial were carefully considered by the Heart Special Projects Committee [13], commissioned by the National Heart Institute of the **National Institutes of Health** (NIH). The report of this committee is often referred to as the Greenberg Report. One of the recommended principles is that comparative trials should be carefully monitored for patient safety and for evidence of benefit. The process is often carried out by a committee, which we shall refer to as the Data Committee Monitoring (DMC). The principles used today in monitoring a randomized control clinical trial are largely influenced by the Greenberg Report. The experience with DMCs has been discussed from several perspectives at an NIH workshop and is described in [7]. Fleming & DeMets [8], DeMets [4], Pocock [20], Fleming [9], Armstrong & Furberg [1], and DeMets et al. [5] discuss various aspects of data monitoring and the role of the DMC. The Task Force of the Working Group on Arrhythmias of the European Society of Cardiology [22] discusses the causes, consequences, and control of early termination, including the role of the DMC. Ellenberg, Fleming, and DeMets provide a comprehensive discussion of DMC organization and activity in their text [8]. This article describes the rationale, responsibilities, and issues that involve the DMC for most trials.

Rationale for Data Monitoring

The goals of a randomized controlled clinical trial are to evaluate the effectiveness of a new intervention, and to assess its safety, so as to estimate the ratio of benefits to risks. One of the ethical principles of clinical trials is that they should continue no longer than necessary to meet the objectives stated in the trial protocol. This is especially true for trials with serious outcomes, such as mortality, morbidity requiring hospitalization, and irreversible adverse effects. Trials may be modified or terminated early if there is overwhelming evidence for a positive benefit to risk ratio, if the evidence strongly suggests harm or a negative benefit to risk ratio, or if the trial has no chance of resolving the primary objectives. Furthermore, if the observed data are not close to the design assumptions, then the trial may need to be modified, such as increasing the sample size, in order to preserve the integrity of the trial. If recruitment goals cannot be achieved in a reasonable time frame, then the viability of the trial must be reassessed. In some cases, logistical or data quality issues must be resolved or the credibility of the trial may be severely jeopardized. All of these aspects must be monitored carefully and considered in the continuation of any trial.

The decision to make protocol modifications, including early termination, is a complex process and several factors must be taken into consideration. This has been discussed by the Coronary Drug Project Research Group [3] and more recently by Fleming & DeMets [10]. Factors include the balance in risk factors between the intervention and control groups, potential biases in outcome ascertainment, compliance to intervention, consistency of results across primary and secondary outcome measures and across clinically relevant subgroups, consistency of results with external information, the effect of repeatedly testing a single outcome or testing multiple outcomes on false positive results, and the impact of early termination on trial participants and future users of the intervention. Examples of these complex decisions have been described for the Coronary Drug Project [3], the Beta Blocker Heart Attack Trial [6], the Cardiac Arrhythmia Suppression Trial [11], and the Physicians Health Study [2]. All of these trials involved early termination, either for an early benefit, an unexpected harmful effect, or for lack of an

effect in the primary outcome. In all cases the decision process was complex and difficult.

A particularly difficult issue is how much evidence indicating potential harm should be allowed to accumulate. In some cases, the choice may be between stopping a trial with a negative trend at the point when the trial has little or no chance to prove treatment beneficial, or continuing a trial with a negative trend until the evidence becomes convincing that the treatment is harmful. In the PROMISE trial [17], which evaluated the drug milrinone in congestive heart failure patients, the trial continued until a statistically significant harmful result was obtained. A similar experience occurred in the PROFILE trial [18], which involved the drug flosequinan in congestive heart failure. Part of the rationale for continuing to this level of evidence was that, unless shown to be convincingly harmful, other beneficial effects of each drug would encourage their continued use in a large patient population. In contrast to this experience, the CONSENSUS II trial [21] with the drug enalapril in congestive heart failure terminated with a negative trend before it became statistically significant. Here, the rationale was that the method of drug delivery would not be used unless it was beneficial. Once the point was reached where that outcome was highly unlikely, there was no reason to continue. In all three cases many factors had to be considered. Another difficult decision is whether the same degree of evidence is required to prove harm as is required for benefit. If the decision process is inherently asymmetric, then the statistical guidelines for data monitoring (*see* **Data and Safety Monitoring**) should also reflect that asymmetry.

While carefully monitoring outcome data in a clinical trial is often ethically mandated, the process of repeatedly examining data also increases the rate of a false positive result; that is, claiming that a difference between two interventions or treatments exists when in fact there is none. Typically, researchers set the false positive rate at 1% or 5% before conducting statistical tests and interpreting P values. However, if a particular outcome such as the primary outcome is tested five times using a P value of 0.05 each time as the criteria for significance, then the actual false positive rate is increased to almost 15%. This is clearly much higher than is scientifically acceptable and five interim analyses are not unusual during the course of a large multicenter trial. This issue is often referred to as repeated testing (*see* **Data and Safety Monitoring**). Another related issue is multiple testing, which refers to conducting statistical tests on multiple outcomes (*see* **Multiplicity in Clinical Trials**), and focusing attention on the one result which has a P value less than 0.05. Clearly, if 20 independent outcomes are statistically tested, then one will by chance alone have a P value less than 0.05. Thus, the ethical mandate of carefully monitoring the outcomes of a clinical trial must take into account the increased chance of falsely claiming a treatment benefit or harm due to the monitoring process. Statistical methods adjusting for the repeated testing and multiple testing have been developed and are discussed in [19, 16], and [14].

To evaluate these diverse factors thoroughly requires a great deal of expertise and experience in clinical trial design, biostatistics, epidemiology, and the subject-matter or disease process involved. No single individual is likely to possess such vast expertise. For this reason, the concept of a monitoring committee evolved, starting with the suggestions made in the Greenberg Report Heart Special Projects Committee [13] (*see* **Clinical Trials, Early Cancer and Heart Disease**). A recent report by the National Institutes of Health has reconfirmed that recommendation [15].

DMC Membership and Responsibility

Since several complex issues must be considered at each interim analysis, requiring expertise from several diverse but relevant disciplines, the membership of the DMC must reflect those disciplines in order to monitor the data and the safety of the patients. The disciplines typically included are the relevant clinical disciplines, laboratory expertise, epidemiology, biostatistics, clinical trials, and medical ethics. Often, three to five individuals are necessary to cover this broad range of expertise. Clinical trial experience by all members of the DMC is highly desirable, but prior experience of serving on a DMC by the DMC chair is essential. Appointment of members may be made by either the sponsor or the trial executive committee, but in either case, the appointments should be acceptable to both parties. The protocol (*see* **Clinical Trials Protocols**) should clearly specify the DMC appointment process.

The authority of this DMC is to review the accumulating data and make recommendations to either

the study chair or the sponsor, or both. While it is rare for a DMC recommendation not to be accepted and fully implemented, the DMC usually does not have the final decision-making authority. That final decision typically resides jointly with the sponsor and the trial executive committee. The trial protocol should carefully specify the lines of the DMC reporting so that any recommendations by the DMC can be properly received and rapidly taken into consideration by those with the final decision-making authority. However, regardless of the lines of reporting, both the trial investigators and the sponsor must be briefed as to the rationale for any DMC recommendation within a reasonably short period of time. Furthermore, the DMC should maintain the view in their deliberations and recommendations that they are primarily responsible to the trial participants, next to the investigators who are placing significant responsibility with them for their patients, then to the trial sponsor, and finally to the regulatory authorities. Any DMC should fully recognize those interests and take them into consideration.

The recommendation of the Greenberg Report was that a trial advisory committee such as the DMC should be independent of the trial. Members of the DMC should not be investigators entering patients or participants into the trial. Otherwise, ethical dilemmas arise as trends in data emerge which are not yet scientifically convincing but could disrupt clinical equipoise about the benefits of the treatment or intervention. In some trials the study chair has been allowed to be an ex-officio member of the DMC, to convey information about the trial to the DMC and to understand better the recommendations of the DMC. In such cases the study chair should not be entering or caring for patients in the trial.

Walters [23] writes that DMC independence is essential for a trial to achieve knowledge with maximum objectivity, respecting the contribution of the patients toward that goal. To be independent, the DMC members should be free of real conflicts of interest, especially since they are reviewing confidential and privileged information. Freedom from any conflict is probably not achievable if the DMC members are expected to have any expertise and experience with the goals of the trial. However, financial conflicts of DMC members should be avoided, including stock ownership and transactions, large consulting arrangements with the sponsor, or frequent speaking engagements on behalf of the intervention. DMC members should at least disclose any consulting or financial arrangements and sources of research funding. If conflicts are identified that could be perceived as serious and possibly damaging to the trial, then the DMC member should either remove the conflict or not continue to participate on the DMC. Neither a sponsor nor a member of a regulatory agency should be a member of the DMC since each has other specific responsibilities and interests and thus is not independent. In some cases, sponsors have been allowed to attend DMC meetings but their role must be limited.

Since the DMC has access to interim results, including primary outcome data (*see* **Outcome Measures in Clinical Trials**), absolute confidentiality is of utmost importance. Results of the trial should not be discussed beyond the DMC meetings and great care must be taken that interim reports are secure. This would include members from sponsoring agencies, should they be allowed to attend. Early in a trial, trends in accumulating data can be quite variable, and any release of early trends could be both misleading and damaging to the conduct of the trial. In some cancer trials, knowledge of interim data and emerging trends had the effect of hampering recruitment and definitive results were not achieved [12]. Of course, if early trends are overwhelming and scientifically convincing, then the DMC might very well recommend early termination. This was the case in the Cardiac Arrhythmia Suppression Trial [11]. However, the DMC must keep interim results confidential until the trial is terminated and the results are properly disseminated.

DMC Meetings

The meetings of the DMC must be structured so that all of the critical elements of a trial are properly reviewed and the patients' safety thoroughly examined. The DMC must meet often enough to carry out its responsibilities. For many trials, the DMC meetings are held at least once a year and may have at least three to five regularly scheduled meetings during the course of the trial. In general, meeting more often than after every 20% increment in patient recruitment or patient outcome is usually unnecessary, and does not lead to substantial gains in early termination. However, it is not unusual to hold an extra meeting if a decision to terminate is approaching. Other considerations such as slow patient recruitment or

unanticipated logistical problems may call for additional meetings of the DMC.

Each DMC meeting must evaluate patient recruitment progress, data quality, baseline characteristics, patient compliance, primary and secondary outcomes, adverse effects, and other safety measures. Interim reports must reflect all of those considerations and can be quite extensive, depending on the complexity of the trial. The DMC must have the authority to request any available data from the trial that is necessary to carry out its primary responsibilities. Reports should be provided through a confidential and secure process to the DMC prior to the meeting so that members have adequate time to review the analysis and identify concerns.

Attendance at the DMC meeting has been discussed by the proceedings edited by Ellenberg et al. [7]. The DMC for the National Institute of Health's AIDS Clinical Trial Group (ACTG) developed a meeting format that addresses most of the concerns of all interested parties [5]. The general format starts with an open session where all interested parties can attend and participate, is followed by a closed session where confidential data are reviewed and discussed by the DMC with the statistical analysis center that prepared the interim report, and concludes with an executive session for DMC members only. Following the executive session, the DMC chair may give the trial chair and sponsor a short briefing on DMC recommendations and any other concerns raised in the closed or executive session.

At the open session, sponsors, representatives of the investigators, and representatives from regulatory agencies may be present to discuss study progress, including recruitment, general data quality, logistical matters such as drug supply or shipment of laboratory specimens, and general compliance issues. Results of other new studies and their impact on the current trial may be discussed as well.

In the closed session, where confidential data are reviewed, the DMC and the trial statistician must be present. For many trials sponsored by the National Institutes of Health (NIH), NIH representatives are present during the closed session. The ACTG DMC did allow NIH representatives to attend, but industrial sponsors who often were also involved did not participate in the closed session. For totally industry-sponsored trials, the practice is not consistent. A few trials have had sponsor representatives present (e.g. PROMISE, PRAISE), but in general this is not recommended routine practice. If representatives of the sponsor do attend, they must abide by the same confidentiality as do members of the DMC, and must not interfere with the DMC deliberations or use the information to affect the trial, unless instructed by the DMC.

The executive session allows the DMC to deliberate and formulate their final recommendations without other influences. This format has been very effective for the ACTG DMC meetings, where several trials are considered during a session, and seems to be useful in many other settings as well.

Summary

The DMC in a clinical trial is central to reviewing accumulating evidence on patient safety and treatment benefit. The complexity of clinical trials makes the decision process to terminate or continue trials challenging and requires a DMC to have a diversity of expertise and experience. DMCs have been utilized in many clinical trials over the past three decades and their value to the clinical trial process is now well established.

DAVID L. DEMETS

Data Quality in Vital and Health Statistics

Data quality is not intrinsically interesting, but it is important. To quote **Greenwood**, writing about this in 1948,

> Most statistics can be used and are used for propaganda; hardly any are used more frequently for this purpose than medical statistics, so the student is once again urged to scrutinize the medical-statistical arguments of very important persons with great care and to verify the statistics used [7].

Analyses can only be as good as the data that underlie them: as the computing aphorism puts it, more succinctly if less elegantly than Greenwood's stricture, "Garbage in, garbage out".

To some extent, like beauty, quality is in the eye of the beholder – assessment of it is dependent on the purpose to which the data are to be put. Nevertheless, there are some general points that need to be considered when using routinely collected vital and health data (termed "routine data" hereafter, for brevity). Before discussing these, however, it is worth considering the particular ways in which data quality is of importance for routine data analyses.

Data Quality in Routine Statistics Compared with *ad hoc* Studies

Data quality is of course not solely an issue for routine data analyses – it is important too in *ad hoc* studies in which data are collected specifically for research. The issues present somewhat differently for routine data, however, for several reasons.

First, routine data sets are often extremely large – this is one of their attractions for scientific analysis, but also potentially one of their drawbacks. Files containing many thousands or even millions of events will inevitably have involved data collection by a very large number of people, often with less-close supervision, or at least less-uniform supervision, than can be achieved in smaller research studies.

Secondly, the data have often not been collected primarily for the purpose to which the research investigator may put them. They may have been collected to fulfill legal obligations, or to supply aggregated large-scale statistics for governmental or administrative purposes, and often it is only secondarily that they are utilized for scientific investigation. As a consequence, the data collection methods and quality controls have usually been organized by individuals who will not use the data for the purposes to which the statistician wishes to put them. In comparison, in an *ad hoc* study, the data collection has usually been targeted deliberately to collect the information the analyst requires. Because of this "second-hand" aspect of routine data, the assessment of quality by the user often has also to be a second-hand process. Information on quality may never have been collected, and often the details of how the data were collected, and with what constraints and instructions, may be known only to those working within the data-gathering organization, whose advice and knowledge may need to be sought.

Assessment of Data Quality

The following subsections discuss issues that need to be taken into account when assessing quality.

Quality of Information in the Underlying Data Sources, Especially with Respect to Diagnosis

Routine data can only be as good as the underlying information from which they are compiled. Thus, for instance, it is likely that advances in diagnostic methods have greatly increased the proportion of leukemias and myelomas that are diagnosed now compared with 50 years ago. Past routine data on these malignancies were highly incomplete, not because of inadequate data collection, but because the cases were often not diagnosed. Similarly, geographical differences in apparent incidence of conditions may reflect better diagnosis in one place than another (*see* **Geographic Patterns of Disease**; **Mortality, International Comparisons**; **Small Area Variation Analysis**).

Incompleteness and inaccuracy of diagnosis may arise at several stages in the process from disease incidence to diagnostic labelling, and each needs to be considered when deciding whether apparent variations in rates are an artefact. There may be variation in whether subjects with illness realize they are ill, and whether they present to a doctor for diagnosis, depending, for instance, on social, financial, and educational factors. If patients present to a doctor, the

diagnosis will depend on factors such as the propensity of the doctor to investigate, his or her diagnostic acumen, whether referral is made to a specialist, and the diagnostic methods and technologies employed, including, for fatal conditions, the extent to which autopsies are performed. Thus, for instance, incidence rates of prostatic cancer have been found to be much greater in Malmö, where "the autopsy service is superb", than in other cities in Sweden, but when cases found "accidentally" at autopsy were excluded, the incidence rates in Malmö and other cities were similar [20]. If screening for a disease is introduced (*see* **Screening, Overview**), then asymptomatic cases will be detected that either would never otherwise have been diagnosed, or would have been diagnosed at a later date after they had become symptomatic; the former detection would be expected to lead to a permanent artefactual increase in rates, the latter to a temporary increase.

For mortality, when a diagnosis has been reached, the quality of the eventual statistics will also depend on how well the person certifying the cause of death (*see* **Death Certification**) (usually a doctor, but not always – see below) knows the patient's past medical history, which diagnosis he or she considers to have caused death (*see* **Cause of Death, Underlying and Multiple**), and the way in which he or she completes the death certificate because the positioning of causes there can affect the underlying cause selected by the coding agency [8]. Studies requesting different practitioners to complete "dummy" death certificates for the same case history have been used to try to ascertain the extent to which, for instance, international differences in certification practice can affect apparent mortality rates [11], and similarly by requesting national statistical offices to code the certificates, to investigate how this coding affects rates [11, 17].

One method frequently used to check the quality of clinical or death certificate diagnostic information is to compare the diagnoses from this source with those reached by autopsy [6, 10]. An often-used general marker of quality of death certificate information in a population is the proportion of deaths recorded as due to senility: a high percentage of deaths certified to this cause suggests a poor quality of diagnostic information, at older ages at least. Quality of diagnostic data is also suggested by its source or basis – for instance, for mortality data, whether the diagnosis is supplied by a doctor or not, and for cancer registrations, the proportion of cases with histological verification, (although new diagnostic technologies, for instance, ultrasound imaging plus serum alpha-fetoprotein estimation for diagnosis of liver cancer [16], can sometimes lead to a reduced percentage histologically verified without reduced quality). For mortality, Alderson [1] gives tables of the extent to which deaths have been certified to ill-defined causes and the percentage of death certificates signed by doctors, in 31 countries (Japan and Western) since early in the twentieth century, and a description of the death registration system in each of these countries over time. For cancer registration (*see* **Disease Registers**), tables of the proportion of cases histologically verified, and other quality indicators – the proportion of cases registered from a death certificate only, the ratio of mortality to incidence, the percentage of cancers for which the primary site is unknown or ill-defined, and the proportion of cases with age unknown – for over 100 cancer registries worldwide, are given in *Cancer Incidence in Five Continents* [16].

As well as differences in diagnostic completeness and capability, routine data will also be affected by medical definitions of diseases, which may vary greatly by time or place, and can lead artefactually to apparent large differences in rates. Thus, for instance, great differences in diagnosis between countries have been shown for psychiatric conditions [3], and substantial apparent secular changes in bladder cancer rates can occur as a result of changes in pathological nomenclature for classifying papillomas (e.g. as "grade O carcinomas") [20].

The above discussion has related to the quality of diagnostic data, but the quality of the source data for other variables such as age, sex, and country of birth, which may be used in analysis, is also important and needs to be considered (see below).

Completeness of Data Collection

For legal reasons, certification of births and deaths is normally virtually complete in Western countries, although there can be exceptions, for instance during wartime [1]. Completeness may be deficient in a particular area within a country: for instance, a study in the West of Ireland, found that in 1966–69, 7.5% of deaths were not registered, and in 1974–77, 6.1% [13]. In the US, satisfactory levels of registration were achieved by different states in different years (the last, of the then-existent states, Texas, reached the level required to be admitted to the

"National Death Registration Area", for which the federal government publishes data, in 1933) [12]. One stratagem to overcome quality deficiencies in particular geographic areas is to analyze only a geographical subset of the overall data set (e.g. particular states), for which good quality data are available.

Registration of morbidity is more often incomplete, and when comparing morbidity rates between places or over time, one must consider whether differences in completeness may explain apparent differences in incidence. Multiple data sources (e.g. death certificates, hospital admissions lists, pathologists' reports) may be needed to gain a high level of completeness, and addition of a new data source, for instance adding death certificates as a source for cancer registration, can lead to an abrupt increase in recorded rates [22]. For cancer registrations [18] and infectious disease notifications [24], countries differ as to whether reporting is legally compulsory, but it is not clear that in practice this affects completeness. In several countries a fee is paid to the notifying doctor for each infectious disease notification [24], but again it is not clear that this provides high completeness.

Often, completeness is better for more-serious than for less-serious conditions, if only because the most serious lead to death. Thus, for instance, nonmelanoma skin cancers (which are rarely fatal) tend to be the worst registered of the common cancers, and notification of infections such as acute poliomyelitis and diphtheria is likely to be far more complete than that for dysentery [21]. For most purposes, substantially incomplete data are very difficult to interpret, especially because the missing data may be biased, but for certain uses they may be serviceable: for instance, if an infectious disease notification system is used primarily to detect epidemics, then it would not in principle invalidate its use if it was substantially incomplete, provided that the percentage incompleteness remained approximately constant over time. Nevertheless, greater confidence can be had in analyses based on reasonably complete data, because one can rarely be sure that the degree of incompleteness has remained unchanged; for example, for measles there is evidence that completeness can differ between epidemic and nonepidemic years, being greater during epidemics [5]. (Of course, if this was reliably the case, then it would actually improve detection of epidemics, although still diminishing the value of the data for scientific uses.)

Assessment of completeness is ideally carried out by comparison with a "**gold standard**" complete dataset collected by independent means, either by an *ad hoc* survey or in another routine data system – for instance, comparison of registration data with death certificates for anencephaly has been used to check completeness of congenital malformation notification [25]. Failing this, however, **capture–recapture** techniques can be used to assess completeness by comparing the data with those collected by other incomplete methods. For cancers, a frequently used but imperfect measure of completeness is the mortality to incidence ratio, comparing the numbers of cancers in mortality and cancer registration data for the same year(s): this can give an approximate guide to completeness, particularly for rapidly fatal cancers, but it is imperfect because it depends on comparable accuracy and precision in identification of cancer site and comparable definitions of place of residence in the two data sets, and on case-fatality and secular trends in incidence and mortality rates, as well as on completeness. It is also imperfect because death certificates are often used as a source of cancer registration, so that incidence and mortality datasets are not independent. Another often-used indicator of completeness of cancer registration is the percentage of cases registered from a death certificate only: a high percentage indicates likely incompleteness, since equivalent nonfatal cases would probably never be registered.

Duplication

Like incompleteness, duplication should not be a problem for mortality and births data in Western countries, but it can be a substantial one for morbidity data. To avoid duplication, the data collection agency must first link multiple notifications that refer to the same person (*see* **Record Linkage**), and then differentiate between genuine double occurrence of the disease or event of interest in the same individual – for instance, two primary cancers incident in the same person, or a particular infectious disease caught on more than one occasion – and inadvertent duplicate recording of the same morbid event, often because it has been reported from more than one source.

Much less tends to be published about the extent of duplication within routine datasets than about their completeness, and this makes it particularly difficult

for the user to be sure to what extent duplication has occurred. One issue that the user may need to clarify is the rules used by data coders to decide what should count as a duplicate – for instance, whether two primary cancers of the same site but different histologies, or two contralateral tumors in paired organs such as kidneys or testes, should count as one or two malignancies; the effect on recorded incidence rates can be appreciable. As another example, for tuberculosis statistics one needs to ascertain whether the data refer to new cases only or to all cases (new and relapses); for some countries the former are not readily available, so that international comparisons may need to use the latter [19]. On a broader question, the user will also need to note whether the dataset is based on persons, disease occurrences, or events.

Having determined the basis of the data set and the rules used for decisions on duplicates, the user needs to compare these with the purpose of the study. Thus, rates of cancer incidence in an analysis including second and subsequent primary cancers will be greater than rates restricted to first primaries; neither is of lower quality for the purpose for which it was intended, but either is inappropriate or of deficient quality if intended for the opposite purpose. Similarly, rates of hospital admission from a hospital in-patient data system, counting two admissions of the same person for the same disease incidence as two records, can give useful information for health care planning, but will generally be unsatisfactory for epidemiology.

Late Registrations, Alterations, and Deletions

Whereas birth and mortality data are normally collected within a few days of occurrence of the event, and will tend to produce complete statistics within a few months, complete collection of morbidity statistics may take several years. For instance, cancer registration inevitably takes a year or two to become reasonably complete: data must be obtained from several sources (for instance, clinical records, pathology records, and death certificates), cross-matched and duplicates eliminated. Furthermore, diagnostic confirmation of an initially suspected cancer may take weeks or months, and cancers initially identified by a registry at death may prove in retrospect to have been incident months or years earlier, and will then need to be registered as having occurred at that date of incidence. Because of these delays, plus the time taken to compile statistics and publish them, cancer registration statistics that are nominally for the same year of incidence may differ appreciably depending on how long after the incidence date they were published. If data are analyzed too soon after incidence, then apparent decreases in rates may prove to be artefacts. Similarly, assessments of completeness of cancer registration need to be conducted sufficient years after incidence, if they are not to confuse lack of timeliness with eventual incompleteness: an apparent recent decline in completeness may be a consequence of premature assessment.

As well as leading to late registration of an event not previously registered, late information may also alter a diagnosis or other variable already recorded – for instance, an autopsy may reveal that a cancer registered years earlier at initial diagnosis was in fact of a different site from that registered, or indeed was not a cancer at all.

Some routine data systems incorporate a specific facility to improve quality after initial data collection, by taking account of new information from subsequent diagnostic investigation: for instance, to amend a death certificate diagnosis on the basis of autopsy findings [23] or to correct (or delete) an infectious disease notification on the basis of laboratory reports [24].

Validity and Precision of Data Collection

Data extraction from original sources, often by clerks, needs to be conducted accurately and without, for instance, miscategorization of adjacent anatomical sites or similar sounding diseases (*see* **Misclassification Error**). Accuracy can be measured by comparison with data re-collected from original sources [2], or by searching the files for the frequency of impossible or unlikely values or combinations, suggestive of inaccuracy – for instance prostate operations on women. It should be noted, however, that this will only provide a proxy for general quality if the data-collecting agency has not already conducted range and consistency checks to rid the data of these particular errors, and that if they have done so, this will not in itself produce a completely "clean" dataset because it will leave all those errors that are not illogical or outside plausible ranges.

Less obviously, but also importantly, apparent rates of a disease will be affected by the extent to which information on diagnosis, even when correct, is sufficiently precise to identify that particular disease, rather than a more vague or general category that includes the disease. Thus, for instance, malignant melanoma of the conjunctiva is coded in the **International Classification of Diseases** to "malignant neoplasm of the conjunctiva" (ICD-9 code 190.3), but the same tumor described as a melanoma of the eye would be coded to a different 4-digit code (190.9), and if stated simply as "melanoma" would be coded to a different 3-digit category (172.9). In more extreme circumstances, if the tumor were simply known to be an eye disorder, unspecified, it would be coded in a different ICD chapter (379.9), and if stated as a death of unknown cause, in another chapter again (799.9). All of these codes are therefore locations where melanomas of the conjunctiva could be allocated, depending on the precision of data available, and the extent to which conjunctival melanoma statistics are valid depends on the extent to which such tumors are precisely specified and coded.

When procedures are introduced to improve precision of information, artefactual increases will occur in rates of precise diagnostic categories. Conversely, discontinuation of such procedures will tend to reduce apparent rates. For instance, in England and Wales from 1881 to 1992, "medical enquiries" were sent to certifying medical practitioners, requesting more precise diagnostic information when a death certificate diagnosis was deemed to be too vague. When this enquiry procedure has been discontinued, for instance, in 1981–82 due to a strike of Registrars, large changes in apparent rates of precise diagnostic categories occurred [23]. The data user can attempt to take account of such changes, first by asking the data collecting agency whether they have used such procedures and when these have changed; secondly by calculating and assessing rates for relevant imprecise ("dustbin") categories in parallel with consideration of the precise category under investigation; and thirdly, by tabulating data by single calendar year and looking for step-changes in rates, which are likely to indicate artefacts (of many types).

As well as the quality of diagnostic data, and of denominators (see below), it is also important to consider data quality, both in source material and in data collection, for variables by which **stratification** or adjustment (*see* **Standardization Methods**) will be made in analysis; for instance, age, sex, and occupation. The percentage of individuals with missing data for such variables (especially age and sex) can provide a useful overall quality indicator, and the extent to which digit preference is present for age (i.e. an excess of ages ending in 0 or 5) can indicate the quality of the age information.

Coding, Bridge-Coding, and Assignment of Underlying Cause

Interpretation of routine datasets is dependent on understanding of the coding system used. This may be an internationally accepted and accessible system, such as the **International Classification of Diseases** (ICD) [26], or, for instance often for operations or occupations, it may be a locally derived classification, which may be difficult to access outside the country. Even when the coding system is internationally agreed, there may be superimposed upon it local interpretations and deliberate deviations. Thus, in England and Wales, mortality coders use in addition to the ICD, a large locally derived manual with numerous instructions on actions to take for particular descriptions of disease for which the ICD does not give sufficient guidance, or the Registrar General has decided that the ICD should not be followed. Similarly, routine data agencies sometimes convert data coded under one revision of a coding system to another, and may not subsequently keep the originally coded data. Interpretation is then dependent on the methods for, and quality of, the conversion as well as the original coding. For instance, for disease coding, since there is not an internationally agreed ICD conversion system, local judgements will have been made, and these may be different from those that the investigator might have chosen.

For underlying cause mortality statistics, the statistical agency must, as well as coding diseases, select the "underlying cause" of death when more than one disease is mentioned on the death certificate (*see* **Cause of Death, Underlying and Multiple**). Again, although there are internationally agreed rules in the ICD for making this choice, local decisions are likely to have been superimposed, and occasionally the ICD rules may deliberately have been broken. For instance, in England and Wales from 1984 to 1992, Rule 3 of the ICD, concerning selection of the underlying cause of death, was deliberately set aside for

individuals with a "major cause" of death such as cancer in part II of the death certificate, but whose cause of death under Rule 3 would have been a "terminal event" such as heart failure or unspecified pneumonia. This change greatly increased apparent mortality from several conditions – for instance a 44% increase occurred in deaths from diabetes and a 22% increase in deaths from multiple sclerosis [15].

The above issues will be compounded when a data set has been formed by aggregation of records collected and coded by several different agencies, rather than only one: for instance, when data for a national morbidity registration system are collected and coded regionally, and then brought together to form a national data set. Artefacts may then occur from each coding source, and also secular discontinuities may occur when there is a change in the level of the hierarchy, e.g. regional vs. national, at which coding is undertaken.

Data Processing and Editing Errors

Clerical processing may produce individual errors or repeated ones (*see* **Data Management and Coordination**). Computers offer the opportunity to create large-scale errors in data at high speed. Often the data have been processed in batches through several stages, and errors may arise if a particular batch is incorrectly processed through a stage, or has a stage omitted. Thus, for instance, cancer registration data from registries using the International Classification of Diseases for Oncology (ICD-O) coding system will need to be re-coded if aggregate data from several registries are to be held and analyzed in ICD-9. Since most codes are the same in these two systems, it may not be immediately obvious if a batch of data has not been re-coded, but the presence of a code that exists in ICD-O but is impossible in ICD-9 (ICD code 169) should alert the user to a likely failure in re-coding.

Computer editing of data can also lead to artefacts. Thus, unknown to the user default values may have been substituted for missing information. In analyses of seasonality, for instance, such default coding for month and day of birth can lead to an apparent large peak of incidence in people born on June 30! Similarly, many editing systems do not allow entry of records with variables missing, and data coders or processors may then invent values, when these cannot be ascertained, to enable records to be entered into the system. One should be suspicious that this has occurred when large datasets, for instance on national mortality, are published with apparently no individuals with missing values.

Denominators

Rates calculated from routine data sources are dependent on the quality of denominators (*see* **Denominator Difficulties**), frequently but not always derived from the **census**, as well as on that of the numerators, to which more attention is often paid. Census data will tend to be reasonably accurate in Western countries, although for groups who are particularly difficult to count, e.g. vagrants, the very old, or immigrants, the quality of these data may be a more serious problem.

Inaccuracy may be a greater problem in population estimates for intercensal years, which need to take account of estimated migration, births and deaths since the last census count. Thus, for instance, Draper et al. [4] found apparent secular increases in childhood leukemia rates of 50% in non-Hispanic whites and 53% in blacks in Los Angeles based on population estimates relating to a previous census, but when the rates were recalculated with denominators that took account of a subsequent census, the increases became only 22% and 24%, respectively.

Numerator/Denominator Discrepancies

A greater problem than the completeness and accuracy of the denominator data is frequently their appropriateness and comparability with the numerator. When denominator data originate (as they usually do) from a different source to that used for the numerator, differences in quality, definitions, and data collection methods between these sources may lead to **bias**. For instance, a census might count university students at their term-time place of residence, but when ill they may return to their parental home for treatment, and hence rates for serious disease in young adults might be underestimated for university towns, especially those where a large proportion of the young population are students. Similarly, the occupational data recorded at the census for an individual will usually be that person's own statement of their occupation, whereas on their death certificate the occupational description will inevitably have been given by someone other than themselves, usually a relative. The relative may view the past career

of the deceased in a flattering light, such that electricians may become electrical engineers, and nursing assistants become nurses, or the relative may report a more prestigious occupation that the deceased left many years ago by early retirement (for instance, military officer or aircraft pilot), rather than a current, less prestigious occupation that might have been reported at the census [14]. In studies of disease risk by country of birth, the census report of an individual's birthplace may be different from that in a relative's statement, and discrepancies can also arise because these two variables are collected at different times, and boundaries of countries can change over time.

Special Issues for Analysis of Clusters and Other Rare Events

As well as the general considerations above, some further issues apply mainly, or with more force, to analyses of spatial or temporal clusters and other rare events (*see* **Clustering**). One is that rates of rare events may be far more disrupted by occasional, random errors or duplications in a dataset than are statistics for the data overall. For instance, a low level of duplication of records can produce an apparently highly significant cluster of cases in a particular small area which is due simply to records for one or two individuals being recorded two or three times, even though overall rates of disease in the dataset will have been little affected by the duplication rate. Similarly, low rates of random **misclassification** between a common and a rare category will have a far greater impact on the rate in the rare category than the common one. For instance, breast cancer is about 100 times more common in women than men. If there is a 1% random error rate in categorization of sex in cancer registration data, this will approximately double the apparent number of breast cancers in men but have a negligible effect on the number in women. Similarly, small random error rates in coding (or data entry) of diagnosis may greatly inflate apparent rates of rare diseases, while having little impact on rates of common diseases.

These considerations suggest that a higher level of data quality is needed for valid analysis of rare categories or clusters than for common categories, and that an effort should be made to verify the original individual records before coming to conclusions on the presence of clusters of small numbers of cases, or rates of rare diseases, within routine datasets.

Record linkage

Many of the most interesting uses of routine statistics relate to linkage between datasets – for instance, linking a births file with a childhood or adult morbidity file to determine whether prenatal risk factors are associated with risk of later disease (*see* **Record Linkage**). It should be noted that the validity of the analyses will be dependent on both the quality of the two datasets to be linked, and the quality of the linkage. Such problems will be cumulated where data are derived by successive linkage, in stages, through several data sets. For instance, in England and Wales notification of incident cancers in study cohorts can be obtained from the National Health Service Central Register (NHSCR); for childhood cancers it has been found that this is 12.5% incomplete, because of the cumulation of shortfalls of a few percent at each of the several stages at which the data are gained, transmitted or linked, starting from initial cancer registration by a regional cancer registry and ending with identification by NHSCR that the cancer occurred in a cohort member, and notification of this information to the investigator [9].

Conclusion

Most epidemiologists have had the disappointing experience of making an apparent discovery in a dataset, only to find on more careful examination that it was in fact due to a deficiency of quality in the data, or to a misunderstanding of the way in which the data were compiled. It is worth paying great heed to data quality, if only to try to ensure that as far as possible one's publications are not similarly in error. As Greenwood noted half a century ago in his discourse on this subject, "This may involve a little trouble – which is worth taking. One should *never* believe that a disease is becoming more, or less, deadly until all other explanations have been excluded" [7].

Database Systems

The word "database" is used here in two overlapping ways to refer to a collection of related data and its storage method, or to programming system software used to organize and integrate a collection of related data. It is management, access, and control (including efficiency and recoverability), not necessarily size, which distinguish a database from a data set [23]. There are other definitions of "database"; see, for example, [21]. The following concentrates on database software: choosing a database management system (DBMS), designing databases, and resources that might be helpful.

Defining a DBMS as "a collection of programs that enables users to create and maintain a database" [8], Date [6] identified the following benefits of using a proper DBMS. First, data can be shared securely. Secondly redundancy can be reduced, inconsistency avoided, and integrity maintained – that is, you have the data you intended to hold, with no repeats, unexplained absences or anomalies. Thirdly, data independence can be achieved – the user does not need to know how or where the physical data are stored, but instead identifies tables and variables by name. Finally, and best of all, (conflicting) requirements can be balanced – and standards can be enforced.

What a DBMS Stores

A DBMS can store data, which are usually alphanumeric, but increasingly include images, sound, and free-format text for multimedia application, as well as the following types of information:

1. "Business rules", namely database description tables containing extra information about the data not immediately apparent from the data – for instance, that a given field cannot be omitted, or that gender must be "M" or "F". A good relational DBMS (RDBMS) can enforce business rules for you (retrospectively) when required.
2. A data dictionary describing the data, and who has access to them, namely the authorization tables and the current access tables.
3. Audit and system performance information.

What a DBMS Does

For the user, a DBMS (and third-party tools that work with it) might offer: database design tools with a data definition language; database administration tools; a data manipulation language, or query language, to query and update information; data-entry screens and screen designers; interfaces to other applications or programming languages; and reporting and statistical summary tools.

Uses of Databases in Biostatistics

As well as all the typical accounting and administrative uses, databases are used in biostatistics for:

1. Administering studies – storing names and addresses of subject participants, generating letters and labels, allocating interviewer schedules, creating progress reports.
2. Collecting data – with answers or results typed straight into a laptop or notebook, or downloaded directly from a measuring instrument.
3. Managing data – data entry, storage, and secure access to all types of data.
4. Analyzing data – validation, description, modeling and analysis.
5. Documenting studies – even the study design can (and should) be stored in a database!

In fact, the limiting factors for how widely databases are used are more likely to be time, energy, and money than database shortcomings!

A Brief History of Databases

The history of databases parallels part of the history of computing. An overview of the history of computing can be found at `http://ei.cs.vt.edu/~history/index.html`. The earliest true DBMSs appeared in the 1960s. For example, in 1960 a new language, COBOL (for "Common Business Oriented Language"), had the novel approach of separating data description from programs – in a database – so data could be easily reused across applications. Programs could then refer to established variable names.

Early databases were built for speed, not flexibility. Database design was dependent on anticipated use. For example, in an (imaginary) early hospital

patient appointment system, you would have had a link from a patient to the point on a file where her appointments began, then all her appointments would be listed one after another. In this "hierarchical" database, some operations would be easy (finding all the appointments a patient had), some would be hard (adding a new appointment meant rewriting the whole file), and some almost impossible (finding all the patients with appointments falling on a certain day). To solve the latter two problems, more links (often called "pointers") were added to records. Then our imaginary patient would be linked to her first appointment, that to the next appointment, with her last appointment completing the circle and joining back to the patient. The name of the committee that made COBOL, CODASYL, is still used in discussions on such "network" DBMSs. The main drawback of CODASYL databases is that they are obscure to program – you need to know which way the links point. In 1997, experienced COBOL programmers are being called out of retirement to check code that might have the "millennium bug" – an artifact of treating all dates as belonging to the twentieth century.

In 1970, Codd [4] proposed a theoretical table-based data storage model, and a universal data manipulation language. His ideas (expressed concisely as a set of 12 rules in 1985 [5]) have yet to be fully realized, but his RDBMSs and Structured Query Language (SQL) are now common, developed by IBM's DB2, Ingres, and Oracle from the mid-1970s, to name a few of the industry leaders. In fact SQL is the standard for both the International Organization for Standardization (ISO) and the American National Standards Institute (ANSI) – see `http://www.jcc.com/sql_stnd.html` – so there is some cross-vendor portability. These fully implemented RDBMSs were (and are) hard to administer – Oracle, for instance, recommends identifying a database administrator (DBA) who should have 2 weeks' training before trying to install any software, with a week's extra training on "tuning". Even writing a data-entry screen is a professional job. It is also very expensive!

The 1980s saw an explosion in personal computers and simple, file-based databases. In these the data structure (as well as the number of records to expect and the length of each record) is held at the top of a data file. Joining data from different files is possible, but not intuitive – but as most people (biostatisticians included) still enter and look at data one table at a time, software like Ashton Tate's (now Borland's) "dBase" remains enduringly popular 10 years on.

For computer users, the 1990s have been characterized by the emergence of graphical user interfaces (GUIs). Accompanying this development has been the need for databases storing nonalphanumeric data – video, audio, images, free-format text – that is, "object" or "multimedia" DBMSs. GUIs also encourage a conceptual separation of the "client" (a program that shows data) and the "server" (a DBMS that manages it). Much effort has been put into hiding the connection between these components. Newer, mouse-driven databases, like Microsoft's "Access", can be self-contained, or can connect transparently as a client to SQL servers over a network, or even over the **Internet**. This "scalability" comes at a price – and setting up a client/server database is (currently) hard and expensive.

Choosing Software to Manage Data

For biostatisticians involved with drug trials (*see* **Pharmaceutical Industry, Statistics in**), the choice is straightforward – SAS (*see* **Software, Biostatistical**) is the *de facto* standard for statistics and data management (see [22] and `http://www.fda.gov/cdrh/ost/points.html`), combined optionally with an industry standard SQL server such as Oracle. However, these are too expensive (involving costs of the same order of magnitude as the servers on which they run) to be a default option outside the drug industry.

Many statisticians manage data in their statistics package of choice, be it (at increasing cost) EpiInfo, Stata, or SPSS (*see* **Software, Biostatistical**). Many health professionals keep data in spreadsheets like Microsoft's Excel (*see* **Spreadsheet**), but care needs to be taken to separate formatting and data.

In buying database software, the first consideration relates to the capabilities required of the database. Is a fully implemented DBMS (such as Oracle) necessary, or is a personal database (like Access or FoxPro) sufficient? Practical issues that suggest a fully implemented DBMS are:

1. More than one person needs to see the same data at the same time.

2. You have a large data set. The limiting factor is not the size of the file, but how quickly you can access it.
3. You have a complicated data set – some smaller databases are unable to make links on more than one variable, or links back to the same table.
4. You are storing unusual types of data (not text or numbers).
5. Your data must be securely managed, protecting confidential data through passworded access, and with a robust backup regime (*see* **Confidentiality and Computers**).

Of these, confidentiality and multiuser access are the two main reasons to centralize data, though limiting factors are that you need networked computers with a server (which rules out laptops, unless you enjoy configuring modems); financial resources; and that there is someone available to run a larger installation – the DBA. The aim is to use appropriate technology. In practice, we tend to differentiate small databases that require daily access by one person (like the administrative databases that are used to recruit and monitor study subjects) and larger multiuser databases that store study data sets.

Once the DBMS level has been decided, questions that help to differentiate products include:

1. How easily can I get data in and out? It should not require programming to upload existing data sets or download data for analysis!
2. Does it "talk to" my statistics package? Often part of the "data dictionary" (variable names and labels, missing value codes, groupings) is lost in transit.
3. What sort of access am I after? Most databases are optimized for quick look-ups and data entry ("transaction processing"), but sweeps through the data can be very slow.
4. Can it handle the throughput of data I have in mind? Uploading tables can be time-consuming.
5. Can I and do I have to program, or can I use a mouse-driven interface to create and manage data? A good package will allow both styles of access.
6. Do I need a new computer? Some laboratory databases are supplied on a "free" computer, usually a PC or Macintosh. For data work in the field a notebook might be necessary. And, a big data set might require more memory, or a faster disk.
7. How much will it really cost? Pricing policy is not always clear.
8. Most important of all, can I get help?

Choosing Between SQL Servers

DBMS Magazine publishes comparative reviews of the leading server-sized DBMSs periodically (see `http://www.dbms.mfi.com/9611d52.html`). Criteria used last time (November 1996) were adherence to the relational model and SQL standards, ability to store nonalphanumeric data (binary large objects or BLOBs), and availability of communication extras. The following "big six" industry leaders were compared: Oracle 7; Sybase; Informix-online; Microsoft SQL Server; IBM's DB2; and CA-OpenIngres.

Database Design

Usually we cannot "optimize" our data structures – they reflect a questionnaire or some other pre-given study data – but some effort is needed to "normalize" data. This is the process of squeezing repeating data out of the main data sets and into look-up tables and subtables. A simple example of a look-up would be giving doctors codes in a hospital database rather than repeating their names endlessly. More problematic is repeating subsets of data – so, in coding drugs, do we allot space for a fixed number (subscripting the variables drug 1 to drug n), or do we start a separate table for drugs, one line per patient per drug? Good database design practice suggests you do the latter, though this "entity-relationship modeling" suffers from diminishing returns. Fortunately products like Logic Work's ERWin data modeling toolset exist to help you – at a price!

A modern DBMS is often described by a task it might be good for: data warehousing, data mining, on-line analytical processing (OLAP), decision support, and management information systems (MIS). All of these mean that data are indexed and possibly stored for maximum efficiency of collation, not (as is the usual case) for speed of individual row selection ("transaction processing"). The jargon obscures a useful tip: that maybe we can design our databases to make analysis easy. In contrast to

the normalized model, the design of a data warehouse is one big table per topic, with only one level of look-ups around it. This star-shaped model (or "multidimensional" database) is far easier to analyze.

Database Interfaces

Many fourth-generation language (4GL) tools are available to build graphical interfaces to databases – newer, personal databases like Access and FileMaker include their own drag-and-drop "Form Wizards", but more scalable products include Powersoft's PowerBuilder, Oracle's PowerObjects, or Borland's Delphi for data-entry design, and Seagate's Crystal Reports for report generation. These are useful if you need a slick presentation for inexperienced computer users. Making pleasing interfaces is very time-consuming, and, as data entry is usually quicker without a mouse, these tools (if bought separately) are often a luxury.

Recent Developments

Relational databases are a mature technology in computer science, having remained remarkably stable over the last decade. Improvements have not changed the fundamental relational database management system (RDBMS) framework. Accordingly, the previous article (from the previous edition of this encyclopaedia) stands as a useful reference. This addendum notes changes in RDBMS usage, and describes the recent development of object-oriented techniques and multimedia databases.

Increments

Improvements to RDBMS have occurred in speed, storage capacity, network capability, and programming language interfaces. General changes in computing infrastructure, such as the continued growth of the internet, faster networks, faster processors, cheaper memory, and cheaper storage have encouraged these changes. Formerly, specialized areas such as data mining and distributed databases have become more widely available.

The open source movement has made this formerly expensive software free to all. The major free RDBMS are MySQL [10] and PostgreSQL [11]. Not free, but still a low cost option for many, is the Microsoft Access database, supplied as a standard component of Office Professional Edition [12]. Databases now form the back end to a multitude of websites, from the smallest personal sites to major online retailers such as Amazon.com [13].

Associated with the increase in usage, means of connecting to databases have also greatly multiplied. Middleware, which inserts a *database driver* between database and application, offers a wide variety of programmer interfaces, pre-built reporting and analysis packages, and graphical interfaces. These all rely on a standard low-level programmers' interface to the database system, such as Microsoft's ODBC [14] (Open Database Connectivity) and Sun's JDBC [15] (Java Database Connectivity). There is a plethora of middleware available for developers, supporting database access from many platforms, languages and across many network protocols; no major development project can afford to be without it [3, 20].

New Developments

Major new database techniques have arisen from use of the object-oriented programming paradigm [1]. In object-oriented programming, the focus is on considering a piece of information as a whole. For example, a "patient" can be considered as having attributes such as a name, address, condition, X-ray images, CAT scan images, and drug treatment history – all of which are stored together. There can also be subtypes of patient, where each type "inherits" the basic structure from the standard patient record, then adds specific information relevant to the group. Thus an "oncology patient" can have very different records to a "maternity patient", while keeping the basic patient data in common. This contrasts with the normal relational model, where information about a patient is scattered across many separate tables, and a set of complex Structured Query Language (SQL) queries may be required to collect everything known.

While this sounds admirable, it also has disadvantages [7]. The separation of data in the relational model is done to prevent repetition, and is an essential part of preserving data integrity. This must be handled in some other way in an object design. Also, the types of objects potentially in use are so varied that specialization remains necessary. There is thus no fully standard way of querying object databases;

each vendor supplies a different query language. A consortium of object database developers, the Object Data Management Group (ODMG) [24] did propose a standard (OQL) [2] in the early nineties, which was not much implemented.

OQL did have a major impact on the design of the 1999 release of ANSI SQL 3 ("SQL99") [16]. SQL99 is not a fully object-oriented query language; it is instead a superset of SQL92, with extensions for generic object structures. Any database implementing this is thus able to function as a standard RDBMS that uses the older SQL92 conventions.

Since SQL99, major vendors have supported steadily more object features in a more standard way. Even so, pure object-oriented database management systems (OODBMS) still tend to go their own way. Pure object-oriented database systems also remain rare, although they have found some success in niche markets. Object relational database management systems (ORDBMS), which implement most of SQL99, are being provided by major vendors including Oracle and IBM, and more recently Microsoft. These form the main stream of current database technology [19].

The ORDBMS is still a fully functional relational database, but has object capabilities added. Naturally, these additional capabilities vary across products. For example, all ORDBMS databases have internal table structures allowing inheritance, but many RDBMS have minor extensions such as support for storing data types other than text and numbers in table columns, with the minimal addition being the binary large object (BLOB) type. Major vendors mostly provide an object layer, in which the database designer specifies the object structure as it maps to the table structure. This relieves SQL users of the programming complexity needed to retrieve data, but hands that complexity over to the database designer. Normal SQL users can query the objects using a simple syntax, without needing to know the details of how the objects are stored.

An important feature of ORDBMS is its support of the notion of abstract data type (ADT). This feature allows database designers to specify objects with associated methods (functions). The database knows only the names of the methods, and that these take input and produce output of specific types. For example, a "photo" data type might have a method to return size in bytes, as an integer; another method to return file type, as a text string; a function that tells whether the picture is of a naked human being, as a Boolean; and another Boolean function that tells whether the picture is of a horse. The first two of these are simple; the latter two either rely on a human evaluation that is stored with the photo file, or on a complex function based on the colors and shapes in the image – indeed, a very interesting problem that no one has fully solved [9]. And yet the user can input queries without knowledge of any of these details.

Multimedia database systems currently tend to be ORDBMS, containing files with manually entered textual descriptions of the object contents. Multimedia systems that are purpose built for film and television may include a bundle of viewers, media files, and relational tables describing the data, together with ADT definitions specifying how data may be viewed and how it must be synchronized. While the common understanding of multimedia limits the binary files to image, audio or video, there is no real restriction. The same problems of storage and search of large sets of large binary data files arise whether one wishes to search television broadcast archives, fingerprints, MRI images, or X-rays [18].

While the size of the data can impose scalability problems for storage and retrieval times, the more difficult questions arise in identifying and searching items that are in some sense similar. Similar numerical and textual values can easily be retrieved with an SQL query, by approximate text matching or numeric ranges. But what counts as "similar" for an image, sound, or video? Classification of data by computational means continues to be a difficult problem, and often highly specific to a particular field. For example, the program that tells whether an image contains a naked human will not be able to tell if it contains a horse, nor whether the image is scanned from a photograph or a Rembrandt oil painting. While support for querying on spatial and temporal relations is currently being addressed with the development of a further SQL extension, SQL/MM [17], there are many problems that remain the subjects of active research.

Resources

Excellent current information is available from the World Wide Web. Some sites with good links, besides DBMS Magazine Online, include: Database Systems Laboratory, University of Massachusetts (`http://www-ccs.cs.umass.edu/db.html`)

which has an extensive collection of links to research and development sites (by specialty), journals, textbooks and manuals, newsgroups, and conferences, as well as to general sites and vendors' details; University of California at Berkeley DBMS Research Group, (`http://s2k-ftp.cs.berkeley.edu:8000/postgres/otherdbms.html`) which has links to vendors and standards (this group authored Postgres, the best server-sized free database); the Association for Computing Machinery's Special Interest Group on Management of Data Information Server, or ACM SIGMOD (`http://bunny.cs.uiuc.edu/`), with links to free software summaries; and Cetus Links: Object-Orientation/Databases (`http://www.rhein-neckar.de/~cetus/software.html`), for everything to do with object-oriented databases (the recent spate of "universal" databases are mixed object/relational databases).

Principal vendors (see the "big six" list above) have Web pages. For personal/desktop databases, the choice is large, but the best known are: Access, from Microsoft; FileMaker Pro, from Claris Software; Visual FoxPro, from Microsoft; and Visual dBase, from Borland International. All of these have Web pages. A "Catalog of Free Database Systems" can be found at `http://cuiwww.unige.ch/~scg/FreeDB/`.

N. WALKER & CATHERINE LAWRENCE

de Finetti, Bruno

Born: June 13, 1906, in Innsbruck, Austria.
Died: July 20, 1985, in Rome, Italy.

Although born in Austria, where his father was designing and building a railroad, de Finetti was Italian. He attended Milan University, where his work came to the attention of Corrado Gini in Rome, whom he briefly joined. He became an actuary in Trieste and held academic posts there and in Padova. Finally, he returned to Rome as a professor. Although he is mainly recognized today as a leading **probability theorist**, he was much concerned with practical applications and regarded probability as an essential tool in the business of life. He believed in an economic system that combined Pareto optimality with a notion of equity, far removed from the notion of greed that, in his view, permeated capitalism.

For de Finetti, the sole interpretation of probability was a number describing the belief of a person, conveniently referred to as "you", in the truth of a proposition. He coined the aphorism, "Probability does not exist"; meaning that it has no reality outside the individual's perception of the world. Probability describes a relationship between you and that world and is not solely of that world, as others contend. For any uncertain quantity X, he introduced the prevision $P(X)$, a number you use to replace X, in the sense that you would engage in *any* transaction that would yield you $s[X - P(X)]$, for sufficiently small s. For a proposition, $X = 1$ (true) or 0 (false), $P(X)$ is your probability that the proposition is true. The rules of probability easily follow in some beautiful, simple mathematics. Generally, prevision plays the role ordinarily occupied by expectation. Previsions that do not lose you money for sure, in a set of the above transactions, are said to be coherent. He established a basic theorem that shows how a set of previsions $\{P(X_i) : i = 1, 2 \ldots n\}$ impose constraints on a further, coherent prevision $P(X_{n+1})$. In this view, the scientific method results in a set of coherent judgments about the world.

In another theorem he showed how this personalistic approach included frequentist views of probability as a special case. If your previsions for a set of 0–1 quantities obey a condition he called **exchangeability**, then the theorem shows that the frequency of quantities that are one will tend to a limit, about which you have a prevision. Since most situations studied in modern statistics incorporate some form of exchangeability, they can be included in the personalistic view. The procedures it recommends are often different from those adopted by frequentists. His approach was Bayesian (*see* **Bayesian Methods**), but he differed from many Bayesians, like **Harold Jeffreys**, in refusing to admit that any value of a probability was more rational than another. You could coherently have one view, I another, and both be rational. Uncertainty is only removed, and agreement reached, by the accumulation of data.

He wrote extensively on the teaching of probability. He held that children should study uncertainty from an early age. In particular, they should be encouraged not to answer "yes" or "no" to a question, when in reality they were uncertain about it, but respond with a probability. He developed scoring rules to assess abilities from such responses. These have found use in medical diagnosis.

De Finetti's views are so original, and his style so parenthetical, that his writings are difficult to understand, even when he writes about statistical issues. His mathematics is always simple and he abhorred much technical writing. He does not use the term **random variable** for X above. There is nothing variable about it; it is a fixed quantity the value of which is uncertain for you. Those who have the patience to follow his writings find them immensely rewarding and correct. His first, important papers date from the early 1930s, but most people, especially those who do not read Italian, will find the most accessible approach to his work in the books from the 1970s [1, 2]. Of all statisticians of this century, **Fisher** and de Finetti are the true geniuses.

DENNIS V. LINDLEY

de Moivre, Abraham

Born: May 26, 1667, in Vitry, France.
Died: November 27, 1754, in London.

Abraham De Moivre is celebrated by statisticians primarily for his derivation of the normal approximation to the **binomial distribution**, and for providing the first tabulation of the normal integral (*see* **Normal Distribution**).

He studied the humanities and mathematics at the Protestant University of Sedan, and later at the University of Saumur and the Sorbonne. After the repeal in 1685 of the Edict of Nantes, he suffered imprisonment, and to avoid further persecution as a Protestant he emigrated to London in 1688. There he worked as an itinerant tutor, and adviser to gamblers and brokers, and was elected to the Royal Society in 1697. His famous work, *The Doctrine of Chances: or a Method of Calculating the Probability of Events in Play*, appeared in successive editions in 1718, 1738, and 1756. His result on the normal approximation to the binomial appeared first in a separate paper in 1733, and used what is now known as Stirling's formula. He seems to have regarded the normal curve merely as a means of approximation, rather than as a distribution in its own right.

De Moivre published also a standard work on annuity theory, *Annuities upon Lives*, in 1718 and 1743 (*see* **Actuarial Methods**). As noted in [1], De Moivre's scope was limited; he excluded from consideration all the forms of insurance then practiced in London (fire, life, and maritime).

For fuller descriptions of De Moivre's life and works, see [2] and [3].

PETER ARMITAGE

Death Certification

The processes through which a civil registration and **vital statistics** system is informed of the facts about each death occurring within its coverage area may involve information supplied by several different informants. Relatives or friends may supply personal particulars of the deceased either directly to the civil registration authorities or indirectly through a funeral director or other intermediary who then gives the information to a civil registrar. However, the legal determination of the fact of death and the statement of the medical **causes of death** are usually the responsibility of an attending physician. In the absence of an attending physician or in the case of death resulting from actual or suspected violence (e.g. accident, suicide, homicide), a medical/legal officer usually investigates to determine the medical and legal facts of the case. In many civil registration systems, the medical/legal officer is known as a "coroner" or "medical examiner" whose specific responsibilities are prescribed by law. The physician or medical/legal officer is required to certify, to the best of his or her knowledge, that the death took place at the time and place specified and was due to the causes recorded on the death certificate. In some countries a shortage of trained medical personnel makes this process impossible or impractical to carry out, but in those vital statistics systems where deaths are attended just prior to death or reviewed after death by qualified medical practitioners, the **World Health Organization (WHO)** recommends a specific format and procedure for the certification of cause of death. The WHO recommendations are based on the concept that for each death occurring, one and only one "underlying cause of death" is to be determined, counted, and statistically analyzed (*see* **Cause of Death, Underlying and Multiple**). WHO defines the underlying cause of death as "(a) the disease or injury which initiated the train of morbid events leading directly to death, or (b) the circumstances of the accident or violence which produced the fatal injury". WHO further recommends the use of the International Form of Medical Certificate of Cause of Death (Figure 1), which is designed to facilitate the selection of the

Cause of death		Approximate interval between onset and death
I Disease or condition directly leading to death*	(a)	. . . . .
	due to (or as a consequence of)	
Antecedent causes Morbid conditions, if any, giving rise to the above cause, stating the underlying condition last	(b)	. . . . .
	due to (or as a consequence of)	
	(c)	. . . . .
	due to (or as a consequence of)	
	(d)	. . . . .
II Other significant conditions contributing to the death, but not related to the disease or condition causing it	. . . . .	. . . . .
	. . . . .	. . . . .

**This does not mean the mode of dying, e.g. heart failure, respiratory failure. It means the disease, injury, or complication that caused death.*

Figure 1 International form of medical certificate of cause of death

underlying cause of death based on the sequence of morbid events reported by the medical practitioner [1].

The medical certificate shown in Figure 1 provides a uniform format for the medical practitioner signing the death certificate to indicate which condition led directly to death and to report any antecedent conditions which gave rise to that condition. The medical certificate is designed to facilitate the selection of the underlying cause of death when two or more conditions are recorded. If only one condition is reported by the certifier, this single condition should be recorded on line (a) of Part I of the Medical Certificate of Cause of Death and is considered as the "originating antecedent cause". If there is more than one condition involved in the train of events leading to death, the direct cause is entered on line (a) and antecedent causes are entered on lines (b), and, if needed, (c) and (d). The lowest used line reflects the originating cause, and the causes entered on the other lines reflect, in sequence, the train of events leading to death. Therefore, in a properly completed Medical Certificate, the lowest used line in Part I is considered to be the originating antecedent cause. Usually, the originating antecedent cause corresponds to the underlying cause of death, the condition used for statistical tabulation and analysis. However, in some circumstances the originating antecedent cause may be superseded by a condition more suitable for use as the underlying cause of death. In cases where the certificate does not appear to be properly filled out (e.g. the reported sequence does not make medical sense, or the originating cause is a vague or nonspecific condition and there are other more specific conditions reported elsewhere on the certificate), there is a set of international rules promulgated by WHO for selecting an underlying cause of death. The selected underlying cause may then be modified by additional rules to make it more useful for statistical and epidemiologic purposes. These rules are particularly useful when it is impractical or impossible to query the medical practitioner who completed the certificate in order to obtain clarification or a more definitive description of the conditions leading to the death. While the rules may, in individual cases, appear to be arbitrary, they are intended to yield improved mortality statistics overall.

When determining the underlying cause of death from conditions recorded on a medical certificate, the international rules and guidelines first call for the application of the General Principle, which states, "... when more than one condition is entered on the certificate, the condition entered alone on the lowest used line of Part I should be selected only if it could have given rise to all of the conditions entered above it". If the General Principle does not apply, there are three Selection Rules that are to be applied sequentially until an originating antecedent cause is identified. However, that originating cause may not be the most useful and informative condition for statistical tabulation and analysis. For example, if senility or a generalized disease such as hypertension has been selected, this is less useful than if a reported manifestation of the aging process or of the hypertension had been chosen. Further, it might be necessary to modify the selected condition to conform with the requirements of the **International Classification of Diseases (ICD)**, either because a single code in the classification might represent two or more conditions that were both reported, or because the classification may give priority to a particular cause when it is reported with certain other conditions. Accordingly, there are six Modification Rules intended to improve the utility of mortality data. The Modification Rules are applied after the selection of the originating antecedent condition. Some Modification Rules require further application of the Selection Rules, resulting in an iterative process of selection, modification, and, if necessary, reselection before an underlying cause of death is determined [2].

In the case of perinatal deaths, WHO recommends a special Certificate of Cause of Perinatal Death. This certificate provides a section for the medical certifier to list diseases or conditions in the fetus or infant as well as maternal diseases or conditions which affected the fetus or infant. In the 10th Revision of the International Classification of Diseases (ICD-10), the perinatal period is defined as the period beginning at 22 completed weeks of gestation and ending at seven completed days after birth. WHO provides a special set of rules for the certification of deaths occurring during this period [3].

Death Indexes

An important aspect of follow-up studies (*see* **Cohort Study**) is the ability to determine which members of the original study cohort have been lost to follow-up because of death, and for many such studies, in addition to the fact of death, the **cause of death** is an essential piece of information. In places where a central register of all deaths is compiled (e.g. population register, or civil registration system) and is available for research use, the identification of individuals in a study who have died during some time period can be accomplished, provided that the necessary identifying information is available. However, even under relatively ideal circumstances, it is sometimes difficult to match study individuals against lists of deaths with 100% certainty that a correct match has been achieved. Most follow-up studies try to match on several variables (e.g. surname, given name, date of birth, mother's maiden name, etc.) and develop algorithms to establish "presumptive matches" (*see* **Matching, Probabilistic**).

While the fact of death is, in most jurisdictions, considered public information, the cause of death may in some places be considered confidential and not releasable to researchers without the expressed permission of a next of kin or legal representative of the deceased. Because of **confidentiality** provisions, some custodians of death files require study protocols to be reviewed for adequate privacy safeguards before authorizing the release of cause of death data.

In a few countries, the problem of adequate follow-up for deaths occurring amongst a cohort is further complicated by the existence of only decentralized death files. A notable example of this is the US where the primary responsibility for registration of vital events rests with the individual states. For many years it was necessary for "death clearance" of study cohorts for researchers to send their list of study participants to each of the more than 50 registration areas to determine if any of their subjects had died there during some stated period of time. This was a costly and time-consuming process and tended to stifle certain kinds of epidemiologic research. In addition, each state has its own laws and procedures regarding confidentiality and release of information. Therefore, in spite of the fact that there was a central statistical file for national **vital statistics** purposes located at the US **National Center for Health Statistics**, the states provided their data with the restriction that the Center not release individual record information without the consent of the states. After lengthy negotiations, an agreement between the states and the National Center for Health Statistics resulted in a US National Death Index which was designed to address these issues. To utilize this index, researchers submit their study protocol to a committee comprising selected state registration officials, federal officials, and representatives of the health research community. If this committee determines that the proposed study is bona fide research and not a commercial activity, and includes appropriate steps to protect confidential information and privacy, the protocol is approved and sent to the Director, National Center for Health Statistics, for final approval. Once the study has been approved, the National Center receives annual lists of study participants from researchers containing the required variables for computer matching against the statistical file of deaths (*see* **Record Linkage**). For each "presumptive match", the researcher receives information about the date, place of death, and death certificate registration number along with some details of the degree of agreement between the required variables. If the study requires cause of death information or other information from the death certificates, the researcher receives enough information to contact the appropriate State Registration Officials to request copies of the pertinent death certificates.

The US National Death Index has been in operation since data year 1979 and has significantly improved follow-up procedures for studies conducted in the US. It has reduced the necessary time and costs of efficient identification of deaths occurring in national follow-up study cohorts.

ROBERT A. ISRAEL

Decision Analysis in Diagnosis and Treatment Choice

Decision analysis is a quantitative method for identifying the optimal course of action among a well-defined set of alternatives under conditions of uncertainty [18] (*see* **Decision Theory**). The optimal course of action is defined as the one that maximizes (or minimizes) the expected value (*see* **Expectation**) of the outcome of interest. The application of decision-analytic methods to medicine is appealing because uncertainty is inherent in diagnosis and treatment choice. Consider the clinical setting where a physician must decide how to care for a patient when the true underlying disease state is rarely known with certainty. Although a particular disease will either be present or absent in any given patient, the physician must make decisions about use of diagnostic tests and treatments based on a subjective assessment of the underlying disease state (*see* **Computer-aided Diagnosis**). In this setting, decision analysis can identify the clinical approach that maximizes average survival, **life expectancy** or quality-adjusted life years (*see* **Quality of Life and Health Status**). More importantly, decision analysis can be used to highlight the critical factors in making decisions about patient care.

The application of decision analysis to clinical medicine was introduced more than 30 years ago [11–13]. Since then, its use in clinical medicine has grown [9, 10, 21], and the role of decision analysis in the economic evaluation of medical practices has also been firmly established [8, 24].

By identifying clinical approaches that maximize health outcomes, decision analysis can be used for guiding the care of individual patients or groups of patients. In the latter context, decision analysis can be useful for clinical guideline development and for informing health policy decision makers. When costs are considered as an end point, decision analysis can be used to identify the least costly course of action or for cost-effectiveness evaluation (*see* **Health Economics**).

The basic steps in decision analysis entail defining the decision problem, structuring the decision tree, assigning parameter values for both probabilities and outcome values to the tree, and analyzing the tree (Table 1). In the sections that follow, each step is described further in the context of a classic clinical decision problem involving a choice between no intervention, immediate testing, and immediate treatment in a patient suspected of having only one possible underlying disease. To demonstrate quantitative aspects of decision analysis, a more detailed clinical example is introduced in the section on analyzing the tree.

Table 1 Basic steps in decision analysis

1. Define the problem
   (a) Identify the decision maker and the objective.
   (b) Specify alternative actions and consequences.
2. Structure the decision tree
   (a) Represent alternative actions as branches emanating from a decision node.
   (b) Represent the temporal sequence of chance events, actions, and outcomes as subsequent chance nodes, decision nodes, and terminal nodes, respectively.
3. Assign values for each parameter in the decision tree
   (a) Assign appropriate probabilities based on their position in the tree.
   (b) Assign appropriate outcome value(s) at each terminal node.
4. Analyze the decision tree
   (a) Average-out and foldback the decision tree.
   (b) Conduct extensive sensitivity analyses.

Define the Problem

Identify Decision Maker(s) and the Objective

The first step in defining the decision problem is to identify the decision maker and to state clearly the decision maker's objective. This entails specifying the outcome of interest and whether it is to be maximized or minimized.

In the classic clinical decision problem, we assume that the physician is the decision maker and that his objective is to maximize survival. If the patient also wishes to maximize survival, then the physician and patient have a shared perspective. If the patient wishes to maximize a different end point, such as time without pain, then the result of the decision analysis may differ when done from the patient's perspective.

Specify Alternative Actions

Once the objective is defined, a complete set of alternative actions must be specified. The possible consequences and temporal sequence of each action must also be delineated.

Using the classic clinical decision problem as the paradigm, the alternative actions are no intervention, immediate testing, or immediate treatment [16]. For the testing alternative, a positive or negative test result is observed and a subsequent treatment decision must be made. Regardless of the actions taken, the end points of death or survival ultimately ensue. The probability of survival, however, varies according to the underlying disease state and the action that is taken.

Structure the Decision Tree

Decision trees are the basic structure underlying most applications of decision analyses in medicine. Other approaches to decision analysis, including the use of influence diagrams, are not discussed here [15]. Decision trees depict the temporal sequence of actions and consequences and are structured from left to right. They comprise nodes, the point from which branches emanate, and branches. Two node types – decision nodes and chance nodes – are always included in decision trees. Decision nodes are depicted by squares and indicate that a choice must be made. Branches emanating from the decision node specify the alternative actions being evaluated. Chance nodes are depicted by circles and indicate that one of several chance events or outcomes may occur. Branches emanating from chance nodes must represent the entire universe of events or outcomes being considered.

Consider the decision tree for the classic clinical decision problem introduced earlier (Figure 1). The tree begins with a decision node from which the alternative actions of "No Intervention", "Test", and "Treat" emanate as separate branches. Each of these branches is followed by chance nodes. The "No intervention" and "Treatment" branches are followed by chance nodes indicating the true underlying disease state. That is, disease may be present ("Disease") or absent ("No disease"). Following each disease state node is another chance node representing the survival outcome as either "Die" or "Survive". The "Test" branch is followed by a chance node indicating that the test result may be positive ("T+") or negative ("T−"). Following the test result node are additional decision nodes that represent the decision that must be made once test results are known. Decision nodes, such as this, that occur following chance nodes, are referred to as embedded decision nodes. (Note that, when embedded decision nodes are eliminated from decision trees and a set of actions contingent upon chance events is specified, then the tree is in strategic form. For example, if the strategy is to "Treat" following a positive test result and to "Do nothing" following a negative test result, then the decision nodes in Figure 1 following "T+" and "T−" would be removed to produce a tree in strategic form.) Regardless of test outcome and subsequent decisions, for the "Test" branch, the tree also includes the disease state and survival chance nodes. Branches at the far right of the decision tree (e.g. "Die" and "Survive" in Figure 1) are called *terminal nodes*.

Assign Parameter Values to the Tree

Assign Probabilities to the Tree

Once the decision tree has been structured, probabilities must be entered for branches emanating from each chance node. These probabilities may represent the frequency with which each chance event occurs. In the simple clinical example, the disease of interest will either be present (D+) or absent (D−) for each patient, and the frequency with which disease is present may be estimated based on observations in large populations of similar patients. Sometimes a clinical prediction rule can be used to estimate the frequency of disease [22] (*see* **Predictive Modeling of Prognosis**). Alternately, the probability that disease is present may reflect the **subjective probability** or strength of belief of the decision maker that disease is present.

Recall that the branches emanating from chance nodes represent the universe of possible (or modeled) events. Thus, by the summation principle of probabilities, regardless of the type of probability represented in the decision tree, the sum of probabilities for branches emanating from each chance node must equal 1.0. We designate the probability of an event as $\Pr(\cdot)$. In the hypothetical clinical example, the probability that disease is present is denoted as $\Pr(D+)$.

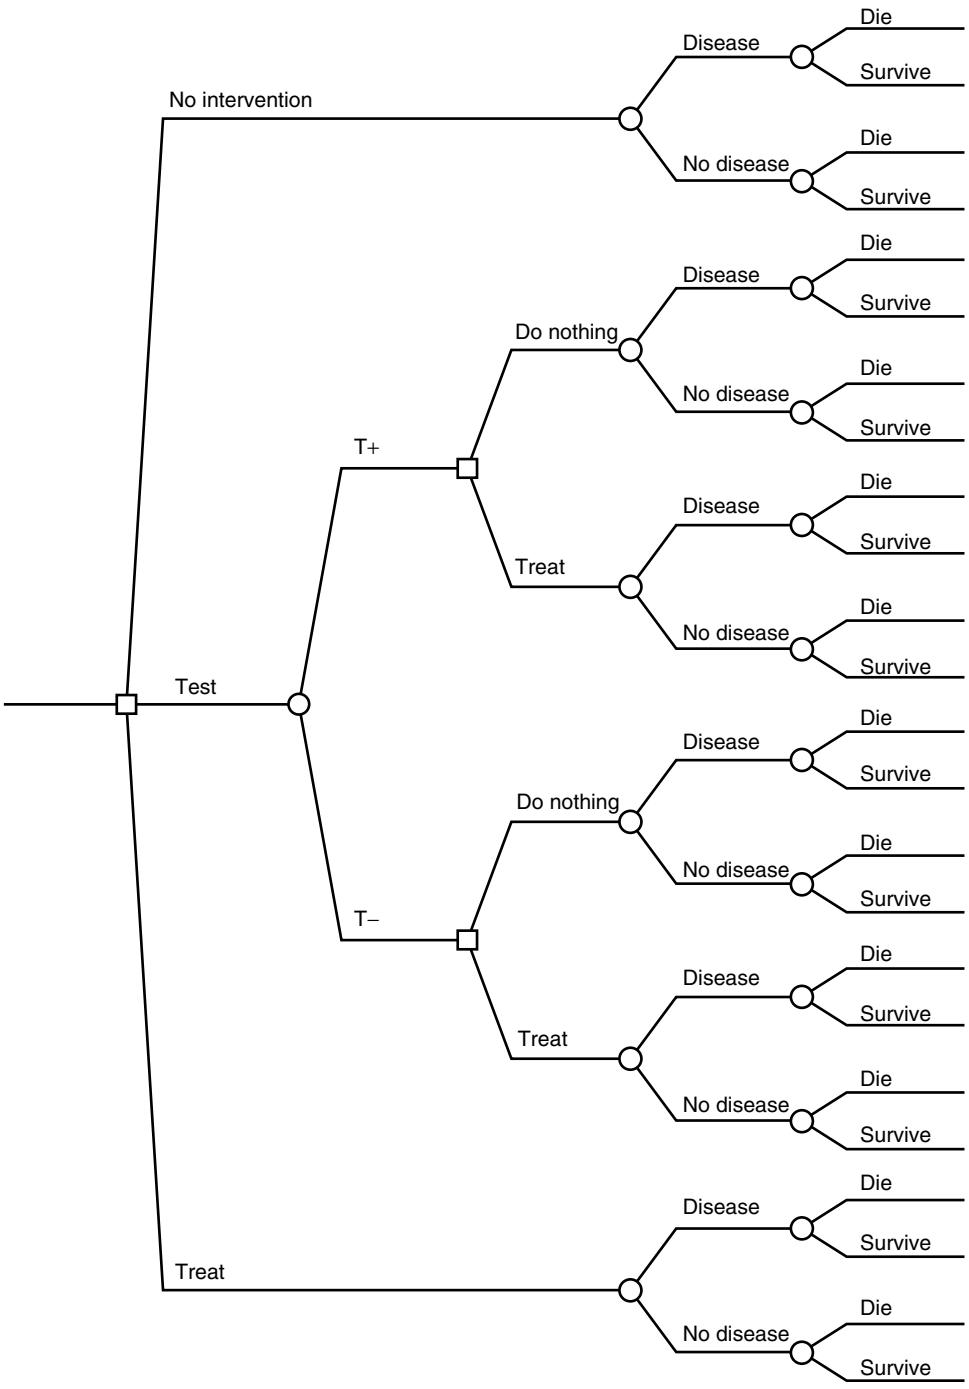

Figure 1 Decision tree for hypothetical clinical example. Decision nodes are depicted by squares (□) and chance nodes are depicted by circles (◯)

Tree Structure and Placement of Joint and Conditional Probabilities

When placing probabilities in a decision tree the correspondence between the position of each branch and the type of probability required is an important consideration. We refer to two general types of probabilities in decision trees – joint probabilities and **conditional probabilities**. Joint probabilities represent the chance that two or more events occur together. If we consider events A and B, then the probability of their joint occurrence is denoted as Pr(A,B). Conditional probabilities represent the chance that an event occurs given that another event is known to have preceded. The conditional probability that event A occurs given that event B has occurred is denoted as Pr(A|B). The relationship between joint and conditional probabilities is

$$\Pr(\mathrm{A}, \mathrm{B}) = \Pr(\mathrm{A}|\mathrm{B}) \Pr(\mathrm{B}).$$

When two events are independent, then

$$\Pr(\mathrm{A}|\mathrm{B}) = \Pr(\mathrm{A}),$$

and the joint probability of their occurrence simplifies to

$$\Pr(\mathrm{A}, \mathrm{B}) = \Pr(\mathrm{A}) \Pr(\mathrm{B}).$$

In our clinical example, the probabilities of disease following "No intervention" and "Treat" are straightforward and represent the **prevalence** or subjective opinion that disease is present, Pr(D+), among such patients. This reflects the assumption that the action taken will not affect the true disease state, though it may (and hopefully will) affect outcomes.

To demonstrate the correspondence between tree structure and use of joint and conditional probabilities, we consider a simplified portion of the "Test" branch in which "Treatment" follows a positive test and "No intervention" follows a negative test (Figure 2).

The four outcomes of test result and disease status may be modeled either as four branches emanating from the "Test" chance node [Figure 2(a)], or as a series of two **binary** chance nodes [Figure 2(b)]. Each terminal node is associated with a path through the decision tree. The path probability for each terminal node is obtained by multiplying the probabilities encountered along the path. In Figure 2, the path probabilities are shown at the end of each branch and correspond to the joint occurrence of true disease state and test result. Note that the path probabilities for each of the four possible outcomes are the same regardless of the structure chosen. What differs in Figures 2(a) and 2(b) is the type of probability used for each branch. In Figure 2(a), the joint probability of disease state and test outcome is modeled. In Figure 2(b), the conditional probability of disease represents the chance that disease occurs given the test result that was observed.

In general, the probability that a test result is positive, Pr(T+) and the complement, $\Pr(\mathrm{T}-) = 1 - \Pr(\mathrm{T}+)$ will depend on the **sensitivity**, $\Pr(\mathrm{T}+|\mathrm{D}+)$, and **specificity**, $\Pr(\mathrm{T}-|\mathrm{D}-)$, of the test and on the prevalence of disease, Pr(D+). Applying the summation principle to joint probabilities allows us to express the probability of a positive test as

$$\Pr(\mathrm{T}+) = \Pr(\mathrm{T}+, \mathrm{D}+) + \Pr(\mathrm{T}+, \mathrm{D}-).$$

The relationship between joint and conditional probabilities allows us to reexpress this as

$$\Pr(\mathrm{T}+) = \Pr(\mathrm{T}+|\mathrm{D}+) \Pr(\mathrm{D}+) + \Pr(\mathrm{T}+|\mathrm{D}-) \Pr(\mathrm{D}-).$$

Probability Revision: Bayes' Rule and Tree Inversion

The probability that disease is present following a test must be conditioned upon the test result. Thus, the post-test or posterior probabilities, $\Pr(\mathrm{D}+|\mathrm{T}+)$ and $\Pr(\mathrm{D}-|\mathrm{T}-)$, often referred to as the positive **predictive value** and negative predictive value, respectively, must be used in the decision tree as appropriate [Figure 2(b)]. Computation of these probabilities may be done using **Bayes' Theorem**, which is shown for the positive and negative predictive values as:

$$\Pr(\mathrm{D}+|\mathrm{T}+) = \frac{\Pr(\mathrm{T}+|\mathrm{D}+) \Pr(\mathrm{D}+)}{\Pr(\mathrm{T}+|\mathrm{D}+) \Pr(\mathrm{D}+) + \Pr(\mathrm{T}+|\mathrm{D}-) \Pr(\mathrm{D}-)},$$

$$\Pr(\mathrm{D}-|\mathrm{T}-) = \frac{\Pr(\mathrm{T}-|\mathrm{D}-) \Pr(\mathrm{D}-)}{\Pr(\mathrm{T}-|\mathrm{D}+) \Pr(\mathrm{D}+) + \Pr(\mathrm{T}-|\mathrm{D}-) \Pr(\mathrm{D}-)}.$$

An alternative to using Bayes' rule to compute post-test or posterior probabilities is first to structure a decision tree to accommodate the probabilities that are known. When structured with the true disease state preceding the test result [Figure 2(c)],

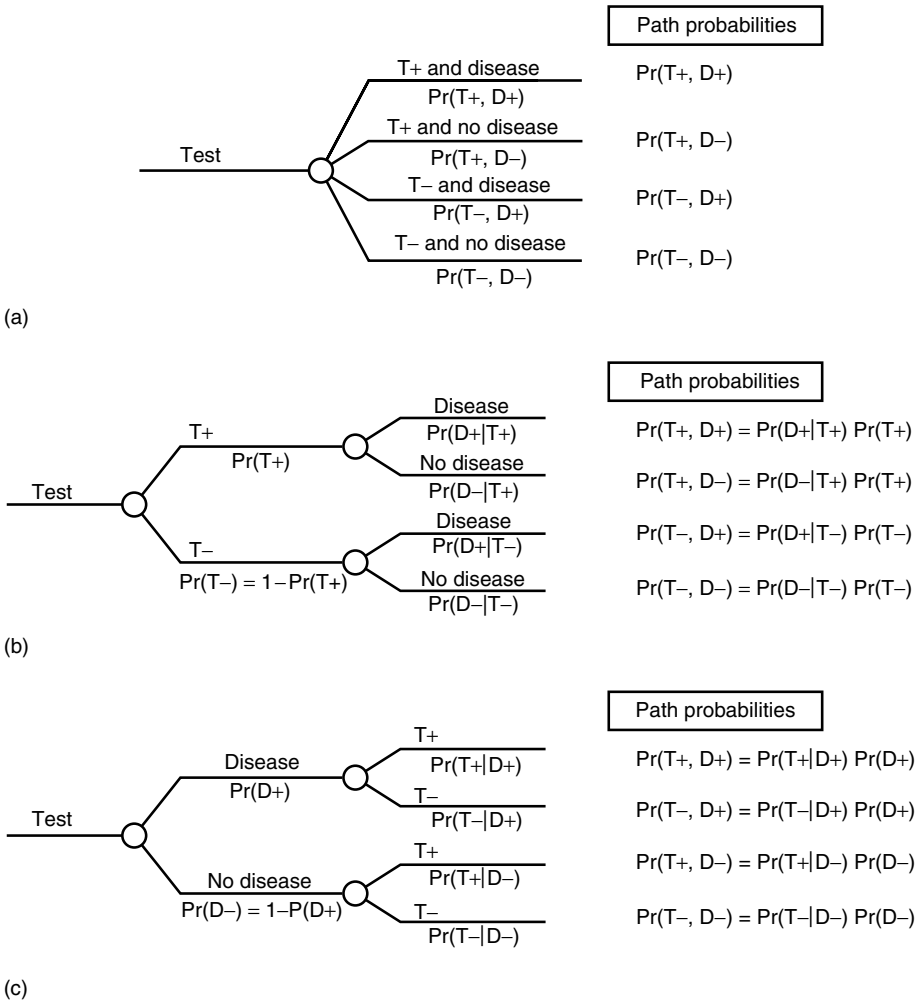

Figure 2 Modeling of simplified test branch and probabilities required: (a) joint outcomes of disease state and test result are modeled and joint probabilities are required; (b) test results and disease state are modeled sequentially and the probabilities of disease conditional on test results are required; (c) test branch modeled with disease prevalence and sensitivity and specificity to determine path probabilities

disease prevalence, test sensitivity, and specificity are entered directly as probabilities in the tree, and the path probabilities are computed. Because the overall probability of a series of chance events is independent of the order of the events, when the tree is inverted [Figure 2(b)] we know that the path probabilities are unchanged. Thus, we can solve for the unknown conditional post-test probabilities, i.e. $\Pr(D+|T+)$ and $\Pr(D-|T-)$, based on the known path probabilities in Figure 2C and known disease prevalence. This is best demonstrated with a numerical example.

Suppose that disease prevalence is 0.60, that test sensitivity is 0.55, and test specificity is 0.99. The tree structure that uses these probabilities directly [Figure 3(a)] models the true disease state as a chance node prior to the test result node. Using disease prevalence and test characteristics, the path probabilities are computed and the overall probability of a positive test is

$$\begin{aligned}\Pr(T+) &= \Pr(T+, D+) + \Pr(T+, D-) \\ &= 0.33 + 0.004 = 0.334.\end{aligned}$$

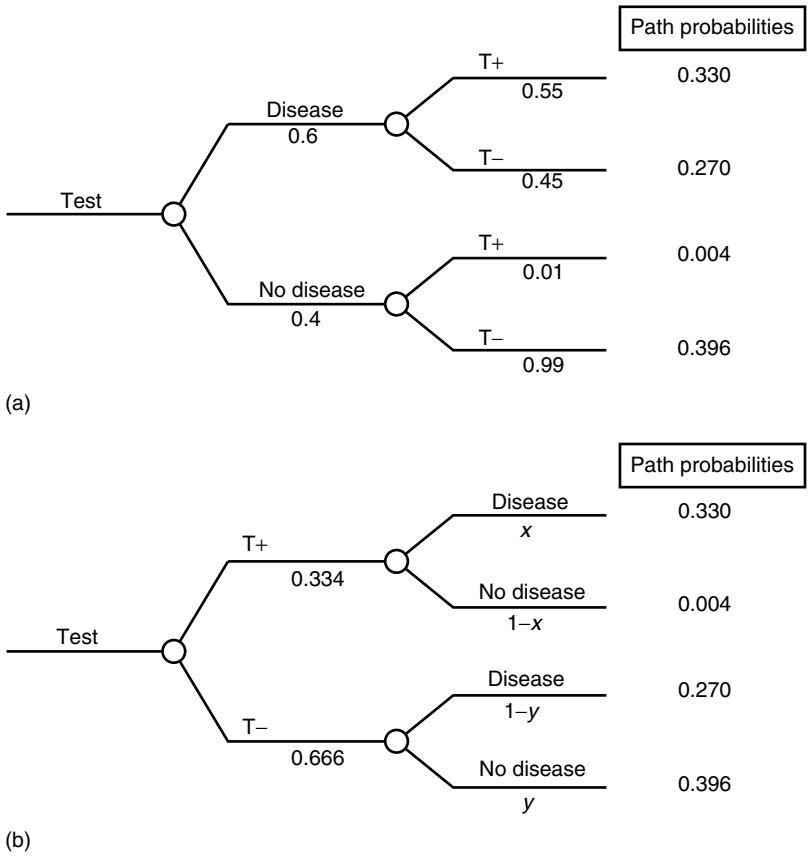

Figure 3 Example of probability revision using tree inversion: (a) test branch modeled with prevalence, sensitivity, and specificity to determine path probabilities; (b) inverted tree where unknown probabilities of disease conditional on test result are solved for based on path probabilities determined in (a)

By placing the path probabilities and probabilities of a positive test in the inverted tree [Figure 3(b)], the unknown positive and negative predictive values, denoted as x and y, respectively, are computed easily using the following equations:

$$0.334x = 0.33 \Rightarrow x = 0.988,$$

$$0.666y = 0.396 \Rightarrow y = 0.595.$$

Probability Revision with Multiple Disease and/or Multiple Test Result Categories

In many clinical applications it is necessary to model more than one disease. Both Bayes' rule and the tree inversion approach to probability revision are easily modified to reflect multiple disease categories, $D_i, i = 1, \ldots, I$. Likewise, when there are multiple test result categories, R_j, $j = 1, \ldots, J$, a general form of Bayes' rule is as follows:

$$\Pr(D_i|R_j) = \frac{\Pr(R_j|D_i)}{\sum_{i=1}^{I} \Pr(R_j|D_i)}$$

The threshold at which a test result is declared positive (T+), referred to as the positivity criterion, corresponds to a single set of test characteristics (i.e. sensitivity and specificity). Changes in the positivity criterion will alter both the sensitivity and specificity of the diagnostic test. To evaluate a diagnostic test over a range of performance, the **receiver operating characteristic (ROC) curve** [14] – a graph of the

true positive rate (sensitivity) against the false positive rate (1-specificity) as the positivity criterion is varied – is useful.

Assign Outcome Values to the Tree

Before analyzing the decision tree, at least one outcome value must be assigned to each terminal node. The relevant outcome and whether it should be maximized or minimized are usually determined when the decision problem is defined. In the classic clinical example introduced earlier, the outcomes of death and survival were modeled. In this setting, we could assign an outcome value of 0 to death and an outcome value of 1.0 to survival. The analysis of this tree would then produce estimates of expected survival.

Other common outcomes to model include life years [2, 3] and quality-adjusted life years (QALYs) [17]. When these outcomes are modeled, the analysis estimates life expectancy and quality-adjusted life expectancy, respectively. In analyses using QALYs, typically, the best possible outcome is assigned a value of 1.0 (e.g. perfect health) and the worst possible outcome (e.g. death) is assigned a value of 0. For intermediate health states formal utility assessment is undertaken to assign a value to the intermediate health states (*see* **Utility in Health Studies**).

When one alternative has probabilistic dominance over other alternatives, it is possible to avoid valuation of intermediate health states. To determine whether or not the principle of probabilistic dominance can simplify the outcome data required, we first order the outcomes from worst to best and index them with the subscript $i = 1, \ldots, I$. Let p_i represent the probability of obtaining outcome i. Then, if the following holds for all $J = 1, \ldots, (I - 1)$, alternative A is said to have probabilistic dominance over alternative B, and a decision can be made without formal valuation of the intermediate outcomes:

$$\sum_{i=1}^{J} p_i^{\text{Alternative A}} \leq \sum_{i=1}^{J} p_i^{\text{Alternative B}}.$$

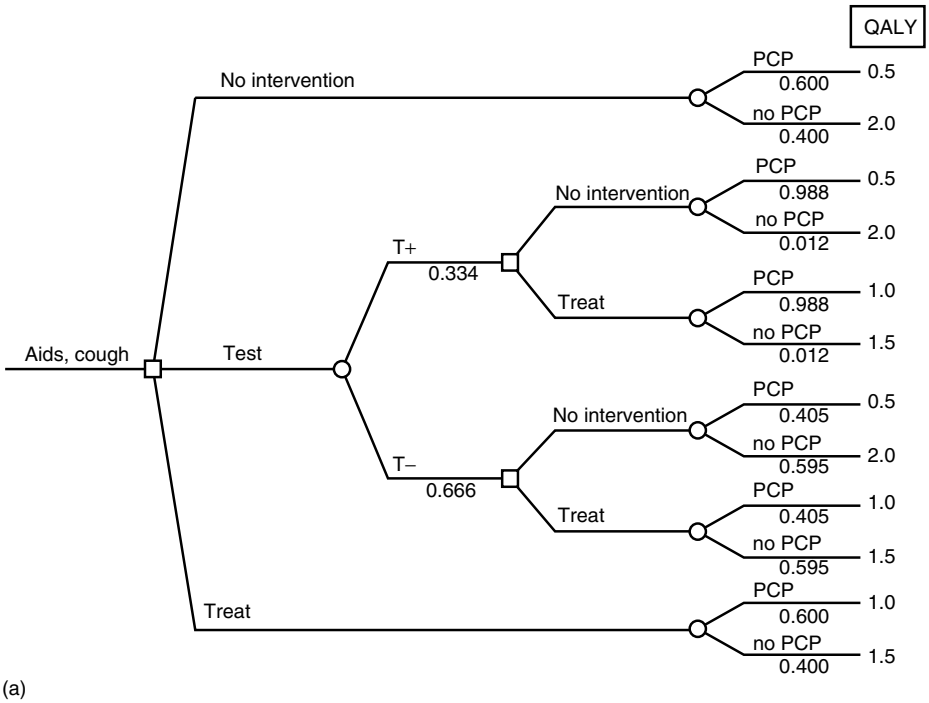
For example, suppose that the alternatives "No intervention" and "Treatment" produce outcomes of death, partial paralysis, and full health with probabilities 0.18, 0.13, 0.65, and 0.2, 0.15, and 0.7, respectively. At first glance it would appear that if death is assigned a value of 0 and full health a value of 1.0, then a value would need to be obtained for the outcome "partial paralysis" before a decision could be made. Because we can rank order the outcomes from worst to best (e.g. death, partial paralysis, and full health) and because "No intervention" is preferred when death only is considered (0.18 vs. 0.2) and when partial paralysis or worse is considered (0.31 vs. 0.35), "No intervention" has probabilistic dominance over "Treatment" and it is unnecessary to assign a numeric value for the intermediate outcome of partial paralysis.

Often there is more than one end point of interest. For example, cost, life years, and quality-adjusted life years may all be relevant. By modeling each of these endpoints, the tradeoffs between increases in expected cost and increases in health can be quantified, and formal cost-effectiveness evaluation can be undertaken [8].

Analyze the Decision Tree

Clinical Example

To demonstrate the process of analyzing a decision tree, consider a hypothetical clinical scenario involving an intravenous drug-using patient who has **AIDS** and comes to the physician complaining about a persistent cough. The primary disease of concern in this setting is *pneumocystis carinii* pneumonia (PCP). Suppose that the physician must choose between no intervention, testing induced sputum (IS) for PCP using a toluidine blue stain, or immediate treatment with antibiotics for presumed PCP, and that the physician's objective is to maximize quality-adjusted life years (QALY). Assume the sensitivity of IS for PCP is 0.55 and the specificity is 0.99. Suppose that the prevalence of PCP among similar patients is 0.60 and treatment of patients with PCP will result in 1 quality-adjusted life year (QALY). Failure to treat PCP results in 0.5 QALY. Assume that no treatment in a patient without PCP results in 2 QALYs, but that treatment in a patient without PCP will result in only 1.5 QALYs. (Although this clinical example is derived from a published decision analysis [7], the QALYs used in this example are purely hypothetical.) The structure for this hypothetical clinical decision problem is shown in Figure 4.



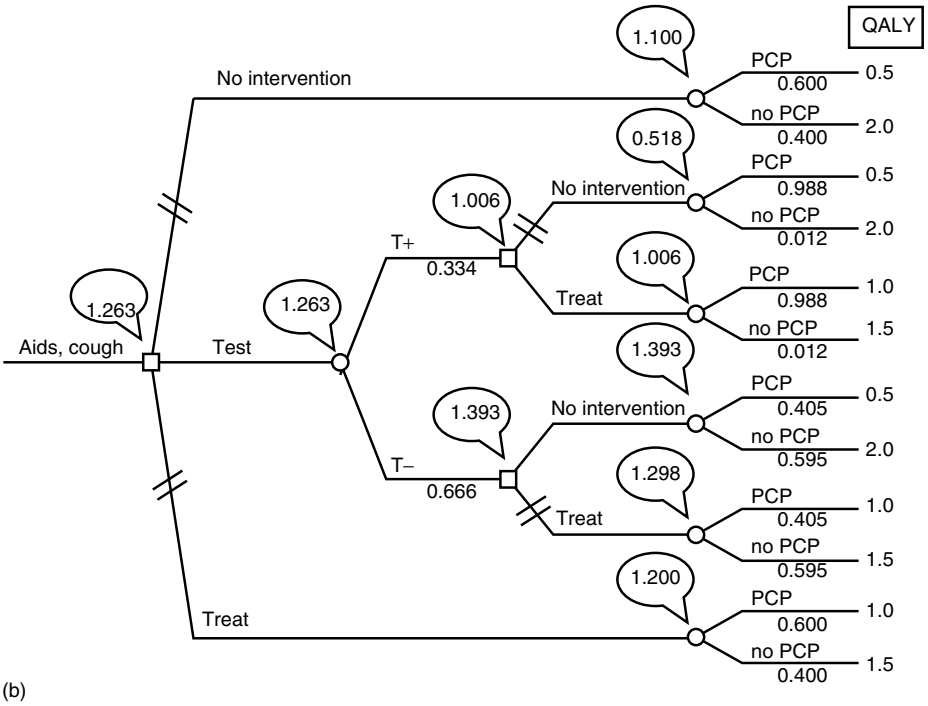


Figure 4 Decision tree and analyzed decision tree for clinical example: (a) decision tree for clinical example involving AIDS patient with persistent cough; (b) analysis of decision tree for clinical example involving AIDS patient with persistent cough

Averaging Out and Folding Back the Decision Tree: Baseline Evaluation

The decision tree is used to facilitate identifying the course of action that produces the best outcome "on average". Decision trees are evaluated by averaging out chance nodes as one moves from left to right and by folding back (i.e. eliminating) all but the branch with the best averaged-out value when a decision node is encountered.

To average out and fold back the tree in Figure 4, we begin at the far right of the tree and first average out the simple branches. The averaged-out value for the "No intervention" branch is 1.100 QALYs ($1.100 = 0.6 \times 0.5 + 0.4 \times 2.0$). The averaged-out value for the "Treat" branch is 1.200 QALYs ($1.200 = 0.6 \times 1.0 + 0.4 \times 1.5$).

For the more complex "Test" branch, the appropriate post-test probabilities are first computed. Based on the test characteristics and prevalence of PCP given above, the probability of a positive test is 0.334, the predictive value of a positive test [i.e. $\Pr(\text{PCP} + |\text{T}+)$] is 0.988, and the predictive value of a negative test [i.e. $\Pr(\text{PCP} - |\text{T}-)$] is 0.595.

Once these revised probabilities of disease are computed, we next focus on the decision following a positive test result. The averaged-out value for no intervention following a positive test result is 0.518 QALYs ($0.518 = 0.988 \times 0.5 + 0.012 \times 2.0$), and the averaged out value of treatment following a positive test result is 1.006 QALYs ($1.006 = 0.988 \times 1.0 + 0.012 \times 1.5$). Because there is a decision node here, we must fold back the tree pruning (denoted with a double slash mark) the option that is suboptimal. Here, we wish to maximize quality-adjusted life expectancy, and the option of "No intervention" following a positive test is pruned. Next, consider the decision following a negative test result. Averaging out the options of "No intervention" and "Treat" following the negative test yields expected values of 1.393 and 1.298, respectively. Thus, we fold back the tree by pruning the "No intervention" option. Now that the embedded decision nodes for the "Test" branch have been pruned, we are ready to average out the "Test" branch. The expected value of the "Test" branch is computed as $1.263 = 0.334 \times 1.006 + 0.666 \times 1.393$.

We are now ready to determine the initial action that results in the best life expectancy and compare the averaged out values for the three alternatives of "No intervention", "Test", and "Treat", which have expected values of 1.100, 1.263, and 1.200 QALYs, respectively. Based on this analysis, the optimal choice is to "Treat".

Expected Value of Clinical Information

The expected value of clinical information is defined as the difference in expected value for the outcome of interest *with* the information relative to the expected value of the best alternative *without* information. In our example of the patient with AIDS, the expected value with clinical information provided by the IS test is 0.063 QALYs and is computed as the difference in expected value between the "Test" and "Treat" branches ($0.063 = 1.263 - 1.200$). Note that, if the expected value of clinical information were negative, this would reflect a situation where the optimal action was not changed by the test result. When we averaged out and folded back the "Test" branch, our analysis resulted in "Treat" following a positive test result and "No intervention" following a negative test result as the optimal course of action. Thus, the optimal action varied according to the test result, and the expected value of clinical information was positive.

A related concept is the expected value of *perfect* information, which is defined as the difference in expected value for the outcome of interest *with* perfect information relative to the expected value of the best alternative *without* perfect information. In our example, if we knew that the patient had PCP we would elect to treat, and if we knew that the patient did not have PCP we would elect no intervention. Thus, with perfect information the expected value is 1.400 QALYs ($1.400 = 0.6 \times 1.0 + 0.4 \times 2.0$). Without a perfect test, the best alternative is the imperfect test, which has an expected value of 1.263 QALYs. Therefore, the expected value of perfect information is 0.137 QALYs ($0.137 = 1.400 - 1.263$).

The expected value of perfect information can be a useful filter for assessing the value of risky tests. In the AIDS example, the expected value of perfect information informs us about the maximum loss of QALYs that one should accept to distinguish PCP from other underlying causes of cough. A loss of 0.137 QALYs or more would be unacceptable even for a perfect test. To determine the probability of death, Pr(die), to which the loss of 0.137 QALYs corresponds, we solve the equation, $1.263 =$

$[1 - \Pr(\text{die})] \times 1.4$. This equation is obtained by setting the expected value of our best alternative, the imperfect test, equal to the expected value of obtaining perfect information among those who do not die from the risky perfect test. We find that a loss of 0.137 QALYs corresponds to accepting no greater probability of death than 0.098. Thus, any risky *imperfect* test must carry an even lower probability of death to be worthwhile.

Sensitivity Analysis

To assess the stability of the baseline results to each decision tree parameter (e.g. probabilities and outcome values), a series of analyses are undertaken in which model parameters are modified systematically over a range of reasonable values to assess whether or not the optimal choice varies. Such analyses are referred to as **sensitivity analyses** and they help identify the parameters that have the greatest influence on the results.

One-Way Sensitivity and Threshold Analyses

In one-way sensitivity analyses, a single parameter is varied over a reasonable range and the expected value of each action is recalculated. Graphical representations of one-way sensitivity analyses are useful for characterizing how the optimal action changes as a single parameter is varied. Such analyses are often valuable when debugging a decision tree.

In the example involving the AIDS patient suspected of having PCP, a graphical representation of the one-way sensitivity analysis for probability of PCP highlights the points at which the optimal action changes [Figure 5(a)]. The points at which the curves of expected value for each strategy cross are threshold values. In our example, Figure 5(a) identifies two thresholds. When the probability of PCP is below 0.018, "No intervention" is preferred; when the prevalence is greater than 0.688, "Treat" is preferred. Analyses that solve for threshold values directly among pairs of alternative actions are referred to as *threshold analyses*.

Multiway Sensitivity Analyses

To assess the impact of changes in multiple parameters simultaneously, higher-order sensitivity analyses are undertaken. Graphical representations of two-way sensitivity analyses are often useful for identifying ranges over which analysis results are stable. In the example involving the AIDS patient, we examined the impact of prevalence of PCP (baseline value = 0.6) and QALYs for patients with PCP and

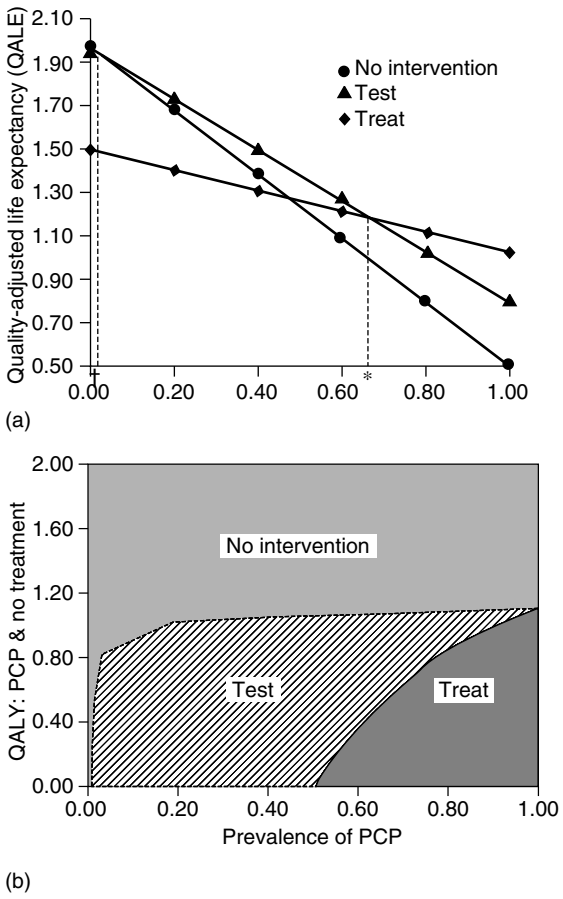

Figure 5 Results of sensitivity analyses for the clinical example involving AIDS patient with a persistent cough: (a) graphical representation of one-way sensitivity analysis. Prevalence of PCP is varied from 0 to 1.0 and the expected value of each strategy is graphed. Thresholds where the optimal action changes from no intervention to testing and from testing to treatment are identified as (+)0.018 and (∗)0.688, respectively; (b) graphical representation of two-way sensitivity analysis. The prevalence of PCP (baseline value, 0.6) and quality-adjusted life years (QALYs) for persons with PCP and no treatment (baseline value, 0.5 QALYs) are varied simultaneously. Regions where each action is preferred are labeled

no treatment (baseline value 0.5 QALYs) simultaneously. The corresponding graph highlights combinations of these two parameters for which each action is preferred [Figure 5(b)]. For high prevalence of PCP and low QALYs for untreated PCP, treatment is preferred. In contrast, for high QALYs for untreated PCP (higher than approximately 1.0 QALY), no intervention is preferred regardless of the underlying prevalence of PCP.

Probabilistic sensitivity analysis [6] is another form of multiway sensitivity analysis, which involves specification of probability distributions for model parameters and **Monte Carlo simulation**.

Extensions to Multiple or Repeated Diagnostic Tests

When **multiple diagnostic tests** are considered either simultaneously or in sequence, the decision tree becomes more complex. In particular, estimating the revised probability of disease based on either two repeated or two separate tests is challenging and often involves strong assumptions.

Conditional Independence

To evaluate the probability of disease on the basis of results from two or more tests requires either knowledge of the joint receiver operating characteristics of the tests or assumptions about the operating characteristics. Because the former is often not available, the assumption of independence of test results conditional on true disease state is often invoked. For results from two tests, denoted as R_1 and R_2, the conditional independence assumption is summarized as:

$$\Pr(R_1, R_2|D+) = \Pr(R_1|D+)\Pr(R_2|D+),$$

$$\Pr(R_1, R_2|D-) = \Pr(R_1|D-)\Pr(R_2|D-).$$

The extent to which such an assumption is reasonable will vary by disease area. To assess the validity or plausibility of the conditional independence assumption in the repeated test setting requires consideration of the nature of variation in test results.

Extensions to More Complex Decision Problems

To evaluate clinical management strategies involving a long time horizon, the use of decision trees becomes cumbersome. For example, consider evaluating whether or not women should be treated with hormone replacement therapy (HRT) at menopause and whether or not such treatment should depend on **screening** tests [23]. To model the effects of HRT accurately, the changing incidence of the multiple diseases that are affected by HRT (e.g. heart disease, breast cancer, and osteoporosis) must be modeled over the course of a woman's lifetime. A decision tree model for evaluation of HRT quickly becomes unwieldy. To evaluate diagnosis and treatment decisions involving long time horizons efficiently, which are common when chronic diseases are considered, **Markov** state-transition models are helpful [1, 20]. Markov state-transition models require that a set of health states be specified along with rules for transition between health states and corresponding transition probabilities, which depend on the current health state. The use of Markov models to evaluate diagnostic and treatment decisions in medicine is increasingly common. In another clinical example, a Markov state-transition model was used to evaluate the use of myocardial revascularization in patients with chronic stable angina [25].

Software for Analyzing Decision Trees

Software packages are available for analyzing decision trees and have been frequently used in decision analyses of diagnosis and treatment [4, 5, 19]. In addition to allowing for the analysis of simple decision trees, these software packages facilitate evaluation of more complex model structures, including recursive decision trees and Markov state-transition models.

Decision Theory

The theory underlying methods for the selection of the best decision to be made in the setting of uncertainty is called statistical decision theory [2, 11, 12, 15, 17–19, 21]. While both frequentist and **Bayesian** approaches to decision problems exist, the Bayesian paradigm for gaining information from data provides the most coherent framework in which to make decisions in the setting of uncertainty [2]. This article gives a general overview of statistical decision theory, emphasizing the Bayesian approach, and illustrates some general classes of problems with examples. We begin by reviewing **Bayes' theorem** and defining some important expectations.

Updating Bayesian Probabilities

Within the Bayesian framework, the probability of any particular value of an unknown parameter being the true value is described by a probability density function (pdf). The unknown parameter, which may be a vector, is denoted by θ and the range of possible values is the parameter space Θ. Experimental data are often obtained in an effort to increase one's knowledge about the unknown parameter. Generally, one can make better decisions with more information about θ.

Before experimental data are available, the pdf describing our knowledge about θ is termed the **prior** pdf and is denoted $\pi(\theta)$. The information contained in the prior may come from previous experience in similar situations, from expert opinion, or from other sources [10]. Methods for determining prior pdfs will not be discussed here [10].

We assume that the probability of observing any particular set of experimental data, x, on the space $\mathcal{X}$, is given by a normalized pdf, denoted $f(x|\theta)$, which in turn is characterized by the unknown parameter θ. Then, given an observed set of data, x, the *posterior* pdf for θ, $\pi(\theta|x)$, is given by

$$\pi(\theta|x) = \frac{f(x|\theta)\pi(\theta)}{\displaystyle\int_{\Theta} f(x|\theta)\pi(\theta)\,\mathrm{d}\theta}.$$

This is the continuous form of Bayes theorem. Considered as a function of θ, $f(x|\theta)$ is called the **likelihood** function.

Decisions may be made before data from the experiment in question become available, on the basis of the prior $\pi(\theta)$, or after the experiment, on the basis of the posterior pdf $\pi(\theta|x)$. The pdf for θ at the time a decision must be made will be denoted $\pi^*(\theta)$ or π^*. Much of the notation used here has been adapted from Berger's excellent monograph [2].

Expectations

When determining the **expectation** of a function, one must distinguish the arguments that are random from those that are fixed. Three expectations will be important for the material that follows: (i) the expectation of a function when the parameter θ is fixed and the data x are random, having pdf $f(x|\theta)$; (ii) the expectation of a function when the data are fixed and θ is random, having pdf $\pi^*(\theta|x)$; and (iii) the expectation of a function when θ is random having pdf $\pi^*(\theta)$, *and* x is random for each θ, having pdf $f(x|\theta)$.

In the first case, in which θ is fixed and x is random, the expectation of $g(x)$ is written as $\mathrm{E}_{\theta}^{X} g(X)$. This is equivalent to $\int_{\mathcal{X}} g(x) f(x|\theta)\,\mathrm{d}x$. When x is fixed and θ is random, the expectation of $h(\theta)$ is written as $\mathrm{E}_{x}^{\pi^*} h(\theta)$. This is equivalent to $\int_{\Theta} h(\theta)\pi^*(\theta|x)\,\mathrm{d}\theta$. In the last case, in which both θ and x are random, the expectation of $j(\theta, x)$ is written as $\mathrm{E}^{\pi^*}[\mathrm{E}_{\theta}^{X} j(\theta, X)]$. This is equivalent to $\int_{\Theta}\int_{\mathcal{X}} j(\theta, x) f(x|\theta)\pi^*(\theta)\,\mathrm{d}x\,\mathrm{d}\theta$. If the function being considered is the loss function (see below), then these three expectations will be called the frequentist risk, the conditional Bayes risk, and the Bayes risk, respectively (see below) [2].

Elements of a Decision Problem

A decision problem consists of three parts: (i) the parameter space, Θ, in which the unknown parameter θ exists; (ii) the set of all possible actions $\mathcal{A}$, from which an action a is to be selected; and (iii) the loss function, $L(\theta, a)$ [2, 15].

Parameter Space or State of Nature

The parameter space, Θ, defines the possible values of θ. Usually the unknown parameter θ represents the true state of nature. In game theory, however,

θ may be the position or tactic of the opponent, and thus may be selected nonrandomly and with specific objectives in mind [15]. In a **classification** problem the parameter space is the list of possible classes. For example, if the objective of a decision problem is to determine the species of an animal on the basis of some measured characteristics, then the parameter space is the set of all possible species. In an **estimation** problem, θ is the parameter to be estimated.

A Set of Possible Actions or Decisions

The set of all possible actions or decisions is denoted $\mathcal{A}$. This set may be discrete, for example selecting a particular medical therapy, determining which disease a patient has, or deciding the number of patients to be enrolled in a clinical trial. An action space may also be continuous, as commonly occurs when the action is an estimate of an unknown parameter, such as the mean of a population. In problems of **experimental design**, $\mathcal{A}$ is the set of all possible study designs. The set of possible study designs may have both discrete elements, such as sample size, and continuous elements, such as a dosage level to be used, the duration of observation, or the parameter estimate to be given (see below).

The Loss Function

The **loss function**, $L(\theta, a)$, represents the loss associated with taking the action a when the true value of the unknown parameter is θ. The loss function must be bounded and defined on the space $\Theta \times \mathcal{A}$. In estimation problems the loss function usually includes a term related to the error of the estimate. In problems involving both estimation and the selection of a data collection or experimental strategy (e.g. deciding the number of subjects to be enrolled in a trial, or selecting an experimental design) the loss function should also include the cost of the data collection itself. The development of realistic loss functions for complex decision problems can be extremely difficult, and can require the consideration of economic, social, psychological, political, and other factors.

Utility is the negative of loss; it is the gain realized if the action a is taken when the true value of the unknown parameter is θ.

Example of Loss Functions. Consider a case in which a patient may have one of three diseases, labeled {A, B, C}, and may be given one of two drugs, labeled {D1, D2}. D1 is the better treatment for disease A, D2 is the better treatment for disease B, and neither drug is effective for Disease C. Table 1 shows a possible loss function. In addition to quantifying the chance of treatment failure with each of the drugs, this loss function should incorporate the monetary costs of the drugs, difficulty in taking the drugs, and the likelihood and seriousness of side-effects. The action that minimizes the expected loss will depend on the probability that the patient has each of the three diseases under consideration.

Table 1 An example of a loss function. Drug D1 is the best treatment for disease A and drug D2 is the best treatment for disease B. Both D1 and D2 are ineffective treatments for disease C

		Action	
		Give drug D1	Give drug D2
Actual disease present	Disease A	1	10
	Disease B	20	5
	Disease C	25	25

As another example, consider the situation in which one wishes to collect data in order to estimate the unknown mean, μ, of a normally distributed variable. There are two parts to the decision problem: (i) choosing the sample size, n, and (ii) estimating μ. In this case the loss function might be $L(\mu, a) = K(\mu - \mu^*)^2 + cn$, where $a = (\mu^*, n)$ incorporates both the estimate of μ to be given, denoted μ^*, and the sample size selected, n. The constant c is the cost per observation. The loss function thus incorporates both the error of the estimate ultimately given, and the cost of acquiring the data. This example is developed more fully later.

The Decision Rule

The decision rule, $\delta(x)$, is a function that maps the data, if any, into the possible set of actions – it is the action to be taken (or the estimate to be given) if the observed data are x. The space of all possible decision rules will be denoted $\mathcal{D}$. During the solution of a decision problem, a decision rule will be chosen to minimize the expected loss, where the expected loss is defined in some specific manner (see later).

A randomized decision rule has the characteristic that, for at least some data $x \in \mathcal{X}$, the action to be

taken is a random variable. Thus the data determine the *probability* of each action being taken, but more than one action may be possible for a given set of data.

Types of Loss and Risk

The term **risk** is used to denote measures of expected loss associated with a specific action or using a specific decision rule (Table 2). We will consider three types of risk: frequentist risk, conditional Bayes risk, and Bayes risk [2]. The definitions of types of risk and the related terminology vary from author to author.

Frequentist Risk. The frequentist risk of a decision rule is denoted $R(\theta, \delta(x))$ and is defined by

$$R(\theta, \delta(x)) = \mathrm{E}_{\theta}^{X}[L(\theta, \delta(X))] = \int_{\mathcal{X}} L(\theta, \delta(x)) f(x|\theta)\, \mathrm{d}x.$$

The frequentist risk is the average loss incurred by using a decision rule $\delta(x)$ when the true value of the unknown parameter is θ. Sometimes this is called the *expected loss*.

In selecting a decision rule according to the **minimax** principle (see below), it is necessary to consider the maximum frequentist risk that might occur, considering all possible values of θ. This maximum frequentist risk is written

$$R_{\max}(\delta(x)) = \sup_{\theta \in \Theta} R(\theta, \delta(x)).$$

Conditional Bayes Risk. The conditional Bayes risk of an action or decision rule is the expectation of the loss incurred by using that action or decision rule, assuming the data are known. In determining the conditional Bayes risk, the data x are assumed fixed, so the action to be taken, $a_x = \delta(x)$, is also fixed if the decision rule is not randomized. This risk is denoted $\rho(\pi^*(\theta), a_x)$ and is defined by

$$\rho(\pi^*(\theta), a_x) = \mathrm{E}_{x}^{\pi^*} L(\theta, a_x) = \int_{\Theta} L(\theta, a_x)\pi^*(\theta|x)\mathrm{d}\theta.$$

The conditional Bayes risk is the expected loss associated with using a specific action, given the data. It is also called the *posterior expected loss*.

Consider the loss function in Table 1. Assume that on the basis of the available data, the current distribution is $\pi^*(\text{disease A}) = 0.3$, $\pi^*(\text{disease B}) = 0.2$, and $\pi^*(\text{disease C}) = 0.5$. The conditional Bayes risk for giving drug D1 is then

$$\rho(\pi^*, D1) = \sum_{\text{disease}=\{\text{A,B,C}\}} L(\text{disease, D1})\pi^*(\text{disease}) = 1 \times 0.3 + 20 \times 0.2 + 25 \times 0.5 = 16.8.$$

Similarly, for drug D2 the conditional Bayes risk is $\rho(\pi^*, D2) = 10 \times 0.3 + 5 \times 0.2 + 25 \times 0.5 = 16.5$. Thus, conditional on the available data, the optimal action is to give drug D2.

Bayes Risk. The Bayes risk of a decision rule is the expected loss, before the data are known, incurred by using the decision rule. Information about possible

Table 2 Definitions of risks used in the analysis of decision problems

Type of risk	Description	Symbol
Frequentist risk	The frequentist risk is the expected value of the loss function, $L(\theta, \delta(x))$, assuming that θ is fixed and the data x have distribution $f(x\|\theta)$.	$R(\theta, \delta(x))$
Conditional Bayes risk	The conditional Bayes risk is the expected loss (with respect to the current probability distribution for θ) after the data are known. It is the posterior expected loss.	$\rho(\pi^*(\theta), a_x)$
Bayes risk	The Bayes risk is the expected loss associated with using a particular decision rule, before the data are known. The expectation is taken with respect to the pdf for θ and the pdf for the data, given θ.	$r(\pi^*(\theta), \delta(x))$

values of θ enters through $\pi^*(\theta)$. This risk is denoted $r(\pi^*, \delta(x))$ and is defined by

$$\begin{aligned} r(\pi^*(\theta), \delta(x)) &= \mathrm{E}^{\pi^*}[R(\theta, \delta(x))] \\ &= \mathrm{E}^{\pi^*}[\mathrm{E}_\theta^X L(\theta, \delta(X))] \\ &= \int_\Theta \int_\mathcal{X} L(\theta, \delta(X)) f(x|\theta) \pi^*(\theta)\, \mathrm{d}x\, \mathrm{d}\theta. \end{aligned}$$

Minimization of the Bayes risk is an important criterion used to determine an optimal decision rule.

Criteria for Selecting Decision Rules

Different criteria can be used to judge which decision rules are "better" than others, or even optimal. The principal Bayesian criterion is minimizing the Bayes risk, $r(\pi^*, \delta(x))$, while an important frequentist criterion is minimizing the maximum risk, $R_{\max}(\delta(x))$.

Admissibility and Bayes Rules

A decision rule, $\delta_1(x)$, is *admissible* with respect to another decision rule, $\delta_2(x)$, if there is at least some value of θ for which the frequentist risk for $\delta_1(x)$, given by $R(\theta, \delta_1(x)) = \mathrm{E}_\theta^X L(\theta, \delta_1(X))$, is less than that for $\delta_2(\theta)$.

A decision rule, $\delta(x)$, is a "Bayes rule" if the decision rule minimizes the Bayes risk, $r(\pi^*(\theta), \delta(x))$; such a decision rule is denoted $\delta^*(x)$. In general, the Bayes rule will depend upon $\pi^*(\theta)$. The minimum risk achieved by a Bayes rule, for the particular $\pi^*(\theta)$, is denoted r^*. Any other decision rule which leads to the same Bayes risk is also a Bayes rule [2].

If a decision rule $\delta_1(x)$ is admissible with respect to all other decision rules in $\mathcal{D}$, meaning that there is at least one value of θ for which $R(\theta, \delta_1(x)) < R(\theta, \delta_i(x))$ for all other rules $\delta_i(x) \in \mathcal{D}$, $i \neq 1$, then $\delta_1(x)$ is a Bayes rule for some $\pi^*(\theta)$.

Minimax Rules

The definition of Bayes risk and the determination of a Bayes rule require specifying the pdf for the unknown parameter θ. In some cases one might desire to use a classical method to select the "best" decision rule, and avoid the use of the Bayesian pdf. One such method for rule selection seeks to minimize the maximum frequentist risk, $R_{\max}(\delta(x))$.

Recall that the maximum frequentist risk that might be incurred using a decision rule $\delta(x)$, as θ varies, is

$$R_{\max}(\delta(x)) = \sup_{\theta \in \Theta} R(\theta, \delta(x)).$$

According to the minimax principle, a decision rule $\delta_1(x)$ is preferred over a second rule $\delta_2(x)$ if

$$R_{\max}(\delta_1(x)) < R_{\max}(\delta_2(x)).$$

The value of θ that leads to the maximum value of $R(\theta, \delta_1(x))$ is not, in general, the same value of θ that leads to the maximum value of $R(\theta, \delta_2(x))$.

The best decision rule will be the one that minimizes the maximum frequentist risk; this is the minimax rule, denoted $\delta^{*\mathrm{M}}(x)$. The resulting minimax risk is given by

$$r^{*\mathrm{M}} = \inf_{\delta(x) \in \mathcal{D}} \sup_{\theta \in \Theta} R(\theta, \delta(x)).$$

The minimax rule is an appropriate method for selecting a decision rule if the goal is to minimize the "worst case" loss that might be incurred. This is a reasonable approach when the selection of θ is performed by an opponent who seeks to maximize your loss, for example when playing a game against an intelligent adversary [15].

Consider again the loss function shown in Table 1. Regardless of the drug given, the maximum loss of 25 occurs if the patient has disease C. Thus, both giving drug D1 and giving drug D2 are minimax rules and the minimax risk is 25. If the disease is selected by an intelligent adversary (say in biological warfare), then a minimax approach to treatment selection would be reasonable.

The Range of Decision Problems

In Bayesian decision theory the range of decisions that can be considered is very broad – limited only by the types of decision space that can be defined. Decision problems include simple classification, parameter estimation, optimal sample size determination, and experimental design [3–11, 14, 18, 24–26].

A distinction should be made between a decision problem and an estimation problem, in which the goal is to return the "best" (in some defined sense) estimate of an unknown parameter. Once a suitable

loss function, such as quadratic error loss, is defined, the goal of an estimation problem is still to minimize the Bayes risk. In an estimation problem, however, the decision rule is an estimator of the unknown parameter. A design problem is a decision problem in which the action space is the set of possible experimental designs. A special case is the problem of choosing a sample size: this is a decision problem in which the action space is $\{0, 1, 2, \ldots\}$.

Some examples of classes of Bayesian decision problems will be given in the following sections.

Example: Choosing a Treatment

Recall the loss function shown in Table 1 for the problem of selecting one of two treatments when the patient might have one of three diseases. Inspection of the loss structure shows that the optimal treatment will depend on the probabilities of the different diseases. Suppose we have a diagnostic test available, at a cost of one unit, the characteristics of which are shown in Table 3. We wish to decide whether to order the test and, if we use the test, what treatment to give for each possible result. As before, the probabilities of the three diseases before the test result is available are $\pi^*(\text{disease A}) = 0.3$, $\pi^*(\text{disease B}) = 0.2$, and $\pi^*(\text{disease C}) = 0.5$. Because the data space $\mathcal{X}$ consists of only two possible test results, we directly calculate the conditional Bayes risk for each test result, and for the strategy of not ordering the test and treating on the basis of prior information alone.

As shown above, if we do not order the test then the optimal action is to give drug D2 and the conditional Bayes risk is 16.5. If we order the test, and the result is negative, then the posterior probabilities for diseases A, B, and C are 0.056, 0.296, and 0.648, respectively. Using these posterior probabilities, the conditional Bayes risk associated with giving drug D1 is 22.2. The total cost, if one obtains a negative test and gives drug D1 anyway, is 22.2 plus the cost of the test, or 23.2. Similarly, the total cost of giving drug D2 after a negative test is 19.2. Thus, if the test is ordered and negative, then the optimal action is to give drug D2.

Table 3 Probabilities of a positive and negative test result, depending on the actual disease present, using a diagnostic test marketed as being useful for the identification of disease A

		Test result	
		Negative	Positive
Actual disease present	Disease A	0.1	0.9
	Disease B	0.8	0.2
	Disease C	0.7	0.3

If the test is positive, then the posterior probabilities of diseases A, B, and C are 0.587, 0.087, and 0.326, respectively. Now the cost of testing and giving drug D1 is 11.5 and the cost of testing and giving drug D2 is 15.5. Thus, if the test is ordered and positive, then the optimal action is to give drug D1. This is not surprising, since the test is meant to detect disease A and drug D1 is the better treatment for disease A.

To decide whether to order the test, one must calculate the prior probability that the test will be negative or positive. The prior (or "predictive") probability of a negative test result is $0.3 \times 0.1 + 0.2 \times 0.8 + 0.5 \times 0.7 = 0.54$. The prior probability of a positive test result is 0.46. Thus, the Bayes risk, if the test is obtained (and the optimal treatment is given for each test result) is $0.54 \times 19.2 + 0.46 \times 11.5 = 15.7$. Since the Bayes risk associated with ordering the test, 15.7, is less than the risk associated with not ordering the test, 16.5, the optimal decision is to order the test. If the test costs two units instead of one unit, however, then it would be better not to order the test and simply treat with drug D2 (*see* **Decision Analysis in Diagnosis and Treatment Choice**).

Example: Choosing a Sample Size

Assume one wishes to estimate the unknown mean, μ, of a normally distributed variable with a known standard deviation, σ. There are two parts to the decision problem, choosing the sample size, n, and estimating μ. We assume a loss function $L(\mu, a) = K(\mu - \mu^*)^2 + cn$, where $a = (\mu^*, n)$ includes both the estimate of μ to be given, μ^*, and the sample size to be used, n. The constant c is the cost per observation. The prior for μ is $\mu \sim \mathrm{N}(\mu_0, \sigma_0)$.

The observed data will be $X = \{X_1, X_2, \ldots, X_n\}$. Since the n observations are independent, $f(X|\mu)$ is given by

$$N_n(\mu, \sigma) = (2\pi\sigma^2)^{-(n/2)} \exp\left[-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(X_i - \mu)^2\right].$$

The Bayes risk after n measurements, using an estimator μ^* which will be a function of the prior

and the observed data, is

$$r(\mathrm{N}(\mu|\mu_0,\sigma_0),a) = \int_{-\infty}^{\infty}\int_{\mathcal{X}}[K(\mu-\mu^*)^2+cn] \times f(X|\mu)\mathrm{N}(\mu|\mu_0,\sigma_0)\,\mathrm{d}X\,\mathrm{d}\mu.$$

It can be shown that minimizing the Bayes risk is equivalent to minimizing the conditional Bayes risk (the posterior expected loss), for each value of X [2]. The posterior for μ is given by $\mathrm{N}(\mu_1,\sigma_1)$ where

$$\mu_1(X) = \left(\frac{\sigma^2\sigma_0^2}{\sigma^2+n\sigma_0^2}\right)\left(\frac{\mu_0}{\sigma_0^2}+\frac{n\overline{X}}{\sigma^2}\right)$$

and

$$\sigma_1^2 = \left(\frac{\sigma^2\sigma_0^2}{\sigma^2+n\sigma_0^2}\right).$$

Since σ^2 is known, $\overline{X}$ is a **sufficient statistic**.

The conditional Bayes risk is given by

$$\rho(\mathrm{N}(\mu|\mu_1,\sigma_1),a) = \left(\frac{1}{(2\pi\sigma_1^2)^{1/2}}\right) \times \int_{-\infty}^{\infty}[K(\mu-\mu^*)^2+cn] \times \exp\left[-\frac{(\mu-\mu_1(X))^2}{2\sigma_1^2}\right]\mathrm{d}\mu.$$

The conditional Bayes risk is minimized by expanding the loss function, differentiating by μ^*, and setting the result equal to zero. Thus,

$$0 = \frac{\mathrm{d}}{\mathrm{d}\mu^*}\int_{-\infty}^{\infty}[K\mu^2-2K\mu\mu^*+K(\mu^*)^2+cn] \times \exp\left[-\frac{(\mu-\mu_1(X))^2}{2\sigma_1^2}\right]\mathrm{d}\mu,$$

$$0 = 2K\int_{-\infty}^{\infty}[\mu^*-\mu]\exp\left[-\frac{(\mu-\mu_1(X))^2}{2\sigma_1^2}\right]\mathrm{d}\mu,$$

and

$$\left(\frac{\mu^*}{(2\pi\sigma_1^2)^{1/2}}\right)\int_{-\infty}^{\infty}\exp\left[-\frac{(\mu-\mu_1(X))^2}{2\sigma_1^2}\right]\mathrm{d}\mu = \left(\frac{1}{(2\pi\sigma_1^2)^{1/2}}\right)\int_{-\infty}^{\infty}\mu\exp\left[-\frac{(\mu-\mu_1(X))^2}{2\sigma_1^2}\right]\mathrm{d}\mu$$

and

$$\mu^* = \mathrm{E}^{N(\mu|\mu_1,\sigma_1)}[\mu] = \mu_1(X).$$

It is a general result that the best squared error loss estimator is the mean of the posterior distribution for the parameter [2, 15]. The Bayes conditional risk of this estimator is then given by

$$\rho(\mathrm{N}(\mu|\mu_1,\sigma_1),\mu_1(X)) = \left(\frac{1}{(2\pi\sigma_1^2)^{1/2}}\right)\int_{-\infty}^{\infty}[K(\mu-\mu_1(X))^2+cn] \times \exp\left[-\frac{(\mu-\mu_1(X))^2}{2\sigma_1^2}\right]\mathrm{d}\mu.$$

Performing the integration leads to

$$\rho(\mathrm{N}(\mu|\mu_1,\sigma_1),\mu_1(X)) = K\sigma_1^2+cn.$$

Thus, the Bayes conditional risk is proportional to the posterior variance plus the sampling cost [2].

To determine the sample size that minimizes the risk, one can differentiate the Bayes conditional risk by n and set the result equal to zero. Thus

$$0 = \frac{\mathrm{d}}{\mathrm{d}n}\left\{K\left(\frac{\sigma^2\sigma_0^2}{\sigma^2+n\sigma_0^2}\right)+nc\right\} = -K\left(\frac{\sigma^2\sigma_0^4}{(\sigma^2+n\sigma_0^2)^2}\right)+c.$$

The minimum conditional risk is given by setting n equal to

$$n^* = \sigma\left(\frac{K}{c}\right)^{1/2}-\frac{\sigma^2}{\sigma_0^2}.$$

This expression has the important characteristic that the optimal sample size depends on the ratio of the error loss to the sampling cost. Since n is not really a continuous variable, the two integer values of n closest to n^* must be checked to see which of the two gives the minimum.

This decision problem is simplified by the fact that the minimum conditional Bayes risk, which is proportional to the posterior variance, does not depend on the data, except through n. If the conditional Bayes risk depends on the data itself (as will occur with binomial sampling, for example), then the predictive distribution of the data is required to calculate the expected Bayes risk plus sampling costs (*see* **Sample Size Determination**).

Example: Sequential Stopping Rules

Bayesian decision theory can be used: (i) to decide the optimal estimate to be given once all data are

available; (ii) to decide the optimal sample size (see previous section); and (iii) if the measurements can be taken sequentially, to decide the optimal time to stop making observations. This last application is termed **sequential analysis** [1, 2, 8, 12, 15, 16].

In a sequential stopping problem, two sets of actions are available at each decision point: (i) the collection of more data; and (ii) stopping data collection and giving an estimate or making a decision on the basis of the data already collected. Many such decision points may exist. The total cost of the experiment includes contributions from both the terminal decision loss function (e.g. squared error loss of the final estimate), and the sampling cost.

The decision function for a sequential decision problem contains both a stopping rule, which determines which results will lead to termination of data collection, and a decision rule, which determines what action will be taken or estimate given once the experiment is terminated. The optimal decision and stopping rules minimize the Bayes risk, which must be calculated using the prior information *and* the predictive distribution of possible future data. The quantity of future data will depend, in turn, on the stopping rule, as the decision to stop the trial results in a truncation of the sequence of available data.

Once data collection has stopped, the optimal decision or estimate is determined by minimizing the conditional Bayes risk. Thus the sequential nature of the study does not complicate the determination of the decision rule.

The complexity of considering all possible future data can make the determination of optimal stopping rules difficult. The solution is greatly simplified if the posterior expected loss is independent of the observations, as this allows the direct determination of the value of n that minimizes the posterior expected loss. This simplification is illustrated by the example in the previous section. In that example the optimal sequential stopping rule is the same as the optimal fixed-size stopping rule.

When risks are finite, and the sampling cost is positive, then the optimal stopping rule will always require stopping after some maximum number of samples have been taken. The actual optimal stopping point will depend on the data. In this case the method of backward induction can be used to determine the optimal stopping rule. Because of the complex notation involved, the description of backward induction given here will be qualitative. The interested reader is referred to the following references for details and examples: [1, 2, 8, 9, 12, 15, 16].

In backward induction, one begins by determining the optimal decision and the associated risk for each result that might occur after the maximum data collection. At this "terminal" point, which we will call stage M, the option of continuing the trial does not exist and the determination of the optimal decision is made by minimizing the conditional Bayes risk. Next, for each possible data set available one experimental step earlier (stage $M-1$) one determines the expected cost of stopping the experiment, assuming the decision that minimizes the conditional Bayes risk is made. This expected "stopping" cost at stage $M-1$ is compared with the expected cost associated with continuing data collection until stage M. The expected cost associated with continuing data collection is calculated using the *predictive* distribution of future data, based on the data available at stage $M-1$. This is an example of "preposterior" analysis. The optimal action at stage $M-1$ is the action (stopping or continuing data collection) that minimizes the expected cost. Typically, there is some decrease in the expected decision loss associated with further data collection, but this gain may or may not offset the additional sampling cost.

In a similar manner, one can step backwards through each stage $\{M-2, M-3, \ldots, 2, 1, 0\}$ and, for each possible set of results at each stage, determine the optimal stopping and decision rule. This "backward induction" continues until stage 0 is reached, before any data collection. It is possible that the optimal action at this initial stage will be to not collect any data at all, and instead make a decision or estimate based solely on prior information. Thus, sequential analysis allows one to decide whether it is optimal to even conduct the experiment at all. An excellent example of the power of this approach is illustrated in [9].

Example: Sequential Allocation of Experiments (Bandits)

In most **clinical trials**, patients are randomized in a balanced fashion to the candidate therapies. The advantage of a balanced design is that it gives maximal information about the differences between therapies. When results of a trial are published they help to guide the treatment of patients who present thereafter. Patients in the trial are not ignored, and

data and safety monitoring boards are charged specifically with ensuring that patients in the trial are not exposed to undue risks. But effective treatment of patients in the trial is not a formal objective.

An alternative approach is to address explicitly the effective treatment of patients in the trial as well as those who present thereafter. The goal is to maximize overall effectiveness. Therapies – or arms – are assigned on the basis of accumulating results; that is, assignment is adaptive (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). An arm that is performing well is more likely to be assigned than is a poor performer. Information gleaned during the trial about the relative effectiveness of the arms has value in that it improves therapy for patients entering later in the trial, and also for patients who come after the trial [4, 5, 7, 8].

The decision space is complicated. Its first component indicates the arm selected initially. Suppose that the first observation is X_1. The second component of the decision is the arm selected next, given X_1 and also given the first arm selected. The third component depends on X_1 and the second observation X_2 and on the corresponding arms selected. And so on.

Temporarily consider only the n patients in the trial and suppose that there are two available arms. Outcomes are dichotomous; arm 1 has success probability θ_1 and arm 2 has success probability θ_2. The goal is to maximize the expected number of successes among the n patients. (From the perspective of losses, this goal is the same as minimizing the expected number of failures.) Arm 1 is standard and has known success proportion θ_1. Arm 2 has unknown efficacy. Uncertainty about θ_2 is given in terms of a probability distribution F. To be specific, suppose that F is **uniform** on (0, 1).

If $n = 1$, then the decision space is simply the list of possible initial selections, $\{1, 2\}$, and the decision problem is easy. Choosing arm 1 has expected number of successes θ_1. Choosing arm 2 has conditional expected number of successes θ_2, and unconditional expected number of successes $\mathrm{E}(\theta_2) = \int_0^1 p F_i(\mathrm{d}p) = \int_0^1 p\,\mathrm{d}p = 1/2$.

Therefore arm 1 is optimal if $\theta_1 \geq \frac{1}{2}$ and arm 2 is optimal if $\theta_1 \leq \frac{1}{2}$. (Both arms – and any randomization between them – are optimal when $\theta_1 = \frac{1}{2}$.)

The problem is more complicated for $n \geq 2$. Consider $n = 2$. There are two initial choices and two choices depending on the result of the first observation. There are eight possible decisions, or sequences of decisions, called *strategies*. We can write a strategy as $\{a; a_{\mathrm{S}}, a_{\mathrm{F}}\}$, where a is the initial selection, a_{S} is the next selection should the first observation be a success, and a_{F} is the next selection should the first observations be a failure. To find the utility (the negative of the expected loss) of a strategy we need to know such quantities as the probability of a success on arm 2 after a success on arm 2 ($\mathrm{E}(\theta_2^2)/\mathrm{E}(\theta_2) = \frac{2}{3}$) and the probability of a success on arm 2 after a failure on arm 2 ($\mathrm{E}(\theta_2(1-\theta_2))/\mathrm{E}(1-\theta_2) = \frac{1}{3}$). The possible strategies and their utilities are given in Table 4.

Table 4 Possible strategies and the resulting expected number of successes

Strategy	Expected number of successes
$\{1; 1, 1\}$	$2\theta_1$
$\{1; 1, 2\}$	$\theta_1 + \theta_1^2 + (1-\theta_1)(1/2)$
$\{1; 2, 1\}$	$\theta_1 + \theta_1(1/2) + (1-\theta_1)\theta_1$
$\{1; 2, 2\}$	$\theta_1 + 1/2$
$\{2; 1, 1\}$	$1/2 + \theta_1$
$\{2; 1, 2\}$	$1/2 + (1/2)\theta_1 + (1/2)(1/3)$
$\{2; 2, 1\}$	$1/2 + (1/2)(2/3) + (1/2)\theta_1$
$\{2; 2, 2\}$	$2(1/2) = 1$

It is easy to check that only three of these utilities are candidates for the maximum, with the optimal strategy depending on θ_1. If $\theta_1 \geq \frac{5}{9}$, then $\{1; 1, 1\}$ is optimal; if $\frac{1}{3} \leq \theta_1 \leq \frac{5}{9}$, then $\{2; 2, 1\}$ is optimal; and if $\theta_1 \leq \frac{1}{3}$, then $\{2; 2, 2\}$ is optimal.

Enumeration of possible strategies is tedious for large n. Most strategies can be dropped from consideration on the basis of theoretical results [5, 7, 20]. For example, there is a break-even value of θ_1, say θ_1^*, such that arm 1 is optimal for $\theta_1 \geq \theta_1^*$. Also, one need consider only those strategies that continue to use arm 1 once it has been selected. But many strategies will still remain. Backward induction can be used to find an optimal strategy. Table 5 gives the expected proportion of successes for selected values of n and for fixed $\theta_1 = \frac{1}{2}$, using an optimal strategy. The asymptotic maximal expected proportion of successes is $\frac{5}{8}$, which is the expected value of $\max(\theta_1, \theta_2)$.

Both arms offer the chance of success on the current patient, but only sampling from arm 2 gives information that can help in choosing between the arms for treating later patients. Table 6 gives the break-even values θ_1^* for selected values of n.

Table 6 shows that information from arm 2 is more important for larger n. For example, if $\theta_1 = 0.75$, then

Table 5 The optimal expected proportion of successes for selected values of n, assuming $\theta_1 = \frac{1}{2}$. Optimal strategies were determined using backward induction

n	Proportion of successes
1	0.500
2	0.542
5	0.570
10	0.582
20	0.596
50	0.607
100	0.613
200	0.617
500	0.621
1000	0.622
10 000	0.6245

Table 6 The break-even values of θ_1^*, as a function of n

n	θ_1^*
1	0.500
2	0.556
5	0.636
10	0.698
20	0.758
50	0.826
100	0.869
200	0.902
500	0.935
1000	0.954
10 000	0.985

only using arm 1 would be an optimal strategy for $n = 10$, but it would be advisable to test arm 2 when $n = 100$ even though arm 1 has probability of 0.75 of being better than arm 2.

When there are several arms with unknown characteristics, the problem is even more complicated. Optimal strategies may well include selections of an arm that was used previously and set aside in favor of another arm because of inadequate performance. Methods and theory for solving such problems are described in [3, 7]. Optimal strategies are generally difficult to describe. Berry provides easy-to-use adaptive strategies that are not optimal and shows that they perform reasonably well [4].

Having the flexibility to choose an arm based on results of all previous patients is not common in clinical trials. Usually there are response delays. For example, when the end-point is survival, only partial information is available until the patient dies. Eick [13, 14] has shown how to handle such delays in the adaptive setting.

We have not yet addressed the matter of patients that are treated after the clinical trial. The patient horizon N is the number of patients who will be treated either in the trial or later with one of the therapies considered in the trial. Clearly, in almost every real situation N is unknown. Information about N can be included in the decision problem in the usual way, by incorporating uncertainty about N into a probability distribution. Alternatively, one can assume particular values of N and assess the sensitivity of the optimal strategy to values assumed. Suppose that the clinical trial allows for adaptive allocation and that later patients will be assigned the treatment that performs best in the clinical trial. Berry & Eick [6] considered the case of two arms in a trial with dichotomous response and showed how to incorporate all N patients into the decision problem. They compare a Bayes strategy assuming θ_1 and θ_2 independent and having uniform prior distributions on (0,1) with various other adaptive strategies and with balanced randomization. The Bayes strategy performs best on average, as it must, and it is robust in the sense that it outperforms the other strategies for essentially all (θ_1, θ_2).

Degrees of Freedom

Different authors have variously described or attempted to define the term *degrees of freedom* as the effective number of independent observations; the number of free variables; the number of observations that are free to vary after applicable restrictions are imposed; the number of observations minus the number of restrictions; the number of observations minus the number of parameters that are estimated from the observations; or something similar. Although descriptions such as these may be appropriate in a number of contexts, they fail to cover certain situations (e.g. those involving noninteger degrees of freedom).

Thus, for full generality it seems more suitable to think of degrees of freedom simply as a *parameter* (ordinarily a *known* parameter) of the different distributions with which the term is associated. There are three such distributions: **chi-square** (χ^2), t (*see* **Student's *t* Distribution**), and $\boldsymbol{F}$. Although the **gamma distribution** is a generalization of the χ^2 distribution, and the **beta distribution** is obtainable from the F distribution through a simple transformation, the term *degrees of freedom* is not customarily used in connection with either the gamma or the beta distributions.

The usual abbreviation for degrees of freedom is df. The χ^2 distribution has just one df parameter, as does the t distribution. The F distribution, however, has two df parameters; if they are shown as "df $= 3, 29$", for example, then this means that there are 3 df for the numerator of the reported F statistic and 29 df for the denominator. Published works that report values of χ^2, t, or F should always indicate the associated df parameters so that readers will be able to make proper interpretations.

In general applications it is the *central* χ^2, t, and F distributions that one encounters. The more complicated, *noncentral* χ^2, t, and F distributions also have df parameters, however, in the same fashion as the central distributions (*see* **Noncentral *t* Distribution**). The noncentral distributions are used for **power** calculations.

Significance tests that involve the χ^2, t, and F distributions, with associated df, are available for numerous applications (*see* **Hypothesis Testing**). These include t tests for a mean and for the equality of two means (*see* **Student's *t* Statistics**), the χ^2 test for a variance, the F test for the equality of two variances, various t and F tests in **regression** and in **analysis of variance**, chi-square goodness-of-fit tests, **chi-square tests** for independence in **contingency tables**, and **likelihood ratio tests** that use χ^2. **Confidence intervals** and confidence regions that are related to these significance tests are also available in many cases.

Noninteger degrees of freedom arise when a variable, u, has a complicated distribution for which one seeks a simple approximation. Specifically, one tries to choose a constant c and a df parameter ν so that $y = cu$ follows approximately a χ^2 distribution with df $= \nu$. One would like to select ν and c so that y has the same mean and variance as χ^2 with df $= \nu$, that is, so that $\mathrm{E}(y) = \nu$ and $\mathrm{var}(y) = 2\nu$. This means choosing $\nu = 2[\mathrm{E}(u)]^2/\mathrm{var}(u)$ and $c = 2\mathrm{E}(u)/\mathrm{var}(u)$; but if $\mathrm{E}(u)$ and $\mathrm{var}(u)$ are unknown, then one has to replace them with estimates. Generally, ν will not be an integer. The technique just described is known as Satterthwaite's [3] approximation. Applications include those involving the **Behrens–Fisher problem**, variance components (see, for example, [1]), and contingency tables [2].

Before the advent of modern computers, an application with noninteger df required interpolation in a table of χ^2, t, or F. Today, however, this is no longer necessary, because values for noninteger df can be obtained through statistical **software** packages.

It may be useful to point out certain special relationships that pertain to degrees of freedom:

1. The t distribution with df $= 1$ is the same as the **Cauchy distribution** with median 0.
2. The χ^2 distribution with df $= 2$ is the same as the **exponential distribution** with mean 2.
3. A table of the t distribution typically has a line at the bottom that shows ∞ for df. For given significance levels (*see* **Level of a Test**), the values on this line are the same as those for a **standard normal deviate**. (This is because the distribution of t approaches the standard normal distribution as the df parameter approaches infinity.)
4. Similarly, tables of the F distribution typically have lines at the bottom that show ∞ for the denominator df. For given significance levels and for ν, ∞ as the df, the F values on these lines are the same as the values for $\chi^2(\nu)/\nu$ that appear in a table of χ^2 divided by its df. [Here the notation $\chi^2(\nu)$ refers to a χ^2 variable with df $= \nu$.]
5. The distribution of F with df $= 1, \nu$ is the same as the distribution of the square of a t variable

with df $= \nu$. In reporting results in a publication, however, it is better and more informative to show the value of $t(\nu)$ rather than the value of $F(1, \nu)$, because the former has a plus or minus sign that indicates the direction of the effect whereas the latter is always positive.

6. The distribution of χ^2 with df $= 1$ is the same as the distribution of the square of a standard normal deviate. In reporting results, though, it is more informative to show the standard normal deviate (with its plus or minus sign indicating direction) rather than $\chi^2(1)$.

RICHARD F. POTTHOFF

Delayed Entry

Analysis of survival data with delayed entry has in principle been known for centuries, since any **life-table** construction involves following persons from an entrance age to an exit age and registering whether exit is due to death or end of observation for other reasons (**censoring**, in modern terminology). Kaplan & Meier [16] briefly mentioned the validity of their product-limit estimator (*see* **Kaplan–Meier Estimator**) also under delayed entry, and Cox & Oakes [5, Section 11.6] gave a brief, but highly informative survey. However, the topic is absent from the authoritative texts by Kalbfleisch & Prentice [15] and Fleming & Harrington [8].

I first introduce the two main approaches to studying delayed entry: *left* **truncation**, or complete observation of a conditional distribution (next section), and *left filtering*, or observing events only when an observation switch is "on" (following section). In spite of the very different conceptual foundations of the ideas of left truncation and left filtering, the modifications of many non- and semiparametric hazard-based survival analysis estimators to delayed entry situations are exactly the same, essentially consisting in modifying the **risk sets** to only include individuals that have entered. As a consequence, also the calculations are the same.

For both left truncation and left filtering, the possibility of defining a concept of *independent* delayed entry is discussed. Conditionally independent delayed entry given **covariates**, as well as the special role of the **Cox regression model** for studying delayed entry, are then outlined. Deviation from independent truncation may happen if there is association between truncation time and survival time not accounted for by observable covariates, as briefly surveyed in a later section.

I then discuss the special delayed-entry problems in the epidemiologic *prevalent cohort* study, in which a cross sectional sample of persons with a certain disease is followed up. At entry to the study the patients will already have had the disease for a certain time. When this current duration is known, analysis by delayed entry at sampling is possible and can be shown to be valid if the statistical model is rich enough. I also briefly comment on the associated **length-bias** problems, and discuss what to do if current duration is not observed (for fuller discussion, *see* **Biased Sampling of Cohorts**).

The next section gives a nonstandard example, employing delayed-entry methods to obtain a faster confirmatory test in a clinical trial with staggered entry. The final section makes some brief comments on the relation to left censoring, right truncation and the retro-hazard, and mentions as an example retrospectively collected time-to-pregnancy data.

Random Left Truncation

Let V and X be independent positive **random variables** with density functions $g(v)$ and $f(x)$, distribution functions $G(v)$ and $1 - S(x)$ and **hazards** $\gamma(v) = g(v)/[1 - G(v)]$ and $\varphi(x) = f(x)/S(x)$. We call $S(x)$ the survival function of X (*see* **Survival Distributions and Their Characteristics**). The random truncation model [19, 29, 33] considers n independent replications $(V_1^*, X_1^*), \ldots, (V_n^*, X_n^*)$ from the conditional distribution of (V, X) given $V < X$. An important property (*independent truncation*) of the random truncation model is that the *the hazard of X given $X > V = v$ at $x > v$ equals the hazard of X at x*: in heuristic notation, for $x > v$,

$$\begin{aligned}\frac{\Pr\{X = x | V = v, X > V\}}{\Pr\{X \geq x | V = v, X > V\}} &= \frac{\Pr\{X = x, V = v\}}{\Pr\{X \geq x, V = v\}} \\ &= \frac{\Pr\{X = x\}}{\Pr\{X \geq x\}} \\ &= \phi(x).\end{aligned}$$

This property is the key to the simple result that the **nonparametric maximum likelihood estimator** $S(x)$ is given by the product-limit estimator

$$\hat{S}(x) = \prod_{X_i \leq x} \left(1 - \frac{1}{Y(X_i)}\right),$$

where $Y(u)$ is the number at risk at u.

This result was briefly mentioned by Kaplan & Meier [16] under the interpretation of counting the delayed entrants as "negative losses" and further discussed and elaborated in the three references just mentioned.

An unsatisfactory aspect of the random truncation model is its formulation in terms of the "latent" random variables (V_i, X_i) which remain unobserved when $V_i > X_i$. It was pointed out by Wellek [32] and Tsai [25] that it is sufficient to require that the conditional density of (V, X) given $V < X$ may be

written as $f(x)g^*(v)$ for $v < x$. Indeed, the above calculation then yields (for $x > v$)

$$\frac{\Pr\{X = x | V = v, X > V\}}{\Pr\{X \geq x | V = v, X > V\}} = \frac{f(x)g^*(v)}{\int_x^\infty f(u)g^*(v)\,\mathrm{d}u} = \varphi(x).$$

The condition for independent truncation may therefore be formulated in terms only of the "observable" area $\{v < x\}$.

The above considerations rather immediately generalize to also accommodating right censoring (cf. [16, 25, 26], and [32]).

Tsai [25] derived a formal *test for independence* of truncation time and survival time, also valid under independent censoring. Tsai's test generalized Kendall's τ (based on the number of concordant and discordant pairs of observations (V_i, X_i), (V_j, X_j)) to a "conditional Kendall's τ" that is estimable from the conditional distribution of (V, X) given $(V \leq X)$ (*see* **Rank Correlation**). Kalbfleisch & Lawless [14] and Jones & Crowley [12] provided important additional discussion.

The Counting Process Approach and Filtering

The counting process approach to survival analysis allows an alternative approach to delayed entry and to the formalization of independence between survival and delay, directly generalizing the concept of *independent censoring*: see the article **Censored Data** or Andersen et al. [3, Chapter III].

For n independent, identically distributed uncensored survival times (random variables) $X_1, \ldots, X_n$ with survival function $S(x)$ and hazard $\varphi(x)$, define the *counting process*

$$N(t) = \sum_{i=1}^n N_i(t) = \sum_{i=1}^n I\{X_i \leq t\}.$$

With respect to the so-called self-exciting family of σ-algebras $(\mathcal{N}_t)$, $\mathcal{N}_t = \sigma\{N(u) : 0 \leq u \leq t\}$, $N(t)$ has the compensator

$$\int_0^t \varphi(u)Y(u)\,\mathrm{d}u,$$

with

$$Y(t) = \sum_{i=1}^n Y_i(t) = \sum_{i=1}^n I\{X_i \geq t\},$$

which means that the difference between $N(t)$ and the compensator is an $(\mathcal{N}_t)$-martingale. The integrand $\varphi(t)Y(t)$ is called the *intensity process*.

Now assume that observation is partially inhibited by some further noise, formalized by the concept of *filtering processes*, **stochastic processes** $C_i(t)$ on $[0, \infty)$ assuming the values 1 or 0 as observation is "on" or "off" and predictable with respect to an increasing family $(\mathcal{G}_t)$ of σ-algebras such that $\mathcal{N}_t \subseteq \mathcal{G}_t$ for all t. Then

$$N_i^c(t) = \int_0^t C_i(u)\,\mathrm{d}N_i(u) = I\{X_i \leq t, C_i(X_i-) = 1\}$$

is again a counting process, indicating whether the event has taken place before time t *and while observation is "on"*.

Independent filtering will be taken to mean that the intensity process of $N(t)$ is $\varphi(t)Y(t)$ also with respect to the larger family of σ-algebras $(\mathcal{G}_t)$ that includes information on the filtering. Intuitively, the intensity when individuals are observed should be the same as when they are not observed. Under this assumption, by stochastic integration theory

$$N_i^c(t) = \int_0^t C_i(u)\,\mathrm{d}N_i(u) = \int_0^t C_i(u)\varphi(u)Y_i(u)\,\mathrm{d}u + \int_0^t C_i(u)\,\mathrm{d}M_i(u),$$

where the last term is a $(\mathcal{G}_t)$-martingale, so that $N_i^c(t)$ has intensity process $\varphi(u)C_i(u)Y_i(u) = \varphi(u)Y_i^c(u)$ with

$$Y_i^c(u) = I\{C_i(u) = 1, X_i > u\};$$

that is, observation is on and the event has not happened. As before, we may aggregate: $N^c(t) = \sum N_i^c(t)$ has intensity process $\varphi(t)\sum Y_i^c(t)$, where $\sum Y_i^c(t)$ is the number at risk under the filtering.

Right censoring at U_i corresponds to $C_i(t) = I\{t \leq U_i\}$ and *left filtering and right censoring* corresponds to $C_i(t) = I\{V_i < t \leq U_i\}$.

With this definition of delayed entry, asymptotic distribution results are immediate and easily interpretable via increasing *number at risk*. This approach was advocated by Aalen [1, 2].

Kaplan & Meier [16] in their brief discussion of delayed entry took care to call this left *truncation*, in contrast to the then relatively newly specified concept of *censoring* (so termed by Hald [10, 11]). Still, the

spirit of Kaplan & Meier's idea seems closer to left filtering.

Consider now, for ease of exposition, a single individual. A minimal family $(\mathcal{G}_t)$ for independent left filtering only, with no right censoring, is then specified by

$$\mathcal{G}_t = \sigma(I\{V \le t\}, VI\{V \le t\}, I\{X \le t\}, XI\{X \le t\}).$$

The intensity process of $N_t = I\{X \le t\}$ with respect to $(\mathcal{G}_t)$ is $\Pr\{N_t - N_{t-} = 1|\mathcal{G}_{t-}\}$, and here are three cases. First, $\Pr\{N_t - N_{t-} = 1|X < t\} = 0$; secondly,

$$\begin{aligned}&\Pr\{N_t - N_{t-} = 1|X \ge t, V = v < t\}\\ &\quad = \Pr\{X = t|X \ge t, V = v < t\} = \varphi(t)\end{aligned}$$

as derived above; and thirdly,

$$\begin{aligned}&\Pr\{N_t - N_{t-} = 1|X \ge t, V \ge t\}\\ &\quad = \frac{\displaystyle\int_t^\infty f(t)g^*(v)\,\mathrm{d}v}{\displaystyle\int_t^\infty\int_t^\infty f(u)g^*(v)\,\mathrm{d}u\,\mathrm{d}v} = \varphi(t);\end{aligned}$$

so that altogether the intensity process

$$\begin{aligned}&\Pr\{N_t - N_{t-} = 1|\mathcal{G}_{t-}\} = \varphi(t)I\{X \ge t\}\\ &\quad = \Pr\{N_t - N_{t-} = 1|\mathcal{N}_{t-}\},\end{aligned}$$

as was to be proved. Hence it is seen that under the assumption that the conditional density of (V, X) given $V < X$ may be written as a product $g^*(v)f(x)$, left filtering is independent.

Delayed Entry and Covariates

If the lifetime X and entry time V are conditionally independent given a covariate Z (but possibly marginally dependent), then the filtering specified by delayed entry at V is still independent in the model for the *conditional intensity* given Z. For example, we then have, heuristically

$$\begin{aligned}&\frac{\Pr\{X = x|V = v, Z = z, X > V\}}{\Pr\{X \ge x|V = v, Z = z, X > V\}}\\ &\quad = \frac{\Pr\{X = x|Z = z\}}{\Pr\{X \ge x|Z = z\}}.\end{aligned}$$

This means that the conditional intensity given Z may be validly estimated also under "conditionally independent" delayed entry.

In particular, the Cox regression model specifies the dependence on time nonparametrically, and the estimation works with "numbers at risk" in the same way as for the fully nonparametric techniques. Delayed entry may therefore be handled – by truncation or filtering – as specified in the two previous sections. Cnaan & Ryan [4] compared this "correct" approach with other approaches and called attention to special problems with time-dependent covariates: see further Keiding & Knuiman [20] and the detailed discussion by Wang et al. [28].

Dependent Delayed Entry: Two Examples

Keiding [18] gave two examples where the assumption of independent delayed entry is violated.

In the first, assume that, given a random variable $Z = z$, V and X are independent, and for simplicity **exponentially distributed** with intensities γz and φz, respectively. The frailty Z is assumed to be an unobserved **gamma-distributed** random variable. A direct calculation then documents that the hazard of X given $X > V = v$ at $x > v$ differs from the marginal hazard of X at x. In this case, *unobserved heterogeneity* is the culprit.

The other example regarded *differential selection into observation* from two states with different hazards of death (such as a *healthy* state and a *diseased* state). A numerical example showed that the net effect of the differential selection can go either way depending on the concrete values of selection and death intensities.

The Prevalent Cohort Study

A cross sectional sample of patients suffering from a certain disease is taken at a particular calendar time t_V and followed up, usually for some fixed time interval.

Assume first that the age of onset of disease Y is known for each patient; let V be age at entry. The calendar time-, age- and duration-specific death intensity $\nu(t, a, d)$ may then be estimated by considering the patients as having delayed entry (with delay $Y - V$) at t_V (and possibly also right censoring at the end of the follow-up interval). Keiding [18] gave a formal calculation within the framework of illness–death processes (*see* **Stochastic Processes**) to show that this delayed entry is independent in the model for the $\nu(t, a, d)$. With $X =$ age at death,

T = time at death, $T_V = T - (X - V)$ time at entry, the hazard of X in the conditional distribution given $(Y = y, T = t, T_V = t_v, X > V)$ was shown to equal $\nu(t, x, x - y)$.

Keiding [18] also compared the delayed-entry estimator to two other possibilities: the *length-biased* estimator relevant if patients are counted from disease onset (see also Wang [27] and the article on **Length Bias**); and the *forward recurrence time estimator* [6] based on time from sampling to death only, not requiring knowledge of age at onset. The latter two possibilities require very strong stationarity assumptions and would rarely be justified in biomedical applications.

There is an extensive literature, primarily motivated by **AIDS**, on how to approach prevalent cohort studies when age at disease onset is unknown (for a survey, *see* **Biased Sampling of Cohorts**).

Example: Confirmatory Analysis of an Unexpected Finding at Interim Analysis

As an example, I quote an analysis regarding the prognostic significance of residual cancer tissue after diagnostic biopsy in breast cancer. The trials of the Danish Breast Cancer Cooperative Group (DBCG) were started during 1978 and, based upon the experience until December 31, 1981, a negative effect on recurrence-free survival of the presence of residual cancer tissue (RCT) after diagnostic biopsy was noted for premenopausal patients considered to be at high risk based on histological findings. The diagnostic biopsy is a tissue specimen that is examined by the pathologist for presence of malignant (i.e. cancerous) cells. If such cells were found, the whole breast was removed shortly thereafter, usually within 0.5–1.0 hours after the biopsy was taken, and only these patients are included in this study. It was considered unexpected, and not easily interpretable, to find a connection between the presence of cancer tissue in the biopsy cavity and recurrence-free survival, and a reanalysis on an independent set of data was therefore judged necessary before the finding could be considered an established fact within breast cancer prognostics. Ordinarily one would use patients accrued *after* January 1, 1982. Since accrual to this protocol was closed toward the end of 1982, only rather few patients were available, and even an average follow-up time of almost four years was not enough to reproduce the early finding. Alternatively, the recurrence-free survivors on January 1, 1982, might be included, counted with *delayed entry* with the duration obtained on that date: these patients are included with *left truncated* disease durations [21] (for full surgical discussion, see Watt-Boolsen et al. [31]).

Assuming that there are no hidden heterogeneities, the simple delayed entry correction provides a valid test based on the experience after January 1, 1982, conditional on survival until then for those accrued earlier (see Keiding et al. [21]). In fact, there were significant covariates (age at operation, pathoanatomical characteristics of the tumor; see Watt-Boolsen et al. [31]); in unpublished analyses by T. Bayer and N. Keiding these were included in the delayed entry approach through a Cox regression model, which did not change the qualitative conclusions.

Parner and Keiding [23] showed, under a broad class of model misspecifications, that the independence between interim and confirmatory analyses is robust.

Left Censoring, Right Truncation, Time-reversal, and the Retro-hazard

It is important to distinguish delayed entry (where the individual under study is only identified if the event (such as death) occurs after the entry time) from *left censoring*, where all individuals are counted, but for some of them it is only known that the event took place before a certain censoring time.

Technically, left censoring can sometimes be handled by the well-established hazard rate and risk set-based survival analysis techniques in *reverse time*; but examples of left censoring are rare in survival analysis – see, however, Ware & DeMets [30] and Andersen et al. [3, Examples I.3.7 and IV.3.5].

Right truncation can also often be handled by reversing time and focusing on the *retro-hazard* $\overline{\varphi}(x) = f(x)/F(x)$; see, for example, Lagakos et al. [22], Kalbfleisch & Lawless [13], Keiding & Gill [18], Keiding [17] and Gross & Huber-Carol [9]. Right truncation has become an important biostatistical tool in connection with **retrospective** epidemiologic observation plans particularly in studying AIDS, where only those individuals who contracted the disease before a certain calendar date are included. see Esbjerg et al. [7] for an application in neuroepidemiology (*see* **Truncated Survival**

Times). Also when retrospectively observing **time-to-pregnancy** it is quite common to observe only those who gave birth before study completion, necessitating correction for right truncation particularly in studying calendar time effects [24].

NIELS KEIDING

Delta Method

The delta method is really a theorem which states that a smooth function of an asymptotically normal estimator is also asymptotically normally distributed (*see* **Large-sample Theory**). The result is applied in numerous contexts for the computation of large-sample tests and confidence limits for nonlinear functions of parameters which have already been estimated. Typically, the method of **estimation** is a standard large-sample technique which cannot be directly applied to the problem of interest.

Let $\hat{\theta}_n$ denote a sequence of estimates of some parameter θ, such that

$$\sqrt{n}(\hat{\theta}_n - \theta) \xrightarrow{\text{L}} \text{N}[0, \sigma^2(\theta)] \tag{1}$$

(*see* **Convergence in Distribution and in Probability**). For example, $\hat{\theta}_n = \theta(X_1, X_2, \ldots, X_n)$, where $X_1, \ldots, X_n$ is a random sample from a distribution F_θ, the simplest cases being $\hat{\theta}_n = \overline{X}_n$, the sample **mean**, with $\theta = \mu_x$, or $\hat{\theta}_n = s_n^2$, the sample **variance**, with $\theta = \sigma_x^2$. Let g be a function which is differentiable in a neighborhood of the true value θ with $g'(\theta) \neq 0$. Then the delta method states that

$$\sqrt{n}(g(\hat{\theta}_n) - g(\theta)) \xrightarrow{\text{L}} \text{N}\{0, \sigma^2(\theta)[g'(\theta)]^2\}. \tag{2}$$

The result follows from (1) using standard convergence theorems [14, 2c.4]. Briefly, substitution of $\hat{\theta}_n$ into a Taylor expansion for g about θ yields

$$g(\hat{\theta}_n) = g(\theta) + (\hat{\theta}_n - \theta)g'(\theta) + (\hat{\theta}_n - \theta)o_p(1),$$

where $o_p(1) \xrightarrow{\text{p}} 0$. Then

$$\begin{aligned}\sqrt{n}(g(\hat{\theta}_n) - g(\theta)) - \sqrt{n}(\hat{\theta}_n - \theta)g'(\theta)\\ = \sqrt{n}(\hat{\theta}_n - \theta)o_p(1) = o_p(1).\end{aligned}$$

In fact, a slightly stronger result is needed, in which we assume that g' and σ^2 are continuous at θ, $\sigma(\hat{\theta}_n)|g'(\hat{\theta}_n)|$ is used to standardize (2), and convergence is to a standard normal distribution [14, 6a.2; 2, 12.1.2]. In practice, the **standard error** (se) of $\hat{\theta}_n$ is taken to be $\sigma/\sqrt{n}$, and the se of $g(\hat{\theta}_n)$ is $|g'(\theta)|\sigma(\theta)/\sqrt{n}$, with θ estimated by $\hat{\theta}_n$. Thus the delta method can also be viewed as a technique for approximating the mean and variance of a function of a random variable, $g(T)$ [10]. For this approximation to be valid we must have $\text{var}(T) = O(1/n)$. The Taylor expansion can also be used to provide a bias correction [8, 8.4(iii)].

In applications, a multivariate version of the theorem is typically needed. Suppose that $\hat{\theta}_n = (\hat{\theta}_1, \ldots, \hat{\theta}_k)$ is an asymptotically [in the sense of (1)] multivariate normal random vector with asymptotic mean θ and variance matrix $\Sigma(\theta)$. Let $\mathbf{g}(\theta) = [g_1(\theta), \ldots, g_q(\theta)]'$ and $\partial\mathbf{g}/\partial\theta$ denote the $q \times k$ matrix of partial derivatives. Then, if for each i, $\partial g_i/\partial\theta_j \neq 0$ for some j, we have

$$\sqrt{n}[\mathbf{g}(\hat{\theta}_n) - \mathbf{g}(\theta)] \xrightarrow{\text{L}} \text{N}\left(\mathbf{0}, \frac{\partial\mathbf{g}}{\partial\boldsymbol{\theta}} \sum \frac{\partial\mathbf{g}'}{\partial\boldsymbol{\theta}}\right). \tag{3}$$

The proof involves either a multivariate Taylor expansion [1, Appendix C; [4], 14.6.3] or, alternatively, an application of (2) using an arbitrary linear combination of the coordinates of $\mathbf{g}(\hat{\theta}_n)$ and well-known characterizations of the **multivariate normal distribution** and of convergence in distribution of random vectors [14, 6a.2]. In most applications $q = 1$.

The delta method is closely related to the method of **maximum likelihood**. As is well known, if $\hat{\theta}$ is the maximum likelihood estimator (MLE) of θ and $\mathbf{g}$ is a one-to-one differentiable transformation, then $\hat{\phi} = \mathbf{g}(\hat{\theta})$ is the MLE of $\phi = \mathbf{g}(\theta)$. A Taylor expansion of the score vector (*see* **Likelihood**) may also be used to show that the **information matrix** becomes [6; [8], Exercise 4.15]

$$I(\phi) = \frac{\partial\theta'}{\partial\phi} I(\theta) \frac{\partial\theta}{\partial\phi}.$$

Thus the asymptotic distribution of $\hat{\phi}$ obtained from the delta method is the same as that of the MLE. Indeed, in single parameter **exponential families**, where there is a **sufficient statistic** for the natural parameter (such as the **multinomial distribution**) the method of maximum likelihood can be regarded as an application of the delta method using the transformation implicitly defined by the score equations [5, 3, 2, 12.2.1]

Two classes of applications may be distinguished. The first involves choosing a transformation $g(\theta)$ so that $\text{var}[g(\hat{\theta})]$ = constant, in which case g is known as a variance-stabilizing transformation. From the delta method,

$$g(x) = c \int \frac{\text{d}\theta}{\sigma(\theta)}.$$

Examples include the angular (arc sin square root) transformation for a binomial proportion, and Fisher's z transformation for the sample correlation coefficient, r, [14, 6g.4]. The multivariate delta method can be used to establish the asymptotic normality of r [15, Chapter 3]; a similar technique can be used to show the asymptotic normality of the sample variance, s^2. Another general class of examples is given by the ladder of powers, $\text{var}(X) = c^2\mu^{2\alpha}$ for $\alpha > 0$ (*see* **Power Transformations**). In this case

$$g(x) = \frac{1}{c(1-\alpha)}\mu^{1-\alpha},$$

with the understanding that $\alpha = 1$ (constant coefficient of variation) gives $g(x) = \log x$. Other special cases include the square root transformation ($\alpha = 1/2$), which is used with the **Poisson distribution**. Strictly speaking, if $X_n \sim \text{Poisson}\,(n\theta)$, then the delta method must be applied to the sequence $\hat{\theta}_n = X_n/n$ [4, Example 14.6-3; [15], p. 121].

The second class of applications involves nonlinear functions of parameters for which large-sample estimates can easily be obtained, often from the **central limit theorem**, or from a **generalized linear model**. The simplest example is provided by the asymptotic normality of the sample **standard deviation** $s = \sqrt{s^2}$. The standard example is the variance of a ratio:

$$\text{var}\left(\frac{T_1}{T_2}\right) \approx \left[\frac{\text{E}(T_1)}{\text{E}(T_2)}\right]^2 \left\{\frac{\text{var}(T_1)}{[\text{E}(T_1)]^2} - \frac{2\text{cov}(T_1, T_2)}{\text{E}(T_1)\text{E}(T_2)} + \frac{\text{var}(T_2)}{[\text{E}(T_2)]^2}\right\}.$$

An application is the estimation of the dose corresponding to a given frequency of response in the analysis of **quantal response** data in toxicology [13, 2.7.1]. Related applications include the variance of the log of the **relative risk**, $rr = p_1/p_2$, and the log **odds ratio** (the logarithms of these quantities being more nearly normally distributed) in epidemiology [11, 15.5]. For example,

$$\text{var}[\log(rr)] \approx \frac{1-p_1}{n_1 p_1} + \frac{1-p_2}{n_2 p_2}.$$

Another interesting class of examples involves the calculation of large-sample standard deviations for various measures of **association** in two-way contingency tables. These have the form $\zeta = \nu(\pi_{ij})/\delta(\pi_{ij})$, where $\nu(\pi_{ij})$ and $\delta(\pi_{ij})$ are known functions of the population proportions [1, 10.3; [4], 11.3]. A special case is the measurement of **agreement** between two raters on a categorical scale. The standard measure of interrater reliability is the observed proportion of agreement corrected for chance, known as **kappa**. A large sample standard deviation may be computed using the delta method [4, 11.4; [9], 13.1].

In multinomial regression models, the delta method can be used to establish the asymptotic distribution of the predicted cell probabilities and residuals, typically standardized cell **residuals** [2, 12.2–12.3]. Cox & Ma [7] used a similar application to develop confidence bands for generalized **nonlinear regression** models. For extensions of the basic result ($g'(\theta) = 0$ and $\sigma_n \to 0$ instead of $\sigma/\sqrt{(n)} \to 0$), see [15, Chapter 3].

Lehman [15, Section 6.3] considers the extension to limit distributions of statistical functionals.

Demography

Demography is the study of human populations with respect to their size, structure, and dynamics. For demographers, a population is a group of individuals that coexist at a point in time and share a defining characteristic such as residence in the same geographical area. The structure or composition of a population refers to the distribution of its members by age, sex, and other characteristics, such as place of residence and marital or health status. The age and sex structure of a population results from past trends in fertility, mortality, and migration. Thus, these processes comprise the components of demographic change. The age and sex structure of a population, in turn, affects birth rates, death rates, and rates of migration. Changes in status such as getting married or divorced interact with population structure in a similar way.

Some authorities reserve the term demography for the mathematical and statistical study of the interrelationships between population size and structure and the components of demographic change. According to this terminology, demography can be contrasted with population studies, which investigate the determinants and consequences of demographic phenomena drawing on the concepts and theories of disciplines such as the **social sciences**, health sciences, and history. Others encompass population studies within demography and use the term *formal demography* to distinguish the statistical core of the discipline. Demography (according to this wider definition) is a multidisciplinary field: subdisciplines such as economic demography, historical demography, anthropological demography, and mathematical demography exist. They differ not only in their subject of study but also in their theoretical orientation and methods.

The term demography has been ascribed to a Belgian statistician, Achille Guillard, who coined it in 1855. However, the origins of modern demography are usually traced back to **John Graunt**'s quantitative analyses of the "Bills of Mortality" published in 1662 [5]. The "Bills of Mortality" provided weekly lists of burials and baptisms in the parishes of London. Graunt used these data to examine the sex ratio at birth and to estimate the population of London. He showed that more deaths than births occurred in London, implying that the growth of the capital was due to in-migration from the countryside. He also estimated the proportion of births surviving to a range of ages, thereby developing the basic concept of the **life table**. Graunt's research prefigures modern applications of demographic science: information on fertility and mortality and population estimates for small areas (*see* **Small Area Estimation**) remain the fundamental results of demographic analysis required by those engaged in policy formulation and planning.

Demographic Data

In most developed countries, civil registration of births and deaths is the primary source of fertility and mortality data. Government agencies routinely collect demographic information when births and deaths are certified for administrative purposes (*see* **Vital Statistics, Overview**, Overview). The primary source of data on the size, structure and distribution of national populations is the population census. **Censuses** aim to enumerate the whole population of a defined geographical area. They collect individual-level data on the population's characteristics that refer to a single point in time. As well as collecting data on the size and composition of the population, most censuses also ask about moves in a fixed period of time before the enumeration. In countries where vital statistics data are incomplete, questions may also be asked about fertility and mortality. Countries that issue identity numbers and require their population to report their place of residence can maintain continuous population registers. In a few European countries these registers now fuse the functions of the registration system with those of the census.

The evolution of demographic analysis and of routine collection of data on populations by the government were interlinked. Standard demographic measures and techniques of analysis were developed largely for the study of vital statistics with census-based denominators. In recent decades, however, demographers have relied increasingly on survey data to supplement those from traditional sources (*see* **Surveys, Health and Morbidity**). In particular, in countries where registration of vital events is incomplete national sample surveys are the main source of vital statistics. One of the first subjects to be investigated in demographic surveys was family planning

(*see* **Reproduction**). Other early surveys collected women-based fertility histories to supplement the event-based data generated by birth registration. Fertility history and family planning data remain the focus of many demographic surveys, including the two major international programs of surveys conducted since the 1970s, namely the World Fertility Survey and the Demographic and Health Surveys.

Issues

Between the mid-nineteenth and mid-twentieth centuries the more developed regions of the world went through a *demographic transition* from a high-fertility, high-mortality, and low-growth demographic regime to a low-fertility, low-mortality, and low-growth demographic regime. As mortality tended to fall before fertility, this transition was marked by rapid population growth. Since 1945, a similar transition has begun in most less developed countries. As a result, the world's population has grown from about 2.5 billion to about 6 billion in the second half of the twentieth century. It is expected to grow to between 9 and 16 billion by 2100.

Efforts to understand the determinants of the transition of fertility and mortality to low levels are a central concern of demography. Many demographers now believe that explanations that focus on economic factors and the provision of health and family planning programs are inadequate and need to be supplemented by accounts that take into account the ideational and cultural determinants of demographic behavior.

Thomas Malthus was the first author to develop a systematic argument that high fertility leading to **population growth** could have adverse effects on economic welfare [7]. He argued that a growing population must eventually outstrip its subsistence base, bringing about rising mortality from famine, pestilence, and war. Although the past two centuries of human history have followed a very different path from that envisaged by Malthus, concern still exists about the impact of population growth on economic development and the environment. Today, however, economic demographers tend to be more sanguine about the consequences of population growth than those with a background in ecology [3].

Many demographic outcomes are of concern to policy makers and much demographic research has an avowedly applied intent. Demography bears on the efforts of international agencies and national governments to promote family planning and improve health in the developing world. In the developed world, population growth has slowed but low fertility and the reduction in death rates in old age are producing an increasingly aged population. Recent changes in patterns of marriage and divorce and of childbearing inside and outside marriage also have major implications for the family and public policy.

Demographic studies of mortality tend to focus on the analysis of routine data. Demographers' research into health and mortality cannot be distinguished clearly from that of epidemiologists. However, demographers tend to be concerned with the distribution of disease and premature death (*see* **Descriptive Epidemiology**) across social groups (*see* **Social Classifications**) and their implications for other aspects of social life, rather than with measuring risk factors for specific conditions.

Demographic Analysis

The aim of formal demographic analysis is to isolate the components of demographic patterns by dividing a population into relatively homogeneous subgroups. Analysis by age and sex has primacy over analysis by other compositional factors. Human biology causes the propensity to die and to give birth to be differentiated by age and sex everywhere. It imposes a degree of uniformity on age patterns of mortality and fertility in all human populations.

Classical demographic analysis is based on a fairly small set of measures and techniques. Most of these are also used in cognate disciplines. Calculation of **rates**, ratios, and proportions represent the basic way for controlling for population size. In demography, rates calculated for the whole population that make no allowance for the influence of population structure on the phenomenon of interest are referred to as *crude rates*. Examples are the crude birth rate and crude death rate (*see* **Vital Statistics, Overview**).

Calculation of age-specific rates and rates specific to other subgroups of the population allow the analyst to isolate the propensity to experience the event being studied from the influence of population structure. A range of methods of standardization are used to produce synthetic indices that summarize such specific rates (*see* **Standardization Methods**). The distinction between cohort analysis and **cross-sectional**

or period analysis is fundamental to demography. Demographers use the term *cohort* to refer to groups of individuals who experience a defining event at the same time. Examples include **birth cohorts** and marriage cohorts. Cohort analysis studies the subsequent experience of such groups. This contrasts with epidemiologic usage, which refers to all those eligible for recruitment into a longitudinal study as a **cohort**.

Period measures are often treated as referring to a synthetic or hypothetical cohort, so that summary indices can be calculated that indicate what would happen to a cohort that went through life experiencing the specific rates of the period under study. For example, the most widely used index of period fertility is the *total fertility rate*. This measures how many children women would bear on average if they went through life with the fertility of a specific period. It is calculated by summing the age-specific fertility rates of a particular year, usually for five-year age groups, over all ages at which women bear children. The total fertility rate is thus a form of directly standardized rate, calculated using a uniform age distribution as the standard.

Two basic aspects of any demographic process are its intensity, or quantum, and its timing, or tempo. The intensity of a nonrenewable event such as death or first marriage can be measured by the proportion of a cohort who eventually experience the event. Both the expected timing of any nonrenewable process and the distribution of times of its occurrence can be studied using **life table** methods. The intensity of a renewable process such as birth or disease incidence can be measured by the **mean** number of events per person, and their tempo by the characteristics of the distribution of the events in time. Renewable events can be categorized by the order of their occurrence, and events of a particular order can be analyzed as a nonrenewable process. For example, the proportion of women who have had a birth of order i that go on to bear a child of order $i + 1$ is known as a *parity progression ratio*.

Investigation of the determinants of fertility and mortality has been facilitated by making a distinction between proximate and distal determinants. The approach is most developed with respect to fertility. A proximate determinant is one that has a direct impact on the outcome of interest while a distal determinant can only affect the outcome via a proximate determinant. The proximate determinants of fertility are those factors that determine a woman's exposure to sexual intercourse, her probability of conceiving, and the probability that a pregnancy ends in a live birth. The strength of the approach is that only a few of the proximate determinants of individuals' fertility differ between populations in their impact at the aggregate level. Thus, the four main proximate determinants of fertility differences between groups and over time are the proportion of women in sexual unions, postpartum infecundity associated with breast-feeding, contraception, and abortion. Socioeconomic determinants of fertility must operate through these few proximate factors and a single characteristic may have countervailing effects on fertility via different proximate determinants.

Demographic Models

Analysis of data on actual populations is paralleled by mathematical models of the interrelationship between population size and structure and the components of demographic change. Stable population theory as developed by Lotka in the 1920s and 1930s demonstrates that any closed single-sex population subject to constant fertility and mortality rates converges on an unchanging age structure and a constant rate of growth. This stable outcome is independent of the initial age structure of the population. The special case of a stable population that is unchanging in size is termed a *stationary population*. Its age structure is a function of the life table. Recent developments, known as generalized stable population theory, demonstrate that the mathematics of stable populations can be extended to populations in which growth rates vary by age because of a history of fertility and mortality change and to populations subject to decrements other than mortality [8].

One crucial application of demography is to the forecasting of future population change. This is usually undertaken using cohort-component methods of population projection [2]. These methods provide a precise way of controlling for the influence of population structure and of working out the implications of any scenario postulated for future vital rates. Despite this, population forecasts have often proved wide of the mark. Fertility, mortality, and migration remain difficult to predict. Forecasts informed by a theoretical understanding of the determinants of these components of population change often perform little better than the simple extrapolation of past trends in vital rates.

The increasing availability of survey data and information technology that makes it practicable to undertake individual-level analysis of data on large samples, have facilitated convergence between demographic methods and other forms of statistical analysis. Thus, many of the developments in demographic analysis during the past few decades have been closely linked to those in statistical methods more generally. Demographers have both adopted and contributed to the development of methods such as event history analysis [10], the modeling of unobserved heterogeneity, and **random-effects** models [4]. Other fields of methodologic research in recent years include the extension of life table methods into multistate models that allow for increments as well as decrements from each state [6] and methods and models for the study of families and households [1]. (*see* **Multilevel Models**)

One particularly successful field has been the development of indirect methods for estimating vital rates in populations with limited and defective vital statistics [9]. Indirect methods use stable population theory and its extensions to describe the relationship between conventional indices of fertility, mortality, and migration and items of information that can be collected more reliably in single-round surveys and censuses in less developed countries. For example, it is possible to estimate life table indices of child mortality from data on the proportion of women's children ever-born who have died, tabulated by the age of the women concerned [9].

Dendrogram

The term "dendrogram" (Greek *dendron*, a tree) is used in **numerical taxonomy** for any graphical drawing or diagram giving a treelike description of a taxonomic system. More generally, a dendrogram is a two-dimensional diagram representing a tree of relationships, whatever their nature.

Some of the earliest examples of dendrograms are the customary phylogenetic trees used by systematists. It seems that the term "dendrogram" was first used by Mayr et al. [13] (see also [16]).

Depending on the nature of the relationships described by the diagram, the term "dendrogram" is sometimes replaced by another, such as phenogram or cladogram. The former is used for a dendrogram representing phenetic, and the latter for that representing cladistic relationships [3, 12].

The representation of a taxonomic system by a dendrogram is particularly suitable in connection with a cluster analysis applied to investigate the structure of the corresponding operational taxonomic units; that is, entities or individuals considered as the lowest-ranking taxa within the system, such as individual patients or case histories initially used to construct disease classifications [16]. This becomes apparent when it is desirable to interpret the results of the analysis in terms of a natural nonoverlapping taxonomic hierarchy. The usual basis for a cluster analysis is a resemblance (proximity) matrix, its rows and columns referring to the operational taxonomic units, and its entries being the estimates (measurements) of the resemblances between the corresponding units (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Similarity, Dissimilarity, and Distance Measure**).

There are various ways of drawing a tree diagram to illustrate the fusions and partitions that have been made at each successive level of the cluster analysis applied. The early practice of drawing dendrograms tended to have the branches of the treelike diagram pointing upward or downward. But later, with ever-increasing numbers of operational taxonomic units, it has become more convenient to place the dendrograms, and particularly the phenograms, almost uniformly on their side, with branches running horizontally across the page. The abscissa is then scaled in the resemblance measure on which the clustering has been based, and the points of furcation between stems along the scale imply that the resemblance between two stems is at the similarity coefficient value shown on the abscissa. It should be realized, however, that the order in which the branches of a dendrogram are presented has no special significance, and can be changed within wide limits without actually changing the taxonomic relationships implied by the dendrogram. This multiplicity of ways in which the same relationships can be represented in a dendrogram may be regarded as a disadvantage. In fact, a dendrogram representation of a resemblance matrix is likely to be satisfactory only if the data are strongly clustered and have an hierarchical type of structure. Otherwise, the dendrogram can be very misleading. Several methods have been suggested to overcome this (see, for example, [14]).

Examples of dendrograms and methods of their presentation are described in many textbooks on numerical taxonomy and multivariate analysis (*see* **Cluster Analysis of Subjects, Hierarchical Methods**) (see also [6, 11, 14, 16], and [17]).

Two different clustering methods may lead to different dendrogram representations of the results, even if both methods are based on the same resemblance matrix. Among the various clustering methods, one is particularly relevant to a dendrogram representation. It is the **single linkage** cluster analysis, also known as the nearest-neighbor technique, introduced by Florek et al. [7, 8] and, independently, by McQuitty [10] and Sneath [15]. As shown by Gower & Ross [9], the most efficient procedure for the single linkage cluster analysis is based on producing the shortest dendrite (the minimum spanning tree; see [1]). In fact, the single linkage clusters can be obtained from the shortest dendrite by successively removing its edges, largest first, the second largest next, and so on. The shortest dendrite itself also gives an alternative graphical representation of the single linkage cluster analysis results (see, for example, [14]). This may appear more convenient than the usual application of a dendrogram, particularly when superimposing the dendrite on the operational taxonomic units scattered in an ordination plot of two or three dimensions obtained, for example, from the **principal components analysis** [16] or the canonical variate analysis [1].

Dendrograms can also be applied when using a cluster analysis in order to partition treatment means in the **analysis of variance**, as shown, for example, by Caliński & Corsten [2] (see also [4]).

Several statistical packages include computation procedures for displaying dendrograms: see Digby [5] in particular (*see* **Software, Biostatistical**).

TADEUSZ CALIŃSKI

Denominator Difficulties

Epidemiologists often report data in terms of **rates** and proportions. These measurements require denominators (defined by Last [3] as the lower portion of a fraction used to calculate a rate or ratio) as well as numerators (the upper portion of such a fraction [3]). A rate is a specific kind of fraction in which the numerator represents the frequency of occurrence of an event during a particular time period and the denominator represents the average population at, or exposed to, risk for occurrence of the event over the time period. Neglect of this "exposed to risk" term is one of the commonest errors made in the everyday use of statistics for calculating rates [2, pp. 238–247].

The essence of the denominator problem is that percentages, proportions, or ratios are misrepresented as rates [1, pp. 289–313; 2, pp. 238–247]. Methodological errors in regards to denominator data usually fall into one of three categories: (1) missing denominators; (2) wrong denominators; and (3) unknown denominators. *Missing denominators* are numbered among the more frequently found flaws in data analysis. When denominators are missing, for whatever reason, numerators may be found serving in their stead, and the proportions and percentages derived from these numerators are mistakenly interpreted as rates [1, pp. 289–313]. Confusion results when the misinformed reader tries to interpret these so-called rates; for example, proportional rates [2, pp. 248–257].

Suppose that physicians compared rates of a new infectious disease (ID) among diabetics and nondiabetics in their clinic and found that diabetics were ill more frequently with this disease. Based on these numerator data, they might wrongly conclude that morbidity rates from this ID were higher among diabetics. However, these data indicate only that diabetics account for the largest *proportion* of the cases. To compare *rates* of disease occurrence, the missing denominator data, representing the exposed population (the total numbers of diabetics and nondiabetics served by the clinic and "at risk" for the ID) must be supplied. If many more diabetics than nondiabetics attended the clinic, when one takes into consideration the magnitudes of the denominators, nondiabetics could have the higher morbidity rate for the ID despite having the lower number of actual cases.

The *wrong denominator* is likely to be used when the population exposed to risk cannot be estimated adequately. Suppose, for example, that a clinic reported rates of disease Z of four per 1000 visits among men but two per 1000 visits among women. Whereas disease Z may account for a greater *percentage*, (or, proportional rate) of visits by men than women, one cannot conclude that the **prevalence** *rate* for disease Z is twice as high in men than in women. These percentages are based on those who presented for evaluation and treatment, and may be specific for this clinic (sometimes called "treated prevalence"). The appropriate denominators for prevalence rates are based on the total numbers of "at risk" men and women in the community served by the clinic, rather than on the number of visits. The two sexes may have similar prevalence rates for disease Z, but because women may visit the clinic for all causes more often than men do, proportionately more men than women present with disease Z.

Another instance of the wrong denominator involves mortality (also, morbidity) rates. The mortality rate for a disease is calculated as the number of deaths due to the specific cause divided by the population at risk for the specific cause of death. Thus, the mortality rate is a measurement of the absolute risk for death from a specific cause (*see* **Vital Statistics, Overview**). If the number of deaths due to a specific cause is divided by the number of deaths due to all causes, the result is a proportion instead of a rate. **Proportional mortality** rates indicate the percentage of deaths due to a given cause in relation to other (or all) causes of death. It has also been argued that cause-specific mortality rates, themselves, are not the most accurate reflection of the **risk** of mortality, and that it would be more meaningful to use the risk of exposure to a specific cause as the denominator term [1, p. 277]. However, population data often are the only denominator data available in sufficient detail to allow rates to be compared.

The *unknown denominator* problem occurs when rates are derived from data that may have been distorted by **selection bias**. In other words, one may be misled by the cases one has at hand. For example, consider 100 depressed patients who initially responded to electroconvulsive therapy (ECT) and later experienced relapse. Prior to relapse and subsequent referral to a consulting psychiatrist, 50 were prescribed maintenance antidepressant therapy after ECT and 50 were not. The consultant may conclude

that maintenance drug treatment does not improve post-ECT one-year remission rates. However, maintenance therapy failures may represent a relatively small fraction of those so treated, compared with those who do not receive post-ECT antidepressant treatment, most of whom will relapse within one year. The fallacy is in calculating relapse rates without knowing the denominator; that is, deriving rates from the number referred for consultation instead of from the population at risk (the number who received each treatment regimen). Those responding to treatment without suffering a relapse will not be in this psychiatrist's series.

HOWARD M. KRAVITZ

Density Estimation

Density estimation is the fitting of a **probability** density function (pdf), $f(x)$, to data. We have the choice of performing a parametric or nonparametric fit. In common usage, the phrase *density estimation* usually refers to the **nonparametric** methodology, which is the focus of this article. We introduce the classic nonparametric estimator, the histogram, and outline its theoretical properties as well as good practice (*see* **Frequency Distribution**). We demonstrate how to improve the histogram, leading to our discussion of popular kernel methods. We conclude with a bivariate example, a way of choosing smoothing parameters, and new directions that promise further improvements (*see* **Nonparametric Regression**).

Why choose nonparametric over parametric density estimation? Parametric density estimation requires both proper specification of the form of the underlying sampling density, $f_{\boldsymbol{\theta}}(x)$, and **estimation** of the parameter vector $\boldsymbol{\theta}$. Parametric modeling entails two risks of bias: in estimation of $\boldsymbol{\theta}$ and incorrect specification of $f_{\boldsymbol{\theta}}$ (*see* **Misspecification**). Nonparametric density estimation provides a consistent **algorithm** for nearly any continuous density and avoids the specification step. Although the cumulative distribution and probability density functions carry the same information, densities are more easily interpreted than distributions, especially in more than one dimension, so our focus on the density is appropriate.

Density estimation is broadly applicable for exploring data relationships, presenting data summaries, and constructing sophisticated nonparametric models of biostatistical data (*see* **Exploratory Data Analysis**). **Graphical** representation of data is a powerful tool for summarization. Three simple exploratory graphical summaries are the box-and-whiskers plot (or boxplot), the stem-and-leaf plot, and the histogram. Consider the cholesterol levels of 320 males with diagnosed coronary artery disease [21]. Figure 1 displays a boxplot of these data. The data appear symmetric with a few outliers. The various percentiles displayed in the boxplot do not hint of any unusual feature such as we see in Figure 2 in the right histogram, which shows mild evidence of bimodality (*see* **Mode**); however, even with 320 observations, the weight of evidence is probably not strong. Observe that the two histograms have the same bin width, but their meshes are shifted. The stem-and-leaf plot (not shown) indicates specific data values but otherwise has no frequency information beyond the histogram.

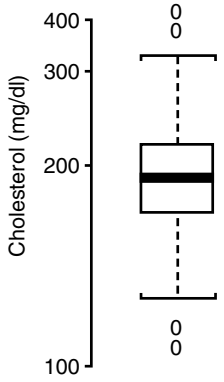

Figure 1 Boxplot of $\log_{10}$ cholesterol data ($n = 320$)

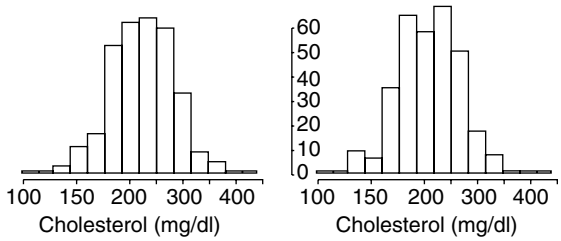

Figure 2 Two histograms of the cholesterol data with the same bin width but shifted meshes. The first appears Gaussian; the second appears bimodal

Histogram

A histogram is the simplest density estimator and is one example of a frequency curve, using tabulation of data in bins. Frequency curves have had an important role to play since their introduction by **John Graunt**, who searched for patterns of death in the Bills of Mortality collected during the London plague of the seventeenth century. Graunt performed a primitive **survival analysis** by grouping age of death in five-year-wide intervals. Here we highlight the theoretical properties of a histogram.

Given a sample $x_1, x_2, \ldots, x_n$ contained in an interval (a, b), the histogram is constructed over a partition $\{t_k\}$ of (a, b) into M intervals, $B_k =$

$[t_{k-1}, t_k)$, such that $a = t_0 < t_1 < \ldots < t_M = b$. Let the bin width of B_k be denoted by $h_k = t_k - t_{k-1}$. Let the bin count be denoted by ν_k, so, that $\sum_{k=1}^{M} \nu_k = n$. Then the histogram estimate of the density, $f(x)$, is given by

$$\hat{f}_{\mathrm{H}}(x) = \frac{\nu_k}{nh_k} = \frac{\nu_k}{n(t_k - t_{k-1})}, \quad x \in B_k,$$

and zero outside $[a, b)$. Observe that $\hat{f}_H$ satisfies both conditions of a density function as $\hat{f}_{\mathrm{H}} \geq 0$ and $\int \hat{f}_{\mathrm{H}} = 1$.

Usually, all the bin widths are chosen to be equal, $h_k = h$, as in the stem-and-leaf plot. While any choice of the bin width will produce an informative diagram, the notion of an optimal bin width has been studied extensively [6, 17]. At each point x, $\hat{f}_H(x)$ is generally biased, so that the **mean square error** (MSE) is an appropriate criterion. A Taylor's series analysis reveals that the sum of the pointwise variance and squared **bias** decomposition is given by

$$\mathrm{MSE}[\hat{f}_{\mathrm{H}}(x)] = \frac{f(x)}{nh} + \frac{1}{12}h^2 f'(x)^2.$$

(Terms omitted are of lower order n^{-1}.) If h is too large, then the histogram has too few bins and is "oversmoothed" – exhibiting low variance but high bias. However, if h is too small, then $\hat{f}_H(x)$ has too many bins and is "undersmoothed" – suffering high variance.

For an entire histogram, the pointwise mean squared error criterion may be integrated to give a global criterion, the integrated mean squared error (IMSE):

$$\begin{aligned}\mathrm{IMSE}(\hat{f}_{\mathrm{H}}) &= \int_{-\infty}^{\infty} \mathrm{MSE}[\hat{f}_H(x)]\,\mathrm{d}x \\ &= \frac{1}{nh} + \frac{1}{12}h^2 R(f'),\end{aligned}$$

where $R(f') = \int_{-\infty}^{\infty} f'(x)^2\,\mathrm{d}x$ is referred to as the "roughness" of the unknown density function. Ordinary calculus reveals the optimal bin width

$$h^*_{\mathrm{H}}(f) = 6^{1/3} R(f')^{1/3} n^{-1/3}.$$

The optimal IMSE decreases to zero at the rate $n^{-2/3}$, far short of the usual parametric rate of n^{-1}. Only one function of the unknown density is relevant to the optimal bin width.

Using a **normal** density, $\phi = N(\mu, \sigma^2)$, as a reference, $R(\phi') = 1/(4\pi^{1/2}\sigma^3)$, so that

$$h^*_{\mathrm{H}}(\phi) = 3.5\sigma n^{-1/3}.$$

In practice, the unknown standard deviation, σ, is replaced by the sample standard deviation or a **robust** estimate. This formula is more general and useful than its motivation might suggest. By considering *all* possible densities in $h^*_{\mathrm{H}}(f)$, it has been found that $h^*_{\mathrm{H}}(\phi)$ is within 7% of a theoretical upper bound [27]. Thus for real data, use of $h^*_{\mathrm{H}}(\phi)$ will almost always result in mild oversmoothing of the data. In no case should a wider bin width be selected. More refined choices will be discussed in the section Choosing Smoothing Parameters below.

Improvements on Histograms

Frequency Polygon

A continuous version of the histogram is the frequency polygon (FP), which is formed by interpolating the midpoints of a histogram. The theoretical properties of the frequency polygon are superior to the histogram. Scott [18] showed that its IMSE decreased at the much faster rate of $n^{-4/5}$, and that $h^*_{\mathrm{FP}}(\phi) = 2.15\sigma\, n^{-1/5}$. (This is within 8% of the oversmoothed upper bound bin width.) The optimal frequency polygon uses wider bins than the optimal histogram. (The optimal histogram requires more and narrower bins to try to approximate the density where the slope is greatest.)

Averaged Shifted Histogram (ASH)

Both the histogram and frequency polygon share a second design parameter that can have a large visual impact, especially for small sample sizes, as demonstrated in Figure 2. This parameter is the bin origin, t_0. For a fixed bin width, there is an unlimited number of possible choices for t_0 in the interval $(a - h, a]$. In many situations, t_0 may be viewed as a **nuisance parameter**. Scott [19] proposed averaging over shifted meshes to eliminate the bin edge effect. To be specific, form a finer (narrower) mesh of width $\delta = h/m$ for some positive integer m, and let B_k and ν_k refer to this new, finer set of bins. Then for $x \in B_k$, there are m different histograms with bin width $h = m\delta$ that cover (include) bin B_k. The bin counts for

these m shifted histograms are $(\nu_{k-m+1} + \cdots + \nu_k)$ to $(\nu_k + \cdots + \nu_{k+m-1})$. A little algebra reveals the mean or averaged shifted histogram (ASH) as

$$\hat{f}_A(x) = \frac{1}{m} \sum_{j=1-m}^{m-1} \frac{(m - |j|)\nu_{k+j}}{nh}$$

$$= \frac{1}{nh} \sum_{j=1-m}^{m-1} \left(1 - \frac{|j|}{m}\right) \nu_{k+j}, \quad x \in B_k. \quad (1)$$

Figure 3 displays an example for $m = 14$ for the cholesterol data as in Figure 2. The estimate is not only visually smoother and more appealing than the histogram, but also shares the improved theoretical properties of the frequency polygon, while, in fact, being about 20% more efficient. The two modes are more clearly uncovered.

Kernel Estimator

As $m \to \infty$, the ASH takes on an equivalent and widely studied form. Since ν_k is either 0 or 1 in the limit (excluding ties), the sum in (1) can be re-expressed as a sum over the n data points:

$$\hat{f}_K(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right), \quad (2)$$

with $K(t) = [1 - |t|]_+$, where $[x]_+$ is the positive part of x, or zero. This so-called kernel estimator was extensively studied by Rosenblatt [12] and Parzen [11] although first proposed in a technical report by Fix & Hodges [5]. Similar ideas were more developed in spectral density estimation at that time (*see* **Spectral Analysis**). The parameter h is no longer a bin width, *per se*, and is called a smoothing parameter.

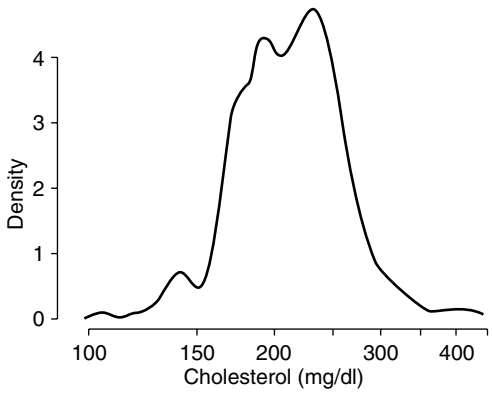

Figure 3 Weighted average of 14 shifted histograms of the cholesterol data. The weights $\{w_m(j)\}$ used were derived from the kernel $K(t) = 315/256(1 - t^2)^4$ according to (3)

The kernel density estimator turns out to be quite general. Any probability density that is square integrable can be selected for the kernel. The usual requirements are that $\int K = 1$ and $\int xK = 0$. Picking a symmetric probability density satisfies both. Even higher order rates of convergence such as $n^{-8/9}$ are possible if $\int x^2 K = 0$, but such kernels must take on negative values.

Apparently, the kernel estimator is a mixture of n densities, each centered on a data point. Computationally, kernel estimation can be quite expensive for large samples. Prebinning the data is an accepted technique for speeding the evaluation. This is equivalent to the ASH with weight function $w_m(j) = 1 - |j|/m$ in (1) replaced by

$$w_m(j) = \frac{mK(j/m)}{\sum_{i=1-m}^{m-1} K(i/m)} \quad (3)$$

for kernels defined on $[-1,1]$. **Fast Fourier transformations** may be used if the kernel is the Gaussian probability density function (pdf) [22].

There are many other techniques based on filtering or orthonormal estimation, but these may be shown to be equivalent to the use of a particular "equivalent" kernel function. Recent interest in the use of **wavelets** as an orthonormal basis illustrates the generality of kernel methodology (*see* **Orthogonality**).

Multivariate Density Estimation

The kernel estimator has a simple extension to two dimensions (and similarly for more dimensions) by using a bivariate probability density, $K(x, y)$, as the kernel:

$$\hat{f}_K(x, y) = \frac{1}{nh_x h_y} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h_x}, \frac{y - y_i}{h_y}\right), \quad (4)$$

where each coordinate direction has its own smoothing parameter. Some authors [29] advocate the use of the **correlation** coefficient as an additional smoothing

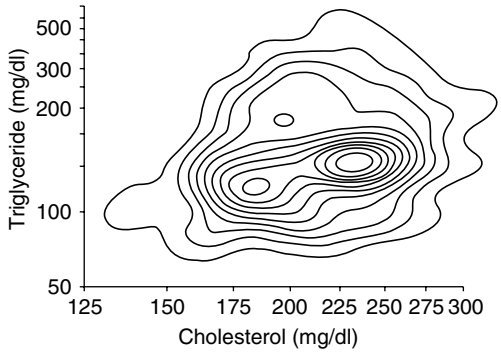

Figure 4 Bivariate averaged shifted histogram of cholesterol and triglyceride blood concentrations for 320 patients as in earlier figures. At least two patient clusters are suggested

parameter. Similarly, the averaged shifted histogram may be defined by averaging over histograms shifted along both the x and y axes. The latter is illustrated in Figure 4 on the coronary artery disease data. (The bivariate kernel was taken as the product of two univariate kernels used in Figure 3.) The bivariate ASH clearly reveals the nonnormality of the data, suggesting an extra mode or two much more strongly.

Examples in three and four dimensions, including visualization, with applications to **clustering, discrimination**, and **regression** are presented by Scott [20].

Choosing Smoothing Parameters

A good deal of research has appeared on improved and automatic algorithms for choosing h in (1), (2), and (4). Some focus on plug-in estimates of quantities such as $R(f')$, while others rely on modification of **maximum likelihood** or **information** measures.

We mention only one method, **least-squares cross-validation**, which if not the most **efficient** procedure, is clearly the most general and widely applicable. The IMSE criterion is the average of the integrated squared error (ISE) between $\hat{f}_h$ and f:

$$\begin{aligned}\mathrm{ISE}(h) &= \int [\hat{f}_h(x) - f(x)]^2 \, \mathrm{d}x \\ &= \int \hat{f}_h(x)^2 - 2\int \hat{f}_h(x) f(x) \, \mathrm{d}x \\ &\quad + \int f(x)^2 \, \mathrm{d}x \\ &= R(\hat{f}_h) - 2E\hat{f}_h(X) + R(f).\end{aligned}$$

Rudemo [13] and Bowman [1] observed that the third term, $R(f)$, is constant for all choices of h and can be ignored. The first integral is directly computable as h varies. Finally, the second term has an **unbiased** estimator:

$$-\frac{2}{n}\sum_{i=1}^{n} \hat{f}_{h,-i}(x_i),$$

where $\hat{f}_{h,-i}(x_i)$ is the density estimate based on the $n-1$ points with x_i omitted. For the histogram, the least-squares cross-validation functional is

$$\mathrm{CV}(h) = \frac{2}{(n-1)h} - \frac{n+1}{(n-1)n^2 h}\sum_k \nu_k^2.$$

The functional can be immediately extended to pick the bin origin, t_0, as well. The minimizer of $\mathrm{CV}(h)$ may be found by grid search or numerical methods (*see* **Optimization and Nonlinear Equations**). Several CV formulae for kernel estimates, including the multivariate case, are given in Sain et al. [14].

New Directions and Resources

Locally adaptive density estimation will play an increasingly important role now that that technology has begun to appear. Promising approaches include plug-in [16], log **spline** [9], wavelet [8], local likelihood [8, 10], and local CV bandwidths [15]. The reader is cautioned about overfitting difficulties, as many degrees of freedom are consumed during the estimation of the adaptive smoothing parameters (either explicitly or implicitly). A more conservative approach is to follow some of the simple transformation ideas of Wand et al. [30].

Historical information and greater detail are available in the following selection of monographs: Tapia & Thompson [25], Silverman [23], Devroye [2], Härdle [7], Scott [20], Tarter & Lock [26], Wand & Jones [29], Fan & Gijbels [4], and Simonoff [24]. These references also discuss the wide array of closely related nonparametric techniques including regression, spectral densities, **time series**, cluster analysis, discrimination, and survival and **hazard** estimation. **Software** is available in packages such as SAS, **S-PLUS**, and Systat, for example, or at **internet** sites such as statlib and netlib.

Density Sampling

Density sampling is a method of sampling **controls** in a **case–control study**. Controls are sampled from the population at risk at the times of incidence of each case or, as is more common in practice, over the period of accrual of the cases. Time-matched analysis of such case–control data yields **unbiased** estimates of the **relative hazard** (or **incidence density ratio**), even when the disease is common [1–4]. An advantage of density sampling is that it can reduce **bias** from secular changes in the **prevalence** of exposure during the course of the study [1].

MITCHELL H. GAIL

Dermatology

Dermatology is the branch of medicine that is concerned with the physiology and pathology of the skin. It is estimated that one in three Americans has a skin condition serious enough to warrant a visit to a physician and that 10% of visits to physicians are at least in part for skin complaints [12]. The most common diseases seen by dermatologists include acne vulgaris, veruca vulgaris (warts), psoriasis, nonmelanoma skin cancer (basal and squamous cell skin cancer), dermatitis, dermatophytosis (fungal infections of the skin), and actinic keratoses [9]. Thus, commonly encountered skin diseases arise from a wide variety of etiologies. For example, warts and dermatophytosis are infections of the skin caused by human papilloma virus and fungi, respectively; nonmelanoma skin cancers are due to a combination of factors including genetic predisposition and exposure to ultraviolet light; and dermatitis is commonly caused by delayed type hypersensitivity (allergy) to a wide variety of chemicals.

Several statistical techniques and methodologies are heavily utilized in the study of skin diseases. Paramount among them are use of **case–control studies** and **multivariate analysis** to identify **risk** and **prognostic factors** in melanoma, development of tools to assess skin disease activity and response to treatment, and the use of **linkage analysis** to identify genetic defects responsible for hereditary skin diseases.

There were approximately 38 300 new cases of malignant melanoma and 7300 deaths attributed to it in the US in 1996. The **incidence** and mortality rates of melanoma have risen steadily since 1930. Finding ways to identify patients at highest risk and to identify alterable risk factors are important since early diagnosis and adequate surgical resection remain the best ways to treat melanoma. However, the development of melanoma is a complex trait that involves the interaction of genetic and environmental factors (*see* **Gene-environment Interaction**). Therefore, carefully conducted case–control studies have been essential to identify important risk factors for the development of melanoma. **Odds ratios** are highest for a family or personal history of atypical moles and melanoma, a family or personal history of melanoma, presence of atypical melanocytic nevi or many melanocytic nevi, a history of multiple sun burns, and intermittent, intense sun exposure [15, 16, 20]. Families that have a genetic susceptibility for developing melanoma have been identified [10, 14, 17]. These families have members who have multiple atypical nevi and have a lifetime risk of developing melanoma that approaches 100%. Many family members develop multiple melanomas.

Many methods have been advocated to predict the prognosis (*see* **Predictive Modeling of Prognosis**) of patients with melanoma. The tumor type, level of invasion, location, clinical features, thickness, cytologic characteristics and lymph node involvement have all been used and advocated as prognostic indicators. No single factor will predict accurately the outcome for all patients. Multivariate analyses of several large cohorts of melanoma patients were, therefore, essential in identifying the best indicators of prognosis in patients with melanoma. They have identified tumor thickness (from the top of the granular layer to the bottom of the tumor) as the best indicator of prognosis in patients with stage I melanoma (localized disease with no clinical or histopathologic lymph node involvement). The pivotal studies of Breslow and others have been confirmed by several groups and have established that the five-year survival of patients with tumor thickness of less than 0.75 mm, 0.76 mm–1.5 mm, 1.51 mm–3.99 mm and greater than 4 mm were 100%, 90%–94%, 76%–83%, and 40%, respectively [2, 4–6, 18]. Whereas the utility of tumor thickness as a prognostic indicator has its detractors [11] it remains the best and most widely used indicator.

Two principal methods are used to assess skin disease activity and to determine patient outcomes in dermatologic clinical trials [1, 3] (*see* **Clinical Trials, Overview**). The first involves examining patients before, during, and at the conclusion of treatment, and reporting how the patients appear at the various time points. The second involves determining the degree of improvement during treatment or during the observation period. An example of the first method was developed to assess the response of psoriasis to novel treatments. The psoriasis area and severity index (PASI) assigns numerical values to the amount of erythema, scaling, and degree of infiltration and multiplies them by the area of the body surface involved to formulate an "index" of the patient's condition [8]. The PASI ranges from 0 to 72. The major problem with indices is that they confound area of involvement with severity of disease. For

example, a patient with thick plaque-type psoriasis of the knees, elbows and scalp may have the same index as a patient with diffuse but minimal psoriasis of the trunk and arms [1, 3]. The second problem with indices is that they lend an undeserved air of precision to the analysis and presentation of data [1, 3]. For example, Tiling-Grosse & Rees [19] demonstrated that physicians and medical students were poor at estimating the area of skin disease and, therefore, some of the components that make up indices may be inaccurate. Finally, calculating the means, differences in means, and percentages of change in indices in response to treatment may not convey an accurate clinical picture of the changes that have occurred. The major limitations of the use of the second method (determining the degree of improvement) are that the categories of improvement are often not well defined and that the categories are often assumed to be, but are, in fact, not, additive [1, 3]. That is, 60%–80% improvement is often assumed to be twice as good as 20%–40%, although no such numerical relationship exists between these subjectively defined categories. To overcome some of the limitations of currently utilized methods, some groups are beginning to use **quality of life** assessment tools to assess skin disease activity [7].

As in other fields of medicine, clinical trials are the best sources for determining the best available treatments in dermatology. However, published clinical trials should be approached with a sense of skepticism. In many reviews of clinical trials, they often are found to be poorly performed or reported. Specific methods must be employed in the conduct of clinical trials to lead to valid conclusions. There are many practical and logistical difficulties inherent in conducting therapeutic trials in dermatology, including limited numbers of patients, difficulties in measuring the outcome of treatment (*see* **Outcome Measures in Clinical Trials**), and difficulties in **blinding**. Adherence to all recommended methods is not always possible. However, investigators must provide readers with adequate information about the methods employed in published clinical trials. Several features strengthen clinical trials and help validate their conclusions. These features include proper selection and allocation of patients, inclusion of an appropriate control group, **randomization**, prior selection of clinically and biologically important outcome variables, blinding of assessment when possible, consideration of patient **compliance** and dropout, and proper presentation and statistical analysis of results [3].

Linkage analyses (used in conjunction with positional cloning) have aided in the identification of the genetic causes of many skin diseases. Linkage analysis consists of finding a model M1 (of inheritance of a **gene** of interest and a phenotype of interest) that is much more likely to have produced the observed data than a null hypothesis M0 (in which the inheritance of an unrelated gene has no linkage to the phenotype) [13]. The evidence for the hypothesis is measured by the lod score [$\log_{10}$ (**likelihood ratio** of the hypothesis vs. the **null hypothesis**; where the likelihood ratio = Pr(data|M1/ Pr(data|M0)))]. Lod scores >3 are conventionally considered significant. Analyses are facilitated with the use of available computer programs (LIPED and LINKAGE) [13] (*see* **Software for Genetic Epidemiology**). Linkage analyses have aided in the identification of the genetic deficits that are responsible for the basal cell nevus syndrome, several forms of epidermolysis bullosa, several of the icthyoses, some cases of Waardenberg's syndrome, dyskeratosis congenita, and pachyonychia congenita. It has also identified possible genetic loci for psoriasis.

Descriptive Epidemiology

Descriptive epidemiology is the study of the incidence and **prevalence** of diseases and associated mortality in populations. Unlike **analytic epidemiology**, descriptive epidemiologic studies usually do not rely on individual-level data, for example on exposures, disease outcome, and potential **confounders**. Instead, descriptive studies estimate the risk of disease in various groups defined by age, gender, and ethnicity (*see* **Ethnic Groups**), evaluate time trends in disease rates, identify geographic localization of populations with high rates of disease (*see* **Geographic Patterns of Disease**), and attempt to **correlate** disease rates in populations with features of the population, such as the average level of exposure to a potential carcinogen. Descriptive studies are used to determine the effectiveness of programs to control disease (*see* **Program Evaluation**), and descriptive studies are used to generate etiologic hypotheses that are then tested in analytic studies (*see* **Age–Period–Cohort Analysis**; **Correlational Study**; **Ecologic Study**).

MITCHELL H. GAIL

Design Effects

For an **estimator**, $\hat{x}$, under a particular sampling design, D, the *design effect* (denoted DEFF) is defined as the ratio of the **variance** of the estimator under the particular sampling design to its variance at equivalent sample size, n, under **simple random sampling** without replacement (*see* **Sampling With and Without Replacement**) [2–4]. That is:

$$\mathrm{DEFF}_{\mathrm{D}}(\hat{x}) = \frac{\mathrm{var}_{\mathrm{D}}(\hat{x})}{\mathrm{var}_{\mathrm{SRS}}(\hat{x})}, \tag{1}$$

where $\mathrm{DEFF}_{\mathrm{D}}(\hat{x})$ is the design effect for an estimate, $\hat{x}$, under sample design, D; $\mathrm{var}_{\mathrm{D}}(\hat{x})$ is the variance of $\hat{x}$ under the sample design, D; and $\mathrm{var}_{\mathrm{SRS}}(\hat{x})$ is the variance of $\hat{x}$ under simple random sampling without replacement.

The comparable ratios of **standard errors**, generally denoted DEFT, is referred to as the *design factor*.

A design effect greater than unity indicates that the particular sample design would yield an estimate having higher variance than what would be obtained from a sample of the same number, n, of units under simple random sampling. Conversely, a design effect less than unity would imply that the particular sampling design would result in the estimate having a lower variance than what would be obtained under simple random sampling. Design features such as **stratification** generally result in design effects less than unity, whereas **cluster sampling** in its many manifestations generally produces design effects greater than unity. Again, the above comparisons are made at equivalent n, whereas it may be more appropriate to make comparisons at equivalent cost (*see* **Multistage Sampling**).

The variance of a sample **mean** under simple random sampling is equal to $(S_x^2/n) \times (1 - f)$, where $S_x^2 = \sum_{i=1}^{N}(X_i - \overline{X})^2/(N-1)$, N is the population size, $\overline{X}$ is the population mean, and f is the sampling fraction, n/N. Thus the design effect for a sample mean under a particular design, D, is given by

$$\mathrm{DEFF}_{\mathrm{D}}(\overline{x}) = \frac{\mathrm{var}_{\mathrm{D}}(\overline{x})}{(S_x^2/n) \times (1 - f)}. \tag{2}$$

From (2), we see that $\mathrm{var}_{\mathrm{D}}(\overline{x})$ can be put in the following form:

$$\mathrm{var}_{\mathrm{D}}(\overline{x}) = \frac{S_x^2(1 - f)}{n^*}, \tag{3}$$

where $n^* = n/\mathrm{DEFF}_{\mathrm{D}}(\overline{x})$ is known as the *effective sample size*. Since the numerator of (3) is that of the numerator for the variance of the estimator under simple random sampling, the effective sample size for the design tells us that a sample of n units under the particular design is equivalent to a sample of n^* units under simple random sampling. For example, if the design effect for a particular multistage sampling design is 2.8, then a sample of 100 units under this design is equivalent to a sample of 40 units under simple random sampling.

Design effects have been estimated numerically for many important surveys and for many variables (see, for example, Groves & Kahn [1]). These are very useful in the planning of sample surveys, particularly in determination of required sample sizes (*see* **Sample Size Determination**).

Detection Bias

Detection (also called diagnostic or unmasking) bias results from closer follow-up or more intense scrutiny of one comparison group than another. In a **case–control study**, the detection of a higher proportion of subclinical outcomes among the exposed leads to an overrepresentation of exposed cases relative to exposed controls in the study population. In a **cohort study**, as subjects are followed over time for the occurrence of a disease, subjects who develop unrecognized subclinical disease would be misclassified as nondiseased. If exposed subjects are under greater scrutiny than the unexposed, then they may be less likely to have such undiagnosed subclinical disease. This implies that detection bias can lead to **selection bias** in a case–control study, and can also be a source of differential misclassification in a follow-up study (*see* **Misclassification Error**).

HOLLY A. HILL & DAVID G. KLEINBAUM

Diagnosis Related Groups (DRGs): Measuring Hospital Case Mix

Introduction

The Diagnosis Related Group (DRG) system constitutes an approach to measuring hospital **case mix**, which may be understood as a "system for separating hospitalized patients into unique groups based on their diagnoses and procedures" [5]. Case-mix measurement has been identified by Hornbrook [9] as one of the three fundamental dimensions of hospital output, the other two being volume and quality. While volume is straightforward and refers to the total number of patients treated by the hospital, the definition of case mix and quality are more complex. Hornbrook defines quality as "the hospital's contribution to the successful outcome or resolution of patients' illnesses or health problems" [9, p. 295] and case mix as "the proportion of cases of each disease and health problem treated in the hospital" [9, p. 296].

While recognizing the importance of all dimensions of hospital output, in particular, the issue of **quality of care**, this paper will focus on one particular dimension, that is, the specification of hospital case mix and, in particular, the DRG case-mix classification system. The DRG system came to international prominence in 1983 when this was the chosen approach for case-mix adjustment within the Prospective Payment System introduced within the **Medicare** program by the US government. While DRGs have been shown to be amenable to a wide range of applications, the strength of the system in providing an accessible framework for the determination of resource requirements for different patient types has meant that it has been increasingly used within the United States and overseas by payment bodies interested in applying a case-mix adjustment within their reimbursement systems.

DRGs: Development and Construction of an Operational Case-mix Measure

If classes of patients that share common clinical attributes can be differentiated according to the "bundle" of services received as part of the therapeutic process, this framework constitutes the basis for a case-mix classification scheme that "provides a means for examining the products of the hospital, since patients within each class are expected to receive a similar product" [3]. The hospital product can therefore be defined by the development and application of a case-mix classification system consisting of discrete classes of patients exhibiting common clinical attributes and similar output utilization patterns.

The complexity of both illness and the therapeutic process means that, in turn, the development of a system for classifying case mix is a complicated undertaking. The development of the DRG patient classification system by the Health Systems Management Group at the Yale School of Organization and Management in the late 1960s was originally motivated by the need to develop operational techniques for utilization review. The importance of developing an explicit link between the clinical characteristics of patients and their use of hospital resources was recognized as an essential prerequisite to the evaluation of the appropriateness of service utilization within the hospital setting [4].

In developing a classification system for the definition of case types within the acute hospital setting, the following attributes were specified for the system by the Health Systems Management Group [3]:

1. The system must be interpretable medically, with subclasses of patients from homogeneous diagnostic categories;
2. Individual patient classes should be defined on variables commonly found on hospital abstract systems and relevant to output utilization;
3. The number of classes in the system must be manageable, mutually exclusive, and exhaustive;
4. The classes should be constituted by patients with similar expected measures of output utilization;
5. Class definitions should be comparable across different coding schemes.

Variable Specification and Measurement

The independent variables (*see* **Explanatory Variables**) used for the purpose of specifying a system to achieve these objectives were selected to be descriptive of the patient, of the patient's disease condition, and of the treatment process. In addition, it was considered essential that information relating to the

selected variables should be easily available on discharge abstract summaries if the resultant system was to be available for general application. The initial stages of the analyses identified a number of variables which, in descriptive studies of hospital activity, had been found to be associated with variations in length of stay and other resource use measures [3]. Ultimately, a set of independent variables were identified as representing the essential demographic and clinical attributes of inpatients. These variables include the following: primary diagnosis, secondary diagnoses, surgical procedures performed, age, sex, and discharge status.

For the specification of an accurate and acceptable measure of hospital case mix, a measure of hospital output had to be incorporated within the development process. To place the choice of output measure for the purpose of case-mix measurement in context, it may be useful at this point to consider the hierarchy of hospital output classification schemes constructed by Hornbrook [8]. This hierarchy follows the sequence of the medical care process and begins with iso-symptom groups, progressing through to iso-disease groups and iso-illness groups. When iso-illness groups are collapsed into classes that are homogeneous in terms of the level of resources used in treatment, iso-resource groups are produced. The DRG system fits into this category, as homogeneity with respect to clinical attributes is an essential prerequisite for class determination, with the additional expectation that resource use at the group level will also be relatively homogeneous.

For the development of the iso-resource groups, or DRGs, limitations on data availability meant that the options available for choosing an appropriate dependent variable (*see* **Response Variable**) were restricted. While costs may be a most desirable measure of output, accurate and comprehensive data on costs for a representative sample of hospitals are very difficult to obtain. Even where cost data are available, it can be very difficult to interpret because of variations in the method of collection and estimation. These data problems led to the Yale researchers choosing length of stay (LOS) as the measure of output to be used as the dependent variable [3]. Length of stay, as a measure of output, has the advantage of being standardized, reliable, and routinely available on discharge abstract summaries. In addition, length of stay and ancillary service use have been found to be significantly interrelated for a number of common medical and surgical conditions [6, 7].

The DRG Assignment Process

In developing a classification system with the required attributes, three key inputs were required: physician review, efficient information systems, and statistical **algorithms**. The objective of ensuring that the patient groups formed by the classification process were medically meaningful was the responsibility of panels of physicians established for this purpose. The basic framework for DRG assignment may be summarized as follows:

Step 1: Hospital discharges are partitioned into mutually exclusive and exhaustive primary diagnostic groupings called *Major Diagnostic Categories* (MDCs). The MDCs were specified under the following conditions [3]:

1. Major Diagnostic Categories must be consistent with regard to the anatomic, physiopathologic classification, or in the manner in which they are clinically managed;
2. Major Diagnostic Categories must have sufficient numbers of patients; and
3. Major Diagnostic Categories must cover all codes without overlap.

There are currently 25 MDCs [11]. This classification is primarily based on the organ system or the specialty that would usually provide patient care. There are a number of exceptions including MDC 12 (Diseases and Disorders of the Male Reproductive System) and MDC 13 (Diseases and Disorders of the Female Reproductive System), where urogenital conditions are split on the basis of the sex of the patient.

Step 2: Where relevant, discharges within the MDC are subdivided according to whether or not a surgical procedure was performed. For specific MDCs, there are some exceptions to this initial major procedure split, for example, MDC14 (pregnancy, child birth, and the puerperium) where the initial split is “delivery during this admission?”.

Step 3: Coming into this level, there are two groups within most MDCs – the medical group and the surgical group. During this stage, the medical patients

are further subdivided into categories based on their principal diagnosis. Surgical patients are categorized according to the procedures performed. The procedures, in turn, are ranked in terms of resource intensity. Surgical patients are categorized into subgroups on the basis of the most resource intensive procedure received, which is related to the primary diagnosis.

Step 4: The final stage in the classification involves the derivation of additional diagnostic or surgical subgroups based on age, specific secondary diagnoses, **comorbidities** or complications (CC), nonoperating room procedures, and discharge status where these variables have been found to be significant in clinical terms and have a significant effect on length of stay.

While this process of assignment represents the generic framework underlying the original development of the DRG system, this system has evolved into a number of manifestations in response to increasing demands on patient classification systems to address a wide range of requirements including (see [1])

- the comparison of hospitals across a range of resource and outcome measures,
- evaluation of differences in inpatient mortality rates,
- the implementation and support of critical pathways,
- facilitation of continuous quality improvement projects,
- support of internal management and planning systems,
- management of capitated payment systems, and so on.

Up to the development of the eighth version of the DRG system (in 1990), the principal diagnosis was the initial variable in DRG assignment. For the eighth and subsequent versions, the procedure performed, if any, is the initial step in DRG assignment. In particular, where liver, bone marrow, and lung transplants, together with tracheostomies are performed, the patients are assigned to the relevant DRGs independent of the MDC of the principal diagnosis (3M, 1998).

Experience with a wide range of DRG applications has now developed into an extensive literature and reflects the variety of such applications in different settings and different countries. One of the early examples of experimentation with DRGs on a European database involved analyses for selected high-volume pathologies on a multinational database including over 3.3 million cases from 12 countries [14]. Differences in length of stay both within and between countries were assessed for three alternative measures of hospital case mix applied to over 119 400 discharges for three surgical DRGs (DRG 39 lens procedures, DRG 198 cholecystectomy without common duct exploration (CDE), without complication/comorbidity (CC), and DRG 119 vein ligation and stripping) and two medical DRGs (DRG 294 diabetes age >35 years and DRG 122 circulatory disorders with acute myocardial infarction (AMI), without cardiovascular complications, discharged alive). The results showed that irrespective of the case-mix measure applied, substantial unexplained variation in hospital length of stay persisted leading to the conclusion that in addition to standardizing for case mix, future research on this issue should also focus on additional potentially influential factors, including health system characteristics, medical practice variation, and patient behavior and expectations.

DRG Grouper Development

Developments in the DRG system are a reflection of the evolution in potential applications as well as developments in expertise, information technology, and data systems. Six main categories of DRG system, as developed in the United States, may be identified [1]

- Medicare DRGs
- Refined DRGs (RDRGs)
- All Patient DRGs (AP-DRGs)
- Severity DRGs (SDRGs)
- All Patient Refined DRGs (APR-DRGs)
- International Refined DRGs (IR-DRGs).

The Medicare DRGs are the closest to the system originally developed in the 1980s and continue to constitute one of the most widely used groupers currently. Following the implementation of the Medicare prospective payment system in 1983, responsibility for the maintenance and modification of this system became the responsibility of the Health Care Financing Administration (HCFA). (HCFA is now known as the Centers for Medicare and Medicaid Services.)

There are currently over 500 groups within the Medicare DRG system that is updated annually.

Under a grant from HCFA to Yale University, the Refined Diagnosis Related Groups (RDRGs) were developed in the mid-1980s incorporating a revised specification of complications and comorbidities. Essentially, this system involved the categorization of the secondary diagnosis groups as moderate, major, or catastrophic [1]. All age and CC splits were eliminated and replaced by four subgroups for surgical patients (non-CC, moderate CC, major CC, and catastrophic CC) and three subgroups for medical patients (non-CC, moderate or major CC and catastrophic CC). The number of groups in the RDRGs approximates 1170 and as there is no single source for this system, versions produced by different vendors may differ.

During the late 1980s, a version of the HCFA DRGs was amended under contract with the National Association of Children's Hospitals and Related Institutions (NACHRI). A New York (NY) grouper was also developed around this time in response to legislative changes in the state of New York. These groupers form the basis for what have become known as the All Patient (AP) DRGs.

Given the origins of this system, it is not surprising that the AP-DRGs are more differentiated to reflect factors like birth weight that are considered significant in a neonatal and pediatric population. In addition, some of the advancements emerging from the development of the RDRGs, specifically, the designation of major CC splits, have also been incorporated into subsequent revisions to the AP-DRGs, which now number over 650 groups.

In the mid-1990s, a severity refined (SR) DRG system was developed following a reevaluation of the complications and comorbidities within the HCFA DRGs. When finalized, this system incorporated over 650 groups, though while published by HCFA in 1994, an implementation date was not established and the system has not subsequently been updated [1]. The All Patient Refined Diagnosis Related Groups (APR-DRGs) took as the starting point the AP-DRGs and focused on development to take account of severity of illness or risk of mortality. Within this system, a discharge is assigned three distinct descriptors: the base APR-DRGs, the severity-of-illness subgroup and the risk-of-mortality subgroup. Averill [1] notes with regard to APR-DRG assignment that "The most important component of determining the final patient subgroup is the recognition of the impact of interactions among secondary diagnoses" (p. 399). Each base APR-DRG may have four severity subgroups representing minor, moderate, major, or extreme severity of illness or risk of mortality amounting to a total of around 1530 APR-DRGs.

The system known as the International Refined Diagnosis Related Groups (IR-DRGs) had a somewhat different starting point to other such systems in that it was originally designed for use in the international health setting and, specifically, to be compatible with differences in coding schemes used in different health systems. The development of the IR-DRGs took as the starting point the AP-DRG concept, applied refinements to the base DRGs, and undertook a consolidation process for the complication and comorbidity splits (CC), the major complication and comorbidity splits (MCC), the age splits and the DRGs founded on the complicated Principal Diagnosis [12]. Unlike previous DRG systems in this series, which were developed from US databases, data from a number of European countries were used for the development of the IR-DRGs, which currently incorporate over 900 groups.

Conclusion

In addition to being applied extensively throughout North America, the case-mix systems described here are now also widely used internationally, particularly in Europe and Australia [13]. Many European countries employ some form of case-mix adjustment for hospital financing and/or management purposes, while local applications may include support for clinical budgeting, waiting-list reduction, increased productivity, and so on [10]. In Australia, states like Victoria and South Australia use case mix for hospital payment purposes in addition to supporting a range of management functions.

Outside of the United States, Australia is probably the country where the most extensive DRG-type development programme has been underway since the early 1990s. Following the initial release of the Australian National Diagnosis Related Groups (AN-DRGs) in 1993, this system was updated annually until 1996. The Australian Refined Diagnosis Related Groups (AR-DRGs) were then developed and a biennial update schedule put in place for subsequent revisions [2]. Since the mid-1990s, the total number of groups has remained stable at around 660 and there are currently 23 MDCs within the

AR-DRG system. While retaining the "DRG" label, it should be noted that the Australian system is now distinctly different from the US-developed systems described above. Specifically, the AR-DRGs are based on an Australian morbidity coding system (International Statistical Classification of Diseases and Related Health Problems, 10th Revision, Australian Modification (ICD-10-AM)) and groups discharges based on data items including diagnoses (up to 30 per record), procedures (up to 30 per record), sex, age, mode of separation, length of stay, leave days, admission weight, mental health status, and same-day status [2]. As the Australian DRG system is copyrighted to the Commonwealth of Australia (Department of Health and Ageing), detailed information on the specifics of the system and updates applied can be found on the government's case mix internet site, `www.health.gov.au/casemix`. (*see* **International Classification of Diseases (ICD)**)

While the US-developed DRG systems are widely used internationally, the Australian DRG system is also being adopted for use in a number of countries. Specifically, the Australian DRG system is used in New Zealand, a number of Asian countries and the German government has adopted this system with some local modifications for use within the German health system. A number of European countries have also developed case-mix systems for use within national health systems. While systems like the Nord DRGs developed and used in the Nordic countries and the Groupes Homogenes de Malades used in France could be considered to fall within the DRG-type framework, other systems like the Leistungsorientierte Krankenanstaltenfinanzierung (LKF) in Austria, the Health Resource Groups in England, and the Diagnose Behandelings Combinatie (DBC) in the Netherlands pursue quite different approaches. Given the dynamic nature of **health service** development, case-mix measures generally and DRG-type systems specifically may be expected to continue to evolve in response to advancements in diagnoses, treatment innovations, and technological developments. Given the range of case-mix measures now applied internationally, it would also be expected that continuing diversification of case-mix-type systems like DRGs will become increasingly in evidence with improvements in the availability of high-quality activity and cost data systems, developments in the skills base, and better access to the appropriate information technology.

Diagnostic Test Accuracy

A diagnostic test is said to have high accuracy if it achieves a high overall proportion of correct diagnoses. The accuracy of a test reflects the **prevalence** of disease in the population being tested and the conditional **misclassification** rates for true cases and noncases of disease, or equivalently on the prevalence, and the test **sensitivity** and **specificity**. Because the clinical implications are quite different for a **false positive** diagnosis on a noncase compared to a **false negative** diagnosis for a disease case, diagnostic test performance is usually not summarized by an overall accuracy index, but by more detailed measures, such as sensitivity and specificity, false positive and negative rates, **predictive values**, or by its **receiver operating characteristic (ROC) curve**.

(*See also* **Gold Standard Test**; **Diagnostic Tests, Evaluation of**; **Diagnostic Tests, Multiple**)

STEPHEN D. WALTER

Diagnostic Test Evaluation Without a Gold Standard

Diagnostic tests are an important part of medical decision making. In daily clinical practice many tests are performed to obtain diagnoses. To interpret a test it is important to realize that a negative answer does not always mean that the disease is absent, because **false negative** results may occur. Also, a positive result does not always mean that disease is present. A finding usually associated with a disease sometimes occurs in patients who do not have the disease: a **false positive** result.

A perfect test is positive in all patients with the disease and negative in all patients who do not have the disease. Usually this test is referred to as the gold standard. After applying the **gold standard test** one knows which patients have the disease and which patients are free of it. However, most tests are imperfect. Measures to assess the performance of a diagnostic test are **sensitivity** and **specificity**. The sensitivity of a test is defined as the proportion of positive test results in those with the disease. The specificity is defined as the proportion of negative test results in those without the disease. To measure the sensitivity and specificity of a test for a disease, the test's results are compared with those on a gold standard test, as shown in Table 1. The sensitivity is the ratio of the number of patients with true positive tests and the number of diseased patients. The specificity is the ratio of the number of patients with false negative tests and the number of nondiseased patients.

Problems arise when the sensitivity and the specificity of the reference test are unknown. The **2 × 2 table** of test vs. reference test contains too little information to estimate all unknown parameters, even if the **prevalence** of the disease is known.

Hui & Walter [3] pointed out that the parameters can still be estimated for two tests if data can be collected from populations with different prevalences and it can be assumed that the test errors are conditionally independent given the disease status.

Notation

Let D stand for disease status; $D = 1$ if diseased and $D = 0$ if not. Let T_i stand for the result of test i, $i = 1$ or 2; $T_i = 1$ if the test is positive and $T_i = 0$ if the test is negative. The sensitivity of test i is denoted by SENS_i and the specificity by SPEC_i, i.e. $\text{SENS}_i = \Pr(T_i = 1|D = 1)$ and $\text{SPEC}_i = \Pr(T_i = 0|D = 0)$. Let there be G subpopulations (groups) indexed by g with prevalences $\pi_g = \Pr(D = 1|\text{ group } g)$. Under conditional independence of T_1 and T_2 given D, the probabilities in the $T_1 \times T_2$ contingency table in group g are given by

$$\begin{aligned}\Pr(T_1 = t_1, T_2 = t_2|\text{group } g) &= \pi_g \times \text{SENS}_1^{t_1} \times (1 - \text{SENS}_1)^{1-t_1} \\ &\quad \times \text{SENS}_2^{t_2} \times (1 - \text{SENS}_2)^{1-t_2} \\ &\quad + (1 - \pi_g) \times (1 - \text{SPEC}_1)^{t_1} \times \text{SPEC}_1^{1-t_1} \\ &\quad \times (1 - \text{SPEC}_2)^{t_2} \times \text{SPEC}_2^{1-t_2}. \qquad (1)\end{aligned}$$

Estimation

The n_g observations in group g follow a 4-nomial distribution (*see* **Multinomial Distribution**) with these probabilities for the four cells. The number of parameters is $G + 4$ (G prevalences, two sensitivities, and two specificities). The number of **degrees of freedom** is $3G$, so the minimal requirement for **identifiability** of the model is that $G \geq 2$. If at least two prevalences are different, identifiability is indeed obtained, provided that it is assumed that

Table 1 The relationship between the results of a test and gold standard

Results of test for disease under study	Results of gold standard		Total
	Disease present	Disease absent	
Positive	True positive	False positive	Positive tests
Negative	False negative	True negative	Negative tests
Total	Diseased patients	Nondiseased patients	

SENS + SPEC > 1. (See [3] for the invariance of the problem under "reflection with respect to 1/2".) The parameters can be obtained by direct **maximum likelihood** applied to the joint **likelihood** of the G tables, as proposed by Hui & Walter [3] for the case when $G = 2$.

In de Bock et al. it is shown that the estimation problem can be solved elegantly by the **EM algorithm** [2]. Multinomial distributions with amalgamated cells is one of the examples given in that paper. The EM algorithm considers the true disease status D of all individuals as the missing observation. If this information were available, the data for each group could be conveyed in the $2 \times 2 \times 2$ table of $T_1 \times T_2 \times D$.

The M-step of the EM algorithm estimates all parameters in a straightforward way. Let $X_{g,ijk}$ be the number in the ijk-cell of the gth $2 \times 2 \times 2$ table. The index i (0, 1) corresponds to T_1, index j to test T_2, and k to disease D. Let "+" stand for summation; then the estimates are given by

$$\hat{\pi}_g = \frac{X_{g,++1}}{X_{g,+++}}, \tag{2}$$

$$\widehat{\mathrm{SENS}}_1 = \sum_g X_{g,1+1} \Big/ \sum_g X_{g,++1},$$

i.e. $$\frac{\text{number positive on } T_1 \text{ and diseased}}{\text{number diseased}}, \tag{3}$$

and

$$\widehat{\mathrm{SPEC}}_1 = \sum_g X_{g,0+0} \Big/ \sum_g X_{g,++0},$$

i.e. $$\frac{\text{number negative on } T_1 \text{ and not diseased}}{\text{number not diseased}}, \tag{4}$$

and similarly for SENS_2 and SPEC_2.

In the E-step, the full table $X_{g,ijk}$ is reconstructed from the available table $X_{g,ij+}$ by

$$\hat{X}_{g,ijk} = \hat{P}(D = k | T_1 = i, T_2 = j, \text{ group} = g) \times X_{g,ij+}. \tag{5}$$

In the estimated probabilities $\hat{P}$ the parameter estimates from the previous step are used.

For example,

$$\hat{P}(D = 1 | T_1 = 1, T_2 = 1, \text{group} = g) = \frac{\hat{\pi}_g \times \widehat{\mathrm{SENS}}_1 \times \widehat{\mathrm{SENS}}_2}{\left\{ \begin{array}{c} \hat{\pi}_g \times \widehat{\mathrm{SENS}}_1 \times \widehat{\mathrm{SENS}}_2 + (1 - \hat{\pi}_g) \\ \times (1 - \widehat{\mathrm{SPEC}}_1) \times (1 - \widehat{\mathrm{SPEC}}_2) \end{array} \right\}}. \tag{6}$$

The EM algorithm converges in a slow but sure way to the ML estimator. The process can be stopped if the increase in total log likelihood is smaller than some prespecified ε. To compute the standard errors of the estimated parameter, second derivatives of log likelihood have to be used as in Hui & Walter [3]. The advantages of EM are that it is very easy to program, and that the estimates never exceed the boundaries of the parameter space.

Generalizations

De Bock et al. [1] generalized the situation sketched above to the case where there are more than two tests, and in each group test results are available for precisely two tests. The generalization of the EM algorithm is straightforward.

A second generalization can be made by relaxing the condition of conditional independence. The model can be extended by introducing **odds ratios** lambda (λ) in the conditional 2×2 tables to model the dependency. The simplest model is when λ is constant. An extension would be to have different λs for diseased ($D = 1$) and not diseased ($D = 0$). See LeCessie & van Houwelingen [4] for a general discussion on modeling dependence in 2×2 tables.

Diagnostic Tests, Evaluation of

The field of diagnostic medicine is complex. In part, this is due to the fact that the process of medical diagnosis is dynamic, and it is difficult to formulate straightforward scientific questions amenable to simple study designs. For example, in interpreting the result of an individual test the doctor must consider the context in which it is applied. Has it been selected to rule-in or rule-out a diagnosis? What other tests have already been performed and what were their results? What options are available for performing subsequent tests? What are the characteristics of the patient that might predispose to the diagnosis under consideration? The evaluation of a test in the context of other tests is addressed elsewhere (*see* **Diagnostic Tests, Multiple**). In this article, discussion is limited to evaluation studies of individual tests, or comparisons of two alternative tests. Furthermore, we consider only *diagnostic* tests, i.e. tests of symptomatic patients in which we wish to rule-in or rule-out a candidate diagnosis. This contrasts with *screening* tests, performed on asymptomatic normal subjects, e.g. the use of mammography on a population at risk of breast cancer (*see* **Screening Benefit, Evaluation of**; **Screening, Models of**; **Screening, Overview**).

Many diagnostic tests, especially radiologic and **psychometric** tests, are evaluated subjectively, leading typically to test results that are classified in ordinal categories which are defined verbally. This contrasts with tests which possess quantitative results, as is the case for most laboratory tests. In either case, a useful conceptual device is to consider the test as having an underlying continuous scale, which may be discretized into ordinal categories either by judgment or by arithmetic rounding. The underlying continuous scale provides a metric for trading off the two different kinds of errors of diagnosis, **false positives** and **false negatives**, and thus for establishing a scale on which to calibrate the results of alternate tests for the purposes of comparison. The notation defined below reflects this assumption. There are various outcomes that can in principle be used to evaluate and compare the utility of medical diagnostic tests. The ultimate outcome involves evaluating whether use of the test, and the subsequent impact on medical therapy, leads to improvements in the natural history of the disease, e.g. lower mortality from the disease. It is rare for tests to be evaluated against this standard. Even studies of the impact of individual diagnostic tests on patient management are unusual. Overwhelmingly, medical researchers have been satisfied with evaluating tests on the basis of measures of diagnostic accuracy. In the following we thus limit attention to the issue of diagnostic accuracy.

Measures of Accuracy

Consider a diagnostic test result denoted x, and let D be a **binary** indicator of the "true" disease status, where $D = 1$ represents disease and $D = 0$ represents absence of disease. Let $F_x(x) = \Pr(X \leq x|D = 1)$ be the distribution of the test result in diseased cases, and let $G_x(x) = \Pr(X \leq x|D = 0)$ be the corresponding distribution in "control" subjects, i.e. patients suspected of having the disease who are candidates for testing in the relevant medical context. The most commonly used measures of accuracy are based on a binary classification of the test result. Suppose that the classification point is x, i.e. the test is positive if $X > x$ and negative otherwise. Then the **sensitivity** of the test is defined to be the proportion of diseased patients who are classified as diseased, i.e. $1 - F_x(x)$. The **specificity** is the corresponding proportion of control patients who are classified as normal, i.e. $G_x(x)$ [25]. High values of the sensitivity and the specificity indicate an accurate test.

There are several other measures in common usage related to the sensitivity and specificity. The *false positive ratio* is the specificity subtracted from 1, i.e. $1 - G_x(x)$. The *false negative ratio* is the sensitivity subtracted from 1, i.e. $1 - F_x(x)$. "Prospective" measures of accuracy are defined in terms of the conditional probabilities that the patient is diseased given the test results [22]. Thus the **positive predictive value** is

$$\Pr(D = 1|X \geq x) = \frac{\pi(1 - F_x(x))}{\pi[1 - F_x(x)] + (1 - \pi)[1 - G_x(x)]},$$

where $\pi = \Pr(D = 1)$ is the "prior" probability of disease, i.e. the **prevalence** of disease in the population under study. Likewise the negative predictive

value is defined to be

$$\Pr(D = 0|X \leq x) = \frac{(1-\pi)G_x(x)}{(1-\pi)G_x(x) + \pi F_x(x)}.$$

In fact, the term "accuracy" is often used in medical circles to mean the overall relative frequency of correct diagnosis in a study. That is, if $A(x)$ is the accuracy, then

$$A(x) = \pi[1 - F_x(x)] + (1-\pi)G_x(x).$$

Finally, the **likelihood ratio** can be used to represent the extent to which the odds of disease is altered as a result of the test, via **Bayes' Theorem** [19] (*see* **Diagnostic Tests, Likelihood Ratio**). In the context of a binary test there are two likelihood ratios, corresponding to a negative and a positive test result, $F_x(x)/G_x(x)$ and $[1 - F_x(x)]/[1 - G_x(x)]$, respectively.

Clearly, all of these measures are limited by the fact that they correspond to a specific, and possibly arbitrary, classification point, x. For the likelihood ratio in particular, knowledge of the actual test result, X, leads obviously to a more appropriate factor for updating using Bayes Theorem, i.e. $f_x(X)/g_x(X)$, where $f_x(\cdot)$ and $g_x(\cdot)$ are the corresponding density functions of the test result. Likewise, changing the classification point will either increase the sensitivity at the expense of the specificity, or vice versa, with corresponding effects on the error rates and the predictive values. The arbitrariness of the classification point is especially a problem when diagnostic tests are being compared, or when the same test is used in different studies with different classification points since the classifications for the two tests are unlikely to be "calibrated" in practice (see later discussion). For this reason **receiver operating characteristic (ROC) curve** analysis has become a preferred method for evaluating and comparing tests. The ROC curve is a plot of $F_x(x)$ vs. $G_x(x)$. If the ROC plot lies along the 45° line, then the test is random and hence uninformative. The higher the curve lies above the 45° line, the more accurate is the test. Thus the area under the curve is often used as a measure of accuracy that does not require a specific classification point. The area, A, is given by

$$A = 1 - \int_0^1 F_x(x)\, \mathrm{d}G_x(x). \qquad (1)$$

The area can be interpreted as the probability that a randomly chosen diseased subject has a test result that is greater than that of a randomly chosen control subject [11].

Biases

Despite the availability of the various measures of accuracy described in the previous Section, diagnostic tests are characterized predominantly by their sensitivities and specificities in the literature. These are often reported on the basis of a **retrospective** analysis of a series of patients treated in a hospital or clinic, and may suffer from incomplete reporting of study details, especially the factors affecting selection of patients for inclusion in the analysis. However, regardless of the quality of the studies, it is empirically evident that the ranges of values reported for the sensitivity and specificity of any important diagnostic test are usually very wide. A typical example is presented in the **meta-analysis** of the use of myelography for the detection of lumbar disk herniation, where the sensitivity estimates ranged from 75% to 98%, and the specificity estimates ranged from 20% to 100% [14]. Wide variation in reported estimates is due to the fact that studies of diagnostic test accuracy are plagued by a number of common **biases** [3]. These have been studied extensively in recent years, and various methods have been proposed for providing bias corrections.

Perhaps the most important factor causing variation in reported estimates of sensitivities and specificities is the fact that the classification point for the test may differ dramatically from study to study. This is, of course, not really a bias, but merely a definitional problem, and one that can be resolved in the meta-analytic context by plotting the pairs of sensitivity/specificity estimates in an ROC format [13]. Usually this will demonstrate the fact that sensitivities and specificities are inversely related, due to the fact that the classification point varies from study to study. Ideally, the classification points used would be defined in the individual studies, but often this is not the case. Indeed, for subjectively interpreted tests, the classification point (or points) cannot be defined precisely, and can only be inferred empirically. If variation in the reported sensitivities and specificities is due only to variation in the classification points used, then the plotted values should lie on a single ROC curve, except for random variation in the estimates. However, a much wider scatter is common, and this can be due to a number of possible biases.

Perhaps the most common biases are those due to problems with the "gold standard" reference test (*see* **Gold Standard Test**). These fall into two major categories: the problem of verification bias in which only a selected subset of patients receive the reference test and where unverified patients are ignored, and the problem in which the reference test is recognized to be an imperfect standard.

Verification bias is an especially serious problem since it has a counterintuitive aspect (*see* **Bias in Observational Studies**). The bias is caused if the selection of patients to receive the reference test is influenced by the result of the test under investigation [18]. If the study is restricted to patients who receive the reference test, say biopsy proven cases, then the study is biased, yet many investigators will believe that such a restriction follows sound scientific practice. It is often impossible to design an **unbiased** study since application of the possibly invasive reference test may be unethical when the test under investigation is negative. That is, the risks or inconvenience of the reference test may be considered to be medically inappropriate in the absence of a positive test. The standard bias correction method is based on the assumption that selection of a patient for the reference test is a conscious decision, and must therefore be based on available clinical factors, such as the test result, x, and the results of other relevant tests or patient factors, denoted collectively by z [5]. Consequently, the predictive values, conditional on x and z, can be estimated without bias from the verified sample, denoted $v+$, i.e.

$$\Pr(D = 1|x, z, v+) = \Pr(D = 1|x, z),$$

and so unbiased estimates of the distributions $F_x(\cdot)$ and $G_x(\cdot)$ can be obtained by combining these unbiased predictive values with the distribution of the test result unconditional on disease status, denoted $h_{x|z}(x)$, estimated from all subjects, both verified and unverified, using

$$f_{x|z}(x) \propto h_{x|z}(x) \Pr(D = 1|x, z, v+)$$

and

$$g_{x|z}(x) \propto h_{x|z}(x) \Pr(D = 0|x, z, v+).$$

Clearly, such an approach requires that data be collected on the test results and **covariates** of all patients in the series on whom the test is applied, regardless of whether the reference test is performed subsequently.

All of the accuracy measures described earlier are defined in relation to a "gold standard" reference test. Inaccuracy in the reference test will invariably lead to bias in the estimated characteristics of the test under consideration. If conditional independence between the two tests can be assumed, then bias corrections are possible. However, this assumption is usually untenable since most tests of the same phenomenon are likely to be positively correlated, even after conditioning on true disease status [24]. In these circumstances, the effect of the bias will be to inflate the sensitivity and specificity estimates artificially.

In evaluating the reported accuracy of diagnostic tests there are a number of other issues that can adversely affect the validity of the estimates, or cause further between-study variation in accuracy measures. Frequently, a test may produce an uninterpretable result. For example, for abdominal examinations bowel gas may obscure the result of ultrasound [17]. Barium in the gastrointestinal tract may obscure the result of computed tomography. A needle aspirate for the diagnosis of hepatic cancer may produce fragments which are inadequate for histological examination [20]. These problems are frequently not reported, the uninterpretable tests being simply removed from the analysis [17]. For subjectively interpreted tests, interobserver variation (*see* **Observer Reliability and Agreement**) can have a substantial impact. This may be reflected by variation in the empirical classification points used, or by genuine variation in accuracy, or both, and only ROC analysis can resolve these issues. Finally, the accuracy of a test may change over time, due to improvements in the ability of the readers to make use of the technology, or due to technological enhancements. For example, it is widely accepted that the quality and resolution of mammograms has improved markedly during the three decades since they became available, and the published accuracy results reflect this trend [9].

Comparisons of Tests

Consider two diagnostic tests, with results denoted by x and y. Parameters of test y have corresponding notation to those of test x, as defined earlier. Comparison of the two tests on the basis of accuracy requires that we calibrate the classification points used, otherwise, for example, the sensitivity of test x may be

larger than that of test y merely because the classification rule was more strict for test x. ROC analysis is a natural way of calibrating the comparison, and this is the reason for its use as the definitive analytic tool.

Calibration of the comparison at a specific classification point is achieved by equating the marginal distributions of the two tests, where the prevalence of disease is standardized. Let the marginal distributions be defined by

$$M_x(x) = \pi F_x(x) + (1 - \pi)G_x(x),$$

and

$$M_y(y) = \pi F_y(y) + (1 - \pi)G_y(y). \qquad (2)$$

Let $x_z = M_x^{-1}(z)$ and $y_z = M_y^{-1}(z)$. Then x_z and y_z represent the classification points corresponding to the zth quantile of these marginal distributions, i.e. $M_x(x_z) = M_y(y_z)$, for all z. It is easily seen from Eq. (2) that if the sensitivity of test x is greater than the sensitivity of test y at this quantile, then the specificity of test x is also greater than the specificity of test y, i.e.

$$1 - F_x(x_z) > 1 - F_y(y_z) \Longleftrightarrow G_x(x_z) > G_y(y_z).$$

Thus the tests are fully equivalent if and only if $1 - F_x(x_z) = 1 - F_y(y_z)$ and $G_x(x_z) = G_y(y_z)$, for every value of z, i.e. throughout the entire ROC curve. The preceding theory relies on π being common to the two tests. In a comparison study this is necessarily true in the paired-sample design (*see* **Crossover Designs**), and indeed this design is the common design in comparison studies for reasons of efficiency [12].

The widely used methods developed for ROC analysis have mostly focused on comparing the areas under the ROC curves rather than comparisons at different calibrated quantiles. In fact, if one constructs the combined ranked sample of test results for a given test, i.e. combining diseased and normal subjects, and then evaluates the Wilcoxon statistic for comparing diseased and normal subjects (*see* **Wilcoxon–Mann–Whitney Test**), then this statistic is the area under the **nonparametric** trapezoidal ROC curve [2]. The asymptotic **variance** of this statistic is well known under the **null hypothesis** that the test is uninformative, i.e. the area is 0.5, and can be modified easily for the more common circumstance in which the area is substantially greater than 0.5 [11]. In the paired-sample setting, i.e. where both diagnostic tests are applied to each subject, the **correlation** between the test results within each subject must be taken into account, and methods have been developed specifically for this purpose [7].

Parametric methods are also widely used, primarily based on the binormal model. In this model it is assumed that if the distribution of tests results in normal (control) subjects is transformed to a standard **normal distribution**, then the same **transformation** on the diseased subjects will also lead to a normal distribution, with mean μ_x and variance σ_x^2, say, for test x [8]. In this case the area under the ROC curve is given by

$$A = \Phi\left(\frac{\mu_x}{(1 + \sigma_x^2)^{1/2}}\right),$$

where $\Phi(\cdot)$ is the standard normal distribution function. However, it is conventional to test for equivalence of the ROC curves by simultaneously testing that $\mu_x = \mu_y$ and $\sigma_x^2 = \sigma_y^2$, rather than simply testing for equality of the areas. In the paired sample setting the two test results are assumed to have corresponding **bivariate normal distributions** in the diseased and nondiseased populations, with correlation parameters to account for the within-patient dependencies [16]. Widely distributed noncommercial software is available for performing these analyses [15].

Finally, methods have recently been proposed for testing the equivalence of the two tests at all possible classification points in a nonparametric fashion, using **bootstrapping** techniques [6]. This can be accomplished for continuous paired data by permuting within pairs the ranks of the marginal rank order statistic, and obtaining a permutation test [23]. Such an analysis does not rely on the comparison of a summarized (parametric) measure of accuracy, such as the area or the binormal parameters as outlined above.

Study Design

In designing a study to evaluate or compare diagnostic tests, great care is necessary to ensure that the data are collected in a format suitable for resolving the problems and biases outlined in the previous Section. A source of detailed practical advice, with an emphasis on radiologic imaging studies, is the text by Swets & Pickett [21]. A recent trend has been the development of multi-institutional field studies,

which parallel the early development of **multicenter trials**, and which have provided guidance on the organizational and methodologic challenges of large-scale accuracy studies [10].

There are five general issues pertinent to comparative studies of diagnostic tests: representativeness of the sample; completeness of data reporting; recording of test results; mapping of test results to "truth" data; and control of the comparison. First, representativeness is especially important since the ease with which a patient can be diagnosed accurately varies widely from patient to patient, and so a nonrepresentative sample of patients could substantially bias the estimates of accuracy. Secondly, completeness of data recording and reporting is important in the context of verification bias and the problems of uninterpretable test results. In cases where verification bias might be a problem, the ideal study is one in which we can be sure that all patients are scheduled for the definitive reference test (e.g. surgery) prior to the conduct of the tests under evaluation, otherwise the **missing data** are likely to be selective, i.e. not missing at random. Thirdly, as we have seen, valid comparison of tests is only possible if a "calibrated" analysis is achievable, i.e. using ROC analysis. Therefore, the test data must be collected in sufficient detail to facilitate such an analysis. That is, binary reporting of test results (positive or negative) is inadequate, and a minimum requirement is several ordinal classifications. Fourthly, it is critical that the data from the experimental tests and from the reference test are recorded in a manner that permit meaningful correlation. In medical imaging studies (*see* **Image Analysis and Tomography**), this means that a precise anatomical mapping of the results is possible. For example, if the purpose of the study is not only to detect disease, but to localize it, each of the test results, including the reference test, needs to be recorded for each of the anatomic regions of interest. Thus, careful form design (*see* **Questionnaire Design**) and data collection is essential. Fifthly, if the tests under evaluation are interpreted subjectively, it is critical that evaluation of the second test is accomplished without knowledge of the first. Thus, **blinding** the test readers, or **randomization** of the test order, is necessary to prevent bias.

Finally, as is the case for all research studies, an adequate sample size is necessary to reduce statistical variation in the accuracy estimates to a level that permits meaningful interpretation of the data (*see* **Sample Size Determination**). Various methods for calculating study **power** are available [11, 15, 21].

Current Developments

There has been a substantial recent increase in research activity in the biostatistical literature on methods pertaining to the evaluation of diagnostic tests. The major themes of this work were summarized in a recent review article [4]. Even more recently, an issue of *Academic Radiology* was devoted to statistical developments in this field pertinent to medical imaging studies [1]. All of the articles addressed either one of two topics: **covariate** analysis of ROC curves, including models for accommodating **random effects**, such as test readers; and **meta-analysis of diagnostic tests**. Interest in covariate modeling stems from recognition of the fact that studies of the accuracy of diagnostic tests can be influenced by multiple factors. Meta-analysis is important in recognition of the fact that there exists a vast literature of published diagnostic accuracy studies, and we need methods that can synthesize these results reliably, in recognition of the limitations and biases that may be present in the individual studies. The field promises to continue to be an active area of biostatistical research in the foreseeable future.

Diagnostic Tests, Likelihood Ratio

The use of **sensitivity** and **specificity** to quantify the performance of a diagnostic test in relation to the true presence or absence of a specific disease is now well established in the medical literature. The emphasis on the formal evaluation of the information yielded by a diagnostic test and its incorporation into the diagnostic process has been an important theme in what is now called **clinical epidemiology** [4]. A renewed methodologic interest in the evaluation of diagnostic tests has led to alternative approaches being proposed, both to quantify test performance and to compare more easily the relative merits of competing tests [2]. One of these newer techniques is the use of **likelihood ratios** [1]. The objective of this article is to define the likelihood ratio in the context of a diagnostic test, to explain its use in the diagnostic process, and to contrast it with other techniques (*see* **Diagnostic Tests, Evaluation of**).

The Diagnostic Process

The term "diagnostic test" is used here to denote any item of diagnostic information derived from patient history, physical examination, biochemical or histologic examination of tissue, blood, or urine, or some sort of imaging. For example, a clinician might use the presence or absence of heart murmur to help diagnose a defective heart valve or a test that detects the presence of a normally intracellular enzyme in the blood of a suspected heart attack victim. In these situations the clinician would modify his/her degree of belief that the patient has the disease of interest on the basis of the test result. This might lead in turn to the immediate application of therapy, a decision to conduct further diagnostic testing which is usually more costly and/or more invasive (e.g. a coronary angiogram or ultrasound) but more definitive, or possibly to cease further workup on the grounds that the disease is unlikely to be present.

The result of the diagnostic test may be inherently dichotomous (e.g. the presence or absence of a physical sign), ordinal (e.g. the grade of murmur), or purely quantitative, as in the case of many laboratory tests. Despite this quantification, test results are often dichotomized into so-called positive and negative results based on some predetermined cutpoint. The choice of cutpoint may be fairly arbitrary (e.g. the 95th percentile for "normal" patients) or selected to yield the best discrimination between truly diseased and not diseased subgroups. Optimally chosen cutpoints would, in addition, take into account the "costs" associated with the consequences of subsequent clinical decisions and the true disease status.

Clearly, the dichotomization of a test result discards some of the diagnostic information but it allows the clinician to incorporate more easily the test information into the diagnostic process. Dichotomization allows the performance of the test to be quantified and the straightforward computation of post-test probability of disease by **Bayes' theorem** [3].

Sensitivity, Specificity, and Predictive Value

In the context of a dichotomous diagnostic test, sensitivity and specificity define the test's inherent ability to be positive when disease is truly present and negative when it is absent. In other words

$$\begin{aligned}\text{sensitivity} &= \Pr(\text{positive test} \mid \text{disease present})\\ &= 1-\beta,\\ \text{specificity} &= \Pr(\text{negative test} \mid \text{disease not present})\\ &= 1-\alpha.\end{aligned}$$

The complementary probabilities are analogous to the type I (α) and type II (β) errors in the context of **hypothesis testing**, hence the notation.

Suppose we have a population of patients in which a proportion, p, truly have a particular disease and the remainder, $1-p$, do not. In other words, the background **prevalence** of disease is p. If the diagnostic test was conducted on each member of the population, then the distribution of the test results that would occur is displayed in Table 1. The expression within each cell of the table represents the proportion of the population with a particular combination of test result and true disease status. Note that the tacit assumption here is that the sensitivity and specificity are known for the test *in this population*.

Faced with a diagnostic challenge for an individual patient in this population, the physician would start from the prior expectation, p, that the disease is present. This would then be modified in

Table 1 Test results in patients with and without disease

Diagnostic test result	Disease status		Predictive value (post-test probability)
	Present	Absent	
Positive	$p(1-\beta)$	$(1-p)\alpha$	$\frac{p(1-\beta)}{p(1-\beta)+(1-p)\alpha}$
Negative	$p\beta$	$(1-p)(1-\alpha)$	$\frac{p\beta}{p\beta+(1-p)(1-\alpha)}$

the light of the test result for the patient, increasing the probability of disease if the test was positive and reducing it if it was negative. Exactly how much the *prior probability* is modified in the light of the test result depends on the test's sensitivity and specificity. In the population as a whole, the proportion $p(1-\beta)+(1-p)\alpha$ would test positive; of this total, $p(1-\beta)$ would actually have the disease (true positives) and $(1-p)\alpha$ would not (false positives). Thus, given a positive test, a proportion $p(1-\beta)/[p(1-\beta)+(1-p)\alpha]$ would truly have the disease. Similarly, a proportion $p\beta/[p\beta+(1-p)(1-\alpha)]$ would have the disease in those who tested negative. These quantities are referred to either as post-test probabilities or **predictive values** and by inspection can be seen to result from a direct application of Bayes' theorem.

Post-Test Odds

Odds are an alternative way of expressing the likelihood of an event. Saying that an event has odds of one to three of occurring (i.e. an odds of 1/3) is equivalent to saying the probability is one quarter. Probabilities are thus converted to odds by the relationship

$$\text{odds} = \frac{\text{probability}}{1-\text{probability}},$$

and odds back to probability by

$$\text{probability} = \frac{\text{odds}}{1+\text{odds}}.$$

If, in the diagnostic situation above, we express the post-test chance of disease in terms of odds, then we produce the following expressions:

$$\begin{aligned}&\text{post-test odds(positive test)}\\ &= \frac{p(1-\beta)/[p(1-\beta)+(1-p)\alpha]}{(1-p)\alpha/[p(1-\beta)+(1-p)\alpha]}\\ &= \frac{p}{1-p}\times\frac{1-\beta}{\alpha}\\ &= \text{pre-test odds}\times\frac{\text{sensitivity}}{1-\text{specificity}}.\end{aligned}$$

The quantity sensitivity/(1 − specificity) is called the *likelihood ratio* (LR) for a positive test result. A similar calculation for the odds of disease given a negative test result leads to

$$\begin{aligned}&\text{post-test odds(negative test)}\\ &= \frac{p}{1-p}\times\frac{\beta}{1-\alpha}\\ &= \text{pre-test odds}\times\frac{1-\text{sensitivity}}{\text{specificity}}\end{aligned}$$

and the quantity (1 − sensitivity)/specificity is called the *likelihood ratio* for a negative test result.

A Numerical Example

The present-day horseshoe crab *(Limulus Polyphemus)* remains virtually unchanged from its primeval ancestors. Its primitive defenses include a blood-clotting mechanism designed to isolate and encapsulate certain types of bacteria infecting its blood stream. A purified extract of horseshoe crab blood forms the basis of the limulus lysate test for detecting the presence of gram-negative infections in humans. This test can yield a result in about one hour compared with two or three days for the definitive blood culture. In a recent study of febrile patients, the limulus test was found to have sensitivity 79% and specificity 96% in a population with a 4% prevalence of septicemia [6]. Thus, using the post-test probability expressions above, we have

$$\text{Pr(septicemia} \mid \text{positive test)}$$

$$= \frac{0.04 \times 0.79}{0.4 \times 0.79 + (1 - 0.04)(1 - 0.96)}$$
$$= 0.4514,$$

$$\Pr(\text{septicemia} \mid \text{negative test})$$
$$= \frac{0.04 \times (1 - 0.79)}{0.04 \times (1 - 0.79) + (1 - 0.04) \times 0.96}$$
$$= 0.0090.$$

In other words, a positive test would increase the probability of septicemia from 4% to 45%, whereas a negative test would reduce it to less than 1%. From the quoted sensitivity and specificity:

$$\text{LR(positive test)} = \frac{\text{sensitivity}}{1 - \text{specificity}} = \frac{0.79}{1 - 0.96}$$
$$= 19.75,$$
$$\text{LR(negative test)} = \frac{1 - \text{sensitivity}}{\text{specificity}} = \frac{1 - 0.79}{0.96}$$
$$= 0.2188.$$

A pre-test probability of 0.04 corresponds to an odds of $0.04/(1 - 0.04) = 0.0417$. The post-test odds are then:

$$\text{post-test odds (positive test)} = 0.0417 \times 19.75$$
$$= 0.8236,$$
$$\text{post-test odds (negative test)} = 0.0417 \times 0.2188$$
$$= 0.0091.$$

Conversion from odds back to probability yields the same probabilities as above. Note that a positive test causes the odds to be multiplied by almost 20, whereas a negative test requires the odds to be reduced by a factor of about five.

Generalization of the LR

The initial objective of the diagnostic workup is to determine the probability that the patient has the disease in the light of the test result. While sensitivity and specificity are simple statistics that describe test performance, their combined influence on post-test probability is not obvious. By contrast, LR has a direct multiplicative effect on pre-test odds, making the impact of the additional diagnostic evidence provided by the test more apparent. The calculation of post-test odds can be done approximately using a little mental arithmetic. Alternatively, simple nomograms are available which convert pre-test to post-test probability via the appropriate LR [4].

The most important advantage of LR is that it can be generalized to handle ordinal (*see* **Ordered Categorical Data**) or purely quantitative tests [1]. While the computation of post-test probability via Bayes' theorem can incorporate a quantitative test result, the terms sensitivity and specificity can only be directly applied if the quantitative test is first dichotomized at some cutpoint into positive and negative categories. Other than for simplicity, there seems little justification for collapsing a quantitative test into this dichotomy. A patient whose test result was only just over the cutpoint for positivity would be assigned the same post-test probability as a patient whose test result was extremely elevated. At some stage the physician must make the decision whether the patient has, or does not have, the disease. However, this ultimate dichotomization should be based on actual post-test probability, not on the intermediate test result. This issue would be especially important if the current test was only one step in a more extensive sequential diagnostic workup.

For a continuous test result, X, the definition of LR is

$$\text{LR}(X) = \frac{\Pr(X \mid \text{patient diseased})}{\Pr(X \mid \text{patient not diseased})}.$$

These probabilities, and thus the LR, can be estimated empirically for an inherently ordinal test (e.g. the traditional +, ++, +++ grading of heart murmur) or, for a purely quantitative test, by dividing the test result into subranges. In either case, the post-test odds are computed as the product of pre-test odds and LR, but now the LR is computed for the patient's own test result, as opposed to an average LR for all test results above or below a cutpoint.

Empirical LR Estimates

Table 2 shows LR computed for various ranges of creatine kinase (CK) for patients with and without myocardial infarction (MI) from a study by Smith [5]. Now, by using the LR for the range of the test result obtained, one can compute a more specific post-test probability. Obviously, the more extreme CK value

Table 2 Creatine kinase (CK) in patients with and without myocardial infarction (MI)

CK range	Proportion of MI patients (A)	Proportion of non-MI patients (B)	LR (A/B)
≥280	97/230 0.4217	1/130 0.0077	54.8
200–279	37/230 0.1609	2/130 0.0154	10.5
120–199	51/230 0.2217	5/130 0.0385	5.8
40–119	43/230 0.1870	34/130 0.2613	0.71
<40	2/230 0.0087	88/130 0.6769	0.013

of ≥280 would lead to a higher post-test probability of MI compared with a relatively mildly elevated CK at say 150.

Purely Continuous LR

Although going some way to creating a LR for each level of the test result, in the example above we have had to combine patients within a range of CKs to provide enough data points to estimate the LR. Conceptually, the purely continuous test result situation is depicted in Figure 1. The individual test results for patients with and without the disease form two continuous *distributions* where the *heights* of the curves at any point are the relative frequencies of that test result for the populations of patients with and without the disease. By definition, the LR at any value of the test result, X, is the ratio of the relative frequency (i.e. probability density) of X in the diseased to nondiseased distributions. If the data for the test results from representative samples of diseased and nondiseased patients can be adequately described by some appropriate mathematical model, then the LR can in turn be described mathematically at each X. For example, if both samples of test results were **normally distributed** with different **means** and **variances** so that

$$X \sim \mathrm{N}(\mu_1, \sigma_1^2) \text{ for diseased patients,}$$

$$X \sim \mathrm{N}(\mu_2, \sigma_2^2) \text{ for nondiseased patients,}$$

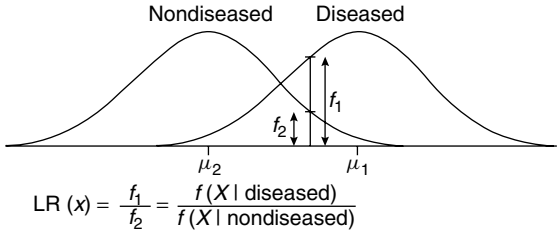

Figure 1 Likelihood ratio for a quantitative test

then the LR would be

$$\mathrm{LR}(X) = \frac{\left(2\pi\sigma_1^2\right)^{-1/2} \exp\left[-\dfrac{(X-\mu_1)^2}{2\sigma_1^2}\right]}{\left(2\pi\sigma_2^2\right)^{-1/2} \exp\left[-\dfrac{(X-\mu_2)^2}{2\sigma_2^2}\right]},$$

which simplifies a little to

$$\mathrm{LR}(X) = \frac{\sigma_2}{\sigma_1} \exp\left[-0.5(z_1^2 - z_2^2)\right],$$

where the z_1 and z_2 are the standardized deviates (*see* **Standard Normal Deviate**) of the test result X with respect to the diseased and nondiseased distributions, respectively.

The CK data from Smith are almost perfectly **lognormally distributed** with $\log_e$ CK having mean = 5.45 and SD = 0.737 for MI patients and mean = 3.19, SD = 1.030 for noninfarct patients. Substitution of these parameter estimates into the expression above leads to the continuous curve (Figure 2), which provides a value for LR corresponding to each individual value of the CK test.

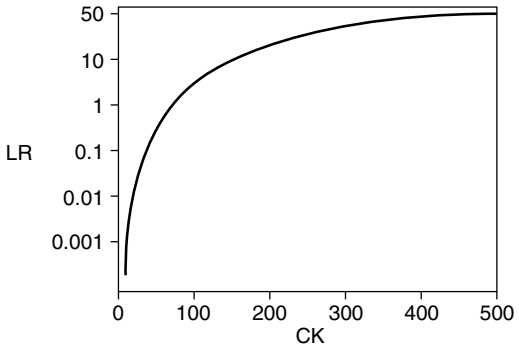

Figure 2 Continuous likelihood ratio curve

Summary

In its simplest form, LR is a useful measure of the diagnostic information conveyed by a diagnostic test. Compared with sensitivity and specificity, it offers a more interpretable measure of the impact of the test result on the probability of disease and also a simplification in the calculation, especially if one is prepared to think in terms of odds rather than probability. More importantly, it allows a natural extension to accommodate truly quantitative test results. The LR can reflect the diagnostic information at any level of test result. This leads to a post-test probability for the actual test result observed in the patient as opposed to a less specific post-probability computed from a test result which has been first dichotomized into positive and negative categories. Full utilization of the diagnostic information would require knowledge of the LR at each value of X and this may be quite feasible in many clinical situations.

Diagnostic Tests, Multiple

In medical practice, diagnostic tests are rarely used in isolation. Typically, the evidence for forming a diagnosis comes from multiple sources, in the form of signs and symptoms and other patient characteristics, in addition to specific tests that are ordered to rule in or rule out a candidate diagnosis. Thus, the evidence from individual diagnostic tests must be used collectively in forming the diagnosis, and the statistical dependency of the information from these multiple sources becomes an important factor in assessing the weight of evidence. In this article we consider the two settings in which data from many diagnostic tests are relevant. In the first, we consider **discriminant analysis**, where one wishes to develop diagnostic rules on the basis of an available data set encompassing information on multiple tests. In the second setting we consider the problem of sequentially updating diagnostic probabilities as new tests are selected and performed in the course of making a diagnosis for an individual patient.

Discriminant Analysis

The general goal of discriminant analysis is to provide a statistical framework for characterizing two or more diagnostic categories on the basis of a set of diagnostic indicator variables (e.g. diagnostic tests), either to provide allocation rules, ideally with low error rates, or to provide realistic probabilities of the diagnostic categories for an individual (future) patient to facilitate decisions about medical management of the patient. Suppose that there is a baseline diagnostic category, denoted by zero, and an additional t diagnostic categories, where $z_d = 1$ is the patient belongs to the dth category, $d = 0, 1, \ldots, t$, and $z_d = 0$ otherwise. Let there be p diagnostic test variables, denoted $s = (s_1, \ldots, s_p)$. Let $\phi_d(\cdot)$ denote generically the probability of category d given the values of the variables in parentheses, and let $f_d(\cdot)$ denote the corresponding **sampling distribution** given the diagnostic category. As examples, $\phi_d(s) = \Pr(z_d = 1|s)$ is the probability that a patient with test vector s belongs to diagnostic category d, while $f_d(s_1|s_2, \ldots, s_p)$ is the conditional density function of s_1, given $s_2, \ldots, s_p$, and $z_d = 1$.

Discriminant analysis is a widely used statistical technique available in numerous commercial statistical packages (*see* **Software, Biostatistical**). The traditional formulation involves the assumption of **multivariate normal distributions** for $f_d(s)$. If a common **covariance matrix** across diagnostic categories can be assumed, then the **likelihood ratio** distinguishing any two diagnostic categories (*see* **Diagnostic Tests, Likelihood Ratio**) is a linear function of s, and so allocation of patients into diagnostic categories can be based on these linear functions. Diagnostic probabilities can then be obtained using **Bayes' theorem** and the **prevalences** or "prior" probabilities of the diagnoses. For a review of traditional approaches to discriminant analysis, see Lachenbruch [6].

An alternative "paradigm" is to model the diagnostic probabilities $\{\phi_d(s)\}$ directly, using models such as **logistic regression** [4]. The linear logistic model, for example, is consistent with the assumption of normal sampling distributions with equal covariance matrices, but is based on a more parsimonious and directly relevant parameterization than the modeling of the sampling distributions. Specifically, the simple linear logistic model is represented as follows:

$$\ln\left(\frac{\phi_d(s)}{\phi_0(s)}\right) = \beta_0 + \beta_1 s_1 + \cdots + \beta_p s_p, \qquad d = 1, \ldots, t.$$

By introducing additional terms the model can be made more flexible. For example, quadratic terms or **interaction** terms could be introduced to accommodate discrimination between multivariate normal populations with unequal covariances. Use of the predicted probabilities of disease categories obtained from a logistic regression on new patients requires the assumption that the relative frequencies of the diagnoses in the "training" data set, denoted $\pi_0, \pi_1, \ldots, \pi_t$, be representative. If one wants to alter these "prior" probabilities to $\pi_0^*, \pi_1^*, \ldots, \pi_t^*$, then the log odds comparing category d with the baseline would need to be changed by the addition of the factor $\log(\pi_d^*\pi_0/\pi_0^*\pi_d)$.

The literature on discriminant analysis encompasses numerous other modeling strategies, including formal **Bayesian** approaches that provide more realistic (i.e. more conservative) diagnostic predictions, kernel estimation techniques (*see* **Density Estimation**), and others. Recently, much attention has been directed toward computer-intensive techniques,

especially those based on classification and regression trees (CART) (*see* **Tree-structured Statistical Methods**), and also methods based on computerized **neural networks**. CART methods involve the partitioning of s into mutually exclusive subgroups of diagnostic test results that are diagnostically informative. It has been argued that this facilitates the interpretation of the rules for clinicians [2]. Neural networks involve the creation of a possibly hierarchical structure of test results, and these tend to be more heavily parameterized than conventional statistical models. For a review, see Cheng & Titterington [3].

Regardless of how the discriminant model is selected and applied, its validity can only be assessed definitively by evaluating its performance on a different data set from the one in which it was derived. In general, parametrically rich models will appear to perform relatively well when the error rates are evaluated on the data set on which the model was derived, and so the inevitably improved fit due to adding greater complexity to the model may be illusory. In the absence of a "test" data set to complement the "training" set, **cross-validatory** techniques can provide guidance on the degree of overfitting [9].

Sequential Testing

In medical practice a diagnosis is not usually reached either on the basis of a single definitive test or on a set of prescribed tests that could form the basis of a discriminant analysis, as outlined above. Tests may be applied in sequence, in an effort to ascertain a single diagnosis with high confidence. Doctors usually select the sequence of tests using medical judgment, and the level of confidence in the resulting diagnosis is assessed nonquantitatively. In recent years clinical epidemiologists have addressed the issue of how to evaluate these diagnostic probabilities quantitatively. Sackett et al. [8] provide examples of this process. The updating of diagnostic probabilities on the basis of the result of a new test, say s_k, given the information from previous tests, say $s_1, \ldots, s_{k-1}$, is the critical statistical problem in this setting.

Updating of diagnostic probabilities can be accomplished using **Bayes' theorem**, which is most conveniently expressed in its **odds ratio** form:

$$\frac{\phi_d(s_1, \ldots, s_k)}{\phi_0(s_1, \ldots, s_k)} = \frac{\phi_d(s_1, \ldots, s_{k-1})}{\phi_0(s_1, \ldots, s_{k-1})} \times \frac{f_d(s_k|s_1, \ldots, s_{k-1})}{f_0(s_k|s_1, \ldots, s_{k-1})}, \quad (1)$$

where $\phi_d(s_1, \ldots, s_{k-1})/\phi_0(s_1, \ldots, s_{k-1})$ is the "prior" odds before the test result s_k is obtained. Setting $\alpha_d(\cdot) = \phi_d(\cdot)/\phi_0(\cdot)$, $d = 1, \ldots, t$, the pairwise odds in (1) are easily converted to probabilities using

$$\phi_d(\cdot) = \frac{\alpha_d(\cdot)}{1 + \alpha_1(\cdot) + \cdots + \alpha_t(\cdot)}, \quad d = 1, \ldots, t.$$

In fact, if we consider, for expository purposes, that each of the tests has been administered sequentially, then it is convenient to express (1) in the form

$$\frac{\phi_d(s_1, \ldots, s_k)}{\phi_0(s_1, \ldots, s_k)} = \frac{\pi_d}{\pi_0} \frac{f_d(s_1)}{f_0(s_1)} \frac{f_d(s_2|s_1)}{f_0(s_2|s_1)} \cdots \times \frac{f_d(s_k|s_1, \ldots, s_{k-1})}{f_0(s_k|s_1, \ldots, s_{k-1})},$$

where each of the sequence of likelihood ratio terms represents the appropriate factor, at that stage, for updating the disease probabilities.

Sequential updating of probabilities using Bayes' theorem has become established as the theoretical paradigm for handling quantitative diagnostic information [8]. However, clinical epidemiologic texts rarely emphasize the critical requirement that the likelihood ratios should be conditioned on the data that have already been used to determine the current "prior" probabilities. In fact, the "current" prior should only be updated using the unconditional likelihood ratio $f_d(s_k)/f_0(s_k)$ if the test s_k is conditionally independent of the "tests" that have contributed to the current prior odds [1]. In practice, this is unlikely to be even approximately true, and so the use of unconditional likelihood ratios will tend to lead to overoptimistic, i.e. anti-conservative, diagnostic probabilities [5]. Moreover, in the absence of such conditional independence, the data requirements to provide the appropriate conditional probabilities for each step in a series of tests are formidable, and such data are generally not available [7].

The application of Bayes' theorem in updating diagnostic probabilities is most commonly utilized

in the construction of **decision analytic** models [10]. It is unlikely that many doctors utilize this formalized paradigm routinely in day-to-day clinical settings.

Diagnostics

Introduction

Diagnostics are methods for identifying and understanding differences between a model and the data to which it is fitted. This article is mainly concerned with the **linear regression** model, although the techniques of regression diagnostics, especially the study of the effect of the deletion of observations, are more widely applicable. Extensions to other models are described in the last section.

Some differences between the data and the model may be due to isolated observations: one, or a few, observations may be **outliers**, or may differ in some unexpected way from the rest of the data. Other differences may be systematic, for example, a term may be missing in a linear model. Systematic departures can often be detected by aggregate statistics, that is, quantities calculated over all the data, such as a t or F test in regression. But there is the important possibility that the evidence, for example, for an extra term, or a **transformation** of the response, may be being unduly influenced by a few observations. The main emphasis of diagnostics in statistical usage is on the effect of individual cases (observations y and the associated vectors of **explanatory variables** or carriers $\boldsymbol{x}$) on inferences about the model. These effects are customarily determined by deletion of individual cases. Exact formulae for the effects of deletion in regression mean that only one fit to the data yields the required diagnostic quantities. When exact formulae are not available, for example, for **Generalized Linear Models**, similar techniques yield useful approximations to the effect of deletion. In some statistical fields, such as econometrics, the term diagnostics is often taken to include aggregate statistics. An example is [Harvey 11, Section 5.4]. Here we discuss deletion diagnostics. Related material is included in the entries **Forward Search**, **Goodness of Fit** and **residuals**.

Outliers

An outlier is an isolated observation that does not agree with the model fitted to the majority of the data. The statistical problem is that fitting the model may disguise the presence of outliers. For simple samples, the effect of fitting is often not crucial. For example, a human **birth weight** recorded as 35 kg, perhaps due to multiplication of the weight by 10 on data entry, is clearly wrong, whatever model is fitted. The early chapters of Barnett and Lewis [5] describe the history of the definition of outliers and methods for their detection in univariate samples. For more complicated models, such as regression, large residuals indicate outliers, but outliers do not necessarily give rise to large **least-squares** residuals, especially if they occur at remote points in the factor space, which is at "leverage points". More formally, the least-squares estimate of the parameters in the linear regression model is

$$\hat{\boldsymbol{\beta}} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y}, \tag{1}$$

where $\boldsymbol{X}$ is the $n \times p$ **matrix** of carriers, that is, of explanatory variables and perhaps functions of them, such as quadratics and **interactions**. It is assumed that the additive errors of observation $\boldsymbol{\varepsilon}$ are independently distributed with constant variance σ^2. The least-squares residuals are then given by

$$\begin{aligned}\boldsymbol{e} = \boldsymbol{y} - \hat{\boldsymbol{y}} &= \boldsymbol{y} - \boldsymbol{X}\hat{\boldsymbol{\beta}} = \boldsymbol{y} - \boldsymbol{X}(\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y} \\ &= (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{y} = \boldsymbol{A}\boldsymbol{y}. \end{aligned} \tag{2}$$

In (2) $\boldsymbol{I}$ is the $n \times n$ identity matrix and $\boldsymbol{H}$ is the "hat" matrix, so-called because $\hat{\boldsymbol{y}} = \boldsymbol{H}\boldsymbol{y}$. The diagonal elements h_i of $\boldsymbol{H}$ are such that $0 \le h_i \le 1$, with average value p/n. Observations with "large" values of h_i are said to be leverage points.

The residuals $\boldsymbol{e}$ are not independent, nor do they have the same variance since $\mathrm{var}(e_i) = \sigma^2(1 - h_i)$. The standardized residuals r_i are given by

$$r_i = \frac{e_i}{\sqrt{\{s^2(1 - h_i)\}}}, \tag{3}$$

where $s^2 = \sum e_i^2/(n - p)$ is used to estimate σ^2. The distribution of r_i^2 is a scaled **Beta distribution**.

The t test (*see* **Student's *t* Distribution**) for the hypothesis that observation i is an outlier is based on the deletion residual r_i^*, which is found by the deletion of case i or, equivalently, by fitting the mean shift outlier model

$$\mathrm{E}(\boldsymbol{Y}) = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{d}_i^T\phi, \tag{4}$$

where $\boldsymbol{d}_i$ is an $n \times 1$ vector of zeroes except for a 1 in the ith position. If $\hat{\boldsymbol{\beta}}_{(i)}$ is the least-squares estimate

of $\boldsymbol{\beta}$ when y_i is not used in fitting, the prediction at $\boldsymbol{x}_i$ is $\hat{y}_{(i)} = \boldsymbol{x}_i^T \hat{\boldsymbol{\beta}}_{(i)}$. The deletion residual is then

$$r_i^* = \frac{y_i - \hat{y}_{(i)}}{\text{s.e. } (y_i - \hat{y}_{(i)})} = \frac{y_i - \boldsymbol{x}_i^T \hat{\boldsymbol{\beta}}_{(i)}}{\text{s.e. } (y_i - \hat{y}_{(i)})}.$$
$$= \frac{e_i}{\sqrt{\{s_{(i)}^2 (1 - h_i)\}}}. \quad (5)$$

In (5) $s_{(i)}^2$ is the residual mean square estimate of σ^2 on $n - p - 1$ degrees of freedom after the deletion of case i. From the further results discussed in **residuals**, it follows that r_i^* can be calculated from the standardized residuals since

$$r_i^* = \frac{r_i}{\sqrt{\left\{\frac{(n - p - r_i^2)}{(n - p - 1)}\right\}}}. \quad (6)$$

In the absence of outliers, the deletion residuals have a t distribution on $n - p - 1$ degrees of freedom so that, unless the degrees of freedom are small, they will give an almost straight normal probability, or $Q-Q$, plot. If the straightness is in doubt, a simulation envelope can be generated of the type described in **residuals**.

As an example, we turn to the analysis of the data from Royston and Altman [14] on mandible length as a function of **gestational age** in 167 fetuses with ages from 12 to 33 weeks. The data are plotted in Figure 2 of **goodness of fit**. The analysis there and in **residuals** suggests that a transformation of y should be taken. Whether or not y is transformed, the skeleton **analyses of variance** in Table 1 indicate that a quadratic in age should be included (*see* **Polynomial Regression**). The F values for both linear and quadratic terms are higher for the transformed data than for the original, especially for the quadratic term. The F value for the cubic term is significant at the 5% level, but not at 1%. Given the number of observations that we have, we ignore the cubic term and work with a quadratic model in the gestational age, x, with log y as the response. Diagnostic scrutiny of both transformation and linear model in the articles on **fan plot** and **forward search** show that this choice does not depend on just a few observations. We also note that the doctors quoted by Royston and Altman felt that younger fetuses might differ systematically from those older than 28 weeks. These are cases 159 to 167.

Table 1 Skeleton analysis of variance for regression models and transformations fitted to data on mandible length

Response	y	log y
Source	F	F
Age	1468.7	1851.1
$(\text{Age})^2$	20.2	161.3
$(\text{Age})^3$	4.8	5.0

Figure 1 shows a normal $Q-Q$ plot of the deletion residuals for all cases. There is no evidence of any outliers. This plot is very different from Figure 3 of the article on **residuals** when a first-order model is fitted to the untransformed data. That $Q-Q$ plot showed three appreciable outliers, cases 149, 165, and 166, which lie well below the trend of the rest of the observations in the scatter plot of Figure 5. The logarithmic transformation of the data seems to reconcile these cases with the remaining data. However, their importance may be masked by the least-squares fit. The purpose of the methods described in this article is to assess the effect of such cases on the fitted model and conclusions drawn from it. Since the $Q-Q$ plot of Figure 1 is virtually straight, further analysis can proceed on the assumption that the residuals, and so the errors, are normally distributed.

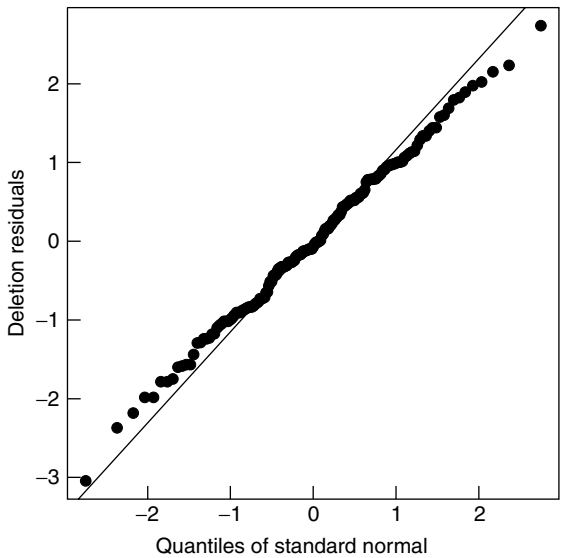

Figure 1 Mandible length data. Normal $Q-Q$ plot of deletion residuals r_i^* from a quadratic model in age and a logged response. The data seem well fitted by this model

Leverage

Several diagnostic measures are combinations of the least-squares residuals e_i and the leverage measures h_i. It is sometimes informative to look at the h_i on their own. Figure 2 is an index plot of h_i, that is, a plot against observation number, for the 167 observations on mandible length. Since the observations are in order of increasing y, they are pretty much in order of increasing x as well. It is clear from the figure, and expected, that observations at the extreme values of x have the highest leverages. For **multiple regression** data, the pattern is often less clear, although sometimes informative. It is however, the combination of y with x, which is important in making inferences about appropriate models.

Influence and Cook's Distance

The deletion residuals r_i^* provide a test for outliers. However, an outlier may or may not have an important effect on inferences drawn from the data. This information can be obtained by considering the change in the parameter estimates when case i is deleted, that is, the distance $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)}$, or components of this distance, preferably suitably scaled. Cook's distance [7] provides a measure of influence for all parameters based on the increase in the residual sum of squares for all the data when the deletion estimate $\hat{\boldsymbol{\beta}}_{(i)}$ replaces $\hat{\boldsymbol{\beta}}$. Cook's distance is defined as

$$D_i = \frac{(\hat{\boldsymbol{\beta}}_{(i)} - \hat{\boldsymbol{\beta}})^T \boldsymbol{X}^T \boldsymbol{X} (\hat{\boldsymbol{\beta}}_{(i)} - \hat{\boldsymbol{\beta}})}{ps^2}. \tag{7}$$

The use of standard deletion formulae (Cook and Weisberg [8, p. 210]; Atkinson [1, p. 19]) leads to the alternative form

$$D_i = \frac{e_i^2 h_i}{\{ps^2(1-h_i)^2\}} = \frac{r_i^2 h_i}{\{p(1-h_i)\}}. \tag{8}$$

For plotting purposes, Atkinson [1, p. 25] suggests the modified Cook Statistic C_i, which is a scaled square root of D_i with s^2 replaced by $s_{(i)}^2$. Thus,

$$C_i = \left(\frac{n-p}{p}\frac{h_i}{1-h_i}\right)^{\frac{1}{2}} |r_i^*|. \tag{9}$$

Figure 3 is an index plot of C_i for the 167 observations of the mandible length data. Six cases, 1, 7, 149, 163, 165, and 167 have large values of the modified Cook statistic, suggesting that they may be unduly influencing the parameters of the fitted model. Three of these are cases, which were originally regarded with some suspicion, three are not. To demonstrate

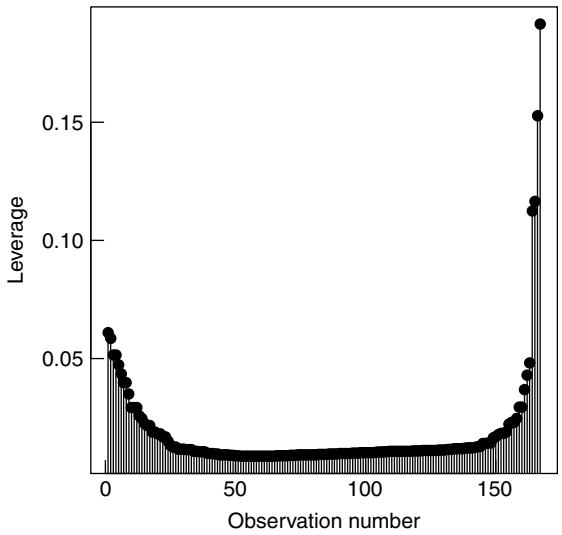

Figure 2 Mandible length data. Index plot of leverage measure h_i for all 167 cases

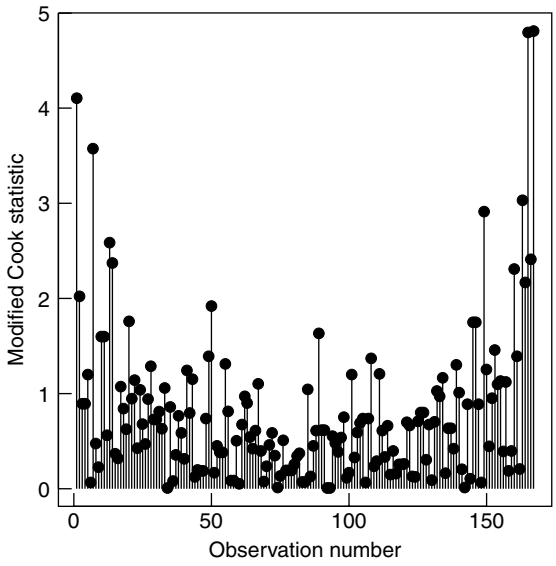

Figure 3 Mandible length data. Index plot of modified Cook's distance C_i for all 167 observations. Cases 1, 7, 149, 163, 165, and 167 appear highly influential

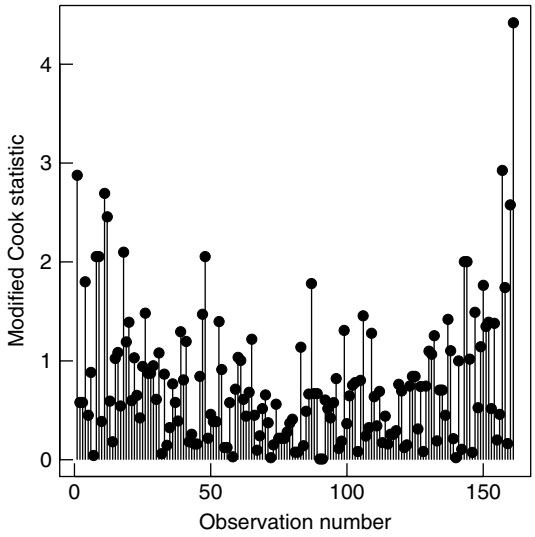

Figure 4 Mandible length data. Index plot of modified Cook's distance C_i after the deletion of six cases. Now original case 166 appears especially influential

what information can be obtained using diagnostic methods, we omit these six and refit to obtain the plot of Figure 4. Now original case 166 appears as especially influential.

As a result of this analysis, seven out of 167 cases have been identified as potentially outlying or otherwise different. It must be stressed that the purpose of diagnostic analyses is not to delete all cases with any egregious characteristics. Rather the purpose is to identify such cases, to ascertain their importance and, if they are crucial to an understanding of the data, to check for transcription errors, unsuspected variations in conditions of measurement or source of the data, or other explanations of apparent anomalies.

Multiple Deletion and very Robust Regression

The deletion diagnostics for individual case deletion can readily be extended to a subset of m observations with index I. However, such procedures are not as useful as the deletion of individual cases, due to the combinatorial explosion in the number of quantities to be considered. Even for the 167 cases of the mandible length data, there are 13 861 diagnostics from deletion of pairs. Often, information on diagnostic matters can be extracted by the repeated use of single deletion diagnostics. But sometimes this can fail, a condition known as "masking", caused for example, by the presence of several outliers at leverage points. In such conditions very **robust regression** can be used, which resists up to 50% of outliers in the data, and the results compared with those from least-squares analyses.

In least trimmed squares (*see* **Trimming and Winsorization**), the model is fitted by least squares to the q data points giving the smallest residual sum of squares. The greatest robustness against outliers is obtained by taking q as approximately half the data, that is,

$$q = \left[\frac{n}{2}\right] + \left[\frac{(p+1)}{2}\right], \qquad (10)$$

when allowance is made for fitting. Calculation of the least trimmed squares estimate involves repeated searches from random starting points. Figure 5 shows the fitted line obtained using the algorithm in the statistical package **S-PLUS**. Although log(length) was used as the response in all models fitted, the plot is on the original scale of the data. One consequence is that the outlying nature of cases 149, 165, and 166 on the original scale is apparent. The plot also shows

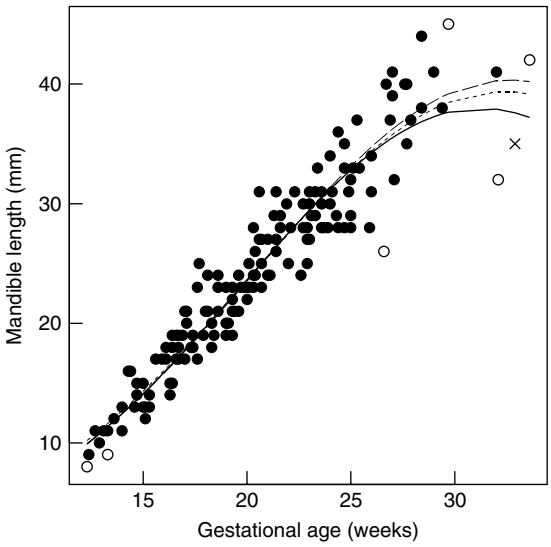

Figure 5 Mandible length data. Data with three fitted quadratic models with logged response: (a) ___ least squares fit to all data; (b) - - - - - - least squares fit when the seven marked cases are omitted; (c) . . . . . least trimmed squares. The very robust and diagnostic-led analyses give similar results. Case 166 is marked with a cross

why case 166, marked with a cross, is shown as influential in Figure 4 when cases 163, 165, and 167 have been deleted, but is not especially influential in the plot for all 167 cases in Figure 3.

Also shown is the fitted line obtained from the diagnostic procedure, which omitted seven cases. This plot is similar to that for the least trimmed squares, especially for the older cases, and distinct from the more curved least-squares fit to all the data. The plot confirms the doctors' suspicion that some readings at higher values of age might be atypical. However, after transforming the data to obtain a normal distribution of errors, it seems that some readings at low ages may also be atypical. Further, some of the readings at high ages are, despite the doctors' suspicions, informative about the general relationship between age and mandible length.

Extensions and Literature

Deletion diagnostics of the sort described here have received book length treatment by Belsley et al. [6], Cook and Weisberg [8], and by Atkinson [1]. They are also emphasized in the regression books of Weisberg [16] and of Ryan [15]. Added variable and constructed variable plots (*see* **Residuals**) indicate the contribution of individual cases to the evidence for inclusion of an explanatory variable, provided cases with high leverage are not important. If they are, deletion versions of the appropriate statistics are useful (Atkinson [2]). Interactive **graphics** allow exploration of multiple aspects of the effect of deletion and of the change of, for example, transformation parameters [9]. The diagnostic use of very robust regression is described by Rousseeuw and Leroy [13]. An example combining diagnostics and such regression is Atkinson [3]. The extension of diagnostics to **generalized linear** models is in Chapter 12 of McCullagh and Nelder [12]. A more detailed description is Atkinson [10]. Methods for determining the influence of several observations are described in the article on the **forward search** and, at greater length, in the book of Atkinson and Riani [4].

A.C. ATKINSON

Differential Error

Suppose a response variable Y has a conditional distribution $F(y|x)$ given a true exposure measurement $X = x$. Suppose that an error process yields Z instead of X. Then the error process is differential if $F(y|x, z) \neq F(y|x)$; namely, if it is not **nondifferential error**. Naive use of Z in place of X in the model $F(y|x)$ leads to estimates of **exposure effect** that can be **biased** in any direction (*see* **Bias in Observational Studies**; **Bias, Overview**; **Measurement Error in Epidemiologic Studies**; **Misclassification Error**; **Validity and Generalizability in Epidemiologic Studies**).

The term differential error can also be applied to errors in the outcome measure, Y. Suppose that one measures the error-prone version W of Y, instead of Y itself. Then the error process is differential if $F(w|x, y) \neq F(w|y)$. Such differential error can also result in bias in any direction if W is simply substituted for Y in the model $F(y|x)$.

Diggle–Kenward Model for Dropouts

A typical longitudinal study design (*see* **Longitudinal Data Analysis, Overview**) specifies a time sequence of measurements on each of a number of subjects. A common feature of the resulting data is that some of the intended sequences of measurements are incomplete because the corresponding subjects withdraw prematurely from the study. We refer to this as attrition or *drop-out*.

Drop-outs can arise for many reasons. For example; the study protocol may specify the removal of subjects who show adverse side-effects of the treatment being administered; subjects may die for reasons related or unrelated to the context of the trial; subjects may be unwilling to continue because they perceive no benefit from further participation. Often, in practice, the exact causes of drop-outs are unknown. This raises a potential difficulty for the analysis of the resulting data, since the processes which govern the drop-out may be related to the measurement process which is the primary focus of the study. Figure 1, reproduced from Diggle et al. [3, Chapter 11] illustrates the problem. It shows a simulated data set in which, for each of 100 subjects, the mean response is constant over the intended duration of the study but the probability that a subject drops out at any time is inversely related to the value of their last recorded measurement. Also,

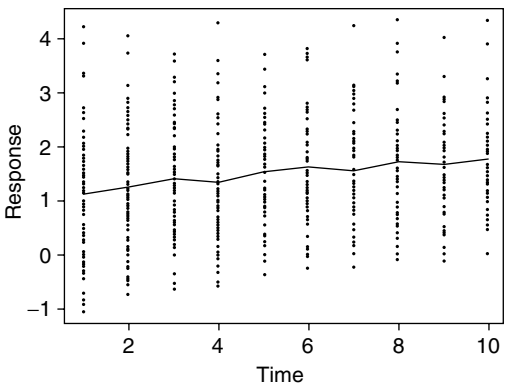

Figure 1 Simulation of a longitudinal data set in which the probability of drop-out is inversely related to the value of the last recorded measurement. Reproduced from [3] with permission from Oxford University Press

the sequence of measurements on any one subject is highly correlated. The result is that the lower-responding subjects are progressively removed from the study and the observed mean response amongst the nondrop-outs rises steadily over time. Suppose that each measurement represents a clinical response to treatment and that an increased response is beneficial. A naive analysis of the data might conclude that the treatment under investigation produces the desired rise in the mean response, whereas in reality no subject receives any clinical benefit from the treatment.

It is convenient to assume that the study protocol specifies a common set of measurement times for all subjects. Let $Y^* = (Y_1^*, \ldots, Y_n^*)$ then denote the intended sequence of measurements on a single subject, and D the subject's drop-out time, with the convention that an observed value $D = d$ means that the values of $Y_d^*, \ldots, Y_n^*$ are missing, whilst $D = n + 1$ signifies no drop-out. A statistical model for longitudinal data with drop-outs can then be thought of as a specification of the joint distribution of Y^* and D. Quite generally, we can write this joint distribution in two equivalent ways:

$$\begin{aligned} f^*(y, d) &= f^*(y)g(d|y) \\ &= g(d)f^*(y|d). \end{aligned} \tag{1}$$

Models derived from the first factorization are called *selection models* [4]. Those derived from the second factorization are called *pattern mixture models* [5]. One advantage of a selection model is that it includes, in the $f^*(y)$ term, a model for the study as designed. A counterbalancing advantage of a pattern mixture model is that it corresponds more directly to what is actually observed, namely the distributions of measurements within the subgroups defined by the different drop-out times.

Diggle & Kenward [2] introduce an explicit class of selection models for longitudinal data. They specify a multivariate Gaussian distribution for $f^*(y)$ and a logistic regression for $g(d|y)$. Explicitly, if $p_t(y)$ denotes the conditional probability of drop-out at time t, given $Y^* = y$, then

$$\text{logit}[p_t(y)] = \alpha_0 y_t + \sum_{k=1}^{r} \alpha_k y_{t-k}.$$

Molenberghs et al. [6] describe a model of the same kind, but for an ordered categorical response vector

Y^*, replacing the multivariate Gaussian specification of $f^*(y)$ by a model due to Dale [1].

From an inferential point of view, it is important to distinguish three subclasses of the Diggle–Kenward model, which correspond to the three kinds of missing data mechanism defined in a more general setting by Rubin [8]:

1. *completely random drop-outs* (CRDs): $p_t(y) = p_t$. The probability of drop-out at time t is independent of the measurement process Y^*
2. *random drop-outs* (RDs): $p_t(y) = p_t(y_1, \ldots, y_{t-1})$. The probability of drop-out at time t may depend on any or all of the observed measurement history $y_1, \ldots, y_{t-1}$, but cannot depend on the unobserved y_t
3. *informative drop-outs* (IDs): $p_t(y) = p_t(y_1, \ldots, y_t)$. The probability of drop-out at time t depends on the unobserved y_t.

For likelihood-based inference, it turns out that the important distinction is between IDs on the one hand and CRDs or RDs on the other. If we assume that the measurement model $f^*(y)$ and the drop-out model $g(d|y)$ are parameterized separately by θ and α, respectively, then under either CRDs or RDs, the log likelihood for θ and α separates into two terms, one involving θ only and, the other involving α only, whereas in the general ID case, the log likelihood is a sum of three terms, the third of which involves both θ and α. It follows that under CRD or RD assumptions, valid likelihood-based inferences about θ can be made without explicitly modeling the drop-out process. For this reason, CRD or RD mechanisms are sometimes collectively known as *ignorable* drop-outs. However, the example of Figure 1, which uses an RD model, makes the point that the practical interpretation of an analysis conducted on this basis still needs some care.

As pointed out in the discussion of Diggle & Kenward [2], the inferences made in the ID case are very sensitive to the underlying distributional assumptions. This is of particular concern because Molenberghs et al. [7] show that the RD hypothesis is not testable without additional assumption.

PETER J. DIGGLE

Dilution Method for Bacterial Density Estimation

There are many methods for measuring bacterial mass and concentration. For example, estimates of protein content, or of optical density, may be used as an index of bacterial mass, but such a measure would ignore heterogeneity of cell size and type and viability of cells. There are various methods for counting numbers of cells [4]. Cell numbers in a given suspension may be estimated by comparison with standard suspensions, but this method, depending on the parameter measured, may not distinguish between viable and nonviable cells. The number of viable bacteria in a suspension may be estimated in several ways. The most precise of these is a direct count of the number of viable bacteria, if these can be identified and counted; an indirect method for obtaining such a count is by determining the number of colony-forming units by counting the colonies produced when the suspension is cultured on a plate. When the number of (viable) bacteria (or other microorganisms) in a given volume of material cannot be directly counted, the dilution method may be used.

In this procedure a suspension of material is diluted to the point at which some samples contain such a small amount of the original suspension that they will contain no viable bacteria, whence dilution to extinction. A known volume of each dilution is inoculated into one or more experimental units, which in the classical method are tubes filled with culture medium. After incubation, the number of experimental units showing the presence or absence of the microorganism of interest is noted; if tubes filled with culture medium are used, the numbers of turbid and clear tubes at each dilution are noted. Experimental units showing a negative response are assumed not to have received even one organism.

If every viable microorganism gives a positive response, and if the organisms are distributed at random throughout the material being assessed, then the number of organisms in any volume of the suspension follows a **Poisson distribution**. These two assumptions, under which the frequency of negative responses, or clear tubes, p, is related to the mean number of microorganisms, m, by the relation $p = \mathrm{e}^{-m}$, provide the basis for estimation of the number of microorganisms. Fisher [2] noted that the ideal proportion of negative responses is just over one-fifth, and further noted that, even under the most favorable circumstances, 155 samples would be needed to reduce the standard error below 10%. Thus this method is rarely used if precise estimates are required.

The dilution method is frequently used when little is known about the likely concentration of bacteria and hence a large dilution factor, commonly tenfold, may be used. Tables of estimates of the "most probable number" are available (see, for example, [3, 4]) and, particularly where computational facilities are limited, experiments may be designed to conform to an arrangement for which the results have been tabulated. Tables of "acceptable results" have also been produced for some designs, based on the probabilities of various results; for example, under the assumptions above, it is virtually impossible for there to be no positives at the highest, and no negatives at the lowest, of three concentrations in an experiment using a tenfold dilution series [5]. For further details of analysis and design *see* **Serial Dilution Assay**.

Any method for the determination of bacterial mass or concentration should only be used after careful consideration of the relation of the measured quantity to the cells of interest together with all factors that affect that relation, since the validity of the determination depends on the validity of the assumed relation. Applications of modern technology have emphasized the heterogeneity of microbial populations, and have thus concentrated on counting and characterizing individual bacterial cells [1].

ROSE E. GAINES DAS

Direct and Indirect Effects

Of considerable interest in **epidemiology** and clinical medicine (*see* **Clinical Epidemiology**) is identifying the causal mechanism by which a risk exposure or treatment has its effect (*see* **Causal Direction, Determination**; **Causation**). One means of doing this is to consider the role of a putative intermediate variable M, shown in Figure 1, as the potentially mediating part of the **association** between the primary causal exposure E and outcome D.

If Pr(D|M,E) = Pr(D|E), then E is considered as having no direct effect on D; its effects are mediated or are indirect through M. The distinction between M being an intermediate variable or a **confounding** variable often depends upon theory or study design issues. For the association of E and D to be interpreted as one of indirect causation, there is an assumption that the association between E and M is one where E causes M.

In psychiatry, biometrical **genetics**, and **community medicine** the estimation of direct and indirect effects has been largely synonymous with the use of **path analysis** and path diagrams. Path diagrams display the directional (single-headed arrows) and **correlational** associations (lines with arrowheads at both ends) among a set of variables. Path analysis, first systematically developed by Sewall Wright [11], exploits linearity assumptions to allow the covariance between two variables on a path diagram to be decomposed into contributions arising from each legitimate path that connects them, with simple rules for determining the legitimate paths [4, 12] in the case of nonrecursive diagrams. If, to the traditional diagram, a residual variance is added to each variable in the form of a double-headed arrow running both from and to that variable, then the path tracing rules for legitimate paths can be reduced to the following: trace backward from a variable, change direction at a two-headed arrow, then trace forward. Multiplication of the (standardized) coefficients along each chain gives the expected (standardized) covariance for that path, and these may be summed to give the total, direct, and indirect expected covariances (or effects). Implicit in these diagrams is the fact that we are modeling these sets of variables as a set of simultaneous equations. These would now be commonly estimated in **software** for **structural equation modeling**.

Biostatistical applications often confront **categorical** outcomes and intermediate variables. Winship and Mare [10] elaborate path modeling in the case of **binary** variables where the simultaneous equations take the probit form (*see* **Quantal Response Models**) and where effects of each variable may arise from two sources: the effect of the observed binary value and the effect of the latent continuous (conditionally normal) variable that may underlie the observed binary variable (*see* **Latent Class Analysis**). This second effect arises where the binary variable reflects an underlying **propensity** that has been measured subject to error in categorical form. Both effects may be of interest, for example, psychiatrists might want to distinguish the effects of an actual episode of depression from the effects of a predisposition for depression, the latter reflecting genetics, among other things.

Where the linearity assumptions of path analysis are considered too strong or where the causal arguments are to be based in the paradigm of explicit counterfactuals, then the consideration and estimation of direct and indirect effects can be undertaken within the less parametric framework of directed acyclic graphs [3, 5, 6, 8]. In this framework, the direct effect of E on D controlling for M is a causal direct effect of E on D when the M value of everybody in the population is physically set to a predetermined value. Moreover, we may need to talk in terms of plural direct effects, one for each level of M. In this framework, G-estimation [7] (*see* **Structural Nested Failure Time Models**) or **marginal modeling** [9] may be the preferred method of estimation.

Whichever framework is used, the diagram or the equivalent algebraic representation of the full causal model plays a critical role in determining what is or is not included in the calculation of direct and indirect effects. The possible presence of other variables not shown in the diagram that could be influencing any or

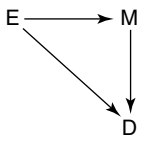

Figure 1 Direct and indirect effects of exposure E on disease D

all of E, M, and D should always be considered [1]. In addition, **measurement error** in the intermediate variable can attenuate the estimated indirect effects, resulting in artifactual residual direct effects. Many **longitudinal** studies of a repeat measure find, that even after controlling for a time 2 measure, a time 1 measure still predicts the time 3 measure but no longer does so once measurement error has been accounted for [2].

ANDREW PICKLES

Discrete Survival-time Models

Most methods for analyzing survival-time data (*failure time* or *event history* data) are based on time as a continuously measured variate. A basic assumption for large parts of theory is that failure times are untied; see Andersen et al. [2]. In practice, there is always some smallest time unit, so that ties can occur (*see* **Tied Survival Times**). A moderate number of ties, while banned in theory, can be treated by appropriate modifications. If many ties occur, e.g. due to grouping in larger time units or intervals, or if time is truly discrete, then discrete survival or failure time models are more consistent with the data. Such situations arise in medical work when patients are followed up at fixed intervals like months, in certain biostatistical problems, for example human fertility studies and time to pregnancy [19], or in labor market studies where duration of unemployment is measured in weeks, at best, or in months. We review parametric models and outline recent nonparametric approaches. More details, in particular for parametric models, are given for example in Fahrmeir & Tutz [11, Chapter 9] and further references cited there.

Basic Concepts

Let time be divided into intervals $[a_0, a_1), [a_1, a_2), \ldots, [a_{q-1}, a_q), [a_q, \infty)$. Usually $a_0 = 0$ is assumed, and a_q denotes the final follow up. Identifying the discrete time index t with interval $[a_{t-1}, a_t)$, a discrete failure time T is considered, where $T = t$ denotes failure within the interval $t = [a_{t-1}, a_t)$. The basic quantity characterizing T is the *discrete hazard function*

$$\alpha(t) = \Pr(T = t | T \geq t), t = 1, \ldots, q, \qquad (1)$$

which is the conditional probability for the risk of failure in interval t given the interval is reached. The *discrete survivor function* for reaching interval t is

$$S(t) = \Pr(T \geq t) = \prod_{s=1}^{t-1} [1 - \alpha(s)], \qquad (2)$$

and the unconditional probability for failure at t is $\Pr(T = t) = \alpha(t)S(t)$.

For a homogeneous population, discrete failure time data are given by $(t_i, \delta_i), i = 1, \ldots, n$, where $t_i = \min(T_i, C_i)$ is the minimum of the survival time T_i and censoring time C_i, and δ_i is the indicator variable (*see* **Dummy Variables**) for failure ($\delta_i = 1$) or censoring ($\delta_i = 0$). In what follows we assume that censoring occurs at the end of the intervals, otherwise appropriate modifications have to be made. Simple estimates for $\alpha(t)$ are *crude death rates* $\hat{\alpha}(t) = d_t/n_t$, where n_t is the size of the population at risk and d_t the number of observed failures in $[a_{t-1}, a_t)$ (*see* **Vital Statistics, Overview**). The so-called *standard* **life table** *estimate* replaces n_t by $n_t - w_t/2$, where w_t is the number of censored observations in $[a_{t-1}, a_t)$, thereby assuming that censored observations are under risk for half the interval. In particular, for large t, where the size n_t of the risk set often becomes small, these estimates may be quite unsteady, and smoothing by one of the nonparametric methods outlined further below will be appropriate. This is illustrated in Figure 1, which shows crude

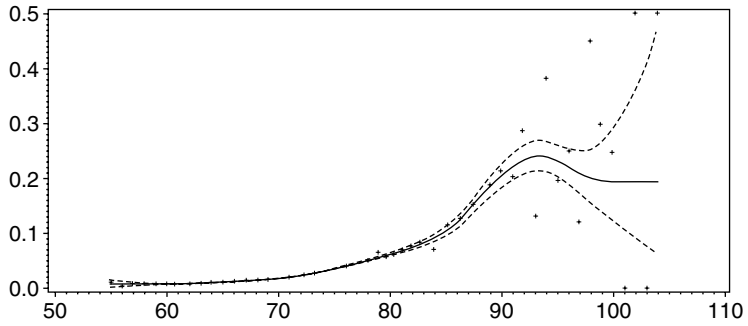

Figure 1 Posterior mean estimates (_____) and pointwise two standard deviation confidence bands (- - - - -) together with crude death rates (+)

death rates at age t in years for a population of retired American white females together with a smoothed estimate. A look at the data (Green & Silverman [13, p. 101]) shows that n_t becomes rather small for higher age t, resulting in unstable estimates towards the end of the observation period.

Discrete failure time data can also be described by a *discrete-time* **counting processes** $N_i(t), i = 1, \ldots, n$, defined by $N_i(0) = 0$ and

$$\Delta N_i(t) = N_i(t) - N_i(t-1) = \begin{cases} 1, & \text{if individual } i \text{ is at risk and fails at } t, \\ 0, & \text{else,} \end{cases}$$

for $t \geq 1$; see, for example, Arjas & Haara [3]. Thus, for every individual i under risk at t, the value $\Delta N_i(t)$ can be considered as the outcome of a **binary** experiment, with $\Pr(\Delta N_i(t) = 1) = \alpha(t)$. The sum $N(t) = \Sigma_i N_i(t)$ counts the number of observed failures up to t, and crude death rates can be derived as **nonparametric maximum likelihood** estimators, in analogy to the **Nelson–Aalen estimator** for continuous time.

In most studies a vector of possibly time-dependent basic or derived covariates $\mathbf{x}_{it}$ is observed in addition to failure times. The **time-dependent** components of $\mathbf{x}_{it}$ are assumed to be fixed within the interval t. Then the hazard function for survival time T_i of individual i will generally depend on covariates and is defined by

$$\alpha_i(t|\mathbf{x}_{it}^*) = \Pr(T_i = t | T_i \geq t, \mathbf{x}_{it}^*), \quad t = 1, \ldots, q, \tag{3}$$

where $\mathbf{x}_{it}^* = (\mathbf{x}_{i1}, \ldots, \mathbf{x}_{it})$ denotes the history of covariates up to time t. Expressions for the survivor function (2) and for $\Pr(T = t)$ have to be modified accordingly. Also, the sequence of binary experiments for $\Delta N_i(t), t \geq 1$, will depend on $\mathbf{x}_{it}$. Unless a separate analysis for homogeneous subgroups can be carried out, it is natural to describe the dependence of **conditional probabilities** of failure by binary regression models. Let F_{t-} denote the history of events registered up to time t, but excluding the failure at t, and let $r_i(t)$ denote a risk indicator, with $r_i(t) = 1$ if individual i is at risk in interval t, and $r_i(t) = 0$ otherwise. Then it will be assumed that the conditional probability of failures can be expressed as

$$\Pr(\Delta N_i(t) = 1 | F_{t-}) = r_i(t)\alpha_i(t|\mathbf{x}_{it}^*),$$

with hazard functions linked to a time-varying predictor η_{it} by

$$\alpha_i(t|\mathbf{x}_{it}^*) = h(\eta_{it}) \tag{4}$$

through a suitable link function h, for example the logistic function (*see* **Logistic Regression**). The predictor η_{it} is modeled parametrically or nonparametrically as a function of time t and basic or derived covariates $\mathbf{x}_{it}$.

Parametric Models

This section deals mainly with parametric models (4), where the predictor has the common linear parametric form

$$\eta_{it} = z_{it}'\boldsymbol{\beta} \tag{5}$$

as in **generalized linear models**, with the design vector $\mathbf{z}_{it}$ formed from basic covariates. In many applications the linear predictor is chosen as

$$\eta_{it} = \beta_{0t} + \mathbf{x}_{it}'\boldsymbol{\beta}_x, \tag{6}$$

where $\boldsymbol{\beta}_x$ is a vector of covariate effects and $\beta_{0t}, t = 1, \ldots, q$, is a time-varying baseline effect. Model (6) can be written in the form (5) by defining $z_{it}' = (0, \ldots, 1, \ldots, 0, x_{it}')$ and $\boldsymbol{\beta}' = (\beta_{01}, \ldots, \beta_{0q}, \boldsymbol{\beta}_x')$. Other predictors are discussed further below.

Different discrete-time failure models are determined by choice of the link function h. Most common are discrete **proportional hazards** and logistic models.

The Discrete Proportional Hazards Model

Suppose that an underlying continuous failure time obeys a proportional hazard or **relative risk** model $\alpha_0(t)\exp(\mathbf{x}_{it}'\boldsymbol{\beta}_x)$. If time T can only be observed as a discrete random variable, $T = t$ denoting failure in $[a_{t-1}, a_t)$, this yields the *discrete* proportional hazards model

$$\alpha(t|\mathbf{x}_{it}) = 1 - \exp[-\exp(\beta_{0t} + x_{it}'\boldsymbol{\beta}_x)], \tag{7}$$

with baseline effects

$$\beta_{0t} = \log \int_{a_{t-1}}^{a_t} \alpha_0(t)\,\mathrm{d}t$$

derived from the baseline function $\alpha_0(u)$ (see, for example, Kalbfleisch & Prentice [17]). An alternate

formulation of (7) is the complementary log–log model $\log\{-\log[1-\alpha(t|\mathbf{x}'_{it})]\} = \beta_{0t} + \mathbf{x}'_{it}\boldsymbol{\beta}_x$ (*see* **Quantal Response Models**). The parameter vector $\boldsymbol{\beta}_x$ is unchanged by the transition to the discrete version, so that the same analysis as with the proportional hazard model is possible as far as the influence of covariates is concerned. However, $\boldsymbol{\beta}_x$ and time-varying effects β_{0t} now have to be estimated jointly. If the number of intervals is large, then the dimension of $\beta_{01}, \ldots, \beta_{0q}$ may become dangerously high often even leading to the nonexistence of **maximum likelihood** estimates. Then more **parsimonious** parametric forms like polynomials $\beta_{0t} = \beta_0 + \cdots + \beta_k t^k$, piecewise constant effects, or regression **splines** with only a few cut points are preferable. Often, cubic-linear splines of the form $\beta_{0t} = \beta_0 + \beta_1 t + \beta_2(t-t_c)^2_- + \beta_3(t-t_c)^3_-$, are useful, where $(t-t_c)_- = \min(t-t_c, 0)$ and t_c is a cut-point. The baseline effect is cubic before t_c and linear after t_c. Such a simple spline model is more robust against few data at the end of the observation period than polynomials, and it is a smooth function as compared with piecewise constant modeling. Of course, other forms of regression splines may be considered. Also one may use the numerically more stable B-spline basis instead of the truncated power form, cf. Sleeper & Harrington [20] in a continuous-time setting. By appropriate definition of the design vector, regression spline models can also be written in linear parametric from (5).

The Logistic Model

An alternate model is the logistic model for the discrete hazard,

$$\alpha(t|\mathbf{x}_{it}) = \frac{\exp(\beta_{0t} + \mathbf{x}'_{it}\boldsymbol{\beta}_x)}{1 + \exp(\beta_{0t} + \mathbf{x}'_{it}\boldsymbol{\beta}_x)}, \tag{8}$$

considered by Thompson [21] and, in slightly different form, by Cox [5]. For short intervals this model becomes rather similar to the discrete proportional hazards model. An advantage of the logistic model is that the covariate effects $\boldsymbol{\beta}_x$ can be estimated semiparametrically, considering baseline effects β_{0t} as **nuisance parameters** and leaving them unspecified as in the continuous-time proportional hazards model; see Cox & Oakes [6].

Other discrete-time failure models result for other choices of h. Very flexible models are obtained if the link is an element of a parametric family of link functions. Examples are the model of Aranda–Ordaz (see Fahrmeir & Tutz [11, p. 318]) or the families considered by Czado [7].

Although choice of the link function is an important issue, we feel that careful modeling of the predictor is often even more essential. To simplify the discussion, we consider only two covariates, x and w, where x is a continuous variable like tumor size or hormone concentration and w is binary, indicating, for example, sex or treatment group.

Models with *time-varying effects* are obtained by assuming

$$\eta_{it} = \beta_{0t} + \beta_1 x_i + \beta_{2t} w_i, \tag{9}$$

where β_{2t} could be the time-varying effect of a therapy, possibly decreasing with time. Alternately, the term $\beta_{2t} w_i$ may be considered as a particular form of interaction between time t and the covariate w. The function β_{2t} may be modeled parametrically in the some way as the baseline effect β_{0t}. A more detailed discussion of parametric time-varying effects is in Yamaguchi [24]. If the simple linear form $\beta_1 x_i$ for the influence of x is too restrictive, then one may also try to replace it by a nonlinear smooth function $\beta_1(x)$ as in generalized additive models. As in Hastie & Tibshirani [15], one may go a step further and consider *varying coefficient models* of the form

$$\eta_{it} = \beta_{0t} + \beta_1(x_i) + \beta_2(x_i) w_i + \beta_{3t} w_i. \tag{10}$$

Here the smooth function β_2 may be viewed as an effect of w varying over x, or it is interpreted as an interaction term between the continuous covariate x and the binary covariate w. Without further prior knowledge it will often be difficult to specify certain parametric forms for the smooth functions in (9) and (10). Instead, it will be reasonable to explore patterns with nonparametric approaches outlined in the next section and to proceed then with a simpler parametric likelihood-based inference.

Likelihood Inference

Under appropriate conditions on censoring and covariate processes, the **likelihood** reduces to the common form known for binary regression models. Introducing the indicators

$$y_i = (y_{i1}, \ldots, y_{it}) = \begin{cases} (0, \ldots, 0), & \delta_i = 0, \\ (0, \ldots, 0, 1), & \delta_i = 1, \end{cases}$$

the log likelihood is proportional to

$$l(\boldsymbol{\beta}) = \sum_{i=1}^{n} \sum_{s=1}^{t_i} \{y_{is} \log \alpha_i(s|\mathbf{x}_{is}^*) + (1 - y_{is}) \times \log[1 - \alpha_i(s|\mathbf{x}_{is}^*)]\}.$$

Arjas & Haara [3] give a careful discussion of assumptions leading to $l(\boldsymbol{\beta})$ as a (partial) log likelihood (*see* **Partial Likelihood**). They will generally hold for noninformative random censoring and time-independent or external covariates, but can become critical for internal covariates. In particular, the likelihood is valid in the presence of ties, by making the weak assumption that failures at t are conditionally independent given covariates and past failures. By appropriate construction of the design vectors $\mathbf{z}_{it}$, the parameters β can then be estimated with **software** for binary regression models, and other tools of likelihood inference for these models may be adopted, see Fahrmeir & Tutz [11 Chapter, 9].

Nonparametric Approaches

Often, the common assumptions of linearity, additivity, and time-constancy of effects are definitely violated and the parametric specifications of more flexible models like (9) or (10) may be difficult. In this situation nonparametric approaches provide useful tools for detecting and exploring nonlinear or time-dependent effects. We outline the roughness penalty approach, leading to spline-type smoothing and related **Bayesian** nonparametric techniques. Other methods are based on discrete kernels (e.g. Fahrmeir & Tutz [11, Chapters 5 and 9] (*see* **Density Estimation**), or local likelihoods (Wu & Tuma [23], and in a continuous-time setting, Tutz [22]). Consider models like (9) or (10) with an unknown parameter vector $\boldsymbol{\beta}$ and unknown "smooth functions" $\beta_1, \beta_2, \ldots, \beta_q$ of time or continuous covariates. The roughness penalty approach maximizes a penalized log likelihood criterion

$$\text{pl}(\boldsymbol{\beta}, \beta_1, \ldots, \beta_p) = l(\boldsymbol{\beta}, \beta_1, \ldots, \beta_p) - \sum_{j=1}^{p} \lambda_j J(\beta_j),$$

where $J(\beta_j)$ are roughness penalties and λ_j are smoothing parameters. A simple roughness penalty for a time-varying effect $\beta_{jt}, t = 1, \ldots, q$, is

$$J(\beta_j) = \sum_{s=2}^{q} \frac{(\beta_{jt} - \beta_{j,t-1})^2}{a_t - a_{t-1}}. \tag{11}$$

The same form may be used for a function $\beta_j(x)$ of some continuous covariate x. Another common penalty is

$$J(\beta_j) = \int [\beta_j(x)'']^2 \, \mathrm{d}x$$

leading to cubic smoothing splines (see, for example, Green & Silverman [13]). Kiefer [18] proposes a discrete proportional hazards model with time-varying effects β_{jt} and penalty function (11). Dannegger et al. [8] use the roughness penalty approach to explore the nonlinear and time-varying effects of risk factors in a breast cancer study with monthly data. Related Bayesian nonparametric approaches put smoothness **priors** on β_{jt} or $\beta_j(x)$ and estimation is based on posteriors, given the data. If, for example, a random walk (*see* **Stochastic Processes**) of first order

$$\beta_{jt} = \beta_{j,t-1} + (a_t - a_{t-1})^{1/2} v_t, \quad v_t \sim \text{N}(0, 1/\lambda_j),$$

is taken as the smoothness prior for the sequence $\{\beta_{jt}\}$, then the posterior mode or MAP estimate is identical to the penalized likelihood estimate with penalty (11); see Fahrmeir [9]. Full posterior analyses can be carried out with **Markov chain Monte Carlo** (MCMC) techniques (see Fahrmeir & Knorr-Held [10]) and in the related context of generalized **additive models** (Biller & Fahrmeir [4]). Nonparametric methods are also useful for smoothing hazard functions in the absence of covariates. The smooth curve in Figure 1 is the posterior mean estimate obtained from a Bayesian MCMC approach. The corresponding cubic spline smoother is very close, see Green & Silverman [13].

Some Extensions

More Complex Discrete-Time Event History Data

Discrete failure time models can be extended in the same way as continuous-time models. Often one may distinguish between several types $R \in \{1, \ldots, m\}$ of failure or terminating events. For example, in a medical study there may be several causes of death, or in studies on unemployment duration one may consider

full-time and part-time jobs that end the unemployment duration. The basic quantities for *models with multiple modes of failure* are now cause-specific hazard functions,

$$\alpha_{ir}(t|\mathbf{x}_{it}^*) = \Pr(T = t, R = r|T \geq t, \mathbf{x}_{it}^*), \qquad (12)$$

i.e. conditional probabilities for failure of type r in interval t (*see* **Competing Risks**). Polytomous response models can be used for regression analysis of cause-specific hazard functions. A common candidate for unordered events is the **multinomial** logit model (e.g. Allison [1]) (*see* **Polytomous Data**). Other discrete choice models like a probit or a nested multinomial logit model [16] may also be considered. If events are ordered, then ordinal response models (e.g. [11]) are appropriate. Again parametric and nonparametric approaches are possible. Penalized likelihood and Bayesian smoothing techniques with models for time-varying effects are applied to unemployment durations in Fahrmeir & Wagenpfeil [12] and Fahrmeir & Knorr-Held [10].

Discrete failure time models can also be extended to general multiepisode–multistate models or, in counting process terminology, marked **point processes**. Hamerle [14] studies parametric regression analysis for such discrete event history data, but generally much less theoretical or applied work has been done here.

Unobserved Heterogeneity and Frailty Models

The above model specifications assume that individual heterogeneity can be described by observed variables. However, it is likely that not all relevant variables are included in a regression model. The conventional approach to account for neglected heterogeneity or **frailty** is to include individual-specific parameters into the predictor, i.e. modifying η_{it} to $\eta_{it}^h = \eta_{it} + \theta_i$, and to assume that the individual-specific parameters are independent, identically distributed (iid) random variables from a prior density function f, e.g. a normal density. Estimation can then be based on approaches for generalized mixed models with **random effects**, and recent MCMC methods seem particularly well suited. However, for single-spell failure time models the estimates can be very dependent on the choice of the prior specification. More experience is needed here. The problem becomes less severe with **repeated events**.

LUDWIG FAHRMEIR

Discriminant Analysis, Linear

Linear discriminant analysis is a statistical method for studying the differences between classes of objects. Broadly speaking, the method may be used with two, rather distinct, objectives in mind. The first is as a predictive tool (*see* **Prediction**). Here the aim is to formulate a rule which will permit objects to be classified into one of several predefined classes. The second is to help understanding. Here the aim is to build a model which helps us understand the structure in data (*see* **Model, Choice of**). We illustrate both of these uses below. Although different, both of these uses are based on the same underlying principles and both are essentially inferential: in the first case the inferences are from a sample of objects to new objects and in the second case from the sample to the underlying population of objects.

We begin with a sample of objects drawn from the population being studied. Usually this sample, often called a *design* or *development* sample, will be a simple random sample, though other sampling schemes can also be used. For each member of this sample we require that (i) we know its true class, and (ii) we know the values of a (fixed) set of variables describing that object. If our aim is prediction, then we will use this sample to construct a model which will allow us to predict the class membership of a new object from only its vector of measurements. If our aim is understanding, then we will use this sample to characterize the main ways in which the groups differ. Some examples will help to clarify these ideas.

1. Our aim is to construct a rule which will assist in diagnosing patients suffering from hepatitis as having either acute infectious hepatitis or hepatitis secondary to infectious mononucleosis. The information on which we must base our diagnosis are the values of two variables: the activity of lactate dehydrogenase isoenzyme-5 and the activity of lactate dehydrogenase isoenzyme-3 [20].
2. Is it possible to predict who is likely to suffer from osteoporosis in later life on the basis of the answers to the questions on a simple noninvasive screening questionnaire [5, 22]?
3. Can we identify which children will respond positively to a new behavioral treatment for enuresis, based on variables such as age, sex, whether or not the child was an only child, type of enuresis, and so on [19]?
4. Can we predict, without the need for surgery, for which patients prostate cancer will have spread to the surrounding lymph nodes [4]?
5. In what way do those infants at high risk of dying from Respiratory Distress Syndrome differ from those at low risk? Variables in the study included sex, responsiveness, gestational age, birthweight, etc. [36].

As far as the prediction problem is concerned, a legitimate question is: "Why bother?" If the true classes of the objects can be found – they were, after all, found for the objects in the design set – why not use the same method for new objects? The answer is indicated by some of the above examples. We might want a prognostic classification (*see* **Prognostic Factors for Survival**), so that we can undertake some treatment intervention, and we cannot wait to discover the true class.

Perhaps discovering the true class requires a postmortem examination. Perhaps it is very expensive to discover the true class so that a cheaper (if less accurate) method is needed. Maybe the procedure for determining the true class is very time-consuming – for example, growing a bacterial culture – and a quicker method of classifying an object is needed, and so on.

Since the objects in the design set have known class memberships, methods for tackling the above problems are sometimes described as methods of *supervised* classification (or supervised pattern recognition). This distinguishes them from *unsupervised* classification methods, where no class memberships are known a priori. The objective of the latter methods, also termed methods of *cluster analysis*, is to determine the class structures, not to model a preexisting such structure. We do not discuss the latter in this article. Details of such methods can be found in [1, 10, 17], and [41] (*see* **Classification, Overview**; **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**).

Many methods of supervised classification have been developed. They include linear discriminant analysis (which is the subject of this article), logistic discriminant analysis (*see* **Logistic Regression**), classification trees (*see* **Tree-structured Statistical Methods**), nearest neighbor methods, neural network

and other highly parameterized models, and innumerable variations on all of the above. Comparative descriptions and reviews of these methods may be found in [21, 37], and [23].

Linear discriminant analysis is the oldest of the methods, at least in terms of formal development. The ideas can be traced back at least as far as Fisher [11]. Although originally described for the case of only two classes, it has been extended to handle more than two classes. It is convenient for us, however, to introduce the ideas via the special case of only two classes, as we do in the next section.

The Two-Class Case

Suppose that we have a sample of objects from each of the two classes. For each of these objects we know its parent class and the values of a vector of measurements taken on that object. Suppose that our aim is the second of the two described in the opening paragraph – to gain an understanding of the nature of the differences between the classes, based on their measurements. To do this, we attempt to construct a measure of "classness", based on the measured variables, such that, for example, large values of this measure correspond to membership of one class and small values to membership of the other class. We can then tackle the first problem of the opening paragraph by imposing a threshold on this measure: those new objects whose "classness" value exceeds the threshold will be classified into one class and those whose value is less than the threshold will be classified into the other class.

Perhaps the most obvious initial approach is to look at each measured variable separately. However, this will not always be very helpful. Suppose, for simplicity (it permits us to draw diagrams), that only two variables, x_1 and x_2, are measured on each object, and that we have only four objects, two from each class, in the design set. Figure 1(a) shows these four objects plotted on a line showing their values for variable x_1 and Figure 1(b) shows them plotted against the x_2 variable. In each case, objects from one class are represented by circles and objects from the other class by crosses. No threshold on the x_1 variable permits good separation between the classes. Wherever we put the threshold, some design set objects lie on the "wrong" side of the line. The same applies to the x_2 variable. Now, however, consider Figure 2, which shows the design set points plotted in the two-dimensional space of the variables. If we project the points onto the direction of the dashed line, as shown in Figure 3, we see that we can easily produce a threshold which perfectly separates the two classes. The position on the dashed line represents "classness".

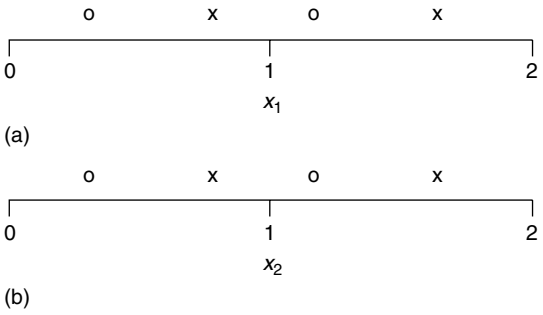

Figure 1 Four objects plotted according to their values on (a) the single variable x_1, and (b) the single variable x_2. In neither case can the two classes be well separated

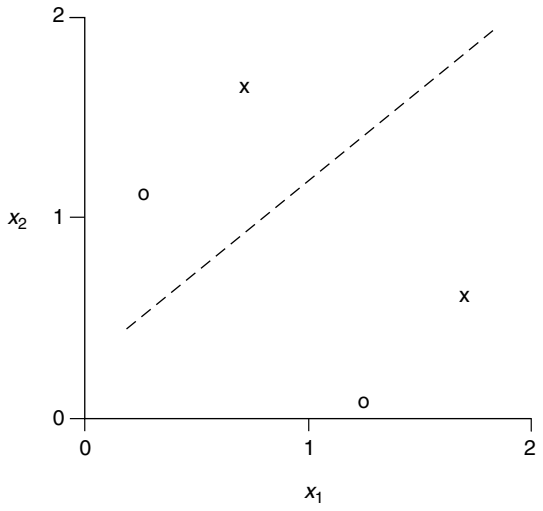

Figure 2 The four objects from Figure 1 plotted in the two-dimensional space of x_1 and x_2

Figure 3 The projection of the four objects onto the broken line in Figure 2 permits the two classes to be easily separated

This is the essence of linear discriminant analysis. We seek some direction in the space spanned by the measured variables such that the projections of the design set points onto that direction are well separated. This direction characterizes the difference between the classes, so that describing the direction permits us to tackle the second objective presented in the opening paragraph. Imposing a threshold on the direction permits us to tackle the first objective. In terms of the complete space, such a threshold corresponds to a surface (a line in the two-dimensional case). For the artificial example above, such a surface (line) is illustrated in Figure 4. This surface is called a *decision surface*.

Directions in a space defined by the measured variables correspond to linear combinations of the defining variables. So our objective is to find some linear combination which leads to good separation of the projections of the points in that direction. Denoting an arbitrary set of weights by $\mathbf{a} = (a_1, \ldots, a_p)$, the projection of a point $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})$, with p measurements x_{ij}, $j = 1, \ldots, p$, onto the direction defined by $\mathbf{a}$, is given by $y_i = \mathbf{a}'\mathbf{x}_i$. An obvious measure of the separation between the projections of the points in the two groups is then the separation between their means. However, for the same reason as with the two group t-test (*see* **Student's *t* Distribution**) Distribution, it makes more sense to take into account the within-group variability, and standardize using the (assumed common) within group standard deviation. That is, denoting the mean of the groups' projections by $\overline{y}^{(1)}$ and $\overline{y}^{(2)}$, and the standard deviation of the projections within each of the groups by $\mathrm{sd}(y)$, the

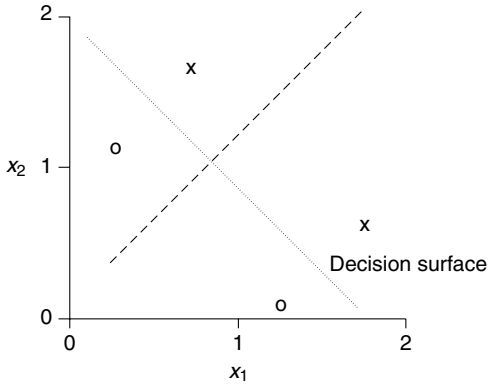

Figure 4 The dashed line shows the position of the decision surface separating the two classes

measure of separation is $(\overline{y}^{(1)} - \overline{y}^{(2)})/\mathrm{sd}(y)$. It will be more convenient to work with the square of this, which is $(\overline{y}^{(1)} - \overline{y}^{(2)})^2/\mathrm{var}(y)$. In terms of the original variables, this is $(\mathbf{a}'\overline{\boldsymbol{x}}^{(1)} - \mathbf{a}'\overline{\mathbf{x}}^{(2)})^2/\mathbf{a}'\mathbf{S}\mathbf{a}$, where $\overline{\mathbf{x}}^{(k)}$ is the mean vector for group k and $\mathbf{S}$ is the average of the sample covariance matrices of the two groups. We now need to find the vector $\mathbf{a}$ which maximizes this measure.

Differentiating the above measure with respect to $\mathbf{a}$ and equating to zero reveals that it is maximized by $\hat{\mathbf{a}} \propto \mathbf{S}^{-1}(\overline{\mathbf{x}}^{(1)} - \overline{\mathbf{x}}^{(2)})$. The function $\hat{\mathbf{a}}'\mathbf{x}$ is then called a *linear discriminant function*. The components of the vector $\hat{\mathbf{a}}$ can thus be studied to understand how the two groups differ, what variables (when taken in combination with the others present) contribute most to the difference, and so on. To classify a new point we still have to decide on a threshold. The most natural way to choose a suitable threshold is revealed if we take a step back and attempt to tackle the classification problem directly.

Let the underlying distribution of points from class $k, k = 1, 2$, be $f(\mathbf{x}|k)$ and let the prior probability of belonging to class k be p_k, so that $p_1 + p_2 = 1$. Then a natural thing to do would be to classify a new point to class k if it seemed more likely to have come from class k. That is, we will estimate the probability that the new point came from classes 1 and 2 and assign it to that class with the highest estimated probability. Now, by **Bayes' theorem**, the probability of belonging to class k is $f(k|\mathbf{x}) = p_k f(\mathbf{x}|k)/f(\mathbf{x})$, where $f(\mathbf{x}) = p_1 f(\mathbf{x}|1) + p_2 f(\mathbf{x}|2)$ is the overall mixture distribution of the $\mathbf{x}$. Thus the solution is, replacing the unknown distributions by estimates, the class which maximizes $\hat{f}(k|\mathbf{x})$. With only two classes, this is equivalent to classifying into class 1 if the ratio $\hat{f}(1|\mathbf{x})/\hat{f}(2|\mathbf{x})$ exceeds 1 and to class 2 otherwise. Again using Bayes' theorem, this is equivalent to comparing

$$\frac{\hat{p}_1 \hat{f}(\mathbf{x}|1)/\hat{f}(\mathbf{x})}{\hat{p}_2 \hat{f}(\mathbf{x}|2)/\hat{f}(\mathbf{x})} = \frac{\hat{p}_1 \hat{f}(\mathbf{x}|1)}{\hat{p}_2 \hat{f}(\mathbf{x}|2)}$$

with 1.

So far we have not assumed any particular distributional form for the class conditional distributions $f(\mathbf{x}|k)$. Suppose we make the assumption, common in multivariate analysis, that they are **multivariate normal distributions**, and suppose we also assume that the **covariance matrices** of the two groups are equal. Then the above classification rule becomes:

compare

$$\frac{\hat{f}(1|\mathbf{x})}{\hat{f}(2|\mathbf{x})} = \frac{\dfrac{\hat{p}_1}{(2\pi)^{p/2}|\mathbf{S}|^{1/2}} \exp\left[-\dfrac{1}{2}\left(\mathbf{x}-\overline{\mathbf{x}}^{(1)}\right)' \mathbf{S}^{-1}\left(\mathbf{x}-\overline{\mathbf{x}}^{(1)}\right)\right]}{\dfrac{\hat{p}_2}{(2\pi)^{p/2}|\mathbf{S}|^{1/2}} \exp\left[-\dfrac{1}{2}\left(\mathbf{x}-\overline{\mathbf{x}}^{(2)}\right)' \mathbf{S}^{-1}\left(\mathbf{x}-\overline{\mathbf{x}}^{(2)}\right)\right]}$$

with 1. This can be considerably simplified if we take logarithms. It reduces to a comparison of

$$\mathbf{x}'\mathbf{S}^{-1}(\overline{\mathbf{x}}^{(1)} - \overline{\mathbf{x}}^{(2)}) + \ln(\hat{p}_1/\hat{p}_2) - \tfrac{1}{2}\overline{\mathbf{x}}^{(1)'}\mathbf{S}^{-1}\overline{\boldsymbol{x}}^{(1)} + \tfrac{1}{2}\overline{\mathbf{x}}^{(2)'}\mathbf{S}^{-1}\overline{\boldsymbol{x}}^{(2)}$$

with 0. The first term in this expression is identical to the optimal $\hat{\mathbf{a}}'\mathbf{x}$ expression derived above. Moreover, the last three terms in this expression depend solely on the design set, and not on $\mathbf{x}$. Thus, approaching the problem from the perspective of classifying a point has led to the same solution as above: we must project the point to be classified onto the direction which we derived as the "best separating direction". The last three terms above are merely constants – they serve to define the threshold with which we compare $\mathbf{x}'\mathbf{S}^{-1}(\overline{\mathbf{x}}^{(1)} - \overline{\mathbf{x}}^{(2)})$ to see if it is greater or less than 0. Put another way, the classification rule is: if $\mathbf{x}'\mathbf{S}^{-1}(\overline{\mathbf{x}}^{(1)} - \overline{\mathbf{x}}^{(2)})$ is greater than $-\ln(\hat{p}_1/\hat{p}_2) + \frac{1}{2}\overline{\mathbf{x}}^{(1)'}\mathbf{S}^{-1}\overline{\mathbf{x}}^{(1)} - \frac{1}{2}\overline{\mathbf{x}}^{(2)'}\mathbf{S}^{-1}\overline{\mathbf{x}}^{(2)}$ assign the new object to class 1, otherwise to class 2. Ties can be settled arbitrarily.

The above derivation assumes that misclassifying a class 1 object as a class 2 object is equally as serious as the reverse. Although this is a common assumption (particularly in methodological studies) it is rarely realistic. More usually, one type of misclassification is more serious, or costly in some sense, than the other. Suppose, then, that the cost of misclassifying a class 1 object to class 2 is c_1 and the cost of misclassifying a class 2 object to class 1 is c_2. Our classification rule will be: if a point $\mathbf{x}$ falls in region Ω_1, classify it as belonging to class 1, and if it falls in region Ω_2 (which is the complement of Ω_1) classify it to class 2. Our aim is to choose these two regions such that the overall cost is minimized. This overall cost is

$$c_1 \int_{\Omega_2} f(1|\mathbf{x}) f(\mathbf{x})\, d\mathbf{x} + c_2 \int_{\Omega_1} f(2|\mathbf{x}) f(\mathbf{x})\, d\mathbf{x}.$$

To minimize this we must choose Ω_1 so that $\mathbf{x}$ is in Ω_1 whenever $c_2 f(2|\mathbf{x}) f(\mathbf{x}) < c_1 f(1|\mathbf{x}) f(\mathbf{x})$. That is, the overall cost will be minimized if we classify $\mathbf{x}$ as belonging to class 1 when $f(1|\mathbf{x})/f(2|\mathbf{x}) > c_2/c_1$ and to class 2 otherwise. Assuming multivariate normal distributions, and replacing them by their estimates, the optimal rule, in terms of minimal cost is then: if $\mathbf{x}'\mathbf{S}^{-1}(\overline{\mathbf{x}}^{(1)} - \overline{\mathbf{x}}^{(2)})$ is greater than $\ln(c_2/c_1) - \ln(\hat{p}_1/\hat{p}_2) + \frac{1}{2}\overline{\mathbf{x}}^{(1)'}\mathbf{S}^{-1}\overline{\mathbf{x}}^{(1)} - \frac{1}{2}\overline{\mathbf{x}}^{(2)'}\mathbf{S}^{-1}\overline{\mathbf{x}}^{(2)}$ assign the new object to class 1, otherwise to class 2. Again ties can be settled arbitrarily. When $c_1 = c_2$ this reduces to the rule above, as it should.

Although the above was described in terms of multivariate normal distributions, exactly the same results apply to any ellipsoidal distribution – that is, any distribution defined in terms of the mean vector and covariance matrix.

For classification rule purposes, we can relax the restriction that the covariance matrices in the two groups are assumed equal. If we do this, the classification rule above becomes more complicated, including separate terms for the two covariance matrices, so that it takes a quadratic form. For purposes of understanding, introducing these extra complications is of limited value – it certainly makes interpretation more difficult. The reason for considering it when classification is the aim is that it might lead to more accurate results: the more flexible the model, the more accurately it can reflect the underlying structure of the populations. While this is true, it is not the only influence on accuracy. In particular, the parameters in the classification rule must be estimated from the design set, and the accuracy of the resulting rule depends on the accuracy with which they are estimated. When a linear decision surface is used, the decision surface involves only $p + 1$ parameters. However, when a quadratic surface is used, an extra $(p + 1)/2$ parameters need to be estimated. As a consequence, the resulting surface has a higher variance. To overcome this a larger design set is needed.

The linear discriminant function can also be derived by a **regression** argument. If we define a response variable (*see* **Dummy Variables**) taking one value for the members of group 1 and some other value for the members of group 2, then the regression function is proportional to $\mathbf{x}'\mathbf{S}^{-1}(\overline{\mathbf{x}}^{(1)} - \overline{\mathbf{x}}^{(2)})$.

There is also a close link between linear discriminant analysis and logistic discriminant analysis. Whereas linear discriminant analysis can be viewed as starting with the class conditional distributions

$f(\mathbf{x}|j)$, and then using **Bayes' theorem** to derive estimates of the $f(j|\mathbf{x})$, logistic discriminant analysis goes straight for the latter. The basic model is

$$f(1|\mathbf{x}) = \exp\left(\alpha_0 + \sum_{k=1}^{p} \alpha_k x_k\right) \Bigg/ 1 + \exp\left(\alpha_0 + \sum_{k=1}^{p} \alpha_k x_k\right).$$

Using this model, the log **odds ratio** is

$$\ln[f(1|\mathbf{x})/f(2|\mathbf{x})] = \alpha_0 + \sum_{k=1}^{p} \alpha_k x_k,$$

that is, a linear function of the x_k. However, we have already seen that, if we assume multivariate normal distributions, then the linear discriminant analysis approach also yields a linear function for the log odds ratio. The difference between the two methods lies in the parameter estimation and the assumptions which are made: logistic discriminant analysis also yields a linear log odds ratio for other distributional forms.

More Than Two Classes

If we assume multivariate normal distributions (more generally, ellipsoidal distributions) then the above generalizes immediately to more than two classes. For a point $\mathbf{x}$ at which a classification is required, we want to find the class j which maximizes $\hat{f}(j|\mathbf{x})$, the estimated posterior probability of belonging to class j. That is,

$$\max_j \hat{f}(j|\mathbf{x}) = \max_j \frac{\hat{p}_j}{(2\pi)^{p/2}|\mathbf{S}_j|^{1/2}} \times \exp\left[-\frac{1}{2}\left(\mathbf{x} - \overline{\boldsymbol{x}}^{(j)}\right)' \mathbf{S}_j^{-1}\left(\mathbf{x} - \overline{\boldsymbol{x}}^{(j)}\right)\right].$$

Since log is a monotonic increasing function, we can, alternatively, seek the j that maximizes

$$\ln \hat{p}_j - \tfrac{1}{2}\ln|\mathbf{S}_j| - \tfrac{1}{2}\left(\mathbf{x} - \overline{\mathbf{x}}^{(j)}\right)' \mathbf{S}_j^{-1}\left(\mathbf{x} - \overline{\mathbf{x}}^{(j)}\right).$$

Also, if we again assume that the covariance matrices are equal, we need the j that maximizes

$$\ln \hat{p}_j - \tfrac{1}{2}\overline{\mathbf{x}}^{(j)'}\mathbf{S}^{-1}\overline{\mathbf{x}}^{(j)} + \mathbf{x}'\mathbf{S}^{-1}\overline{\mathbf{x}}^{(j)}.$$

Such functions, or equivalent variants of them, are often called *classification functions*.

Description requires identifying those dimensions of the spaced spanned by the measured variables which are most important in distinguishing between the classes. For the multiclass situation we can again generalize the approach of the preceding section. There we had two classes and we sought that direction in which the class means were most separated (standardized to take into account the within class variation in that direction). We can do the same sort of thing with more than two classes. In particular, we can seek that direction which maximizes the *variance* between the class means, standardized for the (assumed common) within class variance. Put another way, we seek that direction which gives the largest between-to-within variance ratio. Analogous to the preceding section, if the covariance matrix of the group means is $\mathbf{B}$ and the (common) covariance within the groups is $\mathbf{S}$, then we seek the direction $\mathbf{a}$ which maximizes $\mathbf{a}'\mathbf{B}\mathbf{a}/\mathbf{a}'\mathbf{S}\mathbf{a}$. In fact, a subtle point arises here. $\mathbf{B}$ can be estimated as an unweighted matrix, proportional to $\sum_j (\overline{\mathbf{x}}'_j - \overline{\mathbf{x}})'(\overline{\mathbf{x}}'_j - \overline{\mathbf{x}})$, where $\overline{\mathbf{x}}_j$ is the mean vector for class j and $\overline{\mathbf{x}}$ is the overall mean vector, or as $\sum_j n_j (\overline{\mathbf{x}}'_j - \overline{\mathbf{x}})'(\overline{\mathbf{x}}'_j - \overline{\mathbf{x}})$, where n_j is the number of objects in the sample which belong to class j. The latter is the more common; it places greater emphasis on separating the more important – larger – groups, and so is what is normally required.

The vector $\mathbf{a}$ which maximizes the ratio $\mathbf{a}'\mathbf{B}\mathbf{a}/\mathbf{a}'\mathbf{S}\mathbf{a}$ is given by the eigenvector corresponding to the maximal root of the equation $(\mathbf{B} - \lambda\mathbf{S})\mathbf{a} = 0$. In general, however, this equation will have more than one solution. This reflects the fact that, with more than two classes, more than one direction is needed to describe the differences between the mean vectors of the classes. With g classes and p variables, there will, in general, be $\min(p, g-1)$ solutions. (Special cases arise when the class means lie in a subspace of less than $\min(p, g-1)$ dimensions – if, for example, they were all in a straight line.) The **eigenvector** corresponding to the second solution is that direction which leads to the greatest value of the ratio, subject to this second eigenvector being orthogonal to the first. The third solution maximizes the ratio in the space orthogonal to the first two eigenvectors, and so on.

These "best separating" dimensions, or *canonical variates* (*see* **Canonical Correlation**), are often used to produce a graphical display of the distribution

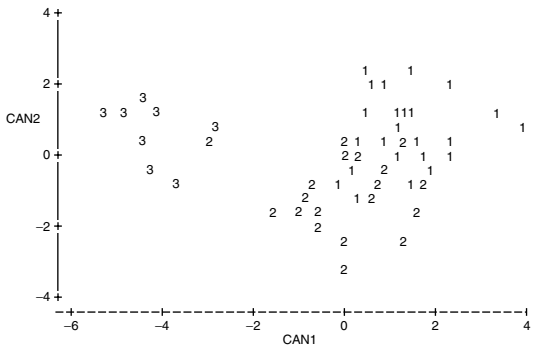

Figure 5 The samples of the three classes of kangaroo skulls, plotted in the space spanned by the first two canonical variates

Table 1 Total-sample standardized canonical coefficients

of the classes in multidimensional space. Figure 5 illustrates this for three species of kangaroos [2]: 1 = *M. giganteus*, 2 = *M.f. melanops*, 3 = *M.f.* fuliginosus. Eight variables were measured, these being the lengths, in tenths of a millimeter, of basilar length, occipitonasal length, nasal length, nasal width, zygomatic width, crest width, mandible depth, and ascending ramus height. The horizontal axis shows the first canonical variate and the vertical axis the second. The separation between the groups is quite clear.

Table 1 shows the coefficients of the canonical variates, standardized so that the canonical variates have zero mean and unit variance. From this it is possible to see which variables are important contributors to each of the canonical variates.

In the preceding section we showed how the linear discriminant function could be derived using **regression** analysis to predict an indicator variable which took different values for the two classes. This can be generalized to more than two classes: define a set of indicator variables to characterize the different groups and use **canonical correlation** analysis. The mathematics here is also equivalent to **multivariate analysis of variance**. The difference lies in what aspects of the results are the focus of interest. Typically in multivariate analysis of variance interest lies in testing particular between-group contrasts and particular combinations of variables. In discriminant analysis, however, interest lies either in describing the linear combinations which lead to overall differences between the groups (and concern is seldom with particular contrasts) or in formulating a rule permitting classification of future objects.

Assessing Classification Accuracy

A convenient way of summarizing the performance of a classification rule is by means of a *confusion matrix*. This is simply a cross-classification of the predicted class by the true class for a set of objects which the rule has classified. An example is given in Table 2

Table 2 Confusion matrix for classifying chromosomes into 10 classes

		True class									
		1	2	3	4	5	6	7	8	9	10
Predicted class	1	171	2	7	0	0	0	0	0	0	0
	2	3	177	0	0	0	0	0	0	0	0
	3	6	1	172	0	0	1	0	0	0	0
	4	0	0	0	344	16	0	0	0	0	0
	5	0	0	1	16	1379	2	2	0	0	0
	6	0	0	0	0	0	535	0	1	0	3
	7	0	0	0	0	0	0	157	16	7	0
	8	0	0	0	0	0	1	12	334	7	6
	9	0	0	0	0	0	0	9	5	343	3
	10	0	0	0	0	0	1	0	4	3	393

(from Tso & Graham [43]). This shows the results of classifying human chromosomes into ten groups (approximating what is known as the "Denver" classification). As is common with such matrices, the diagonal elements are the largest, signifying that most of the chromosomes are correctly classified. Such a matrix can be used to identify the classes which are most commonly confused.

The most popular single measure of performance is misclassification or error rate – the proportion of new objects which the rule will misclassify (*see* **Misclassification Error**). This is simply the proportion of the objects in the confusion matrix which lie off the leading diagonal. Of course, this measure does not take account of different severities of different types of misclassification, but these can be included with the aid of a cost matrix.

To obtain a reliable estimate of future performance, the confusion matrix (or any other measure of performance) must be computed from a data set other than that used to derive the classification rule. After all, the parameters of the rule will have been estimated to optimize, in some sense, performance on the design set. In the above, the $\bar{\mathbf{x}}^{(j)}$ and $\mathbf{S}$ were estimated from the design set, so that they will be particularly well matched to that data set. Any new data are unlikely to fit the model quite as well. Performance estimates based on the design set are known as *resubstitution* or *apparent* measures. Various approaches to estimating true future performance have been adopted. The most straightforward is to use an independent set of data, a *test set*, but this assumes that sufficient data are available. Alternative approaches involve repeatedly splitting the data into two parts, designing on one and testing on the other, and then averaging the results. They include the **jackknife method**, leave-one-out (*see* **Cross-validation**), and **bootstrap method**. Until recently the leave-one-out approach was the most popular. Here a single element is chosen for the test set and the classifier is built using the remaining $n-1$ design set elements. This is repeated for all n design set elements, and the predicted error rate of the rule based on all n is estimated as the proportion of the classifications which are correct. In general, the leave-one-out method is computationally intensive, since it requires n classification rules to be constructed. However, in the case of linear (and quadratic) discriminant analysis simple variants of the resubstitution estimator have been developed which yield the leave-one-out estimate without recalculating n times from scratch [31].

More recently bootstrap methods have gained in popularity. These involve adjusting the optimistic bias of a performance estimate based solely on the design data using estimates of that bias based on subsamples from the design set. There are several variants, but the so-called *632 estimator* [9] seems to be the most widely recommended. This can be approximated by a cross-validation approach based on using half the data for the design set and half for the test set, doing this repeatedly and averaging the results.

The jackknife procedure has a superficial similarity to leave-one-out, in that it requires n computations based on all but one of the data points, but in fact it is based on a different underlying principle.

The case of two classes is particularly important, especially in medical and epidemiological contexts where interest is often in whether or not a particular disease is present. Because of this, special measures of performance of classification rules have been developed for this case. Table 3 shows the confusion matrix for a generic two-class problem. Suppose that class 1 corresponds to "cases" and class 2 to "noncases". Then the **sensitivity** $(Se)^*$ of a rule is defined as $a/(a+c)$ and the **specificity** $(Sp)^*$ as $d/(b+d)$. Sometimes sensitivity and specificity are called *true positive rate* and *true negative rate*, respectively. Sensitivity and specificity define performance in terms of predicted classifications within each of the true classes. Complementary to this, defining performance as proportions correct within those predicted to belong to each class, we have the *positive predicted value* $(a/a+b)$ and the *negative predicted value* $(d/c+d)$ (*see* **Predictive Values**).

All of these measures, as well as the error rate, are dependent on a particular threshold having been chosen. If this is difficult to do (because, for example, precise costs cannot be determined) then one might prefer to examine performance over a range of

Table 3 Confusion matrix notation for the two-class case

		True class	
		1	2
Predicted class	1	a	b
	2	c	d

situations. **Receiver operating characteristic (ROC) curves** do this by plotting sensitivity on the vertical axis against 1-specificity on the horizontal axis (other equivalent variants are also sometimes used).

Classification is all very well, but sometimes more subtle insights into the performance of a rule are required. For example, one might want to know whether 80% of the objects to which the rule assigns a probability of 0.8 of belonging to class 1 really do belong to class 1. Measures of such things have gone under various names, including *reliability, calibration, validity*, and *imprecision*. Detailed discussion of these and the other performance issues discussed above are given in [23] (*see* **Multivariate Classification Rules: Calibration and Discrimination**).

Robustness

Linear discriminant analysis assumes that the covariance matrices of the classes are equal. If this is not the case, then the true decision surface is nonlinear, so that the linear discriminant analysis decision surface is necessarily biased in some parts of the measurement space. This is particularly important in a biostatistical context, where often the variables are categorical, and so cannot be supposed to follow a multivariate normal distribution. The problem is especially severe when the variables are simply binary – as is the case, for example, if they measure the presence or absence of symptoms. In this situation the covariance matrices are very unlikely to be equal if the mean vectors of the classes differ since, for Bernoulli variables, the means and variances are functionally related (*see* **Binary Data**).

Despite all this theoretical argument, practical studies have shown that the method often performs well. A partial explanation may be found in that fact that, as we have already pointed out in the context of the quadratic extension, the *bias* in the estimated decision surface may be more than compensated for by the reduction in variance which follows from the fact that fewer parameters need be estimated in the linear case. In general it seems that, if the true decision surface is approximately linear, the method will perform well, but this is clearly also a function of the number of variables involved, the sample size, and other aspects (*see* **Robustness**).

There have been many empirical and simulation studies comparing classification rules in general and linear discriminant analysis with other methods in particular. Examples include [16, 19, 35], and [42].

Choosing the Variables

Given a large set of potential discriminatory variables, interest often lies in identifying an effective subset (*see* **Variable Selection**). If the objective of the study is understanding, then there may be doubt about the relevance of all of the variables to the difference(s) between the groups. One might want to describe the differences in a concise and convenient summary. On the other hand, if the aim is to construct a classification rule, then one may want to identify an effective separating subset on practical grounds: the fewer variables which need to be measured on future objects the better, in terms of cost, speed, and so on. Moreover, an aspect of the relationship between bias and variance discussed above is that the more variables there are (relative to a fixed size design set) the more parameters there are to be estimated and the greater is the opportunity for overfitting the design set: the bias may be small but the variance may be large. This can be tackled by reducing the number of variables, so yielding better classification rules.

The obvious approach of choosing variables on the basis of the separation between groups using variables one at a time will generally not be very effective (recall Figures 1 and 2 and the associated discussion). What we want to know is which *set* of variables is effective, when they are taken *in combination*, not when examined individually. To answer this question we must, in principle, examine all possible subsets of variables. If there are p variables to choose from, then there are $2^p - 1$ possible subsets – potentially a vast number. When one considers that, for each such subset, a classification rule must be constructed and its performance assessed, the magnitude of the task becomes apparent. Since there are so many possible subsets of variables, a common strategy is to restrict the search through the space of subsets. The most popular way of restricting this search is to use *stepwise* methods. The basic idea is as follows, illustrated by a *forward* stepwise method. This begins by examining all the variables individually and selecting the best single one. Then each of the others is examined, one at a time, to see which of them, when used together with that already chosen, leads to the best results. The best is added to the one already chosen, to yield a pair. Then each

of the others is examined, to see which, when combined with that pair, yields the most effective triple, and so on. Backward stepwise methods work on a similar principle, but progressively eliminating variables according to which leads to least degradation in performance. More sophisticated versions can also be used, in which groups of variables, rather than single ones, are added or deleted at each step. Forward and backward methods can also be combined, for example, adding two variables and taking one away at each step. Forward methods have the advantage that they are generally less computationally expensive, but they may miss **interaction** detected by backward methods.

At each step of such a procedure it is necessary to decide which of the possible contenders is "the best". Clearly a performance criterion which is quick to evaluate is needed: constructing a classification rule and assessing its error rate may not be feasible. Multivariate analysis of variance constructs measures of the difference between the groups (based on comparing the variation between the mean vectors with the within-group variation, in the way discussed above), and these measures can be used. They include measures such as Wilks's lambda and the Pillai–Bartlett trace [25]. A slightly different variant is to find the subset of variables which maximizes **Mahalanobis distance** between the two closest groups. Other measures are possible and are implemented in various packages.

Often the variables are also examined individually, to ensure that they pass some minimum criterion for selection (in a forward procedure) or maximum criterion for exclusion (in a backward procedure). For example, in the former, if the extra separation produced by a possible new variable beyond that due to the variables already included is less than some threshold (sometimes called the *F-to-enter*), then the variable will not be considered (at this stage, at least). The *F-to-remove* serves a similar role for backward methods. Sometimes these are combined (for example checking if previously included variables have lost their separating power during the course of forward selection). A cautionary note is worth making here. Although these measures of (extra) separability are F statistics, they are the result of a sequence of steps in which "the best" has been selected. They therefore do not follow an $\boldsymbol{F}$ **distribution**.

Other approaches to variable selection include studying the canonical variates to see which variables do not contribute significantly to any, and examining "all" subsets though a search strategy such as branch and bound, which permits some subsets to be identified as suboptimal without explicitly testing them.

McKay & Campbell [32, 33], and Hand [18, Chapter 6] review variable selection methods in discriminant analysis.

Other Variants of Linear Discriminant Analysis

Linear discriminant analysis has been extended in many directions in an effort to produce more flexible models, less constrained by assumptions, and to produce more accurate classification rules. We have already referred to the extension to quadratic discriminant analysis which follows from relaxing the requirement that all the classes should have the same covariance matrix. Some other generalizations are as follows.

A compromise between the extremes of linear discriminant analysis and quadratic discriminant analysis is to require the covariance matrices of the classes to be the same apart from certain parameters. For example, in the *common principal components* model one assumes that they are the same apart from the variances, which may be proportional [12, 13].

Regularized discriminant analysis [14] sought to find an ideal compromise between the extra variability of quadratic discriminant analysis and the possible bias of linear discriminant analysis by adopting a weighted sum of the two. In particular, it estimates the covariance matrix of the jth class by $(1-\lambda)\hat{\boldsymbol{\Sigma}}_j + \gamma c_j \mathbf{I}$, where

$$\hat{\boldsymbol{\Sigma}}_j = \frac{(1-\lambda)(n_j-1)\mathbf{S}_i + \lambda(n-g)\mathbf{S}}{(1-\lambda)(n_j-1) + \lambda(n-g)}$$

and $c_j = (\text{trace } \hat{\boldsymbol{\Sigma}}_j)/p$. This thus shrinks the sample covariance matrix for class j towards the overall average within sample covariance matrix, $\mathbf{S}$, and then further shrinks the result towards the identity matrix (*see* **Shrinkage**).

Quadratic discriminant analysis relaxes the constraint of linear discriminant analysis that the covariance matrices should be equal. The penalty for the increased flexibility resulting from this relaxation is a danger of overfitting the design set. Regularized

discriminant analysis seeks to overcome this by averaging the quadratic and linear approaches. Another alternative is to try to model the covariance matrices, perhaps based on some knowledge of the processes underlying the data. For example, if the variables represent repeated measures, then likely structures for covariance matrices have been well explored (e.g. [7] and [24]). They are based on underlying mechanisms such as **random effects** and **serial correlation** between consecutive measurements. More generally one can model the covariance matrix in terms of postulated underlying relationships. In particular, one can hypothesize or identify likely conditional independence relationships: if two variables are conditionally independent given the others in the model, then the corresponding entry in the inverse of the covariance matrix is zero [6]. This leads to a covariance matrix in which fewer parameters need to be estimated, so reducing the overall variance of the final model.

Krzanowski ([28, 29], and other papers), in his *location model*, described extensions of linear discriminant analysis to the case when the variables are a mixture of continuous and categorical. In essence the model assumes that density functions of the classes are each multivariate normal in the space spanned by the continuous variables, but takes the mean vectors (and, perhaps, the covariance matrices) to differ between the cells induced by the cross-classification of the categorical variables.

Computation

Fisher's 1936 paper introducing linear discriminant analysis was written before the age of computer technology. Because of this, all the major packages (*see* **Software, Biostatistical**) include implementations of this procedure. Some examples are described below, but readers should be aware that software, above all else, evolves rapidly. New releases of programs appear regularly, including improvements and advances. In any case, we have simply attempted to indicate the flavor of the programs available and have not attempted a detailed specification of all of their features.

1. The discriminant procedure in SPSS/PC+ [40] provides a comprehensive routine for linear discriminant analysis. A choice of five criteria is given for choosing which variables should be entered in a stepwise variable selection process, including Wilks's lambda and maximizing the minimum pairwise separation between groups. Various options can be specified to control the selection process in stepwise procedures. The number of canonical variates computed can be specified [up to $\min(p, g-1)$] or alternatively a value for the cumulative percentage of the eigenvalues associated with the variates can be specified. Various diagnostics can be requested, such as Box's M test for equality of the covariance matrices. Classification can be on the basis of equal priors, priors proportional to the design set class sizes, or user-given values. A plot such as that in Figure 5 can be requested, as can various other plots and classification tables. Either quadratic or linear discriminant analysis can be selected for classifying objects.
2. SAS PROC DISCRIM [38] provides a variety of discriminant analysis procedures, including linear discriminant analysis and quadratic discriminant analysis but also including methods such as kernel and k-nearest-neighbor methods. Canonical variates are produced. Both the resubstitution and leave-one-out estimates of error rate can be requested, as can a smoothed estimate with lower variance than the leave-one-out method. Various graphical displays are available.
3. SAS PROC CANDISC [38] determines canonical variates, the scores of the cases on those variates, and performs univariate and multivariate analysis of variance.
4. SAS PROC STEPDISC [39] performs stepwise linear discriminant analysis using forward or backward methods, or a combination of the two.
5. BMDP 7M [3] performs stepwise discriminant analysis by either forward or backward methods. Important contrasts between the groups may be specified to guide the selection procedure. Resubstitution classification results may be requested, as may leave-one-out results. Prior probabilities can be specified and plots based on the first two canonical variates are available.

Conclusion

Linear discriminant analysis is just one of a large class of methods for performing supervised classification. It is the oldest and in some senses the simplest.

Other methods include:

1. logistic discriminant analysis, mentioned above
2. **nonparametric methods** such as k-nearest-neighbor and kernel methods (*see* **Density Estimation**). These apply ideas of local smoothing (*see* **Nonparametric Regression**), relating the predicted class of a new object to the classes of those objects which are most similar to it, where similarity is measured in terms of the variables describing the objects
3. recursive partitioning or **tree-structured statistical methods**, in which the space of the measured variables is sequentially split, to yield a partition within which each cell corresponds to a particular class
4. the feed-forward neural network and other flexible regression models, in which sophisticated combination and transformation procedures are applied to the raw measured variables to yield a predicted classification
5. expert systems, in which patterns of values in the measured variables and in derived variables are sequentially matched to stored patterns (*see* **Artificial Intelligence**).

The literature of the area is now huge. Books devoted to linear discriminant analysis include [31, 27], and [26]. More general works on supervised classification include [18, 23, 34], and [37]. Most books on multivariate statistics include sections on linear discriminant analysis; an excellent example is [30]. Books on statistical pattern recognition, such as [8] and [15], also often discuss linear discriminant analysis, though typically from a different perspective.

Discrimination and Clustering for Multivariate Time Series

New sophisticated instrumentation in biology and medicine will routinely result in massive **databases** that often are composed of many series that are measured over time. Examples are micro-arrays in gene studies (*see* **DNA Sequences**), and functional magnetic resonance images (fMRI) or EEG series in brain imaging studies (*see* **Image Analysis and Tomography**; **Clinical Signals**). Classic problems in analyzing such observed multivariate **time series** involve (1) the grouping or clustering of the time realizations into similar categories (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**) and (2) the **classification** of new observed series, possibly belonging to one or more of the categories. Examples are clustering of gene patterns associated with a particular disease using micro-arrays, somatosensory discrimination using fMRI profiles, or detection of early onset Alzheimer's disease using multiple EEG sensors.

All of the above experiments receive data in a similar format, namely, as multivariate time series consisting of observations on a vector $\boldsymbol{y}_t = (y_{t1}, y_{t2}, \ldots, y_{tp})'$ observed over a number of time points, say $t = 1, 2, \ldots, n$. Typically, the number of time points, n, exceeds the number of components of the vector, p. For example, EEG measurements may contain thousands of observations in time measured at $p = 19$ channels monitoring different areas of the brain. Data from such studies are often divided a priori into a number of groups or populations, say $\Pi_1, \Pi_2, \ldots, \Pi_m$. A new measurement comes in and is to be classified into one of the groups using **discriminant analysis**. A more challenging problem materializes in *cluster analysis* when there are no a priori subgroups defined over the database. In that case, one wishes to determine the number of groups, m, and the group membership of experimentally observed series using one of a family of procedures for defining clusters.

Discrimination and clustering problems have, of course, been studied for conventional **multivariate** data and there exists a substantial literature devoted to discrimination and clustering of vector observations (for example, see [3, Chapters 11 and 12]; also **Multivariate classification rules: calibration and discrimination**). The components of the vector can be features extracted from the multivariate time profiles $\boldsymbol{y}_t$ measured by instrumentation like that mentioned above. In the physical and engineering sciences, there is a long history devoted to extracting features of time series that can be used for discrimination. For example, Shumway and Stoffer [6, Section 5.7] show an example that involves distinguishing series originating from earthquakes from those that might be nuclear explosions using various amplitude values extracted from the bivariate seismic recordings. The key to applying this *feature extraction* approach is the reduction of the vector time series to a small vector of discriminating features. Although the feature extraction approach can be moderately successful in the hands of a skilled analyst, the magnitude of the databases suggests that discrimination and clustering techniques based on using the complete waveforms are potentially more powerful.

For general discriminant analysis, one usually has a collection of p-dimensional vector time series representing each of m population groups, say $\boldsymbol{y}_{kti}, i = 1, 2, \ldots, n_k, k = 1, 2, \ldots, m$. The n_k $p \times 1$ vectors from group Π_k are used to find **maximum likelihood** estimators for the common parameters of the group, denoted generically here by $\hat{\Theta}_k$. These common parameters determine a log-**likelihood** function for each of the groups, say $\log L(\hat{\Theta}_k), k = 1, 2, \ldots, m$. We may also evaluate the log-likelihood for a new observation, say $\log L(\hat{\Theta})$ at the estimated parameters for that particular observation. The new observation is classified by choosing the population corresponding to the value of k leading to the minimum value of the log-likelihood ratio, namely $\log L(\hat{\Theta}) - \log L(\hat{\Theta}_k)$. This difference and various forms can be regarded as a rough measure of distance between the observed vector and the k^{th} group. Kakizawa et al. [5] show a number of different forms based on information theoretic measures of discrepancy.

Hierarchical cluster analysis assigns observations to clusters based on the same concept of distance. Since we have no a priori knowledge of either the number of clusters or the cluster composition, we begin with N clusters, each containing a single member, where N is the size of the database. Then, define the two closest members as a new single cluster, leading to a new partition into $N - 1$ clusters composed of $N - 1$ single member clusters and one cluster with

two members. Then, evaluate all between-cluster distances using the distance between the two closest elements of the cluster. Merge the two closest into a new cluster The procedure stops when every element of the database has been merged into a single cluster. An alternative *partitioned cluster analysis* approach begins with a set of clusters of a given size and adjusts the membership by evaluating sequentially the distance of each element in a cluster to every other cluster. If it is closer to a cluster to which it does not currently belong, it is moved to the closest neighboring cluster. When no more interchanges are indicated the current membership determines the cluster configuration for a given number of clusters.

There are two possible approaches to modeling the observed data leading to an evaluation of the log-likelihood function mentioned above. For lack of a better description, we divide the modeling approaches into those emphasizing *time domain* methods and those emphasizing *frequency domain* methods. Frequency domain methods (*see* **Spectral Analysis**) have the advantage that the representation of the data in terms of **stationary** or locally stationary processes agrees with physical intuition, suggesting that periodic phenomena can be modeled best in terms of cyclical behavior. Time domain methods (*see* **ARMA and ARIMA Models**) have the advantage that they can often be couched in terms of regression models for which there will be a large body of statistical software for computations. As a general rule in biostatistical applications, **longitudinal data** can often be fitted using time domain methods, whereas the frequency domain often is better suited for large data sets such are produced in fMRI and EEG analysis.

Time domain approaches usually attempt to model the vector series $\boldsymbol{y}_t$ as linear combinations of fixed **covariates** and **stochastic processes** and characterize population membership in terms of the parameters of the linear model. A number of examples of these kinds of representations for vector series can be found in [2] for fMRI series and in [6, Chapter 4], [4], or [1] for models that can be put into state-space form. In these models, one usually has an equation in mind for the observations that includes fixed covariates capable of modeling smooth behavior and a random series that induces a smoother stochastic component. Structural forms for these models in the multivariate case are given in the previously mentioned references. In general, there will be a parametric form for the process that will be typical of its population grouping, leading to a value of the log-likelihood $\log L(\hat{\Theta}_k), i = 1, 2, \ldots, m$ for each group. Computing the difference between the log-likelihood of the observation and that for the group leads to metrics for discriminant and cluster analysis in this case.

Frequency domain methods may be indicated when the stimuli are repetitive, as in many fMRI experiments, or when the response is expected to contain important information at given frequencies. For example, the alpha and beta frequencies for an EEG series are thought to be important components. In the frequency domain model, it is convenient to parameterize the Fourier transforms (*see* **Fast Fourier Transform (FFT)**) of the multivariate series as being approximately complex **multivariate normal** with covariance or spectral matrices that differ for the different population groups. In this case, we still evaluate a log likelihood, called the Whittle [7] likelihood, over frequencies of interest and follow the same general procedures as above for discriminant and cluster analysis. The population differences in this case are assumed to be characterized in terms of the spectra and coherences between the multivariate recordings. The data in this case are summarized by the *spectral matrix* of the vector. The likelihood classification and clustering then works best when using functionals of the estimated group k spectral matrix, $\hat{S}_k(f, t)$, and the estimated spectral matrix of the observation to be classified, $\hat{S}(f, t)$, where f denotes frequency in cycles per unit time and t denotes time. Examples using this approach for discriminating seismic recordings of earthquakes from those generated by presumed nuclear explosions are given in [6, Chapter 5, Section 5.7]. One can average over informative frequencies and over time windows where the data are locally stationary.

ROBERT H. SHUMWAY

Disease Registers

Disease registers are an important tool for clinicians, epidemiologists, and health service planners. Their nature will vary according to the functions they are serving, but all relate to individuals with, or at high risk of, a specified chronic disease. Often registers are used for more than one purpose.

The following sections describe: examples and objectives of registers of different types; problems of case definition, **ascertainment**, and **biases**; validity checks; and possibilities created by **record linkage**.

Types of Disease Registers

Registers Contributing to the Organization and Quality of Clinical Care

Patient Registers Held by Clinicians. The simplest form of disease register is one set up by individual clinicians relating to their own patients. The conditions registered are usually those that require either regular maintenance therapy or **screening** for early signs of preventable complications. Such registers are essentially part of the normal process of clinical care. They are generally designed for **prevalent cases**, i.e. patients who are alive, have not moved away, and whose condition is clinically important.

One of the most common conditions for which disease registers are used is diabetes mellitus. This is typical in that most patients have an ongoing need of insulin or another prescribable drug. They are also at high risk of future complications, particularly problems of the feet, or eyes, and of the cardiovascular system. Many of these complications have been shown to be either preventable, or less serious if diagnosed and treated early.

In recent years the holding of disease registers has extended from one held by a clinician of his/her own patients, with a special interest in a particular condition, to the sharing of registers by groups of clinicians working in general or hospital practice. Moreover, for an increasing number of conditions, including diabetes [6] and coronary artery disease [11], there are now internationally shared registers, with all the necessary **confidentiality** constraints.

Registers of Relatives of Patients with Genetic Conditions. A more recent development is to extend registration to blood relatives of individuals known to have a serious genetic condition. An example of this is the condition of familial adenomatous polyposis. Persons with this condition have numbers of colonic polyps, initially benign but at high risk of becoming malignant.

One method of management is to screen teenage members of affected families and to remove the colon of those found to have polyps at the age of 18–20 as a prophylactic measure [2]. Another approach under investigation is to treat those at high risk with low-dose aspirin, which may be protective against malignancy. Implementation of such programs on a population scale, and their audit, is greatly assisted by the existence of registers of those at risk.

Registers of Individuals at Risk because of Hazardous Exposure. Where specific hazards are known to increase the risk of subsequent serious disorders, registration of those who have been exposed may be a useful clinical tool. This has been done for babies who were born extremely immature, or who have had severe asphyxial episodes. These babies are at high risk of neurologic damage which may not manifest itself for some years. Early diagnosis of sensory or neurologic problems in children on such registers allows prompt action, although it is mostly in visual and hearing disorders that it has been shown to be effective [5]. Parents of children at risk because of stormy births are normally aware of such risks and appreciate the **surveillance**.

Registers Held for the Implementation of Public Health Functions

Registers of serious common conditions may be held for the purpose of monitoring and improving the health of populations as opposed to that of individuals. They are usually held at the level of residents of an administrative area. Questions of exclusion or inclusion may arise when residents of one area are treated, move into, or are born or die, in another area.

In contrast to most registers held for clinical purposes which need only include *prevalent* cases, registers held for public health functions may need to include all **incident cases** regardless of severity or survival. Moreover, for most public health functions the measures used will be **incidence** or **prevalence rates** rather than absolute numbers of cases.

The calculation of rates implies that the number of individuals at risk is known. In some registers, for

instance those of congenital anomalies, this implies the inclusion of cases lost as late prenatal or postnatal death amongst the numerator and denominator. This is possible where there is a definitive diagnostic test which can be used prenatally or in the early postnatal period, e.g. the detection of a chromosomal anomaly, of a specific genetic defect, or ultrasound visualization of malformations visible during or after pregnancy [10].

The aims of such registers include:

1. the ascertainment of environmental hazards to health (*see* **Environmental Epidemiology**)
2. the provision of current and projected prevalence and severity data for health care planners (*see* **Health Services Research, Overview**)
3. the monitoring of **survival**, or **quality of life**, of affected individuals
4. the monitoring of the efficacy, implementation and acceptance of preventive measures.

Important examples are cancer, diabetes, ischemic heart disease, or congenital anomaly registers, which may be held at regional, national, or international levels.

Ascertainment of Environmental Hazards to Health. New environmental causes of ill-health may be suspected when trends in registration rates of specific conditions change over time, in different places or in persons of different characteristics, or occupations. New patterns of incidence, such as clusters over time and space, may also draw attention to possible causes (*see* **Clustering**). When the conditions concerned are rapidly lethal, or lethal prenatally, it is important to ascertain all incident cases as far as possible, as well as prevalent cases. Where evidence is found that there has been a real change in incidence, registered cases may act as a **sampling frame** to set up **case–control studies** to investigate possible causes.

Negative findings from such studies are as important as positive findings if they can rule out putative associations with environmental exposures.

Provision of Current and Projected Prevalence and Severity Data for Health Care Planners. Health care planners require information to allow them to project future needs of individuals with specific conditions, in terms of prevalence and severity. This requires good quality prevalent disease registers, which include clinical and survival data.

Monitoring of Outcome of Affected Individuals. Registers which provide information on survival, quality of life, and treatment given, are important sources of clinical audit, allowing the comparison of survival after different treatments or treatment in different places. Such audit will, however, also require basic demographic data such as age, sex, place of residence and, if possible, socioeconomic circumstances, which could **confound** comparisons of survival. Such comparisons, although not so rigorous as randomized controlled trials (*see* **Clinical Trials, Overview**), may point to differences that should be further explored.

Monitoring of the Efficacy, Implementation, and Acceptance of Preventive Measures. Preventive measures of disease may include primary prevention, namely the abolition of the cause. In the case of cancers or heart disease, these include smoking or alcohol abuse. Preventable serious congenital disorders include neural tube defects, in part preventable by periconceptional folic acid supplementation, and rubella embryopathy, preventable by preconceptional rubella immunization. Where registers exist of incident cases of such conditions, trends over time, place, or in different population groups will act as an audit of the extent to which the preventive action is being implemented.

In conditions where secondary preventive action may follow the screening out of asymptomatic or prenatal cases, the use of a disease register to monitor the prevalence of symptomatic cases, or births with specific congenital anomalies, will allow the auditing of the efficacy and effectiveness of specific screening programs. Examples are where cervical or breast cancer screening is on offer, and how this affects the mortality due to such cancers; or where prenatal screening programs are available, whether there is a change in ratio of legally terminated pregnancies with Down's syndrome or neural tube defects to registered affected births.

Registers Held for Research Purposes. Registers may be held purely for etiologic research. They typically require the inclusion of incident rather than prevalent cases. Their design and maintenance must

take account of, or may reveal, the **natural history** of the condition registered.

How the Natural History of a Disease may Affect Registration

Congenital Anomalies

Many congenital conditions which lead to permanent impairment are ascertainable and therefore registerable at birth, e.g. spina bifida. Others may not be visible or do not lead to symptoms until some time after birth. These include congenital heart defects, cerebral palsy, or mental retardation. For such conditions it is impossible to estimate true incidence rates since many affected children may have died before ascertainment, and only age-specific prevalence rates can be calculated. Other congenital conditions, e.g. gastrointestinal atresias, are curable by surgery shortly after birth. Such conditions may need to be considered in the ascertainment of incident cases, but not in ascertaining prevalent cases.

The advent of prenatal diagnosis of some conditions, often leading to termination of pregnancy, raises other questions. Had they not been prenatally diagnosed, many fetuses with conditions such as chromosomal anomalies would have been lost as spontaneous miscarriages, and the cause would not have been ascertained. This is an important point in registers of Down's syndrome, where in recent years in England and Wales about half of all affected pregnancies are diagnosed prenatally, leading to an apparent increase in incident cases, although the numbers of affected births are falling [1].

Acquired Diseases

Acquired chronic conditions may lead to permanent impairment which cannot be cured, or they may be "curable", at least in the sense of not recurring. The course of the disease may be variable, as in multiple sclerosis, with attacks and remissions, the patient sometimes having no symptoms or clinical signs in remission. Alternatively, in conditions such as ischemic heart disease, minor symptoms and signs of the disease may persist, but this may be punctuated by acute episodes of myocardial infarction. Tunstall–Pedoe [11] gives a full account of the methodologic problems raised in the registration of ischemic heart disease, stemming from the notification of heart attacks as acute episodes instead of as "abstractions from a chronic disease". He shows that such registration, which has been used for international comparisons, is the only way to measure the burden of chronic heart disease.

Case Definition

The nature and quality of a register is crucially dependent upon the ascertainment of individuals meeting a clear and unambiguous case definition. Case definition must include guidance on which cases should be included and which excluded, including the cutoff points in terms of level of severity or objective test results. Where relevant, it is helpful if registration forms include diagrams which indicate the parts of the body that are affected, or scales which indicate severity.

Sometimes researchers may choose to use a very broad definition on the assumption that they can select specific subgroups from the information requested.

One question that commonly arises is how to handle cases with multiple pathology, e.g. multiple apparently unrelated malformations or cancers. Particularly for research purposes, the setting up of a register must include a protocol which deals with these questions and the method of ascertainment to be used. For clinical registers held by one practitioner this may be less important, but as soon as clinical registers are shared with others (and this often implies a new use as a research tool also), such a protocol is equally important.

Ascertainment

The completeness of registers varies with the methods used for ascertainment and diagnosis.

Methods of Ascertainment

Ascertainment may depend on clinical presentation and the recognition of the defined condition, or it may be the result of a process of screening where this is clinically possible. Both the severity of the condition and the characteristics of the individuals ascertained will usually vary sharply depending on the methods

used. Examples are the marked differences between numbers of cases on registers of individuals with diabetes mellitus who presented for medical care, and those registers which resulted from population screening of urine and glucose tolerance testing [3]. The ease and completeness with which cases are found may be helped if the treatment is standard and unique, as in the case of insulin, where monitoring of prescriptions is a method of ascertainment of cases.

Methods of Diagnosis

Particularly where the register is shared with others, the diagnostic process must be based on a formal protocol. There are many different methods of diagnosis. For those conditions where a definitive diagnostic test is available e.g. an identifiable single **gene** defect or a chromosome anomaly, or the results of bacterial or viral culture, the easiest and most complete ascertainment may be obtained from laboratory results. Where diagnosis is largely based on clinical findings its success may depend on the personal acumen of the physician, but is usually backed up by objective blood, urine, or imaging investigations. Such methods may lead to full, or nearly full, ascertainment where the condition is such that self-referral is the rule. For lethal conditions clinical ascertainment can be backed up by searching for relevant details on **death certificates**.

Multiple Sources of Ascertainment

It is now increasingly common to use multiple sources of ascertainment. This can be particularly useful for chronic conditions of low lethality which may not always require medical care. For instance, individuals with conditions such as cerebral palsy or mental retardation may present to a variety of services – medical, paramedical (such as physiotherapy), educational, or social. Moreover, it has been shown that even the ascertainment of diabetes or cancer can be improved by the use of multiple sources. For diabetes, multiple sources that have been used include prescriptions, family practitioner registers, hospital diabetic clinic records, and, where relevant, health insurance data. For cancer registrations, sources include hospital records or death certificates with a mention of cancer, histology reports, and oncology clinic records.

Multiple ascertainment is designed to lead to duplication of notification, and the information gathered and the design of the register must be such that duplicates can be identified and eliminated.

Duplicate Notification. Duplicate notification will also occur where affected individuals already registered in one place move to another place which keeps a related register, and precautions must be taken to eliminate these. Clerical errors in recording dates, spelling mistakes in recording names, or name changes are all difficulties which must be taken account of in seeking for duplicates. Record linkage techniques can be used to check for duplicates, including phonetic name matching [7].

Case Identification

The degree to which registered cases need personal identification will vary according to the aims of the register. Clinical registers are often part of family practitioner or hospital records, and named identification is essential for their use.

Registers kept for public health or research purposes often do not need to be named except where a follow-up of registered individuals is planned. On the other hand the recording of some personal identifiers is essential, if only to allow the finding and elimination of duplicates, and to have such basic epidemiologic information as date of birth and sex.

If the aims of the register include an investigation of changes in incidence, prevalence, or survival, other dates must be collected, such as at first presentation and, where relevant, of death. Similarly, to seek for evidence of clustering, place of residence, and sometimes of birth or occupation, will be needed, usually recorded in the form of post- or zip-code data. When personal identifiers are kept there must be meticulous care to preserve patient confidentiality.

Record Linkage

The growth of computerized health information (*see* **Administrative Databases**) has led to opportunities to link records from different sources, and thus to enhance register information.

For instance, in the UK it is possible to access information from death registration. Given Ethics

Committee permission, bona fide researchers are permitted to arrange for the linkage of this information with their own register data, thus providing the necessary data to calculate the survival of the individuals on a register, and to find their causes of death. Similarly, linkage with nonconfidential items from birth records may provide valuable information linking birth events with health in later life [9].

Such linkage is an essential part of cancer registration in the UK, since recording of cancer as a **cause of death** is an important method of ascertainment for the regional cancer registers. Moreover, the linkage at national level of data from all regional cancer registers allows for identification and elimination of duplicate records due to patient movements [8].

Validation

An important aspect of maintaining the quality of disease registers is the validation of the data at regular intervals. Validation can include an assessment of completeness of registration and of data on each record, the success with which duplicates are eliminated, and most importantly the rigor to which the given case definition is adhered.

There is a growing literature on methods of examining the likely completeness of ascertainment. Where there are different but independent methods, **"capture–recapture"** techniques can be used [4].

The examination of the validity of case registration can be a difficult task. An area where this has received particular attention is in the **World Health Organization** MONICA study, which was the registration in a number of different countries of heart attacks. This is well described by Tunstall-Pedoe [11], who discusses problems arising from different standards of record keeping, the use of coding rules for clinical history, symptoms and diagnostic tests, and validity checks of the clinical data, coding, and laboratory or other tests.

Conclusions

Disease registers are becoming an increasingly powerful clinical and epidemiologic tool, particularly for international comparisons. Their use predicates clear aims, good design, coverage, complete and accurate recording of validated data, and rigorous methods of preserving confidentiality.

EVA ALBERMAN

Disease-marker Association

The primary aim of a disease–marker association study is to evaluate the potential role of a **gene**(s) in the expression of a measured trait. The gene may be measured directly at the DNA level (such as **DNA sequence** variation), at the level of the gene product (such as blood serum proteins and enzymes), or indirectly by DNA markers (such as restriction–fragment–length–**polymorphisms** or simple sequence repeats) that are on the same chromosome and physically close to, and associated with, the disease-causing gene. It is convenient to refer to any of these measured phenotypes of a gene as a **genetic marker**, which is defined as a genetically determined trait for which the relationship between **genotype** and phenotype is known. The DNA markers chosen for studies are often codominant, i.e. there is a one-to-one relationship between marker genotype and phenotype, allowing unambiguous determination of marker alleles. When a marker is not codominant, the error of classification of the genotype based on the marker phenotype should be considered in analyses, which requires knowing the distribution of the marker phenotype, given the marker genotype, as in a general **penetrance** function.

For a marker to be useful in an association study, it should have sufficient variation (i.e. **polymorphism**) in the population. Measures of polymorphism for a marker are (i) **heterozygosity**, the probability of having a heterozygous genotype and (ii) **polymorphism information content**, which was derived for linkage studies of a rare autosomal dominant disease using a codominant marker, and which corrects the heterozygosity for noninformative matings when parents and child all have the same heterozygous genotype.

Although the cause of association between genetic markers and disease cannot be determined by association studies, it is important to consider the possible causes of association so that potential biases can be evaluated. One most desirable cause is the direct effect of marker alleles on the trait phenotypes, such as in a candidate–gene study. A second, indirect, cause of association is **linkage disequilibrium** (LD), i.e. both linkage between disease and marker loci and nonrandom association of the alleles at these two loci on chromosomes in the population. This type of association is likely to occur if most diseased subjects inherited from a common ancestor a segment of chromosome containing the disease allele and marker allele (founder effect), and is most easily detected in a homogenous population, because the main factor influencing the association is recombination between the two loci. Recombination breaks association between the alleles at the two loci, so that after many recombinations, which accumulate over generations, the alleles at the two loci will be randomly associated on chromosomes in the population. However, this is a slow process when the chance of recombination, θ, is small. Denote by m_i a marker allele with frequency p_i, d_j an allele from the disease-causing locus with frequency q_j, and h_{ij} the frequency of a chromosome bearing alleles m_i and d_j (i.e. **haplotype**). The deviation of the haplotype frequency from random association (i.e. equilibrium) is $h_{ij} - p_i q_j$, which is expected to decrease by the factor $(1-\theta)^n$ after n generations, where θ is the recombination fraction (*see* **Linkage Analysis, Model-based**). Because of this, association studies based on LD are generally not sensitive to $\theta > 1\%$ (1 centimorgan).

A complication of associations caused by LD is that different mutations causing the same disease phenotype can arise on chromosomes that bear different marker alleles. This can cause the associated marker allele to differ across different populations, and can decrease LD in a population mixed with different mutations. To study this effect in detail, one could perform studies of haplotypes composed of multiple marker loci to determine whether particular haplotypes are associated with disease. However, determination of haplotypes may require much work (e.g. family studies), and there are statistical errors when inferring haplotypes. Note that if there are multiple genes over a short chromosomal region, each of which can be associated with disease, then a marker within that region can be associated with disease due to any one (or more) of those genes, making it difficult to determine the causative gene(s). Examples of this complexity occur in association studies of the major histocompatibility complex (*see* **HLA System**).

In addition to direct effects or LD causing associations, there are other less interesting causes of association that can exist at the population level, yet which can cause misleading interpretations. These are joint selection for both marker and disease locus

alleles, small population variation (random genetic drift (*see* **Population Genetics**)), and the structure of the population, which may include **inbreeding**, or stratification due to either **admixture** of different ethnic groups or nonrandom mating. If a population is composed of a recent admixture of different ethnic groups that have different frequencies of marker alleles, then any trait more frequent in an ethnic group will be positively associated with any marker allele that is more frequent in that group, even if these loci are not linked. This spurious association is an example of **confounding** due to ethnic background. Although linkage disequilibrium is often used to describe general associations between disease and marker alleles, it is better to use the term "allelic association", because of the other causes of association described above.

The traits evaluated in association studies are often based on affection status (diseased vs. normal), as in **case–control studies**. For this reason, case-control studies are discussed in detail, although other study designs may be useful: **cohort, cross-sectional**, admixed populations, case–parent, family-based controls, haplotype analyses, and pedigree studies. Furthermore, it is important to recognize that marker association studies are useful to address a number of scientific questions, such as prognosis of survival outcome of diseased subjects based on marker genotypes (using censored **survival analysis** methods), or the amount of variation of quantitative traits, among either diseased or normal subjects, explained by genetic markers (using **regression** analysis and **analysis of variance**).

Criteria for selection of diseased cases often include newly diagnosed **incident cases** (instead of **prevalent cases**, which are confounded by disease duration and survival), and ways to minimize phenocopies (e.g. strong family history, early onset, severe cases). To avoid confounding, it is best to match cases and controls by potential confounders such as age, sex, and ethnicity. Because ethnicity can be difficult to define and measure, and population structure may not be known, the choice of adequate controls can be quite difficult. Although relatives of cases may serve as convenient controls, especially for matching on ethnic background, the statistical dependence between cases and their relatives can lead to less **power** than a random sample of controls.

The comparison of marker phenotype frequencies, say G different types, between cases and controls can be performed using traditional methods for **case–control studies** [4, 27] (*see* **Analytic Epidemiology**): $2 \times G$ tables with **chi-square tests** or **exact tests** [35], cross-product **odds ratios** (for small samples it may be necessary to use Haldane's formula [10] by adding 0.5 to the cells of the table before computing odds ratios), **logistic regression** (unconditional or conditional for matched studies), and population **attributable risk** [1]. When the number of marker phenotypes (G) is large, it is common practice to compare the frequency of the presence of particular marker phenotypes, such as carriers of particular alleles, between cases and controls in multiple, **2 × 2 tables**, with correction for multiple testing (*see* **Multiple Comparisons**). Alternatively, when marker alleles can be unambiguously determined, as for codominant markers, power may be improved by reducing the large number of categories based on marker phenotypes to fewer categories based on marker alleles, say K distinguishable alleles. Allele frequencies can then be compared between cases and controls by constructing a $2 \times K$ **contingency table**, such that each person contributes two alleles, and then calculating a probability value based on either the large sample **chi-square distribution** of the Pearson chi-square statistic or **Monte Carlo** testing [30]. The chi-square statistic has $(K - 1)$ degrees of freedom. When it is plausible that a disease susceptibility allele is associated with only one of K marker alleles, although it is not known which allele is associated, power can be improved by use of a mixture **likelihood**, which uses the frequency of marker alleles to predict which allele is associated with disease, and creation of a **likelihood ratio** statistic [37].

The validity of Pearson's chi-square statistic for comparing allele frequencies requires independence of alleles in the general population. When randomly sampling cases and controls, genotypes are independent between people, but alleles within genotypes may not be independent, such as can occur when there is recent mixture of populations. Independence of alleles can be tested by comparing the observed genotype proportions to those expected when there is **Hardy–Weinberg Equilibrium** (HWE). This test should be performed only among the controls, because even if the general population is in HWE, the

expected marker genotype proportions among diseased cases can deviate from HWE when a true association exists, and the amount of deviation depends on the genetic mechanism. For example, if a marker allele is associated with a disease caused by a rare dominant disease susceptibility allele, then HWE is not expected to hold, yet for association with a recessive disease susceptibility allele, HWE may hold among the cases, but with a marker allele frequency greater than in the general population [21, 42].

If HWE does not hold among the controls, then the variances (and covariances) of allele frequencies should not be based on **binomial** variances (and covariances), because they do not account for the dependence of alleles. For example, let $n_{\mathrm{A}\cdot}$ and n_{AA} be the number of controls **heterozygous** and homozygous, respectively, for allele A, and let N be the total number of controls. The estimated relative frequency of allele A is $\hat{q}_{\mathrm{A}} = (n_{\mathrm{A}\cdot} + 2n_{\mathrm{AA}})/(2N)$, and the estimated frequency of AA homozygotes is $\hat{q}_{\mathrm{AA}} = n_{\mathrm{AA}}/N$. When there is deviation from HWE the estimated variance of $\hat{q}_A$ is $\mathrm{var}(\hat{q}_{\mathrm{A}}) = [\hat{q}_{\mathrm{A}}(1 - \hat{q}_{\mathrm{A}}) + (\hat{q}_{\mathrm{AA}} - \hat{q}_{\mathrm{A}}^2)]/(2N)$ [46], which deviates from the binomial variance because of the term $(\hat{q}_{\mathrm{AA}} - \hat{q}_{\mathrm{A}}^2)$. One can use corrected variances and covariances to compute a valid chi-square statistic for comparison of allele frequencies when HWE does not hold, although the usual Pearson chi-square statistic is robust (*see* **Robustness**) to moderate deviations from HWE.

In contrast, if the assumption of HWE is plausible, then analyses can be improved. For example, if the relationship between the marker genotype and phenotype is not one-to-one, then the assumption of HWE can be used to estimate allele frequencies by **maximum likelihood**; for example, using the **EM algorithm**; the HWE proportions give the relative probabilities of the different genotypes that correspond to the same phenotype. Furthermore, risk estimates can be improved with smaller variances [14]; multivariate statistical tests, which account for correlations among alleles from a single locus due to allele frequencies summing to one, as well as correlations among alleles from different loci, can be used as omnibus tests for association [32]; and one can fit genetic models to assess the effects of marker alleles on **relative risks** for disease [21].

When evaluating multiple alleles at a single marker locus, or multiple marker loci, one can use **logistic regression** and **loglinear models** [8, 45] to assess associations. Advantages of these regression models are that nongenetic covariates can be included (which allows estimation of marker relative risks adjusted for potential confounders), **interactions** of marker alleles on relative risk can be evaluated (say, additive vs. dominant effects of alleles on the log relative risk), and interactions between the marker alleles and nongenetic covariates can be assessed (*see* **Gene-environment Interaction**).

The statistical methods used to evaluate associations with marker alleles can also be used to evaluate associations with haplotypes created by multiple marker loci. Haplotypes can be inferred either by family studies, such as for cases, or statistically by using measures of population linkage disequilibrium to predict the most likely haplotypes [16], such as for controls. Some statistical difficulties are ambiguous haplotypes, error in haplotype prediction, ambiguity of disease genotype, and confounding from population structure. It is not unusual for the largest relative risks to occur with the smallest haplotype frequencies, resulting in large variances of risk estimates. Although it may be necessary to combine rare haplotypes to validate use of chi-square statistics, it may be better to use exact or simulated P values [30, 35]. A novel attempt to improve power in this situation is to use a "cladistic" analysis in which the evolutionary history of haplotypes (i.e. evolutionary tree) is first created, and then to perform nested analyses to determine which tree branches differ most between cases and controls [36].

With the availability of many genetic markers, one of the most challenging statistical issues is the choice of the level of statistical significance to maximize power yet minimize the chance of false positives. The success of an association study depends on the likelihood that the marker is involved (directly or indirectly via LD) in the disease process, so that the most meaningful association studies are those that evaluate markers with clear biological functions. When testing many markers, the prior probability that any one is associated with disease is often so low that one needs to be very conservative to avoid false-positive associations. To account for multiple comparisons with many alleles (or many haplotypes), the **Bonferroni** correction is often used, although one should consider the power of this method vs. omnibus multivariate methods. Also ***P* value** plots [28] and **empirical Bayes shrinkage estimates** [40, 41] may prove useful.

Because of the difficulty in defining an appropriate control group for association studies in heterogeneous populations, Falk & Rubenstein [7] proposed to measure the genetic marker on both the diseased cases and their parents in order to compare the frequencies of those alleles that were transmitted from parents to children with those that were not transmitted. For example, to test the association of allele A, vs. all other alleles combined into group B, in a sample of n cases ($2n$ parents), the alleles of each parent are classified as in Table 1, so that each parent contributes a count to this table. The genotype of each parent can be considered a matched pair of alleles, one transmitted and the other not, and the **McNemar test** for matched pairs, which does not require independence of parental alleles, is valid. This is also called the transmission/disequilibrium test, or TDT [34]. Note that only discordant pairs (*see* **Matching**), i.e. heterozygous parents, contribute to the TDT statistic. An alternative approach, which uses all parental alleles, is to ignore the matching in order to compare the frequency of allele A among the $2n$ transmitted alleles vs. the $2n$ nontransmitted alleles. This can be accomplished by rearranging the marginal totals of Table 1 into the cells of Table 2, and applying Pearson's chi-square statistic (also called the haplotype-based haplotype relative risk statistic, HHRR, for this type of analysis [38]). However, this method requires that parental alleles be independent in the population, which is not true for a stratified population [33]. The statistical properties of various methods of analysis for parental controls have been investigated [2, 6, 11, 12, 18–20, 25, 26, 31, 34, 38, 43, 44] but a general framework can be developed based on a conditional likelihood method [29]. To see this, note that by conditioning on the two alleles of the mother, m_1 and m_2, and the two alleles of the father, f_1 and f_2, there are four child genotypes that can be produced, $m_1 f_1$, $m_1 f_2$, $m_2 f_1$, and $m_2 f_2$. One of these four genotypes is that for the diseased case, and the remaining three can be considered matched hypothetical sib controls. This framework allows development of omnibus **score** statistics [24], as well as use of standard conditional logistic regression software (*see* **Software, Biostatistical**) to compute maximum likelihood estimates of allelic effects and to assess interactions between marker genotypes and environmental covariates [13, 23, 29, 39]. It is critical to recognize that these statistical methods are sensitive only to associations caused by both linkage disequilibrium and linkage.

Table 1 Matched analysis for transmitted and nontransmitted parental alleles: TDT $= (b-c)^2/(b+c)$

	Nontransmitted allele		
Transmitted allele	A	B	Total
A	a	b	w
B	c	d	x
Total	y	z	$2n$

Table 2 Nonmatched analysis for transmitted and nontransmitted parental alleles: HHRR $= (wz-xy)^2 \times 4n/[(w+y)(x+z)4n^2]$

	Allele type		
	A	B	Total
Transmitted alleles	w	x	$2n$
Nontransmitted alleles	y	z	$2n$
Total	$w+y$	$x+z$	$4n$

Association studies using pedigree data offer yet another useful design because members of the same pedigree are likely to have the same genetic etiology, which reduces etiologic heterogeneity, and extended pedigrees give more information about the genetic mechanisms underlying the trait than does a sample of unrelated persons. An important feature of pedigree data is that the statistical dependence of members in the same pedigree needs to be incorporated into analyses to obtain accurate estimates of the variances of parameter estimates. For a large number of independent pedigrees, the robust method of **generalized estimating equations** [15, 47] can be used. However, for one or a few pedigrees, the asymptotic results for generalized estimating equations are not likely to hold, so it is necessary to use a statistical model that incorporates familial correlations. For dichotomous traits, one can use either likelihood methods based on combined association, segregation (*see* **Segregation Analysis, Classical**), and linkage (*see* **Linkage Analysis, Model-based**) [17, 22], or a method called the Marker Association Segregation Chi-squares (MASC) [5], which fits models for the simultaneous segregation and association of marker alleles within pedigrees based on minimization of chi-squares. For continuous traits, methods based on the multivariate normal distribution with covariance matrices determined by the genetic relationships among pedigree members can be used [3, 9] (*see* **Genetic Correlations and Covariances**). It can sometimes be advantageous to confirm case-control population association studies with pedigree

studies in order to rule out spurious associations and to understand better the genetic mechanism causing the trait phenotype.

Distance Sampling

Distance sampling is the most widely used technique for estimating abundance of biological populations. It is used for a diverse range of populations: whales, dolphins, seals, apes, monkeys, deer, antelope, rabbits, seabirds, gamebirds, songbirds, fish, butterflies, trees, bird nests, animal burrows, animal carcasses, etc. There are several strategies available to wildlife managers and ecologists for assessing abundance [10]. The most obvious is to **census** (count) the population. If this is impracticable, sample counts might be made in randomly selected quadrats. Two forms of "quadrat" sampling are point counts, in which numbers of objects (usually birds or plants) in a circle about a point are counted, and strip transects, in which the observer travels along a line, counting all objects within a predetermined distance of the line. Both methods yield an estimated density (objects per unit area) simply by dividing the total count by the total area surveyed. For many populations, it is difficult to ensure that all objects within the circle or strip are detected and counted. Furthermore, for scarce species, the methods are wasteful, because detections of objects beyond the circle or strip boundary are ignored. If the radius of the circle or the width of the strip is made sufficiently small that detection of any object within the surveyed area is almost certain, then perhaps 50% or more of detections are outside the surveyed area, and so are ignored. In distance sampling, distances from the center line or point to detected objects are recorded, which allows us to estimate object density without having to assume that all objects within the surveyed area are counted.

The term "distance sampling" is used because the population can be regarded as the set of distances of objects from the line or point. We sample from this population of distances in a "size-biased" way, because smaller distances are more likely to be sampled. That is, objects closer to the line or point are more likely to be detected.

The two primary methods of distance sampling are line transect sampling, an extension of strip transect sampling in which line-to-object distances are sampled, and point transect sampling, an extension of point counts in which observer-to-object distances are sampled [4]. Related methods are cue counting [7], used on large whale populations, and trapping webs [1], which extend the applicability of distance sampling to small mammals and ground insect populations. The theory for these approaches is closely similar to that for point transects. Free software Distance [8] for analyzing distance sampling data is available from the web site `http://www.ruwpa.st-and.ac.uk/distance/`. Related techniques sometimes used by botanists to estimate densities (and sometimes also termed distance sampling) are nearest neighbor (*see* **Clustering**) and point-to-nearest object methods [5].

Methods for estimating wildlife abundance that do not involve distance sampling include **capture–recapture**, which is often more labor-intensive and more sensitive to failures of assumptions than distance sampling. However, it is applicable to some species that are not amenable to distance sampling methods, and can yield estimates of survival and recruitment rates, which distance sampling cannot do. Capture–recapture methods can be useful for populations that aggregate at some location each year, whereas distance sampling methods are more effective on dispersed populations. They should therefore be seen as different tools for different purposes. In fisheries applications, catch per unit effort, catch-at-age and catch-at-length are all commonly used to estimate abundance, as they require that the commercial catch is sampled, which is more cost-effective than sampling the living fish. Acoustic surveys of fish schools often provide data amenable to distance sampling methods. For difficult terrestrial species, abundance is often indexed using indirect methods, such as dung counts for deer or rabbits. To convert the index to an estimate of abundance, typically one or more rates must be estimated, such as deposition rate and decay rate for "standing crop" dung counts.

Line Transect Sampling

In line transect sampling, a series of straight lines is traversed by an observer. This may be achieved in various ways, depending on the study species. In terrestrial studies, these include walking, horseback, trail bike, all-terrain vehicle, fixed-wing aircraft, and helicopter. Transect surveys for aquatic environments can be conducted by divers with snorkels or scuba gear, from surface vessels ranging in size from small boats to large ships, from fixed-wing aircraft, helicopters or airships, from small submarines, or from sleds with mounted video units pulled underwater by a surface

vessel. In the case of large observation platforms, there is typically a team of observers.

Estimation

Perpendicular distances x are measured from the line to each detected object of interest (usually an animal, or "cluster" of animals). In practice, detection distances r and detection angles θ are often recorded, from which perpendicular distances are calculated as $x = r \sin\theta$ (Figure 1). Suppose k lines of lengths $l_1, \ldots, l_k$ (with $\sum l_j = L$) are positioned according to some randomized scheme, and n animals are detected, at perpendicular distances $x_1, \ldots, x_n$. Suppose that animals farther than some distance w from the line are not recorded. Then the surveyed area is $a = 2wL$, within which n animals are detected. However, not all animals within the surveyed area are detected. Let P_a be the probability that an animal within the surveyed area is detected, and suppose an estimate $\hat{P}_a$ is available. Then animal density D is estimated by

$$\hat{D} = \frac{n}{2wLP_a}. \tag{1}$$

To provide a framework for estimating P_a, we define the detection function $g(x)$ to be the probability that an animal at distance x from the line is detected, $0 \le x \le w$, and assume that $g(0) = 1$. That is, we are certain to detect an animal on the trackline. If we plot the recorded perpendicular distances in a histogram, then conceptually the problem is reduced to specifying a suitable model for $g(x)$, and fitting it to the perpendicular distance data. As shown in

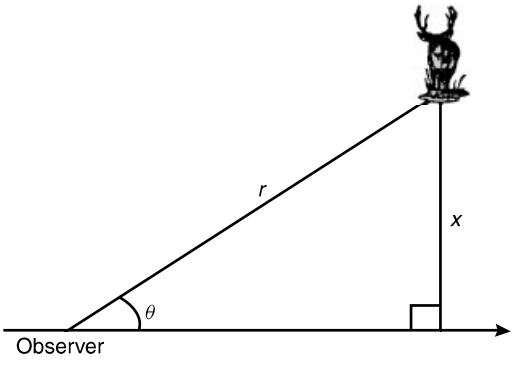

Figure 1 If sighting distance r and sighting angle θ are recorded, then perpendicular distance x of the animal from the line is found as $x = r \sin\theta$

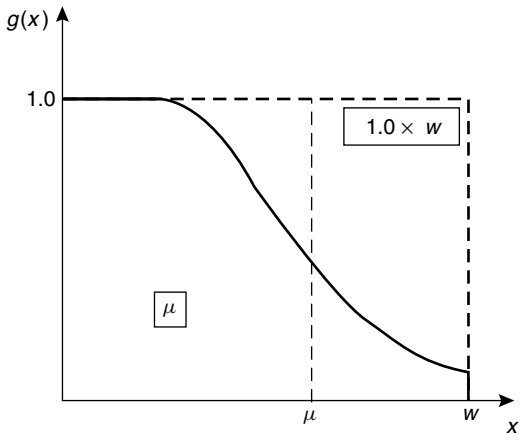

Figure 2 The area μ under the detection function $g(x)$, when expressed as a proportion of the area w of the rectangle, is the probability that an object within the surveyed area is detected; μ is also the effective strip width, and takes a value between 0 and w

Figure 2, if we define $\mu = \int_0^w g(x)\,dx$, then $P_a = \mu/w$. The parameter μ is called the effective strip (half-) width; it is the distance from the line for which as many animals are detected beyond μ as are missed within μ (Figure 2). Thus

$$\hat{D} = \frac{n}{a \times \hat{P}_a} = \frac{n}{2wL \times \hat{\mu}/w} = \frac{n}{2\hat{\mu}L}. \tag{2}$$

We now need an estimate $\hat{\mu}$ of μ. We can turn this into a more familiar estimation problem by noting that the probability density function of perpendicular distances to detected objects, denoted $f(x)$, is simply the detection function $g(x)$, rescaled so that it integrates to unity. That is, $f(x) = g(x)/\mu$. In particular, because we assume $g(0) = 1$, it follows that $f(0) = 1/\mu$ (Figure 3). Hence

$$\hat{D} = \frac{n}{2\hat{\mu}L} = \frac{n\hat{f}(0)}{2L}. \tag{3}$$

The problem is reduced to modeling the probability density function of perpendicular distances, and evaluating the fitted function at $x = 0$. The large literature for fitting density functions is now available to us. Distance uses the methods of Buckland [3], in which a parametric "key" function is selected and, if it fails to provide an adequate fit, polynomial or cosine series adjustments are added until the fit is judged to be satisfactory by one or more criteria.

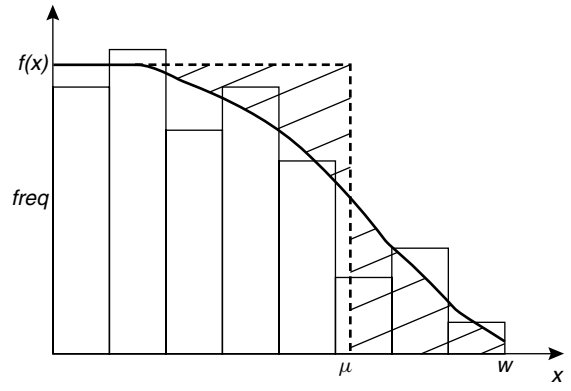

Figure 3 The probability density function of perpendicular distances, $f(x)$, plotted on a histogram of perpendicular distance frequencies (scaled so that the total area of histogram bars is unity). The area below the curve is unity by definition. Because the two shaded areas are equal in size, the area of the rectangle, $\mu \times f(0)$, is also unity. Hence $\mu = 1/f(0)$

Often, the perpendicular distances are recorded by distance category, so that each exact distance need not be measured, or data are grouped into distance categories before analysis. Standard **likelihood** methods for **multinomial** data are used to fit such "grouped" data.

Variance and Interval Estimation

The **variance** of $\hat{D}$ may be approximated using the **delta method**, assuming no **correlation** between n and $\hat{f}(0)$:

$$\hat{V}(\hat{D}) = \hat{D}^2 \left[\frac{\hat{V}(n)}{n^2} + \frac{\hat{V}[\hat{f}(0)]}{[\hat{f}(0)]^2} \right]. \qquad (4)$$

The variance of n is generally estimated from the sample variance in encounter rates, n_j/l_j, weighted by line lengths l_j. When $f(0)$ is estimated by **maximum likelihood**, its variance is estimated from the **information matrix**.

If we assume that $\hat{D}$ is **lognormally distributed**, approximate 95% **confidence limits** are given by $(\hat{D}/C, \hat{D} \times C)$ where

$$C = \exp\{1.96[\hat{V}(\log_e \hat{D})]^{0.5}\}, \qquad (5)$$

with

$$\hat{V}(\log_e \hat{D}) = \log_e \left[1 + \frac{\hat{V}(\hat{D})}{\hat{D}^2} \right]. \qquad (6)$$

Often, **bootstrap** variance and interval estimation (*see* **Estimation, Interval**) is preferred. Resamples are usually generated by **sampling with replacement** from the lines, so that independence between the lines is assumed, but independence between detections on the same line is not. If the model selection procedure is applied independently to each resample, the bootstrap variance includes a component due to model selection uncertainty.

Cluster Size Estimation

Animals often occur in groups, which we term "clusters". These may be flocks of birds, pods of whales, schools of fish, herds of antelope, etc. If one animal in a cluster is detected, then it is assumed that the whole cluster is detected, and the position of the cluster is recorded. Eq. (3) then gives an estimate of the density of clusters. To obtain the estimated density of individuals, we must multiply by an estimate of mean cluster size in the population, $E(s)$:

$$\hat{D} = \frac{n\hat{f}(0)\hat{E}(s)}{2L}. \qquad (7)$$

Probability of detection is often a function of cluster size, so that the sample of cluster sizes exhibits size bias. In the absence of size bias, we can take $\hat{E}(s) = \overline{s}$, the mean size of detected clusters. Several methods exist for estimating $E(s)$ in the presence of size bias [4]. One that works well in practice is to regress $\log s$ on $\hat{g}(x)$, the estimated probability of detection at distance x ignoring the effect of cluster size, and then predict $\log s$ when detection is certain, $\hat{g}(x) = 1$, as there can be no size bias in that circumstance. The prediction is back-transformed using a bias adjustment.

Assumptions

The physical setting for line transect sampling is idealized as below:

1. N objects are distributed through an area of size A according to some **stochastic process** with average rate parameter $D = N/A$.
2. Lines, placed according to some randomized design (*see* **Randomization**), are surveyed and a sample of n objects is detected.

It is not necessary that the objects be randomly (i.e. **Poisson**) distributed. Rather, it is critical that the line

or point be placed randomly with respect to the local distribution of objects. This ensures that objects in the surveyed strip are uniformly distributed with distance from the line. Thus if the strip has half-width w, animal-to-line distances available for detection are **uniformly distributed** between zero and w.

Three assumptions are essential for reliable estimation of density using standard line transect methods:

1. Objects directly on the line are always detected, $g(0) = 1$.
2. Objects are detected at their initial location, prior to any movement in response to the observer.
3. Distances are measured accurately (for ungrouped distance data), or objects are correctly allocated to distance interval (for grouped data).

A fourth assumption is made in many derivations of estimators and variances: whether an object is detected is independent of whether any other object is detected. Point estimates are **robust** to the assumption of independence, and robust variance estimates are obtained by taking the line to be the sampling unit, either by bootstrapping on lines, or by calculating a weighted sample variance of encounter rates by line.

It is also important that the detection function has a "shoulder"; that is, probability of detection remains at or close to one initially as distance from the line increases from zero. This is not an assumption, but a property that allows more reliable estimation of object density.

Point Transect Sampling

In point transect sampling, an observer visits a number of points, the locations of which are determined by some randomized design. The method is usually (but not exclusively) used for songbird populations, in which typically many species are recorded, and most detections are aural. By recording from points, the observer can concentrate on detecting the objects of interest, without having to navigate along a line, and without having to negotiate a randomly positioned line through possibly difficult terrain. The principal disadvantages are that detections made while traveling from one point to the next are not utilized, a problem especially for scarce species, and the method is unsuited to species that are generally detected by flushing them, or to species that typically change their location appreciably over the time period of a count (generally around 3–10 minutes).

Estimation

Detection distances r are measured from the point to each detected object of interest (usually a bird or a small group of birds). Suppose the design comprises k points, and distances $\leq w$ are recorded. Then the surveyed area is $a = k\pi w^2$, within which n objects are detected. As for line transect sampling, denote the probability that an object within the surveyed area is detected by P_a with estimate $\hat{P}_a$. Then we estimate object density D by

$$\hat{D} = \frac{n}{k\pi w^2 \hat{P}_a}. \tag{8}$$

We now define the detection function $g(r)$ to be the probability that an object at distance r from the point is detected, and we again assume that $g(0) = 1$. For line transects, the area of an incremental strip at distance x from the lines is $L\,\mathrm{d}x$, independent of x, which leads to the result that the probability density function of distances differs from the detection function only in scale. By contrast, an incremental annulus at distance r from a point has area $2\pi r\,\mathrm{d}r$, proportional to r, so that the probability density function of detection distances is $f(r) = 2\pi r g(r)/\nu$, where $\nu = 2\pi \int_0^w r g(r)\,\mathrm{d}r$. The respective shapes of the two functions are illustrated in Figure 4. If we define an effective radius ρ, analogous to the effective strip width of line transect sampling, then $\nu = \pi\rho^2$ is the effective area surveyed per point (Figure 5). Hence

$$\hat{D} = \frac{n}{a \times \hat{P}_a} = \frac{n}{k\pi w^2 \times \pi\hat{\rho}^2/\pi w^2} = \frac{n}{k\hat{\nu}}. \tag{9}$$

The area of the triangle in Figure 5 is $\rho^2 f'(0)/2$ where $f'(0)$ is the slope of $f(r)$ at $r = 0$. Since this is equal to the area under $f(r)$, which is unity, it follows that $\nu = \pi\rho^2 = 2\pi/f'(0)$, and

$$\hat{D} = \frac{n\hat{f}'(0)}{2\pi k}. \tag{10}$$

We therefore need to model the probability density function of detection distances, and evaluate the slope of the fitted function at $r = 0$. Distance does this using the same set of models for the detection function as for line transect sampling.

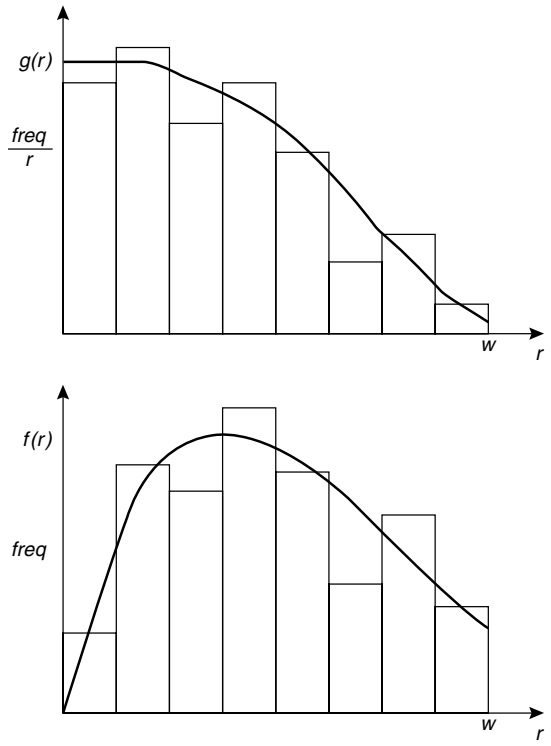

Figure 4 Histograms of detection distances from a point transect survey. In the upper plot, each histogram frequency has been scaled by dividing by the midpoint of the corresponding group interval. Also shown are the corresponding fits of the detection function [$g(r)$, upper plot] and the probability density function of detection distances [$f(r)$]

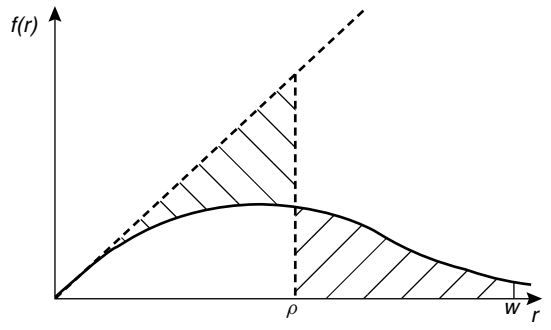

Figure 5 The probability density function of detection distances, $f(r)$. The area under the curve is unity by definition. Because the two shaded areas are equal in size, the area of the triangle, $\rho^2 \times f'(0)/2$, is also unity. Hence $\nu = \pi\rho^2 = 2\pi/f'(0)$

Variance and Interval Estimation

The methods for variance and interval estimation for line transect sampling apply also to point transects with minor modifications. In the case of the bootstrap, resampling is normally carried out by sampling with replacement from the points. However, point transect surveys are often designed by defining a series of lines, as if a line transect survey is to be carried out, then locating a series of points along each line. If the distance between neighboring points on the same line is smaller than the distance between neighboring points on different lines, then resampling should be carried out by sampling lines with replacement. If a line is selected, then all the points associated with that line are included in the bootstrap resample.

Assumptions

Assumptions are virtually unchanged from those given for line transect sampling. As there, the standard analyses are very robust to failure of the assumption of independent detections, but if objects occur in clusters, so that when one of the cluster is detected they all are, then the cluster is generally taken to be the object, and mean cluster size in the population is estimated using the same techniques as for line transect sampling. Point transect sampling is more subject to bias than line transect sampling when objects move through the area around a point. In principle, we try to obtain a snapshot, locating each object at the position it occupied when the count at that point started. However, the count is not instantaneous, because the observer needs time to detect all objects close to that point. If, during that time, movement brings new objects into the neighborhood of the point, then object density will be overestimated.

Current Research

Double platform methods are becoming commonplace in sightings surveys for whales. Observers search simultaneously from two platforms. This allows extension of the standard methods to the case that $g(0) < 1$, and also, given appropriate field methods, allows adjustment for responsive movement of animals prior to detection. There have been advances by several researchers recently in developing methodology for analyzing such data. Perhaps the most promising approach, based on **Horvitz–Thompson-type estimators** [2], has also

led to a unified approach to the analysis of line transect data, in which object density is estimated in a single step, which contrasts with the conventional strategy of independently estimating the three parameters: encounter rate, effective strip width, and mean cluster size.

Generally, probability of detection is a function of many factors other than distance of the object from the line or point. We have considered briefly one other factor, cluster size, because if we do not allow for size bias in detection, then our object density estimator will be biased. Other sources of heterogeneity contribute little to bias, provided $g(0) = 1$, but nevertheless, higher precision might be anticipated if additional **covariates** are recorded and their effects on $g(x)$ modeled. Ramsey et al. [9] modeled effective area surveyed as a function of covariates using **generalized linear modeling** methods. Again, a Horvitz–Thompson formulation provides a natural framework for estimation, if probability of detection is modeled as a function of relevant covariates.

The global spatial coordinates of detections are often recorded in distance sampling surveys so that spatial modeling of density surfaces is possible. Very little has been done on this problem (but see [6]); rather, current practice is simply to estimate average density by strata.

Distribution-free Methods for Longitudinal Data

Repeated measure designs are used in many areas of application and are especially common in biomedical research. The characteristic feature of such studies is that multiple measurements of a response variable are obtained from each independent experimental unit. The repeated measures may be obtained at a set of scheduled time points for each subject or experimental unit. In other applications the response from each experimental unit is measured under multiple conditions, rather than at multiple time points.

There are two main difficulties in the analysis of data from repeated measure designs. First, the analysis is complicated by the dependence among repeated observations made on the same experimental unit. Secondly, the investigator often cannot control the circumstances for obtaining measurements, so that the data may be unbalanced or partially incomplete.

Many approaches to the analysis of data from repeated measure designs have been studied; see, for example, the 1980 review and bibliography of parametric and nonparametric approaches by Koch et al. [28]. When the response variable is normally distributed, classical **multivariate analysis** techniques, repeated measures analysis of variance (*see* **Analysis of Variance for Longitudinal Data**), growth curve analysis (*see* **Nonlinear Growth Curve**), and mixed effects models can be used. The development of methods for the analysis of repeated measures categorical data, for binary, polytomous, and ordered categorical response variables, is also an important area of research (*see*, in particular, **Multivariate Methods for Binary Longitudinal Data**). In addition, recently developed **generalized estimating equations** approaches based on extensions of **generalized linear model** methodology can be applied to a wide variety of types of continuous and categorical response variables with marginal (univariate) distributions from the class of generalized linear models.

While all of the above methods require assumptions on either the joint or the marginal distributions of the response variable, there are at least three situations in which distribution-free methods may be useful (*see* **Nonparametric Methods**). First, when the response is continuous, the assumption of **multivariate normality** may not be reasonable, or the underlying distribution may be unknown. In this case, the use of standard parametric procedures may not be justified. Secondly, when the response is an ordered categorical variable with a large number of possible outcomes, the general categorical data methods may be inapplicable owing to sample size limitations. In addition, the restrictive proportional-odds assumption underlying some of the approaches for analyzing ordered categorical repeated measures may not be justified. Apart from these considerations, there are also situations in which it may be desirable to confirm the results of a parametric analysis using distribution-free methods.

Table 1 displays the general layout and notation for a repeated measures design with n subjects (experimental units) and t_i measurement times for the ith subject, $i = 1, \ldots, n$. The response from subject i at time j is y_{ij} and $\mathbf{x}_{ij} = (x_{ij1}, \ldots, x_{ijp})'$ is the corresponding $p \times 1$ vector of covariates. In general, the covariates can be a mixture of time-independent (between-subject) covariates and time-dependent (within-subject) covariates. Since values of the response variable and/or covariates might be

Table 1 Layout and notation for a general repeated measures design

Subject	Time point	Missing indicator	Response	Covariates		
1	1	δ_{11}	y_{11}	x_{111}	$\ldots$	x_{11_p}
	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
	j	δ_{1j}	y_{1j}	x_{1j1}	$\ldots$	x_{1jp}
	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
	t_1	δ_{1t_1}	y_{1t_1}	x_{1t_11}	$\ldots$	x_{1t_1p}
$\ldots$						
i	1	δ_{i1}	y_{i1}	x_{i11}	$\ldots$	x_{i1_p}
	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
	j	δ_{ij}	y_{ij}	x_{ij1}	$\ldots$	x_{ijp}
	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
	t_i	δ_{it_i}	y_{it_i}	x_{it_i1}	$\ldots$	x_{it_ip}
$\ldots$						
n	1	δ_{n1}	y_{n1}	x_{n11}	$\ldots$	x_{n1_p}
	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
	j	δ_{nj}	y_{nj}	x_{nj1}	$\ldots$	x_{njp}
	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
	t_n	δ_{nt_n}	y_{nt_n}	x_{nt_n1}	$\ldots$	x_{nt_np}

missing, it may be convenient to define indicator variables δ_{ij} by

$$\delta_{ij} = \begin{cases} 1, & \text{if } y_{ij} \text{ and } \mathbf{x}_{ij} \text{ are observed,} \\ 0, & \text{otherwise.} \end{cases}$$

One simplification of the general notation displayed in Table 1 is the case when every subject has the same fixed set of measurement times, so that $t_i = t$, for $i = 1, \ldots, n$. The situation is also simplified when there are no missing data. A special case which has been studied extensively from the distribution-free perspective is the multisample setting in which repeated measurements are obtained from samples from s subpopulations. The s groups may be defined by the s levels of a single covariate or by the cross-classification of several discrete covariates. In terms of the general notation, the s groups can thus be described in terms of $p = s - 1$ dichotomous, time-independent covariates. In this setting, the notation of Table 2 is useful, in which y_{hij} denotes the response at time j from subject i in group h, for $j = 1, \ldots, t$, $i = 1, \ldots, n_h$, and $h = 1, \ldots, s$.

In the case of repeated measurements obtained at t time points from each of n subjects from a single sample, the data can be displayed even more simply in an $n \times t$ matrix, as shown in Table 3. As before, missing value indicators can be defined by

$$\delta_{ij} = \begin{cases} 1, & \text{if } y_{ij} \text{ is observed,} \\ 0, & \text{otherwise.} \end{cases}$$

Univariate Methods

The simplest approach to repeated measures is to reduce the vector of responses from each subject or experimental unit to a single measurement. This avoids the issue of **serial correlation** among the repeated measures for each subject. Several authors [39, 35, 20, 16] refer to these types of methods as the "summary statistic approach" (*see* **Summary Measures Analysis of Longitudinal Data**). Crowder & Hand [11] and Diggle et al. [17] call such methods "response feature analysis" and "derived variable analysis", respectively. The univariate function of the repeated measures from each subject can then be analyzed using distribution-free methods.

For example, in the one-sample setting (Table 3), interest may focus on assessing the extent of association between the response variable and the repeated measures factor. If the Spearman **rank correlation** coefficient between the response variable and the repeated measures variable is used as the summary statistic for each subject, then the **sign test** or the **Wilcoxon signed-rank test** can be used to test if the median of the distribution of the summary statistic is equal to zero. In the multisample setting (Table 2), similar methods can be used. For example, the Mann–Whitney–Wilcoxon (if $s = 2$) or Kruskal–Wallis ($s > 2$) test (*see* **Nonparametric Methods**) can be used to assess if the distribution of the summary statistic is the same across the s groups.

While the summary statistic approach can be useful in certain situations, a shortcoming is that the results may be misleading if the selected univariate summary measure does not adequately describe each subject's data. Ghosh et al. [21] describe multivariate nonparametric methods based on the use of two or more summary statistics for each subject. This extension of the univariate summary statistic approach may be useful when multiple univariate statistics are necessary to adequately summarize each subject's data. Carr et al. [9] describe a different type of multivariate approach based on summary statistics. They consider the situation in which an ordered categorical or interval response variable is measured at multiple time points for each subject in two or more ordered groups. Rank measures of association between group and response are constructed at each time point; the estimated **covariance matrix** of these summary measures is then used to test hypotheses concerning the rank measures of association.

Multivariate Generalizations of Univariate Distribution-Free Methods

Standard asymptotically distribution-free tests for multivariate one-sample and multisample problems can also be used in the repeated measures setting. These rank-based methods are appropriate for samples from continuous multivariate distributions.

For the one-sample case with complete data, Hettmansperger [23, Chapter 6] and Puri & Sen [41, Chapter 4] study multivariate generalizations of the sign and Wilcoxon signed rank tests (*see* **Multivariate Median and Rank Sum Tests**). In the repeated measures setting of Table 3 with no missing data, let θ_t denote the median of the marginal distribution of the response at time t. By transforming each of the n t-component vectors $\mathbf{y}_i = (y_{i1}, \ldots, y_{it})'$ to a $(t-1)$-component vector of differences $\mathbf{y}_i^* = (y_{i1} - y_{i2}, \ldots, y_{i,t-1} - y_{it})'$, these methods can then be used to test the null hypothesis that $\theta_1 = \cdots = \theta_t$.

Hettmansperger [23] also considers the two-sample situation with complete data; the test statistic is a multivariate version of the Wilcoxon–Mann–Whitney test. Puri & Sen [41, Chapter 5] discuss multivariate generalizations of the Kruskal–Wallis [29] and Brown–Mood [8] tests for the multivariate multisample situation with complete data. On the basis of these results, Schwertman [43] gives a computer algorithm for two of these tests, the multivariate multisample rank test and the multivariate multisample median test. These methods can be applied to the repeated measures setting of Table 2. Let $F_h(\mathbf{u})$ denote the t-variate cumulative distribution function (cdf) in group h, for $h = 1, \ldots, s$, where $\mathbf{u} = (u_1, \ldots, u_t)'$. Assume that the cdfs F_h have a common unspecified form with possible differences in their location (or scale) parameters (*see* **Location–Scale Family**). For example, suppose that $F_h(\mathbf{u}) = F(\mathbf{u} + \boldsymbol{\Delta}_h)$, where $\boldsymbol{\Delta}_h = (\Delta_{h1}, \ldots, \Delta_{ht})'$. The null hypothesis of no difference among groups across all time points tests $\mathrm{H}_0 : \boldsymbol{\Delta}_1 = \ldots, \boldsymbol{\Delta}_s = (0, \ldots, 0)'$. The omnibus alternative hypothesis is that $\boldsymbol{\Delta}_1, \ldots, \boldsymbol{\Delta}_s$ are not all equal. Schwertman [44] describes this approach in further detail and gives an example of its application to the analysis of repeated measurements.

Randomization Tests

In the one-sample repeated measures setting (Table 3), a **randomization test** based on the use of **Mantel–Haenszel methods** can be used to test the null hypothesis of no association between a repeated measurement factor and a response variable, adjusting for the effect of subject. The randomization model approach applies to categorical or continuous outcome variables y_{ij}, requires no distributional assumptions, and is useful in small samples. Landis et al. [32] give a general overview of the three types of Mantel–Haenszel statistics; Landis et al. [33] and Crowder & Hand [11, Section 8.6] describe the use of these procedures in analyzing repeated measures.

The basic idea underlying the Mantel–Haenszel randomization model approach to one-sample repeated measures is to restructure the $n \times t$ data matrix of Table 3 as follows. First, let c denote the number of distinct values of the response y_{ij}. If the response variable is categorical with a limited number of possible values, then c will be relatively small. At the other extreme, if each of the n subjects has a unique response at each time point, then $c = nt$. Now define indicator variables

$$n_{ijk} = \begin{cases} 1, & \text{if subject } i \text{ is classified in response category } k \text{ at time } j, \\ 0, & \text{otherwise,} \end{cases}$$

Table 4 Contingency table layout for subject i in the one-sample repeated measures design

	Response category			
Time point	1	...	c	Total
1	n_{i11}	...	n_{i1c}	n_{i1+}
⋮	⋮	⋱	⋮	⋮
t	n_{it1}	...	n_{itc}	n_{it+}
Total	n_{i+1}	...	n_{i+c}	n_i

for $i = 1, \ldots, n$, $j = 1, \ldots, t$, and $k = 1, \ldots, c$. The data from subject i can then be displayed in a $t \times c$ **contingency table**, as shown in Table 4. Thus, the data from a one-sample repeated measures study can be viewed as a set of n independent $t \times c$ contingency tables.

When the data are complete, i.e. the outcome variable is measured at every time point for each subject, the total sample size for each of the n tables is $n_i = t$ and every row marginal total n_{ij+} is equal to one. In this case, each row of Table 4 has exactly one n_{ijk} value equal to one and the remaining values are equal to zero. If, however, a particular subject has a missing response at one or more time points, then the corresponding row of the subject's table will have each n_{ijk} value, as well as the marginal total n_{ij+}, equal to zero. The total sample size n_i will then equal t minus the number of missing observations.

In the framework of Table 4, Mantel–Haenszel statistics can be used to test the null hypothesis of no association between the row dimension (time) and the column dimension (response), adjusted for subject. Under the assumption that the marginal totals $\{n_{ij+}\}$ and $\{n_{i+k}\}$ of each table are fixed, the null hypothesis is that, for each subject, the response variable is distributed at random with respect to the t time points. As discussed in Landis et al. [32], this null hypothesis is precisely the interchangeability hypothesis of Madansky [34]. In turn, the hypothesis of interchangeability implies marginal homogeneity in the distribution of the response variable across the t time points. Although the interchangeability hypothesis is a somewhat stronger condition than marginal homogeneity, the Mantel–Haenszel general association statistic [with $(t-1)(c-1)$df], mean score statistic (with $t-1$df), and correlation statistic (with 1 df) are directed at alternatives that correspond to various types of departures from marginal homogeneity.

Several common nonparametric test procedures are special cases of Mantel–Haenszel randomization model tests. These include the tests of Friedman [19], Durbin [18], Benard & van Elteren [6], and Page [37], as well as the aligned ranks test introduced by Hodges & Lehmann [24] and further studied by Koch & Sen [27]. Randomization tests for other types of repeated measures situations have also been studied. For example, Zerbe & Walker [52] and Zerbe [50, 51] developed randomization tests for the multisample situation of Table 2. These procedures can be used to test the equality of s mean growth curves over a specified time interval.

Other Methods

Asymptotically distribution-free analogs of parametric procedures for normally distributed outcomes have also been studied. Bhapkar [7] discusses nonparametric counterparts of **Hotelling's T^2** statistic and profile analysis (*see* **Longitudinal Data Analysis, Overview**). Sen [45] studies nonparametric analogs of the Potthoff & Roy [40] growth curve model.

Distribution-free methods for the two-sample case (Table 2 with $s = 2$) when the data are incomplete were studied by Wei & Lachin [49] and Wei & Johnson [48]. These approaches allow the missing value patterns in the two samples to be different, but require the assumption that the missing value mechanism is independent of the response. Wei & Lachin [49] study a family of asymptotically distribution-free tests for equality of two multivariate distributions. Although their methodology was motivated and developed for multivariate censored failure time data, an important application is to repeated measures with missing observations. The Wei–Lachin methodology is based on a random-censorship model and they focus on an omnibus test of equality vs. a general alternative. In contrast, Wei & Johnson [48] focus primarily on optimal methods of combining dependent tests and propose a class of two-sample nonparametric tests for incomplete repeated measures based on two-sample **U statistics**. Davis [12, 13] provides further discussion of these methods and a computer program. Lachin [31] proposes additional test statistics and provides estimators of the treatment difference, Palesch & Lachin [38] extend these methods to more than two groups, and Thall & Lachin [46], Davis & Wei [15], and

Davis [14] study related methods for special types of situations with incomplete data.

Another potential approach to the analysis of repeated measures when the underlying parametric assumptions are not satisfied is the **rank transform** method, which consists of replacing observations by their ranks and performing a standard parametric analysis on the ranks [10]. Unfortunately, the rank transform method has been shown to be inappropriate for many common hypotheses [2, 3]. Thompson [47] and Akritas & Arnold [4] provide valid asymptotic tests based on the rank transform for selected hypotheses of interest in several repeated measures models. Kepner & Robinson [25] consider the one-sample situation of Table 3 under the assumption that the repeated measurements y_{ij} from the ith subject are equally correlated. They show the relationships between the rank transform method and the rank tests of Agresti & Pendergast [1] and Koch [26] for testing the null hypothesis of no time effect, expressed as $H_0 : F(x_1, \ldots, x_t) = F(x_{\alpha(1)}, \ldots, x_{\alpha(t)})$, where $F(x_1, \ldots, x_t)$ is the t-variate distribution of the data vectors $\mathbf{y}_1, \ldots, \mathbf{y}_n$ and $[\alpha(1), \ldots, \alpha(t)]$ is any permutation of the first t positive integers.

Müller [36], Diggle et al. [17, Chapter 3], and Kshirsagar & Smith [30, Chapter 10] discuss **nonparametric regression** methods for the analysis of repeated measurements, including kernel estimation, weighted local **least squares** estimation, and smoothing splines. Hart & Wehrly [22] study the theoretical properties of kernel regression estimation for repeated measures and show how the case of correlated errors changes the behavior of a kernel estimator; Altman [5] demonstrates that the standard techniques for bandwidth selection perform poorly when the errors are correlated. Raz [42] describes an analysis procedure for repeated measurements that combines nonparametric regression methods and the randomization tests of Zerbe [50].

Examples

Repeated Measures from a Single Population

As part of a protocol for the University of Iowa Mental Health Clinical Research Center, 44 schizophrenic patients participated in a four-week antipsychotic medication washout. The severity of extrapyramidal side effects was assessed just prior to discontinuation of antipsychotic medication and at weeks 1, 2, 3, and 4 during the washout period (*see* **Psychometrics, Overview**). Table 5 displays the resulting ratings on the Simpson Angus (SA) scale; a few missing values are denoted by a dash. The marginal distributions of the scores are clearly nonnormal.

Table 5 Simpson Angus ratings for 44 schizophrenic patients

Patient	Week 0	Week 1	Week 2	Week 3	Week 4
1	1	4	0	0	0
2	4	5	8	9	3
3	1	2	2	1	1

43	0	0	0	0	0
44	1	0	2	1	1

The summary statistic approach is one possible method of testing if there is an association between SA ratings and measurement week. When the Spearman rank correlation coefficient between SA rating and week is computed for each subject, the correlation coefficients range from -1 to 0.8. Of the 32 nonzero correlations, eight are positive and 24 are negative. On the basis of the sign test, the exact two-sided P value is 0.007. Using the Wilcoxon signed rank test, the sum of the ranks corresponding to positive correlations is 103 and the sum of the ranks of negative correlations is 425. The normal approximation to the distribution of the Wilcoxon statistic yields $P = 0.003$. Both tests indicate the tendency of scores to decrease over time.

The randomization model approach using the Mantel–Haenszel mean score and correlation statistics is also applicable. Using within-subject rank scores for the SA rating, the Mantel–Haenszel mean score χ^2 statistic is 13.674 with 4 df ($P = 0.008$); thus, there is substantial evidence that the distributions are not the same at the five measurement times. Using rank scores for the SA rating and the scores 0, 1, 2, 3, and 4 for the five measurement times, the Mantel–Haenszel correlation statistic is 10.375 with 1 df ($P = 0.001$). This result indicates that there is a consistent monotonic association between SA rating and week across subjects. Both of these methods use all available data from each subject.

Repeated Measures from Two Populations

Table 6 displays plasma inorganic phosphate measurements obtained from 13 control and 20 obese patients 0, 0.5, 1, 1.5, 2, and 3 hours after an oral glucose challenge [50]. The sample means are plotted in Figure 1. Since the relationship between plasma inorganic phosphate level and time is not monotonic, the univariate approach using slopes or correlation coefficients seems inappropriate. Zerbe [50] compared the two groups over the period from 0 to 3 hours using his randomization analysis of growth curves and reported a P value of 0.002.

The two groups can also be compared using the multivariate nonparametric tests of Puri & Sen [41]. Using the multivariate multisample rank sum test, the χ^2 statistic is 21.5 with 6 df ($P < 0.001$). The multivariate multisample median test gives a less significant result ($\chi^2 = 16.2$, df $= 6$, $P = 0.013$).

Table 6 Plasma inorganic phosphate levels in 13 control and 20 obese patients

		Hours after glucose challenge					
Group	Patient	0	0.5	1	1.5	2	3
Control	1	4.3	3.3	3.0	2.6	2.2	2.5

Although the Wei–Lachin [49] and Wei–Johnson [48] procedures were developed for the two-sample case with incomplete data, these procedures can also be applied. The Wei–Lachin vector of test statistics at the six time points is $\mathbf{W}' = (-0.5539, -0.8862, -1.0761, -0.9390, -0.1319, -0.0633)$ with estimated **covariance matrix**

$$\hat{\boldsymbol{\Sigma}} = \begin{pmatrix} 0.080180 & 0.047379 & 0.065353 & 0.062623 & 0.031898 & 0.042313 \\ 0.047379 & 0.088898 & 0.052950 & 0.028881 & 0.014827 & 0.013615 \\ 0.065353 & 0.052950 & 0.095713 & 0.062215 & 0.002469 & 0.021214 \\ 0.062623 & 0.028881 & 0.062215 & 0.093537 & 0.031306 & 0.045055 \\ 0.031898 & 0.014827 & 0.002469 & 0.031306 & 0.071744 & 0.049681 \\ 0.042313 & 0.013615 & 0.021214 & 0.045055 & 0.049681 & 0.075706 \end{pmatrix}$$

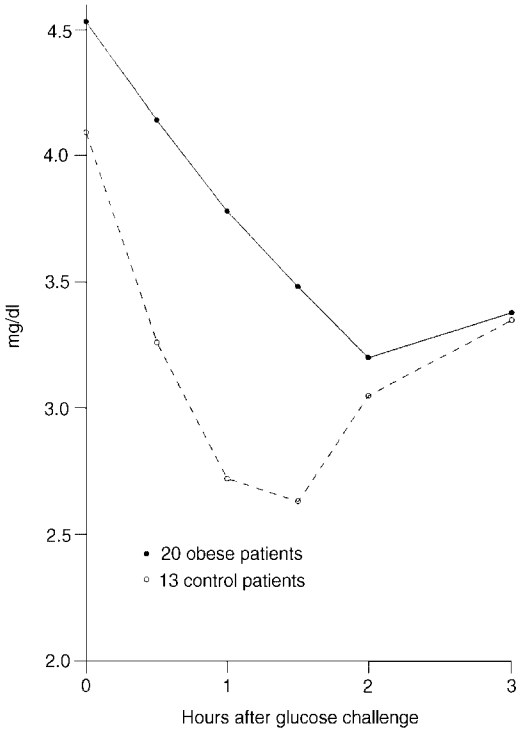

Figure 1 Mean plasma inorganic phosphate levels

The Wei–Lachin omnibus χ^2 statistic for testing equality of distributions is $\mathbf{W}'\hat{\mathbf{\Sigma}}^{-1}\mathbf{W} = 20.9$ with 6 df ($P = 0.002$). The Wei–Johnson procedure using the "kernel" function

$$\phi(x, y) = \begin{cases} 1, & \text{if } x > y, \\ 0, & \text{if } x = y, \\ -1, & \text{if } x < y, \end{cases}$$

gives a vector $\mathbf{U}$ of test statistics equivalent (apart from a scale factor) to the Wei–Lachin $\boldsymbol{W}$, but uses a different estimator of the covariance matrix. Weighting each time point equally, the Wei–Johnson univariate statistic $\mathbf{c}'\mathbf{U}/(\mathbf{c}'\widehat{\mathbf{\Sigma}}_{\mathbf{U}}\mathbf{c})^{1/2}$, with $\mathbf{c}' = (1, \ldots, 1)$, is equal to -2.21. With reference to the standard normal distribution, the two-sided P value is 0.027.

DNA Sequences

The hereditary information of essentially all living organisms is carried by DNA molecules made up of complementary chains of nucleotides twisted around each other into a double-helical structure (Figure 1). The four possible nucleotides are the two purines, adenine (A) and guanine (G), and the two pyrimidines, cytosine (C), and thymine (T). As the first step in the synthesis of proteins, DNA is transcribed to RNA which is usually single-stranded and uses the nucleotide uracil (U) in place of thymine. The primary data on the composition of these molecules are then sequences of nucleotides presented in a four-letter alphabet (A, C, G, or T/U). The ability of molecular biologists to generate nucleotide sequences rapidly has created many new areas of biomedical research and fundamentally changed the focus of many others. The most important technology to facilitate rapid sequencing over the past decade has been the polymerase chain reaction (pcr) technique which was first described in the early 1970s [16] but not made practicable as a standard laboratory technique until the late 1980s [18]. In pcr amplification, two primers that flank the region to be sequenced are used to initiate the reaction. Alternating applications of heat which "melts" the DNA into a single stranded state, followed by slow cooling in the presence of synthetic nucleotides, allow for a heat-stable polymerase to catalyze the synthesis of new DNA. With each cycle, duplicates of the copies of the DNA bridging the two primers are created until they dominate the mixture and can be easily sequenced.

Databases with nucleotide sequences have grown exponentially in size – the most widely used database being GenBank, maintained by the National Center for Biotechnology Information of the US National Library of Medicine, which at this writing contains about a half-billion nucleotides from a half-million sequences. New technologies, such as the use of hybridization techniques to produce "DNA sequencing chips", promise to increase the rate that data are generated by another order of magnitude.

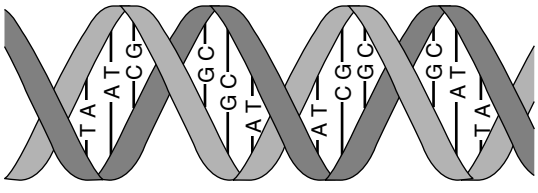

Figure 1 The DNA double helix. Each strand carries equivalent information because of the A:T, G:C pairing across strands

The statistical analysis of nucleotide sequences involves a collection of interrelated, and computationally intensive, problems which have been attacked somewhat in isolation. These include the problem of assembling a single sequence from many overlapping partial sequences, developing **stochastic models** of molecular evolution, aligning homologous combinations of sequences, and studying the common evolutionary history of a large group of sequences.

The Sequencing Chip

The process of assembling DNA sequences has led to many interesting problems in combinatorics [28]. Consider, for instance, the recent proposal to use hybridization techniques to find all distinct k-tuple fragments (i.e. subsequences of k nucleotides) that exist within the chain to be reconstructed. This requires the use of a "DNA sequencing chip" which is typically a matrix of 4^k probes [20]. For example, if $k = 5$ and the (unknown) sequence being constructed is TACGGAACGGAT, then the hybridized 5-tuples specified by the chip will be TACGG, ACGGA, CGGAA, GGAAC, GAACG, AACGG, and CGGAT. Note that the chip cannot tell us that the 5-tuple ACGGA appeared twice in the sequence. The problem is to reconstruct the full sequence from the observed k-tuples. To do this, a graph is formed with directed edges connecting two observed k-tuples if the first $k-1$ letters of one are equal to the last $k-1$ letters of the other. The possible full sequences are then represented by paths connecting all observed k-tuples. Reconstructing long sequences with many repetitive features is obviously a daunting task. However, the sequencing chip idea has recently become more practicable as a general tool with the current production of chips reading all 10-tuples in a sequence. Also, the specialized use of "designer chips" with a variety of different sized fragments geared toward a specific application is already a reality in some laboratories [11].

Models of Sequence Evolution

Stochastic models of molecular evolution typically assume that evolution proceeds independently at each nucleotide site via homogeneous **Poisson** substitution models. Specifically, assume that during a small increment of time $(t, t+h)$, (i) the **probability** that a substitution changes the nucleotide i into nucleotide j has probability $q_{ij}h + o(h)$, (ii) the probability that no substitution occurs at a site currently occupied by the nucleotide i is $1 - \sum_{j \neq i} q_{ij}h + o(h)$, and (iii) the probability that two or more substitutions occur is $o(h)$. This gives the framework for the models studied by Rodriquez et al. [21]. The specific form of the model is fixed by the instantaneous rate matrix, $\mathbf{Q}$, which has off-diagonal elements q_{ij} and diagonal elements $-\sum_{j \neq i} q_{ij}$ (i.e. each row sums to zero). The elements of the matrix $\mathbf{P} = \exp(t\mathbf{Q})(= \sum_{n=0}^{\infty}(\mathbf{Q}^n t^n / n!)$, where $\mathbf{Q}^0$ is the 4×4 identity matrix) then provide the transition probabilities for a single site:

$$P_{ij}(t) = \Pr[\text{nucleotide } j \text{ at time } t | \text{nucleotide } i \text{ at time } 0].$$

The simplest model of this type was introduced by Jukes & Cantor [14] and makes all of the $q_{ij}s (i \neq j)$ identical, say $= \alpha$. Under this model we can derive the explicit expression:

$$P_{ij}(t) = \begin{cases} \dfrac{1 + 3\exp(-4\alpha t)}{4}, & \text{if } i = j, \\ \dfrac{1 - \exp(-4\alpha t)}{4}, & \text{if } i \neq j. \end{cases}$$

If two sequences evolved independently for a time t from a common ancestor, then there is $2t$ time between them and $\theta = \Pr[\text{two sequences are different at a single site}] = 3[1 - \exp(-8\alpha t)]/4$. Also, the expected number of substitutions that occurred along the two branches over this time t is $6\alpha t = -3/4 \ln(1 - 4/3\theta)$. Finally, we may substitute $\hat{\theta}$, the proportion of sites that differ between the two sequences, into this last expression to obtain the Jukes–Cantor distance between the sequences. Jukes & Cantor's one-parameter model was extended by Kimura [15] to allow for a different rate when the substitution is between two purines or between two pyrimidines than when the substitution is from one group to the other. Felsenstein [5] extended the Jukes–Cantor model in a different way by taking $q_{ij} = \pi_j / 4\alpha$, where π_j is the stationary probability of observing nucleotide j at any site. The Kimura and Felsenstein models were combined into the five-parameter model investigated by Hasegawa et al. [12]. Distance measures between sequences can be based on any of these models using a procedure analogous to the one above based on the Jukes–Cantor model. Also, each of these widely used models is time reversible so that the probability of a change from nucleotide i to j is the same as the probability of a change from j to i [i.e. $\pi_i P_{ij}(t) = \pi_j P_{ji}(t)$]. This property makes the direction of time irrelevant, which is helpful in **likelihood**-based phylogenetic analysis. Site independent substitution models with more than five parameters have generally been found to overfit the empirical data. To describe sequence evolution more accurately it is important to account for other complexities – the most discussed being: (i) allowance for the insertion or deletion of nucleotides, singly or in groups; (ii) allowance for time heterogeneity in rate parameters; (iii) allowance for different rates when the amino acid structure in protein coding sequences is changed by a substitution; (iv) allowance for **linkage** between sites; and (v) allowance for recombination events.

Aligning Sequences

Suppose that two sequences are thought to be homologous in some way, for example they might be for the same **gene** from two different species. In the pairwise alignment problem we wish to designate which are the corresponding sites in the two sequences to be related. As an illustration, consider the following two short sequence segments of the 28S rRNA gene from the human and the carp:

site	`123456789··········`
human	`CGGCAAGGCTTCCCTGCCGG`
carp	`CGGTCAAGCCTTCCCTCCGG`

The alignment implied by this way of arranging these two sequences requires at least seven substitutions to have occurred in their common history (the C/T change in site 4, the A/C change in site 5, etc.). However, if we use a model of evolution that also allows for insertions and deletions of nucleotides, the

following alignment becomes possible:

site	123456789·····
human	CGG-CAAGGCTTCCCTGCCGG
carp	CGGTCAAGCCTTCCCT-CCGG

This alignment requires two gaps (insertions or deletions denoted by a "-") but only one substitution (the G/C change at site 9). If insertions or deletions are common, then the second alignment should be preferred, but if they are rare, then gaps should be heavily penalized and the first alignment may be preferred. The choice of alignment then depends on a score function that specifies appropriate weights for different types of substitutions and gaps.

To give the problem a more mathematical framework, suppose the sequence **a**, which has nucleotide a_i at position i for $i = 1, \ldots, N$, is to be aligned with sequence **b**, which has nucleotide b_j at position j for $j = 1, \ldots, M$. The problem is to produce optimal sequences **a*** and **b***, each of length $K \geq \max\{N, M\}$, whose elements are either gaps or the original elements of **a** and **b**. A typical criterion for optimization is the function $\sum_{k=1}^{K} \delta(a_k^*, b_k^*)$. The score function δ may be a measure of similarity (the maximum is optimal) or of distance (the minimum is optimal) between the sequences.

Next, define $S(n, m)$ to be the optimal (say maximum) score aligning sequence **a** up to position n with sequence **b** up to position m. To find the optimal score, $S(N, M)$, for the global alignment of the two sequences, it is possible to use dynamic programming **algorithms** [1]. These are essentially based on the idea that the optimal alignment may be found through the appropriately initialized recursion:

$$\begin{aligned} S(n, m) = \max\{&S(n-1, m-1) + \delta(a_n, b_m), \\ &S(n-1, m) + \delta(a_n, \text{gap}), \\ &S(n, m-1) + \delta(\text{gap}, b_m)\}. \end{aligned}$$

Different dynamic programming algorithms have been proposed for different circumstances (see, for example, [19] for the 20-letter amino acid alphabet of protein sequences; [24] for the problem of finding local similarities). Typically, global alignment algorithms can be proven to produce an optimum in $O(K^2)$ time. Crucial to the implementation here is the decision of what scoring function, δ, is to be used. A simple choice is to take $\delta(x, y) = 1$ if $x = y \neq$ gap, α if x or $y =$ gap, and 0 otherwise. The choice of $\delta(x, y)$ can also be tied to a statistical model. In particular, take $\delta(x, y)$ to be the log of the probability that x is in sequence **a*** and y is in sequence **b*** at a particular site under a model of molecular evolution that assumes independence across sites. The resulting optimal alignment then maximizes the likelihood under this model (*see* **Maximum Likelihood**). Because the simultaneous insertion or deletion of several adjacent nucleotides is common in the evolution of some sequences, it is important to generalize the site independent models to allow for this possibility. In this regard, similarity-based score functions which are concave functions of the length of the gap can still be treated with efficient dynamic programming algorithms [17].

The problem of simultaneously aligning r sequences presents greater computational challenges since a dynamic programming algorithm leading to an exact solution takes $O((2K)^r)$ time. Suboptimal alignments are often found by various methods of merging all pairwise alignments. An alternative approach attempts to find the multiple alignment that is most compatible with a phylogenetic analysis [13, 29].

Instead of starting with sequences known to be homologous, sometimes a single target sequence is compared with a large library of sequences in a search for sequences that have a statistically significant degree of similarity with the target. This leads to a study of the probability distribution for independent sequences of alignment scores and of other measures of coincidence, such as the length of the longest exact match. Alignment procedures are also used extensively in sequence assembly procedures. For example, copying errors made during pcr can sometimes be eliminated by replicating the process several times and comparing the aligned results for differences. An excellent discussion of these problems and other computational, mathematical, and statistical aspects of alignment methodology may be found in [28].

Phylogenetic Analysis

Phylogenetic analysis tries to infer the evolutionary history that is most consistent with a set of observed nucleotide sequences. (Phylogenies are also commonly built from data on amino acids, from data on the allele's of specific genes, or from morphological data using procedures analogous to those described below.) Consider the aligned HIV-1

Table 1 Viral nucleotide sequences from five AIDS patients (84 bases in the TAT region)

Country	Sequence
Djibouti-1	CAGGAAGTCAGCCTAAAACTGCTTGTAATAAGTGTTATTGTAAAAAATGTAGCTATCATTGTCTAGTTTGCTTTCAGACAAAAG
Djibouti-2	**********C***A**
Zambia	*G**********CC**********G***T**********C*C***G*******TA*AC****
Brazil	**********AG****CC**T**C**********G***T***T******C*A******T**CACA*******
US	**********G**********CC**T**C**********G***T**CT******C*A******T**CACA*******
Uganda	**********C******C********T*G**********T**********A**********T**AC****
Cameroon	*T**G**CA****CC****CC******C***T**C*****C****G***CT**********-***TG**TG*****C*A*G***

Note: An asterisk (∗) designates the same nucleotide as the first patient from Djibouti.

sequences (from the TAT gene of the virus) of seven AIDS patients presented in Table 1.

We can see that the sequences from the two Djiboutian patients are very similar – indicating a recent common ancestry. However, the sequence from the Cameroonian patient is quite different from the others, indicating an earlier divergence. This evolutionary history is illustrated by means of a phylogenetic tree, such as the ones in Figure 2. The external nodes at the tips of the phylogenetic tree represent the current nucleotide sequences under consideration. The internal nodes represent ancestors of the current sequences. The trees in Figure 2 are both bifurcating (each node splitting into two branches) and show the same relative relationships among the seven sequences. In the rooted tree of Figure 2(a) evolutionary time proceeds from the root (the common ancestor of all nodes) at node 1 down to the current time. Whether rooted or unrooted, our interest lies in estimating key properties of the true underlying tree, especially (i) the branching structure or topology of the tree, and (ii) the lengths of the branches. The space of trees is very large; there are $\Pi_{k=2}^{n}(2k-3)$ possible distinct rooted topologies relating n sequences (when $n = 40$ this is already $> 10^{57}$).

The wide variety of methods used to estimate phylogenetic relationships generally fall into three categories: distance-matrix, **parsimony**, and maximum likelihood. Distance-matrix methods use pairwise distances to infer the tree. An early algorithm of this type is UPGMA, which is an unweighted recursive pairwise grouping method [25]. The neighbor-joining method [22] weights pairwise distances on the basis of their average distance from all other external nodes, while the Fitch–Margoliash procedure [9] minimizes a **chi-square**-like criterion measuring disagreement between the branch lengths of the tree

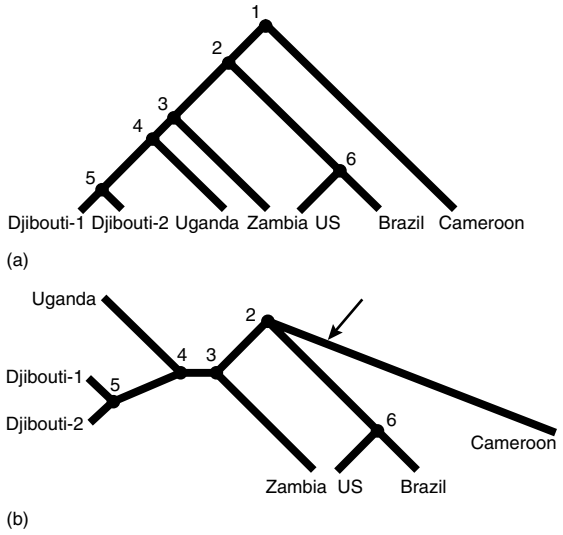

Figure 2 Two phylogenetic trees relating seven HIV-1 DNA sequences identified by country of origin: (a) a rooted tree; (b) an unrooted tree. The arrow indicates the hypothesized position of the root used to make tree (a)

and the corresponding observed distances. Distance-matrix methods are computationally very efficient, although important information may be lost in the reduction to pairwise distances.

Algorithms based on the parsimony concept attempt to minimize the number of evolutionary steps required to explain a given set of data. The idea was introduced for amino acid data by Eck & Dayoff [3] and for nucleotide sequences by Fitch [8]. As an example, the branching structure in Figure 2 is the most parsimonious for the HIV data in Table 1 – it explains the data using a total of 49 nucleotide base substitutions. Parsimony methods ignore the possibility of multiple substitutions at one site along the

same branch and have been shown to give inconsistent estimates of the true phylogeny [4]. However, parsimony methods that give weights to different types of events appear to improve the consistency and efficiency of the technique. Also, parsimony is the preferred method of analysis amongst researchers in cladistics, which concentrates on the branching relationships of species.

The maximum likelihood approach seeks to find the tree that maximizes the likelihood of the observed sequences under a particular model of the evolutionary process. Most algorithms require the stochastic model to be time-reversible and **Markovian** and to assume independence between sites. In this setting the log likelihood is summed across sites and the likelihood at an individual site is computed using Felsenstein's peeling algorithm [5]. In particular, define $L(i \text{at } j)$ to be the conditional likelihood of the subtree descending from node j given that nucleotide i is at j. The peeling algorithm is based on the observation that if node 1 is the parent of nodes 2 and 3 (with corresponding branch lengths t_{12} and t_{13}), then

$$L(i \text{at } 1) = \left\{ \sum_k P_{ik}(t_{12}) L(k \text{at } 2) \right\} \times \left\{ \sum_k P_{ik}(t_{13}) L(k \text{at } 3) \right\}.$$

Using this recursion, the likelihood is finally derived under the further assumption that the probability of each nucleotide being at the root node follows the stationary nucleotide distribution of the evolutionary model. Coincidentally, it turns out for the data of Table 1 that the maximum likelihood method using the Hasegawa–Kishino–Yano model gives the same topology as the parsimony method. The maximum likelihood method is **consistent** if the assumed model is true. However, it is very intensive computationally and when the number of sequences is larger than 20, we must resort to a heuristic search for the maximum.

To evaluate the variability in an estimated tree, Felsenstein [6] introduced the use of the **bootstrap method** to phylogenetic inference. Bootstrap samples are created by sampling the observed sites, with replacement, to create a set of pseudo-sequences of the same length as the original data. For each bootstrap sample, a bootstrap tree estimate is made using the specific phylogenetic construction method being studied. The sampling distribution of the estimated phylogeny is approximated by the empirical distribution of the bootstrap estimates. Care must be taken in the interpretation of the bootstrap results since no information is provided about whether the estimation technique being studied is itself biased.

Phylogenetic tree-building algorithms rely on many key assumptions and there have been a number of proposals to test their validity. Methods that assume rate homogeneity over the whole tree can examine this assumption with a relative rate test (e.g. [23]). Trees based on maximum likelihood are not robust to deviations in the assumption that all sites evolve at the same rate [10] and many proposals are available to deal with this problem (e.g. [27]). A phylogenetic tree cannot depict situations in which recombination events play an important role in the history of a group of homologous sequences. In this case a network, which allows for cycles amongst the nodes, may be appropriate [2]. The preponderance of work in the analysis of DNA sequences assumes that all the relevant information about the history and function of the molecule is contained in the sequence. Although higher-order structure probably plays an important functional role, the lack of data in this area makes the development of useful statistical procedures problematic.

Computer programs to carry out a wide variety of alignment and phylogenetic tree-building algorithms are generally available for little or no cost. A fairly comprehensive list of such programs is distributed as part of the documentation for the program PHYLIP [7]. A broad discussion of phylogenetic methods is provided by Swofford et al. [26].

DENNIS K. PEARL

Dorn, Harold Fred

Born: July 30, 1906, in Tompkins County, New York.
Died: May 9, 1963, in Bethesda, Maryland.

At the time of his death from cancer, Harold Dorn was Chief of the Biometrics Research Branch of the National Heart Institute of the **National Institutes of Health** (NIH). He was originally trained as a sociologist, receiving his Ph.D. from the University of Wisconsin in 1933. His interest in statistical methods was stimulated by his post-doctoral year in London where he attended, among others, the lectures of **Egon Pearson** and **R.A. Fisher**. He joined the US Public Health Service in 1936. Shortly thereafter he was assigned to the NIH where he spent his entire career as a medical statistician and epidemiologist. Dorn will be remembered for the major role he played in starting and developing the statistical program at the NIH. His primary interest, however, was the conduct of his own studies in the epidemiology of cancer. He was responsible for some early work in the association between smoking and lung cancer (*see* **Smoking and Health**) and, as a result of initiating a 10-city survey of cancer morbidity, was the first to collect a fairly large body of data on cancer incidence in the US. For these and other contributions that he made in medical statistics, epidemiology, and demography, he received a number of honors, among which were his designation as the Cutter Lecturer in Preventive Medicine at Harvard University in 1959 and his receiving the distinguished Service Award from the US Department of Health, Education and Welfare. He was a member of the National Committee on Vital and Health Statistics, a member of the **World Health Organization** (WHO) Expert Committee on Health Statistics, and a US representative from 1948 until his death to conferences on the revision of the International List of Diseases, Injuries and Causes (*see* **International Classification of Diseases (ICD)**). Dorn was a Fellow of the **American Statistical Association** (ASA), served on its Board of Directors and its Council, and at his death was Chairman of the Social Statistics Section.

(This account is based on the Dorn obituary written by **Jerome Cornfield** in the *American Statistician*, June 1963.)

SAMUEL W. GREENHOUSE

Dose-response in Pharmacoepidemiology

Since **pharmacoepidemiology** (PE) deals with the action of drugs within the population, the estimation of **dose–response** parameters is somewhat different than that used in either **biological assay** or **clinical trials**. As discussed below, these differences are primarily due to the controlled data collection available in bioassay and clinical trials which usually is not available in PE trials. However, the basic idea behind a dose–response curve is the same. As the amount of drug used increases, the number of subjects who will respond to the drug increases. This relationship produces an S-shaped or sigmoid curve when amount of drug is plotted on the horizontal axis and proportion of subjects responding is plotted on the vertical axis.

Such a dose–response curve is shown in Figure 1. The plotted points indicate the proportion of subjects (usually 3–6) who have responded to a particular dose of the drug being studied. The sigmoid curve has been drawn through this set of points. In practice, the parameters describing this curve would be estimated using **nonlinear regression** or by transforming the data (*see* **Transformations**) so that **linear regression** could be used [5]. The ends of the curve flatten out at the lower end where a certain amount of the drug has to be given to obtain any response, and at the upper end where increasing the amount of drug above a particular dose produces no increase in the effect that the drug produces.

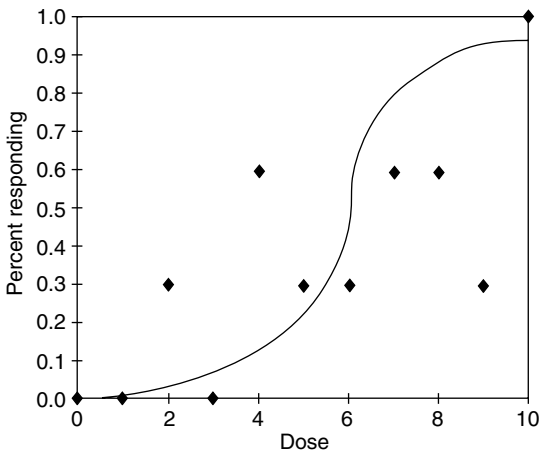

Figure 1 Plotted points and a sigmoid curve for a typical dose–response situation

Dose–response is evaluated with a pharmacodynamic (PD) model. That is, its results are measured in terms of an observable response by the subject. Underlying this response are **pharmacokinetic** (PK) actions of the drug within the body; for example, the time it takes the drug to clear from the body. PK information is thought to provide clues as to how a subject will respond to various doses of a drug, but it is not a perfect predictor of PD response.

The dose–response model in PE shares the S-shaped curve concept and the PD response with similar models in bioassay and clinical trials. In other ways it is quite different from these models. In PE the dose–response information comes exclusively from human subjects. Bioassay and clinical trials models are used in both animals and humans. Although cross species comparisons are difficult to make, the animal studies are used to complement human studies in bioassay and clinical trials.

In PE the dose–response model is best represented by two S-shaped curves. The first curve uses as response the medically intended purpose of the drug, i.e. its benefit. The second curve uses as response the negative or adverse outcomes that the drug produces. The curves in Figure 2 represent the ideal situation in which the adverse and beneficial effects

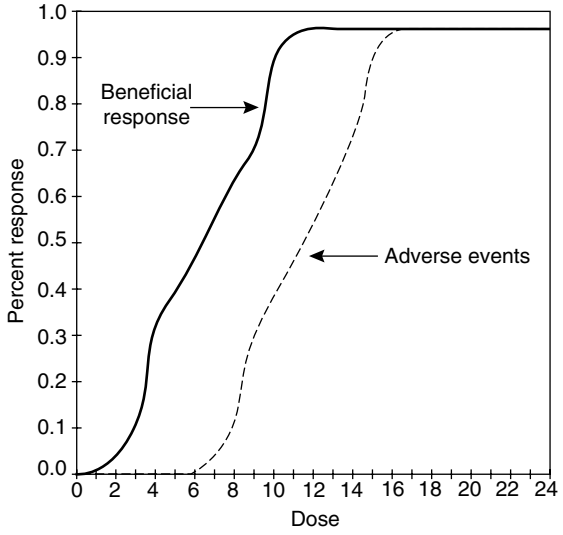

Figure 2 PE dose–response curves

are widely separated in dose and the curves are parallel to one another. In reality the two curves may overlap and cross one another or they may lie on top of one another. They do not have to be parallel, and their shape and relationship to one another may change with changing characteristics of the subjects being studied; for example, the age of the subjects usually affects this relationship. PE studies using dose–response models attempt to estimate parameters for both of these curves, and to estimate the effect that population characteristics have on these parameters and hence on the relationship between the curves.

Bioassay and clinical trials dose–response studies are controlled studies similar to the premarket studies conducted on drugs before they are allowed to be sold to the public. The number of subjects who are tested with a drug before it is put on the market is extremely small compared with the number of patients who will use the drug once it is generally available. For this reason the information about the relationship of the beneficial and adverse effects curves given in Figure 2 that is available from controlled (premarket) studies may not provide a complete picture of this relationship. One of the major research foci for PE is to determine the relationship of the two curves in Figure 2 in the general population. It is not uncommon that an effective dose for a drug can be lower than the doses used in premarket testing. It may also be necessary to increase the dosage for some subgroups in a population. Studies of the drug verapamil have shown that, for a given dose, elderly patients will have a blunted electrophysiologic response and a greater drop in blood pressure than younger patients given the same dose [15]. Using the recommended dose on the package insert for verapamil would therefore result in getting less electrophysiologic response than expected and a greater drop in blood pressure when the person being given the drug was older than the groups on which premarket studies had been done.

Bioassay and clinical trials dose–response experiments are controlled, prospectively planned, experiments. A great deal of the dose–response data in PE is currently gathered as retrospective information obtained from data sets that have been collected for other purposes. Some of the methodologic issues in PE dose–response research have to do with abstracting information from large computer databases (*see* **Administrative Databases**).

Since PE seeks to determine dose–response information for a population, it must deal with variables other than dose which can influence response. Decisions need to be made, often with limited information, about whether these variables are important enough to be studied separately. The alternative is to allow them to become one of the sources of variation for the models developed.

Finally, dose–response results in PE will almost surely be compared with data collected by pharmaceutical companies to determine adverse events, and with physicians' customary prescribing habits. While these results are not always in conflict, there are economic and political consequences that make the method of presenting these dose–response studies very important. The methods of PE are also being used to investigate drug prescribing practices among physicians (*see* **Drug Utilization Patterns**), the economic impact of altered dosing strategies, and the long-term adverse effects of drugs taken over extended periods of time (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**). These are areas of investigation that are difficult to incorporate into the classic bioassay or clinical trials structure.

As with any complicated problem, a good way to proceed is to divide the problem into manageable parts. I have chosen to divide this article into three sections, each dealing with an important aspect of dose–response in PE. First I will discuss the parameters that need to be estimated, next the current techniques for estimating these parameters and, finally, some of the computer software currently available for obtaining the estimates.

Dose–Response Variables

Responses can be divided into two categories – expectation and effect. There are two levels of expectation, anticipated and unanticipated, and two levels of effect, adverse and beneficial. We usually have some prior expectation about how a drug will affect the body both beneficially and adversely. These are the anticipated responses. They are the easiest to deal with, since we can include them in our advance planning. The unanticipated responses cannot be planned for in advance. Again, they can be either beneficial or adverse but they are determined by skillful observation of the effect of the drug on the human subject

during the course of the study. They are frequently detected by their increasing occurrence with increasing amounts of a drug.

The effect levels, adverse and beneficial, refer to PD responses as mentioned in the introduction. These can usually be clearly defined in the same way for all subjects. There are some situations, if for example a **quality of life** measure is used as the response, where some interpretation is necessary to decide what is beneficial and what is adverse.

While our basic dose–response model deals with PD responses, it seems reasonable to assume that the PD responses that we obtain from a drug depend to some extent upon how that drug acts in the body, that is, pharmacodynamics is some function of pharmacokinetics. Therefore the first set of responses that we want to estimate are not dose–response measures but the basic pharmacokinetic actions of a drug.

Pharmacokinetics (PK) has been defined as the "study of factors influencing the absorption, distribution, metabolism, and excretion of a drug" [7]. Pharmacodynamics is the study of the effect of a drug on the body [9], for example, whether or not the patient improves or has an adverse reaction when the drug is given. This effect is related to the drug's effective concentration **(bioavailability)** in the body. This concentration could be measured by the initial dose given, but because of the **confounding** effects caused by a subject's biochemistry other PK parameters may be better.

Several variables of drug administration influence the PK outcomes of any drug. Examples include the route of administration (oral, bolus injection or IV drip, etc.), the timing of administration (once per day, twice per day, etc.), the number of administrations, and the dose per administration. These variables, along with a subject's unique biochemistry, determine the bioavailability of a drug in the body. Aspects of this bioavailability are expressed by several PK parameters. The most common of these are the area under the curve (AUC), peak plasma concentration (C_p), and half-life ($T_{1/2}$). Depending upon the drug and the effect being examined, one of these parameters may be more important than the others in determining the PD response. The effect of some drugs is closely related to their maximum or peak concentration. Other drugs have effects related to their minimum concentration or trough. The PD response of others is most easily predicted by some integrated summation of bioavailability over time (AUC).

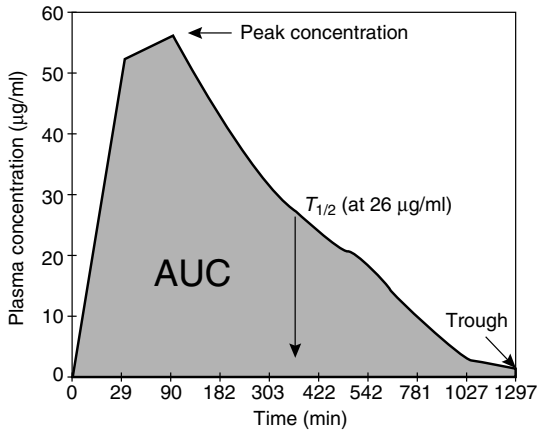

Figure 3 A pharmacokinetic curve for a single dose of cyclophosphamide

Figure 3 is a graphic representation of AUC, C_p, $T_{1/2}$, and trough for a single administration of the drug cyclophosphamide. From the time at which the drug is injected, 0, the plasma concentration rises until it reaches the peak, C_p. The time that it takes to reach half of C_p, about 362 minutes, is $T_{1/2}$, and the lowest value is the trough. The shaded area is the area under the curve, AUC.

In pharmacoepidemiologic dose–response (PDR) we determine the values of these PK parameters not just for a single individual but for a population of individuals. To the extent that PK values determine PD responses this would give us information about how the entire population would react to a drug. Obtaining estimates in this way is called population pharmacokinetic (PPK) modeling. DeVane et al. [4] give an example of this in their paper on alprazolam, a drug used for a number of psychiatric disorders. In that paper mixed-effect modeling was used to determine the mean and standard deviation for the clearance ($= \text{dose}/AUC$) for 94 psychiatric inpatients. The authors found an average clearance of 0.05 liters per hour per kg with a 95% confidence interval of 0.04–0.06. They also found that clearance was increased by 59% in women, and decreased by 26% in patients with multiple organ disease and 23% in patients over the age of 60. Increased clearance indicates that the drug is leaving the body more quickly and may not be in the plasma long enough to be fully effective. Decreased clearance indicates that the drug is remaining in the body longer and that may indicate a greater opportunity to cause an adverse reaction.

Subject factors such as age, gender, and co-morbid conditions can have considerable impact on a drug's effect (*see* **Co-morbidity**). The effect of these variables could be measured directly in planned experiments. What is more frequently done in PDR modeling is to use PPK models to determine how these subject specific variables effect PK parameter estimates and to impute from this what types of PD responses one would see in the population. This was the strategy used in the DeVane study mentioned above. The data for this study were not collected by taking multiple samples from a single patient and measuring the drug concentration at each time as in the linear kinetics example given below. Instead, two blood samples were drawn at random from each patient at some time during the course of their treatment. This method has developed because subject variables, and beneficial and adverse responses, are routinely recorded in medical charts and can be abstracted for the PPK models. To test the effect of these variables directly in planned experiments would be time consuming and expensive. The statistical methods necessary to obtain the PPK parameter estimates when data are collected in this fashion are discussed briefly below.

The final set of parameters to be estimated are the PD parameters which measure the subject's overall response to the drug. Beneficial parameters are typically proportions of subjects completely cured, partially cured, or relieved of symptoms. Adverse event parameters are proportions of patients experiencing these events. There are other measures of these responses that are continuous, e.g. time to remission, and are dealt with using other models such as **survival analysis**.

Both the PD and the PK parameters are needed here because PDR encompasses more than just the classic dose–response model. In its broadest form it can be seen as the reason for PE investigations: "The objective of many pharmacoepidemiologic investigations is to determine the incidence of an adverse event and identify risk factors associated with the event. These risk factors can include patient characteristics such as age, race, sex, and so forth, and drug characteristics such as the dose, the dosing regimen, and the level of systemic response" [7]. The PK parameters provide a broader spectrum of risk factors with which to evaluate a drug than just dose. Given, as above, that it is the availability of the drug to act in the body and not the dose administered that determines the response that we obtain, we should be able to take advantage of the PK parameters to develop active-concentration (bioavailable) response models and not just dose–response models.

It is not always easy to determine if a response can be directly attributed to the action of a drug. Determining this is difficult enough in a controlled experiment. Given the undesigned nature of the data collection for data used in PDR studies, it becomes even more difficult. Unanticipated responses are particularly hard to detect using only a classic dose–response design. The PK parameters can help to corroborate that a response is related, as one might expect, to one of the PD parameters. For example, chart notations of nausea that occurred within the population limits of a drug's peak concentration could more easily be called an adverse reaction than such notations that could not be linked to this PK measure.

What we know about dose–response from controlled experiments provides only a very small part of the response that we see in the larger population to which the drug is ultimately administered. Incorporating the PK parameters as part of PDR models allows us more latitude to explore the nuances of drug activity in this large population.

Using only the PD, **binary** outcome, of classic dose–response (dead/alive, improved/not improved) does not allow us to classify drugs with similar risk profiles into meaningful risk groups. Classifying drugs based upon how many and what types of responses were related to peak concentration, trough concentration or area under the curve will give us more knowledge about drug activity in general. It will also allow us to develop strategies for separating the beneficial dose–response curve and the adverse event curve more completely. Drugs where benefit depends upon the area under the curve, but where adverse events are only noted if a particular peak concentration is exceeded, can be administered to maximize benefit and minimize adverse results.

The final step in PDR modeling is to bring together all of the information available about all of the parameters mentioned above and form a coherent picture of the activity of a drug in the general population. This final model should allow us to predict the PD responses that will occur in any segment of the population as we manipulate the controllable aspects of drug administration in order to produce the most favorable PK responses.

Estimating the Parameters

Estimates for the values of the PK parameters are made using compartment modeling (*see* **Pharmacokinetics and Pharmacodynamics**), with experimental designs developed specifically for obtaining the PK values [14]. The definitions, figures, and procedures given below are based upon the simplest of these models, a single-compartment model with first-order linear kinetics.

In the simplest single compartment model the drug is almost immediately available from an outside source (bolus injection), resides only in one place in the body (the single compartment which is usually taken to be the plasma), and is then eliminated from the body. A representation of this model is shown in Figure 4.

To estimate the PK parameters, an injection of the drug is given at $t = 0$, where t is the time from injection. Blood is drawn from the subject at pre-specified intervals and the amount of drug still in the plasma is measured. Figure 5 indicates what the subsequent natural log (ln) by time concentration curve might look like for a first-order kinetics model, that is, the concentration curve follows an **exponential distribution** and the log of concentration by time curve will be a straight line.

Algebraically, our PK parameters are defined as follows. The concentration at time t, conc(t), is obtained from (2), although (3) is often easier. The concentration in the plasma immediately after the injection is conc(0). In this simple model

$$\text{conc}(0) = \frac{\text{dose injected}}{\text{volume of plasma}}. \tag{1}$$

Subsequent concentrations can be obtained from the following equations:

$$\text{conc}(t) = \text{conc}(0) \times \exp[-k_{10} \times t] \tag{2}$$

or

$$\ln[\text{conc}(t)] = \ln[\text{conc}(0)] - k_{10} \times t. \tag{3}$$

k_{10} is the constant that indicates how rapidly the drug is excreted from the body (plasma), compartment 1, to the outside world, compartment 0.

It is clear that what drives these relationships is the constant k_{10}. From the curve in Figure 5, k_{10} could be estimated by eye, but a more precise way is to perform a simple **least squares linear regression** on the data in this plot of (3). In this model conc(0) is equal to C_p, which is estimated as the intercept of the regression. The parameter k_{10} is then estimated as the slope of this regression. The half life of the concentration then becomes

$T_{1/2}$ = the time it takes to reduce the concentration

$$\text{by half} = -\frac{\ln(0.5)}{k_{10}}. \tag{4}$$

The value, $-\ln(0.5) = 0.693$. In Figure 5 $T_{1/2}$ can be obtained graphically by determining a 0.693 difference on the vertical axis and projecting this on to the time axis.

If we integrate the exponential function in (2) from 0 to infinity we find that the area under the curve is

$$AUC = \frac{\text{conc}(0)}{k_{10}}. \tag{5}$$

Since theoretically the logarithmic curve will never reach zero, the trough is taken as the lowest predicted value that is obtained before the next injection. When multiple injections are not given, the trough is reported as the lowest predicted value within the time of observation.

The values of these parameters for the data in Figure 5 are found as follows. We inject a bolus of drug at time zero. From blood drawn from the subject at times after $t = 0$, we obtain plasma concentrations. Logarithms of these concentrations are the plotted points in Figure 5. By regression, $C_p = 493$ ng/ml,

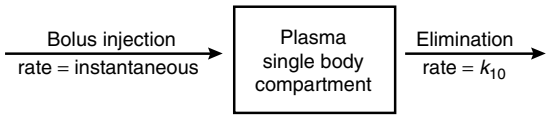

Figure 4 The single-compartment model

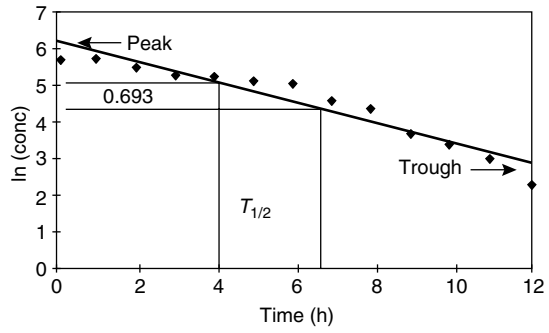

Figure 5 The ln(conc) vs. time curve

trough (at 12 h) = 18.18 ng/ml, and $k_{10} = 0.275$/h. From this we can obtain $T_{1/2} = 2.52$ h, which is also reflected in the drawing in Figure 5. AUC becomes 1127.27 ng h/ml. AUC has units which are difficult to interpret physiologically. It is primarily an intermediate variable which allows us to estimate the system clearance rate as

$$Cl_s = \frac{[\text{conc}(0) \times V_d]}{AUC}. \tag{6}$$

Here V_d is another intermediate variable called the volume of distribution. It is the proportion of drug that remains in the plasma and is not distributed to other body compartments. In this simple model, it equals 1. From the definitions it is clear that in this simple model Cl_s equals $V_d \times k_{10} = 0.275$ ml/h.

The PK models used in practice are much more complicated than those that we have presented here. They use both multiple administrations of a drug and multiple compartments within the body. However, the general approach to the estimation of the PK parameters remains the same.

The example of estimation of PK parameters given above is for data from a single subject. The pharmacoepidemiologic dose–response (PDR) is obtained from need the population values for these PK parameters. This means that we need information from more than one subject, and that we must consider variability in these values both within and between individuals in a population. In addition, we want our population model to provide information about how various subgroups react to the drug. Are older people more inclined to have adverse reactions because they have slower clearance? Is the drug more effective in people with **AIDS** because their condition allows it to reach a higher peak? Can we give a lower dose of the drug (preventing adverse events) because we find that in the general population the minimal effective dose is less than the dose used in the controlled clinical trials used to prove the drug's effectiveness?

Ideally, controlled, planned experiments to answer the above questions should be undertaken. Time and sample size constraints make this unrealistic in most cases. The strategy developed for PDR is to use information that is available in a patient's chart or in a medical database to try to obtain PK estimates that will provide answers to some of these questions [13]. This means that the data collected will be fragmentary, collected under a variety of conditions, unbalanced and subject to many sources of variation. Procedures for analyzing this type of data are currently being developed in the statistical literature. Yuh et al. [16] has an excellent bibliography on current work in this area. The development of standard methods for dealing with these data and appropriate software will greatly increase the effectiveness of PDR research.

As an example of PPK modeling, consider the curves in Figure 6. Here instead of having observations for a single individual for our simple, one-compartment model, we have results from ten individuals. This example is idealized, since PPK models seldom have enough information to estimate individual regression parameters for each individual. Typically, each individual has his or her own response to the drug. In this case, one subject has a response at odds with the other nine subjects. PPK models usually assume that responses of similar subjects are parallel. This nonparallel response should be investigated to see if this subject differs in some meaningful way from the rest of the group. If correction of initial data or adjustments for **confounding** factors is not appropriate, this subject's data should remain in the model. The effect of this decision will be to increase the **variance** of the parameter estimates obtained.

Where the PK example given above had one regression equation we now have ten equations of the following type:

$$\text{conc}(t)_i = \alpha_i \times \exp[-\beta_i \times t] \tag{7}$$

or

$$\ln[\text{conc}(t)_i] = \alpha_i - \beta_i \times t. \tag{8}$$

To emphasize the variability of different subjects to the drug, we have replaced conc(0) by α_i, which is the individual subject's intercept at the time of

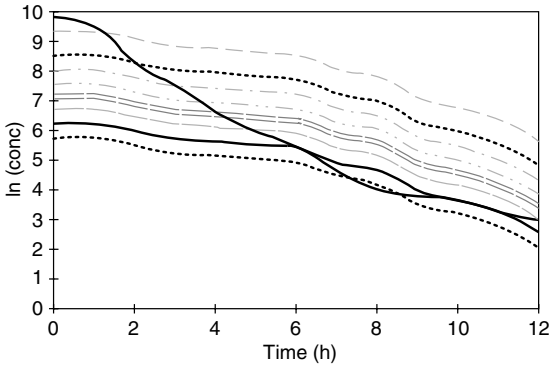

Figure 6 An example of population PK curves

injection. We have also replaced k_{10} by β_i, so that the discussion below is consistent with regression analysis models.

We usually assume that there is enough similarity in the response among individuals that the parameters α_i and β_i can be viewed as representative values from a distribution of such parameters, where the mean of the distribution is the population value α or β. They can then be written as

$$\alpha_i = \alpha + \xi_i, \qquad \beta_i = \beta + e_i. \tag{9}$$

In the simplest case, ξ_i and e_i are assumed to be independently distributed as $N(0, \sigma_1^2)$ and $N(0, \sigma_2^2)$, respectively.

The regression equations required to obtain estimates for α_i and β_i are referred to in various parts of the statistical literature as mixed effects, **stochastic** parameter, or **empirical Bayes** models. Under the appropriate assumptions, these models will yield essentially the same results. Racine-Poon & Smith [12] has a comparison of the models mentioned above. While our simple model is linear using a logarithmic transformation, PK models are usually nonlinear. This increases the difficulty of obtaining the estimates.

Notice that the regression structure provides for much more model complexity than we are using here. In particular, we may want to incorporate some important **covariates** that have their own fixed effect or strata values. If our ten subjects were five males and five females, we might consider having a different α value for each gender, thus removing gender from the undifferentiated sources of variability. It is possible, however, that gender affects the rate of elimination and not the intercept of the concentration curve. In that case we would want a different β for each gender. It is obvious that models which incorporate subject specific covariates into the PK equations can become quite complex. Considerable thought and testing needs to go into the selection of the correct models (*see* **Model, Choice of**) The bibliography in Yuh et al. [16] contains references for the procedures currently being used to obtain estimates for the parameters in these models.

Naively, we might begin by ignoring the fact that these observations came from ten individuals. A single regression could then be performed and the results taken as the values for α and β. This approach ignores the complicated relations of inter- and intraperson variation. Its shortcomings are easily demonstrated if we consider how to deal with different numbers of observations for each subject.

A slightly better approach is first to estimate α_i and β_i from a single linear regression on the data of each individual. These individual estimates can then be combined in some fashion, usually a weighted mean, to produce population estimates of α and β. This approach allows for weighting for different numbers of observations per subject and it provides both individual and population estimates of the parameters. What is missing from this approach is a way of estimating simultaneously both the individual and the population parameters.

Simultaneous estimates of these parameters can proceed along the lines of **maximum likelihood** [10, 11] or **Bayesian** [12] estimation. While these simultaneous estimates are preferred, they too have a drawback. They require assumptions about the variance–covariance structure of these models (*see* **Covariance Matrix**) which are often difficult to make. They also require iterative solutions which may converge slowly to stable estimates. Finally they are currently being estimated using software which is under development. Nevertheless, the advantages which these estimates have in completely specifying the relationship between the population parameters and the individual parameters is thought to be worth the effort.

Computer Software

Several software packages are available for individual PK modeling. A recent paper [3] reviews a number of the programs available in terms of ease of use. In addition, procedures exist within large statistical packages such as SAS, **S-PLUS**, SPSS, and BMDP for mixed-effects analysis and **nonlinear regression** (*see* **Software, Biostatistical**). These procedures can be adapted to produce estimates for many of the individual PK models.

At this time, the only computer program that is specifically designed to deal with the type of data used in PDR is NONMEM [2], a program developed to obtain population estimates of PK parameters from available clinical data. While some studies show that NONMEM provides good estimates in data from Phase III trials [8], controversy still exists about its use in situations with more variability [12]. In addition, NONMEM provides only limited access to model the **variance components**, and it provides only

the population estimates α and β, and not α_i or β_i. It does, however, allow for some limited testing of parameters between different subgroups or strata (*see* **Stratification**) of the population.

Summary

Pharmacoepidemiologic dose–response (PDR) is closely related to the analysis of pharmacokinetic/pharmacodynamic data. In particular, the estimation of population pharmacokinetic parameters is the current analytic tool for PDR. The information that these estimates provide about the dose–response relationships in subgroups of the population is necessary for pharmacoepidemiologic investigation of risk factors associated with drug use. These estimates also provide information for improving the separation between dose–benefit and dose–toxicity curves in the population.

Estimation procedures and associated software for obtaining population pharmacokinetic parameters are still evolving. A bibliography for current estimation procedures is provided in [16] and software reviews and suggested improvements for current software are provided in [3] and [1]. While the procedures in use at this time are providing useful information, this area of pharmacoepidemiologic research will be greatly enhanced when standard methods for design and analysis, and readily available, user friendly, software have been developed.

J.R. MURPHY

Dose–Response Models in Risk Analysis

In biological and health sciences, a **dose–response** model is an expression that describes a measure of a biological or health effect as a mathematical function of a dose of a substance. In risk analysis (*see* **Risk Assessment**; **Risk Assessment for Environmental Chemicals**), the biological or health effect is generally a measure of an adverse outcome, such as the proportion of individuals with a disease or the magnitude of body weight loss. The primary goal is to estimate the proportion of individuals in a population that are expected to experience an adverse health effect when exposed to a specified biological insult, usually a chemical substance. The dose is the amount of the chemically active substance at the affected tissue site. Often the body converts a chemical into other forms (metabolites) that are the biologically active substances. Occasionally, elaborate differential equations based on physiology can be constructed to provide **pharmacokinetic models** to estimate the doses of the active chemical substances at the affected tissue sites. In the absence of this information, the amount of the active chemical is generally assumed to be proportional to the dose of a chemical that is administered by inhalation, dermal, or oral exposure. Since various species of animals tend to react similarly when a dose is administered on a body weight basis, dose often is expressed as milligrams (mg) of a substance per kilogram (kg) of body weight. For many biological effects, similar effects among species are noted when body weight is raised to a power; for example, 2/3 or 3/4. This often corresponds closely to a dose expressed as a concentration; for example, parts per million (ppm) in air, food, or water.

For risk analysis, dose–response data seldom are available for exposures of humans to specific toxic substances. Hence, most dose–response data are obtained from well-controlled animal **bioassays**. Typically, relatively small numbers of animals (generally 5–50) are exposed to a few dose levels (generally 3–5), and there is a group of control animals that are not exposed to the chemical substance under investigation. Generally, the purpose of the bioassay is to establish a dose–response function from which a relatively "safe" dose for human exposure can be estimated. Where the biological mechanism of toxicity is known, it may be possible to represent this situation with a biologically based dose–response model that will provide sufficiently precise estimates of risk at human exposure levels.

Generally, it is desired to limit risk levels (the proportion of adversely affected individuals) to less than 1 in 10 000. Hundreds of thousands of animals would be required to measure such levels of risk directly with precision. Since the resources to do this do not exist, relatively small numbers of animals are exposed to doses well above human exposure levels in order to elicit potential toxic effects. Then, it becomes necessary to extrapolate the results from high-dose experiments to low-dose human exposure levels. That is, the bioassay data are used only to obtain a dose–response model in the experimental dose range and some form of low-dose extrapolation is employed (*see* **Extrapolation, Low Dose**).

Various dose–response models have been employed for quantal (dichotomous) endpoints, where an animal is classified as either possessing an adverse effect (such as cancer or a birth defect) or considered normal. For quantal data, it has been common to use tolerance distributions to relate the probability of disease to dose (*see* **Quantal Response Models**). It is assumed that the probability that an animal will develop an adverse effect at a dose, d, is described by a specified distribution. For example, if the probability density function of tolerated doses is normal (Gaussian), then the probability of an effect at dose d is given by the cumulative normal distribution function (probit):

$$\Pr(d) = \Phi(\beta_0 + \beta_1 d),$$

where the regression coefficients, β_0 and β_1, are estimated from bioassay data [5]. More commonly, for biological endpoints the **lognormal** tolerance distribution provides a better description (log probit):

$$\Pr(d) = \Phi(\beta_0 + \beta_1 \ln d).$$

A second model used extensively for quantal responses is the logistic [2]:

$$\Pr(d) = \{1 + \exp[-(\beta_0 + \beta_1 \ln d)]\}^{-1}.$$

Chand & Hoel [4] showed that when the time-to-tumor distribution is a **Weibull distribution**, the

dose–response model follows an **extreme value** model:

$$\Pr(d) = 1 - \exp[-\exp(\beta_0 + \beta_1 \ln d)].$$

If k similar events are required to produce an adverse biological effect, the probability of this effect is given by the multi-hit model based on the **Poisson distribution**:

$$\Pr(d) = 1 - \sum_{i=0}^{k-1} \frac{(\lambda d)^i \exp(-\lambda d)}{i!}.$$

When λd is small, the multi-hit model is approximately

$$\Pr(d) = \beta d^k \quad \text{or} \quad \ln \Pr(d) = \ln \beta + k \ln d.$$

In the special case in which only one event is necessary to produce an adverse effect (for example, a single mutation in a cell), the resulting model is the one-hit model

$$\Pr(d) = 1 - \exp(-\lambda d).$$

When λd is small, the one-hit model is approximately linear:

$$\Pr(d) = \lambda d.$$

In the above models in which $\ln d$ is used, when $d = 0$ ($\ln 0 = -\infty$), the background rate is $\Pr(0) = 0$. This is often not the case. If a chemical acts independently of the background, the total (background plus induced) probability of an event is

$$\overset{*}{\Pr}(d) = \Pr(0) + [1 - \Pr(0)] \Pr(d).$$

If a chemical adds to the background dose (that is, the background rate is due to an effective dose d_0), then

$$\overset{*}{\Pr}(d) = \Pr(d + d_0).$$

The Armitage–Doll **multistage carcinogenesis model** [1] is widely used to represent the probability of cancer by a given age as a function of dose,

$$\overset{*}{\Pr}(d) = 1 - \exp\left[-\beta_0 \prod_{i=1}^{k} (\beta_{0i} + \beta_{1i} d)\right],$$

where it is assumed that a cell progresses through k stages leading to cancer and that the rate of change of the ith stage is $\beta_{0i} + \beta_{1i} d$, with $\beta_{0i} > 0$ and $\beta_{1i} \geq 0$ for $i = 1, 2, \ldots, k$. The parameter β_{0i} represents the spontaneous background rate and $\beta_{1i} d$ represents the increase in rate of the ith stage due to dose of a carcinogen; β_0 is constant greater than zero. The Armitage–Doll multistage model is generally expressed in a polynomial form,

$$\overset{*}{\Pr}(d) = 1 - \exp\left(-\sum_{i=0}^{k} \beta_i d^i\right),$$

where the constraints $\beta_i \geq 0$ are usually employed. The background tumor incidence is $\Pr^*(0) = [1 - \exp(-\beta_0)]$. In the special case in which the rate of only one stage is increased by a carcinogen, the one-hit model is obtained:

$$\overset{*}{\Pr}(d) = 1 - \exp[-(\beta_0 + \beta_i d)].$$

The Weibull model is a special case of the polynomial form:

$$\overset{*}{\Pr}(d) = 1 - \exp[-(\beta_0 + \beta_1 d^k)].$$

In studies of such duration where death occurs, death from causes other than the specific disease of interest can result in distorted dose–response curves. For example, suppose that mortality increases with increasing doses from causes other than the disease of interest. For a later occurring disease such as cancer, the incidence of cancer at high doses many decrease because the animals die from other causes before the disease is observed. Hence, tumor rates adjusted for intercurrent mortality are required to obtain unbiased dose–response functions. This is accomplished by adjusting the number of animals at risk. Kaplan & Meier [7] provide a nonparametric procedure for estimating the incidence of fatal tumors as a function of time (*see* **Kaplan–Meier Estimator**). Hoel & Walburg [6] present a method for estimating the prevalence of nonfatal (incidental) tumors as a function of time. Kodell et al. [8] combine these two procedures to provide nonparametric estimates for tumor onset. These procedures require assigning a tumor to the most likely category, fatal or nonfatal. All tumors observed as the result of a scheduled sacrifice of animals are considered incidental, even though they may generally progress to cause the death of an animal (*see* **Serial-sacrifice Experiments**).

Moolgavkar & Venzon [13] and Moolgavkar & Knudson [12] propose a **two-mutation carcinogenesis model** that includes proliferation of initiated cells.

In this model a normal cell may mutate to an initiated cell, an initiated cell may undergo clonal expansion, and an initiated cell may be transformed by a second mutation to a cancer cell. The probability that an individual or animal has a particular type of cancer by age t is given by

$$\Pr(t) = 1 - \left[\frac{2C\exp(-1/2(B+C)t)}{(B+C)\exp(-Ct) - (B-C)}\right]^{\nu/\beta}$$

where $C = [(\beta+\delta+\mu)^2 - 4\beta\delta]^{1/2}$, $B = \beta - \delta - \mu$ and the cell kinetic parameters ν, β, δ, and μ are defined as follows. It is assumed that the number of normal cells in a tissue that are at risk of producing initiated cells upon cell division remains relatively constant. Consequently, normal cells generate initiated cells by a **Poisson process** with constant intensity ν. An initiated cell living at time t may undergo cell division producing two initiated cells in the time interval $(t, t+\Delta t)$ with an approximate probability of $\beta\Delta t$, and die (either physiologically or pathologically) with an approximate probability of $\delta\Delta t$, where Δt is small. In this time interval, a living initiated cell may also divide into an initiated cell and a cancer cell with approximate probability of $\mu\Delta t$. New research in this area is increasing the number of stages, considering cell kinetics that change with age, incorporating DNA repair, considering specific events at the nucleotide level, and incorporating dose.

For continuous (nonquantal) data, a multitude of dose–response curves is used. It is desirable that the models reflect pharmacokinetics and physiology. For example, it might be hypothesized that limits are approached due to saturation of biological processes. Once a dose–response model is obtained to describe average levels, the distribution of individual levels about the average is needed for risk estimation. Some biological measures tend to follow a normal distribution (for example, body and organ weights). Frequently, biological measures appear to be lognormally distributed. In these cases, only the standard deviation is needed in addition to the average to describe the distribution of measures of biological effects. If an adverse level has been identified, then the probability of individuals being in the adverse range can be estimated as a function of dose. Where an adverse range is not specified, the probability of abnormal levels (for example, below the first percentile and/or above the 99th percentile of unexposed control individuals) can be estimated as a function of dose.

In reproductive and developmental studies, a chemical is administered to the father and/or mother before or during pregnancy and the results are evaluated in the fetuses or offspring. Hence the litter is the experimental unit. Common endpoints measured near the end of pregnancy are the number of implants per litter, the proportion of implants that result in resorptions or dead fetuses per litter, the proportion of specific types of malformations per litter among the live fetuses, and average fetal weight per litter.

One of the first models devised specifically for use with developmental data was provided by Rai & Van Ryzin [14]. Their model contained the feature that the probability of a malformed fetus is a function of litter size (s) as well as dose:

$$\overset{*}{\Pr}(d, s) = \{1 - \exp[-(\beta_0 + \beta_1 d)]\} \times \exp[-s(\alpha_0 + \alpha_1 d)],$$

where $\beta_0 > 0$, $\beta_1 > 0$, $\alpha_0 > 0$, and $(\alpha_0 + \alpha_1 d) > 0$. Rai & Van Ryzin [14] postulated that larger litters are an indication of healthier litters, so that the probability of a malformation should decrease with increasing litter sizes.

Kupper et al. [10] used a log-logistic dose–response model for litter-type data. A generalization of their model to include litter size s is

$$\overset{*}{\Pr}(d, s) = \beta_0 + \beta_1 s + \frac{1 - \beta_0 + \beta_1 s}{1 + \exp[\beta_2 + \beta_3 s - \beta_4 \log(d - d_0)]}$$

Kodell et al. [9] provide a model for the results of a bioassay with g dose groups (indexed by $i = 1, \ldots, g$), and n_i pregnant females in the ith group receiving a dose d_i. Let x_{ij} denote the number of affected fetuses out of the s_{ij} fetuses in the jth litter of the ith dose group. Kodell et al. [9] use the **beta-binomial distribution** for the x_{ij} given a fixed litter size s_{ij}. It is assumed that the occurrence of an affected fetus in a litter follows a binomial distribution with probability p_{ij}, while the p_{ij} within the ith dose group are distributed according to a beta distribution. The probability of an adverse effect for a fetus in a litter of size s_{ij} at dose d_i is

$$\Pr(d_i, s_{ij}) = 1 - \exp\{-[\beta_0 + \beta_1(s_{ij} - s)]\},$$

for d_i less than or equal to a threshold dose of d_0. For doses above the threshold dose,

$$\overset{*}{\Pr}(d_i, s_{ij}) = 1 - \exp\{-[\beta_0 + \beta_1(s_{ij} - s) + (\beta_2 + \beta_3(s_{ij} - s))(d_i - d_0)^k]\},$$

where s is the average litter size over all dose groups, with $\beta_0 \geq 0$, $\beta_2 \geq 0$, $d_0 \geq 0$, $k \geq 1$, $[\beta_0 + \beta_1(s_{ij} - s)] \geq 0$ for all s_{ij}, and $[\beta_2 + \beta_3(s_{ij} - s)] \geq 0$ for all s_{ij}. The parameters of this Weibull-type model can be estimated by the method of maximum likelihood.

If death and malformation occur independently, the number of dead, malformed, and normal fetuses in a litter can be modeled as a trinomial distribution (*see* **Multinomial Distribution**). In order to account for the **overdispersion** induced by litter effects, the **quasi-likelihood** method of McCullagh & Nelder [11] that inflates the standard multinomial variance can be used. Ryan [15] discusses techniques for estimating the various probabilities assuming a log-probit and logistic model to describe the probabilities as a function of dose. Catalano et al. [3] also include a continuous measurement (fetal weight) along with the quantal endpoints of death and malformation in a multivariate model.

The beta–Poisson model is frequently used for microbial risk assessment. The probability of infection is

$$\overset{*}{\Pr}(d) = 1 - (\beta_0 + \beta_1 d)^{-k},$$

where d is the dose of an organism (generally expressed as number per mass or volume). As k approaches infinity, the dose–response curve approaches the exponential.

Dose–Response

Dose–response refers to a relationship between an amount of exposure or treatment and the degree or probability of an outcome in an individual or population. The dose may represent the amount, duration or intensity of exposure or treatment, and the outcome may represent a favorable effect, such as lowering of elevated blood pressure, or an unfavorable effect, such as increased risk of developing cancer. For example, the risk of lung cancer is known to increase with the number of cigarettes smoked each day and with the duration of smoking. A monotonic relationship of increasing disease risk with increasing exposure is often taken as one indication of a causal relationship between exposure and risk (*see* **Hill's Criteria for Causality**).

(*See also* **Dose-response in Pharmacoepidemiology**; **Dose–Response Models in Risk Analysis**)

MITCHELL H. GAIL

Double Sampling

Double sampling procedures are widely used in sample surveys, in acceptance sampling, for quality control, and also for statistical tests of hypotheses (*see* **Hypothesis Testing**). Hill [36] presents a review of the literature on this method up to 1980, and Hewett & Spurrier [35] summarize the double sampling procedures for tests of hypotheses.

This article contains a review of the developments of this approach for finite population sampling, and related topics. In finite population sampling, double sampling is widely used for determining strata weights (*see* **Stratified Sampling**), estimating the mean of the auxiliary variable for **ratio and regression estimates**, finding sample sizes for comparing the means of domains or subgroups (*see* **Sample Size Determination**), estimating and comparing proportions and percentages from misclassified observations (*see* **Misclassification Error**), and similar purposes. Double sampling is also known as *two-phase sampling*; it should be distinguished from two-stage sampling, where a sample of clusters are selected at the first stage and a sample of elements are chosen at the second stage.

We first present some applications of the double sampling procedures, followed by stratification, ratio and regression methods, and other procedures that employ double sampling.

Selected Applications

Double sampling was employed by Hall [30] for estimating the number of transmission sources in a **Poisson process**, by Ahmed et al. [2] and Catchpole & Catchpole [11, 12] for biomass estimates, by Stockford & Page [96] and Potter et al. [60] for estimation related to the Vietnam service, by Crete et al. [21] for correcting helicopter counts of moose, by Eberhardt & Simmons [25] for estimating sizes of animal populations, by Fairley et al. [27] for estimation related to welfare programs, by Baker [5] for evaluating a new medical diagnostic test, by Heerschop & Lieftinck-Koeijers [34] for estimating employment rates, and by Oderwald [56], Oderwald & Jones [57], and Reich et al. [72] for estimation in forestry. Magden & Holstein [49] use the double sampling method for determining the sample size for estimation related to rare items.

Stratification

Consider a finite population of size N divided into L strata of sizes N_h, $h = 1, 2, \ldots, L$; $N = \sum N_h$. From samples of sizes n_h, $n = \sum n_h$, selected randomly without replacement (*see* **Sampling With and Without Replacement**) from the strata, the estimator for the population **mean** $\overline{Y}$ is

$$\overline{y}_{\text{st}} = \sum W_h \overline{y}_h,$$

where $W_h = N_h/N$ are the weights and $\overline{y}_h$ are the sample means.

In some situations, only the sample means are reported, but the weights are not available. In such cases, as recommended by Neyman [55], initially a large sample of size n' is selected without replacement from the N population units. With the observed sample size n'_h in the hth stratum, $n' = \sum n'_h$, W_h is estimated from $w_h = n'_h/n'$. At the second phase, a sample of size $n_h = \nu_h n'_h$, $0 \le \nu_h \le 1$, is selected without replacement from the n'_h units and the sample mean $\overline{y}_h$ is obtained. The population mean is now estimated from

$$\overline{y}_{\text{st(d)}} = \sum w_h \overline{y}_h.$$

The estimator of this **variance** and its variance are presented by Cochran [18, p. 333] and Rao [63].

The cost of selecting the samples at the two phases is considered to be of the form $C = c'n' + \sum c_h n_h$. Optimum n' and n_h for minimizing the **variance** of $\overline{y}_{\text{st(d)}} = \sum w_h \overline{y}_h$ for a given average cost or for minimizing the average cost for a given variance are presented by Cochran [18, p. 331].

An alternative method for determining n_h was suggested by Srinath [93] and Rao [63], and its consequences were discussed by the author, Rao [68]. Treder & Sedransk [105] also suggest a method of determining the sample sizes at the two phases. Instead of selecting n_h proportional to n'_h, Singh & Singh [81] suggest three alternatives: (i) select the n_h units *with* replacement from the n'_h units, (ii) select the n_h units *with* replacement, but consider only the distinct units, and (iii) for the sample size at the second phase, consider the minimum of $(n_h,\ n'_h)$.

Ratio Estimator

The ratio estimator for $\overline{Y}$ is

$$\widehat{\overline{Y}}_{\mathrm{R}} = \left(\frac{\overline{y}}{\overline{x}}\right)\overline{X},$$

where $(\overline{x}, \overline{y})$ are the means of a sample of n units selected randomly without replacement from the N units, and $\overline{X}$ is the population mean of an auxiliary variable. The double sampling procedure is implemented when $\overline{X}$ is unknown. In this situation, a large and inexpensive sample of n_1 units is first selected without replacement from the N units. The mean $\overline{x}_1$ of these n_1 units provides an **unbiased** estimator for $\overline{X}$. At the second phase, a sample of size n is selected without replacement from the n_1 units and the means $(\overline{x}, \overline{y})$ are obtained. The ratio estimator for $\overline{Y}$ is now

$$\widehat{\overline{Y}}_{\mathrm{Rd}} = \left(\frac{\overline{y}}{\overline{x}}\right)\overline{x}_1.$$

With a cost function of the form $C = c_1 n_1 + cn$, optimum values of n_1 and n can be determined to minimize the cost or variance.

Different procedures, including the **jackknife**, are available for reducing the **bias** of $\widehat{\overline{Y}}_{\mathrm{R}}$. Rao [67] investigates the merits of eight modifications and extensions of these procedures for estimating $\overline{Y}$ through the ratio method and the double sampling procedure.

In some situations, the second sample of n units is selected independently of the first sample. For such a case, Rao [65, 66] considers estimating $\overline{X}$ from $\overline{x}^* = a\overline{x}_1 + (1-a)\overline{x}$ or the mean $\overline{x}_\nu$ of the ν distinct units of the two samples, and compares

$$\widehat{\overline{Y}}^*_{\mathrm{Rd}} = \left(\frac{\overline{y}}{\overline{x}}\right)\overline{x}^*$$

and

$$\widehat{\overline{Y}}_{\mathrm{R}\nu} = \left(\frac{\overline{y}}{\overline{x}}\right)\overline{x}_\nu,$$

with $\widehat{\overline{Y}}_{\mathrm{Rd}}$; the constant a is chosen to minimize the variance of $\overline{x}'$.

With stratification, the combined (RC) and separate (RS) ratio estimators for $\overline{Y}$ are

$$\widehat{\overline{Y}}_{\mathrm{RC}} = \sum W_h \left(\frac{\overline{y}_h}{\overline{x}_h}\right)\overline{X}_h$$

and

$$\widehat{\overline{Y}}_{\mathrm{RS}} = \left(\frac{\overline{y}_{\mathrm{st}}}{\overline{x}_{\mathrm{st}}}\right)\overline{X},$$

respectively. In these expressions, $\overline{X}_h$ is the mean of the auxiliary variable of the N_h units of the hth stratum, $\overline{x}_h$ is the mean of a sample of n_h units selected randomly without replacement from the N_h units, and $\overline{x}_{\mathrm{st}} = \sum W_h \overline{x}_h$. If $\overline{X}_h$ and $\overline{X}$ are not known, then the above estimators can be obtained through the double sampling procedure. Tripathi & Bahl [107] extend such a procedure to the case of more than one auxiliary variable. Ratio estimation with stratification was also considered by Ige & Tripathi [39], and with **poststratification** by Sethi & Srivastava [79] and White [110].

For the chain ratio estimator of $\overline{Y}$, additional information on a variable which is inexpensive to measure but less correlated with y than x is utilized. Srivastava et al. [94, 95] and Singh & Singh [88] apply the double sampling procedure to this method of ratio estimation.

Regression Estimator

The **linear regression** estimator for $\overline{Y}$ is

$$\widehat{\overline{Y}}_{\mathrm{lr}} = \overline{y} + b(\overline{X} - \overline{x}),$$

where b is the regression coefficient obtained from the sample of size n selected randomly without replacement from the N units. As in the case of the ratio estimator, for the double sampling regression estimator the unknown $\overline{X}$ is replaced by the mean $\overline{x}_1$ of the first sample. Cochran [18, Chapter 12] presents the variance of this estimator, the estimator of variance, and the optimum sample sizes for minimizing the variance or the cost. A model-based estimate for the variance is presented by Dorfman [24]. Bellhouse & Joshi [7] examine the admissibility of the double sampling regression estimator.

Selection of the first and second samples independently was considered by Bose [9]. For this case, Rao [64] considers replacing $\overline{X}$ with $\overline{x}^*$ or $\overline{x}_\nu$. Tikkiwal [104] considers the second sample to be selected from the $(N - n_1)$ units.

For a large population, Han [31] first tests whether $\overline{X}$ is zero. If this hypothesis is rejected, then the above estimator can be used for estimating $\overline{Y}$; otherwise, $\overline{X}$ is set to zero. Esimai & Han [26] extend this

procedure to more than one auxiliary variable. Sisodia & Srivastava [91] consider an extension of this procedure by considering two specified alternative values for $\overline{X}$.

The regression method has been extended to more than one auxiliary variable, for example by Kiregyera [43] and Singh [83] for two auxiliary variables. Conniffe [19] considers the double sampling estimator with unequal regression coefficients. Matloff [52] employs the double sampling procedure for **nonlinear regression** and Baker et al. [6] for **logistic regression**. Tamhane [100] uses the double sampling procedure for the regression method and tests of hypothesis. Prediction through the double sampling ratio and regression methods was examined by Agrawal & Jain [1]. Singh & Singh [87] consider the double sampling chain regression estimator. Conniffe & Moran [20] use the double sampling regression estimator for comparative studies.

Multivariate ratio and regression estimators are formed by including information for more than one auxiliary variable. Tripathi [106] and Kiregyera [42] consider the multivariate chain ratio estimator with double sampling.

Further topics related to the regression or ratio methods appear in [6, 17, 53, 59, 88, 100, 108], and [109].

Analytic Surveys

In these types of surveys, importance is given to the determination of the sample sizes for estimating the differences of means of domains or subpopulations. Sedransk [75, 76] and Booth & Sedransk [8] present the double sampling procedures for finding the sample sizes for minimizing the variances or costs.

Nonresponse

When only n_1 of the n sampled units respond, Hansen & Hurwitz [32] suggested subsampling m of the $n_1 = n - n_2$ nonrespondents (*see* **Nonresponse**). The population mean is now estimated from

$$\widehat{\overline{Y}}_{\mathrm{H}} = \frac{(n_1\overline{y}_1 + n_2\overline{y}_{2m})}{n},$$

where $\overline{y}_1$ and $\overline{y}_{2m}$ are the means of the respondents and the subsampled units. If $\overline{X}$ is known, the ratio estimator for the mean is

$$\widehat{\overline{Y}}_{\mathrm{HR}} = \left(\frac{\widehat{\overline{Y}}_{\mathrm{H}}}{\widehat{\overline{X}}_{\mathrm{H}}}\right)\overline{X},$$

where $\widehat{\overline{X}}_{\mathrm{H}}$ for the auxiliary characteristic is defined analogous to $\widehat{\overline{Y}}_{\mathrm{H}}$. When $\overline{X}$ is unknown, Rao [69, 70] constructs estimators for $\overline{Y}$ through the ratio method and also extends them to the regression method.

Multistage Sampling

In two-stage sampling, cluster or primary sampling units (PSUs) are selected at the first stage and elements or secondary sampling units (SSUs) are chosen at the second stage from the units selected at the first stage (*see* **Cluster Sampling**; **Multistage Sampling**). **Stratification** may be implemented at either stage and ratio or regression methods of estimation may be employed. In multistage sampling, this procedure is extended to several stages. Double sampling for multistage sampling was considered by Robson [73], Robson & King [74], Garg & Pillai [28], and others.

Successive Sampling

For some types of survey, samples are selected at two or more periods of time. Stratification and ratio and regression methods of estimation are also used in these types of survey. Double sampling procedures for successive sampling are considered by Arnab & Okafor [4], Singh & Singh [82], Sen et al. [77], Sisodia [89], and Lamba & Singh [45].

Classification Errors

In some applications, errors made in observing or measuring a unit can lead to its classification into the wrong group. In medical diagnosis, these misclassifications are known as **false positives** and **false negatives**. For estimating **binomial** and **multinomial** proportions, Tenenbein [101–103] first considers inexpensive and less than perfect measurements on a sample of units and then expensive and accurate measurements on a subsample of them; the proportions are estimated from the observations of both the samples.

Nedelman [54] uses a double sampling method for estimating the **prevalence** of malaria from the inaccurate observations. Lie et al. [48] estimate the percentage of congenital malformations from double registrations. The double sampling procedure was considered by Hochberg [38] for analyzing misclassified categorical data, by Mak & Li [51] for estimating subgroup means, by Chernoff & Haitovsky [16] and DeWith [22] for comparing two binomial probabilities, and by Swensen [97] for estimating the change in a probability.

Jolayemi [40] considers the above type of estimation for multiple outcomes and misclassifications. Chen [15], Korn [44], and Palmgren [58] also consider it for misclassified categorical data.

Further Topics

Des Raj [23] considers double sampling for **sampling with probability proportionate to size (PPS)**. Bellhouse & Joshi [7] examine the double sampling and regression method of estimation for PPS sampling. Chaudhuri & Adhikary [13, 14] examine varying probability of selection with double sampling.

A double sampling procedure was suggested by J. N. K. Rao [62] for estimation when the **sampling frame** contains duplications and there is nonresponse in the selected sample. Hinkins & Scheuren [37] apply the "hot deck" imputation when nonresponse occurs for a double sampling procedure (*see* **Missing Data Estimation, "Hot Deck" and "Cold Deck"**).

The difference estimator is the regression estimator presented earlier with the regression coefficient set to unity. This method of estimation with double sampling was considered by Talukder [99] and Singh & Singh [87].

The product estimator for the mean is $\hat{\overline{Y}} = (\overline{xy})/\overline{X}$. For large samples, the **mean square error** of this estimator can be smaller than the variance of $\overline{y}$ if the **correlation** of x and y is negatively large. The ratio and product methods can be combined if some of the auxiliary variables are positively correlated with y and some are negatively correlated. For estimating the population mean of the auxiliary variables, double sampling procedures were considered by Ray & Singh [71], Sisodia & Dwivedi [90], and Singh [84, 85].

The jackknife method for reducing the biases of the double sampling ratio and product estimators was examined by Sengupta [78]. **Bayes** estimation with double sampling was considered by Chaudhuri & Adhikary [13, 14], Geng & Asano [29], and Smith [92]. Ahuja & Srivastava [3] consider the double sampling method for **systematic sampling**.

Double sampling for the measurement of process bias was considered by Lessler [46], for the response bias by Talukder [99], and for nonresponse at the second phase with stratification by Swensson [98]. Kawatheker [41] considers a modified ratio estimator with double sampling, and Li et al. [47] consider double sampling for estimating strata means with corrections based on the second phase sampling. Further results on double sampling appear in [10, 33, 50, 61, 80, 83, 108], and [109].

Drug Approval and Regulation

Before it can be marketed, any new medicinal product generally requires the regulatory approval of the appropriate governmental agency. In making the decision whether or not to license the product, the regulatory agency will normally consider evidence relating to the pharmaceutical quality of the product (its purity, and consistency), its efficacy (the extent to which it works, or achieves desired therapeutic effects), and its safety (the extent to which undesirable side effects attributable to the drug are absent). Some, but certainly not all, countries also require evidence that there is a clinical need for such a drug. The set of evidence considered will generally include results from preclinical toxicological studies (*see* **Preclinical Treatment Evaluation**), **pharmacokinetic and pharmacodynamic** studies, dose-finding studies *(see* **Phase I Trials**; **Phase II Trials**), Phase III comparative **clinical trials** of efficacy and safety, and sometimes from **bioequivalence** studies. Subsequently, data collected from **postmarketing surveillance** of adverse events may be reviewed at a later date. Much of what is described here with reference to licensing of medicinal products (drugs) also applies in parallel areas of approval and regulation of **medical devices**, dental and surgical materials, and veterinary products, although consideration of statistical issues is to date rather less well developed in some of these fields.

Regulatory Agencies and Statisticians

Statistical issues arise in many aspects of the process of drug approval and regulation, and statisticians are thus employed in, or used as advisors by, drug regulatory agencies to support that process. What may be more surprising is the relatively recent and haphazard provision for such involvement in some agencies. In the latter half of the twentieth century, the regulatory agencies that have had the greatest influence on pharmaceutical development are those of the United States, the European Union, and Japan. Most pharmaceutical companies have centered their regulatory strategies on satisfying the requirements of these authorities, knowing that relatively little extra work would generally be needed to satisfy the many other national authorities. However, this should not be taken to imply that there is an absence of scientific competence or statistical expertise in other agencies, many of which take strong independent positions on statistical issues when the need arises.

The regulatory agency in the United States is the **Food and Drug Administration** (FDA). Since the 1960s, this agency has employed large numbers of statisticians to review licensing applications. In addition, as part of the process of arriving at licensing decisions, the FDA has regularly elicited the opinions of experienced external statisticians, mainly academics, through their Advisory Committee Meetings.

The statistical resourcing of European agencies has been less generous and there is no consistent model [3]. However, starting in the 1990s, considerable improvements in this situation have been noted [4]. Since 1995, the coordinating and administrative body for the licensing of medicinal products in the European Union has been the European Medicines Evaluation Agency (EMEA). So far this organization has not employed statisticians. Indeed up to the present time, it has not employed any staff to carry out the work of scientific assessment of regulatory dossiers because, under the European procedures that were introduced in 1995, this activity is delegated to the national agencies of the individual Member States. Three national agencies (UK, Germany, and Sweden) have each employed small numbers of professional statisticians for 10 years or more, and their work has been mostly connected with the licensing of new products or modifications to existing licenses but has also extended into pharmacovigilance. All EU agencies, including the EMEA, have made some use of external expert statisticians for advice on statistical and methodological issues but the extent and manner of their use has varied considerably. Some Member States, such as France, have made extensive use of external statistical experts, involving them directly in assessment work, drafting guidelines, and other related activities. Other Member States, such as the Netherlands, have appointed statisticians to the national advisory committees that provide formal advice to aid regulatory decisions. These different ways of involving professional statisticians in the regulatory process are by no means exclusive: in addition to employing full-time professionals, the German agency also makes regular use of external expert statisticians in its assessment work; likewise, the UK agency had a long history of

appointing expert statisticians to its advisory bodies well before it took the step of recruiting full-time statistical staff.

In Japan, the licensing of medicinal products is carried out within the Ministry of Health, Labour and Welfare (MHLW). For several years, a small group of statisticians had been employed within this organization specifically for regulatory work. The MHLW also makes extensive use of academic consultants in providing regulatory advice and ensuring the appropriate conduct of regulatory clinical trials.

Statistical Assessment

In view of the considerable differences in the numbers of statisticians in regulatory bodies and in their manner of employment, it follows that statistical assessment procedures also vary markedly. In the United States, for example, the system ensures that FDA statisticians have access to the complete database of clinical trial and other data. They can thus carry out their own independent analyses of the key findings. These can then be considered in conjunction with the licensing applicant's own analyses by those charged with drawing scientific conclusions to support licensing decisions. This process has a tendency to polarize the analyses. The applicant's statisticians tend to emphasize the methods and aspects that support a more positive conclusion while the regulatory statisticians tend to be more conservative. Although there is clearly a danger that appreciable **bias** can be introduced by partisan presentations from either side, these are natural positions for the two groups to adopt and, by the end of the process, they usually lead to balanced decisions. This approach certainly minimizes the danger of assessors being unduly influenced by biased analyses from the applicant, and it also reduces the possibility of **fraud**.

In other agencies, such as those in the EU, independent analyses are rarely carried out. EU regulatory statisticians focus on verifying the validity and accuracy of the applicant's analyses and the appropriateness of the conclusions drawn from them. If they identify any apparent deficiencies, they may request the applicant to carry out further clarifying statistical work. Only rarely will they ask to be supplied with raw data in order to carry out their own analysis. In view of the limited resources available in the EU agencies, this approach is almost inevitable. However, it has the beneficial consequence that it is in the applicant's interest to submit a balanced analysis that discusses clearly all the pros and cons and presents well-justified conclusions. In this way, the applicant can try to avoid the delays that arise when further work is requested.

In the majority of regulatory agencies, the statistical resource is insufficient to assess all applications. This leads to another varying aspect of assessment, namely the question of which applications should be selected for assessment by a professional statistician. In some agencies, statistical review is invoked on grounds of perceived statistical complexity by nonstatistical reviewers. In others agencies, statistical assessment is routinely invoked for certain types of application or product, such as new chemical entities. Sometimes a senior statistician plays a part in selecting applications for statistical assessment. The different parts of an application also receive varying amounts of statistical attention. The most vigorously and routinely assessed part is the Phase III program of clinical trials and, in particular, the evidence of efficacy provided by these. Other issues, such as those associated with quality or safety, are less likely to be assessed by regulatory statisticians unless they are found to have a difficult methodological aspect.

The relative merits of the various assessment procedures described are a matter of continuing debate. However, the case for some form of statistical assessment of license applications is strong on grounds of both quality of the assessment made and efficiency with which it is made [5]. As noted above, drug license applications inevitably include a complex variety of statistical evidence. Critical professional assessment and review of this evidence is essential if correct licensing decisions are to be made efficiently. Methodological input to the regulatory process, leading to more rapid agreement on appropriate approaches to obtaining the required evidence of safety, quality, and efficacy, may have direct economic benefits to applicant companies in the short term, and thus to potential consumers of their products in the longer term. Erroneous decisions can be of two kinds: (i) inadequately stringent assessment may allow products with unsatisfactory risk/benefit ratios through to the market; or (ii) overcautious interpretation of evidence, perhaps in the light of statistical complexity, may lead to the failure of potentially valuable medicinal products to reach the market. In either case, the human and financial consequences

may be grave. For example, the first kind of error may result in patients being exposed unnecessarily to serious, possibly fatal, side effects of drugs; the second may prevent pharmaceutical companies from profiting from substantial investments in research and development but, more importantly, may prevent patients from receiving beneficial treatments.

License Application

A license application consists of a body of written evidence that supports a number of claims made on behalf of a medicinal product. At the base of the pyramid of evidence is usually a large number of pertinent studies, animal and human, *in vitro* and *in vivo*. The design and analysis of each of these individual studies are presented, and the conclusions that can be drawn from them are described. In addition, there may be summaries, and sometimes **meta-analyses** [2] that bring together the results of the separate studies to support specific licensing proposals.

The presentation of each study can and should involve statistical interpretation of evidence in support of the claims made. Summaries of the results of several studies should receive similar statistical attention. For the most part, this will involve straightforward application of standard methods. For example, we may expect or at least hope to see interval estimation (*see* **Confidence Intervals and Sets**) of the percentage of impurities in samples of the drug, of the response to the drug (on perhaps a **binary** success/failure scale, or as a continuous measure) in clinical trials, and of the **incidence** of adverse events following use of the drug in an identified cohort. We may also expect to find a discussion of the statistical precision and reliability of important estimates and sometimes an investigation of the **robustness** of the estimates to the analytical assumptions that have been made.

Unfortunately, at present some overemphasis on mechanical application of significance testing (*see* **Hypothesis Testing**) remains, and there are also other aspects of analysis where standardized approaches are overemphasized. Although mainstream applications of familiar statistical methods are often necessary, many of the more difficult issues require the intelligent application of a range of statistical approaches. Specification of "standard" approaches deemed acceptable by regulatory authorities are sometimes overzealously sought, perhaps especially by those lacking appropriate technical skills and experience, as a result of the commercial and health-related importance of the regulatory decisions that rest on them. There is often insufficient recognition that statistics is a science that requires interpretation and judgment; this in turn may require the evaluation of alternative approaches coupled with carefully argued justification of the conclusions finally reached.

The desire for the specification of approaches that are acceptable to regulatory authorities and the identification of areas where controversy remains has led to the development of regulatory guidelines in many areas of pharmaceutical science and, in particular, in pharmaceutical statistics. The development of statistical guidelines is fully described elsewhere, including the important ICH E9 **guideline** [1] that was developed as part of the international conference on harmonization (ICH) process. Statistical guidelines provide a consensus view of current methodology. However, they do not, and cannot, take away the need for professional statistical involvement in regulatory work, either in preparing applications or assessing them. Indeed, the ICH E9 guideline emphasizes the importance of the statistician's role. Difficult and contentious statistical issues often lie at the heart of the evidence provided by clinical trials and other experimental work. It is important that these are always investigated, interpreted, and described with care and understanding.

Drug Interactions

Interaction is a familiar term to most biostatisticians. When the effect of one factor differs across levels of a second factor, interaction between the factors is present. Drug disposition refers to the processes of how a drug is absorbed, distributed, metabolized (broken down), and excreted [6]. Variations in drug disposition and/or effect may result from interactions with, for example, diseases or genetic make-up. *Drug interactions* refers to the alteration of the disposition and/or effect of one drug, owing to the presence of a second drug.

What Causes Drug Interactions and Why are They Important?

Drug interactions arise from a myriad of complex physiologic conditions [5]. **Pharmacokinetics** refers to what the body does to the drug (processes of drug disposition), while pharmacodynamics refers to what the drug does to the body (the drug effect). Changes in the processes of drug disposition, known as the pharmacokinetic interaction, may take place when one drug's rate of elimination from the kidneys or liver is altered by a second drug. In such circumstances a drug can improperly accumulate in the body or be excreted too quickly. Another type of pharmacokinetic interaction can occur when specific enzymes that metabolize a drug become inhibited or induced by the presence of a second drug. A pharmacodynamic interaction refers to the alteration of the effects of one drug when given concurrently with another drug. The net result of a pharmacodynamic interaction may be an enhanced or diminished effect or the appearance of a new side-effect that was not seen with either drug alone.

Drug interactions may pose a dangerous threat to public health, especially when two commonly prescribed (and co-administered) drugs interact. A notable example is the gravely serious drug interaction between terfenadine (Seldane), a commonly prescribed anti-histamine, and ketoconazole, a popular anti-fungal drug [2, 4] When these drugs were taken simultaneously, unexpected life-threatening EKG changes (a syndrome known as Torsades de Pointes) and deaths occurred that were later attributed to an interference to the same key metabolizing enzymes shared by both drugs.

How Does Inter-Subject Variability Play a Role?

Studies that measure drug pharmacokinetics and/or pharmacodynamics are often challenged by substantial and unpredictable *inter-subject variability*. How the body processes a drug can differ greatly among subjects. This inherent variability in drug disposition is known as inter-subject pharmacokinetic variation. For a group of subjects given a fixed dose of a single drug, a large variation in serum drug levels (i.e. a coefficient of variation of 60% or greater) is commonly noted. Hence, for a two drug interaction study it is extremely difficult to partition the observed pharmacologic variation of one drug into underlying inter-subject pharmacokinetic variation vs. the variation due to the presence of a second drug. Moreover, identifying the sources of observed variability in drug effect, termed inter-subject pharmacodynamic variation, poses even greater difficulties. Suppose a target serum drug level can be achieved and maintained in a group of subjects. Even though the body's exposure to the drug is the same in all subjects, the variation in effect (e.g. lowered blood pressure) among subjects may be substantial. Introducing an additional source of variability, such as a second drug, further complicates the interpretation of inter-subject differences.

Which Study Design Addresses Inter-Subject Variability?

One design appropriate for testing drug interaction is a repeated measure design (*see* **Longitudinal Data Analysis, Overview**) [1]. This design, commonly called a crossover or **randomized complete blocks designs**, allocates all treatments to each subject, with an adequate "washout" period between treatments. Repeated measures denotes the serial measurements of drug disposition and/or effect after each treatment is administered. As each subject serves as his/her own control, all sources of variability among subjects are controlled. Only variation within subjects (the treatment effect) enters into the analysis. Typically, crossover studies designed to test for pharmacokinetic interaction enroll $10-25$ subjects.

For a two-drug interaction study of drugs A and B, each subject receives drug A, drug B, *and* a combination of drugs A and B. The order of the three treatments is often randomly assigned and balanced

so that the measurements are not **confounded** by treatment order. The model for a repeated measures design for a two-drug interaction study is

$$Y_{ij} = \mu_{..} + \rho_i + \tau_j + \varepsilon_{ij},$$
$$i = 1, \ldots, n,\ j = 1, 2, 3,$$

where i denotes the subjects and j denotes the treatments (let $j = 1$ for drug A, $j = 2$ for drug B, and $j = 3$ for a combination of A and B). Y_{ij} denotes the measure of drug disposition or effect when the ith patient is given the jth treatment, $\mu_{..}$ denotes the overall outcome mean, ρ_i denotes the subject effect, τ_j denotes the treatment effect, and ε_{ij} denotes the error term. Individual subject effects are not of interest and only serve to reduce experimental error due to inherent inter-subject variability. Interaction is tested by a comparison between treatment means (analogous to a **paired *t* test**) and is performed by planned **contrasts**. For example, to test whether the effect of drug A is altered by drug B, the **null hypothesis** of no interaction is tested by

$$H_0 : \mu_{.j} - \mu_{.j'} = 0,$$

where, as noted above $j = 1$ and $j' = 3$. Similarly, to test whether the effect of drug B is altered by drug A, the null hypothesis of no interaction is tested by:

$$H_0 : \mu_{.j} - \mu_{.j'} = 0,$$

where $j = 2$ and $j' = 3$.

A recently published crossover study designed to test for the pharmacokinetic interaction between two agents, atovaquone and zidovudine, serves as an example [3]. Patients with human immunodeficiency virus (HIV) are at risk from adverse drug interactions because of the many drugs commonly prescribed to treat their disease and symptoms, such as *pneumocystis carinii* pneumonia (PCP). Atovaquone is an agent shown to be effective against PCP. Zidovudine is an anti-retroviral agent used as primary treatment for acquired immunodeficiency syndrome (AIDS). A high percentage of patients who receive treatment for PCP are also treated with anti-retroviral agents, so it is likely that these agents may be co-administered. A study was conducted to test whether the drugs could be co-administered without significant pharmacokinetic interaction. The treatment consisted of 26 consecutive days of therapy, defined by three dosing periods. Zidovudine was administered in the first dosing period (on days 1 and 2). Periods 2 and 3 consisted of 12-day intervals in which either atovaquone alone or atovaquone plus zidovudine was administered. The order of periods 2 and 3 was randomly assigned (*see* **Randomization**). Fourteen men with HIV enrolled on the study. Repeated measures analysis revealed that zidovudine and atovaquone could be co-administered without clinically significant pharmacokinetic interaction. Zidovudine had no effect on the disposition of atovaquone, while the systemic exposure of zidovudine was found to be increased by 33% after atovaquone administration.

ROSEMARIE MICK

Drug Utilization Patterns

Exponential growth in prescription drug costs has raised questions about whether the expected cost-benefits (*see* **Health Economics**) of drug therapy are being realized in the population [61, 151]. At least three factors may dramatically alter the population's experience with a drug in comparison with effects observed in a **clinical trial**. First, most drug trials are carried out in populations of middle-aged adults, usually with a single health problem and who take few, if any, medications [52]. Evidence from these studies is generalized to the main users of prescription drugs, the elderly population, who receive 40% of prescription medication even though they comprise only 10 to 12% of the population in Western countries [46, 101, 133]. Seniors differ from middle-aged adults in several important respects. They are much more likely to have concurrent disease and use a number of medications, which may alter the absorption, distribution, and excretion of a drug, and influence the expected risks and benefits of therapy [13]. Secondly, drug use in the population often spans a broader set of indications than those evaluated in the context of a clinical trial. Thirdly, sample sizes in a clinical trial are usually estimated on the basis of the expected benefit of a drug (*see* **Sample Size Determination for Clinical Trials**). Therefore, clinical trials are usually underpowered (*see* **Power**) to detect clinically meaningful differences in less common, but clinically important, adverse outcomes. For example, **placebo**-controlled trials of the efficacy of aspirin in the prevention of myocardial infarction (MI) and stroke (*see* **Prevention Trials**) show a reduction in the occurrence of MI and stroke without evidence of adverse effects [22, 41, 149]. However, the size of the study population in each of the trials was insufficient to evaluate less common, but clinically important, adverse outcomes such as hemorrhagic stroke. When **meta-analysis** was used to pool results across trials, a twofold increase in the risk of hemorrhagic stroke was observed among aspirin users in comparison with placebo [90, 144].

To avoid such limitations, postmarket observational studies have been the primary means of providing information about the utilization of a drug in the population and its corresponding risks and benefits (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**). Skegg [130] discusses many methodological issues related to **observational studies** of postmarketing surveillance. Control of biases in selection, information, and **confounding** are the main challenges in observational studies (*see* **Bias in Observational Studies**). In this respect, the increasing use of population-based **administrative databases** to study prescription drug use in the population [7, 84, 112, 113, 125] and to examine the associations between prescription drug use and morbidity and mortality outcomes [49, 107, 108, 134] has come with its own advantages and particular challenges.

The Use of Administrative Databases in Drug Utilization Studies

To measure drug exposure, two types of administrative databases can be distinguished: (i) prescription claims databases (reimbursement claims for prescriptions dispensed to individuals in drug insurance plans) and (ii) pharmacy networks (pharmacy prescription drug profiles are linked by a computerized network in a region or district). Table 1 outlines the advantages and disadvantages of using these types of databases to ascertain drug exposure.

When a prescription database contains a unique identifier, such as a health insurance number, or nominal information, such as name, age, and birth date, there is the potential to link information describing an individual's exposure to a drug with other health care databases that contain information on morbidity and mortality *(see* **Record Linkage**). A description of the types of databases that are used, and the types and sources of information available, are summarized in Table 2.

Future Opportunities for Research through Point-of-care Data Collection from Electronic Health Records

In the next decade, we can expect to see a dramatic change in the data sources used for drug utilization research (*see* **Health Care Utilization Data**). The increasing use of information technologies to enable health care delivery are gradually replacing a predominantly paper-based system with integrated electronic health records. The integrated electronic health record can initially be expected to provide standardized, coded information on drugs prescribed and dispensed, laboratory, radiology and pathology results, operative reports, and active and past health

Table 1 Prescription databases: advantages and disadvantages

	Advantages	Disadvantages
Comprehensiveness	• All dispensed prescriptions (except exclusions) from all prescribers and all pharmacies documented, not just those known by the primary physician or reported by the patient [140] duration or prescribing	• Over-the-counter drugs excluded • Noninsured drugs excluded (for claims data only) • Borrowed drugs from friends excluded • Drugs during hospitalization may or may not be included • Documentation of prescription physician not always required for reimbursement
Drug information	• Data required for reimbursement is complete, including date dispensed, drug identification number (format, strength, drug), quantity, approximate duration, prescriber (claims data) • Completeness and accuracy of drug information data superior to that obtained from medical charts or by self-report	• Prescribed dosing not documented, which is a problem for drugs prescribed on an "as needed" basis, drugs prescribed on alternate day or graduated regimens (e.g. coumadin) • Substitution of one drug for another not recorded • Indication for prescription not recorded
Efficiency	• Data on prescription drug use can be retrieved at considerably less cost than retrieving the same information by primary data collection	• High-speed computer equipment and technical sophistication required to manage millions of prescription records and to produce usable measures for each patient
Population coverage	• A population-based sample can be readily assembled in many jurisdictions (exclusions noted) without concern for bias due to nonresponse or the significant cost of recruitment	• With claims data, subgroups in the population may not be covered by the drug insurance plan; also, inclusion in the drug insurance plan may be based on factors such as poor health or poverty, which may also influence the risk and benefit of a drug, and produce a biased estimate of its actual impact in the source population

problems. Eventually, with the increasing sophistication of the clinical interface, physicians and other health professionals will document history, lifestyle, and physical examination findings in electronic clinical notes. Hospitals have led the implementation of electronic health records, with the exception of a few countries such as Australia and the United Kingdom, where government initiatives have subsidized implementation in community-based care [12]. The transition to the electronic health records will provide the detailed clinical data that is needed to characterize study populations, and will enable new avenues of research, such as the effects of drugs on physiological parameters, the quantification of primary noncompliance with prescribed treatment and its predictors, and the treatment indications and outcomes associated with hospital-based drug and transfusion therapies. Surprisingly, only a few pioneering institutions [10, 11] have capitalized on the benefits of electronic health records for research; an issue that needs to be redressed through formal links between the health care information technology divisions and the research enterprise [89].

Studying the Effects of Drugs in the Population: Methodological Challenges

In many studies of drug utilization, the purpose of the study is to determine whether a class of drugs or a specific drug is associated with a greater risk of adverse outcomes than either other drugs or no drug. A number of methodological challenges are present in these types of observational studies, irrespective of the source of information: database or primary clinical data.

Assignment of Outcomes to Individual Drugs

Clinical Indication Bias. Patients who are selected for a specific drug treatment may differ considerably

Table 2 Databases available to assess morbidity and mortality outcomes

Database	Population	Source	Relevant data available
Hospitalization	Individuals discharged dead or alive from hospital	Abstraction and coding of the patient chart by medical records archivists [36, 111, 148]	• Cause of accidents leading to admission • Discharge diagnosis and 10–15 secondary diagnoses • Major treatments, surgery, and complications • Date of admission, discharge • Discharge destination • Death in hospital • Type of service delivered (e.g. fracture reduction of femur, carotid endarterectomy, pap smear)
Physician claims	Individuals receiving physician services in community and institutional settings	Reimbursement claims for physicians providing services on a fee-for-service basis	• Date and location of service and type of provider • Diagnosis (not an accurate indicator of reason for visit) • Primary cause of death
Vital statistics	Deaths occurring among national, regional residents	Death certificates completed by physicians, legal requirement for documentation	• Contributing causes of death • Name, birth date, sex, date of death

Table 3 The risk of adverse gastrointestinal events in a random database sample of 51 814 elderly in Quebec in 1990 [42]

Drug treatment group	Odds ratio	95% confidence interval
No NSAID prescription	1	–
NSAID alone	0.74	0.7, 0.8
NSAID + misoprostol	4.14	3.5, 5.4
NSAID + other GI drug prophylaxis	4.44	4.1, 4.8

in their risk of an adverse outcome from patients who are not treated. For example, misoprostol is a drug that has been shown in clinical trials to be efficacious as a prophylactic treatment for nonsteroidal (anti-inflammatory) drug (NSAID)-related ulcers [128]. In clinical practice, however, physicians tend to prescribe prophylactic gastrointestinal (GI) therapy to patients who are at higher risk of NSAID-related GI problems, or avoid prescribing NSAIDs altogether. As a result, as illustrated in Table 3, patients who receive prophylactic misoprostol or other GI-related therapy appear to have a greater risk of experiencing an adverse GI event, and persons receiving NSAIDs alone are at less risk of adverse GI events than the untreated population. These paradoxical findings dramatically illustrate the pitfalls of conducting observational studies on the risks and benefits of specific drug treatment without controlling for baseline differences, independent of the drug use, in risk of the outcome between patients started and not started on the drug.

In this example, the problem was addressed by using baseline preexposure information to measure a patient's risk of an adverse GI event prior to the initiation of NSAID therapy. Data from the prescription and physician claims databases and the hospitalization database were used to measure prior GI bleed, prior ulcer treatment, investigation and/or ulcer diagnosis, concurrent use of medications that would increase the risk of bleeding (e.g. coumadin), and other relevant comorbid conditions.

Propensity Scores. To reduce confounding by indication, it is essential to adjust the estimated drug

effect for the differences in the baseline characteristics of users versus nonusers. Adjustment through multivariable regression (*see* **Multivariate Multiple Regression**) becomes more popular in this context than alternative techniques such as **matching** or **stratification**. However, in some observational studies, the investigators' ability to adjust the drug effect for numerous **covariates** may be limited, for example, because of small number of outcomes, which would affect numerical stability of the estimates if the ratio of observed outcomes to the number of estimated regression parameters decreases below the critical range of 5 to 10. In such situations, the **propensity scores** approach may provide a feasible way to adjust for multiple potential confounders [114], provided these variables are available. A propensity score is an estimated conditional probability of a subject receiving a given drug, rather than an alternative drug or placebo, conditional on subject characteristics (covariates). The propensity scores are estimated using multiple **logistic regression**, with a binary indicator of the drug of interest (versus alternative treatment or placebo) as the dependent variable, and the relevant covariates as independent variables (*see* **Explanatory Variables**). Thus, the logic of the propensity score is, in fact, a weighted average of the original covariates, with weights corresponding to **maximum likelihood** estimates of the respective parameters of the multiple logistic regression model. Accordingly, including a *single* covariate, representing the estimated propensity score, in the model used to assess the effect of the drug on the outcome of interest, provides an approximate method of adjusting simultaneously for all potentially confounding subjects' characteristics that are related to the treatment choice [114]. D'Agostino [30] provides an excellent tutorial on the propensity scores methodology, together with interesting examples of its applications. An acknowledged limitation of the propensity score method is that it weights the importance of pretreatment patient characteristics by the strength of association with treatment assignment, and not the outcome [120]. This limitation may introduce residual confounding as equivalent propensity scores may be assigned to patients on the basis of different characteristics, both of equivalent importance in predicting probability of treatment assignment, but possibly only one being of importance in predicting the outcome.

Multiple Drug Use. In seniors, multiple drug use is the norm. Seniors fill an average of 29 prescriptions per year for seven different drugs [142]. Concurrent drug use creates a host of methodological problems. First, multiple drug exposure increases the risk of potential **drug interaction** (the effect of one drug is altered by the presence of a second drug, thereby increasing the risk of overdose toxicity or treatment failure) (see Figure 1) [137] and adverse drug events [51, 97] *(see* **Pharmacoepidemiology, Adverse and Beneficial Effects**).

Secondly, the assignment of an adverse outcome to a specific drug is complicated by the existence of a host of competing explanations, for example, other drugs and diseases [66]. Thirdly, methods of classifying multiple drug users into comparable groups with respect to the risk of adverse drug outcomes have not been developed. The simplest method has been to count the number of concurrent drugs taken. However, Granek [47] demonstrated that the risk of an injury with exposure to sedative hypnotics varied from 2.4 to 17.8 depending on the specific combination of drugs used. The methodological challenge in drug use research is to move beyond the simple solution of excluding multiple drug users to avoid confounding. Practicing physicians need to identify the subset of multiple drug users who are at greatest risk of adverse outcomes with a specific drug as

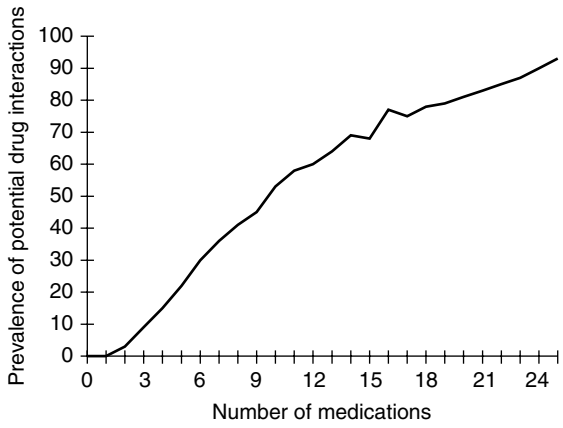

Figure 1 The association between the number of medications used by an individual patient and the prevalence of potential drug interactions. Reproduced from [137] by permission of Societé Française de Pharmacologie

well as the subset who will probably benefit. Population level databases [1, 36, 40, 46, 82, 110, 111, 149, 150] provide the opportunity to address some of these questions as a large number of individuals can be studied at a comparably low cost. Large sample sizes provide an opportunity to model simultaneously the effects of various medications and various diseases, thereby enabling the investigator to dissociate these effects as well as to test for clinically important interactions.

Prescriber Effects. Conventional multiple regression models rely on the assumption that outcomes of patients are independent [72]. Yet, there is substantial evidence that physicians vary considerably in their propensity to prescribe drugs, in their use of new drugs that come into the market, and in the appropriateness of their choice of drug treatment [32, 33, 38, 55, 92, 93, 126, 140]. Indeed, one recent study showed that physicians with lower scores on licensure examinations of clinical competence were not only more likely to prescribe inappropriate medications, but were also even less likely to demonstrate lower levels of quality of care in other domains. This suggests that physician competence may modify the effectiveness of prescribed therapy, and the probability of adverse outcomes [139]. Since most individual patients tend to be treated by one or two physicians [141], it is plausible that outcomes among patients of the same physician are correlated.

Comparison of the results of few recent studies that have provided relevant empirical evidence suggest that the strength of within-physician correlation depends strongly on the outcome. The reported values of the intraclass correlation coefficient (ICC) (*see* **Correlation**), measuring the proportion of the total **variance** in the outcomes of individual patients that can be attributed to physicians, ranged from ICC = 0.04 in a study of physician contributions to managed care pharmacy expenses [27] to ICC = 0.44 for the impact of unobserved prescriber characteristics on the occurrence of generic drug substitution [94]. Moreover, even after adjusting for patients' characteristics, a marked within-physician correlation has been also reported for various clinical outcomes of patients with rheumatoid arthritis, with ICC ranging from 0.16 to 0.25, depending on the outcome [29]. The same authors found a strong impact of individual rheumatologists on the decision to use prednisone and second-line agents. Ignoring such correlations may lead to underestimation of **standard errors** of regression coefficients [18] and inflated type I error rates in **hypothesis testing** [116]. Moreover, ignoring possibly systematic impact of skills, attitudes and/or beliefs of individual physicians on their prescribing choices and/or on the outcomes of their patients, may induce confounding bias if, for example, the choice of a given drug depends on physicians' characteristics that are also correlated with the outcome. Yet, Cowen and Strawderman [27] have recently pointed out that, in spite of the availability of more appropriate statistical models, most studies of the physician prescribing patterns continue to employ ordinary **least squares** regression (OLS), that relies on the independence assumption and ignores potential prescriber effects.

The methods able to account for within-cluster correlations of the outcomes include **generalized estimating equations** (GEE) [152], mixed models [70, 77], and **multilevel modeling** [16, 43, 44]. These methods handle both binary and continuous outcomes [76, 95, 152]. The choice of the specific method should depend on the scope of the analyses and on the plausibility of the underlying assumptions. In the simplest case, when the analyst is interested only in the effects of patient-level covariates, the standard "marginal" GEE model (sometimes referred to as GEE1 [85] may be used to correct the standard errors for the within-physician correlation [53]. In such analyses, the user may prefer to obtain a robust standard error which is not affected by **misspecification** of the structure of the **covariance matrix** of **residuals** (see below) [18]. Hanley et al. [53] provide an excellent nontechnical guide to applications of GEE in epidemiological and clinical studies with correlated outcomes, and identify some practically relevant limitations of this technique. Specifically, the GEE estimates of the regression coefficients for patients' characteristics, including treatment effects, have the "population average" interpretation, implying that they may be substantially different from the average within-physician effects that would be obtained, for example, from conventional matched analyses. This occurs because GEE yields a marginal version of the regression model, that is, the model that is estimated separately from the parameters of the covariance matrix [152]. Moreover, GEE does not provide an empirical criterion for the choice of an appropriate structure for the covariance of residuals [18] which, in our context, would represent deviations between observed outcomes of subsequent

patients of a given physician and the corresponding values predicted from the regression model [70, 146]. When correlations between such residuals are due, for example, to a systematic tendency of a given physician to chose a particular treatment more often than it could be expected based on his/her patients' characteristics, under the estimated regression model, the **exchangeable** covariance structure [142], sometimes referred to as compound symmetry structure [76], is a natural *a priori* choice as it assumes the expected correlation is the same for all pairs of patients of a given physician. However, in some cases the physicians' treatment preferences and the resulting prescribing patterns may change systematically over time [31]. In that case, the strength of between-patients correlations may decrease with increasing time elapsed between their respective prescriptions, making the autoregressive covariance structure, such as AR (1), a plausible alternative [146] (*see* **ARMA and ARIMA Models**).

An alternative approach relies on mixed models with **random effects** for individual physicians [70, 77]. Mixed models combine modeling of fixed effects of independent variables, representing their systematic impact on the outcome, as in the conventional multivariable regression, with random effects of individual physicians ("clusters"), that are not attributed to any observable covariates but are presumed to reflect their latent beliefs and attitudes. The random effects are assumed to be normally distributed (*see* **Normal Distribution**), with mean of 0 and variance that has to be estimated [27]. While the normality assumption may require some **transformation** of the dependent variable [15, 105], the above assumption avoids the need to specify explicitly the structure of the covariance of residuals [70]. Burton et al. [18] provide an excellent tutorial for researchers not familiar with a wide range of multilevel models for clustered and longitudinal data, including different versions of mixed models. Current research on prescribing patterns seems to favor the simplest version of the random effects model in that only intercepts are allowed to vary across physicians, while the associations between the patients' covariates and the outcome, such as treatment choice, are *a priori* assumed to be the same for all physicians [27, 29, 54, 94] The intercepts represent the individual physicians' systematic tendency to prescribe the drug of interest more or less often than it would be expected based on characteristics of their patients [27]. Cowen and Strawderman [27] explain well how to use random effects model with random intercepts in the research on prescribing patterns, and discuss its advantages, compared to either (i) naive OLS regression, or (ii) **fixed-effects** regression with $n-1$ **dummy variables** explicitly identifying each of n physicians. Specifically, random effects model increases efficiency of the analysis by replacing estimation of $n-1$ parameters by a single parameter representing the variance of random intercepts, helps separate the impact of individual physicians from the systematic effects of their characteristics, such as age or education, and avoids overestimating the impact of those physicians that contribute only relatively few patients. A further extension of the random-intercept model would include random slopes modeling [18], which would imply that the dependence of prescribing decisions on patient characteristics may vary across physicians. We found little evidence of the use of random slopes in the studies focusing on prescribing patterns, and the potential advantages of such more complex modeling remain to be investigated [27].

Finally, it should be noted that the mixed models represent a special case of the broader family of hierarchical multilevel models [16]. **Hierarchical models** are able to represent more than two levels of clustering, making it possible to account for clustering of patients within physicians' practices *and* for clustering of physicians within hospitals [17]. This allows for simultaneous modeling of patient-, physician- and hospital-level covariates, as well their interactions, while accounting for random effects of both physicians and hospitals [132]. For example, incorporation of cross-level interactions allows one to test if the impact of the patient health status on the choice on treatment varies between general practitioners and specialists. Finally, it is possible to quantify the proportion of the total variance in outcomes as these powerful models become increasingly available in user-friendly commercial **software** packages [16]. Raudenbush and Bryk [106] and Goldstein [45] present comprehensive descriptions of hierarchical multilevel models while Snijders et al. [132] and Burton et al. [18] provide user-oriented introductions. Burgess et al. [17] discuss many methodological issues relevant to implementation of hierarchical regression in the assessment of physicians' performance. Other examples of medical applications are found in [42] and [20].

Accounting for intercorrelations of either drug choices or potential clinical outcomes of medication use among patients of the same physician presents additional analytical challenges if the analysis has to rely on survival analytical methods such as the **Cox model**. Indeed, we are not aware of any commercial software package that would incorporate the Cox model analyses of multilevel data. Therefore, we tentatively propose two alternative approaches. Firstly, one may use a very recent method for incorporating random effects in Cox model, which relies on its affinity with **Poisson regression** [87]. An alternative approach would resemble the GEE methodology in that it yields "population average" point estimates of regression coefficients while attempting to correct the **confidence intervals** for the reduced amount of available information due to within-physician correlations of outcomes [53]. The proposed approach will adapt the method, developed by Abrahamowicz et al. [3], for **bootstrap** -based inference in complex nonlinear models involving nested or correlated data. The basic idea is to first estimate the conventional Cox model from the data pooled across all patients of all physicians, as for independent data. Next, the computer-intensive bootstrap procedure [35] is employed to simulate directly the effect of various sources of sampling error on the estimates. Specifically, the effects of (i) sampling physicians, and (ii) sampling patients within physicians' practices, are directly simulated by random resampling, with replacement, of (i) n original study physicians, and (ii) m_j patients original patients of each physician ($j = 1, \ldots, n$) sampled in step (i). To adapt this approach to our context, 1000 bootstrap samples should be generated by random resampling of the original data (Efron & Gong), and each sample should be independently analyzed with the Cox model. Finally, the 2.5th and 97.5th percentiles of the empirical distribution of the resulting 1000 Cox model-based **hazard ratio** (HR) estimates will provide the approximate bounds of the 95% confidence interval (CI) for the adjusted HR, and the **null hypothesis** of no effect of a given variable on hazard will be rejected at 0.05 level if the CI excludes 1.0 [3]. Whereas the procedure is computationally expensive, an exponential progress on the computational front makes it nowadays entirely feasible. However, further studies are necessary to assess the accuracy and relative efficiency of these alternative methods.

Measuring Drug Exposure

Compliance. To produce an accurate measure of the risk and benefit of drug treatment, patients need to be classified by the extent to which they were exposed to the respective drugs of interest. Database studies of drug utilization use information about dispensed prescriptions to determine whether an individual is likely exposed, information that tends to be superior to patient self-report or chart documentation of written prescriptions [50, 65, 71, 109, 134]. Although a dispensed prescription does not necessarily mean that a drug is taken, prescription refill rates have proven to be a valid means of measuring an individual's compliance with drugs that are used for chronic disease (e.g. hypertension) [69]. Figure 2 illustrates prescription refill rates for two hypnotic drugs. The beginning of each block is the date the drug was dispensed and the end is the date dispensed plus the recorded prescription duration (in days) (note that in some database files, duration is not specified, and **sensitivity analysis** [8, 39] is conducted to assess several duration time windows). Several approaches can be used to summarize these data, depending on whether the medication obtained by an early refill of a prescription (prescriptions 1 and 2) are added or not to the number of days of potential drug use.

Measuring Drug Dose. Figure 2 also provides information about drug dose, information that is ascertained from data on the quantity dispensed, the duration of the prescription, and the dose per unit of drug (e.g. 5 mg per pill). The first challenge is to decide how these data should be summarized to reflect the dose of drug taken in this 90-day window. For some drugs, such as lipid-reducing agents and prophylactic estrogens, the primary interest may be in the cumulative dose or average dose over time, while in others, such as sedative-hypnotics and nonsteroidal anti-inflammatory drugs, the starting dose, peak dose, or largest change in dose (such as precipitously stopping a high-dose, short half-life drug) may be the most important landmarks with respect to the risk of adverse events. The next challenge is to decide how overlaps of drugs in the same pharmacological class are to be handled, a situation that is relatively common in the elderly [136]. For example, it could be assumed that hypnotic B (prescription 3 in Figure 2) was substituted for hypnotic A (prescriptions 1 and 2), and hypnotic A

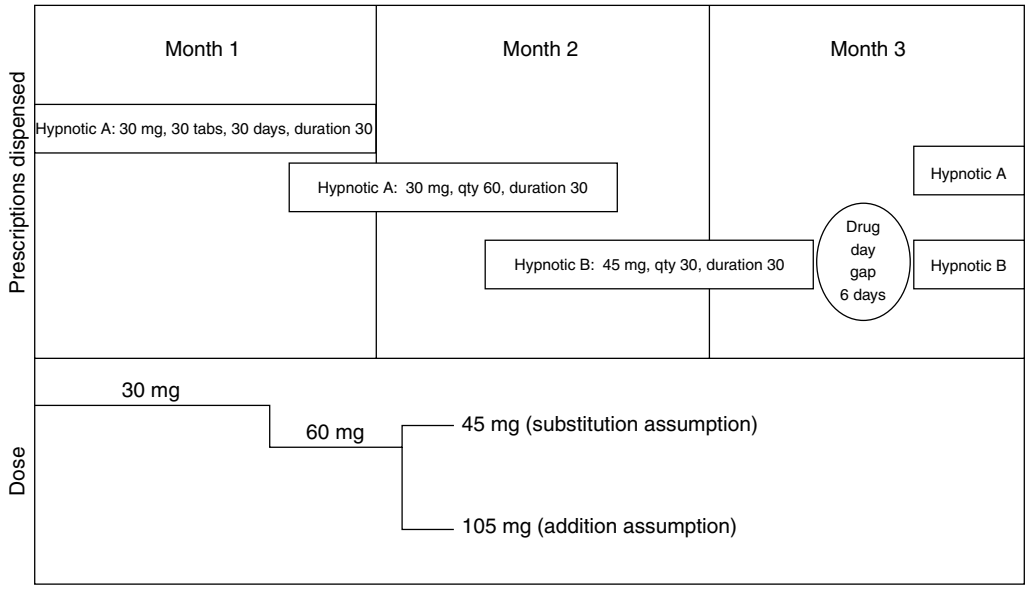

Figure 2 Summarizing drug use over time

was stopped. Using this assumption, daily hypnotic doses during the three-month time window vary from 30 mg per day to 60 mg per day (assuming **bioequivalence** for the sake of simplicity). However, hypnotics A and B were refilled in the subsequent month, suggesting that B was added – not substituted for – A. If it is assumed that both drugs were used concurrently, then the daily hypnotic dose varied from 30 mg per day to 105 mg per day. Generally, it is advisable to carry out the analysis under both types of assumptions as this may substantially alter the estimates of the association between drug dose and risks.

Patterns. Figure 2 also illustrates that drug use can fluctuate considerably, even over short periods of time. In the following section, we outline some methodological issues related to the description of variation over time in drug use and/or dose, and review some promising methods for analyzing such variations.

Describing Longitudinal Patterns. Many studies of drug utilization patterns are limited to simple descriptive *aggregate* statistics such as the **prevalence** of use and distribution of number of prescriptions [117], or temporal changes in either prevalence [115, 154] or the mean defined daily dose (DDD) [6] over time. Yet, a change in DDD is a compound of (i) the changes in prevalence of use, and (ii) changes in dose among users and, thus, may be difficult to interpret. This argument is supported by the results presented by van Hulten et al. [145], one of the very few among many studies of benzodiazepines use that assessed different aspects of longitudinal patterns of use. This study revealed several complexities, such as a nonmonotone change in the age-adjusted point prevalence rates over time, and the **interaction** between the effects of age and sex on the daily dose. Moreover, while the prevalence of use decreased considerably during the 10 years, the average number of prescriptions per user, and the relative proportions of incidental, regular and long-term users, remained quite stable. However, each of the three groups of users showed a different rate of decrease in the average dose per prescription [145]. Finally, the patterns of temporal changes in average dose for different benzodiazepines were quite inconsistent. On average, between 1983 and 1992 the dose increased for hypnotics and decreased for tranquilizers. Moreover, these trends differed substantially across individual compounds in each class of drugs. Among tranquilizers, the average daily dose increased for oxazepam, remained stable for diazepam, and decreased for lorazepam. Among hypnotics, the dose *increased threefold* for temazepam whereas flurazepam dose

showed a *threefold decrease* over the same period. Similarly, Hylan et al. [67] showed that both duration of initial prescription and the number of prescriptions depended on the specific antidepressant. These discrepancies emphasize the importance of separate assessments of each compound within the same class of drugs, and call for a careful modeling of different aspects of temporal patterns of exposure to medication.

Recently, Bartlett et al. [9] proposed some easy-to-implement methods for assessing different aspects of longitudinal patterns of drug use in *individual subjects*. Specifically, they suggested using subject-specific **Spearman rank correlation** between (a) the ordinal variable representing subsequent periods of uninterrupted medication use, and (b) period-specific dose, as a measure of individual's tendency to increase or decrease the daily dose over time. Next, they employed multiple **logistic regression** to identify subjects' characteristics associated with a particularly strong trend toward dose increase, operationally defined as the Spearman correlation above 0.89, corresponding to the 90th percentile of the sample distribution. The cut-off discriminates subjects with a very consistent, strong tendency to increase dose over time. Specifically, for subjects with three periods of use, it requires a systematic increase from each period to the next one. For subjects with four to seven periods of use, it identifies patterns of a strictly monotonic ($r = 1.0$) or reality monotonic (dose may increase or remain stable from interval i to $(i + 1)$ but never decreases) patterns of dose increase, with at least three different, gradually increasing dose levels. An alternative approach was also considered, based on GEE extension of the **multiple linear regression** [153], with the repeated-measures dependent variable defined as the subsequent values of daily dose, and independent variables including both subject baseline (fixed-in-time) characteristics and a time-dependent variable indicating subsequent periods of use. In addition, the GEE model included interaction terms between selected baseline variables and period of use, and the statistical significance of this interaction was tested to assess if the pattern of dose changes over time did depend on the corresponding characteristics [9]. These methods were then employed to demonstrate that longitudinal patterns of dose changes differed substantially across 11 different benzodiazepines.

Bartlett et al. [9] have also analyzed the patterns of switching from one to another benzodiazepine. They argued that a simple proportion of users of drug A who switch to drug B may not be a sufficiently sensitive measure of the popularity of drug B as a "second-line" treatment, because this proportion may largely reflect a current market share of drug B. Instead, they suggested that the proportion of subjects who had been switched from other drugs in the same class (numerator) among all new users of drug B (denominator) will capture the specific preference toward using drug B as the treatment of choice for switchers, over and above what could be explained by drug B's market share. This distinction becomes important, for example, in the context of comparing adverse effects of alternative products. Given that subjects who switch drugs may be expected to have worse outcomes [14] including poorer tolerance and lower probability of positive response [127], a comparison of outcomes between current users of different compounds may be biased if switching is not properly accounted for. Indeed, Bartlett et al. [9] reported that prevalent users of lorazepam were at higher risks of adverse events than prevalent users of several other benzodiazepines. Yet, Bartlett et al. [9] show that lorazepam was a particularly popular "second-line" choice for benzodiazepine switchers, who represented 22% of its new users, compared to 6 to 15% for nine other benzodiazepines. Thus, apparent higher risk among lorazepam users reported by Neutel et al. [96] could be an artifact, reflecting the worse outcomes for (more frequent) switchers rather than the impact of lorazepam *per se.* On the other hand, oxazepam had an almost as high proportion of switchers (20%) among its first users as lorazepam (22%). This would not be captured by the comparison of the proportions of switchers who had switched to oxazepam and lorazepam (17 versus 33%, respectively), which is largely affected by the much higher, and increasing over time, market share of lorazepam.

A different novel approach to assess the patterns was proposed by Coste et al. [25] who emphasize the multidimensionality of the drug prescribing phenomena, and propose the following empirical criteria for appropriateness of prescribing practice: placebo effect, novelty, "exoticism", misdosage, and drug–drug interactions.

Finally, it may be interesting to adapt methods employed to assess longitudinal patterns of changes

in different characteristics of individual subjects, not necessarily related to drug use, to the specific context of patterns of medication utilization. For example, methods proposed by [68, 123] may be employed to (i) identify different, statistically independent aspects of longitudinal changes in, for example, current dose, duration of uninterrupted drug use, and so on, and then (ii) perform **cluster analyses** to classify individual users into clusters of subjects with similar multivariate profiles of drug use.

Assessing Impact of Policy Changes. A related, methodologically challenging, issue of increasing societal importance concerns evaluating the impact of different changes in drug benefits policy on the longitudinal patterns of drug utilization. Schneeweiss et al. [122] and Tamblyn et al. [138] both used some form of interrupted **time series** analyses to assess to what extent the frequency and/or duration of drug use has changed after the policy implementation while accounting for the autoregressive structure of the data (*see* **ARMA and ARIMA Models**). A challenge in such analyses is to separate the impact of the policy change from the concurrent effect of secular trends in medication use. The strong secular trend toward increasing medication use, systematically observed in different populations *not* affected by any policy changes [130] may bias a "naive" pre-post comparison of the use before and after policy change. This may result, for example, in a spurious lack of difference if the reduction entailed by an increased co-payment is counterbalanced by a "natural" increase consistent with secular trends [138]. To avoid such biases, one may compare the actual use after the policy to the *expected* level of use, estimated by **extrapolating** the pre-policy trend over time [122, 138]. This approach may be further refined to discriminate between (i) the "main effect" of the policy change, modeled by a binary time-dependent policy indicator (assigned 0 before and 1 after the policy implementation) (*see* **Dummy Variables**), and (ii) the time-dependent time-by-policy interaction. The former would imply a constant-over-time difference between observed and expected utilization rates, corresponding to their initial drop followed by an increase with the slope on time similar to the pre-policy slope [122]. The latter would result in a post-policy slope being systematically different from the pre-policy slope, entailing a gradual increase in the discrepancy between the observed and expected utilization rates. In either case, subgroup analyses or interaction testing may be necessary to explore if the policy impact varies across different subpopulations. However, to avoid a serious increase of type I error rates, such analyses should be limited to a small number of *a priori* specified, clinically plausible potential **effect modifiers**. For example, one may expect that the impact of changes in the benefits will vary across socioeconomic strata, and will be smaller among users of essential, life-saving medications than among patients prescribed nonessential symptom-relief drugs [138].

Adequate representation of the pattern of within-patient changes in exposure levels and accurate modeling of such data present considerable challenges to biostatisticians. Whereas recent developments in flexible modeling of censored survival data offer some potentially useful tools to address some challenges, to date there is little evidence of their use in the empirical studies of drug effects. Moreover, some analytical problems occurring in modeling all potentially relevant aspects of the relationship between exposure and outcome remain to be addressed. In the next section, we review some promising new methods and suggest some directions for future research.

Modeling the Effects of Exposure to a Drug: Recent Developments in Survival Analysis and Future Challenges

Flexible Dose-response Modeling. In this section, we focus on the situation when an individual patient is assumed to be assigned a fixed dose of a drug, and the drug is prescribed once or at a constant dose throughout the follow-up period (*see* **Dose-response in Pharmacoepidemiology**). In most practical situations, there will be considerable between-patient variation in the duration of follow-up, and the first occurrence of an adverse reaction will often lead to a change in drug therapy or cessation of the drug. Both considerations suggest that time-to-event would be an appropriate outcome measure and, accordingly, that statistical methods for censored survival data should be used.

Medical applications of **survival analysis** are dominated by implementation of the **proportional hazards** model developed by Cox [28]. The theoretical elegance and versatility of the **Cox model** make it an extremely useful "first-line" tool for analyzing survival data in many practical contexts. However,

in some drug studies the assumptions underlying the model may be too restrictive to represent the **dose–response** relationship of interest. First, the conventional Cox model belongs to the parametric family of **general linear models** (GLM). The effect of a continuous **covariate** on the dependent variable, transformed by an appropriate link function (*see* **Generalized Linear Model**), is *a priori* assumed to be linear. In the context of the Cox model, this assumption implies that the logarithm of the **hazard** is a linear function of the covariate value. Yet, the assumption of the **loglinearity** of the dose–response relationship may be questionable in many studies of drug side-effects. *A priori* considerations suggest that, at least in some cases, an increase in dose over an interval of low-to-moderate doses may have very minor effects on the risk of an adverse reaction, whereas a further increase in the dose may result in a dramatic risk increase as the "tolerance threshold" will be exceeded. In such cases, the effect would be better described by an upward concave function, such as an exponential or quadratic curve. It would be advantageous to model the shape of this function in a flexible way. Moreover, it is possible that the "tolerance thresholds" differ systematically from one subgroup of patients to another. In this situation, the dose–response function may have several relatively flat portions interchanged with more abrupt increases at doses corresponding to subgroup-specific thresholds. To model such complex shapes of dose–response curves one may use some of the recently proposed generalizations of the Cox model that replace the loglinear HR by a more flexible function [34, 48, 56, 131]. Hastie & Tibshirani [56] discuss a number of **nonparametric** smoothers that can be used to provide a smooth estimate of the effect (*see* **Smoothing Hazard Rates**; **Smoothing Methods in Epidemiology**) while avoiding *a priori* assumptions about the functional form of the dose–response relationship.

The advantages of flexible nonparametric modeling of dose–response relationships have been demonstrated in many practical applications [2, 104, 105]; however, there is little evidence of the use of such methods in drug studies. This approach is of particular interest in observational studies of the effects of drug utilization where one may expect considerable between-patient variation in the dose. Computer **simulations** have demonstrated the ability of nonparametric methods to provide reasonably **unbiased** and stable estimates of a broad variety of functions, including curves with local plateaus and abrupt increase [56, 104]. These methods may be of interest in studying the effects of increasing dose on the risk of an adverse reaction.

Using nonparametric modeling in practice requires additional methodological decisions regarding the choice of a particular smoothing technique and the desirable complexity of the estimated model. Both decisions are far from trivial as the theoretical understanding of related phenomena and practical experience in this area have only recently begun to accumulate. On the basis of our experience in nonparametric modeling of biomedical data [2, 3, 105] and some computational considerations, we have a few suggestions. First, we suggest selecting *a priori* a specific type of smoother and **degrees of freedom**, otherwise statistical inference about the estimates becomes difficult [4]. Moreover, limited comparisons between methods suggest that the estimates are reasonably **robust** with respect to the smoothing technique chosen [103]. In our experience, the smoothing spline option incorporated in the **generalized additive models** (GAM) proposed by Hastie & Tibshirani [56] has provided numerically stable and clinically plausible estimates [2]. GAM also has two important practical features. First, the use of this methodology is largely facilitated by the fact that the GAM program is included in the **S-PLUS** commercial package and the monograph by GAM authors [56] is a useful guide on how to apply this powerful methodology in practice. Secondly, GAM allows the user to make an inference about the estimates. The simulations reported in the same monograph indicate that both type I error rates at conventional significance levels (0.05 or lower) and point-wise confidence intervals are accurate within a practically acceptable error margin [56].

Finally, flexibility of the GAM estimators can be used to determine if there is a threshold in the dose–response relationship, an issue of considerable importance in the studies of potential adverse effects of medications. Indeed, if one could establish that there is a threshold for the dose below which the risks of adverse effects are similar to those associated with a placebo, such a finding could suggest an "optimal" dose that would offer therapeutic benefits while avoiding negative side effects. In this context, methods proposed in [19, 75] for threshold detection are of interest, although their accuracy and efficiency remains to be systematically

evaluated through simulations. Moreover, statistical inference regarding both the existence of a threshold and the precision with which its location is estimated is complicated by the fact that the underlying model is nonlinear in its parameters (threshold location). Therefore, computer-intensive techniques such as **bootstrap** [35] may be applied to assess "honest" P values for testing the alternative hypothesis of a threshold-based dose–response curve against the null hypothesis of either no association or linear (no-threshold) dose–response, as well as to estimate empirical confidence intervals around the estimated threshold (*see* **Extrapolation, Low Dose**). To ensure the accuracy of bootstrap-based inference, it is essential to replicate the entire estimation and/or model selection process, including, for example, data-dependent selection of degrees of freedom in each individual bootstrap sample [3].

The fractional polynomials methodology may offer an interesting alternative to nonparametric GAM-based estimation of the dose–response relationships. A fractional polynomial model is estimated by first, selecting one or two best-fitting functions from an *a priori*-defined basis of a restricted number of fractional polynomials, that is, polynomials whose degrees are fractions such as, for example, 1/2 or 1/3 [118, 119]. Then, the standard multivariable regression methods (*see* **Multivariate Multiple Regression**) are employed to estimate the regression coefficients defining the "optimal" linear combination of the selected functions. Thus, fractional polynomials combine the **parsimony** and easy interpretation characteristic of parametric regression models with flexibility comparable to low-dimensionality nonparametric models [118]. The method is user-friendly and is implemented in the STATA computer package. In our opinion, further comparisons, involving both carefully designed simulations studies and analyses of empirical data, are necessary to assess relative advantages of GAM versus fractional polynomials, and their dependence on the sample size and/or complexity of the underlying "true" relationships.

Assessing and Modeling Time-dependence of the Drug Effects. Another important assumption underlying the Cox model [28] is that the ratio of hazards, corresponding to different covariate vectors, is constant over the entire follow-up period (i.e. that hazards are proportional). The proportional hazards (PH) assumption implies that the relative risks associated with different drug doses do not change over time. Although several tests of the PH assumption have been proposed in the statistical literature [86], their use in clinical and epidemiologic studies is limited and the PH model is typically accepted a priori as a valid model [5]. However, for many drugs, the effect of a constant dose of medication will change over time. For example, a review of findings on the effects of cholesterol lowering on coronary heart disease risk suggested that about five years of treatment is necessary to achieve the full benefits of lipid-lowering medication [79]. The presence of a lag in the effect of statins is also suggested by the results of a large clinical trial, namely, the 4S study where the **Kaplan–Meier** survival curves for the placebo and active treatment groups are identical for the first year of follow-up and then start to diverge gradually [143]. If the effect of a drug gradually increases with increasing treatment duration, then the PH model, in which these risks are *a priori* forced to be constant, will yield the hazard ratio estimate corresponding to the average-over-time **relative risks** [100]. Such an estimate will overestimate the early effect and underestimate the long-term effects of the treatment [105]. In other situations, the effect of a constant dose may decrease with increasing exposure duration. Analysis of data from a randomized trial of aspirin effectiveness in preventing cardiovascular events among asymptomatic patients with carotid bruits provides an example [26]. A constant dose of aspirin appeared to have a short-term protective effect that did not last beyond the first year. Interestingly, an *in vitro* study suggested a biological mechanism that might underlie such a gradual loss of aspirin efficacy with increasing exposure duration [26].

Moreover, the pattern of time-dependence may vary depending on the specific type of drug's effect. For example, tolerance to the depressant effects of benzodiazepines develops rapidly, in contrast to a gradual process of slowly increasing tolerance to their anxiolytic effect, with increasing duration of use [124].

To avoid such systematic biases, several authors have proposed flexible generalizations of Cox model [4, 48, 57, 63, 74]. In these models, the constant log hazard ratio, β, a parameter of the Cox model is replaced by a flexible function of follow-up time, $j\beta\ (t)$, and this function is estimated using various nonparametric methods. Abrahamowicz et al. [4] recently developed a regression **spline**-based model

for time-varying relative risks. In simulation studies, they demonstrated its ability to uncover a variety of patterns of hazard ratio changes over time. Moreover, by using simple properties of regression splines [105, 147] they were able to propose simple and relatively reasonable accurate inferences about their estimates. Clinical applications of such methods yielded new insights that could not be obtained with more conventional methods [26, 37, 48, 63, 83, 99, 100, 103].

It would be desirable to use similar methods in observational studies of drug utilization, as in many cases the relative risks of adverse reactions may change over time. For example, benzodiazepines are drugs that have a depressive effect on the central nervous system, with side effects of motor incoordination and diminished cognitive function. It is likely that the effect of benzodiazepine use on the risk of adverse events is not loglinear and is more consistent with a threshold model. However, such a threshold remains to be estimated. Moreover, the risk of injury resulting from the side effects of exposure is expected to be greatest when the drug is first started, but it will diminish over time, even at constant doses, because of metabolic adaptation. Sudden cessation of the drug (such as may occur during hospitalization), dose incrementation, or the addition of a second drug which potentiates the effect of benzodiazepines (drug interaction) may all contribute to an increase in the risk of an adverse event.

Thus, it is plausible that the effect of a constant dose of a drug may be at the same time nonloglinear and time-dependent. In these instances, simultaneous flexible modeling of both effects will be necessary to represent the relative risks of interest. Relatively little work has been done to date on hybrid models that could incorporate both effects simultaneously. Gray [48] discusses nonparametric modeling of either nonloglinear or time-varying effects of continuous risk factors, but does not address the issues specific to the situation when both effects are estimated for the same risk factor. Simultaneous modeling of both effects is possible using hazard regression (HARE) [74], a very versatile spline-based methodology. However, HARE relies on adaptive model selection, and none of the examples presented in the article shows the selection and simultaneous modeling of nonloglinear and timedependent effects for the same covariate. This may be partly due to potential **collinearity** between the nonloglinear and time-dependent effects of the same continuous predictor.

A hypothetical example will illustrate the problem. Assume, for example, that the relationship between a drug dose and the logarithm of the hazard is **exponential** rather than linear (i.e. changes in dose within the low-to-moderate dose range have very little effect on the risk, but increases in dose in the high-dose range result in dramatic increases in the risk of an adverse event). Assume, further, that this effect of a dose remains constant, which means that it does not change as a function of treatment duration. The correct modeling of this effect would involve flexible transformation of drug dose, X, but it would conform with the PH assumption that the hazard ratio is constant over time. Accordingly, the effect of drug dose should be represented by $\beta^* f(x)$, where β (constant over time) is the log hazard ratio and f is the flexible transformation (resulting from nonparametric modeling of the effect of dose at a fixed point in time). Yet the same data may be well represented by a loglinear, time-dependent model in which the effect of the dose will be modeled as, $\beta(t)^*x$, where $\beta(t)$ represents the slope of the linear effect of dose (x) at time t. This model is obviously inconsistent with the actual relationship between dose and risk. This incorrect alternative representation may fit the data quite well because the shape of the true "constant-in-time" risk function implies that most patients who are dispensed high doses will have adverse events quite early. Thus, the initial slope of the linear risk function, $\beta(t)^*x$ (for values of t close to zero) will be quite high to reflect the contrast between risks associated with low and high doses. However, as treatment duration increases, most of the individuals with high doses will be filtered out and the slope will be mostly determined by outcomes among those with low to moderate doses. As the dose has little effect in that interval, the slope of $\beta(t)$ will gradually decrease with increasing t, creating an apparent time-dependence of the dose effect. In the absence of *a priori* grounds to prefer a constant nonloglinear model over the time-dependent loglinear alternative, fitting such data may create **identifiability** problems. These theoretical concerns about identifiability have been confirmed in a **simulation** study [129]. The development of an appropriate methodology that is able to offer simultaneous modeling of various effects, as well as accurate inference about the estimates, is a major challenge for further development of survival analytic tools, useful for studying the effects of drug utilization.

Estimating Lags in the Effects of a Drug. Related to the issue of modeling time-dependent changes in the impact of a medication is the problem of assessing the latency or temporal lag between drug exposure and a subsequent change in risks. Indeed, both the therapeutic and adverse effects of many drugs may be observed only after a certain latency and/or may wane after another longer time interval. Conventional methods for assessing latency involve estimating alternative models with exposure lagged by a different time interval, and then selecting the best-fitting of this model as an "optimal" representation of the lag duration [91, 98, 121]. However, the underlying assumption that only exposure that occurred in a specific period is relevant limits the clinical plausibility of the results. An alternative approach is to include several period-specific exposure indicators, for example, representing NSAIDs use in subsequent five-year intervals such as 0 to 5 years ago, 5 to 10 years ago, 10 to 15 years ago, and so on in the same model, and to compare the respective relative risks estimates [21]. However, such an approach induces a risk of multi-collinearity if the exposure status of individual subjects changes little during their lifetime, and the implicit assumption that the impact of exposure is a discontinued step-function of the time since exposure may be questionable.

To avoid such difficulties, more recent methods rely on flexible modeling techniques to estimate smooth functions representing different aspects of the lagged exposure effect, based on different conceptual models. For example, Rachet et al. [102] estimate a smooth distribution of lag time, defined as the time elapsed between the beginning of exposure and the subsequent change in risks, assuming that the relative risks exposed/unexposed remain constant after that time. In contrast, Hauptmann et al. [60] assume that the effect of exposure changes gradually with increasing time since exposure and postulate that the etiologically relevant measure of cumulative exposure should be best calculated as a weighted function of exposure intensity in different time periods. They use cubic regression B-splines to estimate a smooth weight function directly from the data, and propose a **likelihood ratio test** to compare the resulting model with the simple unweighted measure of cumulative exposure. Other promising methods for assessing latency include the bilinear model [78] and the sliding time window approach of Hauptmann et al. [58].

Use of Time-dependent Covariates to Model Changes in Drug Use Over Time. The foregoing illustrates the complexity of analytic problems in studying the effect of drug doses that are fixed over time. It is clear that the same problems are considerably more challenging when modeling involves doses that change over time. In the conventional Cox model [28], dose changes can be represented by a **time-dependent covariate** [i.e. a covariate that is a function of time $X(t)$]. Dose changes also include situations in which cumulative dose rather than a constant daily dose is considered to be the most important determinant of the outcome. If the cumulative dose were treated as a fixed-in-time covariate in survival analysis, then the results will be considerably biased, and even paradoxical due to **length bias** [24]. Indeed, those having early adverse events would have much shorter exposure to the drug and, thus, a lower cumulative dose. Therefore, higher risks, corresponding to shorter time-to-event, would appear to be associated with a lower cumulative dose. Representing cumulative dose by a time-dependent covariate would eliminate the risk of such length-biased confounding (*see* **Screening Benefit, Evaluation of**).

In some applications where the dose changes over time, it may be preferable to separate information about these changes by using two time-dependent variables: one measuring current dose and the other indicating whether the dose had been increased in the last period. The former variable will be used to study the association between current dose and immediate risks and the latter to test the hypothesis that recent changes in dose increase the risks. However, simultaneous estimation of different time-dependent aspects of the same exposure may lead to multi-collinearity problems. A recent study of smoking exposure explores various models with time-dependent covariates that may be used to separate different interrelated aspects of the longitudinal exposure history, while avoiding multi-collinearity and ensuring interpretability of the estimates [81]. An alternative approach is to aggregate different aspects into a single compound exposure measure, representing clinically relevant overall index of cumulative exposure. For example, a one-compartment exponential elimination model (*see* **Compartment Models**) proposed by Hauptmann et al. [59] accounts simultaneously for the duration of use and medication dose, as well as for time elapsed since the end of exposure, while making specific assumptions about the

way they interact. However, further empirical and simulation studies are necessary to assess the performance of such models.

The incorporation of time-dependent covariates in flexible generalizations of the Cox model will be necessary to account for situations where (i) the dose may change over time, and (ii) the effect of a given dose (current or cumulative) may also change as a function of treatment duration. In principle, flexible modeling of time-dependent covariates does not generate major additional theoretical problems; however, very efficient **algorithms** are required to manage the increased computational burden. Indeed, Heinzl et al. [62] have proposed a regression spline model that incorporates time-varying effects of binary time-dependent covariates. This method allows for modeling the changes over time in the impact of the current drug use, so that, for example, one can test if the risk of adverse effects decrease with increasing duration of use, which may occur if the users gradually develop tolerance. Finally, Clarkson and Kooperberg [73] extend the HARE methodology to incorporate flexible modeling of both binary and continuous time-dependent covariates. Such a development would likely allow new insights into the mechanisms underlying the risks and benefits of drug use (*see* **Time-varying Treatment Effect**).

The aforementioned methods, developed in the context of environmental or occupational exposures, may offer new insights into the role of medication, especially in long-term observational studies of large cohorts with detailed data on the time and dose of a drug use that can be derived from administrative prescriptions databases. However, one common limitation of the administrative prescription databases is that exact timing of the actual drug exposure is unknown and has to be inferred from (i) the date when the prescription was filled, and (ii) its duration. Whereas it is reasonable to assume that the patient did start taking the drug at or soon after the date of its purchase, the actual end of the period of active use may be quite different from the date corresponding to the end of prescription. In such situations, some sensitivity analyses of the robustness of the results with respect to various assumptions about the plausible structure and magnitude of errors in the timing of exposure are recommended. This may involve simulating a large number of similar datasets, with randomly distributed errors in the "observed" duration of exposure, and directly assessing the changes in the parameters of interest. To this end, one may use a versatile permutational algorithm for generating censored time-to-events, described in [4] and validated in [88]. As described by Leffondré et al. [80], this algorithm can be adapted for generating events conditional on time-dependent covariates, that are necessary to represent temporal variation in drug use correctly. The analyst may also consider adapting here the simulation extrapolation method (SIMEX) (*see* **Measurement Error in Epidemiologic Studies**) for handling measurement errors in predictors [23, 135]. In some cases, where the expected variance of the measurement errors can be well approximated, for example, based on relevant previous publications, the SIMEX method can accurately estimate the underlying true relationship that would be observed with error-free variables [64].

Dummy Variables

Usually **explanatory variables** take on values that are measured or observed quantities (e.g. height, weight, age). Sometimes, however, they are categorical, or qualitative, and as such have no natural numeric values associated with them (e.g. political affiliation, sex, race). An individual is simply identified as belonging to one specific category out of a set of, say, $K \geq 2$ mutually exclusive categories or levels. To allow such variables to be included in statistical models, a set of so-called dummy variables can be defined to provide numerical representations for a categorical variable.

If there is an intercept term included in a regression model and if a K-level categorical variable is to be included in the model, then $K - 1$ dummy variables must be defined to represent this categorical variable. For example, if we want to include sex in a regression model containing an intercept, we need one dummy variable to represent sex in the model. The $K - 1$ dummy variables are usually chosen to be linearly independent.

The typical choice for the definition of a dummy variable is the use of an indicator variable (0, 1 representation) which indicates whether a particular observation belongs to a specific level of the categorical variable. If an intercept is included in a regression model, then indicators are derived for $K - 1$ of the K possible levels. The remaining level, not associated with an indicator, is termed the referent category or the baseline category. For example, suppose data are available for n individuals to be included in a **linear regression** model and suppose the relationship between sex of the individual and the response variable is of interest. An intercept term, $X_{0i} = 1$, for all $i = 1, \ldots, n$, is included in the design matrix (*see* **General Linear Model**) so we need one dummy variable to represent sex. If we let X_{1i} represent sex in a linear model, then we may choose to define the dummy variable as

$$X_{1i} = \begin{cases} 1, & \text{if individual } i \text{ is female,} \\ 0, & \text{otherwise.} \end{cases}$$

So, if Y_i is the response for individual i, then the model that would be investigated is

$$\mathrm{E}(Y_i) = \beta_0 + \beta_1 X_{1i}.$$

In this case the male category is the referent category. The choice of the referent category often depends on the study situation since specific choices may mean that regression coefficients have a more direct interpretation. This is particularly the case when comparisons relative to some control or unexposed group are of interest. In this case it is natural to have the unexposed category as the baseline.

The use of indicator dummy variables is also valuable if models for each level of a categorical variable are to be derived and compared. Kleinbaum et al. [1] present such an example where the relationship between systolic blood pressure (SBP) and age are compared for females and males. In the data which they present, there are 29 females and 40 males and therefore a total of 69 observations. Let Y_i represent SBP and let X_{1i} represent age for individual $i, i = 1, \ldots, 69$. Also, define

$$X_{2i} = \begin{cases} 1, & \text{if individual } i \text{ is female,} \\ 0, & \text{otherwise.} \end{cases}$$

Now, consider the model

$$\mathrm{E}(Y_i) = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{1i} X_{2i}.$$

Substituting the appropriate X_{2i} value for males, the model is

$$\mathrm{E}(Y_i) = \beta_0 + \beta_1 X_{1i},$$

whereas for females the model is

$$\mathrm{E}(Y_i) = (\beta_0 + \beta_2) + (\beta_1 + \beta_3) X_{1i}.$$

By fitting one model, we can investigate whether the linear model for females has the same slope as the linear model for males ($\mathrm{H}_0 : \beta_3 = 0$) and/or whether the intercept for the model for females is the same as the intercept for the model for males ($\mathrm{H}_0 : \beta_2 = 0$). This example assumes a linear regression model. Note that identical arguments regarding tests for equal intercepts and slopes over varying levels of a qualitative variable can be made for other link functions in the **generalized linear models** framework.

So far, only a two-level categorical variable has been considered (i.e. sex). In [1], an example of a three-level categorical variable is presented. The categories are regions of the US and are listed as western, central, or eastern. One way of representing

this region variable is to define two dummy variables as

$$X_1 = \begin{cases} 1, & \text{if residence is western region,} \\ 0, & \text{otherwise,} \end{cases}$$

and

$$X_2 = \begin{cases} 1, & \text{if residence is central region,} \\ 0, & \text{otherwise.} \end{cases}$$

Note that the eastern region is the referent or baseline category in this representation.

While indicators have been used so far to define dummy variables, other representations can be used. For example, for sex one can use the dummy variable definition:

$$X_{\text{sex}} = \begin{cases} 1, & \text{if female,} \\ -1, & \text{if male.} \end{cases}$$

With this specification, the regression coefficient for X_{sex} provides the departure from an average outcome level (intercept) associated with being female or male. For the three-level region variable one could similarly define two dummy variables as:

$$X_{\text{region 1}} = \begin{cases} 1, & \text{if residence is western region,} \\ 0, & \text{if residence is central region,} \\ -1, & \text{if residence is eastern region.} \end{cases}$$

and

$$X_{\text{region 2}} = \begin{cases} 0, & \text{if residence is western region,} \\ 1, & \text{if residence is central region,} \\ -1, & \text{if residence is eastern region.} \end{cases}$$

Global tests concerning the categorical variable (i.e. testing the hypothesis that all regression coefficients corresponding to a set of dummy variables are equal to 0) will not depend on the choice of dummy variable definitions. Since the goal is to investigate a relationship between a response variable and a categorical variable, then this invariance to the choice of dummy variable representation is important. The interpretation of the coefficient for each dummy variable will, however, depend on the coding selected for a categorical variable.

Duration Dependence

A variety of techniques are available in survival analysis to assess the dependence on **covariates** of the time to some defined event, measured from a defined origin. However, in many problems more than one event may be measured on each subject. For example, a patient with Parkinson's disease is likely to require levodopa therapy within two years of diagnosis. The actual time to this event may be regarded as a measure, albeit imperfect, of the rate of progression of disability. At some later point in the disease process, side-effects of levodopa therapy, such as dyskinesias, may appear, or levodopa may lose its effectiveness in controlling symptoms, leading to the occurrence of end-of-dose "wearing-off" and the more extreme "on–off" phenomenon. Other milestones, such as "freezing", may occur before or after initiation of levodopa therapy. Ultimately, possibly after many years, the patient dies.

A simpler example is common in cancer studies. Patients, once diagnosed with a cancer, alternate between periods of remission and of relapse into active disease, and ultimately die.

There are many choices in modeling such relationships among the several outcomes, and the effect on these outcomes of covariates and treatments administered. First, one may use a single time origin for all types of failure, or reset the clock to zero when certain events occur. For example, in Parkinson's disease, time to freezing, which may occur before or after initiation of levodopa, is most naturally measured from the date of diagnosis. Time of initiation of levodopa may be a preferable origin for assessing time to levodopa-related side-effects, which by definition can occur only after initiation of levodopa. However, if primary interest centers on the occurrence of later events, modeling the full times to these events directly may lead to results that are more interpretable (cf. Parkinson Study Group [20]). The time origin for a randomized study is best taken at the date of randomization to preserve the **randomization** justification for the analysis.

One very simple model is that an individual moves among different states m (e.g. remission, relapse, death) according to a discrete epoch **Markov chain** and that the sojourn time spent in each state is **exponentially distributed**. Then the process $M(t)$ indicating the state at time t becomes a continuous time Markov chain, with death as an absorbing state. Remission and relapse may each be transient, as any number of transitions between these two states may occur before the ultimate transition to the third state. Lagakos et al. [12] allowed the sojourn times to have arbitrary distributions, leading to **semi-Markov** rather than **Markov processes**. It is also straightforward to allow the distribution of the sojourn times to vary with the number of previous transitions, so that successive periods of remission could become shorter, and periods of relapse could lengthen. Nonhomogeneous Markov processes may also be considered – see, for example, the discussion of "dynamic stratification" models below.

One typically observes a fairly short sequence of transitions on each of a large number of individuals. However, standard parametric or nonparametric procedures for estimation and inference may be applied. One may solve the inference problem for the full process by applying standard procedures to each of its probabilistic components – the transition matrix of the embedded discrete Markov chain is estimated by a discrete analog estimate, and the sojourn time distributions are estimated by the usual **Kaplan–Meier estimates** from the sojourn data for each state. These estimates have all the usual desirable features, including asymptotic normality and the availability of a simple variance estimate via Greenwood's formula (*see* **Aalen–Johansen Estimator**) for the sojourn time distributions. The estimates for the several components are asymptotically independent.

Inclusion of baseline covariates in the models via a proportional hazards assumption following Cox [5] is straightforward. Care must be taken with time-dependent covariates. Consider, for example, the modulated renewal processes suggested by Cox [6]. Here there is just a single type of event, which may occur many times, and the intensity of an event at time t is given by

$$h(t) = \exp\{\beta Z[t, \mathcal{H}(t)]\} h_0(U_t).$$

Here U_t is the backwards recurrence time – the time from the immediately preceding event – and $Z[t, \mathcal{H}(t)]$ is any function of the history $\mathcal{H}(t)$ of events experienced by that individual before time t. For example, $Z[t, \mathcal{H}(t)]$ could be the length of the immediately preceding interval, in which case the sequence of interevent times will follow a discrete time continuous state Markov chain. Cox suggested

that the usual **partial likelihood** approach be applied on the reordered time scale U_t. A difficulty pointed out by Oakes [16] and others is that reordering the time scale this way destroys the Markov property needed for the validity of this approach – Oakes [16] gave a simple example involving matched pairs (*see* **Matching**), where naïve use of this procedure would lead to inconsistent estimates (*see* **Consistent Estimator**). However, Oakes & Cui [19] showed that for a single long stationary sequence of events the standard asymptotic theory would hold for Cox's method, even though the standard martingale theory does not apply. Dabrowska et al. [7] allowed time-dependent covariates in a five-state Markov renewal model for bone marrow transplant data. By requiring that the covariates depend only on the backwards recurrence time to the previous event, they preserved the martingale structure of the process. Klein et al. [11] give a somewhat parallel application.

Prentice et al. [22] considered two models for the dependence of the intensity of an event at time t on the $\mathcal{H}(t)$, namely

$$h[t, \mathcal{H}(t)] = h_{0s}(t) \exp[\beta_s Z(t)] \tag{1}$$

and

$$h[t, \mathcal{H}(t)] = h_{0s}(U_t) \exp[\beta_s Z(t)], \tag{2}$$

where in each case the $h_{0s}(t)$ are arbitrary baseline functions – in the first case of the total time on study, and in the second case of the time U_t since the immediately preceding event. Here $s = s[\mathcal{H}(t)]$ is a stratum indicator, which may change over time for a given subject.

Gail et al. [8] also considered the model in (2). Andersen & Gill [2] discussed the special case of (1) with only a single stratum. There is no problem with applying standard partial likelihood approaches to (1). In (2) the partial likelihood can be applied so long as the $Z(t)$ are exogenous covariates (i.e. do not depend on the history of the process), or if the **stratification** is sufficiently fine to ensure that each individual may experience at most one failure in a given stratum. Voelkel & Crowley [25] give a careful discussion. In many examples $s = j$, which is one plus the number of previous failures experienced by that individual. Many of these models can now be seen as special cases of a general counting process formulation; see, for example, Andersen et al. [3, Sections IV.4 and X.1].

Direct modeling of the time to successive events from a common origin was introduced by Wei et al. [26] and has recently been popularized by Therneau [24]. They model the marginal (unconditional) intensity of the jth event at time t as

$$h_j(t) = h_{0j}(t) \exp[\beta_j Z_j(t)]. \tag{3}$$

Under this model separate partial likelihood estimates can be written down corresponding to the first, second, ..., jth, ... event occurring to each individual, and the usual asymptotic properties hold for each j separately. These estimates are also jointly asymptotically normal but, unlike in the model in (1), they are not independent. However, their correlation matrix can be consistently estimated and used to derive tests of hypotheses such as $\beta_1 = \beta_2 = \ldots = \beta_k$ and combined estimates of a common β. Hughes [10] examined the gain (or occasionally losses) in **power** from incorporating second events in the analysis of a randomized **clinical trial**, where covariate effects act on both first and second events through Wei et al.'s model.

Pepe & Cai [21], Oakes [18], and others have criticized the counterintuitive property of Wei et al.'s procedure that individuals are assumed to be at risk of the jth event before they have experienced the $(j-1)$th event. Lin [15] pointed out that this could be avoided by redefining risk set indicators appropriately, but this in effect converts the model to (1) and loses the "marginal" interpretation of the covariate effects. Pepe & Cai [21] proposed conditioning on the number $j-1$ of previous events, but not on their times of occurrence – a compromise between the fully conditional models of counting process theory and the marginal models of Wei et al. However, there is in general no simple relationship between this intensity and the corresponding marginal intensity.

For the model in (1), Pepe & Cai's partly conditional intensity becomes the full conditional intensity. This model, which was also discussed by Clayton [4], can be fitted by the dynamic stratification procedure in BMDP 2L (*see* **Software, Biostatistical**). Oakes [18] showed that the assumption of proportional hazards within a dynamic stratification model is not consistent with the assumption of proportional hazards within Wei et al.'s model.

Oakes [16] indicated how such models also arise naturally from a frailty (heterogeneity) interpretation.

Suppose that there is an unobserved individual-specific random variable W and that the full conditional intensity of an event at time t is just

$$h[t, \mathcal{H}(t), W] = Wb(t)$$

for some baseline intensity $b(t)$. Then the number of events in $(0, t)$ carries all predictive information from $\mathcal{H}(t)$ regarding W, so that the model of (1) applies (without covariates). An interesting special case, due in essence to Greenwood & Yule [9], is when the unobserved W has a **gamma distribution** (*See* **Accident Proneness**). In this case the various $h_j(t)$ turn out to be proportional to each other [though not to $b(t)$]. Covariates can then be included in a proportional hazards model for these conditional intensities and their coefficients estimated together with the index of the gamma frailty distribution from a single partial likelihood. See Oakes [17].

This model must be distinguished from one in which the covariates act on $b(t)$. Estimation procedures for this model have been proposed by Lawless [13, 14] and Self & Prentice [23]. Aalen & Husebye [1] allowed a frailty term in a simple renewal process, giving a conditional intensity of the form

$$h[t, \mathcal{H}(t), W] = Wh_0(U_t),$$

with a power law form for $h_0(t)$ leading to *Weibull* interevent times. These authors also make the very important point that the common practice of omitting the last incomplete interval from the analysis of a sequence of interevent intervals can lead to *biased* estimates, because $t - U_t$ is not a stopping time in terms of counting process theory (cf. Andersen et al. [2]).

DAVID OAKES

Durbin–Watson Test

The standard linear multiple regression model assumes that the conditional expectation of a response variable Y is a linear function of k explanatory variables, $x_1, \ldots, x_k$. The "errors" are usually assumed to be independent $\mathrm{N}(\mu, \sigma^2)$ random variables. When a multiple regression model is fitted to time series data, it is often found that successive **residuals** through time are not independent but are (auto)correlated. There may, for example, be a run of positive residuals followed by a run of negative residuals, which corresponds to positive autocorrelation (*see* **Autocorrelation Function**). With correlated errors it may be possible to improve the model to get a better fit and better forecasts and the Durbin–Watson test is one way of checking for this.

Let $(y_t, x_{1t}, \ldots, x_{kt})$ denote the observed values of all the variables at time t for $t = 1, 2, \ldots, n$. Then the residual at time t is the difference between the observed value of y_t and the value predicted by the fitted regression model, and may be calculated as

$$\hat{z}_t = y_t - \hat{\beta}_1 x_{1t} - \cdots - \hat{\beta}_k x_{kt}. \tag{1}$$

The Durbin–Watson statistic is then given by

$$d = \frac{\sum_{t=2}^{n} (\hat{z}_t - \hat{z}_{t-1})^2}{\sum_{t=1}^{n} \hat{z}_t^2}. \tag{2}$$

The value of d is routinely calculated by most regression packages. It is unfortunate that many analysts misinterpret the result, as the value of d will be close to two, and not to zero, if the errors are independent. The sampling distribution of d under the null hypothesis of independence unfortunately depends on the value of k and on the x values as well as on n, so that it is not possible to give a single critical value for d. Instead, upper and lower critical values, say, d_{L} and d_{U}, have been tabulated for different values of k and n. If the observed value of d lies between d_{L} and d_{U}, then the test is annoyingly inconclusive.

Another difficulty with the Durbin–Watson test is that it is not strictly valid when the explanatory variables include lagged values of the response variable, as is often the case.

The time series analyst will generally be more familiar with checking for autocorrelation by looking at the autocorrelation function of the residuals. In particular, the first-order autocorrelation coefficient of the residuals measures the correlation between successive pairs of residuals and is given by

$$r_1 = \frac{\sum_{t=2}^{n} \hat{z}_t \hat{z}_{t-1}}{\sum_{t=1}^{n} \hat{z}_t^2}. \tag{3}$$

It can be shown that this statistic is related to the Durbin–Watson statistic d by

$$d \simeq 2(1 - r_1). \tag{4}$$

Positive autocorrelation ($r_1 > 0$) corresponds to a value of d less than two, and this is the more normal direction of departure from independence. To test the null hypothesis of independence against positive autocorrelation, we look up values of d_{L} and d_{U} depending on k and n and then, if $d < d_{\mathrm{L}}$, we reject H_0, while, if $d > d_{\mathrm{U}}$, we accept H_0. Otherwise, the test is inconclusive.

When k gets large and n small, the range of inconclusive values can get alarmingly wide, but for k small and n large, it can be much easier to carry out a test on the value of r_1 using the result that, for reasonably large n, r_1 is approximately $\mathrm{N}(0, 1/n)$ for random data. The Durbin–Watson test is usually carried out in a one-tailed form. For $k = 2$ and $n = 100$, say, the one-tailed 5% values of d_{L} and d_{U} are 1.63 and 1.72 when testing for positive autocorrelation, whereas the approximate one-tailed 5% value for r_1 is $1.64/\sqrt{n} = 0.16$. The latter corresponds to a d value of $2(1 - 0.16) = 1.68$, which is halfway between the d_{L} and d_{U} values. This writer's preference is generally to look at the autocorrelation function of the residuals and use an approximate test on r_1 rather than carry out the much more complicated Durbin–Watson test. However, with several explanatory variables, the latter may be advisable and significance points up to $k = 5$ and $n = 100$ are tabulated, for example, by Kendall & Ord [4], as well as in the three original papers by Durbin & Watson [1–3], after whom the test is named.

Dynamic Allocation Index

Dynamic allocation indices (or *Gittins indices*) arise when it is necessary to optimize in a sequential manner the allocation of effort between a number of competing projects. The effort and the projects may take a variety of forms. Examples are: an industrial processor and jobs waiting to be processed; a server with a queue of customers; an industrial laboratory with research projects; any busy person with jobs to do; a stream of patients and alternative treatments; a searcher who may look in different places. In every case, effort is treated as being homogeneous, and the problem is to allocate it between the different projects so as to maximize the expected total reward which they yield. It is a sequential problem, as effort is allowed to be reallocated in a feedback manner, taking account of the pattern of rewards so far achieved. The choice at each stage is determined partly on the basis of maximizing the expected immediate rate of return, and partly by the need to reduce uncertainty, and thereby provide a basis for better choices later on. It is the tension between these two requirements that makes the decision problem both interesting and difficult. The reallocations are assumed to be costless, and to take a negligible time, since the alternative is to impose a traveling-salesman-like feature, thereby adding a serious further level of complication.

The techniques that come under the heading of dynamic programming have been devised for sequential optimization problems. The key idea is a recurrence equation relating the expected total reward (call this the *payoff*) at a given decision time to the distribution of its possible values at the next decision time. Sometimes this equation may be solved analytically. Otherwise a recursive numerical solution may, at any rate in principle, be carried out. This involves making an initial approximation to the payoff function, and then successive further approximations by substituting in the right-hand side of the recurrence equation. As Bellman [1], for many years the chief protagonist of this methodology, pointed out, using the recurrence equation involves less computing than a complete enumeration of all policies and their corresponding payoffs, but nonetheless soon runs into the sands of intractable storage and processing requirements as the number of variables on which the payoff function depends increases.

For the problem of allocating effort to projects, the number of variables is at least equal to the number of projects. An attractive idea, therefore, is to establish a priority index for each project, depending on its past history but not that of any other project, and to allocate effort at each decision time only to the project with the highest current index value. To calculate these indices it should be possible to calibrate a project in a given state against some set of standard projects with simple properties. If this could be done we should have a reasonable policy without having to deal with any function of the states of more than one project.

Gittins & Jones [6] showed that for exponentially discounted independent projects a policy of this form is actually optimal.

Since they may change as more effort is allocated, these priority indices may aptly be, and often are, termed *dynamic allocation indices*. The main methods available for determining the indices are by (i) interchange arguments, (ii) exploiting any special features of the bandit processes concerned, in particular those which lead to the optimality of myopic policies, (iii) calibration by reference to standard bandit processes, often involving iteration using the dynamic programming recurrence equation, and (iv) using the fact that a dynamic allocation index may be regarded as a maximized equivalent constant reward rate.

A detailed account of the theory, calculation, and application of Gittins indices is given in [4]. An important further contribution to the theory has been made by Bertsimas & Niño-Mora [3], who also give a useful review of the recent literature.

An important area of application is the selection of compounds for screening as potential drugs in pharmaceutical research. Here the competing projects are different families of compounds with different, and initially unknown, distributions of the relevant activity. More details are given in [2] and [5].

Dynamic Population

A dynamic population is a population that gains and loses members, unlike a **fixed population**. A dynamic population is stable or in the steady state if the sizes of all subgroups (e.g. age and gender subgroups) remain constant. **Relative hazards** can be estimated in a dynamic population from **case–control studies** based on **density sampling**. The well-known relationship, disease **prevalence** = disease incidence × average disease duration, which holds when a dynamic population is stationary, requires modification for nonstationary dynamic populations (*see* **Incidence–Prevalence Relationships**).

MITCHELL H. GAIL

Dynamic Programming

The term *dynamic programming* was first coined by Richard Bellman as early as 1952. In 1957, his book on dynamic programming [2] provided the first comprehensive introduction to the mathematical theory of "multistage decision processes" or dynamic programming. The term *programming* describes an iterative mathematical approach to problem-solving, which became feasible with the advent of high-speed digital computers [8]. Dynamic programming is not to be confused, however, with *computer* programming, which is subsequently used to implement the mathematical technique. The term *dynamic* referred to the original application of the multistage decision approach to processes in which a time step played an important role. However, *dynamical systems* can be used to model any process in which the order of operations is crucial. In the alignment of molecular sequences, for example, (see the section on "Application to Molecular Sequence Analysis") each stage of the dynamic programming algorithm corresponds to a step along the sequence.

Dynamic programming is an approach to *optimization*, that is, the process of finding the "best solution" among a number of alternatives. This usually involves selecting from a large number of possible strategies, the strategy that will maximize (or minimize) the value of a function, which has been defined by a mathematical model. The dynamic programming method makes a decision at every stage based upon an assessment of the optimal strategy at that stage only. At the end of the process, the maximum value can be calculated by following the path (or course of action) consisting of these individual decisions.

The problems for which dynamic programming can be used are those that can be broken down into smaller iterative steps such that the overall maximum is reached by making the optimal choice at every step. The sum of these optimal choices is called an *optimal policy*. This was stated mathematically by Bellman in the *Principle of Optimality*:

> *An optimal policy has the property that whatever the initial state and initial decisions are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.*

Applying the principle of optimality sequentially from the initial state to each subsequent state implies that the optimal policy will consist of the set of optimal decisions that were made at every stage of the process (The reader familiar with **Markov processes** will note some similarity here. An early generalization to the probabilistic decision-making (Markov) case appears in [6]. The connections between **hidden Markov models** and dynamic programming in molecular sequence analysis (see the section on "Applications") are well-documented in [4] and [3]).

Applications

Initially, dynamic programming was designed to solve problems that arose from calculus, such as time-dependent differential equations. Bellman noted in [2] that although it is possible in principle to find the exact solution to many differential equations using calculus alone, in complex situations involving many variables and multidimensional sets of equations, classical approaches to solving differential equations become infeasible. Referring to "the curse of dimensionality" faced by physicists attempting to solve complex systems of equations, Bellman introduced the idea of an "approximate (solution) in policy space". His more pragmatic approach was feasible due to the rapid development of high-speed computer technology.

A *dynamical system* is essentially a vector of values that describe a set of states. The components of this vector might be, for example, the positions in a queue. The queue might consist of patients who require **scheduling** in a medical clinic. The mathematical model would include factors such as the time required with different practitioners, the nature of the patient's condition, the schedule of each individual practitioner, and so on. The optimal schedule is found by making a sequence of decisions determined by the model.

Dynamic programming had its initial applications in physics, engineering, economics, and resource management. Problems arose, for example, in "the study of optimal inventory or stock control, input–output analysis of a complex of interdependent industries, in the scheduling of patients through a medical clinic, or the servicing of aircraft at an airfield, the study of logistics or investment policies. . .or in **sequential** testing. . ." [2].

But the most important breakthrough occurred in molecular biology where dynamic programming

greatly improved the computational accuracy and efficiency of molecular **sequence** alignment. Indeed, the new era of genetic research (*see* **Bioinformatics**) would have been impossible without the development of reliable computational and statistical methods with which to assemble and search the new **databases**. For publicly available genetic information, see, for example, the website of the National Center for Biotechnology Information (NCBI) at `www.ncbi.nlm.nih.gov`.

Applications to Molecular Sequence Analysis

The most innovative and successful application of dynamic programming to biology has been in the area of molecular sequence analysis, where it has provided an efficient method of finding the *optimal alignment* between two molecular (usually **DNA** or protein) sequences. At each step, the decision is made whether to align (i.e. match) the two next letters or not (in which case a gap is left in one or other of the sequences). At the end of this multistep process, we are able to read off the optimal alignment between the two sequences.

A single strand of DNA is essentially a string of *nucleotides* that contain the information required to build proteins. Protein sequences are strings of *amino acids* rather than nucleotides. The term *residue* refers to either. The residue is represented as a single letter from the four letter DNA alphabet {C,A,T,G} or the 20-letter amino acid alphabet.

Related genes from two different species will have similar DNA sequences. Throughout the evolution of DNA, not only do individual nucleotides change but also whole segments of DNA are inserted into or deleted from the sequence. As a result, if we want to assess the similarity between two possibly related segments of DNA or protein, we will need to count the number of unchanged (or similar) matching residues in some sections while allowing for the possibility of leaving "gaps" or unmatched residues in other sections. This process is called *aligning* the two sequences, and was originally done by eye.

Although no direct mention was made of Bellman's methods in [7], Needleman and Wunsch were the first to apply a dynamic programming method to protein sequence alignment in 1970. The gapped alignment of two sequences corresponds to an optimal path down a scoring **matrix** (see the section on "An Example: The Local Alignment of Two Sequences"). Adjustable *gap penalties* were introduced into the alignment process to discourage the opening of gaps without excluding them completely. The method produces a *global alignment*, which is the optimal alignment between the two sequences in their entirety.

The dynamic programming **algorithm** was modified by Smith and Waterman in 1981 [10]. Noting the existence of numerous noncoding regions or *introns* within the gene, Smith and Waterman altered the algorithm so that the optimal *local alignment* could be found. For local alignments, gaps at either side of the aligned sections were not penalized. The result of this modification was that shorter, biologically relevant regions of similarity (corresponding, for example, to coding regions or *exons*) could be detected efficiently.

It should be noted that in order to make use of the alignment scores obtained using the above methods, further statistical analysis is required; see, for example, [4].

An Example: the Local Alignment of Two Sequences

Say we have two sequences $A = a_1 a_2 \dots a_M$ and $B = b_1 b_2 \dots b_N$, where a_i and b_j are taken from the appropriate alphabet. In practice, when we compare two sequences we want to count not only when the two letters under consideration are the same but also when they are similar. Let $s(a, b)$ be the similarity score between letter a and letter b. (We usually store this information in a square *substitution matrix* $S = [s_{ij}]$ – not to be confused with the scoring matrix. How we create this substitution matrix is complex; see, for example, [3, 5]. In the simplest case, the substitution matrix is the identity matrix.)

We introduce a "gap penalty" g_k, which is some function of the gap-length, k. In the example given in [10], a gap penalty function of $g_k = 1 + \frac{1}{3}k$ was used. This is an example of the commonly used *affine* gap penalty [3]. A penalty of $1\frac{1}{3} = 1 + \frac{1}{3}$ is charged for *opening* a gap and a penalty of $\frac{1}{3}$ is charged for *extending* the gap by one. These values ($1\frac{1}{3}$ and $\frac{1}{3}$ in this case), referred to as *gap opening* and *gap extension* penalties, are set so that a biologically relevant (as opposed to a random) alignment will on average score well.

In Figure 1, we show the Smith–Waterman dynamic programming scoring matrix for the

Figure 1 Smith–Waterman dynamic programming scoring matrix for the DNA sequences CAGCCTCGCTTAG and AATGCCATTGACGG, which are the two example sequences given in [10]. The scoring scheme used is as follows: $s(a, b) = 1$ if $a = b$ and $s(a, b) = -1/3$ if $a \neq b$. The gap penalty function is $g_k = 1 + 1/3\ k$. The first row and first column of D are entered as zeros. The remaining values are then calculated using (1) starting from the top left corner and proceeding to the right and downwards until the matrix is complete. The optimal local alignment is then located by looking for the highest value in the matrix. Once this element is found, the other elements in the alignment are located by tracing back along the path. The traceback ceases when a value of zero is reached as this indicates the end of the optimal local alignment. The elements in the traceback path are shown in bold

DNA sequences AATGCCATTGACGG and CAGCCTCGCTTAG, which are the two example sequences given in [10]. The scoring scheme is as follows: $s(a, b) = 1$ if $a = b$ and $s(a, b) = -\frac{1}{3}$ if $a \neq b$, with the gap penalty function as in the last paragraph.

Starting the $(M + 1) \times (N + 1)$ scoring matrix $D = [d_{ij}]$ with a row of zeros and a column of zeros, the remaining values are then calculated using (1).

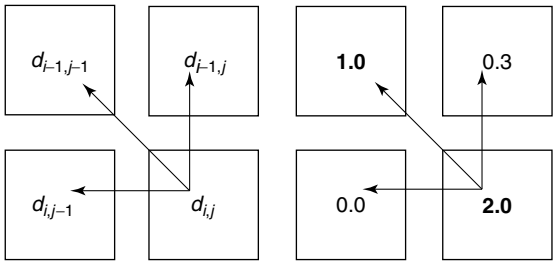

Figure 2 (a) A decision is made at each position i, j. The value of d_{ij} is chosen to be the maximum of three values (or zero) according to (1). The preferred path is recorded (as an arrow facing back towards the previous element) for the traceback procedure. (b) For example, the value of **2.0** in Figure 1 is obtained by taking the maximum value of $1 + 1 = 2$, corresponding to a match between C and C (which scores 1) being added onto the score of 1.0 in the cell diagonally upwards to the left

In Figure 2, the reader can see that at each position three paths are possible, noting that the convention is to draw the arrow backwards because we will want to trace our way back to get the final alignment. As in the global alignment, the optimal path proceeds either diagonally (which corresponds to a match between the ith and jth entry in the two sequences), horizontally or vertically (which corresponds to leaving a gap in the first or second sequence) at each step. At each step, the direction is stored so that we can *traceback* along the path. Starting from the top left corner and proceeding to the right and downwards, each cell is filled in until the matrix is complete.

$$d_{i,j} = \text{maximum} \begin{cases} d_{i-1,j-1} + s(a_i, b_j) \\ d_{i-1,j} - g_k \\ d_{i,j-1} - g_k \\ 0 \end{cases} \tag{1}$$

The optimal local alignment is then located by looking for the highest value in the matrix. Once this element is found, the other elements in the alignment are located using the *traceback* procedure, further details of which can be found in [10]. Essentially, the traceback follows back along the optimal path using the directions that were saved in every cell, although this process can be made more efficient [3]. The traceback ceases when a value of zero is

reached as this indicates the end of the optimal local alignment. The elements in the traceback path are shown in bold.

To read off the alignment in Figure 1, start with the boldface cell uppermost and to the left that contains a **1.0**. This corresponds to a match between G and G. Now go to the next boldface number, **2.0**. Since the path to that number is diagonal the next two letters, C and C, are aligned. As we progress down to **3.0**, the next step is also diagonal and we so match the next two letters, C and C. The next step of the path to **1.7** is vertical. This means a gap is left in the sequence written along the top of the matrix. (A horizontal step leaves a gap in the sequence written along the left of the matrix.) Proceeding in this way, the alignment can be read off the matrix.

The alignment obtained in the example is

G	*C*	*C*	*A*	*T*	*T*	*G*
G	*C*	*C*	-	*T*	*C*	*G*.

which has a Smith–Waterman score of 3.3, the final value in the path.

Computational Efficiency

Dynamic programming became popular due to its efficiency in searching for optimal solutions. In general terms, an exponential or factorial search space can often be reduced to a linear or quadratic time process using dynamic programming techniques.

If we were, for example, to search exhaustively through every possible sequence alignment in the above example of sequence alignment, looking for the highest scoring match according to our scoring scheme, we would require at least some multiple of $(N + M)!$ operations, that is $O((N + M)!)$ (*see* **Orders of Magnitude**). Using the dynamic programming algorithm, this is reduced to $O(MN)$, where M and N are the lengths of the sequences. This is calculated by noting that a finite number of operations must be made at each position of the matrix based upon (1) as illustrated in Figure 1. We refer to this machine complexity as $O(N^2)$ since $M \approx N$. The amount of storage space required is also $O(N^2)$. The algorithm can be made even more efficient by storing only two rows of the matrix at any one time; see, for example, [3].

Quite often in bioinformatics research, we are looking not for one optimal alignment but the highest scoring alignment between a nominated *query* sequence and a large database of sequences such as the human or mouse genome, for example. In this case, quadratic time algorithms are often prohibitively slow, even on the fastest computers. Faster alignment tools such as BLAST [1] and FASTA [9] are based upon a reduction of search space by first looking for high scoring sections. This is then followed by using dynamic programming to find the best alignment among a reduced number of the candidate sequences. Owing to the efficient shortcut made by BLAST, it is currently the most popular tool for searching the genome databases for the best match to a query sequence but it should be emphasized that BLAST itself is *not* a dynamic programming method, but used in conjunction with them.

A reliable Smith–Waterman dynamic programming algorithm, SSEARCH, can be accessed at the FASTA website: `http://alpha10.bioch.virginia.edu/fasta/`.

HILARY S. BOOTH

Ecologic Fallacy

The ecologic fallacy is the mistaken assumption that a statistical **association** observed between two ecologic (group-level) variables (*see* **Ecologic Study**) is equal to the association between the corresponding variables at the individual level in the same population. This assumption is often made implicitly or explicitly when using ecologic data to make **inferences** about the biologic (individual-level) effect of an exposure on the **risk** of a disease or other health outcome. Suppose, for example, we observe a positive ecologic association between exposure **prevalence** and the rate of a disease across many regions (groups). The magnitude and direction of the association between exposure status and disease risk within regions (at the individual level) could be different from the ecologic association, even if there is no error in measuring either ecologic variable. Just because the disease rate is higher in regions with a larger exposure prevalence does not mean that exposed individuals are at greater risk of disease than are unexposed individuals. It is possible that the risk is particularly high for unexposed individuals living in regions with a relatively high exposure prevalence. The underlying problem of the ecologic fallacy, therefore, is that each group is not entirely homogeneous with respect to the exposure. If every region were made up entirely of exposed individuals or unexposed individuals, then there would be no ecologic fallacy because information on the joint distribution of exposure and disease within groups would not be missing.

From a statistical perspective, the ecologic fallacy is due to *cross-level bias* in estimating the biologic effect of an exposure on disease risk on the basis of ecologic data. Thus, the fundamental problem of cross-level inference is not an all-or-none phenomenon, but rather a continuum of **systematic error** in effect estimation. In an ecologic analysis involving **simple linear regression**, cross-level bias arises when the disease rate in the unexposed (reference) population is correlated with exposure prevalence across groups or when the difference in rates between exposed and unexposed populations (biologic effect) varies across groups. (*see* **Ecologic Study** for a contemporary interpretation of "ecologic fallacy" and for a discussion of cross-level bias.)

HAL MORGENSTERN

Ecologic Study

An ecologic or aggregate study focuses on the comparison of groups, rather than individuals. The underlying reason for this focus is that individual-level data are missing on the joint distribution of at least two and perhaps all variables within each group; in this sense, an ecologic study is an "incomplete" design [48]. Ecologic studies have been conducted by social scientists for more than a century [18] and have been used extensively by epidemiologists in many research areas. Nevertheless, the distinction between individual-level and group-level (ecologic) studies and the inferential implications are far more complicated and subtle than they first appear. Before 1980, ecologic studies were usually presented in the first part of epidemiology textbooks as simple "descriptive" analyses in which disease rates are stratified by place or time to test hypotheses preliminarily; little attention was given to statistical methods or **inference** (for example [56]). The purpose of this article is to provide a methodologic overview of ecologic studies, which emphasizes study design, statistical methods, and causal inference. Although ecologic studies are easily and inexpensively conducted, the results are often difficult to interpret.

Concepts and Rationale

Before discussing the design and interpretation of ecologic studies, we must first define the concepts of ecologic measurement, analysis, and inference.

Levels of Measurement

The sources of data used in epidemiologic studies typically involve direct observations of individuals (e.g. age and blood pressure); they may also involve observations of groups, organizations, or places (e.g. social disorganization and air pollution). These observations are then organized to measure specific variables in the study population: individual-level variables are properties of individuals, and ecologic variables are properties of groups, organizations, or places. To be more specific, ecologic measures may be classified into three types:

1. *Aggregate measures* are summaries (e.g. **means** or proportions) of observations derived from individuals in each group, e.g. the proportion of smokers and **median** family income.
2. *Environmental measures* are physical characteristics of the place in which members of each group live or work, e.g. air-pollution level and hours of sunlight. Note that each environmental measure has an analog at the individual level, and these individual exposures (or doses) usually vary among members of each group (though they may remain unmeasured).
3. *Global measures* are attributes of groups, organizations, or places for which there is no distinct analog at the individual level (unlike aggregate and environmental measures), e.g. population density, level of social disorganization, the existence of a specific law, or type of health-care system.

Levels of Analysis

The **unit of analysis** is the common level for which the data on all variables are reduced and analyzed. In an *individual-level analysis*, a value for each variable is assigned to every subject in the study. It is possible, even common in **environmental epidemiology**, for one or more predictor variables to be ecologic measures. For example, the average pollution level of each county might be assigned to every subject who is a resident of that county.

In a *completely ecologic analysis*, all variables (exposure, disease, and **covariates**) are ecologic measures so that the unit of analysis is the group, e.g. region (*see* **Geographic Epidemiology**), worksite, school, health-care facility, demographic stratum, or time interval. Thus, within each group, we do not know the joint distribution of any combination of variables at the individual level (e.g. the frequencies of exposed cases, unexposed cases, exposed noncases, and unexposed noncases); all we know is the marginal distribution of each variable, e.g. the proportion exposed and the disease rate (i.e. the T frequencies in Figure 1).

In a *partially ecologic analysis* of three or more variables, we have additional information on certain joint distributions (the M, N, or A/B frequencies in Figure 1); but we still do not know the full joint distribution of all variables within each group (i.e. the ? cells in Figure 1 are missing). For example, in an ecologic study of cancer incidence by county, the joint distribution of age (a covariate) and disease

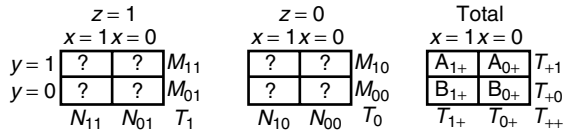

Figure 1 Joint distribution of exposure status ($x = 1$ vs. 0), disease status ($y = 1$ vs. 0), and covariate status ($z = 1$ vs. 0) in each group of a simple ecologic analysis: T frequencies are the only data available in a completely ecologic analysis of all three variables; M frequencies require additional data on the joint distribution of z and y within each group; N frequencies require additional data on the joint distribution of x and z within each group; A and B frequencies require additional data on the joint distribution of x and y within each group; and ? cells are always missing in an ecologic analysis

status within each county (the M frequencies in Figure 1) might be obtained from the **census** and a population tumor registry (*see* **Disease Registers**). From these sources, the investigator would be able to estimate age-specific cancer rates for each county.

Multilevel analysis is a special type of modeling technique that combines analyses conducted at two (or more) levels [7, 27, 100, 101]. For example, an individual-level analysis might be conducted in each group, followed by an ecologic analysis of all groups using the results from the individual-level analyses (*see* **Multilevel Models**). This approach will be described in a later section.

Levels of Inference

The underlying goal of a given epidemiologic study or analysis may be to make *biologic* (or biobehavioral) *inferences* about effects on individual *risks* or to make *ecologic inferences* about effects on group *rates* [62]. The target level of causal inference, however, does not always match the level of analysis. For example, the purpose of an ecologic analysis may be to make a biologic inference about the effect of a specific exposure on disease risk. As discussed later in this article, such *cross-level inferences* are particularly vulnerable to bias.

If the objective of a study is to estimate the *biologic effect* of wearing a motorcycle helmet on the risk of motorcycle-related mortality among motorcycle riders, the target level of causal inference is biologic. On the other hand, if the objective is to estimate the *ecologic effect* of helmet-use laws on the motorcycle-related mortality rate of riders in different states, the target level of causal inference is ecologic. Note that the magnitude of this ecologic effect depends not only on the biologic effect of helmet use, but also on the degree and pattern of compliance with the law in each state. Furthermore, the validity of the ecologic effect estimate depends on our ability to control for differences among states in the joint distribution of **confounders**, including individual-level variables such as age and amount of motorcycle riding.

We might also be interested in estimating the *contextual effect* of an ecologic exposure on individual risk, which is also a form of biologic inference [3, 92]. If the ecologic exposure is an aggregate measure, we would generally want to separate its effect from the effect of its individual-level analog. For example, we might estimate the contextual effect of living in a poor area on the risk of disease, controlling for individual poverty level [45]. Contextual effects can be profound in infectious-disease epidemiology, where the risk of disease depends on the **prevalence** of the disease in others with whom the individual has contact [50, 93] (*see* **Communicable Diseases**).

In evaluating motorcycle-helmet laws in the US, we would probably not expect a contextual *effect* of living in a state that mandates helmet use on the risk of motorcycle-related mortality in riders, controlling for individual helmet use. If a rider's helmet use does not change after the helmet law takes effect, we would not expect his risk of motorcycle-related mortality to change. Nevertheless, we might expect to observe a contextual *association* between the same variables after the law because of differential compliance with the law within states. That is, those riders who comply with the law, but who would not have worn helmets without the law, may be at lower risk than are riders who do not comply with the law. Consequently, the risk of motorcycle-related mortality among riders who do not wear helmets will be higher in states with the helmet law than in states without the law.

Rationale for Ecologic Studies

There are several reasons for the widespread use of ecologic studies in epidemiology, despite frequent cautions about their methodologic limitations:

1. *Low cost and convenience*. Ecologic studies are inexpensive and take little time because various

secondary data sources, each involving different information needed for the analysis, can easily be linked at the aggregate level. For example, data obtained from population registries, **vital statistics** records, large **sample surveys**, and the **census** are often linked at the state, county, or census-tract level.

2. *Measurement limitations of individual-level studies*. In environmental epidemiology and other research areas, we often cannot accurately measure relevant exposures or doses at the individual level for large numbers of subjects – at least not with available time and resources. Thus, the only practical way to measure the exposure may be ecologically [62, 63]. This advantage is especially true when investigating apparent clusters of disease in small areas [94] (*see* **Clustering**). Sometimes individual-level exposures, such as dietary factors, cannot be measured accurately because of substantial within-person variability; yet ecologic measures might accurately reflect group averages [41, 76].
3. *Design limitations of individual-level studies*. Individual-level studies may not be practical for estimating exposure effects if the exposure varies little within the study area. Ecologic studies covering a much wider area, however, might be able to achieve substantial variation in mean exposure across groups (for example [68, 72], and [81]).
4. *Interest in ecologic effects*. As noted above, the stated purpose of a study may be to assess an ecologic effect; i.e. the target level of inference may be ecologic rather than biologic – to understand differences in disease rates among populations [60, 81]. Ecologic effects are particularly relevant when evaluating the impacts of social processes or population interventions such as new programs, policies, or legislation. As discussed later in this article, however, an interest in ecologic effects does not necessarily obviate the need for individual-level data.
5. *Simplicity of analysis and presentation*. In large complex studies conducted at the individual level, it may be conceptually and statistically simpler to perform ecologic analyses and to present ecologic results than to do individual-level analyses. For example, data from large periodic surveys, such as the National Health Interview Survey, are often analyzed ecologically by treating some combination of year, region, and demographic group as the unit of analysis. As discussed later in this article, however, such simplicity of analysis and presentation often conceals methodologic problems.

Study Designs

In an ecologic study design, the planned unit of analysis is the group. Ecologic designs may be classified on two dimensions: the method of exposure measurement and the method of grouping [48, 62]. Regarding the first dimension, an ecologic design is called *exploratory* if there is no specific exposure of interest or the exposure of potential interest is not measured, and it is called *analytic* if the primary exposure variable is measured and included in the analysis. (This use of the term "analytic" is not to be confused with **analytic epidemiology**, which refers to **cohort** and **case–control** studies conducted at the individual level.) In practice, this dimension is a continuum, since most ecologic studies are not conducted to test a single hypothesis. Regarding the second dimension, the groups of an ecologic study may be identified by place (multiple-group design), by time (time-trend design), or by a combination of place and time (mixed design).

Multiple-Group Designs

Exploratory Study. In an exploratory multiple-group study, we compare the rate of disease among many regions during the same period. The purpose is to search for spatial patterns that might suggest an environmental etiology or more specific etiologic hypotheses. For example, the National Cancer Institute (NCI) mapped the age-adjusted cancer mortality rates in the US by county for the period 1950–69 [58]. For oral cancers, they found a striking difference in geographic patterns by sex: among men, the mortality rates were greatest in the urban Northeast; but among women, the rates were greatest in the Southeast. These findings led to the hypothesis that snuff dipping, which is common among rural southern women, is a risk factor for oral cancers [2]. The results of a subsequent case–control study supported this hypothesis [99].

Exploratory ecologic studies may also involve the comparison of rates between migrants and their offspring and residents of their countries of emigration and immigration [41, 56] (*see* **Migrant Studies**).

If the rates differ appreciably between the countries of emigration and immigration, migrant studies often yield results suggesting the influence of certain types of risk factors for the disease under study. For example, if US immigrants from Japan have rates of a disease similar to US whites but much lower than Japanese residents, the difference may be due to environmental or behavioral risk factors operating during adulthood. On the other hand, if US immigrants from Japan and their offspring have rates much lower than US whites but similar to Japanese residents, the difference may be due to genetic risk factors. Such interpretations, however, especially in the first instance, are often limited by differences between countries in the classification and detection of disease or cause of death.

In mapping studies (*see* **Mapping Disease Patterns**), such as the NCI investigation, a simple comparison of rates across regions is often complicated by two statistical problems. First, regions with smaller numbers of observed cases show greater variability in the estimated rate; thus, the most extreme rates tend to be observed for those regions with the fewest cases. Second, nearby regions tend to have more similar rates than do distant regions (i.e. **autocorrelation**) because unmeasured risk factors tend to cluster in space. Statistical methods for dealing with both problems have been developed by fitting an autoregressive spatial model to the data and using **empirical Bayes** techniques to estimate the smoothed rate for each region [12, 17, 61, 64] (*see* **Geographic Epidemiology**). The degree of spatial autocorrelation or clustering can be measured to reflect environmental effects on the rate of disease [96, 97]. The empirical Bayes approach can also be applied to data from analytic multiple-group studies (described below) by including covariates in the model (for example [11], and [15]).

Analytic Study. In an analytic multiple-group study, we assess the ecologic association between the average exposure level or prevalence and the rate of disease among many groups. This is the most common ecologic design; typically, the unit of analysis is a geopolitical region. For example, Hatch & Susser [38] examined the association between background gamma radiation and the incidence of childhood cancers between 1975 and 1985 in the region surrounding a nuclear plant. Average radiation levels for each of 69 tracts in the region were estimated from a 1976 areal survey. The authors found positive associations between radiation level and the incidence of leukemia (an expected finding) as well as solid tumors (an unexpected finding) (*see* **Leukemia Clusters**; **Radiation**).

Data analysis in this type of multiple-group study usually involves fitting a mathematical model to the data. Ordinary **least squares** procedures, however, may be inadequate because the groups typically vary in size and much of the unexplained variability in rates across groups cannot be attributed to sampling error alone. To address these concerns, Pocock et al. [69] proposed a linear model in which the unexplained variation is treated as **random effects**. Model parameters were estimated by an iteratively reweighted least squares procedure. A similar procedure was used by Breslow [6] to fit **loglinear models**. Prentice & Sheppard [73] proposed a linear **relative risk model**, which leads readily to the estimation of rate ratios (assuming the model is properly specified). Prentice & Thomas [77] considered an **exponential** relative risk model, which they argue may be more **parsimonious** than the linear-form model for specifying **covariates**. These methods can be applied to data aggregated by place and/or time (to be discussed below). Use of ecologic modeling to estimate exposure effects (rate ratios and differences) will be described in the next section.

Time-Trend Designs

Exploratory Study. An exploratory time-trend or time-series study involves a comparison of the disease rates over time in one geographically defined population. In addition to providing **graphical displays** of temporal trends, **time-series** data can also be used to **forecast** future rates and trends. This latter application, which is more common in the **social sciences** than in epidemiology, usually involves fitting autoregressive integrated moving average (ARIMA) models to the outcome data [39, 66] (*see* **ARMA and ARIMA Models**). The method of ARIMA modeling can also be extended to evaluate the impact of a population intervention [59], to estimate **associations** betweens two or more time-series variables [9, 66], and to estimate associations in a mixed ecologic design ([85]; see below).

A special type of exploratory time-trend analysis often used by epidemiologists is **age–period–cohort analysis**. This approach typically involves the

collection of retrospective data from a large population over a period of 20 or more years. Through graphical or tabular displays (for example [23] and [25]) or formal modeling techniques (for example [42] and [57]), the objective is to estimate the separate effects of three time-related variables on the rate of disease: age, period (calendar time), and birth cohort (year of birth). By describing the occurrence of disease in this way, the investigator attempts to gain insight about temporal trends, which might lead to new hypotheses.

Lee et al. [54] conducted an age–period–cohort analysis of melanoma mortality among white males in the US between 1951 and 1975. They concluded that the apparent increase in the melanoma mortality rate was due primarily to a cohort effect. That is, persons born in more recent years experienced throughout their lives a higher rate than did persons born earlier. In a subsequent paper, Lee [53] speculated that this cohort effect might reflect increases in sunlight exposure or sunburning during youth, which he hypothesized is a risk factor for melanoma.

From a purely statistical perspective, there is an inherent problem in making inferences from the results of age–period–cohort analyses because of the linear dependency among the three time-related variables [25, 26, 42]. Thus, we cannot allow the value of one variable to change when the values of the other two variables are held constant. As a result of this **identifiability** problem, each data set has alternative interpretations with respect to the combination of age, period, and cohort effects; there is no unique set of effect parameters when all three variables are modeled simultaneously. The only way to decide which interpretation should be accepted is to consider the findings in light of prior knowledge and, possibly, to constrain the model by ignoring one effect.

Analytic Study. In an analytic time-trend study, we assess the ecologic association between change in average exposure level or prevalence and change in disease rate in one geographically defined population. As with exploratory designs, this type of assessment can be done by simple graphical displays or by time-series regression modeling (for example [66]).

In their analytic time-trend study, Darby & Doll [16] examined the associations between average annual absorbed dose of radiation fallout from weapons testing and the incidence rate of childhood leukemia in three European countries between 1945 and 1985. Although the leukemia rate varied over time in each country, they found no convincing evidence that these changes were attributable to changes in fallout radiation.

Causal inference from analytic time-trend studies is often complicated by two problems. First, changes in disease classification and diagnostic criteria can produce distorted trends in the observed rate of disease, which can lead to substantial **bias** in estimating exposure effects. Second, there may be an appreciable induction/**latent period** between first exposure to a risk factor and disease detection. To deal with the latter issue in an ecologic time-trend study, the investigator can lag observations between average exposure and disease rate by a duration assumed to reflect the average induction/latent period of exposure-induced cases. There are two approaches for selecting the lag: (i) an a priori method based on knowledge of the disease; and (ii) empirical methods that maximize the observed association of interest or optimize the fit of the model that includes a lag parameter. Unfortunately, the first method is often problematic because adequate prior knowledge is lacking, and the second method can produce results that are biologically meaningless and very misleading [37].

Mixed Designs

Exploratory Study. The exploratory mixed design combines the basic features of the exploratory multiple-group study and the exploratory time-trend study. Time-series (ARIMA) modeling or age–period–cohort analysis can be used to describe or predict trends in the disease rate for multiple populations. For example, to test Lee's [53] hypothesis that changes in sunlight exposure during youth can explain the observed increase in melanoma mortality in the US, we might conduct an age–period–cohort analysis, stratifying on region according to approximate sunlight exposure (without measuring the exposure). Assuming the amount of sunlight in the regions has not changed differentially over the study period, we might expect the cohort effect described earlier to be stronger for sunnier regions.

Analytic Study. In an analytic mixed design, we assess the association between change in average exposure level or prevalence and change in disease

rate among many groups. Thus, the interpretation of estimated effects is enhanced because two types of comparisons are made simultaneously: change over time within groups and differences among groups. For example, Crawford et al. [14] evaluated the hypothesis that hard drinking water (i.e. water with a high concentration of calcium and magnesium) is a protective risk factor for cardiovascular disease (CVD) mortality. They compared the absolute change in CVD mortality rate between 1948 and 1964 in 83 British towns, by water-hardness change, age, and sex. In all sex–age groups, especially for men, the authors found an inverse association between trends in water hardness and CVD mortality. In middle-aged men, for example, the increase in CVD mortality was less in towns that made their water harder than in towns that made their water softer.

Effect Estimation

A major quantitative objective of most epidemiologic studies is to estimate the effect of one or more exposures on disease occurrence in a well-defined population at risk. A measure of effect in this context is not just any measure of association such as a **correlation** coefficient; rather, it reflects a particular causal parameter, i.e. a counterfactual contrast in disease occurrence [30, 33, 36, 63, 83]. In studies conducted at the individual level, effects are usually estimated by comparing the rate or risk of disease, in the form of a ratio or difference, for exposed and unexposed populations. In multiple-group ecologic studies, however, we cannot estimate effects directly in this way because of the missing information on the joint distribution within groups. Instead, we regress the group-specific disease rates, Y, on the group-specific exposure prevalences, X. (Note that throughout this article uppercase letters will be used to represent ecologic variables and their estimated regression coefficients; lowercase letters will be used to represent individual-level variables and their estimated regression coefficients.)

The most common model form for analyzing ecologic data is the linear model. Ordinary least-squares methods can be used to produce the following prediction equation: $\hat{Y} = B_0 + B_1 X$, where B_0 and B_1 are the estimated intercept and slope. An estimate of the biologic effect of the exposure (at the individual level) can be derived from the regression results [1, 28]. The predicted disease rate ($\hat{Y}_{x=1}$) in a group that is entirely exposed is $B_0 + B_1(1) = B_0 + B_1$, and the predicted rate ($\hat{Y}_{x=0}$) in a group that is entirely unexposed is $B_0 + B_1(0) = B_0$. Therefore, the estimated rate difference is $B_0 + B_1 - B_0 = B_1$, and the estimated rate ratio is $(B_0 + B_1)/B_0 = 1 + B_1/B_0$.

Alternatively, fitting a **loglinear (exponential) model** to the data yields the following prediction equation: $\ln[\hat{Y}] = B_0 + B_1 X$ or $\hat{Y} = \exp[B_0 + B_1 X]$. Applying the same method used above for linear models, the estimated rate ratio is $\hat{Y}_{x=1}/\hat{Y}_{x=0} = \exp[B_1]$.

Note that the ecologic method of effect estimation requires rate predictions be extrapolated to both extreme values of the exposure variable (i.e. $X = 0$ and 1), which are likely to lie well beyond the observed range of the data. It is not surprising, therefore, that different model forms (e.g. loglinear vs. linear) can lead to very different estimates of effect [31]. Fitting a linear model, in fact, may lead to negative, and thus meaningless, estimates of the rate ratio.

As an illustration of rate-ratio estimation in an ecologic study, consider Durkheim's [20] examination of religion and suicide in four groups of Prussian provinces between 1883 and 1890 (see Figure 2). The groups were formed by ranking 13 provinces according to the proportion (X) of the population that was Protestant. Using ordinary least-squares linear regression, we estimate the suicide rate ($\hat{Y}$, per 10^5/year) in each group to be $3.66 + 24.0(X)$. Therefore, the estimated rate ratio, comparing Protestants with other religions, is $1 + (24.0/3.66) = 7.6$. Note in Figure 2 that the fit of the linear model appears excellent ($R^2 = 0.97$). In general, however, ecologic tests of fit can be misleading about the underlying model at the individual level that generated the ecologic data [35].

Confounders and Effect Modifiers

There are two methods used to control for **confounders** in multiple-group ecologic analyses. The first is to treat ecologic measures of the confounders as covariates ($\mathbf{Z}$) in the model, e.g. percent male and percent white in each group. If the individual-level effects of the exposure and covariates are additive (i.e. if the disease rates follow a linear model), then the ecologic regression of Y on X and $\mathbf{Z}$ will also

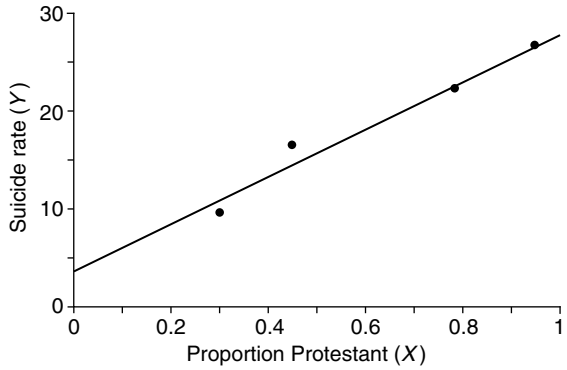

Figure 2 Suicide rate (Y, per 10^5/year) by proportion Protestant (X) for four groups of Prussian provinces, 1883–90. The four observed points (X, Y) are (0.30, 9.56), (0.45, 16.36), (0.785, 22.00), and (0.95, 26.46); the fitted line is based on unweighted least-squares regression. Adapted from Durkheim [20]

be linear with the same coefficients [31, 52] (*see* **Additive Model**). That is, the estimated coefficient for the exposure variable in a linear model can be interpreted as the rate difference adjusted for the covariates, provided the effects are truly additive and there are no other sources of bias. To estimate the adjusted rate ratio for the exposure effect, we must first specify values for all covariates ($\mathbf{Z}$) in the model, because the effects of X and $\mathbf{Z}$ are assumed to be additive – not multiplicative. Thus, the estimated rate ratio, conditional on covariate levels ($\mathbf{Z}$), is the predicted rate in a group that is entirely exposed ($\hat{Y}_{x=1|\mathbf{Z}}$) divided by the predicted rate in a group that is entirely unexposed ($\hat{Y}_{x=0|\mathbf{Z}}$).

Fitting an additive loglinear model to the ecologic data yields an estimate of the adjusted rate ratio that is independent of covariates – i.e. $\hat{Y}_{x=1|\mathbf{Z}}/\hat{Y}_{x=0|\mathbf{Z}} = \exp[B_1]$, where B_1 is the estimated coefficient for the exposure. Thus, the effects of X and $\mathbf{Z}$ are assumed to be multiplicative (*see* **Multiplicative Model**). Unfortunately, this ecologic estimate is a biased estimate of the individual-level rate ratio, even if the effects are multiplicative at the individual level and no other sources of bias are present [31, 79].

The second method used to control for confounders in ecologic analyses is rate standardization for these confounders, followed by regression of the standardized rates as the outcome variable (*see* **Standardization Methods**). Note that this method requires additional data on the joint distribution of the covariate and disease within each group (i.e. the M frequencies in Figure 1). Nevertheless, it cannot be expected to reduce bias unless all predictors in the model (X and $\mathbf{Z}$) are also mutually standardized for the same confounders [31, 34, 82]. Standardization of the exposure prevalences, for example, requires data on the joint distribution of the covariate and exposure within groups (i.e. the N frequencies in Figure 1); unfortunately, this information is not usually available in ecologic studies.

As in individual-level analyses, product terms (e.g. XZ) are often used in ecologic analyses to model **interaction** effects, i.e. to assess **effect modification**. In ecologic analyses, however, the product of X and Z (both group averages) is not, in general, equal to the average product of the exposure, x, and covariate, z, at the individual level within groups. Assuming a linear model, XZ will be equal to the mean xz in each group only if x and z are uncorrelated within groups [31]. Thus, as pointed out in the next section, interaction (nonadditive) effects at the individual level complicate the interpretation of ecologic results.

Methodologic Problems

Despite the many practical advantages of ecologic studies mentioned previously, there are several methodologic problems that may severely limit causal inference, especially biologic inference.

Ecologic Bias

The major limitation of ecologic analysis for making causal inferences is ecologic bias, which is the failure of expected ecologic effect estimates to reflect

the biologic effect at the individual level [22, 28, 34, 35, 62, 79]. In addition to the usual sources of bias that threaten individual-level analyses, the underlying problem of ecologic analyses for estimating biologic effects is heterogeneity of exposure level and covariate levels within groups. As noted earlier, this heterogeneity is not fully captured with ecologic data because of missing information on joint distributions (see Figure 1). Although researchers have long recognized the discrepancy between individual- and group-level associations (for example [24] and [91]), Robinson [80] was the first to describe mathematically how ecologic associations could differ from the corresponding associations at the individual level within groups of the same population. He expressed this relationship in terms of correlation coefficients, which was later extended by Duncan et al. [19] to regression coefficients in a linear model. The phenomenon became widely known as the **ecologic fallacy** [86], and researchers came to recognize that the magnitude of the ecologic bias may be severe in practice [13, 21, 79, 87, 89].

As an illustration of ecologic bias, consider again Durkheim's data on religion and suicide (Figure 2). The estimated rate ratio of 7.6 in the ecologic analysis may not mean that the suicide rate was nearly 8 times greater in Protestants than in non-Protestants. Rather, since none of the regions was entirely Protestant or non-Protestant, it may have been non-Protestants (primarily Catholics) who were committing suicide in predominantly Protestant provinces. It is certainly plausible that members of a religious minority might have been more likely to take their own lives than were members of the majority. The implication of this alternative explanation is that living in a predominantly Protestant area has a contextual effect on suicide risk among non-Protestants, i.e. there is an interaction effect at the individual level between religion and religious composition of one's area of residence.

Interestingly, Durkheim [20] compared the suicide rates (at the individual level) for Protestants, Catholics, and Jews living in Prussia. From his data, we find that the rate was about twice as great in Protestants as in other religious groups. Thus, there appears to be substantial ecologic bias (i.e. comparing rate-ratio estimates of about 2 vs. 8). Durkheim, however, failed to notice this quantitative difference because he did not actually estimate the magnitude of the effect in either analysis.

Greenland & Morgenstern [34] showed that ecologic bias can arise from three sources when using **simple linear regression** to estimate the crude exposure effect: the first may operate in any type of study; the latter two are unique to ecologic studies (i.e. *cross-level bias*) but are defined in terms of individual-level parameters.

1. *Within-group bias*: ecologic bias may result from bias within groups due to **confounding**, **selection** methods, or **misclassification**, even though within-group effects are not estimated. Thus, for example, if there is positive confounding of the crude effect parameter in every group, we would expect the crude ecologic estimate to be biased as well.
2. *Confounding by group*: ecologic bias may result if the background rate of disease in the unexposed population varies across groups, specifically, if there is a nonzero ecologic correlation between mean exposure level and the background rate.
3. *Effect modification by group* (on an additive scale): ecologic bias may also result if the rate difference for the exposure effect at the individual level varies across groups.

Confounding and effect modification by group (the sources of cross-level bias) can arise in three ways: (i) extraneous risk factors (confounders or modifiers) are differentially distributed across groups; (ii) the ecologic exposure variable has a contextual effect on risk separate from the biologic effect of its individual-level analog, e.g. living in a predominantly Protestant area vs. being Protestant (in the suicide example); or (iii) disease risk depends on the prevalence of that disease in other members of the group, which is true of many infectious diseases [50].

To appreciate the sources of cross-level bias, it is helpful to consider simple numerical illustrations involving both individual-level and ecologic analyses with the same population. The hypothetical example in Table 1 involves a dichotomous exposure, x, and three groups. At the individual level, both the rate difference and rate ratio vary somewhat across the groups, but the effect is positive in all groups; the crude and group-standardized rate ratio is 2.0. Fitting a linear model to the ecologic data, however, we find that the slope for the exposure variable, X, is negative and the rate ratio is 0.50, suggesting a protective

Table 1 Number of new cases, person-years (P-Y) of follow-up, and disease rate (Y, per 100 000/year), by group and exposure status (x) (top panel); summary parameters for each group (middle panel); and results of individual-level and ecologic analyses (bottom panel): hypothetical example of ecologic bias due to effect modification by group

Exposure status (x)	Group 1			Group 2			Group 3		
	Cases	P-Y	Rate	Cases	P-Y	Rate	Cases	P-Y	Rate
Exposed ($x = 1$)	20	7 000	286	20	10 000	200	20	13 000	154
Unexposed ($x = 0$)	13	13 000	100	10	10 000	100	7	7 000	100
Total	33	20 000	165	30	20 000	150	27	20 000	135
% exposed ($100X$)			35			50			65
Rate difference (per 10^5/year)			186			100			54
Rate ratio			2.9			2.0			1.5

Individual-level analysis:
Crude rate ratio[a] = 2.0
Adjusted rate ratio (SMR)[b] = 2.0

Ecologic analysis: Linear model
$\hat{Y} = 200 - 100X \quad (R^2 = 1)$
Rate ratio = 0.50

[a]Rate ratio for the total population, unadjusted for group.
[b]Rate ratio standardized for group, using the exposed population as the standard.

effect. The reason for such large ecologic bias is heterogeneity of the rate difference across groups (effect modification by group). In this example, there is no confounding by group because the unexposed rate is the same (100 per 10^5/year) in all three groups.

The example in Table 2 illustrates the conditions for no cross-level bias. First, group is not a modifier of the exposure effect at the individual level because the rate difference (100 per 10^5/year) is uniform across groups (even though the rate ratio varies). Second, group is not a confounder of the exposure effect because there is no ecologic correlation between the percent exposed ($100X$) and the unexposed rate. Thus, the individual-level and ecologic estimates of the rate ratio are the same (1.8) and unbiased, even though the R^2 for the fitted model is very low (0.029).

Unfortunately, the two conditions that produce cross-level bias cannot be checked with ecologic data because those conditions are defined in terms of individual-level associations. This inability to check the validity of ecologic results seriously limits biologic inference. Furthermore, the fit of the ecologic regression model, in general, gives no indication of the presence, direction, or magnitude of ecologic bias. Thus, a model with excellent fit may yield substantial bias, and one model with a better fit than another model may yield more bias. For example, there was substantial bias when fitting a linear model to Durkheim's suicide data in Figure 2, despite an excellent fitting model ($R^2 = 0.97$). Recall that the estimated rate ratio was 7.6, compared with a "true" rate ratio of approximately 2 (see section "Effect Estimation" above). If we fit a loglinear model to the same data, we get $\hat{Y} = \exp[1.974 + 1.418X]$ and $R^2 = 0.91$; therefore, the estimated rate ratio is $\exp[1.418] = 4.1$. Thus, the loglinear model produces less bias even though it has a smaller R^2 than does the linear model. In general, we cannot expect to reduce bias by using better-fitting models in ecologic analysis.

A potential strategy for reducing ecologic bias is to use smaller units in an ecologic study (e.g. counties instead of states) to make the groups more homogeneous with respect to the exposure. On the other hand, this strategy might not be feasible owing to the lack of available data aggregated at the same level, and it can lead to another problem: greater migration between groups (see the section "Other Problems", subsection "Migration Across Groups") [62, 95].

Problems of Confounder Control

As indicated in a previous section, covariates are included in ecologic analyses to control for confounding, but the conditions for a covariate being a confounder are different at the ecologic and individual levels [34, 35]. At the individual level, a risk factor must be associated with the exposure to be a confounder. In a multiple-group ecologic

Table 2 Number of new cases, person-years (P-Y) of follow-up, and disease rate (Y, per 100 000/year), by group and exposure status, x, (top panel); summary parameters for each group (middle panel); and results of individual-level and ecologic analyses (bottom panel): hypothetical example of no ecologic bias

[b]Rate ratio standardized for group, using the exposed population as the standard.

study, in contrast, a risk factor may produce ecologic bias (i.e. it may be an ecologic confounder) even if it is unassociated with the exposure in every group, especially if the risk factor is ecologically associated with the exposure across groups [31, 34]. Conversely, a risk factor that is a confounder within groups may not produce ecologic bias if it is ecologically unassociated with the exposure across groups.

Control for confounders is more problematic in ecologic analyses than in individual-level analyses [31, 34, 35]. Even when all variables are accurately measured for all groups, adjustment for extraneous risk factors may not reduce the ecologic bias produced by these risk factors. In fact, it is possible for such ecologic adjustment to increase bias [34, 35].

It follows from the principles presented in the previous section that there will be no ecologic bias in a **multiple linear regression** analysis if all the following conditions are met:

1. There is no residual within-group bias in exposure effect in any group due to confounding by unmeasured risk factors, selection methods, or misclassification.
2. There is no ecologic correlation between the mean value of each predictor (exposure and covariate) and the background rate of disease in the joint reference (unexposed) level of all predictors (so that group does not confound the predictor effects).
3. The rate difference for each predictor is uniform across levels of the other predictors within groups (i.e. the effects are additive).
4. The rate difference for each predictor, conditional on other predictors in the model, is uniform across groups (i.e. group does not modify the effect of each predictor on the additive scale at the individual level).

These conditions are sufficient, but not necessary, for the ecologic estimate to be **unbiased**, i.e. there might be little or no bias even if none of these conditions is met. On the other hand, minor deviations from the latter three conditions can produce substantial cross-level bias [31]. Since the sufficient conditions for no cross-level bias cannot be checked with ecologic data alone, the unpredictable and potentially severe nature of such bias makes biologic inference from ecologic analyses particularly problematic.

The conditions for no cross-level bias with covariate adjustment are illustrated in the hypothetical example in Table 3. Both the exposure, x, and covariate, z, are dichotomous variables, and there are three groups. At the individual level, the covariate is not a confounder of the exposure effect because there is no exposure–covariate association within any of the groups. Thus, the crude and adjusted estimates of

Table 3 Number of new cases, person-years (P-Y) of follow-up, and disease rate (Y, per 100 000/year), by group, covariate status, z, and exposure status, x (top panel); summary parameters for each group (middle panel); and results of individual-level and ecologic analyses (bottom panel): hypothetical example of no ecologic bias; covariate is an ecologic confounder but not a within-group confounder

[c]Setting $Z = 0.50$ (the mean for all three groups).

the rate ratio are nearly the same (1.3). In the ecologic analysis, however, the covariate is a confounder because there is an inverse association between the exposure, X, and the covariate, Z, across groups. Thus, although the crude ecologic estimate of the rate ratio (0.32) is severely biased, the adjusted estimate (1.3) is unbiased. The reasons for no cross-level bias with covariate adjustment are: (i) the rate (100 per 10^5/year) in the joint reference group ($x = z = 0$) does not vary across groups, i.e. condition 2 is met; and (ii) the rate difference (100 per 10^5/year) is uniform within groups and across groups, i.e. conditions 3 and 4 are met.

The example in Table 4 illustrates cross-level bias when the **null hypothesis** is true. At the individual level, the covariate (z) is a strong confounder because it is a predictor of the disease in the unexposed population and it is associated with exposure status, x, within groups. Thus, the crude rate ratio (2.1) is biased. At the ecologic level, however, there is no association between the exposure, X, and the covariate, Z, so that the covariate is not an ecologic confounder. Nevertheless, both the crude and adjusted rate ratios (8.6) are strongly biased because the rate in the joint reference category ($x = z = 0$) is ecologically correlated with both the exposure, X, and the covariate, Z – i.e. condition 2 is not met.

Lack of additivity at the individual level (refer to condition 3) is common in epidemiology, but unmeasured modifiers do not bias results at the individual level if they are unrelated to the exposure [30]. Furthermore, interactions may be handled readily at the individual level by including product terms as predictors in the model (e.g. xz). In ecologic analyses, however, lack of additivity within groups is a source of ecologic bias, and this bias cannot be eliminated by the inclusion of product terms (e.g. XZ) unless the effects are exactly multiplicative and the two variables are uncorrelated within groups [78]. If x and z are correlated within groups, additional data on the x–z associations (the N frequencies in Figure 1) can be used to improve the ecologic estimate of each predictor effect controlling for the other [68, 76].

Another source of ecologic bias is **misspecification** of confounders [35]. Although this problem can

Table 4 Number of new cases, person-years (P-Y) of follow-up, and disease rate (Y, per 100 000/year), by group, covariate status, z, and exposure status, x (top panel); summary parameters for each group (middle panel); and results of individual-level and ecologic analyses (bottom panel): hypothetical example of ecologic bias due to confounding by group; covariate is a within-group confounder but not an ecologic confounder

also arise in individual-level analyses, it is more difficult to avoid in ecologic analyses because the relevant confounder may be the distribution of covariate histories for all individuals within each group. In ecologic studies, therefore, adjustment for covariates derived from available data (e.g. proportion of current smokers) may be inadequate to control confounding. It is preferable, whenever possible, to control for more than a single summary measure of the covariate distribution (e.g. the proportions of the group in each of several smoking categories), provided the outcome rate is not standardized (see section "Effect Estimation" above). In addition, since it is usually necessary to control for several confounders (among which the effects may not be linear and additive), the best approach for reducing ecologic bias is to include covariates for categories of their joint distribution within groups. For example, to control ecologically for race and sex, the investigator might adjust for the proportions of white women, nonwhite men, and nonwhite women (treating white men as the referent), rather than the conventional approach of adjusting for the proportions of men (or women) and whites (or nonwhites).

Within-Group Misclassification

The principles of misclassification bias with which epidemiologists are familiar when interpreting the results of analyses conducted at the individual level do not apply to ecologic analyses. At the individual level, for example, nondifferential misclassification of exposure nearly always leads to **bias toward the null**. In multiple-group ecologic studies, however, this principle does not hold when the exposure variable is an aggregate measure. Brenner et al. [5] have shown that nondifferential misclassification of a dichotomous exposure within groups usually leads to bias away from the null and that the bias may be severe.

As an illustration of this distinct feature of ecologic analysis, consider the two-group example in Table 5, which contrasts analyses with correctly classified and misclassified exposure data at both the

Table 5 Number of new cases, person-years (P-Y) of follow-up, and disease rate (Y, per 100 000/year), by group, type of exposure classification (correct vs. misclassified[a]), and exposure status (top panel); % exposed by group (middle panel); and results of individual-level and ecologic analyses (bottom panel): hypothetical example of ecologic bias away from the null due to nondifferential exposure misclassification within groups

Exposure classification	Exposure status	Group 1			Group 2		
		Cases	P-Y	Rate	Cases	P-Y	Rate
Correctly classified	Exposed ($x = 1$)	50	20 000	250	100	40 000	250
	Unexposed ($x = 0$)	40	80 000	50	30	60 000	50
	Total	90	100 000	90	130	100 000	130
Misclassified[a]	Exposed ($x' = 1$)	49	26 000	188	93	42 000	221
	Unexposed ($x' = 0$)	41	74 000	55	37	58 000	64
	Total	90	100 000	90	130	100 000	130
% exposed – correctly classified ($100X$)				20			40
% exposed – misclassified ($100X'$)				26			42

Individual-level analysis:
Correct: rate ratio[b] = 5.0
Misclassified: rate ratio[c] = 3.4

Ecologic analysis: Linear models
Correct: $\hat{Y} = 50 + 200X$; rate ratio = 5.0
Misclassified: $\hat{Y} = 25 + 250X'$; rate ratio = 11.0

[a]Sensitivity = specificity = 0.9 for both cases and noncases (nondifferential misclassification).
[b]Common rate ratio within each group.
[c]Common rate ratio, using the Mantel-Haenszel method.

individual and ecologic levels. The **sensitivity** and **specificity** of exposure classification are assumed to be 0.9 for both cases and noncases in the population. The correct rate ratio at the individual level is 5.0; with nondifferential exposure misclassification, the observed rate ratio would be 3.4, which is biased toward the null. Although an ecologic analysis of the correctly classified data yields an unbiased estimate of the rate ratio (5.0), an analysis with misclassified data would yield an observed rate ratio of 11.0, which is strongly biased away from the null. To appreciate the direction of the misclassification bias in this ecologic analysis, notice that the difference in the percent exposed ($100X$) between the two groups decreases from $40\% - 20\% = 20\%$ to $42\% - 26\% = 16\%$ when the exposure is misclassified (see Table 5). Thus, the slope in the misclassified analysis increases from 200 to 250 per 10^5/year. In addition, the intercept decreases from 50 to 25 per 10^5/year. Each of these changes causes the observed rate ratio with the misclassified data to increase (away from the null).

It is possible to correct for nondifferential misclassification of a dichotomous exposure or disease in ecologic analyses, based on prior specifications of sensitivity and specificity [[4], Appendix 1; 32]. Suppose, for example, we wish to correct for nondifferential exposure misclassification when using simple linear regression (no covariates) to estimate the exposure effect. The corrected estimator of the rate ratio derived from the model results is $(B_0 + B_1\text{Se})/[B_0 + B_1(1 - \text{Sp})]$, where B_0 and B_1 are the estimated intercept and slope from the misclassified data, Se is the sensitivity of exposure classification, and Sp is the specificity. For example, the corrected rate-ratio estimate for the misclassified exposure data in Table 5 is $(25 + 250 \times 0.9)/(25 + 250 \times 0.1) = 5.0$, which is equal to the estimate based on Greenland & Brenner [32] also derived a corrected estimator for the variance of the estimated rate ratio.

In studies conducted at the individual level, misclassification of a covariate, if nondifferential with respect to both exposure and disease, will usually reduce our ability to control for that confounder [29, 84]. That is, adjustment will not completely eliminate the bias due to the confounder. In ecologic studies, however, nondifferential misclassification of a dichotomous confounder within groups does not affect our ability to control for that confounder, provided there is no cross-level bias [4].

If the outcome and all but one predictor (i.e. the exposure or a covariate) in a given analysis are measured at the individual level, then this partially ecologic analysis may also be regarded as nonecologic with the ecologic variable misclassified. Thus, the resulting bias may be understood in terms of misclassification bias operating at the individual level.

Other Problems

Lack of Adequate Data. Certain types of data, such as medical histories, may not be available in aggregate form; or available data may be too crude, incomplete, or unreliable, such as sales data for measuring behaviors [62, 95]. In addition, secondary sources of data from different administrative areas or from different periods may not be comparable. For example, disease rates may vary across countries because of differences in disease classification or case detection. Furthermore, since many ecologic analyses are based on mortality rather than incidence data, causal inference is further limited because mortality reflects the course of disease as well as its occurrence [48].

Temporal Ambiguity. In a well-designed cohort study of disease incidence, we can usually be confident that disease occurrence did not precede the exposure. In ecologic studies, however, use of incidence data provides no such assurance against this temporal ambiguity [62]. The problem is most troublesome when the disease can influence exposure status in individuals or when the disease rate can influence the mean exposure in groups (through the impact of population interventions designed to change exposure levels in areas with high disease rates).

The problem of temporal ambiguity in ecologic studies (especially time-trend studies) is further complicated by an unknown or variable induction and **latent periods** between exposure and disease detection [37, 95]. The investigator can only attempt to deal with this problem in the analysis by examining associations for which there is a specified lag between observations of average exposure and disease rate. Unfortunately, there may be little prior information about induction and latency on which to base the lag, or appropriate data may not be available to accommodate the desired lag.

Collinearity. Another problem with ecologic analyses is that certain predictors, such as sociodemographic and environmental factors, tend to be more highly correlated with each other than they are at the individual level [13, 87]. The implication of such **collinearities** is that it is very difficult to separate the effects of these variables statistically; analyses yield model coefficients with very large **variances** so that effect estimates may be highly unstable. In general, collinearity is most problematic in multiple-group ecologic analyses involving a small number of large, heterogeneous regions [19, 92].

Migration Across Groups. Migration of individuals into or out of the source population can produce **selection bias** in a study conducted at the individual level because migrants and nonmigrants may differ on both exposure prevalence and disease risk. Although it is clear that migration can also cause ecologic bias [49, 70], little is known about the magnitude of this bias or how it can be reduced in ecologic studies [63].

Ecologic Results and Epidemiologic Controversy

Contemporary epidemiologists take a conservative view of ecologic studies. Knowing that ecologic estimates of effect may be severely biased because of problems discussed in the previous section, epidemiologists tend to trust ecologic findings only if such findings agree with the results of other studies conducted at the individual level, particularly **case–control** and **cohort studies**. Nevertheless, this conservative view ignores the possibility that in certain situations ecologic results might be less biased than are results from case–control and cohort studies, which may, for example, involve appreciable error in measuring exposures (*see* **Measurement Error in Epidemiologic Studies**). Inconsistencies between the results of ecologic and other studies, therefore, can generate controversy about risk-factor effects and the potential for prevention.

One such controversy involving ecologic evidence concerns the possible effect of dietary fat on the risk of breast-cancer. In 1990, Prentice & Sheppard [74] reported results from three types of ecologic studies: (i) an international comparison of breast-cancer incidence during the period 1978–82 in 21 countries (analytic multiple-group design); (ii) a comparison of trends in breast-cancer incidence between

the 1960s and 1978–82 among 10 of the 21 countries in the previous analysis (analytic mixed design); and (iii) a comparison of breast-cancer incidence in US residents of Japanese descent vs. Japanese residents (exploratory multiple-group design). Using data from the 21-country study, the authors found that a 50% reduction in the supply (disappearance) of total fat is associated with a 60% reduction in the incidence of breast cancer among post-menopausal women (ages 55–69). The magnitude of this association did not change appreciably when controlling for gross national product, per capita supply of non-fat calories, and other ecologic variables available to the investigators. The results were similar when the exposure was measured as grams of fat per day and percent of calories from fat [75]. In addition, the association between fat and breast cancer observed in the 21-country analysis was consistent with the results of the two other ecologic analyses.

Despite the large effect and the consistency of these ecologic findings, causal inference is limited for several reasons (for example [40, 43, 75], and [98]): First, because of food wastage, nonhuman consumption, and poor reporting, the per capita *supply* of fat may not be proportional to the per capita *consumption* of fat across countries. Furthermore, the ecologic analyses were conducted within age–sex strata, but per capita fat supply was obtained only for the total population of each country. Second, there may have been systematic differences in breast-cancer detection across countries. Third, Prentice & Sheppard did not have data to control for certain breast-cancer risk factors, such as reproductive history and energy restriction or physical activity early in life. Fourth, the ecologic estimates of effect are susceptible to cross-level bias for other reasons discussed in the previous section.

Although Prentice & Sheppard [74] could not address the above limitations directly, they conducted additional analyses to demonstrate that their ecologic findings were consistent with the results of a pooled analysis of raw data from 12 case–control studies of fat and breast cancer [44]. Using the effect estimate from the 21-country study, they projected the rate ratios (**"relative risks"**) that would be expected in the pooled analysis of case–control studies, assuming random nondifferential error in measuring dietary fat – i.e. assuming the amount of measurement error does not depend on other variables in the analysis. To estimate the amount of measurement error, Prentice & Sheppard used the results of a **validation study** in which food-frequency data (the type used in the case–control studies) were compared with food-record data for the same subjects. They found, for example, that the projected rate ratio for the highest quintile of fat consumption vs. the lowest quintile was 1.46, compared with an observed rate ratio of 1.53 in the pooled analysis of case–control studies [74].

Reactions to the results of Prentice & Sheppard varied considerably. While Hiller & McMichael [40] called their work "a revitalization of ecological studies", Willett & Stampfer [98] maintained that "virtually all the analyses presented by Prentice and Sheppard are irrelevant to etiologic relationships between fat intake and risk of cancer".

One possible problem with the method of Prentice & Sheppard is their assumption that error in measuring fat intake is **nondifferential** with respect to disease status. Since dietary fat is measured after cases are detected in case–control studies, it is possible that cases were more likely to exaggerate their past consumption of fat or that controls were more likely to underestimate it; thus, the rate ratio would be positively biased. To address this concern, Hunter et al. [46] conducted a pooled analysis of raw data from seven cohort studies in which error in measuring fat intake at baseline would be expected to be non-differential with respect to subsequent disease status. The estimated rate ratio for the highest quintile of (energy-adjusted) fat intake versus the lowest quintile was 1.05, and this estimate did not change much when correcting for random nondifferential error in measuring fat intake. Thus, Hunter et al. [46] concluded that there was no evidence of a positive effect of dietary fat on breast-cancer risk. The implication is that effect estimates from the case–control studies were positively biased by differential recall of fat intake and/or selection methods (*see* **Recall Bias**) and that effect estimates from ecologic studies were also positively biased due to the problems mentioned above.

As coherent as these interpretations may appear, they still depend on rather strong assumptions about the error in measuring fat intake at the individual level. It is possible, for example, that the amount of measurement error depends on relevant variables other than disease status. This possibility was evaluated in a recent study by Prentice [71], who used the fat-effect estimate from the 21-country study to project the rate ratios expected in cohort studies under

more realistic assumptions of measurement error. To assess the amount of measurement error, Prentice used the results of another validation study in which food-frequency data were compared with 4-day food-record data at two times, one year apart. In this way, he allowed the amount of error in measuring fat intake to depend on body mass index; and he allowed for measurement errors for the two assessment instruments to be correlated. Under these conditions, he found that the projected rate ratio for the effect of total fat, comparing the highest and lowest quintiles, is approximately 1.1. Prentice concluded, therefore, that the results of Hunter et al.'s [46] pooled analysis of cohort studies is consistent with an effect of fat intake estimated from the international ecologic study.

It is not likely that these recent findings of Prentice will settle disagreements about the possible effect of dietary fat on the risk of breast cancer. Whether ecologic or nonecologic studies provide more accurate estimates of diet effects on cancer incidence remains controversial.

Multilevel Analyses and Designs

Knowing the severe methodologic limitations of ecologic analysis for making biologic inferences, many epidemiologists who report ecologic results argue that there can be no cross-level bias when their primary objective is to estimate an ecologic effect (for example [8, 10] and [88]). For example, we might want to estimate the ecologic effect (effectiveness) of state laws requiring smoke detectors by comparing the fire-related mortality rate in those states with the law vs. other states without the law [62]. Although this is a reasonable objective, the interpretation of observed ecologic effects is complicated by two related issues.

First, disease occurs in individuals; thus, the disease rate in a population is an aggregate, not a global, measure. Consequently, biologic inference may be implicit to the objectives of an ecologic study unless the underlying biologic and contextual effects are already known from previous research. Can smoke detectors placed appropriately in homes reduce the risk of fire-related mortality in those homes by providing an early warning of smoke? Does living in an area where most homes are properly equipped with smoke detectors reduce the risk of fire-related mortality in homes with and without smoke detectors? The first question refers to a possible biologic (biobehavioral) effect; the second question refers to a possible contextual effect. The ecologic effect of smoke-detector laws depends on these biologic and contextual effects as well as other factors, e.g. the level of enforcement, the quality of smoke-detector design and construction, the cost and availability of smoke detectors, and their proper placement, installation, operation, and maintenance. In an ecologic study without additional information, the ecologic effect is completely confounded with related biologic and contextual effects.

The second complicating issue in interpreting observed ecologic effects is the need to control for confounders measured at the individual level. Even if the exposure is a global measure, such as a law, groups are seldom completely homogeneous or comparable with respect to confounders. To make a valid comparison between states with and without smoke-detector laws, for example, we would need to control for differences among states in the joint distribution of extraneous risk factors, such as socioeconomic status of residents, firefighter availability and access, building design and construction (see also the earlier section "Problems of Confounder Control").

Perhaps the best solution to these problems is to incorporate both individual-level and ecologic measures in the same analysis. This approach might include different measures of the same factor; for example, each subject would be characterized by his or her own exposure level as well as the average exposure level for all members of the group to which he or she belongs (aggregate measure). Not only would this approach help to clarify the sources and magnitude of ecologic and cross-level bias, but it would also allow us to separate biologic, contextual, and ecologic effects. It is especially appropriate in social epidemiology, infectious-disease epidemiology, and the evaluation of population interventions.

There are various statistical methods for including both individual-level and ecologic measures in the same analysis; two will be discussed here. The first method, often called *contextual analysis* in the social sciences, is a simple extension of conventional **(generalized linear) modeling** such as multiple linear regression and logistic regression [3, 47]. The model, which is fit to the data at the individual level, includes both individual-level and ecologic predictors. For example, suppose we wanted to estimate the effect of

"herd immunity" on the risk of an infectious disease. The risk, y, of disease might be modeled as a function of the following linear component: $\beta_0 + \beta_1 x + \beta_2 X + \beta_3 x X$, where x is the individual's immunity status and X is the prevalence of immunity in the group to which that individual belongs [93]. Therefore, β_1 represents the biologic effect of individual immunity, β_2 represents the contextual effect of herd immunity, and β_3 represents the interaction effect, which allows the herd-immunity effect to depend on the individual's immune status. The interaction term is needed in this application, since we would expect no herd immunity effect among immune individuals. Note, however, that the interpretation of the interaction effect depends on the form of the model.

An important limitation of contextual analysis is that outcomes of individuals within groups are treated as independent. In practice, however, the outcome of an individual in one group often depends on the outcomes of other individuals in that group. Ignoring such within-group dependence ("clustering") generally results in estimated variances of contextual effects that are biased downward, making **confidence intervals** too narrow. To handle this problem of within-group dependence, we can add **random effects** to the conventional (contextual) model described above; this approach is called *mixed-effects modeling, multilevel modeling*, or *hierarchical regression* [7, 27, 100, 101]. Multilevel modeling is a powerful technique with many applications. It can be used to estimate contextual and ecologic effects and to derive improved (**empirical Bayes**) estimates of biologic effects. It can also be used to determine how much of the difference in outcome rates across groups (ecologic effect) can be explained by differences in the distribution of individual-level risk factors (biologic effects).

As an illustration, suppose that we want to estimate the biologic and contextual effects of income level on a continuous measure of health status (ignoring other potential confounders). Let y_{ij} = the health status of the ith individual living in the jth census tract (group), and x_{ij} = the annual income of the ith individual living in the jth census tract. At the first level of analysis, we model the individual's health status within each census tract as a function of income level – i.e.

$$y_{ij} = \beta_{0j} + \beta_{1j} x_{ij} + \varepsilon_{ij}, \qquad (1)$$

where ε_{ij} is the error term representing the unique (residual) effect associated with the ith individual in the jth census tract. At the second (ecologic) level, we model the census tract-specific intercepts (β_{0j}) and slopes, β_{1j}, from the first level as a function of average census-tract income, X_j – i.e.

$$\beta_{0j} = B_{00} + B_{01} X_j + E_{0j}, \qquad (2)$$

$$\beta_{1j} = B_{10} + B_{11} X_j + E_{1j}, \qquad (3)$$

where E_{0j} and E_{1j} are error terms representing the random effects associated with the jth census tract. The underlying assumption is that the census tract-specific regression parameters are **random samples** from a population of such parameters. By substituting (2) and (3) into (1), we obtain the following combined two-level model:

$$y_{ij} = B_{00} + B_{01} X_j + B_{10} x_{ij} + B_{11} x_{ij} X_j + E_{0j} + E_{1j} x_{ij} + \varepsilon_{ij}, \qquad (4)$$

where B_{10} represents the biologic effect of individual income on health status, B_{01} represents the contextual effect of average census-tract income on health status, and B_{11} represents the interaction effect of individual income and average census-tract income. Using an empirical Bayes procedure, we can also derive an improved estimate of the individual-income effect (β_{1j}) for each census tract. This is accomplished by computing a weighted average of the estimated slope for census tract j in level 1 (equation 1) and the predicted value of this slope using all census tracts in level 2 (equation 3).

Applying multilevel analysis to survey data collected in the UK, Humphreys & Carr-Hill [45] found that living in a poor area (electoral ward) had a detrimental effect on several health outcomes, controlling for socioeconomic status and other individual-level covariates. In a conventional ecologic analysis, the effects of living in a poor area and being poor (low socioeconomic status) would be confounded, and ecologic estimates of effect would be susceptible to cross-level bias.

Multilevel analysis can also be extended to more than two levels. For example, we might want to predict certain health outcomes in nursing-home residents as a function of characteristics of the residents (e.g. age and health status), their physicians (e.g. type of specialty and country of medical training), and the nursing homes (e.g. size and doctor-to-patient ratio).

In this type of analysis, residents are grouped by their physician (who might provide care to many residents in one home) and by their nursing-home affiliation.

The simplest design for generating multilevel analyses is a single survey of a population that is large and diverse enough so that multiple groups (e.g. counties or ethnic groups) can be defined for ecologic measurement and analysis. In addition to environmental and global variables for regions or organizations, ecologic measures are derived by aggregating all subjects in each group. An alternative, more efficient, approach is a *multilevel* or *hybrid design* in which a two-stage sampling scheme is used first to select groups (stage 1), followed by the selection of individuals within groups (stage 2) (for example [45] and [65]) (*see* **Multistage Sampling**). A hybrid design might involve conducting a conventional multiple-group ecologic study by linking different data sources, then obtaining supplemental data from individuals randomly sampled from each group (*see* **Record Linkage**). For example, by estimating the exposure–covariate association in each subsample, this approach can be used to improve the control of confounders in an ecologic analysis [65, 68, 73]. A variation of this hybrid design might involve a case–control study as the second stage. Cases would be identified in the first (ecologic) stage, and controls would be matched to cases on group affiliation and possibly other factors (*see* **Matching**).

Conclusions

There are several practical advantages of ecologic studies, which make them especially appealing for doing various types of epidemiologic research. Despite these advantages, however, ecologic analysis poses major problems of interpretation when making ecologic inferences and especially when making biologic inferences. From a methodologic perspective, it is best to have individual-level data on as many relevant nonglobal measures as possible. Just because the exposure variable is measured ecologically, for example, does not mean that other variables should be as well. The accuracy of effect estimates from ecologic studies can often be improved by obtaining additional data on the within-group associations between covariates, between the exposure and covariates, or between the disease and covariates.

Several epidemiologists have recently called for greater emphasis on understanding differences in health status between populations – a return to a public-health orientation, in contrast to the individual (reductionist) orientation of modern epidemiology [51, 55, 60, 67, 81, 90]. This recommendation represents an important challenge for the future of epidemiology, but it cannot be met simply by conducting ecologic studies; multiple levels of measurement and analysis are needed. Even when the purpose of the study is to estimate ecologic effects, individual-level information is often essential for drawing valid inferences about these effects. Thus, to address the underlying research questions, we typically would want to estimate and control for biologic and contextual effects, preferably using multilevel analysis. In contemporary epidemiology, the "ecologic fallacy" reflects the failure of the investigator to recognize the need for biologic inference and thus for individual-level data. This need arises even when the primary exposure of interest is an ecologic measure and the outcome of interest is the health status of entire populations.

Econometric Methods in Health Services

Introduction

The purpose of this article is to provide a brief summary of prominent econometric applications in modern **health economics**, by providing a broad overview of problems to which econometric methods have been applied, without a detailed exposition of the underlying mathematics, which can be found elsewhere (see [20, 22]).

These methods typically are used to address problems in health, health care delivery, and health care costs from a cross-section of observations at a given time. Methods to analyze data generated from the same units of observation (typically individuals) over time also have been developed in many cases, but those are not presented here in detail. The methods discussed below have evolved to deal with four common, and sometimes interrelated problems with health economic data:

1. The inability to observe fully a variable of interest. For example, in some situations, the only available measure of the health of an individual is whether he or she died, was hospitalized, or incurred some other health outcome that can be measured only with an indicator variable (i.e. a one if the event occurred or a zero otherwise) (*see* **Dummy Variables**). Even when continuous measures are used, such as health expenditure data or measures of functional status from the SF-36, the data can be truncated. The research cannot detect functional status lower than the lowest score on the SF-36, and cannot observe negative values for health expenditures.
2. The high prevalence of **outliers**. This is especially salient in health care cost data. In virtually every health expenditure data set there are some very high users of medical care, resulting in skewed distributions of costs and other measures of utilization. The section on the two-part model and log **transformations** below discusses these issues.
3. The need to compare two groups that were not created through random assignment (*see* **Randomization**). For example, in comparing patients in a fee for service plan versus patients in a managed care organization, we account for the fact that patients self-select into these plans, instead of being randomly assigned. This self-selection may have implications for the underlying health or health behaviors of the two groups that may be difficult to observe. Thus, differences in outcomes between the two groups may reflect selection process rather than differences in the **quality of care** delivered to the two groups. Techniques of **instrumental variables** and sample selection address this type of problem.
4. The nonrandom sampling structure of many health databases. Many databases used by health economists were developed using nonrandom sampling techniques (*see* **Administrative Databases**). For example, some national databases randomly sample households but then survey several people in the household (e.g. National Health Interview Survey). Others randomly select a zip code or other geographic area and then sample persons within those zip codes to participate in the survey (e.g. Medicare Current Beneficiary Survey, Community Tracking Survey).

This chapter presents an overview of econometric methods that have been used in **health services research** and increasingly in biostatistics [14]. The statistical issues that econometric and biostatistical methods are designed to address are often the same, but different terminology is used to describe the same concept [21]. Table 1 below illustrates the common terms used to describe some of these concepts.

Econometric methods are useful in addressing a range of problems in health services and may be an alternative approach to analysis of health, health care, and health insurance problems addressed by biostatistical methods. A more detailed discussion of the methods reviewed here can be found in the chapter by Jones [18] or textbooks and published papers referenced herein.

The Estimation Problem

Suppose we have a dataset on the three health insurance plans, a fee-for-service (FFS) plan and two managed care (e.g. HMO) plans, offered to 1000 people working for 10 different employers. Also suppose that the dataset includes demographic information of

Table 1 Study design and statistical terms

Common term	Synonymous terms
Panel data study	Longitudinal or cohort study
Time series study	Longitudinal study
Cross-section, time series	Longitudinal study
Choice-based sampling	Case–control study
Dependent variable	Outcome, response, endogenous variable
Explanatory variable of interest	Dose, treatment, exposure, intervention, exogenous variable of interest, predictor variable
Explanatory variable	Confounder, independent variable, regressor, exogenous variable, covariate
Interaction	Effect modification
Parameter estimate	Beta, regression coefficient, treatment effect
Partitioned model	Stratified model
Multiple regression	Multivariate regression
Qualitative analysis	Categorical data analysis
Logit (or probit) model	Binomial logistic regression, logistic regression
Ordered logit regression	Ordinal logistic regression, ordinal log-linear regression
Multinomial logit regression	Polytomous logistic regression
Conditional logit regression	Conditional logistic regression, McFadden's logit
Survival analysis	Cox regression, hazard model, duration model failure-time analysis, event history analysis
Omitted variable	Unmeasured covariate, unmeasured confounder, unobservable
Sample selection bias	Censoring, selection bias, incidental truncation
Selection bias	Unmeasured confounding, omitted variable bias, confounding by indication or contraindication
Simultaneous equations	Multiple multivariate regression

Source: Maciejewski, Diehr, Smith and Hebert, 2002.

these 1000 people, key characteristics of each health plan (e.g. total premium, cost-sharing, benefits provided) in each of the 10 employers. In addition, we observe the total health care expenditures that the 1000 people incurred in their health plan over a one-year period and whether or not any employee died sometime during the year.

In the discussion of econometric methods in health services, there are various outcomes we will consider: (1) the dichotomous choice between the two managed care plans that each employee has to make, (2) the trichotomous choice between all three health plans, and (3) the total health care expenditures of each employee. If the outcome of interest is not continuously distributed, then methods to analyze these discrete dependent variables are necessary. An overview of these methods is discussed in the next section. The following section considers methods for analyzing continuous, nonnormally distributed outcomes, which is followed by a discussion of simultaneous equation methods. A section on methods for count data, such as utilization data (*see* **Health Care Utilization Data**), concludes the chapter.

Discrete Dependent Variables

Discrete dependent variable methods are designed for modeling dependent variables (*see* **Response Variable**) that take specific ordinal or nominal values as representations for a continuous "latent" variable (*see* **Path Analysis**) that is unobserved by the researcher [22]. A common outcome in health services research is whether someone dies or not in a study period. The researcher observes the discrete event of death (Y) but does not observe the latent or "true" propensity to die (Y^*). We would like to estimate whether some set of **explanatory variables** (X), such as age, gender, and race, are related to the propensity to die, such that

$$Y^* = XB + u, \tag{1}$$

where B is a vector of parameters of interest (*see* **Estimation**), and u is a **random error** term. We do this by assuming that the discrete outcome of death is observed if the propensity to die exceeds some threshold. So,

$$\begin{aligned} Y &= 0 \qquad \text{if } XB + u \leq 0 \\ Y &= 1 \qquad \text{if } XB + u > 0. \end{aligned} \tag{2}$$

We can estimate B in one of two basic ways. We can treat Y as if it were a continuous variable and estimate a linear probability model (LPM) (*see* **General Linear Model**) in which B is estimated by ordinary **least squares**. Alternatively, we can use **maximum likelihood** techniques to estimate B by expressing the probability that $Y = 1$ as:

$$\begin{aligned} P(Y = 1) &= P(XB + u > 0) \\ &= P(u > -XB) = 1 - F(-XB), \end{aligned} \tag{3}$$

where F is the cumulative distribution of u. This leads to the **likelihood** function:

$$\frac{\Pr(Y = 1)}{\Pr(Y = 0)} = \mathrm{e}^{X\beta}. \tag{4}$$

Assumptions about the cumulative distribution of u provide a means of estimating B. The probit model (*see* **Quantal Response Models**) assumes a standard **normal distribution**, while the logit model (*see* **Logistic Regression**) assumes a standard **logistic distribution**.

The logistic model is used most often in the health literature, but probit and logit models often give very similar results. An alternative is the (LPM, which has the benefit of not relying on untestable distributional assumptions regarding u, but is naturally heteroscedastic (*see* **Scedasticity**) and therefore inefficient. Moreover, predicted values of Y^* from the LPM can be greater than one or less than zero. The functional form of logit and probit models prevent predicted values from exceeding the [0,1] interval, but heteroscedasticity in the logit and probit models may be a problem and could lead to biased estimates of B.

The next types of discrete dependent variable methods are those that take on three or more discrete values, such as the decision by the 1000 employees in our example to enroll in the FFS plan or one of the two HMO plans. To explain this choice, we can include employees' demographic characteristics (e.g. "characteristics of the chooser") and/or information about the premium, cost-sharing, and benefits of each health plan (e.g. "characteristics of the choice"). With these dependent variables, the method to apply is dependent on two factors: whether there is a natural ranking or ordering to the values of the dependent variable and whether the independent variables are characteristics of the outcome or characteristics of the chooser. Qualitative dependent variables that can be ordered, such as levels of health (e.g. excellent, good, fair, poor) are estimated using ordered logit or ordered probit models (*see* **Ordered Categorical Data**). In this case, Y takes on different values depending on the range of the latent variable (See Figure 1).

From Figure 1 above, it is clear that Y^* crosses several thresholds indicated as c1 and c2. Specific values of Y are determined from the relation of specific values of Y^* with the various thresholds as indicated below:

$$\begin{aligned} Y &= 0 \qquad \text{if } Y^* < 0 \\ Y &= 1 \qquad \text{if c1} > Y^* > 0 \\ Y &= 2 \qquad \text{if c2} > Y^* > \text{c1} \\ Y &= 3 \qquad \text{if c2} < Y^*. \end{aligned} \tag{5}$$

If the dependent variable is unordered, such as patient choice of providers (e.g. primary care physician, specialist, chiropractor), and the independent variables (*see* **Explanatory Variables**) are characteristics of the choices, then a conditional logit is appropriate [22]. If the dependent variable is unordered and the independent variables are characteristics of the chooser, then a multinomial logit or multinomial probit is appropriate [13, 18, 22] (*see* **Polytomous Data**).

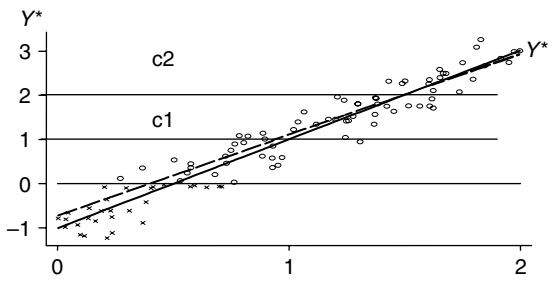

Figure 1 Classification of latent variable Y^* into discrete categories

Dowd et al. [8] describe an example of the multinomial logit model applied to health plan choice. To yield valid interpretations, the multinomial logit and conditional logit models must satisfy the assumption of independence of irrelevant alternatives (IIA), which states that the introduction or withdrawal of a choice will leave the probabilities of remaining choices unchanged. For example, if patients with lower back pain were allowed to choose either a physician or a chiropractor, and twice as many chose the physician, the IIA assumption states that if a new provider were introduced – for example, a physical therapist – the resulting distribution of patients across providers would still have twice as many patients choosing the physicians than the chiropractors.

This assumption often does not hold. If the IIA assumption is not met, nested logit models may be worth considering (*see* **Hierarchical Models**). In these models, choices are grouped into subgroups on the basis of some characteristic that is common to all choices in each subgroup. Feldman et al. [10] estimated a model of health plan choice using a nested logit model. The IIA assumptions held within the nests, but not between the nests. Additionally, recent computer processing advances have made estimation of multinomial and conditional probit models tenable, which do not require the IIA assumption to be met.

Limited Dependent Variables

Limited dependent variables are continuous variables from classical **linear regression** (6) that are **censored** or truncated for some reason [22]. This can be expressed as:

$$Y^* = \alpha + x\beta + e, \qquad \text{where } e \sim N(0, \sigma^2). \quad (6)$$

In classical linear regression, data for Y^* are available for all observations (e.g. individuals), but Y^* is never completely observed in limited dependent variable models. In censored data, Y^* is observed only if Y^* is greater (and/or lower) than some threshold, such as survival time or healthcare costs [22]. Otherwise, Y takes on the value of the threshold(s). For example, survival time can be censored if some people are still alive when the period of observation ends. This is censoring "from above". Health care expenditures often are censored "from below" because we cannot observe expenditures less than zero.

Truncated data are slightly different. For truncated data, we observe Y^* only for people for whom Y^* is greater than (or less than) a given threshold. We have no information on people for whom Y^* does not meet the threshold. For example, a sample of low-income families contains information on income and other variables only for families whose income is below a poverty threshold. No data exist for families above the income threshold.

Figure 2 demonstrates the consequences of censored data. The 'o's represent the true or uncensored data, the 'x's represent the data observed by the researcher, the solid line represents the regression line through the uncensored data, and the dotted line represents the regression line through the censored data points. The mass of observations at the censoring point – zero, in this example – forces the regression line to be more shallow that it should be. In general, the consequences of censored data is to bias the slope coefficients toward zero.

Figure 3 demonstrates the consequences of truncated data. The only data that are observable are those above the truncation point. This means that for

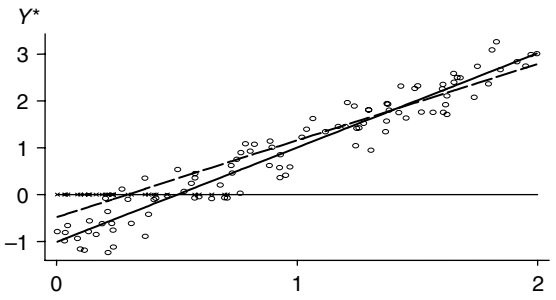

Figure 2 Censored data

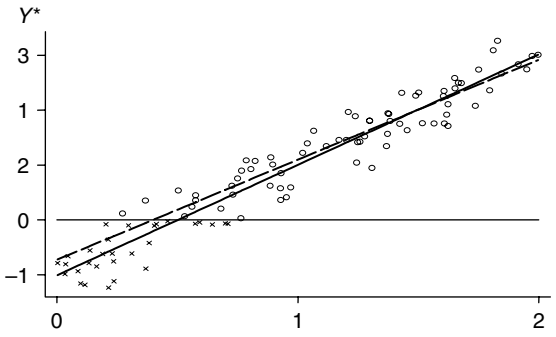

Figure 3 Truncated data

persons with low values of X, only those with unusually high values of Y given X are observed by the researcher. Again, this has the effect of biasing the slope coefficient toward zero.

Truncated data can be estimated using a Tobit model that estimates parameters based only on observations not at the limit(s) [30]. This model has been used to estimate such diverse outcomes as labor supply in depressed people [1], health related quality of life [2, 15], and utilization of health services [16].

Two-part models are a third type of limited dependent variable model that models a continuous variable outcome in which zero is a "true" value not due to censoring or truncation, unlike the Tobit model above. The most common application of two-part models is cost data, where individuals who never interacted with the health care system during the study period have zero costs [7, 23]. Two-part models address particular distributional properties of most cost data, namely, a large preponderance of zeros and tremendous skewness due to several high-cost outliers (*see* **Zero Padding**).

Two-part models estimate the continuous outcome (e.g. cost) in two parts, hence the name. In the first part, the probability of positive costs is estimated using a logit model. The second part estimates the level of positive costs only for those observations with positive costs. The second part may take a variety of distributions and variance structures. Normally distributed costs typically are modeled using untransformed costs, which is appealing for the ease of interpretability and generating predictions. If the positive observations are nonnormally distributed, then logarithmic or square root **transformations** are worth considering. Data that are log-transformed must be retransformed to enable interpretable estimates in the unlogged (or dollar) scale [9, 24]. If heteroscedasticity is a concern, retransformation must take account of the heteroscedasticity [23, 27, 32]. Alternatively, a **generalized linear model** with a **gamma** density and linear or log link may be worth exploring [3].

A fourth type of limited dependent variable model that is closely related to a Tobit model is the sample selection, or incidental truncation model. These models address a special case of truncation in which the process generating unobserved Y is not independent of the process generating specific values of observed Y [18]. For example, nonresponse to survey questions can be modeled using sample selection models. The process generating nonresponse is estimated as well as the process generating the observed values, which is the main equation of interest. These two processes can be modeled in two steps, which is called Heckman's two-step estimator [17]. Alternatively, the two processes can be modeled simultaneously with maximum likelihood, which yields more efficient estimates. The simultaneous model requires that the errors in the selection equation and the errors in the main equation of interest are distributed **bivariate normal**.

Sample selection models have been extended to include bivariate outcomes, such as whether or not someone chooses a zero-deductible plan. For example, if we wanted to use data from our example of the 1000 employers in which employees from 10 employers have a choice of three plans: an FFS plan, an HMO plan with a copayment for an office visit, and an HMO plan without a copayment. If we wanted to estimate whether an employee chooses the FFS plan or one of the HMO plans and then estimate whether the employee chooses the HMO plan with the copayment or the other HMO plan, bivariate probit models with sample selection are appropriate. For more information on these types of models, see papers by Van de Ven and Van Praag [31] and Meng and Schmidt [26].

Simultaneous Equations

For many health services problems, it is important to estimate the response of a variable to another *endogenous* factor determined by the model. For example, the *codetermination* of total health care expenditures and health plan choice must be taken into account in order to identify the effect of choosing an FFS plan on total healthcare expenditures. The steps are twofold; hence, the appropriate econometric procedure is termed two-stage least squares (2SLS). The reason for this two-stage procedure is that an ordinary least squares (OLS) estimate of the coefficient on FFS health plan in an (structural) equation would be biased by the correlation between the disturbance term and the actual health plan choice. A **structural equation** is one that lists all the variables associated with total health care expenditures, even if they are correlated with the disturbance term (e.g. endogenous). A reduced form equation excludes endogenous variables from the equation.

In the first step, one estimates a *reduced form* equation that expresses total health care expenditures

as determined by the type of health plan chosen by an employee and the cost-sharing and benefits of that plan. If health plan choice is endogenous and we want to know the effect of health plan type on total expenditures, we need to include the *predicted* value of total expenditures as a regressor in the second-stage equations.

"Identification" has a specific meaning in econometrics: it implies that the coefficients of the regressors in separate simultaneous structural equations can be uniquely determined (*see* **Identifiability**). The necessary ("order") condition for identification of a given equation requires that the number of variables whose coefficients are constrained to zero or restrictions on the value of some linear combination of coefficients should not be less than the number of endogenous variables in the equation. The rank condition, the second requirement that must be satisfied for identification, states that none of the structural equations in the system can be expressed as a linear combination of one or more of the other equations.

An alternative approach is the **instrumental variables** method that seeks to overcome the same simultaneity bias problem with OLS estimation. The instrumental variables approach also develops a "predictive" equation for the endogenous variable(s), the (causal) influence of which on other endogenous variables in the model is being estimated. As in the first stage of 2SLS, all the "predictors" (regressors) in the equation for the "instrument" (the name given to the endogenous variable whose causal influence on another variable is being estimated) are exogenous and uncorrelated with the error term in the equation of interest. Thus, *in principle,* the predicted value of the instrument will be independent of the disturbance term in the regression of the dependent variable of interest on that instrument.

The major difference between 2SLS and the instrumental variables (IV) method is that in IV applications the investigator does not necessarily develop the model as a simultaneous system of equations in which the reduced form solutions for all the endogenous variables in the system are determined by the same set of exogenous variables. A recent application of IV estimation in health economics was the study by Gaynor & Gertler [12] of physician compensation and physician production within medical groups. In this paper, the investigators acknowledged that physician production levels (e.g. productivity per hour worked and per physician) would likely be influenced by the method of physician compensation *and* would themselves affect the choice of compensation method by the medical group. They then developed instrumental variable estimates for choice of compensation using logistic regression and estimated the effect of compensation method on individual physician production using the instruments.

IV estimation also is often used to deal with **selection bias** issues in health services research applications. Selection bias is a common problem of **cohort studies** where the treatment (or intervention) is not randomly assigned, but rather is chosen by the parties being studied. A paper by McClellan et al. [25] dealt with this issue.

Given the importance of discerning causal effects *(see* **Causation**) in health economics, the need for econometric models that deal with two-way causation, and that eliminate (or at least mitigate) simultaneity bias in estimates of those causal effects, is apparent. Nelson & Startz [28] and Bound, Jaeger and Baker [4] have shown that the results of IV estimation can be highly misleading when the instrument is a poor one. This is often likely to be true in health services applications using administrative or health plan claims databases *(see* **Administrative Databases**) since these sources typically do not include information on key exogenous variables (e.g. household income, occupation, family size, and marital status) that might otherwise act as useful instruments.

Specifically, they show that, in cases where there is "feedback" between the dependent variable and an independent variable of interest (precisely the "two-way causation" that we discuss) *and* the instrument is a "poor one" (in the sense of low R^2 – in the IV estimating equation):

1. The probability limit of the estimated coefficient will approach "a value that is related to the amount of feedback, rather than to the true coefficient" [28]; and
2. even when the true coefficient is zero, the (spurious) level of significance of the IV estimate will increase with the amount of feedback.

They conclude, ironically, that in the very cases in which OLS is a poor estimator because of feedback, a poor instrument will be even worse. The analysis of Nelson and Startz [28] offers, therefore, an important cautionary note in the application of IV estimation to empirical health economics.

In **cross-sectional** analysis of a particular outcome, a different type of simultaneous equation may be useful. Switching regression methods are appropriate when the intercept *and* slope coefficients may be expected to vary from observation to observation. Typically, there are two regimes that may correspond to health states (e.g. healthy, sick) or policy environments. In **longitudinal data**, regimes typically correspond to time periods. Switching regressions are considered a type of simultaneous equation model, because two regressions are run simultaneously (one for each regime). The likelihood function for the switching regression model is listed below.

Gaynor [11] estimated a switching regression model of physician group practices, where demand for their services was constrained in one regime and demand was not constrained in another regime. Bretteville-Jensen [5] estimated a switching regression model of heroin consumption for men and women, where gender was the regime determination. Regimes can be exogenous variables, such as gender or age, or endogenous variables, such as a choice of provider. In the case of endogenous switching that is explicitly determined by the unit of observation, the choice of which regime to be in can be modeled explicitly. O'Donnell [29] models such an endogenous switching process and the regressions in each of the regimes in a model of disability benefits and labor participation by disabled people in the United Kingdom. Readers interested in these methods are directed to [19] for more information.

Count Data Variables

Count data variables are those that take on integer values [6, 18]. As in the two-part model discussed above, count data typically have a preponderance of zeros that leads OLS methods to be biased. Count data in health services commonly refers to events, such as number of physician visits, weeks of care, or length of stay.

Count data have most frequently been modeled as **Poisson processes** with a **Poisson distribution** where the expected number of events equals the variance of events [20]. In count data, the mean number of events may not always equal the variance of events. In cases where the mean number of events is greater than the variance, these data are defined as overdispersed. In the presence of overdispersion, count data can be modeled as **negative binomial distribution** that is a special case of the gamma distribution [13].

Finally, developments in these basic count models have addressed the possibility that count data will have a preponderance of zeros. Zero-inflated Poisson and zero-inflated negative binomial models have been developed to address this scenario [6]. These models allow explicit modeling of the zeros, akin to the Tobit model. Alternatively, there may be cases where there is some process that differentiates observations with values at zero and observations with positive values. In this case, it may be useful to model the zero observations in count data separately from the process determining the positive integer-valued observations in a hurdle model, which is akin to the two-part model [18, 27]. Readers interested in these methods are directed to [6] for more information. Panel data methods (*see* **Panel Study**) also are available and are discussed in [6].

Conclusion

This chapter summarizes some of the econometric methods currently used to address problems of health, health care, and health insurance. The focus was largely on cross-sectional methods using observational data, since most health services applications rely on nonexperimental settings. Application of these methods to longitudinal data is becoming more widespread.

Many statistical problems addressed in biostatistical methods have analogues in econometrics, as illustrated by Table 1. Survival and duration models have relatively recently been applied to econometric problems. Selection models (and other approaches to endogeneity) and count data models used to analyze utilization and costs may represent more unfamiliar ground for biostatisticians [14]. Most of the methods for analysis of cross-sectional models are available in SAS and STATA, while longitudinal models are increasingly available in these statistical packages (*see* **Software, Biostatistical**).

Econometric applications to health services are also expanding into semiparametric and nonparametric versions of the parametric methods presented here. Terminological differences aside, econometric methods represent another set of tools that biostatisticians should add to their toolbox, particularly if they expect to conduct analyses of nonexperimental data.

Edgeworth Expansion

The expansions named for Edgeworth were developed by P.L. Chebyshev [6] and F.Y. **Edgeworth** [9–11]. Chebyshev was a Russian mathematician whose interest in the expansions derived from his earlier contributions to probability theory and to the theory of orthogonal functions (*see* **Orthogonality**). Edgeworth was a self-taught Irish mathematician, who trained as a linguist and lawyer but made his academic career as an economist in England. His contributions to the expansions that bear his name were motivated by a desire to explore, in a statistical setting, properties of probability distributions.

The Edgeworth expansion of one density, f say, with respect to another, ϕ, may be formally defined in terms of cumulants (*see* **Characteristic Function**). Specifically, writing D for the differential operator $\mathrm{d}/\mathrm{d}x$, it may be shown that

$$f(x) = \exp\left[\sum_{i=1}^{\infty} \left(\kappa_i^f - \kappa_i^\phi\right) \left\{\frac{(-D)^i}{i!}\right\}\right] \phi(x)$$
$$= \phi(x) - \left(\kappa_1^f - \kappa_1^\phi\right) \phi'(x) + \cdots, \qquad (1)$$

where κ_i^f and κ_i^ϕ denote the ith cumulants of the indicated densities, and, among other assumptions, it is supposed that κ_i^f and κ_i^ϕ become "close" sufficiently quickly as i increases. The latter condition is most likely to hold when the density f is converging to ϕ, in some sense (*see* **Convergence in Distribution and in Probability**). The context suggests the **central limit theorem**, where ϕ is the **standard Normal** density.

Indeed, the central limit theorem is the standard setting for studying Edgeworth expansions. In this case, assuming f and ϕ have been standardized for location and scale (so that the corresponding distributions have zero **mean** and unit **variance**), and noting that all cumulants of the standard Normal distribution vanish, we see that (1) simplifies to

$$f(x) = \exp\left\{-\kappa_3^f \left(\frac{D^3}{3!}\right) + \kappa_4^f \left(\frac{D^4}{4!}\right) + \cdots\right\} \phi(x). \qquad (2)$$

It is at this point that a connection is made to Chebyshev's interest in orthogonal functions. The Chebyshev–Hermite polynomials (*see* **Polynomial Approximation**), $H_0(x) = 1$, $H_1(x) = x$, $H_2(x) = x^2 - 1$, and so on, sometimes written in the notation He_j rather than H_j, are orthogonal with respect to the Normal N(0, 1/2) density:

$$\int_{-\infty}^{\infty} H_i(x) H_j(x) \exp\left(-\frac{1}{2}x^2\right) \mathrm{d}x = 0, \qquad (3)$$

for $i \neq j$. The right-hand side of (2) may be formally expanded in terms of these functions, giving:

$$f(x) = \left\{1 + \frac{\kappa_3^f}{3!} H_3(x) + \frac{\kappa_4^f}{4!} H_4(x) + \frac{\kappa_5^f}{5!} H_5(x) + \frac{\kappa_6^f + 10\,(\kappa_3^f)^2}{6!} H_6(x) + \cdots\right\} \phi(x). \qquad (4)$$

The special case where f is the density of a sum of n independent and identically distributed **random variables** X_i, corrected for location and scale so that it has zero mean and unit variance, is of particular interest. Assume the summand distribution, after standardizing for location and scale, has ith cumulant λ_i. Then the ith cumulant, κ_i^f, of the distribution of the standardized sum is simply $n^{-(i-2)/2}\lambda_i$, for $i \geq 1$. Making this substitution into (4), we see that the expansion here assumes a particularly simple form, the coefficient of $H_i(x)$ now being of size $n^{-(i-2)/2}$. (The function f on the left-hand side of (4) is now the density of $n^{1/2}(\overline{X} - \mu)/\sigma$, where $\overline{X}$ denotes the mean of independent random variables $X_1, \ldots, X_n$, with $E(X_i) = \mu$, $\mathrm{var}(X_i) = \sigma^2$, and the ith cumulant of $(X_i - \mu)/\sigma$ equal to λ_i.)

In particular, noting that H_i is an odd or even polynomial according as i is odd or even, respectively, we see that we can write

$$f(x) = \left\{1 + n^{-1/2}\, p_1(x) + n^{-1}\, p_2(x) + \cdots\right\} \phi(x), \qquad (5)$$

where $p_i(x)$ is an odd or even polynomial according as i is odd or even. If we integrate (5) term by term, we obtain:

$$F(x) = \int_{-\infty}^{x} f(x)\ \mathrm{d}x = \Phi(x) + n^{-1/2}\, P_1(x)\, \phi(x) + n^{-1}\, P_2(x)\, \phi(x) + \cdots \qquad (6)$$

where P_i is an odd or even polynomial according as i is even or odd, respectively. (Therefore, parities

are reversed in passing from the density to the distribution expansion.)

The properties we have just described are common to a great many distributions, which are asymptotically Normal, not just to the distribution of a standardized sample mean. Details are given by Hall [14, Chapter 2]. Modulo regularity conditions, in particular, **moment** and continuity conditions on the distribution of the data, expansions (5) and (6), and the parity property of the associated polynomials p_i and P_i, apply when f and F are the density and distribution functions, respectively, of a statistic T, which can be expressed as a smooth function of a vector of means.

For example, they apply when $T = n^{1/2}\{\theta(\overline{Y}) - \theta(\nu)\}$ and

$$F(x) = \Pr\Big[n^{1/2}\{\theta(\overline{Y}) - \theta(\mu)\} \le \sigma x\Big], \qquad (7)$$

where $\overline{Y}$ denotes the average value of a sample of n random d-vectors with mean ν, θ is a smooth function of d variables, and $n^{-1}\sigma^2$ denotes the asymptotic variance of the statistic $\theta(\overline{Y})$. Examples include the case where $\theta(\overline{Y})$ is the sample variance, which is a function of two means – the mean of the X_i's and the mean of the X_i^2's. Therefore, in this case, $\overline{Y}$ is the mean of 2-vectors $Y_i = (X_i, X_i^2)$. Likewise, an empirical variance ratio (a function of four sample means), an empirical **correlation** coefficient (a function of five sample means), and so on, may be treated in this way. This approach uses the so-called "smooth function model" for developing valid Edgeworth expansions, introduced by Bhattacharya and Ghosh [2].

The expansion (6), of $F(x)$ defined by (7), continues to hold if σ in (7) is replaced by an estimator of σ, provided that estimator too can be expressed as a smooth function of means of independent random vectors. This is the so-called Studentized, or t, case (*see* **Studentization**). Again the parity properties hold, but the polynomial sequences $p_1, p_2, \ldots$ and $P_1, P_2, \ldots$ are different in the Studentized and non-Studentized settings. However, in either case, P_i is a polynomial of degree $3i - 1$, and the degree of p_i equals $3i - 2$.

Therefore, Edgeworth expansions for sample means, sample variances, variance ratios, the sample correlation coefficient, and related quantities can be derived in a unified way, and all have the same basic properties. There are of course many other statistics that admit Edgeworth expansions. Results there are usually derived using special properties of individual cases. Note, however, that the previously mentioned parity properties of polynomials will not necessarily hold.

The parity properties are important when using Edgeworth expansions to elucidate properties of two-sided **confidence intervals**. Indeed, note from (6) that, provided P_1 is an even polynomial, and P_2 is odd,

$$F(x) - F(-x) = 2\Phi(x) - 1 + 2n^{-1} P_2(x)\,\phi(x) + O\big(n^{-2}\big). \qquad (8)$$

This fortuitous cancellation of terms of size $n^{-1/2}$ can be used to show that, in cases where the parity properties hold, two-sided confidence intervals generally have coverage error no worse than $O(n^{-1})$, even though their one-sided counterparts may do no better than $O(n^{-1/2})$. (Coverage error is the difference between the true coverage of a confidence region and its nominal level, for example, 0.95.)

This type of application of Edgeworth expansions is the predominant one today; they are used mainly to explore properties of procedures that are not themselves based on those expansions. Modern methods for constructing confidence regions and **hypothesis tests** are often highly **computer-intensive**, and mathematical techniques based on Edgeworth expansions allow us to elucidate their behavior; see [14] for discussion of the **bootstrap** in this context.

In the past, however, Edgeworth expansions were sometimes relied upon to produce confidence intervals with good orders of coverage accuracy. Such an approach is not always particularly effective, since Edgeworth series, like those at (5) and (6), generally do not converge as infinite series. They are only "asymptotic" series, in the sense that the order of magnitude (as a function of n) of the remainder in a truncated form of either series equals the order of the first omitted term. Therefore, including more terms in the series can actually make the approximation less accurate, unless sample size, n, is sufficiently large.

Edgeworth expansions and Cornish–Fisher expansions [7, 12] are related, in that the latter are expansions of a **quantile** for a given probability level, while the former are expansions of a probability level for a given quantile. They are, therefore, essentially inverses of one another, and indeed either can be obtained by inverting the other; see [14, Chapter 2].

Gram–Charlier expansions (e.g. [15, p. 17ff] can be viewed as Edgeworth expansions with the terms rearranged in a different order. This operation degrades their convergence properties, however, and partly as a result, Gram–Charlier expansions are seldom studied today.

Surveys of Edgeworth expansions, and significant papers of historical interest in the development of statistical and econometric applications of the expansions, include those of Wallace [18], Bickel [4], Sargan [17], Albers, Bickel and van Zwet [1], Bhattacharya and Rao [3], Bhattacharya and Ghosh [2], Bowman, Beauchamp and Shenton [5], Phillips [16], Cressie [8] and Götze and Hipp [13].

PETER HALL

Edgeworth, Francis Ysidro

Born: February 8, 1845, in Edgeworthstown, Ireland.
Died: February 13, 1926, in London, England.

Edgeworth, a rather reclusive figure, contributed importantly to the development of statistical theory at the end of the nineteenth century. After an Oxford degree in classics, he trained as a barrister while self-studying advanced mathematics. From 1880, he held university appointments in logic, and in economics and statistics, before accepting a chair in political economy at Oxford in 1891, which he occupied until retirement in 1922.

He published extensively in mathematical economics. His interest in probability and statistics, starting in the 1880s, was stimulated by contact with **Francis Galton** and later with **Karl Pearson**. His approach was usually, although not consistently, **Bayesian**, and included early advocacy of **maximum likelihood**. Many publications deal with the **normal distribution**, including the **bivariate** and **multivariate** forms, and with associated problems of **correlation** and **regression**. His work on skew distributions (*see* **Skewness**), involving the "Edgeworth expansion", brought him into conflict with Karl Pearson, whose own system of curves (*see* **Pearson Distributions**) had been criticized by Edgeworth.

For fuller accounts, see [1] and [2], and further references listed on p. 373 of [2].

Effect Modification

The term *effect modification* is due to Miettinen [5], and is highly related to the concept of **interaction**. When we analyze the **association** of an exposure with disease incidence, an effect modifier is a variable over which the effect of exposure on disease risk varies. For example, we might use the **relative risk** to describe the association of cigarette smoking to lung cancer risk. If the relative risk associated with cigarette smoking is statistically different among asbestos-exposed subjects from that among subjects with no asbestos exposure, then we say that asbestos exposure modifies the effect of cigarette smoking on lung cancer risk, and we call asbestos exposure an effect modifier.

We study effect modification for a variety of reasons. We may be interested in effect modification for its public health implications: if the effects of certain modifiable risk factors for breast cancer are confined to a subgroup of women, for example, efforts to modify these risk factors or increase **screening** might be targeted only at subpopulations where the intervention will prevent the most women from developing advanced disease.

Or we may think that the joint biologic effect of two exposures may be either to inhibit or to enhance each others' individual effects, and we might expect this to cause effect modification. Siemiatycki & Thomas [7] and Thompson [8] have argued, however, that in most cases it is foolish to infer much about biological interaction from the pattern of disease rates in an epidemiologic study because so little is known about biologic mechanisms. The one exception to this is the case where an exposure decreases risk for one value of the effect modifier and increases risk for another value of the effect modifier. Thompson [8] has called this "crossover", and has argued that it is the one case where some form of biologic interaction may be inferred (*see* **Synergy of Exposure Effects**).

Relationship to Interaction

Effect modification is highly related to statistical interaction in **regression** models. In relative risk regression models, where regression coefficients for main effect exposure variables have the interpretation of log relative risks, a significant interaction between exposure and a second variable means that the second variable is an effect modifier (*see* **Relative Risk Modeling**). This is true because the model with interaction says the relative risk associated with exposure will be different depending on the value of the effect modifier.

However, the relationship between statistical interaction and effect modification depends on the correspondence between what measure we choose for the effect of exposure on disease risk and the form of the regression model we use to assess interaction. To see this, we examine three possible regression models and their corresponding measures of effect.

Multiplicative Models and Relative Risks

Logistic regression, Poisson regression with a log link function (*see* **Generalized Linear Model**), and multiplicative **Cox regression** are all examples of **multiplicative models** for which the relative risk is the implicit measure of effect [1, 2]. For example, if we applied the logistic regression model to data from a **case–control study** of smoking and asbestos exposure as risk factors for mesothelioma, then for

$$X_{\mathrm{A}} = \begin{cases} 0, & \text{no occupational asbestos exposure,} \\ 1, & \text{occupational asbestos exposure,} \end{cases}$$

$$X_{\mathrm{S}} = \begin{cases} 0, & \text{never smoked,} \\ 1, & \text{ever smoked,} \end{cases}$$

and $p =$ the probability of being a case in the case–control sample, a simple logistic model without interaction is

$$\text{logit } p = \ln \frac{p}{1-p} = \beta_0 + \beta_{\mathrm{A}} X_{\mathrm{A}} + \beta_{\mathrm{S}} X_{\mathrm{S}}.$$

In a **cohort study**, a similar model would hold with $p =$ the population probability of developing the disease during the study period.

This model implies that the **odds ratio** associated with ever having smoked, $e^{\beta_{\mathrm{S}}}$, is the same whether or not an individual has had occupational exposure to asbestos. To allow the odds ratios associated with smoking to differ according to whether or not the subject had been exposed to asbestos, we add the interaction term $\beta_{\mathrm{AS}} X_{\mathrm{A}} X_{\mathrm{S}}$ to the model. Thus, if we use the logistic regression model, the presence or absence of interaction corresponds to presence or absence of effect modification, where the measure of effect we use is the odds ratio, or the relative

risk, which it approximates. This correspondence also holds for the following Poisson regression model:

$$\ln \lambda = \beta_0 + \beta_A X_A + \beta_S X_S,$$

where λ is the disease incidence rate for a time interval/covariate combination (*see* **Time-dependent Covariate**), and for the multiplicative Cox regression model

$$\ln \lambda(t) = \ln \lambda_0(t) + \beta_0 + \beta_A X_A + \beta_S X_S,$$

where $\lambda(t)$ is the hazard function. If we are interested in whether the relative risk difference (see below) associated with smoking is different among asbestos-exposed individuals from what it is among non-asbestos-exposed individuals, the presence or absence of an interaction term in a multiplicative model will not give us this information. Instead, we need to look for interaction in an additive relative risk regression model.

Additive Relative Risk Models and Relative Risk Differences

Most investigators would agree that when they are considering public health implications of some exposure, additive measures of the effect of exposure on risk are more useful than multiplicative measures for identifying subgroups where interventions should be targeted. In addition, Rothman has argued that the additive scale is better for assessing whether there is biological interaction, and that **additive models** should be used instead of the multiplicative models when assessing whether there is effect modification [6]. However, this has been disputed by Siemiatycki & Thomas [7] and Thompson [8] among others, who show that, depending on the biologic model for how exposure affects disease risk, biologic interaction may or may not manifest itself as a statistical interaction on either the additive or multiplicative scales.

In a case–control study, the additive measure of effect that can be estimated is the additive relative risk. For a case–control study of lung cancer like the one described above, the additive relative risk is defined as follows. Let $p(0, 0)$ be the probability of being a case among those exposed to neither smoking nor asbestos, and $p(X_A, X_S)$ the probability of being a case among those with asbestos and smoking exposure given by X_A and X_S. Then the relative risk difference comparing combinations of exposure (X_A, X_S) and (X'_A, X'_S) is

$$RRD = \frac{p(X_A, X_S) - p(X'_A, X'_S)}{p(0, 0)}.$$

If this is the measure of the effect of exposure (X_A, X_S) compared with exposure (X'_A, X'_S), then we say that asbestos exposure modifies the effect of smoking if the relative risk difference associated with smoking is different among those occupationally exposed to asbestos from what it is among those without occupational asbestos exposure. Whether or not this type of effect modification exists depends on whether or not there is an interaction term in the additive relative risk regression model:

$$\frac{p}{1-p} = e^{\beta_0}(1 + \beta_A X_A + \beta_S X_S).$$

Similar correspondences hold for the additive relative risk versions of the Poisson regression model

$$\lambda = e^{\beta_0}(1 + \beta_A X_A + \beta_S X_S),$$

and the Cox regression model

$$\lambda(t) = \lambda_0(t)(1 + \beta_A X_A + \beta_S X_S).$$

See Breslow & Day [2] for more details.

Additive Risk Models and Risk Differences

The relative risk difference measures the difference in risk of disease for different exposure combinations relative to the disease risk in a baseline group where all the covariates have the value zero. Using data from a cohort study, it is also possible to estimate absolute differences in the risk of disease or the disease **incidence rate**. Letting $p(x_A, x_S)$ denote the disease risk or probability of developing disease during the study period for those with asbestos exposure given by X_A and smoking exposure given by X_S, then the risk difference comparing combinations of exposure (X_A, X_S) and (X'_A, X'_S) is

$$RD = p(X_A, X_S) - p(X'_A, X'_S).$$

If the risk difference is the measure of the effect of exposure (X_A, X_S) compared with (X'_A, X_S), then we say asbestos exposure modifies the effect of smoking if the risk difference associated with smoking is different among those occupationally exposed to

Table 1 History of having given birth, family history of breast cancer, and breast cancer risk, from Colditz et al. [3]

	No family history				Family history			
	Cases	Person-years	Relative risk	95% CI	Cases	Person-years	Relative risk	95% CI
Never given birth	150	69 666	1.0[a]	–	16	5 816	1.0[a]	–
Ever given birth	1788	994 628	0.83	(0.71, 0.99)	5816	78 559	1.4	(0.83, 2.3)

[a]Reference group

asbestos from what it is among those without occupational asbestos exposure. Whether or not this type of effect modification exists depends on whether or not there is an interaction term in the additive risk model:

$$p = \beta_0 + \beta_A X_A + \beta_S X_S.$$

Similar correspondences hold for additive versions of the Poisson regression model

$$\lambda = \beta_0 + \beta_A X_A + \beta_S X_S,$$

and incidence rate regression models

$$\lambda(t) = \lambda_0(t) + \beta_A X_A + \beta_S X_S.$$

See Lin & Ying [4] for inference under the additive incidence rate model.

Example

Colditz et al. [3] studied how a variety of known risk factors for breast cancer were modified by family history of breast cancer. Data abstracted from the article are given in Table 1, broken down by whether the woman had ever given birth and whether she had a family history of breast cancer in a mother or sister. Crude relative risks based on a Poisson regression model are also given in Table 1.

From these results we see that without adjustment for other factors, among women without a history of breast cancer in their mother or sisters, the birth of a child appears to confer protection from breast cancer. However, among women with a history of breast cancer in the mother or a sister, the birth of a child is associated with, if anything, an increase in risk. If these differences are also seen in other studies, they might argue that screening schedules should be the most frequent in parous women with a family history of breast cancer. If the relative risk associated with parity among women with a family history were statistically different from one, these data would satisfy Thompson's [8] criteria for crossover, from which some interaction in the biological mechanisms might be inferred.

Egret

Egret is a commercial software produced by Cytel Software Corporation. It was originally developed as a DOS-based software but a Windows version has been available since 1999, which makes Egret fairly easy to use. It is devoted to the analysis of epidemiologic and biomedical studies. It allows users to perform some data editing. Its main strength is its fairly extensive analytical capabilities. They include **linear regression**, unconditional and conditional **logistic regression** (with the useful option of including **random effect** terms), **Poisson regression**, and semiparametric and parametric **survival analysis**. Moreover, Egret offers additive and multiplicative versions of logistic and Poisson regression models (*see* **Relative Risk Modeling**), fairly extensive regression **diagnostics**, and **goodness-of-fit** procedures for all models, some exact or quasi-exact tests (*see* **Exact Inference for Categorical Data**) and procedures for the analysis of **contingency tables**, and has some graphical capabilities. Besides Egret, Egret-SIZ is a separate DOS-based program also produced by Cytel Software, which performs advanced **sample size** calculations for unconditional and conditional logistic regression, Poisson regression, and **Cox regression**, and offers the option of performing **power** calculations based on **Monte-Carlo** simulations.

(*See also* **Software, Biostatistical**; **Software, Epidemiological**; **Survival Analysis, Software**)

JACQUES BENICHOU

Eigenvalue

Eigenvalues (also known as eigenroots or latent roots) are a feature of square matrices. The definition and calculation of eigenvalues involves determinants. The eigenvalues of square matrix $\mathbf{A}$, of order n, are the n solutions for λ to what is called the *characteristic equation* of $\mathbf{A}$, namely,

$$|\mathbf{A} - \lambda\mathbf{I}| = 0, \tag{1}$$

i.e. the determinant of $\mathbf{A} - \lambda\mathbf{I}$ is equated to zero.

The nature of the determinant of a matrix (*see* **Matrix Algebra**) is such that for $\mathbf{A}$ of order n (1) is a polynomial equation of order n, thus having n solutions for λ. Those solutions are the eigenvalues of $\mathbf{A}$. As an example, for

$$\mathbf{A} = \begin{bmatrix} 3 & 1 \\ 2 & 4 \end{bmatrix},$$

$$\begin{aligned} |\mathbf{A} - \lambda\mathbf{I}| &= \begin{vmatrix} 3-\lambda & 1 \\ 2 & 4-\lambda \end{vmatrix} \\ &= (3-\lambda)(4-\lambda) - 2 \\ &= \lambda^2 - 7\lambda + 10, \end{aligned}$$

and so the characteristic equation is

$$\lambda^2 - 7\lambda + 10 = 0,$$

which has solutions $\lambda = 2$ and 5. Thus 2 and 5 are the eigenvalues of $\mathbf{A}$.

General Properties

1. An eigenvalue, through being a solution of a polynomial equation, can be positive, negative, zero, real, or complex.
2. Eigenvalues of a matrix need not all be different. If λ is a root m times, then it is said to be a multiple root with multiplicity m.
3. For a scalar c, an eigenvalue of $c\mathbf{A}$ is c (eigenvalue of $\mathbf{A}$).
4. When λ is an eigenvalue of $\mathbf{A}$, λ^r is an eigenvalue of $\mathbf{A}^r$, for r being zero or a positive integer. This extends to a polynomial function of $\mathbf{A}$: $p(\mathbf{A})$ has $p(\lambda)$ as an eigenvalue.
5. The sum of all n eigenvalues of $\mathbf{A}$ of order n equals the trace of $\mathbf{A}$, the sum of its diagonal elements.
6. The product of all n eigenvalues of $\mathbf{A}$ is the determinant of $\mathbf{A}$.

Special Cases

1. Nonsingular matrices: all eigenvalues are nonzero.
2. Inverse matrices: $\mathbf{A}^{-1}$ has eigenvalue $1/\lambda$ where λ is an eigenvalue of $\mathbf{A}$.
3. Positive (semi)definite matrices: all eigenvalues are positive (zero or positive).
4. Symmetric matrices: all eigenvalues are real and the number of nonzero eigenvalues equals the rank of the matrix.
5. Orthogonal matrices: eigenvalues come in pairs λ and $1/\lambda$, with one value being ± 1 when the matrix is of odd order.
6. Idempotent matrices: all eigenvalues are $+1$ or zero; the number that is $+1$ is the rank of the matrix.

There are numerous uses of eigenvalues in **multivariate analysis** (see, for example, [1, Section 11.2]). One is in **principal components analysis** applied to a vector $\mathbf{X}$ of random variables. The linear combinations of these variables known as *principal components*, are $\boldsymbol{\beta}_r'\mathbf{X}$, where $\boldsymbol{\beta}_r'$ is the **eigenvector** corresponding to an eigenvalue λ_r of the **variance–covariance matrix** of the variable $\mathbf{X}$. Then the variance of $\boldsymbol{\beta}_r'$ is λ_r, and so one can rank the principal components according to the size of their variances.

A second use of eigenvalues is in **linear discriminant analysis** where one wants to classify observational units on the basis of a vector of variables, $\mathbf{X}$, say, measured on each unit. This is done using some $\mathbf{t}'\mathbf{X}$, often through maximizing the ratio of two quadratic forms, $\mathbf{t}'\mathbf{A}\mathbf{t}$ and $\mathbf{t}'\mathbf{B}\mathbf{t}$, say. This is achieved by choosing λ and $\mathbf{t}$ so that $(\mathbf{B} - \lambda\mathbf{A})\mathbf{t} = \mathbf{0}$, or equivalently $(\mathbf{A}^{-1}\mathbf{B} - \lambda\mathbf{I})\mathbf{t} = \mathbf{0}$. Thus, λ is the eigenvalue of $\mathbf{A}^{-1}\mathbf{B}$ and $\mathbf{t}$ a corresponding eigenvector.

Other uses of eigenvalues involve what is known as Wilks's test criterion for testing a linear hypothesis in the multivariate linear model. It consists of a ratio of the form of $\det \mathbf{A}/\det(\mathbf{A} + \mathbf{B})$, where $\mathbf{A}$ and $\mathbf{B}$ are matrices of sums of squares and products: $\det(\mathbf{A})$ represents the determinant of $\mathbf{A}$, which is the product of all the eigenvalues of $\mathbf{A}$ (see [3, Chapter 8]). Some alternatives to this are Hotelling's [2] trace

of $\mathbf{BA}^{-1}$, which is the sum of the eigenvalues of $\mathbf{BA}^{-1}$, or Pillai's [4] trace of $\mathbf{B}(\mathbf{A}+\mathbf{B})^{-1}$, being the sum of the eigenvalues of $\mathbf{B}(\mathbf{A}+\mathbf{B})^{-1}$, or Roy's [5] criterion of the largest eigenvalue of $\mathbf{A}(\mathbf{A}+\mathbf{B})^{-1}$.

SHAYLE R. SEARLE

Eigenvector

Eigenvectors and eigenvalues (or eigenroots) are features of any square matrix. For square $\mathbf{A}$, of order n, its **eigenvalues** are the n solutions for λ to what is known as the characteristic equation:

$$|\mathbf{A} - \lambda\mathbf{I}| = 0. \tag{1}$$

For each solution λ_i there is always a vector, $\mathbf{u}_i$, say, such that

$$\mathbf{A}\mathbf{u}_i = \lambda_i\mathbf{u}_i, \quad \text{or equivalently } (\mathbf{A} - \lambda_i\mathbf{I})\mathbf{u}_i = \mathbf{0}. \tag{2}$$

The vector $\mathbf{u}_i$ is called an eigenvector of $\mathbf{A}$ corresponding to the eigenvalue λ_i. Sometimes "characteristic" (or even, old-fashionably, "latent") is used in place of "eigen".

Example

For

$$\mathbf{A} = \begin{bmatrix} 3 & 1 \\ 2 & 4 \end{bmatrix},$$

(1) simplifies to $\lambda^2 - 7\lambda + 10 = 0$, giving $\lambda_1 = 2$ and $\lambda_2 = 5$ as eigenvalues. The second equation in (2) is satisfied as follows:

$$\begin{bmatrix} 3-2 & 1 \\ 2 & 4-2 \end{bmatrix}\begin{bmatrix} a \\ -a \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad \text{and}$$

$$\begin{bmatrix} 3-5 & 1 \\ 2 & 4-5 \end{bmatrix}\begin{bmatrix} b \\ 2b \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{3}$$

Thus $\mathbf{u}_1 = [a \quad -a]'$ is the eigenvector corresponding to $\lambda_1 = 2$, and $\mathbf{u}_2 = [b \quad 2b]'$ corresponds to $\lambda_2 = 5$.

General Properties

For scalar c, an eigenvector of $\mathbf{A}$ is also an eigenvector of $c\mathbf{A}$. This is so because $\mathbf{A}\mathbf{u} = \lambda\mathbf{u}$ implies that $c\mathbf{A}\mathbf{u} = c\lambda\mathbf{u}$, i.e. $(c\mathbf{A})\mathbf{u} = (c\lambda)\mathbf{u}$. The latter is also $\mathbf{A}(c\mathbf{u}) = \lambda(c\mathbf{u})$, showing that if $\mathbf{u}$ is an eigenvector of $\mathbf{A}$ so is $c\mathbf{u}$. This is evident in (3), where a and b can be any scalars.

There is also the simple algebraic result that $\mathbf{A}\mathbf{u} = \lambda\mathbf{u}$ gives $\mathbf{A}^2\mathbf{u} = \mathbf{A}(\mathbf{A}\mathbf{u}) = \mathbf{A}(\lambda\mathbf{u}) = \lambda\mathbf{A}\mathbf{u} = \lambda(\lambda\mathbf{u}) = \lambda^2\mathbf{u}$. Thus $\mathbf{u}$ as an eigenvector of $\mathbf{A}$ is also an eigenvector of $\mathbf{A}^2$. This extends to $\mathbf{u}$ being an eigenvector of any integer power of $\mathbf{A}$ (and negative powers for nonsingular $\mathbf{A}$).

Because every eigenvalue λ_i has a corresponding eigenvector $\mathbf{u}_i$,

$$\mathbf{A}[\mathbf{u}_1 \quad \mathbf{u}_2 \ldots \mathbf{u}_i \ldots \mathbf{u}_n] = [\lambda_1\mathbf{u}_1 \quad \lambda_2\mathbf{u}_2 \ldots \lambda_i\mathbf{u}_i \ldots \lambda_n\mathbf{u}_n] \tag{4}$$

and, on defining $\mathbf{U} = [\mathbf{u}_1 \quad \mathbf{u}_2 \ldots \mathbf{u}_i \ldots \mathbf{u}_n]$ and $\mathbf{D}$ as the diagonal matrix of the λs, (4) is

$$\mathbf{A}\mathbf{U} = \mathbf{U}\mathbf{D}. \tag{5}$$

Calculation

For eigenvalue λ_i, the matrix $\mathbf{A} - \lambda_i\mathbf{I}$ is always singular. The theory of solving linear equations then yields a solution for $\mathbf{u}_i$ to (2) as $[(\mathbf{A} - \lambda_i\mathbf{I})^-(\mathbf{A} - \lambda_i\mathbf{I}) - \mathbf{I}]z$ for $(\mathbf{A} - \lambda_i\mathbf{I})^-$ being a generalized inverse (*see* **Matrix Algebra**) of $\mathbf{A} - \lambda_i\mathbf{I}$, and $\mathbf{z}$ being an arbitrary vector of order n.

Multiple Eigenvalues

Since (1) is a polynomial equation of order n it has n solutions for λ, which need not be all different. Suppose λ_t is a root m_t times, for $t = 1, \ldots, k$, for $\lambda_1 \ldots \lambda_k$ being all different. Then m_t is called the multiplicity of λ_t, and $\sum_{t=1}^{k} m_t = n$. When $(\mathbf{A} - \lambda_t\mathbf{I})$ has rank $n - m_t$ one can always find m_t linearly independent eigenvectors corresponding to λ_t. When this rank property holds for all $t = 1, \ldots, k$ (and it always holds whenever $m_t = 1$), then all eigenvectors are linearly independent and $\mathbf{U}$ is nonsingular.

Nonsymmetric Matrices

For nonsymmetric $\mathbf{A}$ it is the preceding rank condition (known as the diagonability theorem, e.g. [1, p. 305], which determines whether $\mathbf{U}$ is nonsingular or not. When it is nonsingular, (5) yields $\mathbf{D} = \mathbf{U}^{-1}\mathbf{A}\mathbf{U}$ and $\mathbf{D}$ is known as the canonical form under similarity, or equivalently as the similar canonical form. Likewise $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^{-1}$ and $\mathbf{A}^r = \mathbf{U}\mathbf{D}^r\mathbf{U}^{-1}$.

Symmetric Matrices

For symmetric $\mathbf{A}$:

1. All λ_i and $\mathbf{u}_i$ are real.
2. $\mathbf{U}$ is always nonsingular.

3. Eigenvectors are pairwise orthogonal: $\mathbf{u}_i'\mathbf{u}_j = 0$ for $i \neq j$.
4. Each $\mathbf{u}_i$ can be standardized to be a unit vector $\mathbf{v}_i = \mathbf{u}_i/(\mathbf{u}_i'\mathbf{u}_i)^{1/2}$, so that $\mathbf{v}_i'\mathbf{v}_i = 1$.
5. Replacing each $\mathbf{u}_i$ in $\mathbf{U}$ by $\mathbf{v}_i$ makes $\mathbf{U}$ orthogonal: $\mathbf{U}'\mathbf{U} = \mathbf{U}\mathbf{U}' = \mathbf{I}$.
6. $\mathbf{D} = \mathbf{U}'\mathbf{A}\mathbf{U}$ is called the canonical form under orthogonal similarity; $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}' = \sum_{i=1}^{n} \lambda_i \mathbf{u}_i \mathbf{u}_i'$, the latter being known as the spectral decomposition of $\mathbf{A}$.

These properties are important to statistics wherein symmetric matrices occur in a variety of situations, e.g. dispersion matrices, and $\mathbf{X}'\mathbf{X}$ in linear models.

Eligibility and Exclusion Criteria

The choice of eligibility criteria in a **clinical trial** can increase or decrease the magnitude of between-patient variation, which will in turn decrease or increase the statistical **power** of the trial for a given sample size. Theoretically, the more homogeneous the trial population, the greater is the power of the trial, but the more limited is the ability to generalize the results to a broad population. Thus, the choice of eligibility criteria can profoundly influence both the results and the interpretation of the trial. Besides controlling variation, the Institute of Medicine (IOM) Committee on the Ethical and Legal Issues Relating to the Inclusion of Women in Clinical Studies [16] discusses four other issues related to the choice of trial population; namely, disease stage, clinical contraindications, regulatory or ethical restrictions, and compliance considerations. We will discuss these and the related issues of explanatory vs. pragmatic trials, screening and recruitment processes, and the impact of eligibility criteria on the generalizability of trial results. Other factors influencing the selection of patients, such as factors in the selection of institutions in **multicenter studies** and physician preferences are discussed elsewhere [2, 22].

Explanatory vs. Pragmatic Trials

The objectives of a trial affect the appropriate eligibility criteria [20]. If the trial is designed to estimate the biological effect of a treatment (explanatory trial), then the eligibility criteria should be chosen to minimize the impact of extraneous variation, as in early investigations of protease inhibitors against human immunodeficiency virus (HIV) infection [18]. If, however, the trial is designed to estimate the effectiveness of a treatment in a target population (pragmatic trial), then the eligibility criteria should be chosen to allow valid **inferences** to that population. For example, the Hypertension Prevention Trial (HPT) was aimed at normotensive individuals 25–49 years old with diastolic blood pressure between 78 mm Hg and 90 mm Hg, and these were the main eligibility criteria [3]. Choosing the narrow eligibility criteria often appropriate for an explanatory trial can make it difficult to apply the results to a broader population [11]. Yusuf [23], moreover, argues that a truly homogeneous cohort cannot be constituted because even apparently similar individuals can have very different outcomes. The consensus is that most Phase III randomized trials should be regarded as pragmatic.

The Uncertainty Principle

Byar et al. [4] describe the simplest possible form of eligibility criteria for a trial, in which patients are eligible provided the treating physician and the patient have "substantial uncertainty" as to which of the treatment options is better. This definition, known as the *uncertainty principle*, incorporates all factors that contraindicate one or more of the treatment options including stage of disease, co-existing disease, and patients' preferences (*see* **Ethics of Randomized Trials**). However, it also largely devolves definition of eligibility to the individual physicians participating in the trial. The consequent lack of control and strict definition of the cohort of patients entering the trial has been unattractive to some investigators.

Control of Variation vs. Ease of Recruitment

The debate over the uncertainty principle highlights the tension between two different ways of improving the precision of the estimated effect of treatment in a randomized trial. By using very strict eligibility criteria we seek to reduce between-patient variation in clinical outcomes, leading to improved precision of the treatment difference estimate. By using very flexible eligibility criteria (as with the uncertainty principle), we seek to allow a wider entry to the trial, thereby increasing the number of eligible patients and usually the precision of the treatment difference estimate. The question is, therefore, do we try to control variation and accept the smaller size of the sample, or do we try to increase the sample size and accept a wider between-patient variation? While this debate continues, the general consensus among clinical trial statisticians is that it is generally difficult to control between-patient variation successfully because often we do not know the important determinants of prognosis. Therefore, attempts to use very strict eligibility criteria are less successful than attempts to gain precision by entering very large numbers of patients into

trials [23]. However, if there are categories of patients who are considered very unlikely to benefit from the treatment, it is clearly conceivable to exclude them from the trial (see later sections on Stage of Disease and Clinical Contraindications).

Begg [2] criticizes the common practice of introducing a long list of eligibility criteria in clinical trials, particularly in the treatment of cancer. Such an approach greatly increases the difficulty of recruiting patients in large numbers. In examining such lists it is often found that many of the criteria are of questionable importance and do not relate directly to the safety of the patient or to the lack of benefit to be derived from the treatment.

Issues in the Screening and Recruitment Process

Establishing eligibility often involves a screening process. Examples include choosing individuals for a heart disease trial with ejection fraction between 0.35 and 0.8 and a specific number of ectopic beats, or choosing HIV-infected individuals with slowly rather than rapidly progressing disease [15].

Some eligibility criteria may be implicit in this process. For example, the recruitment method may require the patients to be accessible by telephone contact or to be able to read and write in English, such as trials in which the initial contact is via a prepaid postal response card. Multiple "baseline" visits that are sometimes used in the screening process can provide multiple opportunities for exclusion, e.g. the Coronary Primary Prevention Trial used five baseline visits and the HPT used three baseline visits. Thus, those ultimately enrolled may affect the recruitment and screening mechanisms and resources for multiple participant contacts as much as the protocol-specific eligibility criteria.

The impact of eligibility criteria and of recruitment procedures on the overall cost of the trial has rarely been investigated. Borhani [3] indicated that the ordering of the application of eligibility criteria can substantially affect costs. These costs are also sensitive to the cutoffs applied to continuous responses, e.g. diastolic blood pressure, high density lipoprotein cholesterol, coronary ejection fraction, and T-cell lymphocyte counts.

As mentioned earlier, eligibility criteria can have a strong impact on the ease of recruitment. For example, the need to enroll newly diagnosed or previously untreated patients can severely restrict the ability to recruit. The need to enroll rapidly after a stroke, myocardial infarction, head trauma, or exposure to infectious agent can lead to difficulties. If the condition renders the patient unconscious for some period of time, or the patient lives far from the treatment center, or is unaware that an infection, stroke, infarction, or other event has occurred, it is less likely that they will be available for enrollment. Similarly, Carew [5] suggests that recruitment be enhanced by broad eligibility criteria, allowing potentially more sites and more individuals to participate.

Stage of Disease

Often the stage of disease strongly affects the outcome of treatment, and is a primary source of variation. Eligibility is often restricted to the stages of disease most appropriately managed by the treatment.

For many diseases, classification or staging systems have been developed to aid clinical management. Eligibility criteria involving stage of disease are best defined using an established classification system that is in wide use. Examples of such classification systems include the coronary functional class [7], Dukes' colon cancer staging system, and the **World Health Organization** staging system for HIV infection [26].

Clinical Contraindications

Exclusions arising because one of the treatments is clearly contraindicated are common [14]. For example, 18% of those screened for the Beta Blocker Heart Attack Trial were excluded due to contraindications to the administration of propranolol [12]. Since these prior conditions would preclude use of some of the treatments in a trial, the trial results could not apply to individuals with those conditions. Some argue that contraindications should be clearly delineated in the protocol to avoid investigator or regional differences in their use.

Compliance Considerations

A run-in (or qualification) period is sometimes built into the trial design so as to identify potential noncompliers and exclude them from enrollment. This reduces the dilution of treatment differences that noncompliance introduces. In some studies, this period

can also be used to eliminate placebo (*see* **Blinding or Masking**) responders. In these cases, the determination of noncompliance becomes one of the **outcome measures of the trial** (*see* **Compliance Assessment in Clinical Trials**).

Regulatory or Ethical Considerations

Various demographically or otherwise defined populations have been excluded from clinical trials in the past. For example, in trials of heart disease prevention, women have been excluded as their incidence of heart disease is lower than in men and their inclusion would have required a larger sample size. Similarly, minority groups have sometimes had little or no representation because no special efforts had been made to include them. Recent changes in US regulations have required special justification for the exclusion of women, minorities, or the elderly from **National Institutes of Health** sponsored trials. The scientific argument for including these groups is that it provides a more solid basis for **extrapolating** the results of the trial to the general population [6, 8, 10, 13, 17, 19, 24, 25] (*see* **Validity and Generalizability in Epidemiologic Studies**). There will usually be inadequate statistical power for detecting different effects in subpopulations, but sometimes **meta-analysis** of several studies may be able to detect such differences.

Implementing the Eligibility Criteria

The characterization of the **target population** and baseline homogeneity can be subverted by deviations during the conduct of the trial from the protocol specified eligibility criteria. If extensive, these can adversely affect the assumptions underlying analyses and the interpretation of the results. Thus, monitoring the determination of eligibility criteria during the conduct of the trial is an important component of the implementation of the trial. Often, the office that conducts the **randomized treatment assignment** checks the eligibility criteria before enrolling the patient. Finkelstein & Green [9] discuss the exclusion from analysis of individuals found to be ineligible after enrollment in the trial.

Generalization of Results to Broader Populations

Treatment trials (or prevention trials) are usually conducted on samples of convenience, enrolling participants who present at specific hospitals or clinical sites. Therefore, the population to whom the trial results apply is generally not well defined. External validity – the ability to generalize from the trial to some broader population – is the ultimate goal of any trial. Adequately randomized trials can be assumed to produce valid results for the specific group of individuals enrolled, i.e. internal validity; the difficulties arise in extending the inference beyond that limited cohort. Since complete enumeration of the target population is rarely possible, inferences from studies are based on substantive judgment. A strong argument that is often used is that treatment *differences* in outcome are generally less variable among different patient populations than the outcomes themselves [23].

Following publication, critics questioned the generalizability of the results of the International Cooperative Trial of Extracranial–Intracranial (EC/IC) Arterial Anastomosis to evaluate the effect of the EC/IC procedure on the risk of ischemic stroke. The results showed a lack of benefit that surprised many in the surgical profession. It became clear that many of the eligible patients at the participating clinical sites did not enter the trial, while those enrolled in the trial were considered to have poorer risk and some argued that they were less likely to benefit from surgery [1, 21]. The ensuing controversy slowed acceptance of the trial results by the surgical community, although eventually they had a profound effect on the frequency with which EC/IC was performed.

Conclusions

The goals and objectives of the trial, the intended target population, and the anticipated inferences from the trial results should all be carefully specified from the outset. If that is done, then the appropriate choice of eligibility criteria usually becomes clearer. Experience has shown that simplifying eligibility criteria generally enhances recruitment, allows a wider participation, and gives greater justification for generalizing the results to a broader population.

MARY A. FOULKES

Eligibility Restriction

Eligibility restriction, or simply restriction, is a design strategy used to control for a potential **confounder**. For example, if gender is a potential confounder in a study of heart disease and diet, then one might choose to restrict the study to females. This design would eliminate gender as a potential confounder, but it would yield no direct information on the effect of diet on heart disease risk in males (*see* **Matching**).

Eligibility restrictions are also used in **clinical trials** for various other purposes, such as eliminating individuals not thought to benefit from the treatments under study or eliminating subjects not thought to be healthy enough to comply with protocol requirements (*see* **Eligibility and Exclusion Criteria**).

MITCHELL H. GAIL

Elston–Stewart Algorithm

Define a pedigree of size n to be a set of n related persons such that for each person in the set either neither parent or both parents are also in the set. Suppose that the first n_1 of these persons have no parents in the pedigree, and call them founders; and that the last $n - n_1$ of these persons have both parents in the pedigree, and call these nonfounders. Let g_i denote the **genotype**, and y_i the phenotype, of individual i. Assume that, conditional on the genotypes g_i, all the phenotypes y_i are independent. Then the joint probability of the g_i and y_i for all the pedigree members can be expressed as

$$\prod_{i=1}^{n_1} \Pr(g_i) \prod_{i=n_1+1}^{n_2} \Pr\left(g_i | g_{i_M}, g_{i_F}\right) \prod_{i=1}^{n} \Pr(y_i | g_i), \quad (1)$$

where $\Pr(g_i)$ is the population probability of founder i's genotype, $\Pr(g_i | g_{i_M}, g_{i_F})$ is the probability of nonfounder i's genotype conditional on the genotypes of the mother and father of i (**genetic transition probability**), and $\Pr(y_i | g_i)$ is the probability of i's phenotype conditional on genotype (**penetrance** function). Any of these probabilities may be a function of model parameters, and as a function of these the probability (1) is a joint **likelihood**. However, the genotypes are unobserved latent variables, so that the likelihood of interest, given only the observations y_i, is

$$\sum_{g_1} \sum_{g_2} \cdots \sum_{g_n} \prod_{i=1}^{n_1} \Pr(g_i) \prod_{i=n_1+1}^{n_2} \Pr\left(g_i | g_{i_M}, g_{i_F}\right) \times \prod_{i=1}^{n} \Pr(y_i | g_i). \quad (2)$$

Elston & Stewart [2] derived this likelihood by a different argument, specifically for a pedigree of simple structure – i.e. a pedigree in which there are no loops and each pedigree member traces back to the same single set of ancestral parents. This results in a formulation in which each summation sign in (2) is pushed as far to the right as possible, suggesting a recursive algorithm for its calculation that decreases the amount of computing time necessary. In particular, the amount of computation in this Elston–Stewart algorithm increases linearly with the size of the pedigree, but exponentially with the number of loci in the genotype g. The algorithm was soon adapted to pedigrees of complex structure [1, 6], but at increased computational cost. Later, with the advent of **multipoint linkage analysis**, a completely different algorithm for calculating a pedigree likelihood was proposed by Lander & Green [5] (see also [4]); the computational time for this algorithm, for which pedigree loops are no impediment, increases exponentially with the size of the pedigree but linearly with the number of loci. These two algorithms are widely used in the analysis of pedigree data.

The likelihood for a pedigree under **polygenic inheritance** can be expressed in a form analogous to (2): each summation is changed to an integration and each probability function becomes a normal density function (*see* **Normal Distribution**). Elston & Stewart [2] similarly expressed this likelihood with each integration sign pushed as far to the right as possible, and gave an algorithm to perform each integral in sequence analytically (see also [3]). In this way the likelihood under polygenic inheritance for a simple pedigree of size n, which can also be expressed as an n-variate normal density (*see* **Multivariate Normality, Tests of**), can be evaluated without needing inversion of an $n \times n$ symmetric matrix.

EM Algorithm

In the practice of biostatistics, one is often faced with the problem of estimation with incomplete or missing data. Some common examples include **grouped**, **censored** or **truncated data**, and multivariate data with some individuals having missing responses (*see* **Missing Data**). Many simple techniques have been developed for this problem, which are based on a "filling in" or "successive substitution" algorithm. The idea is based on the intuitive notion that (i) if we had the values of the missing observations we could estimate the parameters in the "standard" way, often without iteration, and (ii) if we knew the parameters, we could "fill in" the missing observations by setting them equal to their expected values under the model. This suggests estimation can proceed iteratively, alternating between computing expectations for the incomplete data and estimating parameters with "complete data".

The EM Algorithm [5, 11, 17, 18, 30, 47, 57] is a general computational method for calculating **maximum likelihood** estimates with incomplete data. Its implementation capitalizes on the intuitive notion behind "filling in" algorithms. The name EM was introduced by Dempster et al. [11], hereinafter referred to as DLR; its name is derived from the two steps required at each iteration: an E-step for computing the expectation of the missing data and an M-step for computing the maximum likelihood estimates of the parameters assuming complete data. Not all "filling in" algorithms are versions of the EM algorithm; both the E-step and the M-step must be specified with reference to an appropriate formulation of the incomplete data and its likelihood in order for the resulting parameter estimates to be ML.

Before describing the EM algorithm and presenting some of its properties, we present two simple examples which illustrate many of the features of the EM. The first is a very simple version of the gene counting algorithm in genetics, one of the earliest uses of the EM algorithm. The second example is two-way **analysis of variance** (ANOVA) with missing cells. In this case, a naive "filling in" algorithm is not EM, but a simple adjustment can be made which leads to the EM, using the general theory presented in the following section.

Example 1: Gene Counting

Suppose we wish to estimate the frequency of an allele A at a gene (*see* **Gene Frequency Estimation**), based on a random sample of N individuals. Each person has two alleles; we assume **Hardy–Weinberg equilibrium** and random mating, so that if we could observe the value of each allele directly, the desired probability estimate would be the observed proportion of A alleles out of $2N$ independent alleles. To formalize this idea, we introduce some notation. Let p_{A} be the proportion of A alleles, n_{AA} be the number of individuals who are AA, and likewise for n_{Aa} and n_{aa}, so that $n_{\mathrm{AA}} + n_{\mathrm{Aa}} + n_{\mathrm{aa}} = N$ and $\hat{p}_{\mathrm{A}} = (2n_{\mathrm{AA}} + n_{\mathrm{Aa}})/2N$. Here, lower-case "a" is used to denote an allele which is not A.

Depending upon what data are available on the N individuals, the value of an allele may not be directly observable. However, p_{A} can still be estimated by assuming a specific genetic model. For illustration, we will assume we observe a recessive trait with $Y = 1$ if a person is AA, and $Y = 0$ otherwise. Here we know an individual has two A alleles if $Y = 1$, but if $Y = 0$ we only know they have less than two A alleles. Denote by n_1 and n_0 the number of individuals with $Y = 1$ and $Y = 0$, respectively. Notice that $n_1 = n_{\mathrm{AA}}$ and $n_0 = n_{\mathrm{Aa}} + n_{\mathrm{aa}}$. Given n_0 and n_1 and a provisional estimate of p_{A}, say $\tilde{p}_{\mathrm{A}}$, we can calculate the expected number of A alleles as

$$\mathrm{E}(2n_{\mathrm{AA}} + n_{\mathrm{Aa}}) = 2n_1 + \mathrm{E}(n_{\mathrm{Aa}}|n_0, n_1, \tilde{p}_{\mathrm{a}}).$$

The last term can be easily calculated assuming Hardy–Weinberg equilibrium as

$$\begin{aligned}\tilde{n}_{\mathrm{Aa}} &= \mathrm{E}(n_{\mathrm{Aa}}|n_0, n_1, \tilde{p}_{\mathrm{A}}) = n_0 \Pr(\mathrm{Aa}|\mathrm{Aa \text{ or } aa}) \\ &= \frac{n_0 2\tilde{p}_{\mathrm{A}}(1-\tilde{p}_{\mathrm{A}})}{2\tilde{p}_{\mathrm{A}}(1-\tilde{p}_{\mathrm{A}}) + (1-\tilde{p}_{\mathrm{A}})^2} \\ &= \frac{n_0 2\tilde{p}_{\mathrm{A}}}{1+\tilde{p}_{\mathrm{A}}}. \qquad (1)\end{aligned}$$

Now, treating $\tilde{n}_{\mathrm{Aa}}$ as if it were actually the count of Aa individuals, we get our updated estimate of p_{A} as

$$\begin{aligned}p_{\mathrm{A}}^{\mathrm{new}} &= \frac{(2n_{\mathrm{AA}} + \tilde{n}_{\mathrm{Aa}})}{2N} \qquad (2) \\ &= \frac{2n_1 + 2n_0\tilde{p}_{\mathrm{A}}/(1+\tilde{p}_{\mathrm{A}})}{2N}. \qquad (3)\end{aligned}$$

In this example, iterating between (1) and (2) to solve for p_A will yield the ML estimate. Note that setting $\tilde{p}_A = p_A^{new} = \hat{p}_A$ in (3) yields an equation for $\hat{p}_A$ which can be solved to yield

$$\hat{p}_A = \frac{\sqrt{n_1}}{N}.$$

This estimate can be derived directly by noting that under Hardy–Weinberg equilibrium $\Pr(Y = 1) = p_A^2$: showing that it is a fixed point of the EM algorithm shows that $\hat{p}_A$ is ML. Although no iteration is required in this simple example, with three or more alleles iterative computations are required and the EM is often used. Ceppellini et al. [8], present the gene counting algorithm for the general case, and also consider estimation of allele frequencies when the data consist of random samples of families. Hartl & Clark [16] and Lange [29] give examples implementing the EM for estimating the allele frequencies which control the ABO **blood groups**.

Example 2: ANOVA with Missing Cells

Suppose we have the usual two-way layout with one observation per cell, $x_{ij}, i = 1, \ldots, I, j = 1, \ldots, J$. We assume the standard model (*see* **Analysis of Variance**):

$$x_{ij} = \mu + \alpha_i + \beta_j + e_{ij},$$

where $\sum \alpha_i = \sum \beta_j = 0$ and the e_{ij}s are taken to be independent with zero mean and variance σ^2. With complete data, the standard estimates for μ, α_i, β_j and σ^2 are

$$\begin{aligned} \mu &= \overline{x}_{..}, \\ \alpha_i &= (\overline{x}_{i.} - \overline{x}_{..}), \\ \beta_j &= (\overline{x}_{.j} - \overline{x}_{..}), \end{aligned} \tag{4}$$

$$\sigma^2 = \frac{\sum_{ij}(x_{ij} - \overline{x}_{i.} - \overline{x}_{.j} + \overline{x}_{..})^2}{(I-1)(J-1)}. \tag{5}$$

If observations are missing for some cells, one can still obtain **least squares** estimates for the parameters by setting up a design matrix (which is no longer **orthogonal**), and using any standard regression package (*see* **Software, Biostatistical**). Prior to the easy availability of regression packages, a popular alternative to the required matrix inversion was to use "filling in" algorithms. Several versions were proposed; Little & Rubin [35] give a rationale for using "filling in" algorithms in this setting and review the literature. The version we describe is due to Healy & Westmacott [19] and is also given in Little & Rubin [35].

One can start the algorithm with any set of initial values for the parameters. One could, for example, use (4) and (5) where the means and sum of squares are based only on those cells where x_{ij} is observed. Having provisional estimates, any missing cell, say x_{lk}, is filled in by

$$x_{lk} = \mathrm{E}(x_{lk}|\tilde{\mu}, \tilde{\boldsymbol{\alpha}}, \tilde{\boldsymbol{\beta}}) = \tilde{\mu} + \tilde{\alpha}_l + \tilde{\beta}_k. \tag{6}$$

Since (4) and (6) do not involve σ^2, we may iterate between (4) and (6) to obtain the least squares estimates of $\mu, \boldsymbol{\alpha}$, and $\boldsymbol{\beta}$. That is, given the current estimates, fill in for any missing cells using (6) and then use (4) to reestimate $\mu, \boldsymbol{\alpha}$, and $\boldsymbol{\beta}$, treating the $\tilde{x}_{lk}$ as observed data.

Using "filling in" algorithms to obtain estimates of variance components is more complicated. A naive approach would be to continue to use (6) to fill in for the missing values and to use (5) for estimating σ^2. But since $(\tilde{x}_{lk} - \tilde{\mu} - \tilde{\alpha}_l - \tilde{\beta}_k)^2 = 0$ for all missing cells, this would be equivalent to ignoring the missing cells in computing the sums of squares and dividing by an inflated number of degrees of freedom. Healy & Westmacott [19] suggested just this, but replacing $(I-1)(J-1)$ with the correct number of degrees of freedom, $(I-1)(J-1) - m$, where m denotes the number of missing cells.

Alternatively, notice that for least squares estimates, (5) can be written

$$(I-1)(J-1)\hat{\sigma}^2 = \sum_{ij} x_{ij}^2 - \sum_{ij}(\hat{\mu} + \hat{\alpha}_i + \hat{\beta}_j)^2. \tag{7}$$

This suggests filling in $\mathrm{E}(x_{lk}^2|\mu, \boldsymbol{\alpha}, \boldsymbol{\beta})$ in (7) for the missing x_{lk}. Since

$$\mathrm{E}(x_{lk}^2|\mu, \boldsymbol{\alpha}, \boldsymbol{\beta}, \sigma^2) = \sigma^2 + (\mu + \alpha_l + \beta_k)^2,$$

this would lead to the following iterative equation for σ^2:

$$\sigma_{new}^2 = \frac{\sum_{ij}(x_{ij} - \tilde{\mu} - \tilde{\alpha}_i - \tilde{\beta}_j)^2 + m\tilde{\sigma}^2}{(I-1)(J-1)}. \tag{8}$$

Since $(\mu, \hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})$ do not depend upon σ^2, (8) can be solved directly for $\hat{\sigma}^2$ to yield

$$\hat{\sigma}^2 = \frac{\sum_{ij}(x_{ij} - \hat{\mu} - \hat{\alpha}_i - \hat{\beta}_j)^2}{(I-1)(J-1) - m}, \tag{9}$$

yielding the Healy & Westmacott estimator. This is not ML under the assumption of normality for the error terms because the maximum likelihood estimate of σ^2 is the error sums of squares divided by the sample size rather than the number of degrees of freedom. Substituting IJ for $(I-1)(J-1)$ in (8) and (9) yields the EM equations and the ML estimator for σ^2.

These simple examples illustrate several features of the algorithm. First is the simple and intuitive nature of the algorithm. This is particularly true for the gene counting algorithm. For the second example, filling in $\mathrm{E}(x_{lk}^2)$ for the missing cells in estimating the variance is not so obvious. The general principle, discussed in the next section is that one must "fill in" by computing expectations of the **sufficient statistics** (in the case of **exponential families**). If all sufficient statistics are linear in the data, as they are in standard multinomial problems, then filling in by computing expectations of the data is appropriate. Second is the simple nature of each step of the algorithm. Although it can be implemented in a wide variety of situations, it is easiest to implement when maximum likelihood with complete data has closed form solutions and when the required expectations can be computed in closed form. Third is the fact that the EM is not always the best computational procedure; in both of our simple examples, the existence of a closed form solution and widespread availability of computing resources make the EM obsolete in these cases. Even in this setting, characterizing an estimate as the fixed point of the EM can be an easy method for deriving formulas for maximum likelihood estimates. We now turn to a discussion of the general theory underlying the EM.

Maximum Likelihood Estimation with Incomplete Data: The EM Algorithm

We discuss here the problem of maximum likelihood with incomplete data in complete generality, but will refer back to our two examples to make ideas concrete. We denote the complete data vector by $\boldsymbol{x}$ and its associated density by $f(\mathbf{x}|\boldsymbol{\phi})$, where $\boldsymbol{\phi}$ denotes an r-vector of parameters. Here $\mathbf{x}$ could be an n-vector of independent scalar observations as in Example 2 where $\mathbf{x} = (x_{11}, \ldots, x_{IJ})^{\mathrm{T}}$. In Example 1, there are many choices for $\mathbf{x}$; it could be the $2N$ vector of allele values, the N vector of genotypes for each subject, or the counts $n_{\mathrm{AA}}, n_{\mathrm{Aa}}$, and n_{aa}. Any choice leads to equivalent results, but potentially different implementations of the algorithm. We will take $\mathbf{x}$ to be the $2N$ vector of allele values. In many settings, each sampling unit will contribute a vector of observations to the complete data vector.

Denote the observed data by $\mathbf{y}$. There are two sample spaces, X and Y, and the data vectors $\mathbf{x}$ and $\mathbf{y}$ define a many-to-one mapping from X to Y. For example 2, X is R^{IJ} and Y is R^{IJ-m}; $\mathbf{y}$ is the $IJ-m$ vector of observed x_{ij}s. For Example 1, X is the space of $2N$ vectors whose components are binary, x_{i1} and x_{i2} being indicator vectors for the ith subject's two alleles, i.e. $x_{ij} = 1$ if A, and 0 otherwise. We shall take Y to be the space of N vectors whose components are also binary, $y_i = 1$ if a person is AA, $y_i = 0$ otherwise.

By definition, the density of the observed data $\mathbf{y}$ can be written as

$$g(\mathbf{y}|\boldsymbol{\phi}) = \int_{X(\mathbf{y})} f(\mathbf{x}|\boldsymbol{\phi})\, \mathrm{d}\mathbf{x}, \tag{10}$$

where $X(\mathbf{y})$ denotes the subset of X where $\mathbf{x}$ must lie, having observed $\mathbf{y}$. For example 2, $X(\mathbf{y})$ is just R^m and (10) simply integrates out the missing x_{ij}s, leaving the normal density of the observed data vector. For Example 2, we have $y_i = x_{i1}x_{i2}$; hence the integral is a summation over all values of x_{i1} and x_{i2} which yield y_i. This implies that each y_i is binary with probability density

$$\begin{aligned} g(y_i) &= (p_{\mathrm{A}}^2)^{y_i}(2p_{\mathrm{A}}(1-p_{\mathrm{A}}) + (1-p_{\mathrm{A}})^2)^{1-y_i} \\ &= \sum p_{\mathrm{A}}^{x_{i1}} p_{\mathrm{A}}^{x_{i2}} (1-p_{\mathrm{A}})^{1-x_{i1}} (1-p_{\mathrm{A}})^{1-x_{i2}}, \end{aligned}$$

where summation is over all (x_{i1}, x_{i2}) such that $y_i = x_{i1}x_{i2}$.

Notice that this formulation is quite general and does not apply merely to missing data in the usual setting where one or more subjects are missing some or all of their observations. It also applies to convolutions, where each component of y is the sum of several components of x, and to latent variable problems (*see* **Random Coefficient Repeated Measures Model**), **random effects** models and **mixtures**

(*see* **Method of Moments**), where inherently unobservable variables are considered to be part of the complete data.

Since $\mathbf{y}$ is completely determined by $\mathbf{x}$, their joint density is simply $f(\mathbf{x}|\boldsymbol{\phi})$. Thus, by definition,

$$f(\mathbf{x}|\boldsymbol{\phi}) = k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})g(\mathbf{y}|\boldsymbol{\phi}),$$

where $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})$ denotes the conditional density of $\mathbf{x}$ given $\mathbf{y}$. Taking logs yields

$$l(\boldsymbol{\phi}; \mathbf{x}) = l(\boldsymbol{\phi}; \mathbf{y}) + l(\boldsymbol{\phi}; \mathbf{x}|\mathbf{y}), \tag{11}$$

where $l(\boldsymbol{\phi}; \cdot)$ denotes the log likelihood associated with the density of $(\cdot|\boldsymbol{\phi})$. To obtain the ML estimate of $\boldsymbol{\phi}$ we maximize $l(\boldsymbol{\phi}; \mathbf{y})$, or equivalently $l(\boldsymbol{\phi}; \mathbf{x}) - l(\boldsymbol{\phi}; \mathbf{x}|\mathbf{y})$. Taking the expectation of both sides of (11) with respect to $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi}')$, we get

$$Q(\boldsymbol{\phi}|\boldsymbol{\phi}') = L(\boldsymbol{\phi}) + H(\boldsymbol{\phi}|\boldsymbol{\phi}'), \tag{12}$$

where

$$L(\boldsymbol{\phi}) \equiv l(\boldsymbol{\phi}; \mathbf{y}),$$

$$Q(\boldsymbol{\phi}|\boldsymbol{\phi}') = \mathrm{E}(\log f(\mathbf{x}|\boldsymbol{\phi})|\mathbf{y}, \boldsymbol{\phi}'),$$

and

$$H(\boldsymbol{\phi}|\boldsymbol{\phi}') = \mathrm{E}(\log k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})|\mathbf{y}, \boldsymbol{\phi}').$$

As a consequence of the **information** inequality [30], $H(\boldsymbol{\phi}|\boldsymbol{\phi}')$ is maximized as a function of $\boldsymbol{\phi}$ by setting $\boldsymbol{\phi} = \boldsymbol{\phi}'$ for any $\boldsymbol{\phi}'$. Furthermore, the ML estimator, $\hat{\boldsymbol{\phi}}$, maximizes $L(\boldsymbol{\phi})$ by definition. Thus $L(\boldsymbol{\phi})$ and $H(\boldsymbol{\phi}|\hat{\boldsymbol{\phi}})$ are both maximized when $\boldsymbol{\phi} = \hat{\boldsymbol{\phi}}$, and it follows that $Q(\boldsymbol{\phi}|\hat{\boldsymbol{\phi}})$ is maximized by setting $\boldsymbol{\phi} = \hat{\boldsymbol{\phi}}$. This fact both provides a characterization of the MLE in terms of the complete data log likelihood, and also suggests a computing **algorithm**. The algorithm in its general form is as follows. Given the current estimate of $\boldsymbol{\phi}$ at the pth iteration, say $\boldsymbol{\phi}^{(p)}$:
E-step: Compute

$$\mathrm{E}[\log f(\mathbf{x}|\boldsymbol{\phi})|\mathbf{y}, \boldsymbol{\phi}^{(p)}] = Q(\boldsymbol{\phi}|\boldsymbol{\phi}^{(p)}).$$

M-step: Maximize $Q(\boldsymbol{\phi}|\boldsymbol{\phi}^{(p)}$ as a function of $\boldsymbol{\phi}$ to obtain $\boldsymbol{\phi}^{(p+1)}$. It follows immediately that the MLE is a fixed point of the EM algorithm, since $\hat{\boldsymbol{\phi}}$ will maximize $Q(\boldsymbol{\phi}|\hat{\boldsymbol{\phi}})$.

Although this general formulation can be successfully implemented in many examples, it is easiest to implement the EM when the complete data density has a regular **exponential family** form. In this case, ignoring any functions of $\mathbf{x}$ alone, we can write

$$\log f(\mathbf{x}|\boldsymbol{\phi}) = \boldsymbol{\phi}^{\mathrm{T}}\mathbf{t} - \log a(\boldsymbol{\phi}),$$

where we now assume $\boldsymbol{\phi}$ denotes an r-vector of the canonical parameters and $\mathbf{t}$ is an r-vector of sufficient statistics which are functions of $\mathbf{x}$. Since $\log f(\mathbf{x}|\boldsymbol{\phi})$ is linear in the sufficient statistics, the E-step is easily implemented by setting:
E-step: $\mathbf{t}^{(p)} = \mathrm{E}(\mathbf{t}|\mathbf{y}; \boldsymbol{\phi}^{p})$.

For the M-step we maximize $\boldsymbol{\phi}^{\mathrm{T}}\mathbf{t}^{(p)} - \log a(\boldsymbol{\phi})$, treating $\mathbf{t}^{(p)}$ as if it were the sufficient statistic based on completely observed data. For regular exponential families, $\partial \log a(\boldsymbol{\phi})/\partial\boldsymbol{\phi} = \mathrm{E}(\mathbf{t}|\boldsymbol{\phi})$, hence the likelihood equations are obtained by setting $\mathbf{t}$ equal to its expected value, or solving

$$\mathrm{E}(\mathbf{t}|\boldsymbol{\phi}) - \mathbf{t} = 0.$$

Thus, regarding $\mathbf{t}^{(p)}$ as data, and maximizing $\boldsymbol{\phi}^{T}\mathbf{t}^{(p)} - \log a(\boldsymbol{\phi})$ to find $\boldsymbol{\phi}^{p+1}$ leads to:
M-step: Solve

$$\mathrm{E}(\mathbf{t}|\boldsymbol{\phi}^{(p+1)}) - \mathbf{t}^{(p)} = 0.$$

At convergence $\boldsymbol{\phi}^{(p+1)} = \boldsymbol{\phi}^{(p)}$, and we have

$$\mathrm{E}(\mathbf{t}|\hat{\boldsymbol{\phi}}) - \mathrm{E}(\mathbf{t}|\mathbf{y}, \hat{\boldsymbol{\phi}}) = 0.$$

This striking representation for the likelihood equations provides an easy derivation in settings where the complete data can be chosen to have an exponential family distribution. The recipe is: (i) find the vector of sufficient statistics t, assuming complete data (ii) find an expression for its expectation, $\mathrm{E}(\mathbf{t}|\boldsymbol{\phi})$, as a function of $\boldsymbol{\phi}$ with respect to the complete data, (iii) find an expression for the expectation given the observed data $\mathbf{y}$, $\mathrm{E}(\mathbf{t}|\mathbf{y}, \boldsymbol{\phi})$, and (iv) equate the two expectations to solve for $\boldsymbol{\phi}$. Since the representation for the complete data is not unique, there may be several choices for $\mathbf{x}$ and thus $\mathbf{t}$; some choices may lead to an easier solution of the M- and E-steps than others. In multivariate settings, such as multinomial or normal, the conditional distribution of the complete data conditional on observed data will often have the same form as the complete data, making the conditional expectations easy to compute.

Having given a general characterization of the EM, we now return to our two examples. The properties of the algorithm and other applications are discussed in the following sections.

Example 1

Since we chose $\mathbf{x}$ to be the $2N$ vector of indicators for each allele, our complete data likelihood is binomial $(p_A, 2N)$; hence the sufficient statistic is the number of A alleles, or $t = \sum_i (x_{i1} + x_{i2})$. The M-step is $\tilde{p_A} = t/2N$ and given $\tilde{p}_A$ the E-step computes $E(\mathbf{t}|\mathbf{y}, \tilde{p}_A)$. Since t is linear in $x_{i1} + x_{i2}$, its expectation can be computed by considering

$$E(x_{i1} + x_{i2}|y_i, \tilde{p}_A) = \begin{cases} 2, & \text{if } y_i = 1, \\ 2\tilde{p}_A/(1 + \tilde{p}_A), & \text{if } y_i = 0. \end{cases} \tag{13}$$

Thus, $E(\mathbf{t}|\mathbf{y}, \tilde{p}_A) = 2n_1 + 2n_0\tilde{p}_A/(1 + \tilde{p}_A)$, as before. Note that (13) is based on $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})$; in this example, and in many others, it is not necessary to calculate this density in complete generality, but only to be able to take conditional moments of x_{ij}.

Example 2

Assuming the error terms are independently and normally distributed gives an exponential family form for $f(\mathbf{x}|\boldsymbol{\phi})$. Two choices are possible for dealing with the parameter space. We can take $\boldsymbol{\phi}$ to consist of μ, σ^2, the $I\alpha_i$s, the $J\beta_j$s and impose constraints, or take only $(I-1)\alpha_i$s and $(J-1)\beta_j$s. We choose the former because it yields a simpler set of sufficient statistics and illustrates the implementation of the EM with constraints; either choice gives equivalent results.

When $\boldsymbol{\phi}$ is the vector of $(I + J + 2)$ parameters, the sufficient statistics are easily found to be

$$\begin{aligned} t_1 &= x_{++}, \\ \mathbf{t}_2^T &= (x_{1+}, \ldots, x_{I+}), \\ \mathbf{t}_3^T &= (x_{+1}, \ldots, x_{+J}), \\ t_4 &= \sum\sum x_{ij}^2. \end{aligned} \tag{14}$$

Here a $+$ replacing a subscript indicates summation over that index. The complete data log likelihood can be maximized by setting $\mathbf{t}^T = (t_1, t_2^T, t_3^T, t_4)$ equal to its expected value, subject to the constraints $\sum \alpha_i = 0$ and $\sum \beta_j = 0$. Assuming these constraints hold, the expectations of $\mathbf{t}$ are:

$$\begin{aligned} E(t_1) &= IJ\mu, \\ E(\mathbf{t}_2^T) &= J(\mu + \alpha_1, \ldots, \mu + \alpha_I), \\ E(\mathbf{t}_3^T) &= I(\mu + \beta_1, \ldots, \mu + \beta_J), \\ E(t_4) &= IJ\sigma^2 + \sum\sum(\mu + \alpha_i + \beta_j)^2. \end{aligned} \tag{15}$$

Equating (14) and (15) and solving for the parameters gives the well-known estimates (apart from the denominator of σ^2):

$$\begin{aligned} \hat{\mu} &= \overline{x}_{++}, \\ \hat{\alpha}_i &= \overline{x}_{i+} - \overline{x}_{++}, \\ \hat{\beta}_j &= \overline{x}_{+j} - \overline{x}_{++}, \\ \hat{\sigma}^2 &= \frac{1}{IJ}\sum(x_{ij} - \overline{x}_{i\cdot} - \overline{x}_{\cdot J} + \overline{x}_{\cdot\cdot})^2. \end{aligned} \tag{16}$$

If cells are missing, then the E-step is easy, since $\mathbf{t}$ is just summations of x_{ij} and x_{ij}^2 over individuals. Explicit derivation of the sufficient statistics shows why $E(x_{lk})$ is substituted into the formulas for $(\hat{\mu}, \hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})$ and $E(x_{lk}^2)$ is substituted into the formula for $\hat{\sigma}^2$. In this case the conditional expectations are particularly easy since the x_{ij} are all independent. This implies $f(x_{lk}|\mathbf{y}, \boldsymbol{\phi}) = f(x_{lk}|\boldsymbol{\phi}) \sim N(\mu + \alpha_l + \beta_k, \sigma^2)$, i.e. the distribution of the unobserved xs is independent of the observed ys, but it does depend upon the unknown parameters.

Notice that it is not actually necessary to identify the vector of canonical parameters, $\boldsymbol{\phi}$. It is only necessary to identify the vector of sufficient statistics $\mathbf{t}$ and to be able to express $E(\mathbf{t}|\boldsymbol{\phi})$ as a function of the parameters of interest. In our Example 2 it was particularly easy to solve the complete data maximization problem subject to the constraints. In other settings Lagrange multipliers can be used.

The use of the term EM *algorithm* is sometimes criticized because it is actually only a prescription for an algorithm. The exact formulas for its implementation will vary in each application. In many examples the E- and M-steps will be obvious and easily implemented. In other cases, either the E- or the M-step will be difficult; later we will consider extensions of the EM designed to deal with several problems which arise in practice. First we will consider the properties of the EM.

Properties of the EM Algorithm

As previously mentioned, the MLE of ϕ is a fixed point of the EM. In addition, the EM is numerically very stable and each iteration increases the likelihood. This fact is easily proved. By definition of the algorithm,

$$Q(\boldsymbol{\phi}^{(p+1)}|\boldsymbol{\phi}^{(p)}) \geq Q(\boldsymbol{\phi}^{(p)}|\boldsymbol{\phi}^{(p)}), \qquad (17)$$

and, as previously noted, the information inequality implies

$$H(\boldsymbol{\phi}^{(p+1)}|\boldsymbol{\phi}^{(p)}) \leq H(\boldsymbol{\phi}^{(p)}|\boldsymbol{\phi}^{(p)}).$$

Thus

$$\begin{aligned} L(\boldsymbol{\phi}^{(p+1)}) &= Q(\boldsymbol{\phi}^{(p+1)}|\boldsymbol{\phi}^{(p)}) - H(\boldsymbol{\phi}^{(p+1)}|\boldsymbol{\phi}^{(p)}) \\ &\geq Q(\boldsymbol{\phi}^{(p)}|\boldsymbol{\phi}^{(p)}) - H(\boldsymbol{\phi}^{(p)}|\boldsymbol{\phi}^{(p)}) = L(\boldsymbol{\phi}^{(p)}). \end{aligned}$$

See also Baum et al. [5]; DLR, and Lange [30].

The EM algorithm naturally incorporates parameter bounds and constraints whenever the complete data come from an exponential family. For example, with a complete data sample from the **multivariate normal**, the sample variance–**covariance matrix** is the MLE; it is also nonnegative definite. With missing data, using the EM to estimate $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ means that, provided the initial value for $\boldsymbol{\Sigma}$ is nonnegative definite, each iterate will remain so. Another common example is estimates of probabilities which are equal, with complete data, to x/n, say, for a count $0 < x < n$. When x and possibly also n are incompletely observed, the probability estimate will remain between zero and one with the EM, since $0 < \mathrm{E}(x) < \mathrm{E}(n)$. Parameter bounds such as these will not hold in general for other iterative algorithms.

The EM is not guaranteed to converge, even to a local maximum, except in special circumstances. The original proof of convergence given in DLR is flawed. Wu [63] and Boyles [6] have studied convergence. Two general results given by Wu [63] are (1) if the complete data density is a curved exponential family with a compact parameter space, then all limit points of any EM sequence are stationary points of the likelihood and (2) if the likelihood function is unimodal and the first derivative of the Q function with respect to $\boldsymbol{\phi}$ is continuous in both $\boldsymbol{\phi}$ and $\boldsymbol{\phi}'$, then the EM converges to a unique maximum. In most instances it will be difficult to show that an incomplete data likelihood is unimodal; thus case 1 is of more interest. Since convergence guarantees only a stationary point, and not even a local maximum, much less a global one, it is sometimes useful to use several starting values for the algorithm. Multiple solutions are a feature of many incomplete data problems, especially boundary solutions. See Baker et al. [3] and Baker & Laird [4].

Even though the EM algorithm may not provide the most efficient computational approach, it often provides an easy way to characterize the derivatives of the log-likelihood, and thus expressions for the ML score equations and observed information matrix, in terms of the complete data log likelihood. In addition, because of its stability and simplicity, the EM algorithm can be easily programmed in many cases; its property of increasing the likelihood can be useful in debugging programs. These facts make it worthwhile to represent data as incomplete in cases where it is possible to do so, while choosing the complete data to correspond to an easily handled case.

As an optimization procedure, the EM enjoys many advantages over its main competitor, Newton–Raphson. Although more iterations are generally required, each iteration may be faster and easier to program. It is less sensitive to poor starting values, it automatically bounds parameter values in their proper space and it is easier to implement with many parameters.

The EM algorithm is a method for computing ML estimates which does not require second derivatives. This is attractive when second derivatives are difficult to evaluate and often makes it easy to program the equations, but it can also mean slow convergence and the asymptotic variance–covariance matrix is not available as a byproduct of the computations. Enhancements to the basic algorithm to deal with these and other issues are discussed in the next section.

Enhancements and Modifications to the EM Algorithm

Because of its popularity, many enhancements and modifications have been suggested for the EM algorithm. If the M-step and/or the E-step are difficult, i.e. the E-step requires numerical integration or the M-step requires numerical methods to maximize the Q-function, then it may be infeasible to implement the EM easily. In their original paper, DLR

proposed a Generalized EM (GEM) designed to deal with the case where maximization is difficult at the M-step. A GEM algorithm is an EM, with the M-step changed to

M-step: Choose $\boldsymbol{\phi}^{p+1}$ so that

$$Q(\boldsymbol{\phi}^{(p+1)}|\boldsymbol{\phi}^{(p)}) \geq Q(\boldsymbol{\phi}^{(p)}|\boldsymbol{\phi}^{(p)}).$$

Clearly the GEM retains many of the properties of the EM and will be easier to implement in some cases.

Various other proposals have been suggested for dealing with a Q-function which is difficult to maximize. One obvious approach to maximizing the Q-function at each iteration is to use some rapidly converging algorithm, such as Newton–Raphson, and only take one iteration away from $\boldsymbol{\phi}^{(p)}$ at each M-step. Providing the single iteration increases the likelihood, this would provide an instance of a GEM. This approach has been formalized by Lange [27] who describes a gradient algorithm locally equivalent to EM. Meng & Rubin [45] propose using a series of "conditional" maximization steps (hence the name ECM), or cyclic coordinate ascent to maximize $Q(\boldsymbol{\phi}|\boldsymbol{\phi}^{(p)})$. Liu & Rubin [36] extend this idea with the ECME algorithm, which allows some components of $\boldsymbol{\phi}^{(p+1)}$ to be chosen to maximize the observed data log likelihood rather than $Q(\boldsymbol{\phi}|\boldsymbol{\phi}^{(p)})$. Green [14] proposes an extension of the EM for the Bayesian setting, where addition of the log of the prior to the Q function makes its maximization intractable.

There have been fewer proposals for how to deal with intractable E-steps arising because numerical methods are required to evaluate the expectations. One approach is to approximate $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi}^{(p)})$ by a distribution which makes the E-step expectations easy to compute. This approach was used by Laird [23] and by Stiratelli et al. [56] in estimating **variance components** in a random effects model with binary data. They assumed that the conditional distribution of the missing random effects was approximately normal, given an individual's observed data; this makes it easy to compute the required expectations, but the approximation fails if individuals have only a few data points. More recently, Steele [55] used Laplace's method to obtain an analytic approximation for the E-step which performs well in simulations.

Other ways for dealing with this problem are based on **Monte Carlo methods** or data augmentation. Tanner & Wong's [58] data augmentation method for iteratively computing the entire posterior density of $\boldsymbol{\phi}$ with missing data is similar in spirit to the EM algorithm. Wei & Tanner [62] introduce the Monte Carlo EM (MCEM) for use when the E-step is difficult to implement. If one can generate a sample $\mathbf{x}^1, \ldots, \mathbf{x}^m$ from $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi}^{(p)})$, Q can be approximated by

$$Q(\boldsymbol{\phi}|\boldsymbol{\phi}^{(p)}) = \frac{1}{m}\sum_{j=1}^{m} \log f(\mathbf{x}^j|\boldsymbol{\phi}).$$

Although this avoids integrals, one must be able to generate data from $k(\cdot|\cdot)$ and maximizing the Q function may be more difficult because of the mixing. Meng & Schilling [46] describe the use of Gibbs sampling (*see* **Markov Chain Monte Carlo**) to carry out a MCEM for item factor models.

The convergence of the EM can be very slow and several authors have suggested methods for speeding convergence. Louis [37], Laird et al. [24], and Lindstrom & Bates [34] suggested Aitken acceleration; its use has met with mixed success. Jamshidian & Jennrich [20] apply generalized conjugate gradient methods to accelerate the EM and term the resulting algorithm the AEM (accelerated EM). Lange [28] suggests a version of quasi-Newton which uses EM type ideas to approximate the Hessian used by the Newton–Raphson algorithm to maximize the observed data log likelihood. An alternate method [2] is to start with the EM and switch to Newton–Raphson. This is advantageous because just when the EM slows down, near a maximum, the Newton–Raphson works best.

Because the convergence rate of the EM is determined by the amount of missing information, if one can find ways to specify the complete data so as to decrease the amount of "missing data", one should increase the rate of convergence. Meng & van Dyk [42] give a general approach for choosing the complete data to minimize the fraction of missing data with applications to fitting **Student's *t* distribution**, random effects models, and image reconstruction (*see* **Image Analysis and Tomography**). The approach is like the EM itself in that there is only a general methodology and the implementation must be worked out independently for each case.

Besides slow convergence, the absence of second derivative computations means that asymptotic standard errors require additional computation. As noted below, there have been a considerable number of proposals for approximating the asymptotic variance–covariance matrix. However, in practice it is often simplest to calculate the observed information

matrix numerically and invert it. Because derivatives of Q with respect to its left variable coincide with the score, one can compute second derivatives by taking finite differences of the exact first derivatives of Q. This approach will be attractive whenever the first derivative of Q is easily computed. In early work, Hartley & Hocking [18] present a general method for computing the observed information in an incomplete data setting which is based on creating a system of simultaneous equations from successive iterations of the EM algorithm, one for each parameter to be estimated.

Many recent procedures have been proposed for computing the second derivatives of $L(\boldsymbol{\phi})$ which capitalize on the representation of the data as incomplete. By rearranging (12), differentiating twice under the integral signs and evaluating at $\boldsymbol{\phi}' = \boldsymbol{\phi}$, we can derive an expression for the observed information, $\mathbf{I}_{\mathbf{y}}$, as

$$\mathbf{I}_{\mathbf{y}} = \mathbf{I}_{\mathbf{x}c} - \mathbf{F}_{\mathbf{x}|\mathbf{y}}. \tag{18}$$

Here $\mathbf{F}_{\mathbf{x}|\mathbf{y}}$ is the expected or Fisher information in $\mathbf{x}|\mathbf{y}$:

$$\mathbf{F}_{\mathbf{x}|\mathbf{y}} = \mathrm{E}\left[\frac{\partial^2 \log k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})}{\partial\boldsymbol{\phi}\partial\boldsymbol{\phi}^{\mathrm{T}}}\middle|\mathbf{y}, \boldsymbol{\phi}\right],$$

where expectation is with respect to $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})$ and $\mathbf{I}_{\mathbf{x}c}$ is the expected value of the information in $\mathbf{x}$, conditioned on $\mathbf{y}$:

$$\mathbf{I}_{\mathbf{x}c} = \mathrm{E}\left[\frac{\partial^2 \log f(\mathbf{x}|\boldsymbol{\phi})}{\partial\boldsymbol{\phi}\partial\boldsymbol{\phi}^{\mathrm{T}}}\middle|\mathbf{y}, \boldsymbol{\phi}\right].$$

Eq. (18) has the appealing interpretation as

observed data information
= complete data information
− missing data information,

which Orchard & Woodbury [47] termed the *missing information principle*. Taking expectations of both sides of (18) with respect to $g(\mathbf{y}|\boldsymbol{\phi})$ yields

$$\mathbf{F}_{\mathbf{y}} = \mathbf{F}_{\mathbf{x}} - \text{ave } \mathbf{F}_{\mathbf{x}|\mathbf{y}},$$

where ave denotes expectation over $\mathbf{g}(\mathbf{y}|\boldsymbol{\phi})$. When the complete data have the exponential family form, expression (18) simplifies to

$$\mathbf{I}_{\mathbf{y}} = \mathrm{var}(\mathbf{t}|\boldsymbol{\phi}) - \mathrm{var}(\mathbf{t}|\boldsymbol{\phi}, \mathbf{y}),$$

and the expected information in $\mathbf{y}$ is

$$\mathbf{F}_{\mathbf{y}} = \mathrm{var}[\mathrm{E}(\mathbf{t}|\mathbf{y}, \boldsymbol{\phi})].$$

Louis [37] shows that $\mathbf{F}_{\mathbf{x}|\mathbf{y}}$ can also be expressed in terms of the derivatives of $\log f(\mathbf{x}|\boldsymbol{\phi})$:

$$\mathbf{F}_{\mathbf{x}|\mathbf{y}} = \mathrm{E}[\mathbf{S}(\mathbf{x}; \boldsymbol{\phi})\mathbf{S}(\mathbf{x}; \boldsymbol{\phi})^{\mathrm{T}}] - [\mathrm{E}\mathbf{S}(\mathbf{x}; \boldsymbol{\phi})][\mathrm{E}\mathbf{S}(\mathbf{x}; \boldsymbol{\phi})]^{\mathrm{T}}, \tag{19}$$

where $\mathbf{S}(\mathbf{x}; \boldsymbol{\phi})$ is the derivative of $\log f(\mathbf{x}|\boldsymbol{\phi})$ and expectations are with respect to $k(\mathbf{x}|\mathbf{y}, \boldsymbol{\phi})$. Under regularity conditions on the Q function, it will be maximized by setting its derivatives to zero; hence the second term in (19) vanishes at $\hat{\boldsymbol{\phi}}$. Assuming $\mathbf{x}$ consists of n independent vectors, say $\mathbf{x}_i$, and $\mathbf{y}_i(\mathbf{x}) = \mathbf{y}_i(\mathbf{x}_i)$, a simple expression can be derived for $\mathbf{I}_{\mathbf{y}}$ using expressions for the first and second derivatives of $\log f(\mathbf{x}_i|\boldsymbol{\phi})$ [37]. For this same setting of independent observations, Meilijson [41] and Redner & Walker [50] propose the use of the empirical Fisher information to estimate the asymptotic variance:

$$\hat{\mathbf{F}}_{\mathbf{y}} = \sum_{i=1}^{n} \mathbf{s}(\mathbf{y}_i, \boldsymbol{\phi})\mathbf{s}^{\mathrm{T}}(\mathbf{y}_i, \boldsymbol{\phi}) - \frac{1}{n^2}\mathbf{S}(\mathbf{y}; \boldsymbol{\phi})\mathbf{S}^{\mathrm{T}}(\mathbf{y}; \boldsymbol{\phi}), \tag{20}$$

where $\mathbf{s}(\mathbf{y}_i, \boldsymbol{\phi})$ is the derivative of $\log g(\mathbf{y}_i|\boldsymbol{\phi})$, and $\mathbf{s}(\mathbf{y}_i; \boldsymbol{\phi})$ is the sum of the $\mathbf{s}(\mathbf{y}_i; \boldsymbol{\phi})$, hence the derivative of the observed data log likelihood. At the maximum, $\mathbf{S}(\mathbf{y}; \hat{\boldsymbol{\phi}}) = 0$. As shown in Louis [37],

$$\mathbf{s}(\mathbf{y}_i; \boldsymbol{\phi}) = \mathrm{E}[\mathbf{s}(\mathbf{x}_i; \boldsymbol{\phi})|\mathbf{y}_i, \boldsymbol{\phi}], \tag{21}$$

where $\mathbf{s}_i(\mathbf{x}_i, \boldsymbol{\phi})$ is the derivative of $\log f(\mathbf{x}_i|\boldsymbol{\phi})$. Thus $\mathbf{s}_i(\mathbf{y}_i, \boldsymbol{\phi})$ is available from the E-step computations. Meilijson [41] attributes (21) to Fisher [12]; (20) and (21) combine to give a method for estimating the asymptotic variance with independent data vectors which is very easy to implement in many settings, but is not a fully efficient estimate.

Meng & Rubin [44] propose a method for computing the asymptotic variance which is based on a reexpression of (18) which represents $\mathbf{I}_{\mathbf{y}}$ in terms of $\mathbf{I}_{\mathbf{x}c}$ and the "fraction of missing information" matrix given by

$$\mathbf{DM} = \mathbf{F}_{\mathbf{x}|\mathbf{y}}\mathbf{I}_{\mathbf{x}c}^{-1}.$$

Their method, like Louis's [37], requires the code for the complete data asymptotic variance–covariance matrix. It does not require independently distributed data, and uses numerical differentiation only to approximate the "fraction of missing information" matrix.

Baker [1, 2] has developed a general method for computing the observed information matrix when using the EM with **categorical data**. It is used

when the incomplete data is a vector of cell counts which can be expressed as a linear function of complete data cell counts. The basic approach is to express the vector of expected cell counts in terms of matrix functions; the variance–covariance matrix can be easily obtained as a function of these matrices and the vector of expected cell counts. Baker [1] also gives a review of methods for computing the information matrix with incomplete categorical data.

Applications

Perhaps the most attractive feature of the EM algorithm is the very wide range of problems which can be characterized as incomplete data problems. Meng & Pedlow [43] conducted a bibliographic search of the EM literature from 1977 through 1991. They found over 1000 articles from almost 300 statistical and nonstatistical journals that contain material on the EM. Many of these articles describe applications in medicine, genetics, engineering, psychology, animal breeding and economics, to mention a few. Clearly, the range of application is broad. In their original paper, DLR described applications in missing data, grouping, censoring and truncation, finite mixtures, variance components, hyperparameter estimation, iteratively reweighted least squares (*see* **Generalized Linear Model**) and **factor analysis**. We refer the reader to that paper for detailed discussion of those applications, concentrating here on more recent work and applications in genetics.

Indirect Measurement Problems, Including Image Reconstruction

An application of the EM which has met with much success is its use in image reconstruction problems, including positron emission tomography [31, 52], transmission tomography [32], **stereology** [53], and particle size reconstruction via diffusion batteries [38]. These problems are also sometimes called indirect measurement problems. A related problem is back projection, or using prevalence data to estimate the distribution of incident cases of a disease which has a long and variable incubation period [39, 40] (*see* **Back-calculation**).

The general problem is to estimate a distribution, usually of particle sizes or intensities, when the particles undergo some known thinning process before being observed. The approach is to discretize the original distribution, into bins or pixels, and estimate the density in each bin, say μ_j. The complete data can be represented as independent **Poisson** counts; with complete data the density in each bin is estimated by the count in the bin divided by the total count. Because of the thinning process, the observed data are also Poisson counts, with a mean which can be expressed as an integral, or in the discretized version, as a linear combination of the μ_j and known coefficients which characterize the thinning process. Given the observed data, the μ_j, and the characteristics of the thinning process, it is easy to compute expectations of the complete data and implement the EM. Transmission tomography is somewhat more complex, since here the logarithms of the mean of the observed Poisson counts are linear in the μ_j.

Because the problem can sometimes be formulated as a standard regression problem, except that the responses are counts, and the unknown coefficients are constrained to be positive, ordinary least squares, or nonnegative least squares have been used in some cases [38], but the results are not very satisfactory. The EM is attractive in this setting because the nonnegativity constraints are automatically satisfied (as they would be if complete data were observed), the algorithm can converge to a boundary maximum (some $\hat{\mu}_j = 0$), and is computationally feasible in the tomography applications where the number of parameters range in the thousands. In this case, and others, the maximization is often ill-conditioned, and a penalty function (*see* **Penalized Maximum Likelihood**) or a Bayes **prior** have been used both to enhance the quality of the reconstructed image and eliminate the ill-conditioning [13, 32, 39, 53]. In fact, Lange & Fessler [32] are able to establish global convergence for the EM when the log posterior is maximized.

A related example concerns estimation of the distribution of infectivity (*see* **Infectivity Titration**), as measured by infectious units in a fixed volume of blood, in a sample of AIDS patients [64]. Here, infectivity cannot be directly measured, but must be assessed using blood from uninfected donors and **serial dilution assays**. The complete data are the infectivity levels for each individual and with complete data the empirical cumulative distribution function (cdf) could be used to estimate the distribution nonparametrically. The observed data are a vector of

binary observations for each individual, each component indicating whether or not the individual's blood infected the donor blood at a given concentration. The EM can be used to recover the empirical cdf of infectivity, estimating both the support points and the probability mass at each point. The general method extends easily to other serial dilution assays and for use with parametric assumptions for the underlying distribution.

Molecular Biology

Alignment and restoration of **DNA sequences** are another area where the EM algorithm has proven useful. With the advent of the Human Genome Project and the goal of sequencing the entire human genome, methods for large-scale DNA sequencing are important. Sequencing means determining the values (A, C, G, or T) of a sequence of nucleotides in a strand of DNA. In large-scale DNA sequencing, the goal is to determine the sequence of large segments of DNA made up of many thousands of bases. Because the current technology can only sequence relatively short fragments ($<$1000 bases) using size separation on electrophoretic gels, the process of sequencing involves breaking the original large fragment into multiple overlapping smaller fragments, this process being repeated sequentially. To obtain the DNA sequence of the original segment, one must reconstruct the order of the smaller fragments, using the information in the overlap. Depending upon the strategy used, the location of the fragments may not be known, but must be deduced from determining the overlap with other fragments. Churchill & Waterman [10] and Thorne & Churchill [60] describe EM methods for the restoration of sequences; Lawrence & Reilly [33] and Cardon & Stormo [7] discuss the use of the EM for the related problem of finding common protein binding sites in a series of unaligned fragments. Churchill [9] gives an overview of statistical issues in DNA sequencing.

Genetics

The use of the EM algorithm is quite natural in genetics because the genetic data one would like to use for inference about genetic models and parameters are typically not directly observable, but only indirectly observable by measured traits, referred to as phenotypes. The gene counting algorithm used to estimate allele frequencies is one of the earliest uses of the EM algorithm [8, 54]. These authors also noted its application to other areas of genetics, including **segregation** and **linkage** analysis.

The general idea behind segregation analysis is to test the fit of a specific genetic model to phenotypic data from families. Smith [54] shows how the EM can be used to estimate a 'segregation ratio' and thus test whether it differs from the ratio specified by the genetic model. The specific example he considers is an assumed recessive model for a common trait with disease allele G. Individuals with genotypes GG are affected, and those with Gg or gg are not. We draw random samples of families with one affected parent, one unaffected parent, and at least one affected child. The unaffected parent can be assumed to be Gg, since they are unaffected, but they have an affected child. The segregation ratio is the ratio of the number of affected to unaffected children in families of a given mating type; it should be 1:1 in the given model since a child always gets a G gene from the affected parent, and gets a G gene from the unaffected parent with probability 1/2. The difficulty is that some Gg $\times$ GG matings will have no affected children, hence be absent from our sample (*see* **Ascertainment**). To get a proper test, the segregation ratio must be estimated. Smith [54] does this by treating the "lost" families as missing data and using the EM to estimate the number of unobserved unaffected cases. Weeks & Lange [61] give a general treatment of this problem.

Segregation analysis is somewhat more complicated with quantitative phenotypes, largely because realistic genetic models are more complicated and involve numerous parameters which need to be estimated. Ott [49] shows how the EM may be used to obtain ML estimates of the parameters in **polygenic** and **mixed models**. Ott [48] also shows how the Mendelian transmission probabilities,

$$p_1 = \Pr(\text{child inherits g}|\text{parent gg}) = 1,$$

$$p_2 = \Pr(\text{child inherits g}|\text{parent Gg}) = 1/2,$$

$$p_3 = \Pr(\text{child inherits g}|\text{parent GG}) = 0,$$

can be tested by assuming general values for (p_1, p_2, p_3), writing down the likelihood based on samples of families, and using EM to estimate the transmission probabilities.

Linkage analysis is another area where the EM algorithm is used. In the typical linkage study, one

seeks to locate the position of a disease gene by correlating inheritance of the disease with inheritance of a "marker" whose position in the genome is known, at least approximately. A marker is a segment of DNA whose alleles can be observed directly; usually markers are highly polymorphic, meaning they have multiple alleles with nontrivial frequencies. In the formation of gametes, parental chromosomes may break and recombine, so that the chromosome inherited by a child may consist of a combination of disease and marker alleles that did not exist in the parent; this is called a recombination event. If the disease and marker alleles inherited by the child are identical to those located on one of the parental chromosomes, then no recombination event has occurred. The distance between two locations on a chromosome is measured statistically by the recombination fraction, which gives the probability that a recombination occurs between the marker and the disease gene during the formation of gametes. The larger the recombination fraction, the farther apart the marker and disease gene are. Even if one could directly observe both marker and disease alleles for parents and children, it might still not be possible to tell if a recombination has occurred because one can only infer from genotypes which allele is inherited from which parental chromosome. Thus if there is duplication of allele values for the parental marker and disease genes, there may be several possible transmission patterns (and hence possible recombinations) consistent with a child's genetic values. When one can only observe marker alleles directly, and only disease phenotypes, there are additional missing data with some mating types.

In this setting, the missing data which would make the estimation of the recombination fraction trivial are an indicator for each child's data, telling us whether or not a recombination occurred between the two locations of interest. Thus, unlike gene counting and segregation analysis, the values of the alleles are not used directly; the relevant information is knowing the parental source of DNA at each child's location so that recombination can be determined unambiguously.

In plant and animal genetics, crosses can be arranged between parents with known genetic combinations (called haplotypes), so that recombinants and nonrecombinants can be directly observed from the offspring of phenotypes. Smith [54] shows how the EM can be used with "repulsion single backcross" data, where even though parent haplotype data are known, it is not possible to count recombinants directly. He also developed a general framework for linkage and applied it to estimate the recombination fraction between the genes for color blindness and muscular dystrophy, both conditions assumed to be sex-linked recessives. Ott [48] gives a very general treatment of using the EM in linkage analysis, considering the multiparameter situation where the recombination fraction might depend upon age, sex, etc. and also permitting the estimation of additional parameters in the genetic model.

Thompson [59] discusses the utility of a simultaneous analysis of three or more markers as opposed to considering a series of pairwise analyses. She proposes the use of the EM to estimate the recombination fractions and also Sundberg's [57] formulas for curvature with incomplete data, to compute the information gain in a joint marker linkage analysis. Lander & Green [26] present another approach to estimating recombination fractions between multiple markers using the EM with data from three-generation pedigrees, assuming that the order of the markers is known. Here the complete data are the inheritance vectors at each location, telling which founder alleles are inherited by each person at each marker location. With this information it is easy to tell where recombinations have occurred, and estimate the recombination fractions between each location (M-step). Having the recombination fractions, the observed marker data at each location, and knowing the pedigree relationships, one needs to compute the expected number of recombinations in each interval (E-step). They give three alternative methods for carrying out the E-step which are useful in different settings. Using the EM in this setting permits the simultaneous analysis of many more markers than previously possible, using large numbers of small pedigrees. In related work, Lander & Botstein [25] propose the use of the EM for linkage studies involving multiple markers and quantitative outcomes. Guo & Thompson [15] suggest using a Monte Carlo EM for a combined linkage and segregation analysis, again with quantitative outcomes.

An alternate method for testing linkage is to count the number of alleles which are identical-by-descent (IBD) in pairs of affected relatives, and compare the observed to that expected based on the relationship alone. An allele shared IBD in two relatives means they share two copies of a single

gene by inheritance; for example a parent and his or her offspring share exactly one allele IBD at each location in the genome provided there is no inbreeding. They might also share other alleles by chance, called IBS for identity-by-state, if parents share the same type of alleles at some locations. It is not always possible to determine IBD status, either because of missing relative information or duplicate versions of the same allele in relatives. To solve this problem, Risch [51] suggested a simple EM algorithm for estimating the proportions shared IBD based on the observed data at a single locus. This approach was extended by Kruglyak & Lander [22] to incorporate information from markers at other locations by calculating the distribution of the inheritance vectors to determine IBD status. They also extend this basic approach to carry out a maximum likelihood analysis of allele sharing when the disease outcome is measured quantitatively. These approaches were extended to incorporate parametric methods of linkage analysis with multiple marker locations by Kruglyak et al. [21]. Other applications of the EM in genetics, and a review, are given in Weeks & Lange [61].

Empirical Bayes

"Empirical Bayes" is the term Herbert Robbins coined in his 1955 paper [26] to describe how, if certain **estimation** situations are encountered many times, the data from all these situations can be used in combination to construct estimates for each individual case that approach the greater accuracy of a Bayes estimator (*see* **Bayesian Methods**). This is without knowing the Bayesian's **prior distribution**. Since then, the concept of empirical Bayes has been widened periodically so that today the term is used by authors in biostatistics [5] and in other sciences to embrace an array of models and methods that include, for example, **hierarchical models**, **random effects** models, **linear mixed effect models for longitudinal data**, and **multilevel models**. Empirical Bayes derived from the frequency perspective, emphasizing asymptotic evaluations of procedures. Today's **inferences** often are developed by using Bayesian methods, although less emphasis is often placed on evaluating new procedures.

Empirical Bayes research concerns analyses of observed data $\boldsymbol{y}$ that follow a two-level (hierarchical) model with known density function f at level 1:

$$Y|\theta \sim f(y|\theta) \tag{1}$$

Here, θ is a vector of random effects. At level 2, with α, an unknown parameter vector (hyperparameter) that governs the possible distributions of θ, and with G, having density $g_\alpha(\theta)$, modeled as a known (distribution) function

$$\theta \sim g_\alpha(\theta). \tag{2}$$

Robbins' empirical Bayes referred to this framework with θ a k-dimensional vector of unknowns $\theta = (\theta_1, \ldots \theta_k)$ and $\boldsymbol{y} = (y_1, \ldots y_k)$ independent and with k going to infinity. In (2), G corresponds to letting g be a one-dimensional completely unspecified density for θ_1, and then letting all the other parameters $\theta_2 \ldots \theta_k$ be independently identically distributed (i.i.d.) with the same g. In the context of (2), the parameter α is identified with g here, and the key assumption for repeated problems is that among all possible distributions on k-dimensions, the θ are i.i.d.

$$Y_i|\theta_i \sim f(y_i|\theta_i) \text{ indep} \quad i = 1, \ldots, k. \tag{3}$$

$$\theta_i \sim g(\theta_i) \text{ indep} \quad i = 1, \ldots, k. \tag{4}$$

This setup allows for building up of information about this unknown g.

A scientist who knows $g(\,)$ would use it to calculate the Bayes estimate for each θ, for example, the posterior mean

$$\hat{\theta}_{i,g}(y_i) = \mathrm{E}(\theta_i|y_i, g) = \frac{\int \theta f(y_i|\theta) g(\theta)\, \mathrm{d}\theta}{\int f(y_i|\theta) g(\theta)\, \mathrm{d}\theta}. \tag{5}$$

Robbins

Robbins and his direct successors focused on the construction of estimates for each θ_i that asymptotically, as $k \to \infty$, perform as well as the Bayes rule in (5), as summarized in Maritz and Lwin [24]. Robbins [26] made independence assumptions of (3) and (4) in his initial example, with y_i having a **Poisson distribution** with mean θ_i, and θ_i having an unknown distribution, as in (4). Such a model could apply to evaluations of medical units if, for example, y_i were the number of patients who experienced bad outcomes (mortality, or postoperative infection, assuming these are rare events) at treatment center i ($i = 1, \ldots k$), and then θ_i would be the expected number of bad outcomes. Under these assumptions, the marginal distributions of the observed y_i values are i.i.d. and depend on the unknown g (*see* **Marginal Models**). Then, it is easily seen for any component i with outcome Y and $\mathrm{E}(Y) = \theta$ in this Poisson setup, that Bayes' formula gives $\mathrm{E}(\theta|Y = y) = (1 + y) * P(Y = y + 1)/P(Y = y)$. Robbins used this fact and **consistency** of the sample distribution function based on the marginal distribution of $(y_1, \ldots y_k)$ to approximate the Bayes estimate of θ_i in (5) by his "empirical Bayes" estimate

$$\hat{\theta}_i = (1 + y_i)\frac{N_{1+y_i}}{N_{y_i}}. \tag{6}$$

Here, N_{y_i} is the number of units (treatment centers, here) that observed exactly y_i Poisson events, and N_y/k is a consistent estimate of $P(Y = y)$ as $k \to \infty$.

This two-level Poisson model (3) and (4) applies in practice if the expected number of bad outcomes at center i are i.i.d. and the number of patients exposed is the same in every center. (This is rare, in practice.) Robbins' estimate (6) of the Bayes rule is consistent so that, as $k \to \infty$, it improves as an approximation to the Bayes estimate (5) for most centers if k is sufficiently large.

Unfortunately, no matter how many treatment centers, k, are considered, some centers always will be estimated badly by (6). To see this, let $y_{\max}$ denote the maximum number of bad outcomes in any center. This is a finite number for any k (but it goes to infinity as $k \to \infty$). By definition of $y_{\max}$, $N(1 + y_{\max}) = 0$, so (6) estimates the corresponding θ_i to be 0. We see that the treatment center with the worst outcome record is estimated by (6) to be the best!

Better empirical Bayes estimates than (6) were developed by Robbins' immediate successors for this Poisson situation and other distributions, and Maritz' book [24] summarizes many of these investigations. While those advances improved the estimation techniques, they still required $k \to \infty$, and the models considered (3) and (4) often were prohibitively restrictive for real applications, which require much less symmetry at both levels. For example, treatment centers almost always treat different numbers of patients, so the level-1 distribution f in (3) must depend on i. Also, in real problems, the identically distributed assumption for the $\{\theta_i\}$ values in (4) becomes harder to meet, especially if k must be large. And, methods were needed that work for small and moderate values of k, for example, for a moderate number of treatment centers.

Parametric Empirical Bayes

Stein first proved in 1955 [27] that the means of k independent **Normal distributions**, in the setup of (3) (but not introducing or considering (4)), could be estimated better, for sums of squared error **loss functions** if k is at least 3. A specific, simple estimator was introduced by James and Stein [18]. Efron and Morris [10–13] added (4) and reinterpreted Stein's estimator as an empirical Bayes estimator of the posterior mean of θ_i, given the data. They allowed for different distributions f in (3), replacing f by f_i, so that sample sizes (or "exposures", in the Poisson case) could differ across units. Since the level-2 distributions were Normal, for example, although with unknown moments, this was a "parametric empirical Bayes". In this Normal case, (3) and (4) become

$$Y_i|\theta_i \sim N\left(\theta_i, V_i = \frac{\sigma^2}{n_i}\right) \text{ indep } i = 1, \ldots, k \quad (7)$$

$$\theta_i \sim N(\mu_i, \tau^2) \text{ indep } i = 1, \ldots, k. \quad (8)$$

Then the posterior distribution of θ_i, assuming $\alpha = (\beta_0, \beta_1, \tau)$ in this case, is known, with $B_i = V_i/(\tau^2 + V_i)$, $V_i \equiv \sigma^2/n_i$, takes the form

$$\mathrm{E}\theta_i = \mu_i = \beta_0 + \beta_1 x_i, \quad (9)$$

with x_i a **covariate** (more generally x_i could be a vector).

The y_i's, are observed, and the n_i values are known. Usually σ, needed in V_i, is known or is so accurately estimated that it can be assumed known. Then V_i is known, and unknown hyperparameters $\alpha = (\beta_0, \beta_1, \tau)$ are the α in (2) and must be estimated (with errors, but that diminish as k increases). The terms μ_i and τ are of central interest in random effects research, but the emphasis in empirical Bayes focuses on making inferences about the many values of θ_i.

Efron and Morris, in the 1970s, [10–13] developed parametric empirical Bayes that were useful in practice for moderate values of k, and with varying V_i values, but these papers were mainly about point estimation of the parameters θ_i. Parametric empirical Bayes estimators took the form, for example, [11]

$$\theta_i|Y_i, \alpha \sim N((1 - B_i)y_i + B_i\mu_i, V_i(1 - B_i)). \quad (10)$$

$$B_i = \frac{V_i}{V_i + \tau^2}, \quad (11)$$

The B_i in (10) are "**shrinkage** factors", in the sense that the estimate $\hat{\theta}_i$ is shrunken away from y_i by the fraction B_i toward the mean μ_i. Thus B_i represents the fraction of **regression toward the mean**, μ_i. Their developments were that **shrinkage estimates** of the θ's emerging from this two-level structure had lower risk (often for mean squared error) for each i. Risks, as a function of α, are computed by averaging over the data and assuming the level-2 distribution (8) holds while not knowing the hyperparameter vector α (= β and τ, here). In keeping with the evaluation requirements of the empirical Bayes perspective, various resulting shrunken estimators were shown to improve uniformly (every component i, all α) on the best procedures that do not combine data for fixed k, including for fairly small k. Other developments included letting each y_i be multivariate, and including regressions at level 2, so that the θ_i need not be identically distributed. That is, the distribution in (8) extends to let μ_i depend on i (so α is $(\tau, \beta_0, \ldots, \beta_r)$, with a constant term and with r observed predictors).

Empirical Bayes estimates of θ_i then typically mimic the posterior mean in (10) using estimates of B_i and μ_i, so that

$$\hat{\theta}_i = (1 - \hat{B}_i)y_i + \hat{B}_i\hat{\mu}_i. \quad (12)$$

Making Full Inferences for Each Unit

Until the 1980s, research from the empirical Bayes perspective said little about interval estimates. Actual applications generally require interval estimates, and empirical Bayes methods would be of limited interest without them. If α in (2) or (8) were known exactly, or if a hyperprior distribution were known for α, then posterior probability (Bayes) intervals provide such intervals.

Large-sample approaches are unreliable for empirical Bayes interval estimates. To illustrate, an often-applied approach to deriving interval estimates in the Normal case has been to find the **maximum likelihood** estimate (MLE) of α (e.g. of μ and τ in (8)) and then to plug those values into (9) to obtain an estimated variance for θ_i. However, the MLE of the shrinkage factor B_i is biased toward overshrinkage, and noticeably so for small values of k and for B_i not near 0. Worse yet, in some data sets (even with large k), the MLE of τ^2 can equal 0. Then, the MLE estimates B_i as 1 and the posterior variance $V_i(1 - B_i)$ in (10) as 0. This is likely if the true τ is near 0, even for large k. Then, the corresponding MLE interval estimates for θ_i are given zero width, and they cannot possibly cover the true value. Despite this, rules based on the MLE or on other "plug-in" estimates for τ used in $V_i(1 - B_i)$ continue to be proposed and used, even though they give intervals that are much too small.

Conditional probability and Bayesian reasoning can guide construction of procedures meant to have good frequency properties. Bayes rules based on an uninformative hyperprior distribution on α show how to account for the added variability due to not knowing the level-2 mean parameters and the variance τ^2 by identifying additional terms needed in the posterior variance of θ_i. That approach was used [25] to construct interval estimates in the Normal case. Standards for empirical Bayes inference are defined in [25], requiring that procedures meet those standards in repeated sampling for every value of the hyperparameter vector, α. One then seeks prior distributions on α that lead to empirical Bayes inferences that also meet these standards. For Normal problems (7) to (12), choosing a **uniform distribution** on τ^2 (and flat distributions on μ, or on β_0, β_1 in (8) or (11)) has produced interval estimates that approximately meet or exceed the nominally claimed coverages. Certain other distributions, including some uniform shrinkage priors [7] also meet these standards. Such intervals then cover all θ_i values appropriately in settings covered by (7) to (12). Evaluations of these procedures, which do not allow knowledge of α, must be checked to hold for every possible value of $\alpha = (\beta, \tau^2)$, and for various values of k, including fairly small k. These empirical Bayes evaluations depend on the distributional assumptions (e.g. Normal, independence) made at both levels of the model. If one does not allow averages over the level-2 distributions of θ_i (for each fixed value of α) then no shrinkage interval estimate can achieve the empirical Bayes nominal coverage standard for every i.

Bayes, Hierarchical Bayes, and Other Approaches

Bayesian ideas for carefully chosen prior distributions on the hyperparameter have been so successful, even in the frequency sense, that in recent years, there have been a variety of such approaches that address the two-level model (1) and (2) in many forms, for example [19], [23]. That includes the approach of Lindley and Smith [21], which deals with models similar to (7) and (8) from the Bayesian perspective. More recently, powerful computation coupled with **Markov chain Monte Carlo** (MCMC) sampling tools has made Bayesian computations feasible. The texts by Carlin and Lewis [5] and by Gelman et al. [15], as well as Greenland's article [16], are excellent sources for these developments. Other frequency approaches include analysis of the two-level model (1) and (2) with random and mixed effect models, repeated measurement models, models for **longitudinal data**, **generalized linear mixed models**, **random coefficient** models, models for latent variables (*see* **Latent Class Analysis**), graphical models, **hidden Markov models**, **variance components**, and so on. Some of these topics are covered in this encyclopedia and probably all could be models for biostatistical applications. The term empirical Bayes may not often appear, even when interest is on estimating multiple values θ_i, but such methods could be considered under this term.

Empirical Bayes Evaluation

A key concern of empirical Bayes has always been the attempt to evaluate the performance of such procedures over a range of incidences. That needs to be done more often when methods are being proposed under these other names. In particular, Bayesian methods depend on choices of a hyperprior distribution on α, and such evaluations can identify which hyperpriors are likely to produce rules that can be broadly applied. Asymptotic methods often are used by frequentists to evaluate estimates, and many methods such as **generalized estimating** equations (GEE), MLE, penalized **quasi-likelihood** (PQL), and **overdispersion** approaches are used.

Such methods, justified for large samples (large k), may or may not work for a small k. For example, let us return to the original empirical Bayes–Poisson setting of Robbins, (3), but now with parametric assumptions for $g(\theta)$ in (4). Christiansen and Morris [7] studied several such methods, including when the hyperparameters α for the prior **gamma distributions** are estimated by MLE or by standard GLM overdispersion methods, and the Poisson parameters θ_i are assumed to follow their estimated posterior distribution (via plugging in $\hat{\alpha}$ for α). When $k = 15$, their examples show that resulting nominal 95% **confidence intervals** cover only about 70% of the time for the MLE, and 80% of the time for GLM. However, accurate interval estimates are derived in the paper [7] that do meet their nominal 95% coverages.

Small-sample empirical Bayes methods can be derived, often drawing on parametric models at level 2, and often relying on Bayesian methods or Bayesian heuristics. With sufficient analysis and **simulation**, some of these can be shown to meet their nominal risk and coverage claims.

Applications: Empirical Bayes and Gene Expression Data

Analyzing DNA microarray data and other gene expression data leads to testing many hypotheses, each meant to measure whether a gene is an effective marker (*see* **DNA Sequences**). There may be thousands of such tests made, one for each gene in the array. That raises the **multiple comparisons** problem, in that many "statistically significant" genes will found, even when none are true markers. Benjamini and Hochberg [3] introduced the false discovery rate (FDR) to help measure and control the seriousness of this problem in such applications. Several authors, including Efron and Tibshirani [9, 14], and Kendziorski, Newton, Lan, and Gould [20] have shown that empirical Bayes, and parametric empirical Bayes modeling and analyses offer a powerful way to clarify and attack these multiplicity issues, and produce methods closely related to the FDR.

To see how these tests are related to empirical Bayes, Efron and Tibshirani suppose there are k statistical tests made independently (*see* **Hypothesis Testing**). More complicated assumptions are considered, but in simpler settings the ith case might be based on a test statistic y_i that is $N(0, 1)$ under the **null hypothesis**, but when the site is a genuine marker, has mean θ_i that differs from 0. Then, a model like (7) and (8) is assumed, but with a distribution function $G(\theta_i)$ that is more general than Normal at level 2:

$$\theta_i \sim G() \text{ indep}, \; i = 1, 2, \ldots, k. \qquad (13)$$

The problem then is to learn about the conditional distribution of each θ_i value, given all the data $(y_1, \ldots, y_k)$. For hypothesis testing, G in (13) would give substantial positive probability p_0 to θ_i being 0. Since the same G is assumed for every gene, the observed marginal distribution of y_i is available to learn about the unknown G. If G were known, then Bayes rule could be used for inferences about θ_i, and, of course, it would depend only on y_i. That is, the role of the other $k - 1$ values y_j is only to help learn about G. Efron and Tibshirani study this model and its inferences without making parametric assumptions about G.

In a related study of breast cancer data, Kendziorski et al. [20] observe positive intensities y_i, and so their parametric empirical Bayes model starts with Gamma distributions at level 1 and then specifies conjugate Gamma distributions at level 2. Another model in [20] considers **lognormal** distributions at level 1, in which case, their log transformations and Normal distributions at level 2 provide a structure much like (7) and (8). For each gene, results are the posterior odds that different rat strains have differential expressions for that gene. The authors use simulations to verify that their procedures are reliable for the empirical Bayes model assumed.

Empirical Bayes applications abound in the literature. Some examples appear in [1, 2, 4, 6, 8, 17, 22, 28].

Endocrinology

There are two systems that we commonly envisage to control the functioning of animals: the nervous system, and the endocrine, or hormonal, system. A simple model would view the endocrine system as consisting of several well-defined ductless glands (pituitary, thyroid, parathyroid, adrenals, gonads, and pancreas) that secrete chemical messengers, called hormones, directly into the blood stream. The hormones then travel, via the circulatory system, to certain target cells that then respond in specific ways. By contrast, the faster-acting nervous system functions by transmitting electrical impulses down specially constructed nerve cells.

We can, then, define the subject of endocrinology as the study of all aspects of the endocrine system. These include: the physiology of the glands; the action and effect of the hormones; and the genetic sequencing (*see* **DNA Sequences**) of the **genes** responsible for the hormones. Since many metabolic diseases and impairments result from some deficiency in the endocrine system, endocrinology has always been considered under the remit of clinical medicine, and, to a large extent, still is. However, endocrinology is now beginning increasingly to come under the remit of molecular biology (*see* **Molecular Epidemiology**).

Most of the "true" endocrine glands were discovered in antiquity by such early workers as Aristotle and Galen. The last endocrine gland discovered was the parathyroid in 1891 by Gley. The anatomy of "true" endocrine glands has, therefore, essentially long been completed. The bulk of research is currently focused on trying to determine the effect and method of action of hormones, and optimal therapeutic treatments.

The first real scientific experiment was conducted by Berthold in the mid-nineteenth century. Berthold demonstrated that by transplanting testes from roosters into previously castrated roosters (heterotransplantation) he could maintain the male characteristic of these roosters; in particular, crowing. Yet, even to this day, this type of *in vivo* experiment, where a gland is surgically removed (a process known as ablation), forms the basis of much physiological endocrine research. An excellent account of the history of endocrinology can be found in [6].

One key feature often encountered in endocrinology is the negative feedback mechanism. Here, high levels of a particular hormone within the circulatory system inhibit secretion of more hormone. This usually results in a **dose–response** curve that peaks at a single maximum, and then declines with additional stimulation [1]. It should also be noted that any individual hormone may have a variety of effects.

All of this makes for a complex picture of the endocrine system. This is even more the case when it is considered that many of the current models are very experimental [7] and current research is constantly updating them. Fortunately, the system is not as difficult to control as it might first appear, since there is often a natural hierarchy of hormones within any endocrine system.

Experimental Methods Used

The experimental process in endocrinology typically follows a step-by-step methodology. Usually, different teams of researchers work on each step in the research process. The entire process is typically motivated from a clinical aspect, through a metabolic disease, with a measurable response.

The first step in endocrinology is to isolate the gland responsible. This is usually done through ablation. Next, it is necessary to demonstrate that this is the gland *directly* responsible for the metabolic response of interest. This is usually done using *in vitro* experimental techniques, or transplanting the gland to another site in the body (homotransplantation). The third stage is then to isolate the hormone in question. This is usually demonstrated by ablation of the gland, and hormone replacement therapy to remove the clinical symptoms. Typically, a dose−response curve is constructed at this point. Having isolated the hormone, molecular biology techniques are then used to sequence the DNA responsible for the hormone, with the aim of using recombinant techniques to synthesize it. Since the use of such techniques is relatively new, with the hormone insulin being the first such product [4], well over half of the published work in endocrinology in the last decade has taken place in this area. Finally, therapeutic trials (*see* **Clinical Trials, Overview**) are undertaken to discover the optimal treatment regimes for those who suffer from the metabolic condition.

There is a great deal of literature on therapeutic trials, mainly within the medical journals. This is

because the selection of a particular treatment regime usually needs very careful consideration. The reason for this difficulty lies in medicine's inability to match exactly the body's own homeostatic regulation system. So that, although taking one tablet per day of hormone will give a correct **mean** normal serum level of hormone, it will lead to wide fluctuations in hormone level, which can cause complications. This is particularly important as a single hormone can have several functions. For example, oestrogen replacement in post-menopausal women has been linked to an increased risk of breast cancer. Therefore, determining the correct therapeutic regime can require much investigation, often over many years. Finally, the treatment regime must be tailored to the individual. For example, in diabetes it is necessary not only to tailor treatment, with insulin, around the physical characteristics of the patient, but also around their lifestyle.

The consequences of such a step-by-step approach are that at each stage the **experimental design** rests on the conclusions of the previous stage. However, these assumptions must be interpreted from a variety of sources. Endocrinology is, therefore, clearly an area of research requiring good review articles, and many endocrinology journals do include a forum for such articles; for example, Campbell & Scanes [2]. Yet such review articles rarely employ a systematic review, or the use of meta-analysis techniques (*see* **Meta-analysis of Clinical Trials**).

Statistical Methods Used

Much endocrinology is investigative and, because of this, some researchers, particularly in the past, have employed only descriptive statistics. Yet most of the main hormones are now probably known and so the remaining investigations need to be increasingly sophisticated. Therefore, most studies are now accompanied by some form of **hypothesis testing**, or **confidence intervals** and, indeed, this is often now expected by the relevant subject journals; for example, the *Journal of Endocrinology*. However, in general, the coverage of statistics within endocrinology journals involves routine techniques.

The analysis of an ablation experiment is usually fairly simple and typically uses routine methods. A more complex experiment may involve monitoring the effect of hormone replacement, or ablation, over a time course. This is becoming increasingly popular with the advent of slow-release hormonal implants and more sophisticated monitoring systems. The analysis involved for this type of experiment is almost without exception carried out as a **multivariate analysis of variance** repeated measures analysis (*see* **Longitudinal Data Analysis, Overview**).

Another type of analysis often conducted is the calculation of a dose–response curve. It is often difficult to fit a prior functional form to the dose–response curve, since the particular characteristics may vary considerably, and, indeed, the appropriate dose range may be known only very vaguely. For example, in two articles on diabetes research, two growth curves were postulated. The first article, [8] plotted empirically the means of the data, with confidence intervals, and suggested a bi-modal response resulting from a complex negative feedback mechanism. The second [5] postulated that there was no negative feedback mechanism involved and fitted parametric hyperbolic responses to the data (*see* **Nonlinear Growth Curve**).

Future Developments

The use of modeling (*see* **Model, Choice of**), or **multivariate multiple regression** techniques should, and almost certainly will, become more popular because the administration of complex schemes of hormone replacement and monitoring is now beginning to become practical. This is necessary if for no other reason than that the large amount of data generated will be difficult to handle using the current visual inspection techniques. In addition, such monitoring techniques will allow for the adjustment of responses by **covariates**, which is rarely done at present.

Once a fairly complete understanding has been gained of the entire system being studied it should then be possible to use the techniques of **pharmacokinetics**, such as compartmental modeling, to try to gain some deeper model-based description of the system. Unfortunately, at present the best understood endocrine system is the glucose regulation system. However, even here knowledge is not yet sufficient to undertake such an analysis competently, although such analyses have been attempted. Yet, as endocrinology progresses, a more detailed knowledge of the endocrine system can only go toward providing a higher confidence in such models, and increase their usage.

For the future, the development of mainstream techniques, hopefully incorporated within statistical **software**, for the analysis of repeated measures categorical data and ranked data (*see* **Ranks**) is one area of applied, and theoretical, statistical research that would benefit researchers in this field. This is because there are many measurements of disease that can only be measured somewhat indirectly; in particular, behavioral response. Such a response can often only be based on a ranked, or an **ordered categorical** scale. For example, if modeling dominance or aggression, which are known responses of androgen hormones, a ranking procedure, or ordered scale, may be the only feasible outcome measure [3].

Environmental Epidemiology

Environmental epidemiology encompasses a wide array of topics related to the study and evaluation of the determinants of diseases in human populations. The term "environmental" as used here is general in scope, and pertains to all aspects of our environment that may influence disease **risk**. Environmental exposures include substances that might affect our immediate surroundings, such as pollutants in the air we breathe or water we drink, as well as factors related to our occupation, recreation, and lifestyle that might influence probabilities of disease occurrence. Thus, for example, the dominant environmental determinant of lung cancer in nearly all populations around the world is cigarette smoking, while diet and nutrition contribute to risk of several other cancers and cardiovascular and other diseases. Since molecular and genetic traits may predispose individuals to the adverse effects of exposure to specific environmental factors, environmental epidemiology can be considered to include the entire spectrum of research into the etiology and prevention of human diseases.

In this article we describe methods for and examples of epidemiologic studies of the environmental determinants of chronic diseases, the major killers in human populations today. Emphasis is placed upon epidemiologic and statistical methodologic tools for the detection and evaluation of risks associated with environmental exposures. Acute diseases are not considered, although some of the basic techniques for assessing environmental factors have arisen from principles developed in tracking outbreaks of infectious diseases.

The article is divided according to method of study of environmental factors in disease risk. First are **descriptive epidemiologic** studies. These investigations, which study patterns of disease in general populations and their **correlations** with environmental indices of the populations, are useful primarily for generating hypotheses about disease etiology. More important are **case–control** and **cohort studies**, which are **analytic epidemiologic** studies that evaluate risk of disease in individuals characterized by presence and level of exposure to environmental variables of interest. These **observational** (nonexperimental) epidemiologic studies form the basis for most of what is known about the causes of chronic diseases. Finally, are randomized trials (*see* **Clinical Trials, Overview**), whereby agents or procedures that are thought to have potential for reduction in disease risk are evaluated experimentally with random assignment of individuals to various exposure groups (*see* **Randomization**; **Randomized Treatment Assignment**). The credibility of evidence from these clinical intervention trials is usually higher than from observational studies, but for practical reasons only a limited number of such trials have been undertaken.

Providing Clues to Environmental Factors

Clues to environmental causes of disease are often uncovered by examining patterns of disease mortality and incidence. For extremely rare diseases, even occurrence of a few cases within a short period of time and at a particular space can raise suspicion. Such "clusters" of disease (*see* **Clustering**), often detected by alert clinicians, can in some situations lead to the eventual discovery of the causal agents. For instance, the development of hepatic angiosarcoma among three workers in a single manufacturing plant in Kentucky led to the identification of vinyl chloride as the likely causal agent [24], and the observation of vaginal adenocarcinoma in several young women in Boston was traced to synthetic estrogens taken by their mothers during pregnancy [38]. The large majority of clusters of a few cases of a disease, however, have proven to be uninformative with respect to discovering or evaluating a causal agent. Heath [36], for example, described investigations by the **Centers for Disease Control** of clusters of childhood cancer in a number of communities in the US, none of which conclusively linked the leukemia or other cancer cases with environmental exposures. **Leukemia clusters** around nuclear power facilities have also failed to be causally related to **radiation** exposures from the plants [46]. Similarly, clusters of birth defects and other abnormalities have been assessed among residents near hazardous waste sites with potential for exposure to solvents, metals, and other compounds, but firm conclusions have been difficult to achieve [55, 65]. Although some clusters may be due to environmental determinants, it seems likely that many apparent clusters have resulted from **selection bias**, limitations of geographic boundaries or time periods, or chance [46, 56].

The play of chance is sometimes underestimated in assessment of clusters of small numbers of disease events, especially when the clusters occur in one of many arbitrarily and narrowly defined space-time units. Occurrence of a cluster of two events when 0.2 are "expected", for example, can result in a "significant" ($P = 0.02$ for a one-sided test under **Poisson** assumption) excess. If the boundaries of the cluster were drawn specifically to encompass the cases, however, the statistical significance loses its nominal meaning. Furthermore, if the cluster was in one of many time–space units evaluated, the **multiple comparisons** may generate at least one with a "significant" excess. Sometimes investigators are tempted to include the index cluster (that is, the cases that generated the cluster) in determining whether the disease excess occurs in other time–space units, but this fundamental violation of principles of independence invalidates such an evaluation. Finally, the existence of a cluster *per se* of a small number of disease events in a time–space unit conveys no information about the causes of the cluster.

Geographic clustering can also occur for more common chronic diseases, and be based on fairly large numbers of disease events. Excess occurrences of more common diseases are not so obvious to the practicing physician, but broad clustering may be uncovered through a systematic monitoring of disease morbidity and mortality (*see* **Surveillance of Diseases**). These clusters, typically based on large enough numbers of cases for the calculation of stable rates across time and space, may more often prove to be useful in generating productive leads to disease **causation**. Primary examples are the clusterings of high rates of certain diseases in contiguous areas seen in national atlases, which depict the distribution of mortality rates across small geographic units, such as counties in the US [47, 62] (*see* **Geographic Epidemiology**; **Mapping Disease Patterns**).

Geographic variation suggestive of environmental determinants can be particularly useful for leads to cancer studies. The US cancer maps have shown distinctive patterns of clearly nonrandom distributions of various cancers [47, 62]. Sharply elevated rates of oral cancer mortality among women, for example, have clustered in the southeastern part of the country. The finding led to several hypotheses, including one concerning occupational exposures in the textile industry, an industry employing large numbers of southern women, and one concerning smokeless tobacco, used by some women in rural areas of the South [8]. Subsequent analytic epidemiologic studies generated by the patterns seen in the cancer maps identified the use of oral snuff as the key risk factor and the cause of the large majority of cheek and gum cancers, tumors occurring where the tobacco powder was typically placed [70].

Mortality records have generally been the primary source of health data for generating clues to environmental factors for chronic diseases. In most countries of the world, systematic recording of all deaths is conducted by local governments (*see* **Death Certification**) and used for the compilation of national death rates by **causes of death**. Using population estimates generated from the national **censuses** as denominators, mortality **rates** by age, sex, and race can be computed for deaths due to various causes across time and for various geographic units. The ascertainment of deaths is nearly 100% complete in most populations, but inaccurate determination of the cause of death and certain other limitations may affect routinely collected mortality data. Cancer deaths are generally properly identified on death certificates, although the accuracy and completeness in recording cancer deaths vary by the type of cancer [59], but **misclassification** can be problematic for some other causes of death. Changes in recording practices and the coding of cause of death (*see* **International Classification of Diseases (ICD)**) also may contribute to the apparent changes in secular trends of cause-specific mortality [33]. Mortality data are of limited use for diseases with low fatality, and disease-specific death rates can be influenced by nonenvironmental factors such as improved survival due to changes in treatment modalities or early detection (*see* **Vital Statistics, Overview**).

Some limitations that may affect mortality patterns can be circumvented by using incidence data. Registries sometimes exist for various diseases, most notably cancer, with population-based registries in many parts of the world [58] (*see* **Disease Registers**). In the US, registries participating in the Surveillance, Epidemiology, and End Results (SEER) Program supported by the National Cancer Institute have been collecting diagnostic, treatment, and survival information on newly diagnosed cancer cases in about 10% of the population across the country since 1973 [43]. These data have been used for monitoring cancer incidence trends and patterns of cancer occurrence by demographic and geographic subgroups [27]. For

instance, it has been observed recently that adenocarcinomas of the esophagus and gastric cardia are among the cancers with the most rapid rise in incidence during the past two decades in the US, particularly among white men [12]. This striking trend has led to the generation of multiple hypotheses about environmental factors. One hypothesis is that the increasing use of exposures that promote reflux, particularly obesity and pharmaceutical agents that relax the lower esophageal sphincter, may contribute to the rising incidence trends [20, 69].

Registries of incident cases of nonmalignant diseases are more limited in number and tend not be national in scope. If the population base from which the cases arise is well defined, however, these too can provide the basis for the calculation of rates and trends which may trigger hypotheses about environmental causes. Thus, for example, in Sweden and Denmark, all hospitalizations are registered, so that national patterns of various diseases requiring hospitalizations can be routinely monitored [1]. Illnesses not resulting in hospitalization will be missed, but the incidence and **prevalence** of serious conditions can be ascertained for the entire country.

Information on births is usually routinely collected in populations throughout the world. In addition to sociodemographic variables such as maternal age, race and occupation, information on **birthweight**, Apgar score and method of delivery is often collected. In the US birth certificates were standardized nationally in 1989 to include a checkbox for congenital abnormalities and medical risk factors, including tobacco and alcohol use, medical history, and prenatal care [19, 71]. The birth certificate data therefore can be used not only for monitoring disease occurrence among newborns [49], but also as a research tool to identify potential risk factors for these newborn illnesses, such as maternal sociodemographic characteristics in relation to congenital syphilis [26] and maternal smoking, ethnicity, and birthweight in relation to sudden infant death syndrome [45].

Systematically ascertained data on exposure to environmental agents are less readily available than data on measures of disease mortality or incidence. Thus, for example, the prevalence of cigarette smoking – the single most important environmental cause of disease in the US – is not known for counties across the country. National probability sample surveys, such as the National Health Interview Surveys conducted periodically beginning in 1960 and the series of National Health and Nutrition Examination Surveys (NHANES) starting from NHANESI in 1971–75 to the NHANESIII in 1988–94 have estimated smoking prevalences by broad, but not small-area, geographic regions. These **National Center for Health Statistics (NCHS)** surveys can be useful for monitoring national estimates of prevalence of a number of environmental exposures classified by demographic subgroups and over time [23, 42, 63]. The exposures include not only tobacco consumption, but also diet and nutrition, medical variables, occupation, and other characteristics measured over time and by geographic areas.

Census data often provide a rich source of exposure data for generating clues to environmental risk factors. In addition to population counts by age, sex, and race, the census yields information on income, education, urbanization, occupation, and other factors for various geographic units, the smallest in the US being census tracts and postal zip codes. Usually this information is provided every 10 years. In some countries special censuses of manufacturing provide detailed industrial data at the small-area level, enabling calculation of indices of the percent of the population employed in hundreds of industrial categories. Although small-area data are generally not routinely available on average levels of general population exposures to chemical or physical agents, some registries of environmental exposures (e.g. to radon) exist in selected areas. In Sweden, a number of registries of exposure to chemical substances have been established for **record linkage** with national registries of cancer and mortality [1].

Statistical analyses of correlations of mortality or other aggregate health data with measures of average environmental exposures for the populations can help generate and refine hypotheses about disease causation. The correlations can assess not only concordance across geographic areas but also across time, and can be useful in helping to refute as well as refine hypotheses. Thus, rising then recently declining trends in lung cancer mortality correlate well with the rise and decline in smoking prevalence among American men [11, 31]. However, mortality rates of all cancers combined in the US have been relatively steady since the 1930s once lung cancer is removed [3, 21, 43], a pattern not consistent with the theory that increases in environmental exposures from pesticides or other chemicals are causing large-scale

increases in cancer. Rising incidence of breast and prostate cancers, the major cancers among women and men, respectively, has been reported recently, but the increases seem related to changes in diagnostic techniques rather than environmental influences [27]. Furthermore, complete explanations for the rising incidence of non-Hodgkin's lymphoma are not clear. Geographic correlations have indicated that rates of lymphoma were highest in the north central part of the country, and have led to case–control studies evaluating workplace and environmental exposures associated with farming and other occupations [72] (*see* **Occupational Epidemiology**). Similarly, rates of lung cancer in US counties among workers employed in the chemical, petroleum, paper/pulp, and shipbuilding industries, adjusted for urbanization and other demographic factors (but not cigarette smoking), suggested that exposures associated with these industries may be contributing to lung cancer in the affected counties [9]. As described later, some of these hypotheses have been confirmed and some dismissed through subsequent analytic epidemiologic studies.

One of the reasons the descriptive studies linking rates of disease and exposure for groups may generate spurious leads is that correlation can occur among group averages in the absence of associations between disease and exposure at the individual level, the so-called "**ecologic fallacy**" (*see* **Ecologic Study**). Thus, studies of individual patients and their exposures typically are required to evaluate adequately hypotheses about the environmental determinants of disease. Such investigations are described in the next section.

Testing Hypotheses About Environmental Risk Factors

There are many environmental substances for which sufficient exposure is known to increase risk of certain chronic diseases. Foremost is cigarette smoking, believed to result in premature death in nearly half of all individuals who smoke and to account for more than one in every six deaths in the US [68] (*see* **Smoking and Health**). Table 1 lists a number of substances besides cigarette smoke which have been classified as causes of cancer in humans [16, 40]. Many are drugs used to treat some cancers that can subsequently increase risk of other cancers,

Table 1 Agents classified by the International Agency for Research on Cancer as carcinogenic to humans

Aflatoxins
Aluminum production
4-Aminobiphenyl
Analgesic mixtures containing phenacetin
Arsenic and arsenic compounds
Asbestos
Auramine, manufacture of

Tobacco smoke
Treosulphan
Vinyl chloride
Wood dust

but also included are environmental substances to which certain occupational groups or certain segments of the general population may be exposed. Almost all of these substances have been identified by means of epidemiologic studies, although supporting evidence from experimental studies in animals generally exists. There are other compounds for which carcinogenicity is suspected because the compounds (often at very high doses) have induced tumors in one or more species of nonhuman animals (*see* **Tumor Incidence Experiments**), but evidence from environmental epidemiology is required before a substance can be considered a known human carcinogen.

Determining whether an environmental exposure has caused an increased risk of disease is generally not easy. A series of criteria need be satisfied before an **association** between the exposure and the disease can be considered causal in nature (*see* **Hill's Criteria for Causality**), and evidence regarding whether they are met is not always clear. The primary tools for making such an assessment are epidemiologic case–control and cohort studies; their utility in environmental epidemiology is described below.

Case–Control Studies

The most common epidemiologic study design for evaluating the environmental determinants of chronic diseases is the case–control study. This approach provides the advantage of the ability to assemble relatively large numbers of patients with the disease of interest (often not feasible via cohort studies) whose exposure histories can then be ascertained. These histories are then compared with those obtained in a similar manner from appropriately selected **controls**, and **odds ratios** calculated as the measure of association between the environmental exposure of interest and the risk of the disease. The case–control approach typically enables the collection of information not only on the key exposure, but also on other factors that may influence risk, so that **confounding** by these other disease determinants can be controlled.

Methods for the appropriate selection of controls, a key concern in case–control studies, are described in detail in the article on **case–control studies**. The essential feature is that the controls be selected from the same base population (study base) from which the cases arise. Thus, if cases arise, say, from among patients with lung function impairment detected by screening employees in a particular industrial facility, whereas controls are selected from the general population of the area where the facility is located, it is possible that case–control differences could be influenced by nonenvironmental determinants that led to employment in the facility. Some of these confounding factors (e.g. age, sex, education) might be controlled for in the statistical analysis, but differences in unmeasured factors may exist.

This fundamental requirement of the same study base for cases and controls is sometimes violated in studies of environmental risk factors because the underlying population from which the cases arose is not always well defined. For example, in studies of rare diseases, specialty treatment centers are often sought for the ascertainment of cases. Selecting controls from other patients is generally advantageous when cases are restricted to a particular one or several hospitals, but in this situation the case patients come not only from the surrounding areas, but also from far distances to receive the specialized care. Patients admitted to the same facility for other conditions might not have the same referral patterns, and thus selecting the most appropriate controls is problematic.

The method of ascertainment of information should also be similar for cases and controls. Suppose the cases with lung function abnormalities mentioned above and the controls were both drawn from employees of similar characteristics (except for their disease) at the industrial facility. Suppose also that information on exposure to silica, the environmental factor of interest, and on presence of concomitant silicosis, was obtained for the cases as part of their evaluation of lung abnormalities. Then if information

for the controls came not from a review of personnel or radiographic information as for the cases, but from questionnaires about silica exposures and about diagnoses of silicosis, differences between cases and controls could be due to the way the information was ascertained rather than to the presence of silica exposure or silicosis *per se* (*see* **Bias in Case–Control Studies**).

Issues regarding **selection**, information or other biases must be considered in all case–control studies. When evaluating certain environmental exposures, additional concerns need be addressed. One is **recall bias**. Individuals afflicted with a disease, particularly if life threatening in themselves or in a close relative, often tend to wonder about what may have caused the illness, or may have been prompted to examine past events during medical work-up and treatment. Sometimes this involves attempts at reconstructing events that may have taken place many years before, and can involve a process of speculating as to possible critical initiating "environmental" events. Controls, on the other hand, will typically have not gone through such prompting or soul searching. Thus, when cases and controls are interviewed, the responses may be different in part because the cases may have thought more about their illness (*see* **Bias in Observational Studies**).

Such recall biases can be mitigated in part by asking structured and specific as opposed to open-ended questions (*see* **Interviewing Techniques**; **Questionnaire Design**). At one time it was thought that exposure to chicken pox and the Varicella virus during pregnancy might increase the risk of cancer in the offspring. The suggestion came from a case–control study in which mothers were asked to list illnesses occurring during pregnancy, and mothers of the cancer patients more often listed chicken pox than mothers of the controls [7]. When prenatal medical records were examined for mention of chicken pox, however, no case–control differences were found. Furthermore, when the questionnaire for the mothers was changed to ask specially about chicken pox during pregnancy, again no case–control difference was apparent [13]. The main effect of medical record review and specific questioning was to raise the reported prevalence of chicken pox among the controls to match that among the cases. The controls had underreported the infection when asked the nonspecific open-ended question about illnesses during pregnancy, probably because they had not thought about and recalled antecedent conditions to the extent of the mothers whose children had developed cancer.

Despite the potential problems with the case–control approach, if conducted properly these studies can provide crucial information about environmental determinants of disease. Case–control studies are often the most appropriate mechanism to test hypotheses generated by the ecologic studies of grouped cancer rates and their correlates described in the previous section. Thus, the US cancer maps spawned a series of case–control studies in areas of the country where rates of particular cancers were elevated. The case–control studies obtained detailed information on the lifestyle, occupational, medical, and other characteristics of the subjects. These studies determined, for example, that although cigarette smoking was the dominant risk factor for lung cancer, employment in shipyards during World War II (and presumed exposure to asbestos) contributed to the clustering of excess rates of this cancer in the 1960s–1980s in southern coastal areas [10, 14]. Other case–control studies showed that use of herbicides in farming was associated with the higher rates of non-Hodgkin's lymphoma in the plains states [66], factors associated with northern European ancestry contributed to the clustering of excess kidney cancer mortality in north central states [52], and use of moonshine whiskies was largely responsible for the excess of esophageal cancer among black men in coastal South Carolina [18].

Case–control studies have also helped elucidate environmental factors for other diseases, especially when used to test etiologic hypotheses. The studies also have been used for hypothesis generation. An advantage of the case–control approach is the ability to look at many different antecedent exposures simultaneously. Often multiple associations are examined in case–control studies with a tendency to report in separate articles those associations based on odds ratios whose **confidence limits** exclude the value 1.0. The inherent **multiple comparison** problem is sometimes masked by the splitting of findings into multiple publications, especially when *ex post facto* explanations of the findings emerge as if they were a priori hypotheses, which can lead to undue emphasis of their importance. The case–control study, however has proven to be the key tool of environmental epidemiology, and its strengths generally outweigh

its disadvantages. Some of the problems that beset case–control studies of environmental factors can be overcome in cohort studies, as described below.

Cohort Studies

Cohort studies involve the identification of individuals characterized by exposure status and followed for the occurrence of disease after exposure. The studies tend to be much larger, and often more expensive than case–control studies, because sizable numbers of participants must be enrolled and followed to generate sufficient numbers of cases for meaningful analysis.

Cohort studies are especially useful in tracking occupational groups exposed to chemical or physical substances hypothesized to increase risk of cancer or other diseases. The hypotheses about potential risks can best be tested among groups of people with the widest range of exposure to the substance, typically workers involved in the manufacture or use of the agent. Of the over 50 compounds or processes classified as capable of causing cancer in humans following sufficient exposure (Table 1), more than half are found in occupational settings. Hence studies, typically cohort studies, among occupational groups have provided key evidence regarding whether human exposure might increase risk of cancer.

Occupational cohort studies also are of direct relevance to assessing effects of general environmental exposures. If no excess risk is seen among workers handling or otherwise heavily exposed to the agents, then it is highly unlikely that off-site exposures, generally at much lower doses, would increase risk. If an occupational excess is found, detailed study would be undertaken to characterize the risk as a function of level, timing and duration of exposure. The resultant **dose–response** trends would then be informative in predicting risks at low environmental levels. Hence, much of the information on potential effects of general environmental exposures arises from occupational studies, typically cohort studies (*see* **Occupational Mortality**).

In evaluating environmental agents with cohort studies, a key element is the measurement and classification of exposure status of cohort members. One of the strengths of a cohort study, besides its ability to ascertain a broad spectrum of health outcomes, is its ability to characterize all participants by exposure level prior to disease outcome. In principle, a prospective cohort study (where current cohort members are followed forward in time) should generally be able to obtain more reliable exposure data than a case–control study. Special problems may arise in **historical cohort studies** (where cohort members identified in the past are traced to the present) and in difficult settings where there may be imprecision of exposure assessment, including misclassification of categorical levels of exposure. In occupational studies of potentially hazardous substances, especially retrospective or historical cohort surveys where rosters of past employees are assembled, complete knowledge of levels and duration of exposure to individual workers is seldom known, even for relatively heavily studied substances. For example, asbestos is a well-known carcinogen, substantially increasing risk of lung cancer and mesothelioma when exposure levels are sufficiently high, but in nearly 50 cohort studies of various groups of asbestos-exposed workers, estimates of cumulative exposures to individual workers are available in less than a dozen, and even in those the individual estimates are based on rough approximations of presumed average airborne asbestos exposure concentrations associated with specific jobs across broad time periods [39]. Thus, some level of misclassification of exposure is bound to occur. For dichotomous categorization of exposure, if misclassification is random (nondifferential), then *on average* the **relative risks** associated with the exposure will be dampened and pulled towards the null (*see* **Bias Toward the Null**), although this is not necessarily the case when multiple categories are involved (*see* **Measurement Error in Epidemiologic Studies**). Of course, in any particular investigation, chance errors in classification could result in exaggerated as well as attenuated **relative risk** estimates.

One cohort study with relatively precise exposure estimates is the study of survivors of the atomic bombs of Hiroshima and Nagasaki. Since the early 1950s, a cohort of nearly 100 000 individuals has been tracked for mortality, and subsets have been tracked for other health outcomes [41]. Each cohort member at enrollment into the study was questioned about his/her whereabouts at the time of explosion. The event was so traumatic that nearly all individuals could recall exactly where they were and even what position they were standing in when the blast occurred. The radiation from the bombs was released almost instantaneously, so

that exposure occurred within seconds (there was little radioactive fallout). Experimental models had demonstrated that levels of gamma and neutron radiation declined exponentially as distance from the hypocenter increased and provided the basis, after taking into account shielding from metal, wooden, brick, and other structures, for estimates of radiation received for almost all cohort members. Subsequent statistical analyses have shown that rates of mortality from leukemia, breast, and several other cancers, but not nonmalignant disease, varied in proportion to radiation dose [66], and have provided a valuable base of information for the establishment of radiation safety standards worldwide.

Cohort studies of nonoccupational population groups exposed to environmental chemicals or other pollutants seldom are able to measure exposure very precisely. For example, in 1976 an explosion in a plant near Seveso, Italy, resulted in 2,3,7,8-tetrachlorodibenzo-*p*-dioxin contamination in surrounding neighborhoods. Chloracne and other reversible acute effects of exposure were observed in some residents closest to the plant, and a long-term monitoring for mortality, cancer, and other health outcomes was established. Cohorts of over 50 000 residents, classified in residential zones according to degree of potential for dioxin exposure, have been followed since. Results have been mixed, with little departure from expectations in mortality, suggested excesses of certain types of cancer, and no evidence of birth abnormalities following the contamination [4–6, 48, 60]. There have been difficulties in estimating exposure, but average exposure levels may have been below the limits of epidemiology as a tool for detecting and quantifying risks of chronic diseases in this population [17].

Other prospective cohort studies also may enable precise exposure classification for exposures occurring at the start of or during follow-up. In the **Framingham** [25, 30] and other cohorts where heart disease was the primary endpoint, measurement of blood pressure, serologic indicators, and other exposure markers could be assessed using best available methodology, and participants could be classified by baseline levels of these variables. Many of the markers are measured with error, sometimes with the particular measured value being a realization from an underlying probabilistic distribution with a large **variance**, so that even in these investigations perturbations in exposure classification can occur. Nevertheless, cohort studies have provided key information on the environmental determinants, including lifestyle factors, and disease risk. In the Framingham study, follow-up of approximately 5000 residents beginning in 1948 has demonstrated the predictive value of serum cholesterol (originally total and subsequently LDL and HDL fractions), hypertension, smoking, and dietary factors in cardiovascular disease risk [32, 64]. Other cohorts established from the 1950s classified individuals by tobacco smoking status. Reports from the US Surgeon General in a series of comprehensive US governmental monographs which unequivocally declared that cigarette smoking increases risk of lung cancer, relied heavily on results from cohorts of British physicians [28], American Cancer Society volunteers [34], US veterans [51], and other groups in reaching this conclusion.

One of the problems facing case–control studies, the potential for recall bias associated with the differential recollection of events because of the disease, is eliminated in cohort studies since the environmental exposure is determined prior to and independent of the disease occurrence.

Cohort studies also are less likely than case–control studies to be affected with selection or information biases, because the study base can often be unambiguously defined and data on all cohort members may be more readily collected in a standardized fashion (*see* **Bias in Cohort Studies**). Potential study base problems can arise, however, in situations where the cohort consists of exposed individuals whose disease experience is compared with that of an external population, for example with national rates of disease. Such comparisons are common in occupational and other cohort studies, but the resulting indices of risk (e.g. relative and **absolute risks**, standardized incidence or mortality ratios; *see* **Standardization Methods**) can be influenced by differences between the cohort and external populations other than the exposure itself. Among the 50 cohort studies of asbestos-exposed workers, for example, only a minority involved comparisons of disease rates among heavy vs. light vs. nonexposed workers, but instead usually compared the overall occupational group vs. national or local populations [39]. It is known that employed populations tend to have a somewhat more favorable mortality experience than the general population because ill and less fit individuals are less likely

to be employed (see discussion of the "healthy worker effect" in **Occupational Epidemiology**). On the other hand, some groups, especially of blue collar workers, may have higher prevalences of cigarette smokers (this is the case for heavily asbestos exposed insulation workers [35]) or have other attributes which could increase risk relative to general population norms. This problem is mitigated by use of internal comparisons by level of exposure, but even here nonexposure-related differences could confound comparisons. Thus, for example, neurologic and behavioral differences of production workers in the same facility could be related to social or other traits rather than to exposure to solvents or other chemicals.

Hence, cohort studies, like case–control studies, must take care to control for confounding in evaluations of potential adverse effects of environmental exposures. Cohort studies, however, are often at a disadvantage compared to case–control studies with respect to control for confounding. With their smaller size, case–control studies usually seek information on all known or suspected risk factors for the disease being studied. Cohort studies, on the other hand, typically with multiple disease endpoints and large number of participants, generally do not have this luxury and must limit the amount of information obtained per subject. A solution to this problem is offered by conducting case–control studies nested within cohort studies (*see* **Case–Control Study, Nested**). This approach enables detailed exposure and confounding variable assessment in samples of cohort members rather than in the entire cohort. In a cohort study of over 35 000 workers in mines and factories in Southern China, for example, broad classification of exposure to silica was obtained for all cohort members, but detailed occupational exposure, smoking, and other histories were obtained only for the nearly 300 persons with lung cancer plus about twice as many matched controls [29, 50]. The study found mixed results, suggesting a small increase in lung cancer among those with silicosis but not with silica exposure *per se*.

Cohort studies, particularly those involving a large number of lifestyle variables, can also suffer from the tendency to report on one variable at a time in a publication, as mentioned earlier when discussing case–control studies. Thus, the **multiple comparison** problem can arise in cohort studies when results are divided and described according to the least publishable unit.

Together, cohort and case–control studies provide the basis for most of what is known about the environmental determinants of human illness. Nevertheless, because of methodologic limitations these nonexperimental studies often fall short of providing sufficient evidence to determine whether exposure to a particular environmental agent can increase risk of disease. The most definitive epidemiologic evidence for determining a cause-and-effect relation can come from an experimental trial, whereby random assignment of individuals to exposed and unexposed groups mitigates against the biases that can afflict observational studies (*see* **Bias in Observational Studies**; **Bias, Overview**). Such trials are described below.

Randomized Trials

Trials involving exposure of individuals to environmental substances are ethical only when there is sufficient suspicion that the substance may lower risk of disease (*see* **Ethics of Randomized Trials**). Trials involving the evaluation of new drugs, for example, have been common and have provided the mechanism for the discovery and/or confirmation of the effectiveness of various treatments for human illness. The principles of these clinical trials also apply to the evaluation of a variety of agents that offer potential for the prevention of disease.

A number of randomized **prevention trials** have been launched, many within the past decade or so. The largest investigations have involved nutritional interventions, randomly assigning participants into groups receiving vs. not receiving certain vitamins, minerals or dietary modifications. Follow-up has typically been concurrent with the intervention, with cancer and heart disease generally the primary endpoints. In some instances the randomization unit is not the individual, but rather a group, for example, as in the one trial where communities were randomized to receive intense vs. routine educational programs aimed at smoking cessation [22] (*see* **Group-randomization Designs**). In this trial the direct endpoint was not a health outcome, but rather an exposure (cigarette smoking), which if reduced would lower subsequent disease risk. Some of the key trials in cardiovascular disease research also have involved interventions to lower exposure markers. The Multiple Risk Factor Intervention Trial, a large trial enrolling nearly 13 000 males age 35–57 at high

risk of heart disease, sought to alter several exposure (e.g. smoking), biomarker (e.g. serum cholesterol), and precursor conditions (e.g. hypertension) that increase risk of cardiovascular disease [53, 54]. Thus, intervention trials can be used to provide experimental tests both of whether increasing exposure to an environmental agent thought to reduce disease risk or decreasing exposure to an agent thought to be hazardous results in a lower risk.

The primary advantage of clinical/intervention trials over observational studies arises from randomization. The random assignment of persons to treatment groups tends to reduce differences between the groups with respect to all variables except the intervention or variables correlated with the intervention. Thus two of the main afflictions of case–control and cohort studies, namely bias and confounding, are removed. Chance is still an issue, but by choosing a sufficiently large study size for the trial, the effects of random errors can be minimized. One of the largest intervention trials involved random assignment, within strata defined by age and sex, of nearly 30 000 individuals in Linxian, China, into one of eight treatment groups [15]. The groups were defined by a one-half replicate of a 2^4 factorial experimental design (*see* **Fractional Factorial Designs**), whereby four types of vitamin/mineral supplements were being assessed as potential inhibitors of esophageal and stomach cancer in a population with one of the world's highest rates of these cancers. Cigarette smoking status, a risk factor for these cancers, was not matched for in the design, but the randomization accomplished this task. After randomization, the prevalence of smoking across the eight intervention groups varied by less than 1% [44]. Similarly, other measured differences across the treatments were all uniformly small, providing confidence that unmeasured variables were also likely to be evenly distributed by treatment, and thus bias and confounding were unlikely to affect study results.

The large vitamin/mineral intervention trials thus far have shown mixed results for the effects of supplementation on subsequent cancer or heart disease risk, despite the consistent demonstration from both case–control and cohort studies of lowered risks among persons with high intakes of foods (especially fruits and vegetables) with high contents of carotenoids, vitamin C, and other nutrients. The Linxian trial [15] found a small (13%) but significant reduction in cancer mortality following 5 years of supplements with a combination of beta carotene, vitamin E, and selenium. Large trials in Finland [2] and the US [57], however, found significantly increased, rather than decreased, risks of lung cancer among smokers supplemented with beta carotene or beta carotene plus retinol, respectively, while a 12-year follow-up of among 22 000 US physicians, few of whom smoked, found no effect of beta carotene supplementation on cancer or heart disease [37].

The beta carotene results from these trials provide a stark reminder of the limitations of the observational (case–control and cohort) studies. The vast majority of observational studies have shown lowered cancer risks, with reductions typically of 30%–50% among heavy compared with light consumers of foods rich in beta carotene [67]. Limited evidence of cancer inhibition from beta carotene studies in experimental animals provided a biologic basis for the hypothesis, and even a potential mechanism of action, in particular beta carotene's ability to quench singlet oxygen radicals. Publication in 1981 of a prominent review article [61] helped to stimulate enthusiasm for the beta carotene hypothesis and to lead to the incorporation of beta carotene in several randomized trials. The results of these trials now indicate that the enthusiasm may have been misplaced, and that correlates of beta carotene rather than beta carotene *per se* may have been responsible for the reduced risks associated with intake of beta carotene-containing foods seen in the case–control and cohort studies. This unfolding of events suggests that caution be applied in the interpretation of case–control or cohort studies linking various environmental exposures with disease risk, and heightens the necessity for careful assessment of bias, confounding, and chance before etiologic interpretations are offered, especially since few environmental exposures will be able to be evaluated via randomized intervention trials.

Epi Info

Epi Info is a free software originally developed by the US **Centers for Disease Control** (CDC) and further developed from a collaboration between the CDC and the **World Health Organization**. It was originally developed as a DOS-software but a Windows version has been available since 2002. Epi Info is devoted to the design and analysis of epidemiologic studies. It has several functions for performing basic **sample size** calculations, developing a study **questionnaire** and creating a **database**, helping with data entry and checking (*see* **Data Management and Coordination**), performing statistical analysis, and displaying study data on maps (*see* **Statistical Map**) and graphs. Whereas its capabilities are extensive regarding questionnaire development, data entry, and checking, its analytical capabilities are more limited. Complex survey analysis (*see* **Sample Surveys in the Health Sciences**) and **logistic regression** can be performed in Epi Info 2002 for Windows. The software can be downloaded from the Epi Info web site (`http://www.cdc.gov/epiinfo/`). Epi Info is a widely known and used software worldwide. According to information on the web site, over 280 000 downloads of Epi Info had been documented in 2001 (one million according to an update in 2003) and the manual had been translated from English into 13 additional languages.

Epicure

Epicure is a DOS-based commercial software, produced by HiroSoft International Corporation (`http://www.hirosoft.com`). It is devoted to the analysis of epidemiological and biomedical studies. It is structured as a package of five programs, GMBO, PECAN, PEANUTS, DATAB, and AMFIT. It allows users to perform some data editing (*see* **Data Management and Coordination**; **Clinical Trials Audit and Quality Control**). Its main strength is its fairly extensive analytical capabilities. They include **linear** and **nonlinear regression**, unconditional and conditional **logistic regression**, **Poisson regression**, and semiparametric and parametric **survival analysis**, through the use of the programs, GMBO, PECAN, PEANUTS, and AMFIT. Moreover, Epicure allows additive and multiplicative versions of regression model forms (*see* **Relative Risk Modeling**) and a number of unique alternative and generalized forms, as well as an easy creation of **person-year** tables through the use of the program DATAB, and a fairly advanced standardized mortality ratio analysis (*see* **Standardization Methods**) with the program AMFIT. Being a DOS-based program, Epicure may have a slightly steeper learning curve than Windows-based programs, although it is not particularly difficult to use. No **sample size** calculations are available, although the developers of Epicure have produced a free, separate program, "Power", that can be downloaded from the website of the US National Cancer Institute's Division of Cancer Epidemiology and Genetics (`http://dceg.cancer.gov`) and can be easily used for tests of **interaction**, a rare feature in sample size calculation programs.

Epidemic Curve

An epidemic curve is a plot of time trends in the occurrence of a disease or other health-related event for a defined population and time period. The epidemic curve can help to demonstrate that the events are in excess of what would be expected based on past experience [4]. Time intervals are indicated on the x-axis and the event rate is shown on the y-axis. The event rate may measure the number of cases per unit time (e.g. cases per day or year), or it may express the numbers of events relative to the number in the study population (cases per 100 000 person–years). The latter **incidence rates** may be age-adjusted (*see* **Standardization Methods**).

Historically, the epidemic curve has been widely used by infectious disease epidemiologists to document the scope and duration of an epidemic, to help determine the source of the infection and the modes of transmission or exposure, and to glean information about the **incubation period** of the disease [6]. Epidemic curves are used in other settings to document the scope of public health problems.

Example 1 An estimated 224 000 persons nationwide became ill with salmonellosis during 1994 after eating a nationally distributed brand of ice cream that was contaminated with *Salmonella enteritidis* [5]. Epidemic curves for Minnesota, an epicenter of the outbreak, and for the entire US helped to determine that the outbreak occurred during September and October of that year as a result of contamination that occurred between mid-August and mid-October.

Example 2 The number of **AIDS** cases in the US exhibited exponential growth during the early 1980s, followed by a slowing of the rate of increase beginning in mid-1987 [2]. This pattern likely reflects a decline in the number of new HIV infections compared with peak infection rates in the mid-1980s.

Example 3 Age-adjusted lung cancer death rates per 100 000 men in the US climbed 15-fold between 1930 and 1990 [7], a result of trends in tobacco consumption during earlier decades [3] (*see* **Smoking and Health**). The epidemic curve is expected to decline in the US as a result of smoking cessation [3]; but epidemiologists predict a rising epidemic curve for tobacco-related deaths in the next century among Chinese men, as a result of their recent increase in cigarette smoking [8].

While it is reasonable to speak of an "epidemic" of violent death or of specific neoplastic diseases (Example 3), analysis of the epidemic curve is currently most refined in the field of infectious disease epidemiology.

In a *common source outbreak*, susceptibles are exposed to a pathogen about the same point in time (Example 1). In this type of outbreak the resulting epidemic curve tends to be relatively short and sharp, as the cases distribute according to the incubation period of the disease. With food-borne outbreaks, a point source of exposure is sometimes identified from the case reports and the pathogen may be recognized from the observed incubation period. In a *propagated* or *progressive outbreak*, cases result from person-to-person transmission, often yielding a broader epidemic curve (Example 2).

Statistically, if the infection curve is known, one can estimate the distribution of the incubation period from the observed epidemic curve [1]. Conversely, if the incubation period is known, one can estimate the infection curve from the observed epidemic curve (*see* **Back-calculation**). To avoid bias, it is essential that the epidemic curve be constructed using a well-defined case definition and that surveillance for the event is as complete and consistent as possible. In practice, the case definition may include both clinical and epidemiologic criteria [9].

PHILIP S. ROSENBERG

Epidemic Models, Control

The main reason for studying mathematical models of disease spread must surely be the hope that improved understanding of the transmission processes may lead to more effective control strategies.

In the literature on mathematical modeling (whether deterministic or stochastic) of infectious disease spread, there have been essentially two approaches to epidemic control (*see* **Epidemic Models, Deterministic**; **Epidemic Models, Stochastic**). These are (a) to intervene in such a way as to reduce the basic reproduction ratio R_0 to below (*see* **Reproduction Number**) 1; and (b) to define explicit costs of intervention and of infection and choose the intervention policy which minimizes the expected total cost. In either case, there are a variety of possible forms of intervention that may be considered, including vaccination of susceptible individuals, isolation of infective individuals from the susceptible population, or interventions (such as public education campaigns) aimed at reducing the rate of contact between infectives and susceptibles.

A third approach that has been suggested more recently is that of *contact tracing*. This may be regarded as a variant of (a) above, in which individuals to be vaccinated are chosen not at random, but rather by tracing potential infectious contacts made by known infected individuals.

Threshold-based Intervention

Much work has concentrated upon vaccination strategies aimed at reducing R_0 to below 1. The motivation for this is provided by threshold theorems such as that of Kermack and McKendrick [8], which tell us that if $R_0 < 1$, then a major epidemic is not possible; only a minor outbreak can occur (*see* **Epidemic Thresholds**). To be more specific, consider a particular model for disease spread. The most commonly used continuous time stochastic model, sometimes referred to as the general stochastic **SIR** (Susceptible – Infective – Removed) epidemic, is defined as follows.

For $t \geq 0$, denote by $X(t)$, $Y(t)$, $Z(t)$ the numbers of susceptible, infective, and removed individuals, respectively, in the population at time t. The population is supposed closed, so that total population size $X(t) + Y(t) + Z(t)$ remains constant over time. Thus, the process is completely described by $\{(X(t), Y(t)) : t \geq 0\}$, which is taken to be a continuous time **Markov chain** with infinitesimal transition probabilities

$$\begin{aligned}\Pr(X(t+\delta t) = x-1, Y(t+\delta t) = y+1 \mid X(t) \\ = x, Y(t) = y) = \beta x y \delta t + o(\delta t), \\ \Pr(X(t+\delta t) = x, Y(t+\delta t) = y-1 \mid X(t) \\ = x, Y(t) = y) = \gamma y \delta t + o(\delta t), \qquad (1)\end{aligned}$$

where β is the infection rate parameter and γ the removal rate parameter.

For the general SIR model, the basic reproduction ratio is given by $R_0 = \beta X(0)/\gamma$, so that (by the threshold theorem) major outbreaks are only possible if $X(0) > \gamma/\beta$. If $R_0 > 1$, then in order to prevent a major outbreak, we must vaccinate at least a proportion $\theta = 1 - (1/R_0)$ of the susceptible population, so that the vaccinated population has reproduction ratio $R_0' \leq \beta(1-\theta)X(0)/\gamma = 1$.

For more complicated models, such as those featuring nonhomogeneous contact structure between individuals, reducing R_0 to below 1 can be a more challenging problem. It may not be merely a matter of calculating how many susceptibles to vaccinate, but also of deciding which particular individuals should be vaccinated. For instance, Ball et al. [4] define (*inter alia*) a stochastic model for the spread of infection through a population consisting of a large number of households, the rate of infectious contact being greater between individuals within the same household than between individuals in distinct households. In [4], it is conjectured (and proved in certain particular cases) that the policy that requires the least number of vaccinations in order to reduce the value of its threshold parameter $\tilde{R}_0$ to below 1 is the *equalizing strategy* of vaccinating in such a way as to leave the remaining numbers of susceptibles in each household as nearly equal as possible.

Contact Tracing

Usually, vaccination models suppose that the individuals to be vaccinated will be chosen at random, whether from the entire population or from particular groups within the population. An alternative approach is via *contact tracing*. One now attempts to identify infectious contacts of each known infected index case, targeting the vaccination effort toward

such contacted individuals. Such an approach has been suggested for STDs, tuberculosis, and infections spread by needle sharing ([12] and references therein). The advantage is that vaccinations are targeted at those most in need. The disadvantage is that tracing such individuals may be costly and time-consuming, so that the total number of vaccinated individuals at any time will be smaller than under a mass vaccination strategy; furthermore, vaccinations might be better directed to protect those who have not yet been contacted.

There has been particular interest recently in whether mass vaccination or targeted vaccination based on contact tracing would be more effective in combating a bioterrorist smallpox attack. The possibility of combining the two approaches has also been considered, either with targeted vaccination in the early stages of an epidemic, switching to mass vaccination if the number infected grows beyond a certain point, or alternatively, mass vaccination applied to a certain proportion of the population prior to any outbreak, with further targeted vaccinations once an outbreak begins.

The conclusion as to which method is more efficient is found to depend upon the particular modeling assumptions, such as whether a continuous population or discrete individual model is used, how one allows for the time taken to carry out vaccinations, and whether the population is assumed to mix homogeneously or in some more structured way ([9] and references therein). The importance of realistic models, and of considering a variety of models capturing different aspects of the reality, is thereby vividly illustrated.

Control Theoretic Approaches

For practical implementation, the approach of vaccinating susceptibles so as to reduce R_0 to below 1 has the great advantage of simplicity. However, such an approach does not make explicit the costs of infection or of intervention. One effectively assumes that prevention of a major epidemic is worth any cost, whereas intervention that does not prevent a major epidemic is worthless, even if the spread of infection is reduced. Thus, for instance, a policy of isolating some infectives from the susceptible population, which clearly will tend to decrease the spread of infection, nevertheless, has no effect upon the value of R_0.

A more thoroughgoing approach to epidemic control can be provided through mathematical control theory. When adopting such an approach, it is necessary to set out explicitly the costs of intervention and of infection. One then aims to find the intervention policy which minimizes the expected total cost. A comprehensive review of applications of control theory to infectious disease models up to 1977 is given in [14].

Isolation of Infectives

To give a specific example, we return to the general stochastic SIR epidemic described above. For this model, Abakuks [2] considered a form of intervention, which allows for the instantaneous isolation of any number of infective individuals from the susceptible population. The cost of disease spread was taken to be proportional to the number of individuals infected during the epidemic, while the cost of intervention was taken proportional to the number of infectives artificially isolated.

Suppose that at time t the epidemic is in state $(X(t), Y(t)) = (x, y)$. Then one must decide whether to isolate a single infective, or do nothing until the next natural transition occurs. (Isolation of several infectives can be achieved by repeatedly choosing to isolate single infectives.) Take the cost of an individual being infected to be the unit of cost; denote by L the cost of isolating one infective, and denote by $V(x, y)$ the expected total future cost of adopting an optimal policy. Then for $x, y \geq 1$, the expected future cost of waiting until after the next natural transition, and adopting an optimal policy from then on, is given by

$$W(x, y) = \frac{\beta x}{\beta x + \gamma}(1 + V(x - 1, y + 1)) + \frac{\gamma}{\beta x + \gamma} V(x, y - 1). \quad (2)$$

The expected future cost of isolating an infective immediately, then adopting an optimal policy, is $L + V(x, y - 1)$. The optimal policy is to take whichever of the above two actions results in the smaller expected cost, and so the expected cost of such a policy is

$$V(x, y) = \min\{W(x, y), L + V(x, y - 1)\} \quad (x, y \geq 1). \quad (3)$$

Equations (2) and (3) are the Bellman optimality equations for this system (*see* **Dynamic Programming**). Together with the boundary conditions $V(x, 0) = 0$ for $x \geq 0$ and $V(0, y) = 0$ for $y \geq 0$, the Bellman equations may be recursively solved to determine the cost function $V(x, y)$ and the optimal policy itself. From (2) and (3), it was shown in [2] that the optimal isolation policy takes the following simple form. For each $x \geq 0$, there exists an integer $s(x) \geq 0$ such that the optimal policy is to isolate *all* infectives if $1 \leq y \leq s(x)$, but to isolate none otherwise. Furthermore, $s(x + 1) \geq s(x)$ for $x \geq 0$. So if an epidemic starts from a state (x, y) with $y \leq s(x)$, then the optimal policy immediately isolates all infectives, thereby terminating the epidemic; on the other hand, if $y > s(x)$, then the epidemic is allowed to proceed unimpeded until the first time that $Y(t) \leq s\,(X(t))$, at which point the epidemic is terminated by the isolation of all infectives.

The intervention considered in [2] is of *impulse* type, meaning that intervention causes an instantaneous change in the state of the system. An alternative to this is intervention to change the *rate* at which transitions occur. For instance, for the general stochastic SIR epidemic Wickwire [13] considers intervention to increase the removal rate parameter at time t from γ to $\gamma + v(t)$ $(0 \leq v(t) \leq 1)$. The cost of infection is taken equal to the time spent in an infectious state by all individuals during the course of the epidemic, $\int_0^\infty Y(s)\,\mathrm{d}s$, while the cost of intervention is taken to be proportional to $\int_0^\infty v(s)Y(s)\,\mathrm{d}s$, so that the total expected cost is

$$E\left[\int_0^\infty (1 + hv(s))Y(s)\,\mathrm{d}s\right] \tag{4}$$

for some constant h.

The expected cost $V(x, y)$ of an optimal policy starting from state (x, y) then satisfies the Bellman equations

$$V(x, y) = \min_{v \in [0,1]} \frac{\begin{array}{c}(1 + hv) + \beta x V(x - 1, y + 1) \\ +(\gamma + v)V(x, y - 1)\end{array}}{\beta x + \gamma + v} \qquad (x, y \geq 1). \tag{5}$$

An analysis of (5) allows Wickwire [13] to show that the form of the optimal policy is as follows:

If $h\gamma \leq 1$ then take $v = 1$ for all (x, y) with $x, y \geq 1$.

If $h\gamma > 1$ then for each $x \geq 1$ there exists an integer $\tilde{s}(x) \geq 0$ such if $1 \leq y < \tilde{s}(x)$ then take $v = 1$, if $y \geq \tilde{s}(x)$ take $v = 0$.

The optimal policy is thus of *bang-bang* type; that is, the value of v is always taken to be either 0 or 1, never any intermediate value. Notice that this policy is of the same form as the optimal impulse control policy of [2]. In each case, if the number of infectives y lies above some boundary then we intervene to isolate infectives as rapidly as possible; if the value of y lies below the boundary, we do not intervene.

In the examples above, the spread of infection is reduced by isolation of infective individuals from the susceptible population. One could alternatively intervene by immunizing susceptible individuals, or by reducing the rate of contact between susceptible and infective individuals.

Immunization

Policies which allow the instantaneous immunization of susceptible individuals are studied in [1]. Equations corresponding to (2) and (3) can be written down and solved recursively just as for isolation policies, but the structure of the optimal policy proves somewhat more complicated. For this reason, in [3] attention is restricted to total immunization policies, in which the only possible intervention is to immunize all x susceptibles simultaneously, at cost $A + Kx$. In this case it is found that for each $x \geq 0$ there exists an integer $t(x)$, $0 \leq t(x) \leq \infty$, such that the optimal policy is to immunize all susceptibles if $y > t(x)$, but not otherwise.

Alternatively, one may allow for immunizations at a finite rate. Some results for this problem are outlined in [14]. The transition rates of the general stochastic SIR epidemic are now modified by allowing additional transitions $(x, y) \to (x - 1, y)$ to occur at rate $u(t)$, where the value of $u(t)$ is to be chosen in $0 \leq u(t) \leq 1$. Higher values of $u(t)$ incur higher costs, but reduce the spread of infection. A cost function similar to (4) can be written down, and Bellman equations corresponding to (5) derived. The structure of the optimal policy is found to be of similar form to the impulse control of [1].

Deterministic Models

Although our discussion so far has been based on stochastic models, similar considerations apply when

dealing with deterministic models. As an illustration, consider the general deterministic SIR epidemic. This is described by the differential equations

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -\beta xy, \frac{\mathrm{d}y}{\mathrm{d}t} = \beta xy - \gamma y, \tag{6}$$

where $x(t)$, $y(t)$ denote, respectively, the numbers of susceptible and infective individuals in the population at time t. We can, for instance, control the spread of infection by increasing the removal rate parameter from γ to $\gamma + v(t)$, where $0 \leq v(t) \leq 1$. This control problem has been studied in [13], where the total cost was taken to be $\int_0^\infty (1 + kv(s))y(s)\,\mathrm{d}s$. As for the corresponding stochastic problem, it is found that the optimal control is of bang-bang type; that is, $u(t)$ should always be taken to be either 0 or 1.

Extensions

In the above examples, quite simple cost functions have been used, as much for mathematical convenience as from considerations of realism. Consider first the cost due to infection. In [1, 2, 3], this was taken to be proportional to the number of individuals becoming infected, whereas in [13], it was taken to be proportional to the total time spent in an infectious state by all individuals during the epidemic. (If we assume that infectious individuals are those displaying symptoms and unable to work, then this latter cost function has an economic interpretation as the number of hours work lost due to the infection.) More generally, the cost due to infection could be some more complicated function of the number of individuals to become infected and of the time spent in the infectious state. Other possible contributions to the cost function include the total duration of the epidemic and the maximum number of infectives to be present at any time during the epidemic.

Secondly, consider the cost of intervention. For impulse control policies, this can most simply be taken proportional to the number of individuals isolated, or vaccinated, but in general, could be some more complicated function of the number of interventions. When we intervene by altering the rates of transitions, for instance, by increasing the removal rate parameter from γ to $\gamma + v(t)$, then the cost due to intervention could reasonably be taken proportional to either $\int_0^\infty v(s)\,\mathrm{d}s$, or $\int_0^\infty v(s)Y(s)\,\mathrm{d}s$. More generally, the cost due to intervention could be taken as $\int_0^\infty f(v(s))\,\mathrm{d}s$ or $\int_0^\infty f(v(s))Y(s)\,\mathrm{d}s$ for some nondecreasing function $f(v)$.

In practical applications, it is clearly important to ensure that the cost function used reflects the reality of the situation. This may well be difficult to achieve. Quantification of the cost of intervention, while not entirely trivial, seems relatively straightforward; quantification of the cost due to infection seems much more problematic, particularly for serious diseases. However, for nonserious infections it seems reasonable to express the cost of infection in terms of the number of working hours lost. For infections of livestock, the cost of any infection can be taken to be the monetary cost to the farmers involved. A further difficulty is that if the cost function is not sufficiently simple, then the mathematics required in order to evaluate an optimal policy analytically may well prove intractable.

For more complicated models than the general stochastic SIR epidemic, finding an optimal policy can be considerably more difficult. However, some progress has been made for various specific models. For instance, for models of SIR type, with infection rate $\beta(x, y)$ in place of βxy and removal rate $\gamma(x, y)$ in place of γy, Clancy [6] found conditions on the functions $\beta(x, y)$ and $\gamma(x, y)$ under which the results of [2], [3] for the general stochastic SIR epidemic still apply. Kyriakidis [10], [11] considered adapting the results of [2], [3] to a model for two competing diseases. Greenhalgh [7] investigated isolation policies for a model in a heterogeneous population, in which the contact rate between a pair of individuals depends upon the particular individuals involved.

For practical implementation, there remain substantial difficulties with the use of optimal control theory. First, one must specify an appropriate cost function; then the optimal policy must be found, which is often a nontrivial problem; finally, implementation of the optimal policy may be difficult, since one must keep track of the numbers of susceptible and infected individuals in the population at all times. Even if taking the simpler approach of reducing R_0 to below 1, practical problems remain. One must take account of the fact that vaccines are generally not 100% effective. The true values of parameters such as β and γ are not known, but must be estimated from data. In a control theoretic context, the issue of estimating parameter values has been addressed in [5].

For the time being, and for more serious infections whose cost is not easily quantified, the more simple-minded strategy of aiming to reduce R_0 to below 1 appears to remain the more practical approach. However, for nonserious infections or for diseases of livestock, when the cost of infection can reasonably be measured in economic terms, the control theoretic approach should ultimately lead to control policies which explicitly take into account the relative costs of infection and of intervention. The mathematics involved in evaluating such optimal policies for realistic models for specific diseases is, however, quite involved, and much remains to be done.

DAMIAN CLANCY

Epidemic Models, Deterministic

In this article we review some of the approaches, both standard and recent, to the theory of deterministic epidemic models. By deterministic we mean that one considers populations consisting of sufficiently many well-mixed individuals. At the level of the individuals, however, we do consider processes such as infection and the individual course of infection to be stochastic events. What separates the deterministic models from the approach taken in stochastic epidemic models (*see* **Epidemic Models, Stochastic**) is that we invoke a **law of large numbers** argument to lift these individual stochasticities to population determinism.

There are many ways in which an article like this could be structured. We have chosen to use four concrete infections as stepping-stones to review current issues in epidemic modeling and the types of deterministic model employed and questions studied. These infections are measles, malaria, helminths, and HIV, respectively, reflecting the order in which they were important historically in shaping epidemic theory. Of course, many of the models discussed under these headings are used in a great variety of settings and there is a certain degree of arbitrariness in the place in which they occur here. We do not intend to provide detailed mathematical results, but on the contrary stress the evolution of the subject and the practical problems faced. Our main aim is to point the interested reader to more advanced literature.

The current issues in epidemic modeling – both stochastic and deterministic – are illustrated in the recent review books by Mollison [42], Isham & Medley [33] and Grenfell & Dobson [20]. In these most of the issues touched on below are discussed and reviewed extensively. For a review of the recent mathematical deterministic theory, see [13].

Measles

As in stochastic epidemic modeling, the diseases that sparked the development of modern deterministic theory are the childhood infections, most notably measles. This arises predominantly from their large public health importance in the late nineteenth and early twentieth centuries. In late nineteenth century England a sophisticated system of **vital statistics** had been initiated by **William Farr**, and data series became available that were both reliable enough and long enough to generate hypotheses about the possible mechanisms underlying epidemic spread. It should be noted that the germ theory of infection became firmly established only after the 1880s. Germ theory is the notion that certain diseases are caused by living organisms multiplying within the host and capable of being transmitted between hosts.

The most striking aspect of measles epidemics, i.e. their regular cyclic behavior, was noticed first by Arthur Ransome around 1880. Speculation about the underlying cause centered around the availability of sufficiently many susceptible individuals of the right age-class in close enough proximity to each other. Early shimmers of the modern notion of critical community size for sustaining endemic measles [4, 5] were also present. Two factors that commonly occur in many current models to investigate epidemic spread of measles and other infections are the importance of age-structure and of periodicity in contacts. The age and school season were recognized as important as early as 1896 [25].

Against this background it was William Hamer who published a discrete time epidemic "model" for the transmission of measles [26]. The mathematical rendering was later given in [52]. Hamer's observation can be reformulated as stating that the incidence of new cases in a time interval is proportional to the product SI of the (spatial) density S of susceptibles and the (spatial) density I of infectives in the population. This assumption of mass action – in analogy to its origin in chemical reaction kinetics – is fundamental to the modern theory of deterministic epidemic modeling (*see* **Random Mixing**). When densities are constant and one would like to express the incidence in terms of numbers of individuals, the incidence is proportional to SI/N, where N is the total population size [9].

The popularity of mass action is explained because of its mathematical convenience and the fact that at low densities it is a reasonable approximation of a much more complex contact process. At higher densities it grossly overestimates contact opportunities. As a side remark we note that Frost and Reed in 1928 recognized for measles that although multiple contacts of infectives with the same susceptible can occur, this susceptible can become infected

only once. This led them to develop the stochastic Reed–Frost model that does not have this particular problem (*see* **Chain Binomial Model**). Incidentally, this problem with mass action had already been solved by P.D. En'ko long before it was introduced. He studied a model for measles transmission that is very similar to the Reed–Frost approach (see [14]). For a comparison between all approaches, see Dietz & Schenzle [16].

Currently, expressions like $\beta C(N)SI/N$ are frequently used for the incidence, where $\beta C(N)$ gives the successful contacts per unit of time for a given infective. A fraction S/N of these contacts will be with a susceptible in a homogeneously mixing population. The function $C(N)$ is taken to saturate with increasing density, reflecting the fact that contacts take time and moreover satiation occurs (think of sexual contacts and insect vectors taking blood meals; see, for example, [28], [53]). A standard compartment model for infection transmission with a **latent period** and lasting immunity (a so-called SEIR model) is

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \mu N - \beta C(N)\frac{SI}{N} - \mu S, \tag{1}$$

$$\frac{\mathrm{d}E}{\mathrm{d}t} = \beta C(N)\frac{SI}{N} - (\sigma + \mu)E, \tag{2}$$

$$\frac{\mathrm{d}I}{\mathrm{d}t} = \sigma E - (\gamma + \mu)I. \tag{3}$$

An equation for R is superfluous here since $N = S + E + I + R$ is constant in this model. A very large number of variants of this model – usually denoted by strings of S, E, I, and R – are studied in the literature for a large number of different infections. In most cases this entails analysis of the dynamic behavior with practical applications to problems concerning control of the infection (see [31] for a brief review of this area). Examples of important extensions are introducing an additional death rate due to the disease, loss of immunity with re-entering of the S-class, a birth rate directly into the infective class (vertical transmission) (see [7] for all of these), density-dependent demography, and of course heterogeneity which we will discuss later. In [34] a comprehensive treatment of the mathematical theory of compartmental systems is given. Whether certain possible additions matter depends partly on the time scale of the phenomenon one is interested in. For example, on the time scale of individual epidemic outbreaks, the population can often be regarded as being in a demographic steady state (see [12]), and the inflow of new susceptibles can often be neglected in a short enough period (closed population). Useful results include the so-called final size equations for closed populations. These relate the initial size S_0 of the susceptible population to the basic **reproduction number** R_0 (see below) and the size $S(\infty)$ of the susceptible population that remains after the epidemic has come to an end. Both S_0 and $S(\infty)$ might be observable in practical situations or estimated from population data. Estimates of R_0 can then be obtained from a final-size relation. In the case of system (1)–(3), with $C(N) = N$ (mass action) and disregarding latency (i.e. $\sigma \to \infty$), we obtain

$$\ln\frac{S(\infty)}{S_0} = R_0\left[\frac{S(\infty)}{S_0} - 1\right]. \tag{4}$$

One of the many present-day approaches towards understanding the dynamics of measles epidemics (see [6] for a review) is to include a periodic forcing $\beta(t) = b_0[1 + b_1 cos(2\pi t)]$ in the contact rate of compartmental models to mimic the increase in successful contact opportunities during school seasons (see [21]). The dynamics of these models have been extensively studied (see, for example, [49], [51]) and compared with data. Detecting nonlinearity and **chaos** from stochastic effects in data of recurrent epidemics is an important theme in this area [17].

In contrast to seasonal contact rates – that are studied in only a few other settings (see malaria section below) – the incorporation of age structure is relevant to almost all important human infections (see [3], [7]). Age-structured models come in discrete age-class systems of differential equations and continuous age systems of partial differential equations [54]:

$$\frac{\partial S}{\partial t} + \frac{\partial S}{\partial a} = -\mu S - \lambda S, \tag{5}$$

$$\frac{\partial I}{\partial t} + \frac{\partial I}{\partial a} = -\mu I + \lambda S - \gamma I, \tag{6}$$

$$\frac{\partial R}{\partial t} + \frac{\partial R}{\partial a} = -\mu R + \gamma I, \tag{7}$$

with

$$S(t,0) = \int_0^\infty b(a)N(t,a)\ \mathrm{d}a,\ \ I(t,0) = R(t,0) = 0, \tag{8}$$

and appropriate initial conditions. The so-called *force of infection* $\lambda(t)$ is defined by

$$\lambda(t) = \int_0^\infty k(a')I(t, a')\,\mathrm{d}a'. \tag{9}$$

Often the force of infection depends on the age a of the susceptible with the kernel $k(a')$ replaced by $k(a, a')$ to reflect the different mixing patterns of individuals of different ages. Extensions of models like this have been compared with data for measles, notably by Schenzle [50], and showed remarkable accuracy even in following the shift in trend after vaccination was implemented. Mathematical theory centers around dynamic behavior and stability criteria for endemic steady states for various variants of this model (see [32]).

One of the applied issues in studying age-structured models is to predict the effects of changes in vaccination strategies [18] (*see* **Vaccine Studies**). For childhood infections not all strategies of vaccinating children at various ages can result in eradication of the infectious agent from the population. For this to occur the basic reproduction number R_0 has to be less than 1 in a population where the distribution with respect to age and vaccination status is in a demographic steady state. The basic reproduction number is one of the central notions of epidemic theory. It is defined as the expected number of secondary cases caused by a single infective in a susceptible population that is in a demographic steady state. For modern theory of calculating R_0 for infections in heterogeneous populations (see [11], [27]). Consider system (5)–(9). Let the stable age distribution be given by $S(a) = S_0 e^{-ra}\mathcal{F}_d(a)$, where r is the intrinsic **population growth** rate and $\mathcal{F}_d$ is the survival function. One can show that

$$R_0 = S_0 \int_0^\infty k(a)\mathrm{e}^{-ra}\mathcal{F}_d(a)\,\mathrm{d}a. \tag{10}$$

In the article on **Reproduction Number** a relation is given for the fraction of the population that needs to be vaccinated in order to assure eradication:

$$\nu > 1 - \frac{1}{R_0}. \tag{11}$$

If we vaccinate a fraction ν at birth, then we have a susceptible population of size $S_0(1-\nu)$ and the relation is the same as above with R_0 given by (10).

Optimal vaccination policies can also take economic considerations into account using similar methods (see, for example, [24], [43]).

These models have shown that some vaccination strategies in use can have unforeseen detrimental effects in a population (see [3], for exposition and review). If fewer susceptibles are around in certain age-classes as a result of vaccination, then the average age at acquiring infection will rise. For infections such as rubella, complications can arise when the infection is contracted for the first time during pregnancy. This leads to the situation where even though rubella prevalence can decrease due to vaccination, the number of serious complications can increase as a result. It is in this type of application for childhood infections that age-structured models and their analysis have provided important epidemiologic insight that might otherwise have been difficult to obtain.

Malaria

Independently from Hamer, Ronald Ross in 1911 introduced the mass action idea in continuous time in his study of the transmission of malaria [46]. Ross's work in subsequent years (see [47]) qualify him as the true founding father of modern epidemic theory. It was partly under his influence that **Anderson McKendrick** started his own studies into the mathematical modeling of epidemic phenomena, initially also in the context of malaria and other tropical infections. His series of papers with Kermack from 1927 onwards, see below, is regarded as the foundation upon which much of modern theory rests. The papers have recently been reprinted [36].

One of the distinguishing characteristics of malaria is that the protozoan parasite is indirectly transmitted between humans by mosquitoes. Several important human infections depend on similar vectors for their transmission. For modeling this brings about a new problem in that the population dynamics of the vector have to be described. A simple model capturing the essentials is (see [3])

$$\frac{\mathrm{d}x}{\mathrm{d}t} = ab\frac{M}{N}y(1-x) - \gamma x, \tag{12}$$

$$\frac{\mathrm{d}y}{\mathrm{d}t} = acx(1-y) - \mu y, \tag{13}$$

where x and y are the fractions of infected humans and mosquitoes, respectively, and where M/N is the

number of (female) mosquitoes per human host in an infection free steady state. Common extensions in a similar vein are seasonality in vector emergence and the incorporation of heterogeneity in the human population. The basic reproduction number for the above model is given by

$$R_0 = \frac{M}{N}\frac{a^2bc}{\gamma\mu}. \tag{14}$$

Since the work of Ross and notably Macdonald [38], eradication campaigns have been aimed at controlling the mosquito population strongly enough to achieve $R_0 < 1$. With the emergence of both vector resistance to chemical control and parasite resistance to drug treatment malaria is regaining its strength as arguably the most severe infectious disease of man.

There has been much debate over the possibility of eradicating malaria by vaccination. We have seen that the minimum proportion of hosts that must be vaccinated to prevent a disease from establishing, or to eradicate it when present in the population, is $1 - 1/R_0$. Estimates of $R_0 > 80$ based on the age at first infection would then imply that eradication by vaccine would be a hopeless task. However, Gupta & Day [22] have suggested that malaria could be composed of several strains, each of which confers strain-specific lifelong immunity. This observation is consistent with sero prevalence data obtained from the Gambia. The age at first infection would then be

$$A = \frac{L}{\sum_j R_0^j}, \tag{15}$$

where the R_0^j are the basic reproduction numbers of the individual strains, and L is the life expectancy of the host. The proportion that must be vaccinated is then $1 - 1/\max(R_0^j)$. As max (R_0^j) could be in the range 5–10 this analysis implies that the eradication of malaria by vaccination could be a feasible proposition. See Saul [48] for a critique of this theory.

One of the most important outstanding issues in malaria and in many other infections is to understand the phenomenon of acquired immunity. Here, an individual's immune level to disease rises with frequent reinfection. It is unclear how this should be modeled mathematically. An infection pressure in the vector population gives rise to a distribution of initial doses of infection that a human receives. The infectious output towards biting mosquitoes of a given infected human is the result of a complex battle with the immune system. This output distribution then feeds back into the population. Currently the word immunoepidemiology is used to signify an area of modeling that tries to link both immunologic processes within individual hosts with epidemiologic processes of transmission between hosts. Given the implications that this interaction between immunity and epidemiology has for control strategies that affect the build-up of natural immunity, this area is likely to see much activity by epidemic modelers in the near future.

Helminths

Chronologically speaking, the tropical helminth infections such as schistosomiasis are the next step in the genesis of epidemic theory. Early work by Kostitzin in 1934 was followed 30 years later by Macdonald's study of schistosomiasis [39] and a flourishing of activity in the 1970s and 1980s (see [3] for a review).

A major difference between microparasites and macroparasites is that the former reproduce rapidly within the host, whereas the latter reproduce by releasing infective stages into the environment, which eventually complete a life cycle and (re)infect hosts. Hence, for infections caused by parasitic helminths the compartment models that classify a host as susceptible, infectious, etc. become inappropriate, and a model that allows multiple infections is required. A second problem then presents itself. The notion that the pool of susceptibles diminishes during the course of an epidemic does not necessarily hold, differential equation models no longer have a negative feedback mechanism that is automatically incorporated, and careful attention must be paid to the mechanisms that regulate the parasite population. Early models for parasites of wild animals [1] included increased mortality of the host due to parasitic infection, therefore heavily parasitized hosts had a short life expectancy, and upon dying removed large numbers of parasites from the system. For many helminth infections of humans this would not be the case, and cognisance must be taken of regulatory mechanisms such as acquired immunity.

A simple model for the dynamics of a parasitic helminth in a population of constant size would be

$$\frac{\mathrm{d}M}{\mathrm{d}t} = \mu(Q(M) - 1)M, \tag{16}$$

where M is the mean number of parasites per host, μ is the loss rate of parasites from the system and $Q(M)$ is the ratio of parasite transmission rate to loss rate. This model could stand as a prototype for many similar formulations to be found in [3] and other sources, and would be appropriate where host immunity was a function of current mean parasite burden. Hence Q is a positive nonincreasing function of M, at steady state $Q(M) = 1$, and the parasite population can persist whenever $Q(0) > 1$.

The number $Q(0)$ is the basic reproduction number (ratio, quotient) for the parasite population. It may be defined as the expected number of offspring of a typical parasite that reach reproductive maturity, in a completely susceptible host population [2]. Hence, whereas for microparasites the reproduction number is defined in terms of secondary infections of hosts, for macroparasites it is defined in terms of the parasite population dynamics. This definition has been formalized in Heesterbeek & Roberts [29].

The model presented above incorporates simplistic expressions for parasite transmission and host immunity. Many helminth parasites have complicated development stages outside the definitive host that must be modeled explicitly. For example, cestode parasites are tapeworms, with an obligatory intermediate host and transmission maintained by a carnivore–herbivore relationship (see [45]). The dominant feedback is provided by immunity to the larval stage acquired by the intermediate host. For trematodes, such as the parasites that cause schistosomiasis, there is an obligatory two host cycle (for example human/snail) with a free-living stage, and immunity to superinfection is acquired by the definitive host.

Immunity acquired against adult helminth parasites may be stimulated by larvae (hence challenge) or adult parasites, and may act against larvae by protecting the host from further infection, against adult parasites by increasing their rate of mortality, or against continued transmission by reducing their egg output. A theoretical framework for these mechanisms has been developed by Woolhouse [55]. Essentially, the model presented above was extended to include the age structure of the host to obtain

$$\frac{\partial M}{\partial t} + \frac{\partial M}{\partial a} = \mu(Q(M) - 1)M(a, t), \qquad (17)$$

where, for fixed time t, $M(a, t)$ is the density of mean parasite burden over host age a. Woolhouse [55] remarks that the function Q (in our notation) "represents the entire process of transmission between hosts, incorporating the dynamics of any free-living or vector-born stages, host exposure and innate susceptibility to infection". The inclusion of an age structure in the model was motivated by the fact that host–parasite data are often presented via age–intensity curves, and age-structured models may be used to analyze these. Assuming that the epidemiology of the parasite has remained constant for some time we set $\partial M/\partial t = 0$ and obtain predicted age–intensity relationships.

Acquired immunity may be included in a variety of ways, for example if Q were also a function of past worm burden we could have $Q(M, H)$ with $\partial Q/\partial H < 0$ and, when $\partial M/\partial t = 0$, write

$$\frac{\mathrm{d}H}{\mathrm{d}a} = M - \sigma H, \qquad (18)$$

where σ is the rate of fade of immunity. Woolhouse [56] used this framework to compare the age–intensity and age–egg output curves generated by four assumed mechanisms with data from studies of schistosomiasis infections. See [8] for the incorporation in a more comprehensive model for schistosomiasis control. For a review of the epidemiology and modeling of schistosomiasis, see [57].

Since parasite numbers within hosts are frequently too low to warrant a deterministic description at that level, models have been developed that allow for stochasticity within individuals but continue to treat the host population deterministically with an age-structured model (see [23], [37]). In addition, these models incorporate the fact that as a rule there is large variation in individual parasite burden. This implies that a description using only mean burdens is often less appropriate.

HIV/AIDS

The infection that has sparked off a tremendous increase in epidemic modeling activity is undoubtedly HIV, starting with seminal papers by Anderson and May (e.g. [40]) (*see* **AIDS and HIV**). The effect has been that in the past 10 years more different infections of humans and animals have been studied with more realistic models than ever before. Progress of the whole area of epidemic modeling is no longer attached to specific classes of infections as it was

in the early days. There is now much progress not only on the applied front, but also in mathematical advances necessary to cope with the more involved models that aim to take relevant heterogeneity in the population into account. One of the reasons could be that sexually transmitted diseases, and certainly AIDS, call for the incorporation of much structure combined. Examples are age structure for differences in infectivity, susceptibility, and certainly also contact structure and discrete characteristics such as sex, sexual preferences, and sexual activity. Two complications are particularly important: varying infectivity as a function of time elapsed since infection and long-lasting partnerships. The first complication is relevant to almost all infectious diseases, the second is related to sexual transmission. We deal with both below. One of the key notions to come out of HIV modeling is that of a core-group of infecteds. This is a small group that is very active in contacts and can keep the epidemic going in a much larger group where the internal contacts alone cannot sustain it [35] (*see* **Partner Study**).

It was realized early on in the modeling of HIV that humans generally form (sexual) partnerships that last longer than individual sexual contacts. Let us assume monogamous partnerships. During such a partnership two susceptible partners are not at risk to infection, and an infective can only cause a single new case until the partnership dissolves. This has consequences for the spread of infection. This observation has given rise to pair formation models where the formation and breaking up of partnerships is explicitly taken into account [15]. These models differentiate in the most basic case between single susceptibles and infectives and three types of pairs. If one lets partnership duration tend to zero while keeping the infection potential during a partnership constant, then one obtains the mass action models we discussed previously. In recent years progress has turned to more complicated contact structures such as circles of friends [10] and beyond deterministic theory to random graphs that reflect an underlying dynamic social contact structure in a population.

We now turn to variable infectivity. Chronologically this important aspect of deterministic epidemic theory was introduced by Kermack and McKendrick in 1927 after McKendrick's ventures into epidemiology had broadened beyond tropical infections. Their integral equation model incorporates – in modern notation – a function $A(\tau)$ to describe the average infectivity of an individual at a time τ since this individual became infected. For childhood infections, influenza, and other infections with long-lasting immunity $A(\tau)$ is a one-humped curve with narrow support. Usually the function does not rise away from zero immediately since many infections have a nonnegligible latency period between infection and becoming infectious. The latency period should not be confused with the **incubation period** which separates infection from the occurrence of symptoms. We consider incubation periods below. For HIV, the function $A(\tau)$ is typically a two-humped function. There is a peak in the early months of infection, followed by a long period of very low but probably nonzero infectivity (typically lasting several years), and ending in a second rise to high levels as the infection progresses to full-blown AIDS and ultimately death.

One striking feature of infection with the HIV virus is the long (>8 year) incubation period of AIDS. A proposed explanation is that the virus mutates within the host, with each strain stimulating both strain-specific and nonspecific immune responses; and although each strain is able to multiply in the presence of specific responses, it is regulated by the combination of specific and nonspecific responses. A simple mathematical model then shows that initially the individual virus strains are suppressed at a low level by the immune system of the host, but eventually the number of strains exceeds a "viral diversity threshold". When this occurs the nonspecific responses can no longer contain the virus population, and all viral strains are able to multiply [44]. Here a mathematical model has generated a hypothesis for the within-host dynamics of a disease that has yet to be tested against observation.

Now imagine an infection that results in complete immunity or death, in a population that is closed (i.e. inflow of new susceptibles is negligible on the time scale of the epidemic), where contacts are described by mass action. Let $S(t)$ be the density of susceptibles in the population at time t. Assume that a single infection triggers an autonomous process within the host. This allows an age representation for the infectivity. We can describe the infection process by the following integral equation:

$$\frac{\mathrm{d}S}{\mathrm{d}t}(t) = S(t)\int_0^\infty A(\tau)\frac{\mathrm{d}S}{\mathrm{d}t}(t-\tau)\,\mathrm{d}\tau. \qquad (19)$$

The incidence of new infecteds $i(t,0) = -\,\mathrm{d}S/\,\mathrm{d}t(t)$ and we can reformulate the above in terms of the incidence $i(t,\tau)$ as

$$i(t,0) = S(t)\int_0^\infty A(\tau)i(t-\tau,0)\,\mathrm{d}\tau, \qquad (20)$$

where the latter integral is the force of infection. This equation can be understood by noting that the infected individuals of infection age τ that are infecting susceptibles at time t are doing so with infectivity $A(\tau)$. These infecteds are precisely those who became infected at time $t-\tau$. Only if we choose $C(N) = N$ (mass action) and the unrealistic $A(\tau) = \beta\exp(-\gamma\tau)$, and if we neglect latency, can we reduce the above to the system of ordinary differential equations (1)–(3) by calculating $I(t) = \int_{-\infty}^{t}\exp[-\gamma(t-\tau)](\,\mathrm{d}S/\,\mathrm{d}t)(\tau)\,\mathrm{d}\tau$ and differentiating. Kermack and McKendrick already showed that the disease will spread in the population of constant density S_0 if and only if $R_0 > 1$ with

$$R_0 = S_0\int_0^\infty A(\tau)\,\mathrm{d}\tau. \qquad (21)$$

This basic result of deterministic epidemic theory can be extended to populations with arbitrary heterogeneity. Consider the individuals labeled with a variable ξ, say, taking values in some state space $\Omega \subset \mathbb{R}^m$. Now, both S and A can depend on the type of individual. The general integral equation formulation for a closed population is

$$i(t,\xi) = S(t,\xi)\int_\Omega\int_0^\infty A(\tau,\xi,\eta)i(t-\tau,\eta)\,\mathrm{d}\tau\,\mathrm{d}\eta. \qquad (22)$$

The compartmental ordinary differential equation models, with and without heterogeneity, and the age-structured model above are special cases of this equation for specific choices of A. One can show that R_0 generalizes naturally to the spectral radius of the so-called *next generation operator* associated with equation (22) [11, 13, 30].

To show the connection with age-structured models let $\Omega = [0,\infty)$ and $\xi = a$ and disregard demography. Under the condition

$$A(\tau,a,b) = k(a,b+\tau)\exp\left[-\int_b^{b+\tau}\gamma(c)\,\mathrm{d}c\right] \qquad (23)$$

define

$$I(t,a) = \int_0^a i(t-\tau,a-\tau)\exp\left[-\int_{a-\tau}^a \gamma(c)\,\mathrm{d}c\right]\mathrm{d}\tau. \qquad (24)$$

Differentiating I leads to the system (5)–(6) (with $\mu = 0$).

In the HIV/AIDS context questions relate again to evaluating effects of control measures (including behavior change). In an age-structured setting the possible demographic impact of HIV in developing countries is an important issue [41]. In Heesterbeek & Dietz [27] it is shown how models with continuous age structure in the form (22) relate to models with discrete age-classes and the so-called WAIFW matrices (Who Acquires Infection From Whom). These matrices are studied as an approach to link theory to population data [3, 19]. One can also give a final size relation for (22) in a closed population.

The modeling process within the deterministic frame of model (22) has shifted to specifying the infectivity kernel A. The modeling depends of course on the type of question to be studied. Often the modeling will make use of **stochastic processes** – notably **Markov processes** – to describe change in an individual's set of characteristics. Many models are in some sense special cases of (22). In a way, these models have already made a choice for A, as we have seen in the age-structured and compartmental model for measles. The modeling of A for more realistic (measurable) situations combining heterogeneity (in individual traits, individual behavior and space) and immunologic and evolutionary processes is one of the major challenges in the near future. This modeling will draw on deterministic but increasingly also on stochastic techniques and theory. It is likely that the days are numbered for realistic progress in theory that is only deterministic. The theory has reached a stage where progress on current issues of epidemiologic importance (e.g. understanding persistence and critical community size) can only be achieved if deterministic and stochastic theory go hand in hand.

Epidemic Models, Inference

Introduction

Statistical inference for epidemics is most often based on stochastic epidemic models (*see* **Epidemic Models, Stochastic**). A special property of such models is that individuals are dependent in that the chance of getting infected depends on whether or not other individuals are infected. When making inference, another complicating property is that most often the underlying epidemic process is only partially observed. It is very rare that information about who infected whom is available. The most common type of data actually consists of only knowing who was infected and who was not, that is, having no information about the time evolution of the spread. This type of data is called *final size data*.

In the present overview, we present inference procedures for what is known as the *general epidemic model*, which assumes a homogeneous community, and a model for a structured community (*see* **Epidemic Models, Structured Population**) in which the community is partitioned into households. Which inference procedure to use depends on the underlying model, but also on the type of available data. Below, both **maximum likelihood** and martingale methods are used on the general epidemic model, depending on the type of data. Further, in a separate section, **Markov chain Monte Carlo** (MCMC) methods for more complex models, having other structured communities or partial observations, are discussed.

Outbreak in a Homogeneous Community

Below, we present inference procedures for the general epidemic model. It assumes a community of homogeneous individuals that mixes uniformly. One way to relax the assumption of homogeneity is to allow for different types of individual, where different types may have different susceptibility, infectivity, and/or mixing patterns. Inference procedures for such extended models can for example be found in [10], where inference for a multitype epidemic in a closed community is considered, or Farrington et al. [18], who consider estimation procedures for an endemic situation where types corresponds to age-cohorts.

The general epidemic is an SIR model (*see* **SIR Epidemic Models**) for a closed community. Let $S(t)$, $I(t)$, and $R(t)$ respectively denote the number of susceptible, infectious, and removed (= recovered and immune) individuals, at time t, and let n denote the community size. One way to define the general epidemic is by specifying the intensities for the two **counting processes** $N(t) = n - S(t)$ (the number of individuals who have been infected) and $R(t)$: given the process at time t, the rate of new infections (the intensity for $N(t)$) is $\lambda_N(t) = \beta\overline{S}(t)I(t)$, where $\overline{S}(t) = S(t)/n$, and the rate of removals (the intensity for $R(t)$) is $\lambda_R(t) = \gamma I(t)$; see [2] for theory on counting processes. The parameter β is hence the rate at which an infectious individual has contact with other individuals, so $\beta\overline{S}(t)$ is the rate at which he or she infects other individuals since only susceptible individuals can be infected. The parameter γ is the recovery rate of infectious individuals, so $1/\gamma$ is the average length of the infectious period.

Complete Data

First, we sketch how to perform inference assuming the epidemic process is observed continuously – so-called complete data. If $(S(u), I(u), R(u))$, or equivalently $(N(u), R(u))$ is observed continuously up to time t, then the log-likelihood is given by

$$\begin{aligned}\ell(\beta,\gamma) = &\int_0^t [\log(\beta\overline{S}(u-)I(u-))\,\mathrm{d}N(u)\\ &- \beta\overline{S}(u)I(u)\,\mathrm{d}u]\\ &+ \int_0^t [\log(\gamma R(u-))\,\mathrm{d}R(u) - \gamma R(u)\,\mathrm{d}u].\end{aligned} \tag{1}$$

The first term of each integral above is actually a sum. The counting process $N(u)$ increase 1 unit at a time making $\mathrm{d}N(u) = 1$ at these time instants and $\mathrm{d}N(u) = 0$ otherwise. The first term of the first integral is hence the sum of $\log(\beta\overline{S}(u-)I(u-))$ evaluated at these time instants, and similarly, for the first term of the second integral.

From this, the maximum likelihood estimates can be derived and shown to equal:

$$\hat{\beta}_{\mathrm{ML}} = \frac{N(t)}{\int_0^t \overline{S}(u)I(u)\,\mathrm{d}u}, \tag{2}$$

$$\hat{\gamma}_{\mathrm{ML}} = \frac{R(t)}{\int_0^t I(u)\,\mathrm{d}u}. \tag{3}$$

Standard errors can also be derived using large population results from the general epidemic (e.g. [8]). The most important parameter, the basic **reproduction number** R, for the general epidemic is given by $R = \beta/\gamma$, so the maximum likelihood estimator of R, given complete data, is

$$\hat{R}_{\mathrm{ML}} = \frac{\hat{\beta}_{\mathrm{ML}}}{\hat{\gamma}_{\mathrm{ML}}} = \frac{N(t)\int_0^t I(u)\,\mathrm{d}u}{R(t)\int_0^t \overline{S}(u)I(u)\,\mathrm{d}u}. \tag{4}$$

The critical vaccination coverage v^*, the community proportion necessary to vaccinate in order to obtain herd immunity assuming a 100% effective vaccine, is given by $v^* = 1 - 1/R$ (*see* **Epidemic Thresholds**). Accordingly v^* is estimated by

$$\hat{v}^*_{\mathrm{ML}} = 1 - \frac{1}{\hat{R}_{\mathrm{ML}}}. \tag{5}$$

Standard errors for $\hat{R}_{\mathrm{ML}}$ and $\hat{v}^*_{\mathrm{ML}}$ can be obtained using the **delta method**.

Final Size Data

As mentioned in the introduction, the most common type of data is final size data in which only the final state of the outbreak is observed, that is, how many were infected and how many were not. It is not possible to estimate β and γ separately for such data, since both parameters are related to time, and final size data contains no information about the time evolution of the epidemic. In fact, the log-likelihood in (1) is not observable for final size data. Instead, we use that $M_1 = N(t) - \int_0^t \beta\overline{S}(u)I(u)\,\mathrm{d}u$ and $M_2 = R(t) - \int_0^t \gamma I(u)\,\mathrm{d}u$ are martingales (*see* **Counting Process Methods in Survival Analysis**; also [2] for the underlying theory). From M_1 and M_2, we can form a new martingale such that the unobservable quantities of M_1 and M_2 cancel out. It turns out that the "right" martingale is

$$\begin{aligned} M(t) &= \int_0^t \frac{1}{\overline{S}(u-)}\,\mathrm{d}M_1(t) - \frac{\beta}{\gamma}M_2(t) \\ &= \int_0^t \frac{1}{\overline{S}(u-)}\,\mathrm{d}N(t) - \frac{\beta}{\gamma}R(t) \end{aligned} \tag{6}$$

$$\begin{aligned} &= \frac{n}{n-1} + \frac{n}{n-2} + \cdots + \frac{n}{S(t)+1} \\ &\quad - \frac{\beta}{\gamma}R(t) \approx n\log\left(\frac{n}{S(t)}\right) - \frac{\beta}{\gamma}R(t). \end{aligned} \tag{7}$$

The second equality relies on the assumption that initially one individual was infectious and the rest were susceptible, that is, $(S(0), I(0), R(0)) = (n-1, 1, 0)$. At the end of the epidemic ($t = \tau$) there are no infectious individuals present, so $R(\tau) = n - S(\tau)$ and $M(\tau) \approx -n\log(1-\tilde{p}) - n(\beta/\gamma)\tilde{p}$, where $\tilde{p} = R(\tau)/n$ is the observed final proportion infected. Since M is a zero mean martingale, we can apply the method of moments to get an estimate of $R = \beta/\gamma$ from final size data:

$$\begin{aligned} \hat{R}_{\mathrm{FSD}} &= \frac{\left(\frac{n}{n-1} + \frac{n}{n-2} + \cdots + \frac{n}{n-R(\tau)+1}\right)}{R(\tau)} \\ &\approx \frac{-\log(1-\tilde{p})}{\tilde{p}}. \end{aligned} \tag{8}$$

This is the same estimator as if estimation would be based on the deterministic limit of the general epidemic (*see* **Epidemic Models, Deterministic**) where the final proportion infected p is known to solve the equation $1 - p = \exp(-Rp)$. However, in the stochastic setting we can also obtain standard errors for the estimator using martingale theory (e.g. [24]):

$$\begin{aligned} s.e.(\hat{R}_{\mathrm{FSD}}) = \Bigg[&\frac{1}{(n-1)^2} + \frac{1}{(n-2)^2} \\ &+ \cdots + \frac{1}{(n-R(\tau)+1)^2} + \frac{\hat{R}^2_{\mathrm{FSD}}}{n}\tilde{p}\Bigg]^{1/2} \Big/ \tilde{p}. \end{aligned} \tag{9}$$

The critical vaccination coverage $v^* = 1 - 1/R$ is of course estimated by $\hat{v}^*_{\mathrm{FSD}} = 1 - 1/\hat{R}_{\mathrm{FSD}}$ from final size data. Standard errors can as before be obtained by applying the delta method.

The maximum likelihood estimate of R, and hence also of v^*, given final size data can in principle be derived using formulae for the final size distribution (e.g. [5, pp. 93, 94]). However, these formulae quickly become cumbersome for large communities, making such inference computationally involved and numerically unstable.

Outbreak in a Community of Households

We now present inference procedures in a different setting where individuals reside in households and where it is believed that infection rates are much higher between individuals of the same households than between individuals of different households. We do this for a fairly simple model originating from Longini and Koopman [20], where households are treated as if they were independent. Since then these ideas have been refined in several ways, for example, by allowing individuals of different types and/or treating a fully stochastic model where households are dependent (e.g. [1], [6], [11] and [21]). The key idea in the Longini–Koopman model [20] is to treat the probability of getting infected from outside the household during the course of the epidemic as a parameter. In reality, this probability depends on the number of individuals who get infected and is hence a stochastic quantity, but the simplifying assumption reduces computational complexities tremendously. Further, by estimating the parameter it will be close to its "correct" value.

A Simple Household Model

Individuals reside in households. An individual who gets infected has infectious contacts with other individuals in the household independently and with equal probability $p_W = 1 - q_W$. Additionally, each individual receives an infectious contact from outside the household with probability $p_B = 1 - q_B$ (the indices stand for within and between households). Individuals who receive at least one infectious contact from infected household members, or from outside the household, get infected. Only those who escape infectious contacts both from within and outside the household avoid getting infected during the epidemic outbreak. Let $p_h(j); j = 0, \ldots, h$ denote the probability that j individuals get infected in a household having h (initially susceptible) individuals. Then these probabilities can be derived recursively from the following equations:

$$p_h(j) = \binom{h}{j} q_W^{j(h-j)} q_B^{h-j} - \sum_{r=0}^{j-1} \binom{h-r}{j-r} \times p_h(r) q_W^{(h-j)(j-r)} \qquad j = 0, \ldots, h, \quad (10)$$

(e.g. [1]). For example, $p_h(0) = q_B^h$ and $p_h(1) = \binom{h}{1}(1 - q_B)q_B^{h-1}q_W^{h-1}$, which can easily be explained. No one gets infected if everyone escapes infection from outside. One individual gets infected if 1 out of h gets infected from outside, and the remaining $h - 1$ individuals escape infection both from outside and from the infected household member. The probabilities quickly become complicated as the requested number of infected increases, but for households smaller than say 5 or even 10, formulae for them can be obtained using a computer algebra package.

Inference for the Simple Household Model

Inference is quite straightforward once the relevant $p_h(j)$'s have been calculated, since households were assumed independent. Let $\{n_h(j)\}$ denote the collected data, where $n_h(j)$ denotes the observed number of households of size h in which j individuals got infected during the epidemic. Then the log-likelihood for the data is simply

$$\ell(q_W, q_B) = \sum_{h,j} n_h(j) \log(p_h(j)), \qquad (11)$$

where the dependence on the parameters is implicit from the definition of $\{p_h(j)\}$ in (10). The parameters are simply estimated by maximizing the log-likelihood with respect to q_W and q_B. Because households are assumed independent, standard large population theory is applicable when the number of households is large, and the maximum likelihood estimators are **consistent**. Standard errors for the estimates can be obtained from the observed **information matrix** by differentiating the log-likelihood twice (e.g. [13]).

As the model is defined, there is no basic reproduction number R, because households behave independently. In Ball et al. [6], a related fully stochastic model is considered, enabling estimation of the basic reproduction number R.

Inference Using MCMC Methods

In previous sections, we have mainly treated models and data for which it was possible to derive expressions for outcome probabilities. In more realistic (i.e. complex) settings, this may not be practically possible. Often, the detail in the data does not allow

for straightforward estimation of parameters. Then some **missing data** method can sometimes be helpful. There are a few examples where the **EM algorithm** can be helpful (see e.g. [4]), but here we focus on MCMC methods (e.g. [17]). This methodology has been successfully applied in a few situations but its real breakthrough in epidemic inference still lies ahead.

The main idea of MCMC analysis in epidemic inference is to explore the outcome space of unobserved (latent) variables for which inference procedures would have been much easier, had these variables been observed (*see* **Instrumental Variables**). Most often, uninformative priors are used for model parameters, but in specific cases prior knowledge can of course be incorporated into informative **prior distributions**. Below, we list some inference problems where MCMC methods have been applied, and refer to listed references for details.

Inference is nontrivial even for the general epidemic model when the removal times, but not the infection times, are observed. Such data is quite common since the removal time of an individual is approximately the same as detection time, which is quite often known. The reason for the complication is that the likelihood then has to be integrated over all possible infection times, a time-consuming task even for very small community sizes. In O'Neill and Roberts [23], this problem is analyzed using MCMC methods in which the Markov chain explores the space of possible infection times. (A different approach, using martingales, is performed in [9].)

Also for household data, detection times but not infection times may sometimes be available. For a model allowing a fairly general distribution for the infectious period, perhaps preceded by a latency period, inference is complicated even for households of size two and when treated as independent. In O'Neill et al. [22], such data is analyzed using MCMC methods, where the unobserved infection times and latency periods are explored in the Markov chain.

It is of course hard to include all heterogeneities into a model. For example, to determine all social connections between individuals in a community is impossible. A way out of this problem is to model unknown social structures by introducing unobserved random social contacts. In [12], a first step in this direction was taken by modeling the social structure using a random graph, and assuming that transmission may only occur between neighboring individuals of the graph. Inference is performed without assuming any information about the social graph, and the Markov chain explores the possible graphs, where detection times close in time increase the probability of a social link between the corresponding pair of individuals.

Concluding Remarks

The emphasis of this article has been on inference procedures for epidemic models in general, rather than on models for specific diseases. The methods are suited for diseases in which transmission occurs by person-to-person contact, and not for vector-borne diseases like malaria or **infectious diseases** caused by contaminated water or food like salmonella. Examples of such diseases are childhood diseases like measles and mumps, smallpox, HIV (although heterogenous structures tend to be very complex here; *see* **AIDS and HIV**), influenza, and common cold.

We have described inference procedures for a few stochastic epidemic models. In many applications, the underlying setting is too complicated to enable inference from stochastic models, for example when long term endemic situations are considered and the community changes dynamically, or when there are too many types of heterogeneities. Then data can be calibrated to deterministic models thus giving parameter estimates. A thorough treatment of many such situations is given in [3] (*see also* **Epidemic Models, Deterministic**). Inference using stochastic models, as opposed to deterministic, has the advantage that it provides uncertainty estimates of parameters. Stochastic models are also better suited for situations where small social units, such as households, play an important role in the disease spread. In this case deterministic models, relying on large population results, may give misleading results. Deterministic models on the other hand, have the clear advantage of being simpler to analyze, thus permitting more complex models to be used.

The practical problem to estimate the effect of a vaccine against an infectious disease, the vaccine efficacy, is not treated in the present article (*see* **Vaccine Studies**). Clearly, this is an important inferential problem within infectious disease epidemiology, but it is left out from the presentation as epidemic models play a minor role in such analyses. Estimation

procedures for such problems can, for example, be found in [19] and [15] and the references therein.

For more detailed presentations on statistical inference for epidemic models, we recommend the monographs by Becker [7] and Andersson and Britton [4], and the survey paper [8]. More on epidemic models in general can be found in [5], [3], [14], and [16].

Epidemic Models, Multi-strain

Multi-strain epidemics typically refer to the simultaneous development of infectious processes in a population, caused by different strains of a pathogenic agent, where the fact of having been infected by one or more of the agents may modify the sensitivity to infection by the other agents. In general, as in the single strain situation, the focus may be either on the endemic or on the epidemic timescale. Typical "endemic" questions are – which strains will dominate in the long run, whether sustained oscillations are possible (*see* **Epidemic Models, Recurrent**), or whether new strains will be able to gain a foothold in the population, in the presence of already established strains. In the epidemic perspective, the main question usually is what happens upon introduction of the diseases in a human population and what composition outbreaks will have, in terms of the different strains.

The endemic aspect is usually dealt with in deterministic, differential equation, models based on the classic **SIR** (susceptible $\rightarrow$ infective $\rightarrow$ removed) model, but with an I and R class for each one of the strains and demographic dynamics (*see* **Epidemic Models, Deterministic**). The description of the effects of previous infections on the sensitivity to further infections may be complicated (the phenomenon is often referred to as cross-immunity, in the literature), and the behavior of the resulting models also seems to be quite complicated (for some recent studies, see e.g. [2, 6]).

We will explain the epidemic case in some detail, starting with two mutually exclusive strains that confer immunity after infection. This is the only situation for which some definite results seem to be available (see [5, 7]). The evolution of the two infections in a population may be modeled by a system of differential equations, in the same style as the classical SIR epidemic. The population size is assumed to remain constant (closed population), $s(t)$ represents the proportion of susceptible individuals, $i_1(t)$ and $i_2(t)$ the proportions currently infected and infective with each one of the two strains, and $r_1(t)$ and $r_2(t)$, the respective proportions of removed individuals, that is, immune to further infection after having been infected by one of the two strains. Infection with one strain is assumed to confer immunity to further infection from the same strain, but also from the other strain. Each infection lasts, on average, $1/\mu_i$ time units ($i = 1,2$) and each infected is assumed to cause β_i ($i = 1,2$) new, secondary cases per time unit, in a completely susceptible population. The equations representing the evolution are (it is customary to write the involved functions without the time argument, since time is not explicitly used in the description; a so called autonomous system)

$$\begin{aligned} s' &= -(\beta_1 i_1 + \beta_2 i_2)s \\ i_1' &= \beta_1 i_1 s - \mu_1 i_1 \\ i_2' &= \beta_2 i_2 s - \mu_2 i_2 \\ r_1' &= \mu_1 i_1 \\ r_2' &= \mu_2 i_2 \end{aligned} \tag{1}$$

with initial conditions $s(0) = 1 - \varepsilon_1 - \varepsilon_2$, $i_1(0) = \varepsilon_1$, $i_2(0) = \varepsilon_2$, $r_1(0) = r_2(0) = 0$, where ε_1 and ε_2 are assumed to be small (a few initial infectives enter a wholly susceptible population).

This system does not admit explicit solutions, but its properties may be studied in a qualitative way. Eventually, the numbers of infective will tend to zero and the spread will stop. This will leave the population with a proportion $s(\infty)$ of individuals not having been infected during the epidemic and proportions $r_1(\infty)$ and $r_2(\infty)$ having had, respectively, disease 1 or 2. The question whether one or both diseases may give rise to large outbreaks is answered by considering the reproductive values $\theta_i = \beta_i/\mu_i$ ($i = 1,2$) of the two diseases (these are the same as the basic **reproduction number** R_0 in models of one disease) and the **epidemic threshold** conditions $\theta_i = 1$ ($i = 1,2$). If both parameters are below or on threshold, both diseases die out quickly after introduction and no large outbreaks may arise. If one is above and the other one is below threshold, there will be a large outbreak of the first one and few cases of the other one. The large outbreak will have affected a proportion $r(\infty)$ of the population, where $r(\infty)$ is the largest solution of the final size equation (see [4] for this and many other useful results on epidemic models)

$$r = 1 - \exp(-\theta r) \tag{2}$$

(with the appropriate θ-parameter and assuming that ε_1 and ε_2 are negligible, i.e. essentially zero), just as in the case with one disease in a closed population.

When both parameters are above threshold, both diseases start to spread, and using the same technique as used to derive the one-strain final size equation, one finds that the final proportions of the two diseases satisfy the equation

$$r_1(\infty) + r_2(\infty) = 1 - \exp(-\theta_1 r_1(\infty) - \theta_2 r_2(\infty)) \tag{3}$$

This equation does not have a single solution; in fact, if one thinks of the two axes in the plane as representing possible $(r_1(\infty), r_2(\infty))$ values, the equation describes a curve connecting the two solutions describing one-strain epidemics only (the other component is set to zero and the equation reduces to the one-strain case) on the two axes in the first quadrant. The equation also admits (0,0) as a solution, representing small outbreaks of both diseases. In order to determine a specific point in the plane, a second equation would be needed, but in their paper [5], Kendall and Saunders conclude that no such relation has been found.

Some recent results [7] on the asymptotics (essentially large population size) of the corresponding stochastic model (*see* **Epidemic Models, Stochastic**) cast some light on the problem. In essence, depending on parameter values, there may be no single final point, as expected from one-strain theory, but stochastic variability at the start of the spread (in deterministic theory represented by the pair (r_1, r_2) still in, or very close to, the origin) may yield "unpredictable", stochastic final size proportions distributed along the whole curve. The results are also interesting because they show that the classical parameters (θ_1, θ_2) are not sufficient to describe the final size of the spread in the population. In addition to these parameters, two new parameters $\zeta_i = \beta_i - \mu_i$ $(i = 1,2)$, the "initial speeds of spread", and the numbers of initial infectives need to be considered. In order to understand the results, it is useful to recall some classical results on the time course of a stochastic epidemic in large population, first strictly given by Barbour [3] (see also [1] for stochastic epidemic models in general). The stochastic model itself uses the same terminology and parameters as the deterministic model (1) in the two-strain case, with a corresponding natural reformulation in terms of just s, i and r in the one-strain case. However, individuals are thought of as remaining infected for a random, **exponentially distributed**, time with average $1/\mu$ and the term *bis* in the (1) is seen as the intensity with which a susceptible becomes infected, adopting a standard **Markov process** formulation. It is also more natural in the stochastic model, to have the numbers of susceptible, infective, and removed individuals as basic quantities, described as integers. The basic difference between a deterministic and a stochastic one-strain model is that, if $\theta \leq 1$, both models predict, in large populations, only small outbreaks $(r(\infty) \approx 0)$, while, if $\theta > 1$, the deterministic model predicts that there will always be a large outbreak with $r(\infty)$ close to the solution of (2), while the stochastic model asserts that the outbreak may still be small (with a certain probability that can be determined from the parameters) due to chance, but if it becomes large, $r(\infty)$ will again be close to the solution of (2). Associated with these possibilities, there is a description of the time course. If the outbreak is small, the disease dies out rather quickly, and the distribution of this time is independent of population size. If the outbreak is large, the numbers of infectives (and removed) grow exponentially, as a **branching process**, for a time that is proportional to the logarithm of population size, until the epidemic reaches a size of the same order of magnitude as the population size, then moves quickly, essentially following the deterministic differential equations, through the culmen of the epidemic, then again, now being very close to the final size, spend a time proportional to the logarithm of population size until effective die-out of the disease is achieved.

The asymptotic behavior of the two-strain model can now be explained in the following way, omitting some details. First, if one or both the θ-parameters are below threshold, the two epidemics (one for each strain) will behave as independent one-strain epidemics, according to the behavior explained above. If both parameters are above threshold, chance may still lead to a small outbreak of one of the strains; in that case, the other strain may give rise to either a small or a large outbreak, as in a one-strain model. These three possibilities (both small or one small and one large) have well-defined probabilities and correspond to the solutions (0,0) and the two points on the two axes of the (3). Finally, if both epidemics start growing, the fastest one (with the largest ζ-parameter), which we assume is denoted as type 1, completes its course as if it were alone in the population, reaching its final proportion $r_1(\infty)$, which is the solution of (2) with the parameter θ_1. The slower strain will

then achieve a final proportion corresponding to a redefined θ-parameter equal to $(1 - r_1(\infty))\theta_2$ (representing the effective secondary cases that can be achieved in the susceptible population left untouched by the first strain). This point is a point on the curve defined by (3). Finally, if initial speeds are equal, both epidemics reach the same order of magnitude as the total population at the same time, but the initial proportions of infectives have now been modified by stochastic effects coming from the exponential growth phase. With these new, random, proportions as starting points, the two epidemics follow the corresponding trajectory of the differential equations (1) to a corresponding point on the final curve (3) (there is a one-to-one mapping between starting points $\neq (0, 0)$ and points on the curve). Thus, the random distribution of the "population-size" starting points maps to a random distribution on the curve. This distribution does not have an explicit expression, but can be computed numerically. A notable case is when, in addition to equal speeds, the two strains also have equal θ-parameters. Then, the curve (3) is a straight line and, if one initial infective of each strain is assumed, the above described distribution becomes uniform on this line.

There are two main directions in which the model could be made more general. One is allowing more than two strains. As long as each one confers immunity to all the others, the results should be in line with those for two strains, only more complicated to state. A more significant generalization would be to consider other forms of interaction than complete exclusion, that is, allowing susceptibility to one strain to depend in a general way on the previous infections, maybe only decreasing it slightly or even increasing it. At the present time, there seem to be no results about such epidemic models.

Epidemic Models, Recurrent

Observations of the number of childhood infections, such as measles, are available over long time periods from a large number of cities in developed countries. Data from the time before large-scale vaccination was introduced show two interesting properties. One is recurrence of infection outbreaks, and the other one is spontaneous disappearance of the infection in small populations. It is a classical challenge in mathematical epidemiology to understand the mechanisms that cause these phenomena. A description of the work in this area will follow the two lines formed by the competing branches of deterministic and stochastic modeling (*see* **Epidemic Models, Deterministic**; **Epidemic Models, Stochastic**). A major finding is that the deterministic model is a poor approximation of the stochastic one. All models for recurrent epidemics are based on the idea that an inflow of new susceptibles is necessary before a new outbreak can occur. This goes back to the model formulated by Soper [38], based on ideas by Hamer [15]. It means that the model accounts for both epidemic and demographic forces.

The Classic Endemic Model – Deterministic Version

The deterministic model given by the following system of differential equations is denoted the classic endemic model by [18]. We use this term in a broader sense, since we shall study both deterministic and stochastic versions of the same model.

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \mu N - \frac{\beta}{N} SI - \mu S, \tag{1}$$

$$\frac{\mathrm{d}I}{\mathrm{d}t} = \frac{\beta}{N} SI - (\gamma + \mu) I, \tag{2}$$

$$\frac{\mathrm{d}R}{\mathrm{d}t} = \gamma I - \mu R. \tag{3}$$

Here, S, I, R denote the number of individuals that are susceptible, infective, and removed, respectively. The total population size $S(t) + I(t) + R(t) = N$ is constant, provided $S(0) + I(0) + R(0) = N$. Four parameters are used, namely, the contact rate β, the death rate μ, the recovery rate γ, and the total population size N. This model has, with some variation in the parameterization, been studied by a number of authors, including [1, 11, 16, 17, 24, 25, 26] (*see* **SIR Epidemic Models**).

The model is two-dimensional, since R does not affect S and I. The parameter space can be simplified by the following reparameterization:

$$R_0 = \frac{\beta}{\gamma + \mu},$$
$$\alpha = \frac{\gamma + \mu}{\mu}. \tag{4}$$

Here, R_0 is the basic reproduction ratio (*see* **Reproduction Number**), and α is the ratio of life length to time infected. Note that the parameter α is large for the recurrent epidemic models. After the reparameterization, we still have four parameters. By using the parameter classification introduced in [32], we find that two of the parameters, R_0 and α, are essential, while the remaining ones, N and μ, are innocent. (A parameter is innocent if it can be eliminated by rescaling of state variables or of time). The results for the deterministic version of the model can be described with reference to the two-dimensional space of essential parameters (R_0, α), modulo rescaling if necessary.

We single out three properties of major interest, namely, the threshold (*see* **Epidemic Thresholds**), the recurrence, and the extinction.

With regard to the first of these properties, the deterministic model has a threshold at $R_0 = 1$; see [18]. This means that if R_0 is less than or equal to one, then any infection will ultimately disappear, while an endemic infection level will establish itself at

$$\overline{I} = \frac{R_0 - 1}{\alpha R_0} N \tag{5}$$

if $R_0 > 1$ and $I(0) > 0$.

The recurring outbreaks of infection are reflected in the deterministic model solutions as damped oscillations about the endemic infection level if $R_0 > 1$. The quasi-period of these oscillations is found from the **eigenvalues** of the **matrix** determined by linearization of the system of differential equations about the critical point corresponding to the endemic infection level. It is approximately given by (for

large α)

$$T_0 \approx \frac{2\pi}{\mu}\frac{1}{\sqrt{\alpha(R_0-1)}}. \tag{6}$$

The tendency to oscillate is a realistic feature, while the damping is not.

The third item of interest, the extinction of the infection for $R_0 > 1$, cannot be explained by the deterministic model.

Mainly for historical reasons, we describe also the deterministic model due to Hamer and Soper:

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \mu N - \frac{\beta}{N}SI,$$
$$\frac{\mathrm{d}I}{\mathrm{d}t} = \frac{\beta}{N}SI - \gamma I. \tag{7}$$

This model allows for inflow of new susceptibles, but it does not allow for death of susceptible or infected individuals. It has no threshold, but it is quite similar to the classic endemic model with regard to recurrence and extinction. The model is further discussed by [5] and [30].

The Classic Endemic Model – Stochastic Version

The stochastic version of the model is a so-called **Markov** population process. This means that it is a **Markov chain** with continuous time and discrete state space, where only transitions to nearest neighbors are possible. The size of any population can only take nonnegative integer values. This is clearly more realistic than the continuous state space used for the deterministic model. The stochastic version of the model takes the form of a bivariate Markov chain $\{S(t), I(t)\}$, as described in detail by [30].

The deterministic version of the model can be derived as an approximation of the stochastic one by first scaling the state variables S and I with N and then letting N approach infinity. This explains why N, which is essential for the stochastic version, becomes innocent as we go to the deterministic version. The stochastic model has a reputation of being difficult to analyze. **Monte Carlo simulation** is therefore a useful method.

The states $(s, 0)$, where the number of infected individuals is equal to zero, correspond to absence of infection and form what is called an *absorbing class* for the **stochastic process**. Absorption can be interpreted as extinction of the infection. The stochastic process of concern here will reach the absorbing class in finite time. After that, it will be confined to this class forever. The remaining states (s, i), where $i \geq 1$, are transient. It turns out that there exists an important distribution, called the *quasi-stationary distribution*, which is a stationary distribution, conditional on nonextinction. The concept of quasi-stationarity for continuous-time Markov chains was introduced by [10]. It is supported on the transient states. It is a useful approximation of the distribution of states of the process before extinction. The long-term behavior of the state of the process can be described by two quantities: the quasi-stationary distribution and the time to extinction. (There is also a stationary distribution, without any conditioning. It is mathematically easier to deal with than the quasi-stationary distribution, but it is much less informative. It is supported on the absorbing class, and deals therefore only with susceptible individuals. It is completely independent of the parameter R_0.)

The powerful threshold result for the deterministic model is based on bifurcation for the system of differential equations (1)–(3). An extension of this result to the stochastic setting is highly desirable. It can be achieved by first noting that the deterministic threshold can be described as a partition of the parameter space where R_0 takes its values into two subsets $0 < R_0 < 1$ and $R_0 > 1$, where phase portraits for the differential equations differ qualitatively. The counterpart for the stochastic model is an identification of three subsets of the parameter space, where R_0 and N take values, in which the quasi-stationary distribution and the time to extinction differ qualitatively. Exact expressions for these quantities are not available. (And if they were, they would not be useful in this connection, since they would not show qualitative differences in different parameter regions.) Progress in this situation is made by seeking asymptotic approximations. It turns out that the asymptotic approximations for both of these quantities show qualitative differences in different parameter regions, exactly as required for an extension to the stochastic setting of the threshold result for the deterministic model.

The approach for a qualitative analysis of a stochastic model outlined in the preceding paragraph can be followed for univariate models, as exemplified by the Verhulst logistic model analyzed by [31]. There are still mathematical difficulties to overcome

for multivariate models, as exemplified by the one treated here.

The stochastic version of the Hamer–Soper model was introduced and analyzed by Bartlett in some classical papers [6, 7, 8]. Bartlett's main conclusion was that both the recurrence and the extinction phenomena, which were not well modeled by the deterministic Hamer–Soper model, could be explained with the aid of the stochastic feature.

For the recurrence, Bartlett claimed that the damping in the deterministic model was offset by random variability. This result was supported in his 1956 paper by Monte Carlo simulations. Bartlett's recurrence result was strengthened by [33]. This paper uses the important mathematical result that the deterministic model solution is an approximation of the expectation over a large number of realizations of the stochastic model with the same initial point. It is important to realize that this expectation does not necessarily share properties with the individual realizations. This is, in particular, true for the troublesome damping associated with the deterministic model solutions. Individual stochastic model realizations that avoid extinction show recurrent outbreaks with stochastically varying periods and amplitudes, and essentially without damping. One consequence of this stochastic variability is that early outbreaks are closely synchronized, but that the synchronization is weaker for later outbreaks. This implies that the expectation over a large number of such realizations gives damped oscillations. The damping associated with the deterministic model is thus explained as a measure of the stochastic variability in periods and amplitudes.

With regard to extinction, Bartlett derived an analytic approximation of the expected time to extinction that showed it to be an increasing function of the population size N. Improvements of these analytic results are given by [30]. Bartlett showed also that this qualitative result was supported by data from several cities in England and the United States: Fade-out was observed in small cities, but not in large ones. He therefore introduced the concept "Critical Community Size" (CCS) as "the size for which measles is as likely as not to fade out after a major epidemic." This constitutes a threshold result for the stochastic model, as discussed by [29, 30]. It generalizes the deterministic model threshold $R_0 = 1$ by giving a threshold value for R_0 as a function of N that approaches the value one as $N \to \infty$. The inverse of this function gives the critical community size as a function of R_0.

A crude approximation of the expected time to extinction is derived in [30]. It takes the form

$$E(\tau_Q) \approx \frac{\rho}{\mu R_0} \frac{\Phi(\rho)}{\varphi(\rho)}, \tag{8}$$

where

$$\rho = \frac{\sqrt{(R_0 - 1)N}}{\alpha}, \tag{9}$$

and where Φ and φ denote the **normal distribution** function and the normal density function, respectively. Putting the right-hand side of (8) equal to a constant defines R_0 as a function of N for fixed values of μ and α. This function is an approximation of the persistence threshold, since the latter is defined by the requirement that the expected time to extinction is constant. By putting this constant equal to K/μ and using the approximation (8) for $E(\tau_Q)$, we can derive the following crude approximations of the persistence threshold value in the case where average life time is $1/\mu = 70$ years, $K/\mu = 3$ years, and $\alpha = 1 + \gamma/\mu = 3500$: If $N = 10^4$, then $\rho \approx 2.86$, and the threshold value for R_0 is approximately 10 000. If $N = 10^5$, then $\rho \approx 1.59$, and the threshold value for R_0 is approximately 310. In these cases, therefore, the deterministic threshold value $R_0 = 1$ is a poor approximation of the persistence threshold.

We summarize by noting that the deterministic model is an unacceptable approximation of the stochastic one (unless the population size is really huge), with respect to all three of the major indicators, namely, threshold, recurrence, and extinction.

Variations and Extensions of the Classic Endemic Model

The phenomenon of recurring epidemic outbreaks has aroused a large interest among deterministic modelers. As described above, the deterministic version of the classic endemic model (or the rather similar Hamer–Soper model) is unrealistic since it predicts *damped* oscillations. A broad search for alternative mechanisms that predict *undamped* oscillations has therefore taken place. A review of the work in this area up until 1989 is given by Hethcote and Levin in [19]. Most of this work has taken the form of suggesting a variation or extension of the deterministic model. It has tended to disregard the explanation

put forward by Bartlett, and supported by the later work by Nåsell, that undamped oscillations can be explained by the stochastic version of the model, without any additional hypotheses. The review in [19] deals with five different types of variations or extensions of the deterministic version of the classic endemic model, namely, (1) Models with periodic coefficients, (2) Models with delays in the removed class, (3) Models with nonlinear incidence, (4) Models with variable population size, (5) Models with age structure. For all of these cases, deterministic models with undamped periodic solutions exist.

Among the models with periodic coefficients, particular attention has been paid to an SEIR model, with a state E (for exposed, meaning infected but not yet infective) inserted between the states S and I. The contact rate was assumed to be periodic, with a period of one year reflecting the periodicity in contact caused by the aggregation of children in schools (*see* **Seasonal Time Series**). The resulting seasonally forced SEIR model can exhibit **chaos**, as was reported in a series of papers, [4, 9, 12, 27, 34–36]. Arguments similar to those in the preceding section can be given to argue that the deterministic SEIR model with constant infection rate is a poor approximation of the corresponding fully stochastic model. The prospects that periodicity in the contact rate would improve this approximation are slim. The chaos phenomenon was studied in a very concrete way by [33], using the stochastic version of the SEIR model with periodic forcing. It was found with parameter values typical for measles that the minimum "number" of infected individuals between outbreaks could go down to the order of 10^{-11} in a population of 1 million individuals. (This low value resembles the "atto-fox" discovered by [28] in a model for rabies. One atto-fox equals 10^{-18} foxes.) The conclusion reaffirmed an easy extension of our previous finding, namely, that the deterministic approximation of the stochastic model is unacceptable. A direct consequence is that the chaos phenomenon is driven by an unacceptable mathematical approximation.

In search for additional realism, Schenzle established an SEIR model in [37] that combined age structure and seasonality in transmission. It explains prevaccination data on measles in England and Wales very closely. It is referred to as the RAS (Realistic Age-Structured) model by [14]. The model formulation is deterministic, and evaluations are numerical, but the author notes that it is straightforward to formulate and simulate the corresponding stochastic formulation.

Schenzle's work has stimulated a study of deterministic models with age dependence, but without seasonal variation in the contact pattern. One goal of these studies has been to search for conditions that lead to undamped oscillations. Some positive answers, but involving rather extreme conditions, are given by [3, 39].

An additional possible reason for periodic solutions in deterministic models was suggested by Feng and Thieme in [13]. They study an SIQR model, where a state Q (for quarantine) is inserted between the states I and R. They argue that infected individuals stay at home after they develop disease symptoms. Their isolation (quarantine) reduces their ability to infect others. Analysis of the resulting ODE model shows that periodic solutions are possible for a range of lengths of isolation period. Further extensions of these results are given by [20].

Keeling and Grenfell in [21] showed that the stochastic version of the Schenzle model, formulated in the natural way as a Markov population process, predicted much less persistence than is observed. They point to one consequence of the Markov population model, namely, that the distribution of waiting time in each state is **exponential**. This is quite unrealistic. They claim that considerable improvement in the prediction of persistence can be achieved by assuming a more realistic distribution of the duration of infection. Investigations along the same line were undertaken by Lloyd in [22]. The question of what influence a more realistic distribution of infectious period has on the persistence is far from settled: Some of the conclusions reached by Lloyd are opposite to those of Keeling and Grenfell. Further studies in the same direction have been undertaken by Andersson and Britton, [2].

Spatial heterogeneity is believed to play an important role in the persistence of recurrent epidemics, with asynchrony between subpopulations allowing global persistence, even if the infection dies out locally (*see* **Epidemic Models, Spatial**). A study of such questions, accounting for both stochastic and deterministic aspects, is contained in [23].

INGEMAR NÅSELL

Epidemic Models, Sensitivity Analysis

Recent years have seen the use of increasingly complex models for epidemic dynamics. For example, the emergence of the AIDS epidemic has resulted in the development of models including a variety of features [2, 3, 5–9, 13–15, 19, 27, 28] (*see* **AIDS and HIV**).

All these developments are necessary to increase our understanding of the mechanics of transmission. For example, again referring to the AIDS epidemic, certain features have had to be included to explain such things as:

1. the variability in infectiousness observed in **partner studies**;
2. the long duration of the **incubation period**;
3. the pattern of early growth of the epidemic; and
4. the differences between high- and low-risk subgroups of the population.

These complex models have developed out of a range of much simpler models. When we consider simple models with relatively few parameters it is a straightforward task to analyze and compare models: for example: To which changes in parameters is the model sensitive? What ranges of epidemic dynamics are possible? Are two models similar?

Consider, for example, the two models, A and B, described in Figure 1. There is only one difference between these models: where model A has two parameters c (the contact rate) and p, model B has a single parameter β. It is clear that if β is equal to cp and if all other parameters are equal, then the two models will give precisely the same dynamics. So, in one sense, model A contains a parameter that is redundant. The reason for why we might use the formulation described in model A is that it gives us, in a simplistic way, a more detailed understanding of the mechanics of transmission.

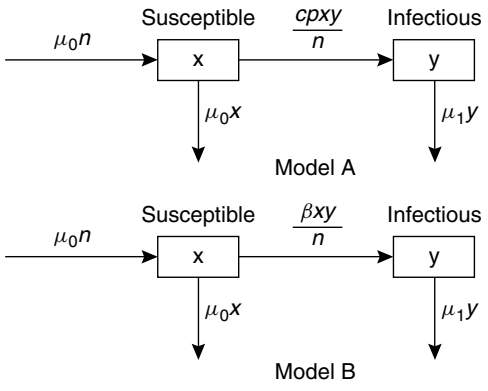

Figure 1 Two simple models for epidemic spread

This sort of reasoning has been the driving force behind the development of the complex models for AIDS described above. However, an important aspect of the development of more complex models is the need to identify whether or not the addition of an additional parameter makes a substantial difference to the dynamics of an epidemic model. The example which compares models A and B described above is a special case: the extra parameter in model A has absolutely no effect on the dynamics. In other cases the situation may not be so clear-cut. In most cases the addition of an extra parameter will add to the variety of outcomes which may be observed, but this may range from a substantial to a very insignificant change.

The reduction in the number of parameters between model A and model B is similar to the approach described by Nåsell [29]. Nåsell, who considers equilibrium incidence of malaria, uses dimensional analysis to strip out a number of unnecessary parameters.

The question of how much influence individual parameters have on certain quantities of interest was first considered in a systematic fashion by Bailey & Duppenthaler [4]. They presented a detailed approach to sensitivity analysis by considering the full set of basic parameters. By incorporating the uncertainty associated with each parameter they assessed which parameters have the most influence on the level of incidence in the equilibrium state. The use of random input parameters to investigate sensitivity is a method which has rarely been used since. The most significant development along these lines is the method described by Blower & Dowlatabadi [6]. Their method is described in more detail in a later section and conforms to the conventional notion of a **sensitivity analysis**.

Sometimes it is possible for us to reparameterize a model to give us more obvious insight into its

workings. Let us look again at the dynamics of model B:

$$\frac{dx}{dt} = \mu_0 n - \mu_0 x - \frac{\beta x y}{n},$$
$$\frac{dy}{dt} = \frac{\beta x y}{n} - \mu_1 y.$$

Suppose the value of β is known to be equal to 0.1. What can be said about the epidemic? The answer is, of course, "very little": the epidemic could die out or it could take off and be quite substantial. We can only say something about the dynamics when we know the values of some of the other parameters.

Suppose, instead, that we define

$\tau_0 = \frac{1}{\mu_0}$, the mean lifetime in the absence of infection,
$\tau_1 = \frac{1}{\mu_1}$, the mean duration of infectiousness,
$R_0 = \beta\tau_1$, the basic reproductive ratio: the mean number of secondary cases of infection caused by one primary infective in the early stages of the epidemic (*see* **Reproduction Number**), and
$\theta = \beta - \mu_1 = \frac{R_0 - 1}{\tau_1}$, the initial growth rate.

Then

$$\frac{dx}{dt} = \frac{n}{\tau_0} - \frac{x}{\tau_0} - \frac{R_0}{\tau_1}\frac{x}{n}y,$$
$$\frac{dy}{dt} = \frac{R_0}{\tau_1}\frac{x}{n}y - \frac{y}{\tau_1}.$$

Using this formulation, if we know the value of R_0, then we immediately know something about how the epidemic will progress: there will be an epidemic if and only if $R_0 > 1$ and the disease will become endemic again only if $R_0 > 1$. If we also know the value of τ_1, then we begin to get a picture of how quickly the epidemic will progress: the higher the value of τ_1 the slower the progress. Furthermore we can derive the value of θ from R_0 and τ_1 and this tells us about the early dynamics (*see* **Epidemic Thresholds**).

A conventional sensitivity analysis is carried out without such a reparameterization. As a consequence, a typical conclusion is that all parameters have a relatively significant impact on the dynamics of the epidemic. Blower & Dowlatabadi [6] developed this by using methods which allow us to make statements along the lines of "parameter θ_i explains 25% of the variation in the total number of cases".

We later describe the method of primary components [9, 10]. This is a method that formalizes the process of reparameterization. In particular, the aim is to find a parameterization in which there is a small number of parameters (or *primary components*) which between them explain a very large part of the dynamics of the epidemic. Put another way: suppose the primary components are fixed. The remaining *secondary parameters* may be uncertain or random, but, within the possible range of values that they can take, the dynamics of the epidemic model are largely unchanged. The approach is similar to a **principal components analysis**. The important distinction is that the primary components have a simple interpretation (for example, the basic reproductive ratio R_0) and, therefore, lose the optimality of principal components.

There are three differences from the Blower–Dowlatabadi approach. First, the method of primary components considers the whole epidemic curve or some subsection of it rather than a single outcome. This is the aim of many sensitivity analyses, and the later section describes how this can be done in a systematic way and with reference to past data. Secondly, by reparameterizing the model, a small number of inputs (the primary components) explain a much larger part of the variance in the output. Thirdly, the method is easily applied to model fitting and **projection** of an epidemic curve.

Reasons for Carrying Out a Sensitivity Analysis

Before thinking about why a sensitivity analysis is necessary and desirable it is important to consider why we are modeling in the first place. There are various reasons:

1. to explain the observed pattern of epidemic spread;
2. to explain the mechanics of transmission;
3. to predict
   - the total numbers of cases
   - the evolution of the epidemic curve

- the severity of spread into different subgroups
- the chance that the epidemic dies out;

4. to make provision for future healthcare;
5. to investigate and devise strategies for epidemic reduction or eradication through

- vaccination (*see* **Vaccine Studies**)
- treatment of infected individuals
- education;

6. to determine modes of behavior

- thresholds
- endemicity
- stability.

Let us consider a general model. Let

$\boldsymbol{\theta} = (\theta_1, \ldots, \theta_k)^{\mathrm{T}}$ the vector of input parameters,

$\mathbf{y}(t) = y(t, \boldsymbol{\theta})$, the vector of output variables of interest.

For example, $\mathbf{y}(t)$ might include numbers of susceptible, infectious, removed, immune or dead (**prevalence** curves) or the rates of new infection, recovery or death (**incidence** curves). $\mathbf{y}(t)$ might be deterministic or stochastic, certain components may be incompletely observed, or not observable at all, and most components will be subject to some degree of **measurement error**.

The purpose of a sensitivity analysis is to assess how sensitive $\mathbf{y}(t)$ (or some of its components) is to changes in the values of the various components of the parameter vector $\boldsymbol{\theta}$. The reasons behind such an analysis are partially motivated by the reasons for modeling in the first place.

1. to consider the effects of uncertain parameter values;
2. to consider the sensitivity of the outcome of modeling to the choice of model;
3. to assess uncertainty in the future;
4. to assess the likely effectiveness of specified control strategies;
5. to identify which parameters we should obtain improved estimates of in order to reduce future uncertainty by the maximum amount;
6. to gauge how much information about the underlying model can be obtained from an observed incidence curve;
7. to assess the importance of certain components or structures in a model;
8. to assess which parameter combinations are consistent with existing data;
9. to be aware of the possible existence of bifurcations within the likely range of parameter values.

This list does not intend to be comprehensive, but it does indicate the wide variety of questions that need to be considered.

The driving force behind the need for sensitivity analyses are the first two items: parameter and model uncertainty. If both of these were known, then the task of an epidemic modeler would be considerably easier, but also rather boring! However, even if parameter values are known for the past, changes can happen in the future as a result of control strategies, changes in the underlying population, or mutations of the disease. The effects of these sorts of changes are rather harder to predict, but sensitivity analysis is still desirable since we can get some sort of a feel for the magnitude of the effect.

It is important that a sensitivity analysis should be as comprehensive as possible in terms of how parameter values are varied. Bailey & Duppenthaler [4] warn against the risks of focusing on a subset of the parameter set: "Examination of small numbers of supposedly important parameters may be substantially affected by unconscious bias".

Sensitivity Analysis for Single Quantities

The approach described here follows that of Blower & Dowlatabadi [6]. For the basic form of analysis we make the following assumptions:

1. we are interested in a single quantity (for example, cumulative cases of AIDS over the next 30 years or the equilibrium incidence of new infection);
2. the input parameters are independent random variables;
3. we do not use past incidence or prevalence data.

Assumptions 2 and 3 imply that we can use only data from secondary studies which, for example, follow the progress of specific individuals. Each of these assumptions can be relaxed: a point that will be discussed later in this section.

Let $y = y(\theta)$ be the quantity of interest and $f(\boldsymbol{\theta})$ be the probability density function for $\boldsymbol{\theta}$. Under

assumption 2:

$$f(\boldsymbol{\theta}) = f_1(\theta_1) f_2(\theta_2) \cdots f_k(\theta_k).$$

We are interested in the unconditional distribution of $y(\boldsymbol{\theta})$ and also in the degree of **correlation** between $y(\boldsymbol{\theta})$ and each of the inputs $\theta_1, \ldots, \theta_k$.

Let $\boldsymbol{\theta}^*$ be the mean value of $\boldsymbol{\theta}$ given the density function $f(\boldsymbol{\theta})$. Then

$$y(\boldsymbol{\theta}) = y(\boldsymbol{\theta}^*) + \mathbf{h}^{\mathrm{T}}(\boldsymbol{\theta} - \boldsymbol{\theta}^*) + o(|\boldsymbol{\theta} - \boldsymbol{\theta}^*|)$$

where $\mathbf{h} = \mathbf{h}(\boldsymbol{\theta}^*)$ is the response vector.

If the range of values for $\boldsymbol{\theta}$ around $\boldsymbol{\theta}^*$ is relatively small, and if there are no bifurcation points nearby, then $\hat{y}(\boldsymbol{\theta}) = y(\boldsymbol{\theta}^*) + \mathbf{h}^{\mathrm{T}}(\boldsymbol{\theta} - \boldsymbol{\theta}^*)$ gives a good approximation to $y(\boldsymbol{\theta})$. We then have (in a similar fashion to Bailey & Duppenthaler [4]):

$$\begin{aligned}
\mathrm{E}[\hat{y}(\boldsymbol{\theta})] &= y(\boldsymbol{\theta}^*), \\
\mathrm{var}[\hat{y}(\boldsymbol{\theta})] &= \sum_{i=1}^{k} h_i^2 \mathrm{var}(\theta_i), \\
\mathrm{cov}[\hat{y}(\boldsymbol{\theta}), \theta_i] &= h_i \mathrm{var}(\theta_i) \\
\Rightarrow \rho_i &= \mathrm{cov}[\hat{y}(\boldsymbol{\theta}), \theta_i] \\
&= \frac{h_i \mathrm{var}(\theta_i)^{1/2}}{\left[\sum_{j=1}^{k} h_j^2 \mathrm{var}(\theta_j)\right]^{1/2}}.
\end{aligned}$$

Under this assumption of linearity, the correlation coefficient, ρ_i, is a measure of the sensitivity of $y(\boldsymbol{\theta})$ to changes in θ_i. The closer ρ_i is to 1 or -1 the more sensitive $y(\boldsymbol{\theta})$ is to changes in θ_i. Note that this measure explicitly accounts for the level of uncertainty in the input parameters. Now the ρ_i indicate the levels of sensitivity relative to other input parameters. Absolute levels of sensitivity can be gauged by combining this information with the variance of $y(\boldsymbol{\theta})$.

The response vector, $\mathbf{h}(\boldsymbol{\theta}^*)$ can be estimated by carrying out only $k+1$ **simulations** of the model: one with $\boldsymbol{\theta} = \boldsymbol{\theta}^*$, and one for each $i = 1, \ldots, k$ with $\theta_i = \theta_i^* + \varepsilon$ and $\theta_j = \theta_j^*$ for $j \neq i$ (where ε is small).

Latin Hypercube Sampling and Partial Rank Correlation Coefficients

Now $y(\boldsymbol{\theta})$ may in fact be sufficiently nonlinear within the range of values of $\boldsymbol{\theta}$ (possibly with a bifurcation point) so that $\hat{y}(\boldsymbol{\theta})$ gives a poor approximation to $y(\boldsymbol{\theta})$ except near to $\boldsymbol{\theta}^*$. The method described above still gives a good guide to the sensitivity of $y(\boldsymbol{\theta})$ to changes in θ_i. However, if we wish to be more precise, then the method of *partial rank correlation coefficients* (as described by Blower & Dowlatabadi [6]) is appropriate.

A complete, deterministic analysis would need to cover all possible values of $\boldsymbol{\theta}$. This is only feasible if the model has very few parameters and if $y(\boldsymbol{\theta})$ can be computed relatively quickly. Often there are 10 or more parameters and $y(\boldsymbol{\theta})$ can be computationally very expensive, so that another approach is necessary.

A simple approach is to use simple **random sampling**. This takes N independent and identically distributed realizations of $\boldsymbol{\theta}$. By analyzing correlations between each parameter $\theta_1, \ldots, \theta_k$ and $y(\boldsymbol{\theta})$ we can assess the level of sensitivity of $y(\boldsymbol{\theta})$ to each input parameter. The approach described by Blower & Dowlatabadi [6] is similar but they make use of Latin hypercube sampling to choose the N parameter sets.

The Latin hypercube sampling technique was first described by McKay et al. [24]. The method can significantly reduce the variance of various estimates relating to the distribution of $y(\boldsymbol{\theta})$ (for example, its mean and variance) and its relationship with each of the input parameters. Put another way, Latin hypercube sampling requires a smaller number of simulations of $y(\boldsymbol{\theta})$ to match the variance of various estimates under simple random sampling.

Some of the mathematics behind the technique were tightened up by Stein [34] who, in particular, proved that the variance of estimates under Latin hypercube sampling is lower for large N in all cases. In the worst cases the advantage in using Latin hypercube sampling might be small, but in practice the difference between the two methods can be very significant.

Owen [30] and Park [31] have both devised **algorithms** for choosing Latin hypercube designs which optimize certain criteria. The technique proceeds as follows. We wish to generate N values for $\boldsymbol{\theta}$. For each $i = 1, \ldots, k$ let θ_{i0} be the left-hand end of the range of θ_i and θ_{iN} be the right-hand end. We also define $F_i(x) = \int_{-\infty}^{x} f_i(u)\,\mathrm{d}u$ to be the marginal cumulative distribution function for θ_i. Thus, $F_i(\theta_{i0}) = 0$ and $F_i(\theta_{iN}) = 1$. We also define $\theta_{i0} \leq \theta_{i1} \leq \cdots \leq \theta_{iN}$ such that $\Pr(\theta_{ij} < \theta_i \leq \theta_{ij+1}) = F_i(\theta_{ij+1}) - F_i(\theta_{ij}) = 1/N$. Let $P_1 = (P_{11}, \ldots, P_{1N})$, $P_2, \ldots, P_k$ be k independent random

permutations of $(1, 2, \ldots, N)$. For $i = 1, \ldots, k$ and $j = 1, \ldots, N$ let ξ_{ij} be independent and identically distributed random variables with a **uniform distribution** on [0, 1] and let

$$Z_{ij} = F_i^{-1}\left[\frac{(P_{ij} - 1 + \xi_{ij})}{N}\right].$$

For each i and j the unconditional distribution for Z_{ij} is the same as the marginal distribution for θ_i. We also have, for each i, exactly one Z_{ij}, $j = 1, \ldots, N$, in each of the intervals $(\theta_{i0}, \theta_{i1}], \ldots, (\theta_{iN-1}, \theta_{iN}]$. This gives a rather more uniform look to a Latin hypercube sampling scheme than a typical random sample.

For each j let $\mathbf{Z}_j = (Z_{1j}, Z_{2j}, \ldots, Z_{kj})$ and $y_j = y(\mathbf{Z}_j)$. We can immediately now look at the estimated or empirical distribution for $y(\boldsymbol{\theta})$. The empirical distribution derived from $y_1, \ldots, y_N$ will tend to that of $y(\boldsymbol{\theta})$ as N gets large. Furthermore, for a given N, the arguments of McKay [24] and Stein [34] indicate that this empirical distribution is likely to be more accurate than that using simple random sampling.

If the output variable is significantly nonlinear within the normal range of values for the input parameters, then a conventional analysis of correlation will tend to understate the importance of those input parameters to which $y(\boldsymbol{\theta})$ is most nonlinear. To avoid this problem, Iman et al. [18] suggest making use of the ranks of the input parameters and of the outputs rather than their absolute values.

This approach was used by Blower & Dowlatabadi [6] in their analysis of a model for the spread of AIDS. They suggest that partial rank correlation coefficients should be used to investigate the sensitivity of $y(\boldsymbol{\theta})$ to changes in each of the input parameters.

The method proceeds as follows. Recall that each of the P_i is a random permutation of $1, 2, \ldots, N$. Thus P_{ij} is the **rank** of Z_{ij} in the set $\{Z_{i1}, \ldots, Z_{iN}\}$. Let $\mathbf{R} = (r_{ij})$ be a $(k + 1) \times N$ matrix with $r_{ij} = P_{ij}$ for $1 \le i \le k$ and $1 \le j \le N$, and $r_{k+1,j}$ be equal to the rank of $y_j = y(\mathbf{Z}_j)$ in the set $\{y_1, \ldots, y_N\}$. Let $\mathbf{C} = (\rho_{ij})$ be the symmetric $(k + 1) \times (k + 1)$ matrix defined by

$$\rho_{ij} = \frac{\sum_{t=1}^{N}(r_{it} - \mu)(r_{jt} - \mu)}{\left[\sum_{t=1}^{N}(r_{it} - \mu)^2 \sum_{s=1}^{N}(r_{jt} - \mu)^2\right]^{1/2}},$$

where $\mu = (N + 1)/2$ is the mean rank. The matrix $\mathbf{C}$ is the matrix of **rank correlation** coefficients. Another matrix, $\mathbf{B}$, is defined as the inverse of $\mathbf{C}$, i.e. $\mathbf{B} = \mathbf{C}^{-1}$. The partial rank correlation coefficient between parameters i and j [or between parameter i and $y(\theta)$ if $j = k + 1$] is then defined as (see [12] and [20])

$$\gamma_{ij} = \frac{-b_{ij}}{(b_{ii}b_{jj})^{1/2}}.$$

$\gamma_{i,k+1}$ is the correlation between the rank of θ_i and the rank of $y(\boldsymbol{\theta})$ given that all other input parameters are fixed. The larger the value of $\gamma_{i,k+1}$, the more sensitive $y(\boldsymbol{\theta})$ is to changes in θ_i.

There exist tests of significance of the hypothesis that θ_i and $y(\boldsymbol{\theta})$ are independent (for example, see [12]). This independence, of course, is very rarely the case. With a limited sample size, however, some of the $\gamma_{i,k+1}$ might not be significantly different from 0. On the other hand, if we take a large enough sample size, then we will eventually find that all of the $\gamma_{i,k+1}$ are significantly different from 0.

Both the rank correlation coefficients, $\rho_{i,k+1}$, and the partial rank correlation coefficients, $\gamma_{i,k+1}$, give us information about the sensitivity of $y(\boldsymbol{\theta})$ to changes in parameter i. If the input parameters are independent, then the ρ_{ij} will tell us as much as the γ_{ij}. However, if $y(\boldsymbol{\theta})$ gets closer to being a deterministic function of $\boldsymbol{\theta}$, then the $\gamma_{i,k+1}$ will all get closer to 1 while the ρ_{ij} converge to values that still reflect, more obviously, the relative importance of each input parameter. Blower & Dowlatabadi [6] use the transformation

$$t_i = \gamma_{i,k+1}\left(\frac{N - 2}{1 - \gamma_{i,k+1}}\right)^{1/2}.$$

The t_i, relative to one another, give a much better measure of the relative importance of each parameter. In this respect the values of the t_i relative to one another give a much better measure of the relative importance of each parameter.

If the input parameters are not independent, then this will tend to distort the ρ_{ij} and the γ_{ij}. For example, take model A in Figure 1. Suppose that the two infection parameters, c and p, are correlated in such a way that $cp = \beta + \varepsilon$, where β is constant and ε has zero mean and a relatively low variance. Then we will find that the partial rank correlation coefficients are very high while the rank correlation coefficients are very low.

The use of both sensitivity measures is discussed by Iman & Helton [17]. They note that while they will

give qualitatively similar results, they may indicate significantly different levels of sensitivity to certain input parameters.

Relaxation of Assumptions

Often we are interested in a projection of the epidemic curve rather than a single quantity at a single point in time: that is, $y(t, \boldsymbol{\theta})$ for $t > T_0$, the time of the last observation. Clearly it is not sensible to repeat the exercise, say m times (at times $T_0 < t_1 < \cdots < t_m$), in succession. Instead, the exercise should be run m times in parallel, to take advantage of the fact that $y(t_1, \boldsymbol{\theta}), \ldots, y(t_m, \boldsymbol{\theta})$ are all directly connected. Thus, for each $\mathbf{Z}_j$, $j = 1, \ldots, N$, we generate a full epidemic up to time t_m and extract values for $y(t_1, \mathbf{Z}_j), \ldots, y(t_m, \mathbf{Z}_j)$. This allows the construction of some sort of confidence band for the epidemic. However, in the sensitivity analysis, we can still only talk about the sensitivity of $y(t_j, \boldsymbol{\theta})$ to changes in parameter i. We are not able easily to talk about the sensitivity of the whole curve to changes in parameter i.

The input parameters do not need to be independent, although random but dependent input parameters can be more difficult to generate. Blower & Dowlatabadi [6] give a simple example of how this can be done: they specify that θ_2 has a triangular distribution with minimum value θ_1 and maximum 1. Stein [34] describes a more general method for generating dependent input parameters within a Latin hypercube sampling framework.

Besides using secondary data to help specify the distributions for the input parameters it is desirable to make use also of the observed epidemic curve itself. This can be a lengthy process since it involves first, numerical evaluation of, for example, the **maximum likelihood** or **Bayesian** estimators; and secondly, derivation of a suitable approximate distribution around this central estimate. Taking account of the observed epidemic curve is not easy, therefore, within the framework described in this section.

Since it is essential that we should take account of the observed epidemic curve, the method of primary components was devised.

Primary Component Analysis

This section describes an alternative method of sensitivity analysis which considers the whole epidemic curve, and which is appropriate for model fitting and projection. The method seeks to reparameterize the model leaving us with a small number of *primary components* which dictate epidemic dynamics. A common example of a primary component is the basic reproductive ratio, R_0, as in the development of model B at the beginning of the article.

The concept of such a set of primary components has been described by Mollison [25] and Cairns [9, 10]. Typically, a complex model will have many parameters but perhaps only three or four primary components. Knowledge of the values of the primary components will provide enough information to describe the epidemic curve to within a very high degree of accuracy.

The central idea behind this section is the notion that, in many cases, it is sufficient to estimate the primary components of a model to be able to obtain an adequate fit of past data and an adequate projection of the future course of an epidemic.

An important problem is that of how to fit a model to primary data (the epidemic curve) and secondary data (data gathered indirectly through medical and other studies related to the epidemic). Full maximum likelihood or a full Bayesian analysis would take all this data together resulting in a rather complex and difficult-to-evaluate function. First, maximization would take a long time. Secondly, the **likelihood** surface often will be very flat in some dimensions, meaning that the estimates of some parameters are subject to large standard errors.

The primary component method offers two principal advantages over full maximum likelihood methods:

1. estimation of the small number of primary components is much easier and faster than estimation of the full set of basic parameters; and
2. primary components can still be estimated reliably when secondary parameters are only backed up by unreliable or statistically unsound secondary data.

The fundamental requirements for a set of primary components are as follows:

1. A primary component is a function of the basic epidemic parameters which dictates epidemic dynamics.
2. Each primary component should be simple to interpret. The reason for this is that it makes it

much easier to transmit our conclusions from an analysis to nonexperts or laymen. Often these are the people who will make decisions about, for example, future provision of healthcare facilities. If results can be presented in a way that is simple to interpret, then it is more likely that an epidemic modeler will be in a position to influence what decisions are made.

3. The set of primary components should be as small as possible. This ties in with an overall objective of minimizing the time spent in fitting a model to a set of data: "Why estimate 10 parameters when 3 will do?" However, this can conflict with the previous requirement. It may be that a set of primary components could be reduced further but at the cost of leaving a set in which one or more of the primary components no longer has a simple interpretation. In such circumstances it may be undesirable to proceed with this final shrinkage of the set in order to retain the ease of interpretation.

It is also desirable (but not essential) that each primary component affects either short- or long-term dynamics, but not both. This is a useful criterion from the point of view that it eases comparison of epidemic curves generated by different parameter sets and it can speed up the process of estimation of parameter values.

The requirement that primary components should be easy to interpret provides the main distinction over the more rigorously founded theory of principal component analysis. This would produce a set of **orthogonal** components in order of their magnitude of influence on the likelihood function (and hence on the dynamics of the epidemic). While this would provide a theoretically optimal set of primary components, the result would be both at the expense of interpretability and also of restricting the effect of individual components to either short- or long-term dynamics. It is no coincidence, however, that a set of primary components will be closely aligned with the principal components.

Complementing the set of primary components we have the set of *secondary parameters*. The characteristics of this set are that provided the primary components remain fixed, then we can vary the remaining set of secondary parameters without significantly altering the dynamics of the epidemic. The range of values tested is designed to be consistent with the various sources of secondary data. In terms of model fitting this means that it is not of significance whether we optimize over the full set of parameters or just over the set of primary components in combination with a *realistic* rather than optimal set of secondary parameter values.

If, however, we do find that we can vary the secondary parameters within a realistic range and significantly alter the dynamics, then this indicates that the set of primary components is in some way incomplete or inadequate.

Cairns [9, 10] describes how primary components can be identified by subjective means:

1. Identify a potential first primary component (or the first two, say). Typically this might be the basic reproductive ratio, R_0, or the initial exponential growth rate of the epidemic. Let this set be denoted by $\boldsymbol{\theta}_P$.
2. Subject to $\boldsymbol{\theta}_P$ being fixed, vary the remaining parameters, $\boldsymbol{\theta}_S$, within a realistic range around a central value, $\boldsymbol{\theta}_0$ (without specific reference to probability distributions).
3. If there is no significant variation, then the set of primary components, $\boldsymbol{\theta}_P$, is complete.
4. Otherwise we need either to choose an alternative set of primary components of the same size or to increase the size of the set by one. Let $\boldsymbol{\theta}_P$ be the new, altered set of primary components and then return to step 2.

An example of this process applied to a simple model for the spread of HIV and AIDS can be found in [10]. Cairns [10] also discusses how the number of components depends on whether we consider just the incidence of new cases of AIDS or include the numbers of new infections in addition.

An objective means of carrying out a primary component analysis of an epidemic model was first proposed by Cairns (in discussion of Mollison et al. [26]). Hearne [16] has described the use of a similar objective function in the sensitivity analysis of a systems dynamics problem. This will be developed in the next section.

A Measure of Sensitivity

Previous work (for example, [9] and [10]) has relied on a degree of subjectivity when a decision must be made as to whether or not two epidemic curves are significantly different.

Consider Figure 2. It is clear that there is a much better match between curves (a) and (b) than curves (a) and (c). In this example the distinction is clear, but often this is not the case and this section aims to aid this process.

Let us consider the problem of modeling the AIDS epidemic. Suppose we assume that observed cases of AIDS occur as a **Poisson process** with an intensity following the deterministic curve (this is only valid when the population is large) then the log likelihood will be

$$l(\mathbf{A}, \boldsymbol{\theta}) = \sum_{t=1}^{T} [A_t \log(a_t) - a_t] + \text{constant},$$

where A_t is the observed incidence of AIDS in time period t and $a_t = a_t(\boldsymbol{\theta})$ is the predicted incidence based on the parameter values $\boldsymbol{\theta}$.

If the aim of modeling is at some stage to fit the model to a set of data $\{A_t\}$, then it seems appropriate to design a sensitivity function that reflects the characteristics of the log likelihood. An appropriate function is thus

$$l(\boldsymbol{\theta}_0, \boldsymbol{\theta}) = \int_0^T [a_t(\boldsymbol{\theta}_0) \log a_t(\boldsymbol{\theta}) - a_t(\boldsymbol{\theta})] \, \mathrm{d}t,$$

where $\boldsymbol{\theta}_0$ is the central or "true" parameter set, and $a_t(\boldsymbol{\theta}_0)$ and $a_t(\boldsymbol{\theta})$ are the epidemic curves generated by $\boldsymbol{\theta}_0$ and $\boldsymbol{\theta}$, respectively. $\boldsymbol{\theta}_0$ is chosen to reflect existing primary and secondary data, a task that becomes easier as we reparameterize the model.

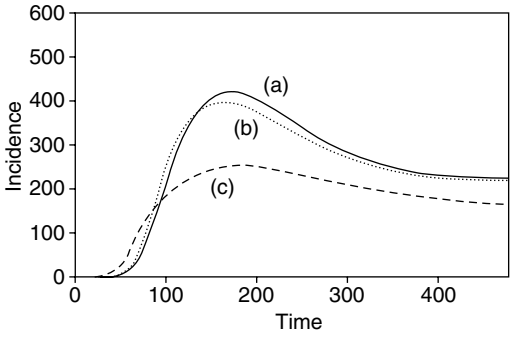

Figure 2 Three epidemic curves: (a) and (b) are better matched in some sense than (a) and (c).

It may be appropriate to consider the discrete form of the sensitivity function. This is

$$l(\boldsymbol{\theta}_0, \boldsymbol{\theta}) = \sum_{t=1}^{T} [a_t(\boldsymbol{\theta}_0) \log a_t(\boldsymbol{\theta}) - a_t(\boldsymbol{\theta})].$$

In what follows we consider the continuous and discrete forms interchangeably.

A further alternative is to note that $-2 \times$ (log likelihood) is asymptotically equivalent to the **chi-square statistic** (*see* **Likelihood Ratio Tests**). The equivalent sensitivity function would therefore be

$$c(\boldsymbol{\theta}_0, \boldsymbol{\theta}) = \sum_{t=1}^{T} \frac{[a_t(\boldsymbol{\theta}_0) - a_t(\boldsymbol{\theta})]^2}{a_t(\boldsymbol{\theta})},$$
$$\approx 2[l(\boldsymbol{\theta}_0, \boldsymbol{\theta}_0) - l(\boldsymbol{\theta}_0, \boldsymbol{\theta})].$$

For a given value of t note that $a_t(\boldsymbol{\theta}_0) \log a_t(\boldsymbol{\theta}) - a_t(\boldsymbol{\theta})$ is maximized when $a_t(\boldsymbol{\theta}) = a_t(\boldsymbol{\theta}_0)$ (for example, if $\boldsymbol{\theta} = \boldsymbol{\theta}_0$). Hence

$$l_{\max} = \sup_{\boldsymbol{\theta}} l(\boldsymbol{\theta}_0, \boldsymbol{\theta}) = l(\boldsymbol{\theta}_0, \boldsymbol{\theta}_0).$$

Furthermore, by Taylor's expansion we have

$$l(\boldsymbol{\theta}_0, \boldsymbol{\theta}) = l_{\max} - \tfrac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\theta}_0)^{\mathrm{T}} \mathbf{H} (\boldsymbol{\theta} - \boldsymbol{\theta}_0) + o(|\boldsymbol{\theta} - \boldsymbol{\theta}_0|^2), \quad (1)$$

where $\mathbf{H} = -D^2_{\boldsymbol{\theta}} l(\boldsymbol{\theta}_0, \boldsymbol{\theta})|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}$ (the matrix of second derivatives evaluated at $\boldsymbol{\theta}_0$) is a positive semidefinite $k \times k$ matrix and k is the number of basic parameters in the model.

If $l(\cdot)$ is thought of as a likelihood function, then $\mathbf{H}$ is an **information matrix** in the normal statistical sense. The **eigenvalues** of $\mathbf{H}$ are $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k \geq 0$ and the corresponding **eigenvectors** are $\mathbf{e}_1, \ldots, \mathbf{e}_k$ with $\mathbf{e}_i^{\mathrm{T}} \mathbf{e}_j = \delta_{ij}$. A large eigenvalue, λ_i, means that $l(\cdot)$ is more sensitive to changes in the parameter values in line with $\mathbf{e}_i$ (at least in absolute terms). This also means that $\mathbf{e}_1$ gives us the most information about the shape of the epidemic curve, $\mathbf{e}_2$ the second most information, etc.

In theory, we should select primary components that match exactly the principal eigenvectors. However, the resulting components would not have a simple interpretation, and would violate the second requirement for a primary component. We therefore investigate different potential sets of primary components which are not necessarily optimal in the

sense of providing maximum information but which are, nevertheless, closely aligned with the principal eigenvectors.

The following sections develop the sensitivity function from a statistical point of view, but the first step is always to reparameterize the model in such a way that we can divide the set of parameters $\boldsymbol{\theta}$ into $\boldsymbol{\theta}_{\mathrm{P}}$, the p potential primary components, and $\boldsymbol{\theta}_{\mathrm{S}}$, the remaining $s = k - p$ secondary parameters.

Model Fitting

Before carrying out a projection of an epidemic and a sensitivity analysis of this projection with respect to variation of the input parameters, it is necessary to fit the model to what data we have available. We then have an approximate joint distribution for the primary components, $\boldsymbol{\theta}_{\mathrm{P}}$, and the secondary parameters, $\boldsymbol{\theta}_{\mathrm{S}}$, derived from the existing data. This can be used to generate random input parameter values, each producing a different projection of the epidemic. A sensitivity function for the projected part of the epidemic curve, of the form described in the previous subsection, can then be analyzed for sensitivity to changes in each of the input primary components or secondary parameters.

To aid comprehension, the remainder of this section will continue to consider a model for the spread of HIV and AIDS.

Two types of data are assumed to be available: (primary) AIDS incidence data; and (secondary) data from other studies which give us information about the secondary parameters and perhaps also about the primary components. Within the field of AIDS modeling, an example of such secondary data is that which relates to the distribution of the infectious period (for example, [21–23]).

These data can be treated in a number of different ways. One of these is to pool the data and maximize the likelihood over the full set of basic parameters. When the model is complex this may be a very lengthy or perhaps even impossible task if the data are not suitably detailed.

Here we describe an alternative approach.

1. Use the secondary data to estimate the secondary parameters. These estimates will then be used in the second stage.
2. Use the primary data and maximize their likelihood over the set of primary components only.

A modeler needs to be satisfied, however, that the use of fixed rather than uncertain secondary parameter values does not produce a significantly narrower range of fits and projections.

The estimation procedure will inevitably result in some loss of accuracy. However, it is intended that if the set of primary components has been chosen carefully, then this loss of accuracy will be minimal. Conversely, if the loss of accuracy is significant, then the set of primary components should be considered as being inappropriate or inadequate in some way.

The major advantage is that by breaking down the process of estimation we can make the task much simpler and faster without having a significant loss of accuracy.

We consider four different estimators for $\boldsymbol{\theta}$:

1. $\hat{\boldsymbol{\theta}}$: the maximum likelihood estimator (MLE) based on primary data alone;
2. $\tilde{\boldsymbol{\theta}}$: the MLE based on secondary data alone;
3. $\dot{\boldsymbol{\theta}}$: the MLE based on pooled primary and secondary data; and
4. $\overline{\boldsymbol{\theta}}$: the primary component maximum likelihood estimator (described below).

Let $l(\mathbf{A};\boldsymbol{\theta})$ be the likelihood function given only the primary AIDS incidence data $\{A_t\}$. Then

$$l(\mathbf{A};\boldsymbol{\theta}) \approx l_{\max} - \tfrac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathrm{T}}\mathbf{H}_p(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}),$$

where $l_{\max} = l(\mathbf{A};\hat{\boldsymbol{\theta}})$ is the maximum likelihood, and $\mathbf{H}_p$ is the information matrix for the primary data as defined in (1).

Suppose, also, that secondary data have been collected and that we wish to fix the secondary parameters at $\boldsymbol{\theta}_{\mathrm{S}} = \tilde{\boldsymbol{\theta}}_{\mathrm{S}}$. Estimation of the primary components, $\boldsymbol{\theta}_{\mathrm{P}}$, is then reduced to the problem

$$\text{minimize } f(\boldsymbol{\theta}) = (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathrm{T}}\mathbf{H}_p(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})$$

$$\text{subject to } \boldsymbol{\theta}_{\mathrm{S}} = \tilde{\boldsymbol{\theta}}_{\mathrm{S}}.$$

Given that $\boldsymbol{\theta}_{\mathrm{P}}$ is $p \times 1$ and $\boldsymbol{\theta}_{\mathrm{S}}$ is $s \times 1$, we write

$$\mathbf{H}_p = \begin{pmatrix} \mathbf{H}_{p11} & \mathbf{H}_{p12} \\ \mathbf{H}_{p21} & \mathbf{H}_{p22} \end{pmatrix},$$

where $\mathbf{H}_{p11}$ is a $p \times p$ matrix, $\mathbf{H}_{p12} = \mathbf{H}_{p21}^{\mathrm{T}}$ is $p \times s$, and $\mathbf{H}_{p22}$ is $s \times s$.

The minimization with the constraint is then equivalent to the unconstrained problem:

$$\text{minimize } f(\boldsymbol{\theta}_{\mathrm{P}}) = (\boldsymbol{\theta}_{\mathrm{P}} - \overline{\boldsymbol{\theta}}_{\mathrm{P}})^{\mathrm{T}}\mathbf{H}_{p11}(\boldsymbol{\theta}_{\mathrm{P}} - \overline{\boldsymbol{\theta}}_{\mathrm{P}}) + C,$$

where

$$\overline{\boldsymbol{\theta}}_{\mathrm{P}} = \hat{\boldsymbol{\theta}}_{\mathrm{P}} - \mathbf{H}_{p11}^{-1}\mathbf{H}_{p12}(\tilde{\boldsymbol{\theta}}_{\mathrm{S}} - \hat{\boldsymbol{\theta}}_{\mathrm{S}})$$

and

$$C = (\tilde{\boldsymbol{\theta}}_{\mathrm{S}} - \hat{\boldsymbol{\theta}}_{\mathrm{S}})^{\mathrm{T}}[\mathbf{H}_{p22} - \mathbf{H}_{p21}\mathbf{H}_{p11}^{-1}\mathbf{H}_{p12}](\tilde{\boldsymbol{\theta}}_{\mathrm{S}} - \hat{\boldsymbol{\theta}}_{\mathrm{S}}).$$

It is clear that this is minimized when $\boldsymbol{\theta}_{\mathrm{P}} = \overline{\boldsymbol{\theta}}_{\mathrm{P}}$.

Note that $C = f(\overline{\boldsymbol{\theta}}_{\mathrm{P}}, \tilde{\boldsymbol{\theta}}_{\mathrm{S}}) \geq 0$ since $\mathbf{H}_p$ is positive semidefinite. Also, since $\tilde{\boldsymbol{\theta}}_{\mathrm{S}}$ is a random variable depending on the secondary data, C is a random variable.

We define $\overline{\boldsymbol{\theta}}_{\mathrm{S}} = \tilde{\boldsymbol{\theta}}_{\mathrm{S}}$ and call $\overline{\boldsymbol{\theta}} = (\overline{\boldsymbol{\theta}}_{\mathrm{P}}, \overline{\boldsymbol{\theta}}_{\mathrm{S}})$ the primary component maximum likelihood estimate (PCMLE). We can then write.

$$\overline{\boldsymbol{\theta}} = \mathbf{E}_p\hat{\boldsymbol{\theta}} + \mathbf{E}_s\tilde{\boldsymbol{\theta}},$$

where $$\mathbf{E}_p = \begin{pmatrix} \mathbf{I}_p & \mathbf{H}_{p11}^{-1}\mathbf{H}_{p12} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}$$

and $$\mathbf{E}_s = \begin{pmatrix} \mathbf{0} & -\mathbf{H}_{p11}^{-1}\mathbf{H}_{p12} \\ \mathbf{0} & \mathbf{I}_s \end{pmatrix}.$$

We are concerned with the accuracy of the PCMLE, $\overline{\boldsymbol{\theta}}$, relative to the full MLE, $\dot{\boldsymbol{\theta}}$, and to do this we need to know about $\hat{\boldsymbol{\theta}}$ and $\tilde{\boldsymbol{\theta}}$.

With a large population, it is well known that $\hat{\boldsymbol{\theta}} \dot{\sim} \mathrm{N}(\boldsymbol{\theta}_0, \mathbf{A}_p^{-2})$, where $\mathbf{A}_p^2 = \mathbf{H}_p$. Similarly, we have $\tilde{\boldsymbol{\theta}} \dot{\sim} \mathrm{N}(\boldsymbol{\theta}_0, \mathbf{A}_s^{-2})$, where $\mathbf{A}_s^2 = \mathbf{H}_s$ and $\mathbf{H}_s$ is the information matrix for the secondary data.

Assuming that these distributions apply, we have the following distributional results:

$$\overline{\boldsymbol{\theta}} - \boldsymbol{\theta}_0 \dot{\sim} \mathrm{N}(\mathbf{0}, \mathbf{A}_b^{-2}), \tag{2}$$

where

$$\mathbf{A}_b^{-2} = \mathbf{E}_p\mathbf{H}_p^{-1}\mathbf{E}_p^{\mathrm{T}} + \mathbf{E}_s\mathbf{H}_s^{-1}\mathbf{E}_s^{\mathrm{T}},$$

and

$$(\overline{\boldsymbol{\theta}} - \boldsymbol{\theta}_0)^{\mathrm{T}}\mathbf{H}_p(\overline{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \approx X_p + X_s, \tag{3}$$

where $$X_p \sim \chi_p^2$$

and $$X_s = \sum_i \lambda_i' Y_i^2,$$

and where $\mathbf{Y} \sim \mathrm{N}(\mathbf{0}, \mathbf{I}_{p+s})$ and $\lambda_1' \geq \lambda_2' \geq \cdots \geq \lambda_s' \geq 0 = \lambda_{s+1}' = \cdots = \lambda_{s+p}'$ are the eigenvalues of the matrix $\mathbf{A}_s^{-1}\mathbf{E}_s^{\mathrm{T}}\mathbf{H}_p\mathbf{E}_s\mathbf{A}_s^{-1}$.

Eq. (2) tells us about parameter estimates; (3) tells us about how well we have estimated the true underlying epidemic curve up to time T. We anticipate that if the set of primary components has been well chosen, then the "error" term, X_s, will be small relative to X_p (that is, $\lambda_1', \ldots, \lambda_s' \ll 1$).

To facilitate comparison with the results of full maximum likelihood described below, we define $\lambda = (\lambda_1, \ldots, \lambda_{p+s})$, where $\lambda_1 = \cdots = \lambda_p = 1$ and $\lambda_{p+k} = \lambda_k'$ for $k = 1, \ldots, s$.

Suppose, on the other hand, we consider the full MLE, $\dot{\boldsymbol{\theta}}$. Using a similar normal approximation we have:

$$\dot{\boldsymbol{\theta}} - \boldsymbol{\theta}_0 \dot{\sim} \mathrm{N}(\mathbf{0}, \mathbf{A}_f^{-2}), \tag{4}$$

where $$\mathbf{A}_f^2 = \mathbf{H}_f$$

and $$\mathbf{H}_f = \mathbf{H}_p + \mathbf{H}_s,$$

and $$(\dot{\boldsymbol{\theta}} - \boldsymbol{\theta}_0)^{\mathrm{T}}\mathbf{H}_p(\dot{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \approx \sum_i \nu_i \mathbf{Y}_i^2 \tag{5}$$

where $\mathbf{Y} \sim \mathrm{N}(\mathbf{0}, \mathbf{I}_{p+s})$ and $1 \geq \nu_1 \geq \cdots \geq \nu_{p+s} \geq 0$ are the eigenvalues of the matrix $\mathbf{A}_f^{-1}\mathbf{H}_p\mathbf{A}_f^{-1}$. If the primary component maximum likelihood method is appropriate, then we should find that of the eigenvalues, ν_i, of $\mathbf{A}_f^{-1}\mathbf{H}_p\mathbf{A}_f^{-1}$, p will be close to 1, and the remaining s will be close to 0, so that

$$(\dot{\boldsymbol{\theta}} - \boldsymbol{\theta}_0)^{\mathrm{T}}\mathbf{H}_p(\dot{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \dot{\sim} \chi_p^2.$$

In (2) and (3) we also found that

$$(\overline{\boldsymbol{\theta}} - \boldsymbol{\theta}_0)^{\mathrm{T}}\mathbf{H}_p(\overline{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \dot{\sim} \chi_p^2;$$

that is, the accuracy of the model fitting will be improved only marginally if the full process of maximum likelihood is performed instead of primary component maximum likelihood.

Departures from these approximations may occur if:

1. The secondary data contain significant information about some of the primary components. That is, if $\mathbf{v}^{\mathrm{T}}\mathbf{v} = 1$ and $\mathbf{H}_p\mathbf{v} = \gamma\mathbf{v}$, where γ is large (so $\mathbf{v}$ is predominantly aligned within the space of primary components) and if $(\mathbf{v}^{\mathrm{T}}\mathbf{H}_s\mathbf{v})/\gamma$ is *not* close to zero, then one or more of $\nu_1, \ldots, \nu_p$ will be significantly less than 1. Hence full maximum likelihood will produce a better estimate of the true underlying epidemic curve.

2. The secondary data contain little information about some of the secondary parameters. That is, if $\mathbf{v}^{\mathrm{T}}\mathbf{v} = 1$ and $\mathbf{H}_p\mathbf{v} = \gamma\mathbf{v}$ where γ is small (so $\mathbf{v}$ is predominantly aligned within the space of secondary parameters) and if $(\mathbf{v}^{\mathrm{T}}\mathbf{H}_s\mathbf{v})/\gamma$ is not very large, then one or more of the $\nu_{p+1}, \ldots, \nu_{p+s}$ will be significantly greater than zero. This will have a similar effect on the primary component estimate by making the error term, X_s, more significant. However, whereas the ν_i will always be bounded above by 1, no such bound exists for the eigenvalues used in X_s. For a given set of primary components this problem is more likely to occur as the size of the population increases. This indicates that, when one of the λ_i exceeds, say, 0.5 or 1, the set of primary components should be reviewed and perhaps enlarged.

The process described here is similar in some respects to the process of model selection (for example, *see* **Akaike's Criteria** [1, 32, 33]). In simple terms, the model selection process keeps adding in extra parameters until the fit of the next model is no longer a significant improvement on the previous, simpler model. This matches the process described here of increasing the set of primary components until the dynamics of the model are no longer sensitive (in a significant way) to changes in the remaining (secondary) parameters.

Projection

A great variety of problems exist here, so that it is only possible to discuss a small but typical subset. Our starting point is that the projected epidemic curve for $t > T$ is $a_t(\dot{\boldsymbol{\theta}})$, using full maximum likelihood, or $a_t(\overline{\boldsymbol{\theta}})$, using primary component maximum likelihood.

We are concerned with the following questions:

1. Given the past data, to what input parameters is the projected epidemic curve sensitive?
2. Are the ranges of projections (confidence bands) for the full MLE and PCMLE approaches similar?

We can also consider how the level of uncertainty in the future can be reduced in the most effective way by carrying out further secondary studies. The framework described here will identify whether or not a proposed study will have the effect of reducing this uncertainty by a significant margin.

Projection of the Epidemic Curve. Suppose we wish to consider the accuracy of the projected curve between times T_0 and T_1 (commonly T, the end of the period of observation, and T_0 will coincide). Again we may use the sensitivity function

$$l(\boldsymbol{\theta}_0, \boldsymbol{\theta}) = \int_{T_0}^{T_1} \left[a_t(\boldsymbol{\theta}_0) \log a_t(\boldsymbol{\theta}) - a_t(\boldsymbol{\theta})\right] \mathrm{d}t$$
$$\approx l_{\max} - \tfrac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\theta}_0)^{\mathrm{T}}\mathbf{H}_q(\boldsymbol{\theta} - \boldsymbol{\theta}_0),$$

where $a_t(\boldsymbol{\theta}_0)$ is the true future incidence rate and $a_t(\boldsymbol{\theta})$ is the projection based on the (PC)MLE, $\boldsymbol{\theta}$.

It is appropriate, first, to carry out a preliminary analysis similar to that described in an earlier section. The starting point will be the set of primary components, $\boldsymbol{\theta}_{\mathrm{P}}$, relevant for the observed epidemic curve up to time T. This set may already, in effect, fix dynamics between times T_0 and T_1 (that is, the projected curve is not sensitive to changes in $\boldsymbol{\theta}_{\mathrm{S}}$). If this is the case, then there is no need to proceed any further and it should be found that the observed epidemic curve will provide enough information to permit an accurate projection. On the other hand, the dynamics between T_0 and T_1 may be sensitive to changes in $\boldsymbol{\theta}_{\mathrm{S}}$. If this is the case, then $\boldsymbol{\theta}_{\mathrm{P}}$ should be enlarged in such a way that it fully describes the dynamics both up to time T and between T_0 and T_1. (For convenience we will call the revised set $(\boldsymbol{\theta}_{\mathrm{P}}, \boldsymbol{\theta}_{\mathrm{Q}})$, where $\boldsymbol{\theta}_{\mathrm{Q}}$ is the set of additional primary components). In these circumstances the observed epidemic curve will not contain much (if any) information about $\boldsymbol{\theta}_{\mathrm{Q}}$. $\boldsymbol{\theta}_{\mathrm{Q}}$ is, however, required for an accurate projection between T_0 and T_1. If we cannot get good estimates of all of $\boldsymbol{\theta}_{\mathrm{Q}}$, then potentially there will be considerable uncertainty in the projected curve. In particular, the projected curve:

1. will be sensitive to changes in $\boldsymbol{\theta}_Q$;
2. will not be sensitive to changes in the remaining reduced secondary parameter set, $\boldsymbol{\theta}_{\mathrm{R}} = \boldsymbol{\theta}_{\mathrm{S}} \backslash \boldsymbol{\theta}_{\mathrm{Q}}$; and
3. may be sensitive to changes in the original set of primary components, $\boldsymbol{\theta}_{\mathrm{P}}$.

The sensitivity to changes in $\boldsymbol{\theta}_Q$ could be reduced if the existing secondary data contain enough information to get a good estimate of $\boldsymbol{\theta}_Q$.

This heuristic approach can be placed in a more rigorous framework in the following way.

Recall that $\overline{\boldsymbol{\theta}} \approx \mathbf{A}_b^{-1}\mathbf{Z}$, where $\mathbf{Z} \sim \mathrm{N}(\mathbf{0}, \mathbf{I}_{p+s})$ and $\mathbf{A}_b^{-2} = \mathbf{E}_p\mathbf{H}_p^{-1}\mathbf{E}_p^{\mathrm{T}} + \mathbf{E}_s\mathbf{H}_s^{-1}\mathbf{E}_s^{\mathrm{T}}$ [Eq. (2)]. Hence,

$$2(l(\boldsymbol{\theta}_0, \boldsymbol{\theta}_0) - l(\boldsymbol{\theta}_0, \overline{\boldsymbol{\theta}})) \approx \mathbf{Z}^{\mathrm{T}}\mathbf{A}_b^{-1}\mathbf{H}_q\mathbf{A}_b^{-1}\mathbf{Z} = \sum_i \psi_i Y_i^2,$$

where $\psi_1 \geq \psi_2 \geq \cdots \geq \psi_{p+s} \geq 0$ are the eigenvalues of $\mathbf{A}_b^{-1}\mathbf{H}_q\mathbf{A}_b^{-1}$ and $\mathbf{Y} \sim \mathrm{N}(\mathbf{0}, \mathbf{I}_{p+s})$.

The accuracy of the projection is therefore determined by the magnitudes of the ψ_i. Clearly, the accuracy depends on how well the primary components of the observed epidemic curve relate to the primary components of the projected curve. For example, if the primary data contain good information about all the primary components of the projected curve, then the projection will be accurate. On the other hand, if the primary data contain relatively little information about one or more of the primary components of the projected curve, then the projection may be quite inaccurate (this is a problem with long-term projection based on a limited amount of early incidence data – see [9]).

If accuracy of projection is our objective, then it may be appropriate to choose a number and set of primary components which will be estimated using the observed incidence data which minimizes the eigenvalues of $\mathbf{A}_b^{-1}\mathbf{H}_q\mathbf{A}_b^{-1}$.

Similarly, recall that $\dot{\boldsymbol{\theta}} \approx \mathbf{A}_f^{-1}\mathbf{Z}$, where $\mathbf{Z} \sim \mathrm{N}(\mathbf{0}, \mathbf{I}_{p+s})$. Hence

$$2[l(\boldsymbol{\theta}_0, \boldsymbol{\theta}_0) - l(\boldsymbol{\theta}_0, \dot{\boldsymbol{\theta}})] \approx \mathbf{Z}^{\mathrm{T}}\mathbf{A}_f^{-1}\mathbf{H}_q\mathbf{A}_f^{-1}\mathbf{Z} = \sum_i \xi_i Y_i^2$$

where $\xi_1 \geq \xi_2 \geq \cdots \geq \xi_{p+s} \geq 0$ and $\mathbf{Y} \sim \mathrm{N}(\mathbf{0}, \mathbf{I}_{p+s})$.

Because $\mathbf{H}_q$ is quite independent of $\mathbf{H}_p$ and $\mathbf{H}_s$, it is impossible to make any theoretical remarks on the relative accuracy of the two methods of projection. This can only be done by considering specific examples.

Sensitivity Analysis of the Projected Epidemic Curve. From the earlier discussion, it is necessary only to carry out a sensitivity analysis with reference to the set of primary components $(\boldsymbol{\theta}_P, \boldsymbol{\theta}_Q)$. Such an analysis could be carried out in the same way as in the section "Sensitivity Analysis for Single Quantities". One immediate advantage of having first carried out a reparameterization to separate out the primary components is that we now find that the small set of primary components will explain a very large part of the variation in dynamics. The usual form of sensitivity analysis would have found that knowledge of a much larger number of the basic parameters would be required to get the same level of accuracy.

This reduction in the number of significant components can be put to advantage. Instead of carrying out a sensitivity analysis of the full parameter set it is only necessary to consider the primary components. The preceding analysis took a quadratic approximation around the PCMLE. It may be felt, however, that this approximation may not be adequate within the range of values for $(\boldsymbol{\theta}_P, \boldsymbol{\theta}_Q)$. Typically, the number of primary components will be as small as three or four. This allows quite a wide range of combinations to be investigated, far more than would be possible to consider if the full parameter set was being investigated.

This can be done in a number of ways:

1. Latin hypercube sampling can be employed, followed by an analysis of the rank and partial rank correlation coefficients.
2. A regular lattice framework around the PCMLE, as described by Cox & Medley [11] and Cairns [9], can be used, taking into account the relative likelihood of each point on the lattice.
3. Or a quadratic approximation around the PCMLE can be assumed.

The small number of primary components, in particular, allows investigation of interactions between different combinations of components and over the full range. Method 1 can be employed in an investigation of the sensitivity of single quantities of interest to changes in the primary components. Methods 2 and 3 can be applied to the sensitivity function defined in the previous subsection. If there are only two or three primary components, then it is possible to present the results of the sensitivity analysis graphically, for example using contour plots. Methods 2 and 3 are also appropriate for the construction of **confidence intervals** [9–11].

ANDREW J.G. CAIRNS

Epidemic Models, Spatial

If we are to gain proper understanding of the dispersal and control of diseases such as malaria, rabies, and **AIDS**, then we have to recognize that they develop within a truly spatial framework. The common assumption that individuals mix homogeneously over the whole region available to them stems mainly from mathematical convenience (*see* **Random Mixing**); in real life, we have to accept that both individuals and disease often develop within separate subregions. Classic examples of such spatial catastrophes include: 25 million deaths in fourteenth century Europe from Black Death out of a population of 100 million; the Aztecs lost half their population of 3.5 million from smallpox; around 20 million died in the world influenza pandemic in 1919; whilst millions of people are believed to be currently affected by HIV/AIDS. A particularly interesting case is the spread of one of the world's greatest cholera pandemics, the El Tor strain. It was first identified outside Mecca in 1905, and was later recognized in the 1930s as being endemic in the Celebes. Little was heard of it until 1961, when it suddenly exploded out of the Celebes, reaching India in 1964, and advancing into central Africa, Russia, and Europe by the early 1970s. The total burden of misery and suffering that results from such disease is clearly immense, and any understanding that modeling techniques can bring to alleviate this terrible state of affairs *has* to invoke spatial transmission properties.

Disease is spread through two different mechanisms. First, infected individuals may *migrate* to a different location, thereby infecting susceptibles at this new site. Migration patterns can be truly local (spread of HIV in "shooting galleries"), mid-range (sexual transmission between neighboring cities), or global (spread of human disease through intercontinental travel). Second, the disease itself may spread through *cross-infection*, either locally (between neighboring trees) or globally (aerosol dispersal of plant disease). Some situations may involve both mechanisms, such as the UK outbreaks of foot-and-mouth disease. Hengeveld's account [6] of documented invasion scenarios contains many varied examples, including cholera in North America, stripe rust in wheat, the expansion of cattle egret in North and South America, and rabies in Central Europe.

If migration or cross-infection is highly localized, then infectives/infection may *diffuse* over a continuous region. In contrast, if it results in substantive changes in location, then we either have a *spatial jump* process (plants infected by windblown spores), or a *stepping-stone* process if infection can only occur at specific sites (influenza epidemics in Icelandic coastal settlements).

Given that many populations develop within reasonably well-defined subregions, the stepping-stone approach is a sensible one to consider first. We envisage the process as being spatially distributed amongst n sites, with migration and/or cross-infection being allowed between them. This may involve nearest neighbors, all sites with a common transmission rate, or all sites but with the transmission rate changing with intersite distance (called the *contact distribution*). Such migration scenarios were first posed by Kimura [8] in a genetics context, but substantive theoretical development really began following Bailey's simple birth–death–migration process [1]. In this model, the population develops on an infinite set of colonies (thereby avoiding edge-effect problems), all individuals undergo a simple birth–death process with rates λ and μ, respectively (*see* **Stochastic Processes**), and individuals in colony i can migrate at rate ν_1, ν_2 to the two nearest neighbors $i+1$, $i-1$. For the equivalent general epidemic process, with $X_i(t)$ susceptibles and $Y_i(t)$ infectives in colony i at time t, the infective population at i increases at rate $\beta X_i(t)Y_i(t)$. In the opening stages, $\beta X_i(t) \simeq \beta X_i(0) = \lambda$ (say), so there the two processes are roughly equivalent. Unfortunately, even Bailey's process teeters on the edge of mathematical tractability, so the prospects for making substantial theoretical progress with more complicated spatial epidemic processes are remote. Replacing migration with cross-infection (at rate α_1, α_2) makes this situation even worse, since the infective population birth rate changes to $X_i(t)[\beta Y_i(t) + \alpha_1 Y_{i-1}(t) + \alpha_2 Y_{i+1}(t)]$.

Consider, for example, the recent (nonspatial) upsurge of interest in modeling the population dynamics of the AIDS epidemic. Much of the mathematical development is deterministic (*see* **Epidemic Models, Deterministic**), though this does facilitate the allowance of many sources of change [7]. One surprisingly tractable nonlinear model is that of Ball & O'Neill [2], and to place this within a spatial nearest-neighbor setting, let $x_i(t)$, $y_i(t)$, and $z_i(t)$ denote the

number of susceptible, HIV-infected, and removed (i.e. full-blown AIDS or dead) individuals at site i. Then allowing for the migration of infectives gives rise to the deterministic representation

$$\begin{aligned}\frac{dx_i}{dt} &= \frac{-\beta x_i y_i}{x_i + y_i},\\ \frac{dy_i}{dt} &= \frac{\beta x_i y_i}{x_i + y_i} - (\nu_1 + \nu_2)y_i + \nu_1 y_{i-1} + \nu_2 y_{i+1},\\ \frac{dz_i}{dt} &= \gamma y_i. \end{aligned} \tag{1}$$

This situation is in marked contrast with the spatial general epidemic model with cross-infection, with

$$\begin{aligned}\frac{dx_i}{dt} &= -x_i[\beta y_i + \alpha_1 y_{i-1} + \alpha_2 y_{i+1}],\\ \frac{dy_i}{dt} &= x_i[\beta y_i + \alpha_1 y_{i-1} + \alpha_2 y_{i+1}] - \gamma y_i,\\ \frac{dz_i}{dt} &= \gamma y_i. \end{aligned} \tag{2}$$

Such equations are easily modified to enable general migration at rate ν_{ij} from site i to site j, and cross-infection at rate α_{ij} between infectives in site i and susceptibles at site j. Exact solution is usually not possible, though approximate results may be obtained using careful linearization procedures: for numerical solutions use MATLAB, and so on. Often, we are interested in qualitative, rather than quantitative, behavior, and visual inspection of graphical output over a range of parameter settings is usually sufficient to highlight the most important aspects of the process.

Although the propagation of an epidemic through towns or villages is easily visualized in terms of a stepping-stone process, for disease dispersal in animals or plants, a diffusion model may be more appropriate. Near the wavefront itself, the number of susceptibles may be assumed to be fairly constant, and so there the process reduces to a simple birth–death process amenable to Skellam's diffusion approach [21]. On describing the infective density at position (u, v) by **Brownian motion** with zero drift and displacement variances $\mathrm{var}[u(1)] = \mathrm{var}[v(1)] = D^2$, we have the polar normal probability density function (pdf) (*see* **Bivariate Normal Distribution**)

$$\phi(r, \theta; t) = (2\pi D^2 t)^{-1} r \exp\left[\frac{-r^2}{2D^2 t}\right]. \tag{3}$$

Since there is no drift, this pdf spreads out in ever-expanding circles, and for an infective population of final size N, the radial velocity $R(t)/t$ is $D\{[2\ln(N)]/t\}^{1/2}$, which decreases as $t^{-1/2}$. For a long timescale, say, several decades, which is the case for fox rabies in Europe and the El Tor cholera strain, we might assume exponential growth at rate ψ, whence N is replaced by $N\exp(\psi t)$ and the velocity now remains constant at $D\{[2\psi\ln(N)]\}^{1/2}$. The combination of population growth and diffusion is essential if spatial expansion is not to fade out.

The diffusion approach involves a poor Taylor series expansion, and so the two scenarios can give rise to substantially different results. For example, with Bailey's birth–death process, the wavefront velocities (for $\lambda > \mu$) are the solutions to the equation [13]

$$\begin{aligned}\nu_1 + \nu_2 + \mu - \lambda &= (c^2 + 4\nu_1\nu_2)^{1/2}\\ &\quad - c\ln\left\{\frac{[c + (c^2 + 4\nu_1\nu_2)^{1/2}]}{(2\nu_1)}\right\}, \end{aligned} \tag{4}$$

while the equivalent diffusion velocities take the much simpler form

$$c_{\mathrm{diff}} = (\nu_1 - \nu_2) \pm \{2(\lambda - \mu)(\nu_1 + \nu_2)\}^{1/2}. \tag{5}$$

These two results are compatible only if $\lambda - \mu \ll \nu_1 + \nu_2$.

Mollison [9] argues strongly that when considering the velocity of spread, one should lean heavily towards using basic linear deterministic models, claiming that their assumptions are relatively transparent, they are easy to analyze, yet they generally give the same velocity as more complex linear stochastic and nonlinear deterministic models. Their relative simplicity allows more freedom to choose a biologically/epidemiologically realistic model, and hence, greatly facilitates examination of the dependence of conclusions on model components. Note, however, that such linear models provide only an upper bound for the velocity of more realistic stochastic nonlinear models. Further, both deterministic and stochastic linear models are usually completely unsuitable for modeling complex features such as the transition to endemicity and endemic patterns. Nonlinear deterministic models may provide useful information regarding the transition to endemicity but they are usually wholly inadequate for fluctuations about an endemic state.

Many useful conclusions from models for spatial spread are sensitive to the assumptions made in formulating and fitting them, and incorporating realistic epidemiological parameters will make exact theoretical analysis impossible to achieve. Such parameters can be framed in terms of the following concepts. The *basic reproductive ratio* R_0 is the mean number of contacts made by an infective, and this plays a crucial role in determining whether an epidemic outbreak can occur (*see* **Reproduction Number**); the *carrying capacity* K, which enters via R_0, denotes the maximum population density. The time T of a typical infection relative to that of its parent infective is called the *generation gap*, and its relative location in space X, the *dispersal distance*; whilst the distribution of T itself is called the *reproduction kernel* and that of X, the *dispersal* or *contact* distribution. The *wavefront velocity* c can then be expressed as a function of $R_0\beta(x, t)$, where $\beta(x, t)$ is a probability kernel describing the joint distribution of X and T; see [9] for details.

Note that when determining *population size*, linearization is a highly suspect technique, since different nonlinear models can have the same linearization (e.g. epidemics with (i) removals and (ii) recovery); though it is strongly conjectured that nonlinear differential equations for population spread will always have the same *velocity* as their linear approximation.

Given that substantial behavioral differences can occur between deterministic and stochastic analyses of the same process, ideally, a deterministic approach should always be performed in parallel with a stochastic analysis. Unfortunately, even the simplest stochastic spatial scenario of a two-site birth–death–migration process produces intractable mathematics. Some degree of success is possible using approximation techniques, such as regarding $\{x_i(t), y_i(t), z_i(t)\}$ as a **multivariate normal distribution** with **moments** obtained from the cumulant equations by replacing third- and higher-order cumulants by zero. Though a far more powerful way of using such moment closure is to evaluate cumulants up to the third- or fourth-order, and then use these in the multivariate saddlepoint approximation, thereby determining a much more realistic approximating probability density function [17]. Any awkward algebraic manipulation may be easily overcome through the use of a **computer algebra** package, whilst direct numerical computation of the original population probability equations presents another option.

The problem with probability "solutions" is that they usually convey information only on population values at a fixed time t. What we really require is the full history of process development. **Simulation** provides the answer, for given the rapidly expanding nature of affordable computer power, moments and probabilities may be obtained using standard **Monte Carlo** procedures. Detailed examples of how to construct simulation code for space–time stochastic models are contained in [14], and these are easily modified to cope with any spatial epidemic construction. No matter how complicated, a process can always be described as a series of events $E_1, E_2, \ldots$ occurring at times $t_1, t_2, \ldots$. First, detail all possible infection, removal, migration, and cross-infection changes. Then, in essence:

1. evaluate the corresponding rates $r_1, r_2, \ldots$ and put $R = r_1 + r_2 + \cdots$;
2. generate two **uniform** U(0,1) random variables U_1 and U_2;
3. select the jth event if $r_1 + \cdots + r_{j-1} \leq U_1 R < r_1 + \cdots + r_j$;
4. evaluate the interevent time $s = -\ln(U_2)/R$;
5. update population sizes and time $t \to t + s$, and return to 1.

Figure 1 shows two simulations of a two-colony Ball & O'Neill process under both migration and cross-infection regimes. At time $t = 0$ there are 100 susceptibles in each colony, with one infective in colony 1 and none in colony 2. For illustration, only one-way spatial rates are used, namely, from colony 1 to 2. Thus, an epidemic in colony 2 has to be kick-started from colony 1 before all the infectives there have been removed. Whilst the deterministic and stochastic developments for cross-infection are broadly comparable, under migration, substantial time-shift differences occur between them, especially in colony 2. Though rough agreement between stochastic and deterministic realizations will usually occur, the problem is one of consistency. Unlike cross-infection, with migration, total colony sizes are not fixed, so individual sites may pass through their threshold population values and thereby undergo considerable behavioral change.

Such differences can become even more marked when the system comprises three or more sites, and susceptibles may both migrate and give birth. For with appropriate parameter values, susceptibles can move ahead of epidemic flare-ups and grow to

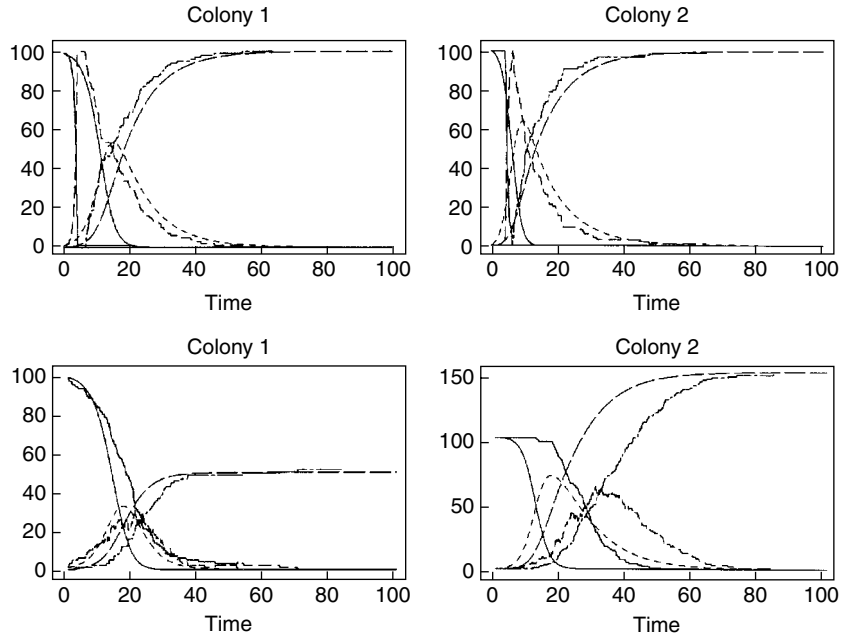

Figure 1 Deterministic (smooth) and stochastic (rough) realizations of a two-colony Ball & O'Neill model under cross-infection (upper) and migration (lower) showing the number of susceptibles (————), infectives (- - - - -) and removals (— — — —): parameter values are $\beta = 0.5$, $\gamma = 0.1$, $\nu_1 = 0.1$, $\nu_2 = 0$, $\alpha_1 = 0.01$, $\alpha_2 = 0$ (produced by Ian Hirsch)

above the local threshold population value before either a migrating infective or cross-infection starts a fresh epidemic outbreak (*see* **Epidemic Thresholds**). Persistence occurs through a *stochastic dynamic*: it is precisely the ability of susceptibles to be constantly on the move recolonizing empty sites, and infectives to pursue them, that keeps the whole process alive. In such situations, we have to rely on simulating individual stochastic realizations. For even if exact probability expressions could be constructed, they would tell us little, being an average over all possible realizations. Moreover, if the behavioral variability between realizations is considerable, then even using a basic deterministic approach can be risky, especially when it relates to epidemic control (*see* **Epidemic Models, Control**). Mollison [9] provides a striking example of this, in which he challenges Murray et al.'s deterministic study [12] of how fox rabies might invade a new country: they predict a roughly circular expanding wave of advance, followed after a quiet phase of about seven years by another wave originating from the same starting point. First, European evidence suggests that after a short while, the rabies invasion could break back across the devastated territory immediately behind it and induce an epidemic equilibrium there. Second, the later wave is an artifact of modeling population size as continuous, rather than discrete. For the model has fox density declining not to zero, but to 10^{-18} of a fox per square kilometer, and this "atto-fox" restarts the epidemic wave as soon as the susceptible population has grown sufficiently large. Though such numerical nonsense may be easily eliminated by replacing any population size below a given cut-off value by zero, the discrepancies between the overall predictions and reality are a serious cause for concern, and highlight the danger in using deterministic models at very low levels of infection prevalence.

The mathematics surrounding spatial stochastic processes is notoriously difficult, and where deterministic solutions can be of considerable help is in determining *qualitative* behavior when there exists an underlying endemic equilibrium level $\{X^*, Y^*\}$ of susceptibles and infectives. In a brilliant pioneering paper, Turing [23] developed elegant deterministic solutions that predict the types of behavior likely to

be encountered when N colonies lie on a ring. In general, let $f(X_i, Y_i)$ and $g(X_i, Y_i)$ denote the rates of change at colony i in susceptibles, $X_i(t)$, and infectives, $Y_i(t)$, respectively. Then if susceptibles and infectives migrate to neighboring sites at rates μ and ν,

$$\frac{dX_i}{dt} = f(X_i, Y_i) + \mu(X_{i+1} - 2X_i + X_{i-1}),$$
$$\frac{dY_i}{dt} = g(X_i, Y_i) + \nu(Y_{i+1} - 2Y_i + Y_{i-1}). \quad (6)$$

On considering local departures from equilibrium by writing $X_i(t) = X^* + x_i(t)$ and $Y_i(t) = Y^* + y_i(t)$, the functions f and g may be approximated by linear forms in x_i and y_i [14, 16]. The resulting equations are amenable to Laplace transform solution, whilst adding white noise (*see* **Noise and White Noise**) to the linearized deterministic equations allows the construction of second-order moments and **spectra** [15]. Cross-infection may be treated similarly. Turing's aim was to examine whether it is feasible to generate *spatially* stable waves, and his idea is simple but profound. For, if in the absence of diffusion, X_i and Y_i tend to a *linearly stable* uniform state, then under certain conditions, spatially inhomogeneous patterns can evolve through *diffusion-driven instability*. Since diffusion is usually considered to be a stabilizing process, care is clearly needed when "guessing" how nonspatial models will behave when they are placed in a spatial environment. Furthermore, the behavior of nonlinear stochastic models can change radically with dimension, as even the number of local sites affected by the migration or cross-infection contact distribution increases markedly as the dimension increases.

Whilst so far we have considered population *numbers* of infected, susceptible, immune, recovered, and so on individuals, for processes that develop over a grid, it is worthwhile highlighting the close link with *percolation processes*. For a wealth of asymptotic theory has been developed (see references in [5]), which can be carried across directly to epidemic scenarios. Here, the information is essentially qualitative, rather than quantitative, with each site being in (say) one of three states, namely, immune, healthy, or infected. Note the close interpretation here with models for "forest fires", which have the equivalent states burned, live, and on fire. Typically, an infected individual emits germs according to a **Poisson process**, which then move to one of the four nearest neighbors chosen at random. If a germ goes to a healthy site, then that site becomes infected and immediately starts to emit more germs, staying infected for a random time with known distribution function until it recovers and is immune to further infection. Questions of interest revolve around the set of sites that will ever become infected if initially the origin is infected and all other sites are healthy. Though this structure lends itself to substantial mathematical analysis, to study time-dependent behavior, we have to revert to using simulation. The advantage of this latter approach is that there is no need to make unrealistic assumptions in order to achieve mathematical tractability, and that with a little practice, computer codes can be developed extremely quickly. A prime example relates to the 2001 UK foot-and-mouth epidemic, whose aftermath left heated discussion over the control policies employed. A simple QBASIC program with good screen graphics output can be developed almost instantaneously to show (for example) an array of farms where each site is either healthy, infected, burned, or culled [18]. Everyday, each healthy site next to an infected site becomes infected itself with probability q; healthy sites neighboring an infected site are culled with probability p; whilst infected sites are burned (i.e. become removed) with probability r. Simulation experiments quickly reveal not only threshold values of p and r for fixed q, above which the disease soon stops but below which the infection keeps on advancing, but also the existence of "creep" in which slow advance relentlessly continues in spite of the process appearing to be under control. This latter behavior was observed for real in parts of the United Kingdom. Had such qualitative features been known at the start of the outbreak, far better control strategies could have been developed, especially since the position, size, and network connections of all farms are held on GIS (geographic information system) **databases**, thereby enabling this simple grid-based simulation exercise to be extended to the UK itself through the development of a more refined space–time structure.

Although the spread of infectives/infection through local migration/contact is commonplace, propagation will often occur between nonnearest colonies. Provided the colonies lie on a regular grid, such as a Turing ring, spatial measures of autocorrelation and frequency may be obtained by using **time-series** techniques [19]. However, sites will often not be regularly spaced: for example, cities, towns, and villages

connected by air, road, and rail; and we need to use weighted measures based upon local population size, area of location, extent of links with other areas, and so on. [4]. We therefore have a space–time bivariate marked point process $\{(X_{u,v}, Y_{u,v}); (u, v) \in R\}$ with association between the locations (u, v) in a region R, local epidemic reactions at each location, and spatial epidemic migration/infection between different locations. The study of such complexity is still in its infancy (see [20] for a single-"species" discussion), and stochastic modeling has to proceed through simulation. Appropriate measures of spatial correlation that are applicable to both marks (X, Y) and points (u, v) can be found in Stoyan and Stoyan's excellent overview [22].

For the purpose of illustration, we have concentrated on purely spatially homogeneous scenarios. However, recent interest in AIDS has stimulated much progress in diverse areas of epidemic modeling, particularly with regard to the treatment of heterogeneity, both between individuals and in mixing of subgroups of the population. The study of epidemics is an exciting, active, and rapidly expanding field, and the review papers of Mollison et al. [11] and Bolker et al. [3] provide excellent starting points for investigating the dynamics of diseases in human, animal, marine, and plant populations. Key theoretical issues are addressed in [10]. Moreover, improved computer technology has led to the availability of better databases and computationally intensive methods in the analysis of data: it has also allowed the simulation of more detailed and realistic models. We can therefore now tackle major challenges to our understanding of spatial epidemics, including the effects of: heterogeneity due to differences between both individuals and mixing; the dependence of persistence on chaotic behavior and spatial patchiness (*see* **Chaos Theory**); nonstationarity due to weather, demographic variables, and evolution; varying migration and cross-infection scenarios; and boundary edge-effects.

Epidemic Models, Stochastic

Although the development of an epidemic in a population susceptible to disease is a **stochastic** (random) **process**, it can often be described with reasonable accuracy by a deterministic model, provided the initial number of susceptibles is sufficiently large (*see* **Epidemic Models, Deterministic**). The deterministic results for the numbers of susceptibles and infectives in the population at time $t \geq 0$, are taken to represent the equivalent means of the more accurate stochastic process.

When the initial number of susceptibles is moderate or small, as in a school or a household, the deterministic model is inadequate and it becomes necessary to rely on a stochastic model. Such a model can be constructed in discrete time $t = 0, 1, 2, \ldots$, with the unit being the latent period of infection, or possibly a day or a week. It may also be constructed in continuous time $t \geq 0$; in both cases the models are usually Markovian (*see* **Markov Chains**; **Markov Processes**). Most of the models assume homogeneous mixing (law of mass action), which states that the probability of a susceptible becoming infected is proportional to the number of possible contacts between susceptibles and infectives, or the product of these in the population at the instant of infection (*see* **Random Mixing**).

Explicit solutions can be found for some of the main stochastic models in use, but, however intractable the problem may be analytically, one can always describe the development of an epidemic by **simulation** methods. In this article we give a brief outline of the most common discrete- and continuous-time stochastic epidemic models.

Stochastic Models in Discrete Time

The most commonly used models in discrete time are the **chain binomial models**; these are due to Reed & Frost (see [1]), and Greenwood [12]. Since the Greenwood model is simpler, we consider it first.

The Greenwood Chain Binomial

In this model, we assume that at time $t = 0$, there are $X(0) = n$ susceptibles subject to an infection which is not dependent on the existing number of infectives in the population. We follow the progress of the epidemic at times $t = 1, 2, \ldots$, the epochs at which the number of infectives and surviving susceptibles are recorded. Suppose that the probability of instantaneous infection of a susceptible at time $t = 0$ is $p < 1$. If each susceptible is infected independently, then the distribution of the remaining susceptibles at time $t = 1$ will be **binomial**, with the probability $q = 1 - p$ of noninfection, so that

$$\Pr\{X(1) = x_1 | X(0) = n\} = \binom{n}{x_1} q^{x_1} p^{n-x_1}, \quad x_1 = 0, 1, 2, \ldots, n. \quad (1)$$

The infectives $Y(1) = n - x_1$ are now removed, and the infection process is repeated for $t = 1, 2, \ldots, T$ until either no further infectives are produced at T, $Y(T) = 0$, or all the susceptibles have been infected, $X(T) = 0$. The infection process then ceases, and T is referred to as the duration of the epidemic. The evolution of the epidemic is dictated by the sequence of binomial distributions, whence the name "chain binomial" for the model. Gani & Jerwood [10] noted that the process $\{X(t); t = 0, 1, \ldots, T\}$ was in fact a simple Markov chain with transition probability matrix

$$\mathbf{P} = \begin{array}{c} \nearrow \\ 0 \\ 1 \\ \vdots \\ n \end{array} \begin{array}{c} \begin{array}{cccccc} 0 & 1 & \cdot & \cdots & n \end{array} \\ \begin{bmatrix} 1 & 0 & \cdot & \cdots & 0 \\ p & q & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ p^n & \binom{n}{1} p^{n-1} q & \cdot & \cdots & q^n \end{bmatrix} \end{array}. \quad (2)$$

This formulation allows one to carry out simple calculations on the probabilities of such quantities as the number of infectives generated up to time t, or the duration of the epidemic, within the Markov chain framework. For example, the probability of the duration T of the epidemic is given by

$$\Pr\{t = T\} = E' \begin{bmatrix} 0 & \cdot & \cdots & 0 \\ p & 0 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ p^n & \binom{n}{1} p^{n-1} q & \cdots & 0 \end{bmatrix}^{T-1} \begin{bmatrix} 1 \\ q \\ \vdots \\ q^n \end{bmatrix}, \quad (3)$$

where the $1 \times (n+1)$ row vector $E' = \{0 \ldots 0\ 1\}$ indicates that $X(0) = n$, the $(n+1) \times 1$ column vector $\{1\ q \ldots q^n\}'$ gives the probabilities that $Y(t) = 0$ at any time t, and the central matrix is the **P** of (2) with its diagonal elements replaced by zeros. This matrix **geometric distribution** states that $X(t)$ circulates among the states $0, 1, 2, \ldots, n$ for the first $T-1$ epochs, before $Y(T) = 0$ at T.

The Reed–Frost Chain Binomial

In this slightly more complex model, we assume that at time $t = 0$ there are $X(0) = n$ susceptibles and $Y(0) = y_0$ infectives. Infection is now dependent on the *number* of infectives y_0. The probability of contact of each susceptible with an infective is $p < 1$, with a contact resulting in infection; $q = 1 - p$ is the probability of no contact. If each infective is independent of all other infectives, then the probability of at least one infectious contact will be $(1 - q^{y_0})$. If the susceptibles are also independent, then at time $t = 1$, with $x_1 + y_1 = n$,

$$\Pr\{X(1) = x_1, Y(1) = y_1 | X(0) = n, Y(0) = y_0\} = \binom{n}{x_1} (q^{y_0})^{x_1} (1 - q^{y_0})^{y_1}. \quad (4)$$

Note that if q^{y_0} is replaced by q, then (4) reduces to the Greenwood formula (1).

We see that we now have a bivariate Markov chain $\{X(t), Y(t); t = 0, 1, 2, \ldots\}$ which provides us with standard methods for calculating probabilities related to the epidemic. We also remark that for small values of p, the probability of at least one infective contact is $1 - q^{y_0} \sim p y_0$, so that the mean number of new infectives is $p y_0 n$, as for the law of mass action. At $t = 1$, the infectives y_1 are again removed, but not before they can infect the remaining susceptibles, which they are assumed to do instantaneously. The process is now repeated for $t = 2, 3, \ldots, T$ until either $Y(T) = 0$, $X(T) > 0$, or $X(T) = 0$, when the epidemic terminates.

An example for $X(0) = 3$, with $Y(0) = 1, 2$, or 3 may help to visualize the Markov chain more clearly. The transition probability matrix **P** takes the form shown at the top of the opposite page or, in abridged form

$$\mathbf{P} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{Q} & \mathbf{A}_{11} & \mathbf{A}_{12} & \mathbf{A}_{13} \\ \mathbf{Q}^2 & \mathbf{A}_{21} & \mathbf{A}_{22} & \mathbf{A}_{23} \\ \mathbf{Q}^3 & \mathbf{A}_{31} & \mathbf{A}_{32} & \mathbf{A}_{33} \end{bmatrix}, \quad (5)$$

One can carry out Markov chain calculations with **P** in much the same way as for the Greenwood model. The structure of larger matrices for $n > 3$ is similar, with probabilities of the form (4).

In the present example, the duration T of the epidemic with $X(0) = 3$ and $Y(0) = 1$, will have the distribution

$$\Pr\{t = T\} = E' \times \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & \mathbf{A}_{11} & \mathbf{A}_{12} & \mathbf{A}_{13} \\ 0 & \mathbf{A}_{21} & \mathbf{A}_{22} & \mathbf{A}_{23} \\ 0 & \mathbf{A}_{31} & \mathbf{A}_{32} & \mathbf{A}_{33} \end{bmatrix}^{T-1} \begin{bmatrix} \mathbf{I} \\ \mathbf{Q} \\ \mathbf{Q}^2 \\ \mathbf{Q}^3 \end{bmatrix}. \quad (6)$$

where $E' = \{0000,\ 0001,\ 0000,\ 0000\}$.
Here, the initial 1×16 row vector records the values $X(0) = 3$ and $Y(0) = 1$ at $t = 0$, the final 16×4 matrix gives the probabilities that $Y(t)$ is zero at any time t, and the central matrix indicates that $X(t)$ circulates among the states 0, 1, 2, 3, for $T - 1$ epochs before $Y(T) = 0$ at time T.

While the structure of the bivariate Markov chain in the Reed–Frost model is more complex than that of the simple Markov chain in the Greenwood model, both follow the same basic principles. It should be pointed out that for $X(0) = 2$ and $Y(0) = 1$, the two models yield exactly the same probabilities, but this is not the case for larger values of $X(0)$ or $Y(0)$. For further details of these models, the reader is referred to Bailey's treatise [4] and Daley and Gani's monograph [6]. It may be worth mentioning that the models can be modified to allow for immigration into and emigration out of the population subject to infection; for such an example on the spread of HIV (*see* **AIDS and HIV**) among intravenous drug users, see [11].

Stochastic Models in Continuous Time

There are many continuous time models in use, of which three are the most common. The first is the simple epidemic (SI model) in which the population is subdivided into two categories, susceptibles (S) and infectives (I). This is not entirely realistic, but may hold approximately over a short period of time. The second is the general epidemic (SIR model) where there are three categories, susceptibles (S), infectives (I) and removals (R), that is individuals who have recovered and are immune, or who have

$$
\begin{array}{cc|cccc|cccc|cccc|cccc}

\end{array},
$$

died from the disease. This is a more realistic model for a population of fixed size. The third is the carrier-borne epidemic (CSR model) consisting of infective carriers (C) of the disease who may not know that they are infectious and are gradually dying off, and a separate category of susceptibles (S) subject to infection by the carriers, who are then removed (R) directly after they become infected. We consider each of these in turn.

The Simple SI Epidemic

In this model, we shall consider an initial population consisting of $X(0) = n$ susceptibles, and $Y(0) = 1$ infective for simplicity, subject to homogeneous mixing. At any time $t > 0$, we assume that in any time interval $(t, t + \delta t)$, the infinitesimal transition probability of a further infection is given by

$$
\begin{aligned}
&\Pr\{X(t+\delta t) = x-1,\ Y(t+\delta t) = y+1 | X(t) = x,\\
&\quad Y(t) = y\} = \beta x y \delta t + o(\delta t),
\end{aligned}
\tag{7}
$$

where $y = n + 1 - x$, and β is the infection rate. Note that the infectives remain infectious for all time, and $X(t) + Y(t) = X(0) + Y(0) = n + 1$, so that we need keep track of only one quantity, say $X(t)$ at $t \geq 0$. The equation (7) indicates that $\{X(t); t \geq 0\}$ is a Markov chain in continuous time, namely a death process with the state-dependent death parameter

$$\mu_x = \beta x(n + 1 - x).$$

It is readily shown that the state probabilities $p_x(t) = \Pr\{X(t) = x | X(0) = n\}$ satisfy the system of Kolmogorov forward differential equations

$$
\begin{aligned}
\frac{\mathrm{d}p_x}{\mathrm{d}t} &= \beta(x+1)(n-x)p_{x+1} - \beta x(n+1-x)p_x,\\
&\qquad 0 \leq x \leq n-1,\\
\frac{\mathrm{d}p_n}{\mathrm{d}t} &= -\beta n p_n,
\end{aligned}
\tag{8}
$$

subject to the initial condition $p_n(0) = 1$. Bailey [3] has shown that an explicit solution of these equations is possible by solving the partial differential equation for the **moment generating function** (or the probability **generating function**) of the process, in terms of **hypergeometric** functions, but these prove rather difficult to handle.

A simpler method relies on the use of the Laplace transforms

$$p_x^*(s) = \int_0^\infty \exp(-st)\, p_x(t)\, \mathrm{d}t, \quad \mathrm{Re}(s) > 0,$$

of the state probabilities. From (8), it is easily seen that

$$p_n^*(s) = \frac{1}{s + \beta n}, \tag{9}$$

or $p_n(t) = \exp(-\beta nt)$, and

$$p_x^*(s) = \frac{\beta(x+1)(n-x)}{s+\beta x(n+1-x)} p_{x+1}^*(s), \quad 0 \le x \le n-1. \tag{10}$$

Thus, in principle, the transform $p_x^*(s)$ can be found as

$$p_x^*(s) = \frac{n!(n-x)!}{x!}\beta^{n-x} \prod_{j=x}^{n} \frac{1}{s+\beta j(n+1-j)}, \tag{11}$$

so that $p_x(t)$ may be derived explicitly. Unfortunately, the values $s+\beta j(n+1-j)$ are repeated for $j=n$ and $j=1$, $j=n-1$ and $j=2$, and so on, with the result that $p_x(t)$ is rather more complicated than a simple sum of exponentials.

The problem can be overcome by an approximation which replaces the integer n by the number $N=n+e$, where $e>0$ is some small positive quantity. Then, the Laplace transforms $p_x^*(s)$ of (11) are replaced by the approximate $q_x^*(s)$ of the form

$$q_x^*(s) = \frac{n!(n-x)!}{x!}\beta^{n-x} \prod_{j=x}^{n} \frac{1}{s+\beta j(N+1-j)}, \tag{12}$$

where the values $s+\beta j(N+1-j)$ are now distinct for all values of j. It follows that $q_x(t)$ is a sum of exponentials of the form

$$q_x(t) = \sum_{j=x}^{n} c_{xj} \exp[-\beta j(N+1-j)t], \tag{13}$$

for which the coefficients c_{xj} can be readily evaluated (see [4]). Letting $e \to 0$ in (13) allows us to derive the exact values $p_x(t)$.

Since the random intervals between each infection have negative **exponential** density functions

$$\beta j(n+1-j)\exp[-\beta j(n+1-j)t], \quad 1 \le j \le n,$$

the mean duration of the epidemic has the form

$$\mathrm{E}(T) = \sum_{j=1}^{n} \frac{1}{\beta j(n+1-j)}. \tag{14}$$

This can be approximated by

$$\frac{1}{\beta(n+1)} \int_1^n \left(\frac{1}{x} + \frac{1}{n+1-x}\right) \mathrm{d}x = \frac{2\ln n}{\beta(n+1)}. \tag{15}$$

Kendall [16] has obtained the elegant result that for large values of n, the distribution of $W = (n+1)T - 2\ln n$ can be approximated explicitly by a modified Bessel function of the second kind.

The General SIR Epidemic

This is possibly the most frequently used continuous-time epidemic model; it was foreshadowed in a paper by **McKendrick** [18] and analyzed in more detail by Bartlett [5]. Here the closed population is subdivided into three categories: susceptibles (S), infectives (I) and removals (R), with their initial values being respectively $X(0)=n$, $Y(0)=1$ for simplicity, and $Z(0)=0$, the total population remaining fixed at $n+1$.

We assume that in any time interval $(t, t+\delta t)$, the infinitesimal transition probabilities of the process are given by the probability of a further infection

$$\Pr\{X(t+\delta t) = x-1,\ Y(t+\delta t) = y+1 | X(t)=x,\ Y(t)=y\} = \beta xy\delta t + o(\delta t), \tag{16}$$

precisely as for the SI epidemic in (7), and the probability of a removal

$$\Pr\{X(t+\delta t) = x,\ Y(t+\delta t) = y-1 | X(t)=x,\ Y(t)=y\} = \gamma y\delta t + o(\delta t). \tag{17}$$

These hold for all $0 \le x \le n$, $0 \le y \le n+1-x$, with β as the infection rate and γ as the removal rate, except when the values of $X(t)$ or $Y(t)$ are outside their permissible ranges. Note that $x+y \le n+1$ for all $t \ge 0$; we do not need to keep track of the value of $Z(t)$, since $X(t)+Y(t)+Z(t) = n+1$ for all $t \ge 0$.

In this model, $\{X(t), Y(t); t \ge 0\}$ is a bivariate Markov chain in continuous time. $X(t)$ is a death process with parameter $\mu_{xy} = \beta xy$, dependent on both the number of susceptibles x and the number of infectives y, while $Y(t)$ is a birth and death process with birth parameter $\mu_{xy} = \beta xy$ and death parameter γy (*see* **Stochastic Processes**).

The state probabilities $p_{xy}(t) = \Pr\{X(t) = x, Y(t) = y | X(0) = n, Y(0) = 1\}$ satisfy the forward Kolmogorov differential equations

$$\frac{dp_{xy}}{dt} = \beta(x+1)(y-1)p_{x+1,y-1} - (\beta x + \gamma)yp_{xy} + \gamma(y+1)p_{x,y+1}, \quad 0 \le x \le n, \quad 0 \le y \le n+1-x, \quad (18)$$

with $p_{xy}(t) = 0$ when x or y is outside the permissible range, and $p_{n1}(0) = 1$. Gani [9] was able to obtain an explicit solution for the Laplace transforms of the $p_{xy}(t)$ based on a matrix formulation of the problem, but this is rather complicated, and a simpler approach such as that of Griffiths et al. [13] may prove more suitable in practice.

Quantities of interest are the final size of the epidemic, apart from the initial $Y(0) = 1$, and its distribution for varying parameters β and γ. Bailey [4] lists the probabilities of this final size for $X(0) = 1, 2, 3, 4, 5$, and $Y(0) = 1$, and exhibits graphs for the cases $X(0) = 10, 20, 40$ for increasing values of $\rho = \gamma/\beta$. But perhaps the most illuminating result about the final size of the epidemic is the Threshold Theorem of Whittle [24] (*see* **Epidemic Thresholds**). This is obtained by bounding the stochastic process for the number $Y(t)$ of infectives above and below by birth and death processes with a simpler birth parameter than the actual value βxy. We shall simply quote Whittle's results, which the reader can study in greater depth by reference to his paper.

Assuming an intensity i for the epidemic, so that the final number of infectives other than the initial $Y(0) = 1$ is ni, and writing $\rho = \gamma/\beta$ and

$$\pi_i = \sum_{w=0}^{ni} P_w,$$

where the $P_w = \Pr\{X(\infty) = n - w\}$, $0 \le w \le n$, are the probabilities of a final size w of the epidemic, Whittle [24] proves that for large n

$$\begin{aligned} &\frac{\rho}{n} \le \pi_i \le \frac{\rho}{n(1-i)}, && \text{for } \rho < n(1-i), \\ &\frac{\rho}{n} \le \pi_i \le 1, && \text{for } n(1-i) \le \rho < n, \\ &\pi_i = 1, && \text{for } n \le \rho. \end{aligned} \quad (19)$$

This may be interpreted as stating that if $\rho \ge n$, then there is a zero probability that the epidemic exceeds any preassigned intensity i, while if $\rho < n$, then the probability of an epidemic is approximately $1 - \rho/n$ for small i. Similar results hold for the case where $Y(0) = a > 1$ with ρ/n and $\rho/n(1-i)$ now raised to the power a in the inequalities (19). This threshold theorem is the stochastic analog of Kermack & McKendrick's threshold theorem [17] for the deterministic general epidemic.

The Carrier-Borne CSR Epidemic

In this model, the carriers $U(t)$, $t \ge 0$, form a separate category, with an initial number $U(0) = b \ge 1$. The process $\{U(t); t \ge 0\}$ is a pure death process with parameter $\mu_u = \mu u$, such that the infinitesimal probability of a carrier dying in $(t, t + \delta t)$ is

$$\Pr\{U(t+\delta t) = u - 1 | U(t) = u\} = \mu u \delta t + o(\delta t), \quad 1 \le u \le b,$$

independent of the number of susceptibles in the population. The state probabilities of this process at any time $t \ge 0$ are known to be of the binomial form

$$\Pr\{U(t) = u | U(0) = b\} = \binom{b}{u} [\exp(-\mu u t)][1 - \exp(-\mu t)]^{b-u}, \quad 0 \le u \le b. \quad (20)$$

The susceptibles $X(t)$ are infected by homogeneous mixing with the carriers $U(t)$, and the infinitesimal probability of such an infection in any interval $(t, t + \delta t)$ when $U(t) = u \ge 1$, is

$$\Pr\{X(t+\delta t) = x - 1, U(t+\delta t) = u | X(t) = x, U(t) = u\} = \beta x u \delta t + o(\delta t), \quad 1 \le x \le n,$$

where β is the infection parameter. After becoming infected, a susceptible is removed directly from the population.

The process $\{X(t), U(t); t \ge 0\}$ is a bivariate Markov chain in continuous time, in which $U(t)$ is itself an independent Markov chain which influences the process $X(t)$. If we denote the state probabilities at

time $t \geq 0$ by

$$p_{xu}(t) = \Pr\{X(t) = x, U(t) = u | X(0) = n, \quad U(0) = b\}, \quad 0 \leq u \leq b, \quad 0 \leq x \leq n,$$

we can derive the forward Kolmogorov differential equations of the process as

$$\frac{\mathrm{d}p_{xu}}{\mathrm{d}t} = \beta(x+1)up_{x+1,u} - (\beta x + \mu)up_{xu} + \mu(u+1)p_{x,u+1}, \tag{21}$$

with $p_{xu}(t) = 0$ when x or u are outside their permissible ranges, and $p_{nb}(0) = 1$.

The model was originally formulated by Weiss [23], and solved by him, Dietz [7] and Downton [8]. A straightforward method of solution, also outlined in Bailey [4], involves the derivation of the partial differential equation of the probability generating function obtained from (21). Its solution is found by the method of separation of variables. An alternative method relies on the more general approach presented by Puri [21], and outlined in Daley and Gani [6]. The probabilities $p_{xu}(t)$ are found explicitly as

$$p_{xu}(t) = \binom{n}{x}\binom{b}{u}\sum_{j=x}^{n}(-1)^{j-x}\binom{n-x}{j-x} \times \left(\frac{\mu}{\mu+j\beta}\right)^{b-u}(\exp -u(\mu+j\beta)t) \times [1-\exp -(\mu+j\beta)t]^{b-u}, \tag{22}$$

with the expectation of $X(t)$ given by

$$\mathrm{E}[X(t)] = n\left(\frac{\mu+\beta\exp -(\mu+\beta)t}{\mu+\beta}\right)^{b}. \tag{23}$$

The distribution of the duration time T of the epidemic, which ends when either $U(t) = 0$ or $X(t) = 0$, can also be derived explicitly. The model can be made more complex by making the parameters time-dependent, and also allowing emigration and immigration of both the susceptibles and carriers.

Concluding Remarks

A very large number of stochastic models have been developed for a variety of diseases, including most recently AIDS. These include spatial models for the geographic spread of infections (*see* **Epidemic Models, Spatial**), models for parasitic or host–vector diseases such as malaria and schistosomiasis, and models for sexually transmitted diseases. While each disease may require a slightly different model in order to approximate realism, the principles used in constructing them are similar to those displayed in the small range of examples above.

There is a wealth of recent literature on stochastic epidemic research, and the reader may wish to refer to the recent review paper by Mollison et al. [20], the book of papers on AIDS epidemiology edited by Jewell et al. [15], or the books on more general epidemic models edited by Mollison [19] and Isham & Medley [2, 14, 22].

Epidemic Models, Structured Population

The use of mathematical models to describe the spread of **infectious disease** has become a topic of increasing importance in recent years. Carefully formulated models play a vital role in helping to understand the dynamics of disease outbreaks that have already occurred, and in analyzing the effectiveness of potential strategies to deal with future outbreaks. Diseases such as HIV/**AIDS**, **BSE/CJD** and Foot-and-mouth disease have all received considerable modeling attention. However, in order to correctly describe real-life disease dynamics, it quickly becomes apparent that models need to capture something of the mixing behavior of individuals within the at-risk population. For example, it is rarely realistic to assume that an entire population mixes homogeneously, that is, that each currently susceptible individual is equally likely to be infected by any currently infective individual in the population. Predictions based on models defined using unrealistic assumptions should be viewed with considerable caution. Motivated by such concerns, a number of models have been developed that attempt to take into account some elements of structure within the population of interest. In the following, we review some of these models and draw attention to their salient features.

Independent-households Model

For many infectious diseases, the mode of transmission involves the sort of close contact between individuals that would be facilitated by those individuals living or working together in a shared environment. It is therefore natural to consider models in which individuals who commonly spend time together have a different (usually greater) chance of transmitting the disease to one another than individuals who seldom meet. Longini and Koopman [11] describe the following model, in which the population is divided into households, and infections can arise either from infected household members, or from the community at large.

Consider a population of N individuals that is partitioned into households, which need not necessarily be all of the same size. Individuals are assumed to be equally susceptible to contracting the disease in question. Every individual in the population has a fixed probability, q_c, of avoiding infection from outside their household. This probability is assumed to be once-and-for-all, rather than per unit time, and can be thought of as the probability of not acquiring the disease from the community at large for the duration of the epidemic. The fates of different individuals with respect to this community-acquired infection are assumed to be independent. Thus, the number of individuals who are infected from the community has a **binomial distribution** with parameters N and $1 - q_c$.

Within a household initially comprising n susceptible individuals, the disease spreads as follows. First, suppose that a number $Y_0 = a$ of the individuals become infected from the community. If $a = 0$, the household epidemic is over, with no infections occurring. Otherwise, each infective has a probability $1 - q_h$ of transmitting the disease to each of the still-susceptible household members, independently, during their infectious period. Thus, to remain susceptible, a susceptible individual must avoid infection from all a infectives, which occurs with probability q_h^a. Thus, the number of newly created infectives, Y_1 say, has a binomial distribution with parameters $n - a$ and $1 - q_h^a$. Each of these new infectives then has a probability $1 - q_h$ of infecting any one of the remaining $n - Y_0 - Y_1$ susceptibles as before, and so on. The household epidemic continues in this way until zero new infections occur. The within-household epidemic is thus described by a Reed–Frost model [4, Chapter 1] with a initial infectives, $n - a$ susceptibles, and infection probability $1 - q_h$ (*see* **Chain Binomial Model**).

We mention three important features of the above model. First, there are two parameters, q_c and q_h, which control, respectively, community-acquired and within-household-acquired infections. Thus, the model allows consideration of two different routes of infection, and can, for example, be used to determine which route is most important in disease spread in specific applications. Second, the fates of different households are independent of each other, in the sense that the number infected in one household is independent of the number infected in another. Third, the model as described above is essentially not temporal, in the sense that it only describes final outcomes (infected or not), rather than the times at which events occur.

The probability mass function of the final number infected (i.e. the *final size* of the epidemic) in a given

household can be obtained as follows. Let π_{jk} denote the probability that the epidemic produces a total of j infective individuals in a household initially containing k susceptibles. There are $\binom{k}{j}$ ways to select the j individuals who become infected. For the subepidemic propagated among these j individuals, the probability that all become infected is π_{jj}. Additionally, each of the remaining $k-j$ individuals must avoid infection both from the community, and also from the j infected individuals, the probability of these avoidances being $q_c^{k-j} q_h^{(k-j)j}$. We thus obtain that for $k \geq 1$,

$$\pi_{jk} = \binom{k}{j} \pi_{jj} q_c^{k-j} q_h^{(k-j)j}, \quad 0 \leq j < k, \qquad (1)$$

where

$$\pi_{kk} = 1 - \sum_{j=0}^{k-1} \pi_{jk}, \quad \text{and } \pi_{00} = 1. \qquad (2)$$

Equations (1) and (2) can be used to recursively determine the π_{jk}'s. It is also possible to find a closed-form expression for π_{jk} in terms of certain nonstandard polynomials; see [14]. Finally, since households are independent, the probability of observing a particular set of final outcomes in the community of households is obtained by multiplying the relevant π_{jk} values together. Viewed as a function of the model parameters, this probability is simply the **likelihood**, which provides a basis for statistical inference procedures.

The basic model above can be extended in a number of ways, of which we now mention a few. The within-household epidemic can be generalized by removing the independence assumption between the fates of individuals who may be contacted by a given infective 1. This situation arises naturally when one assumes that an infective individual can infect others during an infectious period of random length T. Suppose that, during their infectious period, the individual makes contact with each susceptible in the household at times given by the points of a **Poisson process** of rate β. It is assumed that the Poisson processes corresponding to different susceptible-infective pairs are mutually independent. Then, the probability that a given set of $k-j$ susceptibles escape infection from a single infective during his or her infectious period is simply $\mathrm{E}_T[\exp(-\beta T(k-j))] = \phi(k-j)$, say. Within the nontemporal framework of the model, we can without loss of generality set $\beta = 1$, so that ϕ then depends only upon the parameters of T. The corresponding equation to (1) is obtained by replacing the avoidance probability q_h^{k-j} by $\phi(k-j)$. Note that the original model is obtained when T is constant.

An alternative generalization of the basic model is to introduce some kind of heterogeneity into the population. O'Neill et al. [14] consider a model in which each individual in the population independently has immunity to the disease with some fixed probability v. This could represent, for example, immunity acquired via vaccination, or by previous exposure to the disease. This essentially corresponds to a **random-effects** model for individuals. Alternatively, individuals could be categorized according to some known quantity (e.g. age, or a physiological measure), and then assumed to be susceptible to the disease in a manner that depends on their category. In this setting, extra model parameters are introduced, corresponding to the different categories [1, 12].

Models with Two Levels of Mixing

In the independent-households model described above, the probability of acquiring infection from outside the household is not dynamically altered by the numbers infected within each household. This slightly unrealistic assumption can be overcome by allowing person-to-person transmission both within a household, and in the entire population, at two (possibly) different rates. Ball et al. [8] define the following model. Consider a population of N individuals that is partitioned into households. Initially, all but a small number of individuals are susceptible, and the rest infective. An individual j who becomes infected remains so for a period of time $T^{(j)}$, where $T^{(j)}$ is distributed according to some prespecified nonnegative random variable T. The infectious periods of different individuals are assumed to be mutually independent. During their infectious period, individual j makes contact independently with each susceptible in the population at times given by the points of a Poisson process of rate λ_G/N. The first such contact results in the immediate infection of the susceptible. Simultaneously, and independently, j also has infectious contacts with each member of his or her household according to a Poisson process of rate λ_L. Thus λ_L and λ_G determine, respectively, the

local (i.e. within-household) and global (i.e. with any population member) rates of infection. At the end of its infectious period, j can make no further contacts, and moreover is assumed to be immune to reinfection. The epidemic continues until there are no more infectives remaining in the population. Note that this model is temporal, because all events are explicitly modeled with respect to time.

Note that the scaling factor of N in the global contact rate λ_G/N appears in order to maintain a realistic model as N becomes large. Specifically, as N increases so the Poisson rate of global contacts made by an individual, namely, $N(\lambda_G/N) = \lambda_G$, remains the same. Conversely, it is natural to suppose that as N increases, individual household sizes should remain roughly constant, so that it is the number of households that increases rather than their size. Thus the local infection rate parameter, λ_L, need not be scaled. Note also that the fact that household sizes remain locally "small" as N increases mean that a corresponding deterministic model (*see* **Epidemic Models, Deterministic**), defined by a set of differential equations describing the epidemic within each household, is inappropriate as an approximation of the stochastic model (*see* **Epidemic Models, Stochastic**), and, in particular, has different **epidemic threshold** behavior (see [8] for details).

As might be expected, the interdependence of households within the two-level mixing model complicates any analysis considerably. For example, the exact final size distribution is essentially intractable for any realistic population, because evaluation implicitly involves summing over all possible paths of infection. However, by appealing to asymptotic considerations as the number of households tends to infinity, it is possible to make analytic progress (see [8]). This is essentially due to the fact that, in an infinite population, households contained in any specified finite set are mutually independent of one another. There are two key results. First, a threshold theorem can be obtained, which indicates that the early stages of an epidemic can be approximated by a suitable **branching process**. Moreover, there is a threshold parameter, R_T, such that, in the limit as the number of households tends to infinity, an epidemic of infinite final size can occur with positive probability if and only if $R_T > 1$. Second, there exists a **central limit theorem** for the final size and final severity, where the latter represents the total amount of person-time units of infection. This result essentially says that, when the number of households is large, and conditional upon a major outbreak occurring, the joint distribution of final size and severity can be approximated by a **bivariate normal distribution** whose mean vector and **covariance matrix** depend on λ_L and λ_G. Methods of both classical and **Bayesian** statistical inference for this model have also been considered; see [5] and [13], respectively.

The notion of two levels of mixing, namely, local and global, can be extended to more general models. Examples include the great circle model ([7, 8]) in which individuals are situated on the circumference of a circle, and in which local contacts occur with adjacent or other nearby neighbors, while global contacts are chosen uniformly at random from all individuals in the population. Such a model can be motivated by disease spread among certain kinds of spatially structured populations, such as animals living in lines of pens, or animals that inhabit adjacent stretches of a coastline. Models of this kind are closely related to so-called small-world models [15, 16], which have attracted considerable attention within the Social-Sciences and Physics literatures. Another generalization of the household model is to allow populations to be partitioned in more than one way, for example, by household and school/workplace [6, 9]. Finally, it is also possible to formulate models with three or more levels of mixing, for example, representing within-household, within-city, and between-city mixing.

Epidemics on Graphs

Given a population of individuals, it is mathematically natural to represent their contact structure by means of a graph. Specifically, suppose that each vertex in a graph corresponds to an individual, and each edge, joining two vertices, corresponds to some form of social contact, which is sufficient to allow the possibility of disease transmission between two individuals. Given such a graph, an epidemic process can be defined as follows. A small number of vertices are initially infectious, the rest susceptible. If a vertex j becomes infected, it remains so for a period of time given by some random variable $T^{(j)}$, which is distributed according to some prespecified nonnegative **random variable** T. During its infectious lifetime, a vertex makes infectious contacts with each of its

neighbors in the graph (i.e. those vertices to which j is joined by an edge) at times given by the points of a Poisson process of rate λ. Any such contact results in the immediate infection of the neighbor, provided that the vertex has not been previously infected. At the end of its infectious period, a vertex becomes immune to further reinfection, and essentially plays no further part in the epidemic. All infectious periods and Poisson processes are assumed to be mutually independent. The epidemic continues to spread until there are no more infectives remaining.

The above formulation is clearly very general, and contains several special cases of importance.

Complete Graph

The complete graph (in which every pair of vertices is connected) corresponds to a homogeneously mixing population, and the model reduces to a standard **SIR** (Susceptible-Infected-Removed) model (see [4, Chapter 2].)

Lattice Model

Suppose that vertices are situated at all points (x, y) in the plane, where both x and y are integers, and that the vertex at (x, y) is connected to the four nearest vertices in the plane according to Euclidean distance. Suppose further that the infectious period T is constant, so that $\theta = 1 - \exp(-\lambda T)$ is the probability that a given vertex infects any of its susceptible neighbors, independently of the fate of its other neighbors. This model is equivalent to a percolation model on the two-dimensional integer lattice, in which each "infected" edge corresponds to an open channel, and vertices are either "wet" (no longer susceptible) or "dry" (susceptible). Suppose that, initially, precisely one site is wet. It is well-known from percolation theory that, for $\theta > \frac{1}{2}$, there is a positive probability of an infinite wet connected cluster. Conversely, for $\theta < \frac{1}{2}$, all wet clusters are finite in size with probability one. In terms of the epidemic, this translates to a threshold result stating that infinitely many vertices become infected with positive probability if $\lambda > T^{-1} \log 2$, and with probability zero if $\lambda < T^{-1} \log 2$.

Random Graphs

In some contexts, the exact contact structure of a population is unknown, and thus it is reasonable to also attempt to model this structure stochastically. Andersson [3] considers various cases of this kind, including a simple Bernoulli structure (described below), graphs with predetermined vertex degree sequences, and dynamic graphs in which social structure changes over time (see also [2]). The extent to which such models can be analyzed mathematically varies considerably, depending upon the exact structure considered.

As an example, consider the case where the contact structure is described by a Bernoulli random graph. Specifically, each vertex has a fixed probability p of sharing an edge with any other given vertex, independently of all other vertex pairs. Thus the number of edges emanating from a single vertex has a Binomial distribution with parameters $n - 1$ and p, where n is the total number of vertices in the graph. Setting $p = \mu/n$, so that the average of this Binomial distribution is bounded as $n \to \infty$, and assuming that the infectious period T is **exponentially distributed** with mean γ^{-1}, it can be shown that the threshold parameter of this model is

$$R_0 = \frac{\mu\lambda}{\lambda + \gamma}, \tag{3}$$

see [10]. The quantity R_0 should be interpreted as meaning that, in an infinite population, an epidemic can infect infinitely many individuals with positive probability if and only if $R_0 > 1$.

The temporal behavior of this stochastic model is not straightforward to analyze in detail, although under suitable assumptions the model behaves as a limiting deterministic model as $n \to \infty$. For this deterministic model, it is possible to (numerically) find time-dependent trajectories for the numbers of infective and susceptible individuals at a given time, and to analytically determine the final outcome [3]. Regarding inference reference, [10] contains methods of Bayesian inference, using **Markov chain Monte Carlo** techniques, for the stochastic model.

Epidemic Thresholds

The practically most important result to come out of the mathematical theory of epidemics is the threshold theorem, which broadly states that an epidemic can only become established in a population if the initial susceptible population size is larger than some critical value, which depends on the parameters governing the spread of disease. The threshold theorem is important because it immediately tells us what proportion of susceptibles need to be vaccinated in order to prevent an epidemic occurring.

Two broad classes of epidemic models are considered in this article. The majority of the article is devoted to *closed population* epidemic models, which assume that the timescale of the epidemic is sufficiently short so that demographic changes in the population can be ignored. The models considered are of the SIR (susceptible $\rightarrow$ infective $\rightarrow$ removed) type, in which a susceptible individual becomes infected by having "adequate contact" with an infective. It then remains infectious for a while before being removed, by either death, the termination of its infectious period or public health measures. Removed individuals are assumed to be immune to further infection and thus play no further role in the epidemic. The threshold behaviors of a homogeneously mixing deterministic model and its stochastic counterpart, the so-called deterministic and stochastic general epidemics, are considered first, before moving on to more general stochastic models incorporating, for example, more realistic infection mechanisms, heterogeneous populations, and spatial effects. The article closes with a brief description of the threshold behavior of *open population* models, which incorporate demographic effects.

Closed Population Epidemics

General Deterministic Epidemic

The general deterministic epidemic is defined by the following system of differential equations:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -\beta xy, \qquad \frac{\mathrm{d}y}{\mathrm{d}t} = \beta xy - \gamma y, \qquad \frac{\mathrm{d}z}{\mathrm{d}t} = \gamma y, \tag{1}$$

where $x(t)$, $y(t)$, and $z(t)$ denote, respectively, the numbers of susceptible, infectious, and removed individuals at time t, and the parameters β and γ are known as the infection and removal rates (*see* **Epidemic Models, Deterministic**). The model assumes a homogeneously mixing population, with adequate contacts between two given individuals occurring at rate β. Thus if there are x susceptibles and y infectives at time t, there are xy possible contacts, each occurring at rate β, that will result in a new infection occurring; hence the term βxy in (1). The model also assumes that infectious individuals are each removed at rate γ, giving rise to the term γy in (1).

Suppose that at time $t = 0$ there are a infectives, n susceptibles, and no removed cases. It follows from the second formula in (1) that, provided that $y > 0$, $\mathrm{d}y/\mathrm{d}t > 0$ if and only if $x > \rho$, where $\rho = \gamma/\beta$.

Thus a build-up of infection will occur in the population if and only if $n > \rho$. This is part of the celebrated threshold theorem of Kermack & McKendrick [17].

General Stochastic Epidemic

The general stochastic epidemic is obtained by replacing the infinitesimal transition rates governing (1) by infinitesimal transition probabilities (*see* **Epidemic Models, Stochastic**). For $t \geq 0$, let $X(t)$, $Y(t)$, and $Z(t)$ be, respectively, the numbers of infective, susceptible, and removed individuals at time t. Suppose that $(X(0), Y(0), Z(0)) = (n, a, 0)$, so that $X(t) + Y(t) + Z(t) = n + a \ \ (t \geq 0)$. Then the epidemic is completely specified by $\{(X(t), Y(t)); t \geq 0\}$, which is a continuous time **Markov chain** with infinitesimal transition probabilities

$$\Pr\{(X(t+h), Y(t+h)) = (i-1, j+1) | (X(t), Y(t)) = (i, j)\} = \beta ijh + o(h)$$

for an infection, and

$$\Pr\{(X(t+h), Y(t+h)) = (i, j-1) | (X(t), Y(t)) = (i, j)\} = \gamma j + o(h)$$

for a removal.

The epidemic terminates as soon as the number of infectives becomes zero. Let $T = n - X(\infty)$ be the total size of the epidemic; that is, the number of initial susceptibles that are ultimately infected. Note that rescaling the time axis so that the infection rate β is one shows that the distribution of T depends on β and γ only through $\rho = \gamma/\beta$. A system of linear equations governing the distribution of T is given

in Bailey [3, p. 94], in which diagrams illustrating the distribution for various values of n and ρ are also given [3, pp. 98–99]. When $n < \rho$ the distribution of T is unimodal, with the mode at some small argument value (often zero), while if $n > \rho$ the distribution of T is bimodal, with a second mode at a large argument value. Thus again there is a threshold at $n \approx \rho$, although, because of the presence of chance effects, the change in behavior at the threshold is less sharp than in the deterministic model. Also, the value of n at which the distribution of T changes from being unimodal to bimodal is slightly larger than ρ [20].

To understand its threshold behavior it is fruitful to give a more detailed, but equivalent, description of the general stochastic epidemic. The assumptions underlying the general stochastic epidemic are consistent with a model in which infectives behave independently, making contacts at the points of a **Poisson process** with rate $n\beta$ throughout an infectious period that follows a negative **exponential distribution** with mean γ^{-1}. For each contact, the individual contacted is chosen independently and uniformly from the n initial susceptibles. If a contacted individual is susceptible then it becomes infected; otherwise, nothing happens. Clearly, the rate at which an infective is removed is γ, and if there are x susceptibles and y infectives at time t the rate at which infectious contacts are being made is $yn\beta$. However, the probability that a given contact is with a susceptible is x/n. Hence, the rate at which new infections occur is $yn\beta \times x/n = \beta xy$, as required by the general stochastic epidemic.

Note that if all the contacts in the above epidemic were to result in the spread of infection, then the process of infectives would follow a birth-and-death process (*see* **Stochastic Processes**) (see for example, [12, pp. 270–273]) with birth rate $n\beta$ and death rate γ. Of course, it is unlikely that all the contacts made in the epidemic are with susceptibles, so the birth-and-death process is usually only an upper bound to the process of infectives. However, if n is large the probability of contacting a previously contacted individual will be small, particularly in the early stages of the epidemic. Thus, for large n, the early stage of the epidemic is well approximated by the above birth-and-death process and occurrence of a minor/major epidemic may be associated with extinction/nonextinction of the birth-and-death process. Hence, by standard results for birth-and-death processes, the probability that a major epidemic occurs is given by

$$p_{\mathrm{MAJ}} = \begin{cases} 0, & \text{if } n\beta \le \gamma, \\ 1 - (\gamma/n\beta)^a, & \text{if } n\beta > \gamma, \end{cases}$$

so major epidemics can occur only if $n > \rho$.

The above threshold behavior can be made mathematically precise in several ways: see, for example, Whittle [23], who gave the first stochastic epidemic threshold theorem, Williams [24] and Ball [4].

Although the deterministic and stochastic general epidemics both have the same threshold value of $n = \rho$, the interpretation of the threshold behavior is quite different in the two models. In the deterministic model, if $n \le \rho$ ($n > \rho$) minor (major) epidemics will always occur. In the stochastic model, for large n, if $n \le \rho$ minor epidemics always occur, while if $n > \rho$ a major epidemic occurs with a probability lying strictly between 0 and 1.

R_0 and Vaccination Strategies

A unifying concept in the analysis of the threshold behavior of epidemic models is the **reproduction number** (or ratio) R_0 of the epidemic, which is usually defined informally as the expected number of infectious contacts made by a typical infective during its entire infectious period, in a population consisting of susceptibles only (see, for example, [13, 14]). The difficulty in applying this definition for complex models is in determining what is a typical infective. Diekmann et al. [10] show that, for a very broad class of deterministic models, R_0 is given by the maximal **eigenvalue** of an appropriate "next generation" linear operator, thus providing a formal definition. However, in the general stochastic epidemic, it is clear that a typical infective makes infectious contacts at the points of a Poisson process with rate $n\beta$ throughout an infectious period that follows a negative exponential distribution with mean γ^{-1}. Thus, $R_0 = n\beta/\gamma$ and from the previous section major epidemics can only occur if and only if $R_0 > 1$.

Now consider a general epidemic that is above threshold and suppose that a proportion θ of initial susceptibles are vaccinated against the disease being modeled. After vaccination, the initial number of susceptibles is reduced to $n' = (1 - \theta)n$ and hence R_0 is reduced to $R_0' = (1 - \theta)R_0$. Thus major epidemics

will be prevented if $R_0' \leq 1$; that is if

$$\theta \geq 1 - \frac{1}{R_0}.$$

This formula, which gives the critical level of vaccination coverage to prevent an epidemic occurring, holds quite generally for single population epidemic models. It was given first by Smith [22].

General Single Population Epidemic

The approximation of the process of infectives by a birth-and-death process holds for a very wide class of epidemic models, although the approximating process is generally a branching process. Now consider an epidemic, initiated by a infectives among n susceptibles, in which infectious individuals have independent and identically distributed life histories, $H = (T_I, \eta)$, where T_I is the time elapsing between an individual's infection and its eventual removal or death, and η is a point process of times, relative to an individual's infection, at which infectious contacts are made. As before, for each contact, the individual contacted is chosen independently and uniformly from the n initial susceptibles and an infection occurs only if the contacted individual is still susceptible.

If the initial number of susceptibles n is large, the process of infectives can be approximated by a **branching process** (corresponding to the case in which all contacts result in new infections), in which a typical individual lives until age T_I and reproduces at ages according to η. Moreover, the approximation can be made precise in the limit as $n \to \infty$ (see [6]). Let R be the number of contacts made by a typical infective in the epidemic model, let $R_0 = \mathrm{E}(R)$, and let $f(s) = \mathrm{E}(s^R)$ be the probability **generating function** of R. Then, by standard branching process theory (see, for example, [16]), a major epidemic occurs with nonzero probability if and only if $R_0 > 1$ and the probability of a major epidemic is $1 - p^a$, where p is the smallest solution of $f(s) = s$ in [0, 1].

A few examples illustrate the generality of the model:

1. Suppose that η is a Poisson process with rate β. Then R follows a Poisson distribution with random mean βT_I, so $R_0 = \beta \mathrm{E}(T_I)$. Note that if T_I follows a negative exponential distribution with mean γ^{-1}, then the general stochastic epidemic is obtained.
2. In most, if not all, real-life epidemics the infectious period of an infective is preceded by a **latent period** during which a recently infected individual is unable to infect other susceptibles. Let T_L and T_I be random variables describing the lengths of typical latent and infectious periods, respectively. Suppose that η is a Poisson process with rate $\beta(t)$, where

$$\beta(t) = \begin{cases} \beta, & \text{if } T_L < t < T_L + T_I, \\ 0, & \text{otherwise.} \end{cases}$$

   Then, again, $R_0 = \beta \mathrm{E}(T_I)$. Note that the introduction of a latent period does not change R_0.
3. Suppose that η is a Poisson process with random rate $\Lambda(t)$ $(0 \leq t < \infty)$. Then R is **Poisson** with random mean $\int_0^\infty \Lambda(t)\, \mathrm{d}t$, so $R_0 = \int_0^\infty \mathrm{E}[\Lambda(t)]\, \mathrm{d}t$. Such a model might be appropriate for the spread of **AIDS**, as it is known that the infectiousness of an infective varies considerably throughout the long **incubation period** (see, for example, [1]).

General Multipopulation Epidemic

Now consider the spread of an epidemic among a population that is partitioned into m groups, labeled $1, 2, \ldots, m$, with group i consisting initially of a_i infectives and n_i susceptibles. The partitioning of the population into groups could reflect important heterogeneities (such as owing to age, sex, and genotype), geographic location, or a multispecies population, as in host–vector epidemics such as malaria. Infectious individuals have independent life histories, with life histories of infectives in the same group being identically distributed. For $i = 1, 2, \ldots, m$, the life history of a typical group i infective is $H_i = (T_I^{(i)}, \eta_{i1}, \eta_{i2}, \ldots, \eta_{im})$, where $T_I^{(i)}$ denotes the infectious period and, for $j = 1, 2, \ldots, m$, η_{ij} is a point process governing times when infectious contacts are made with group j individuals. For each contact, the individual contacted is chosen independently and uniformly from the initial susceptibles in the contacted group.

If the initial numbers of susceptibles in every group are all large, then the process of infectives approximately follows a multitype branching process, and the approximation can be made precise

in the limit as $n_i \to \infty$ $(i = 1, 2, \ldots, m)$ [5]. For $i, j = 1, 2, \ldots, m$, let R_{ij} be the total number of group j contacts made by a typical group i infective throughout its infectious period. Let $\mathbf{M} = (m_{ij})$ be the $m \times m$ matrix with elements $m_{ij} = \mathrm{E}(R_{ij})$ and let R_0 be the eigenvalue of $\mathbf{M}$ having maximum modulus. Then, by standard multitype branching process theory [18], subject to mild regularity conditions, a major epidemic occurs with nonzero probability if and only if $R_0 > 1$.

The models of the last two sections can be extended to allow for some or all previously infected individuals to become susceptible again, either immediately following their infectious period or at some later time. The process of infectives for such models can be sandwiched between that of the corresponding SIR model and its branching process approximation, so the two models have identical threshold behavior. Models in which all infectives become susceptible immediately following their infectious period are known as SIS (susceptible $\to$ infective $\to$ susceptible) models.

Deterministic versions of the models of the last two sections can usually be written down, although they will often involve a continuous partitioning of the population; for example, to incorporate nonexponential infectious periods. The framework of Diekmann et al. [10] can be used to determine R_0 for such a deterministic model. The value of R_0 will be the same as for the corresponding stochastic model.

Structured Populations

The threshold behavior of the above multipopulation epidemic assumes that all the group sizes are large. Although this may be reasonable in some practical situations, in others it clearly is not. Two such cases are now outlined.

Epidemics Among Households

Consider the spread of an epidemic among a population consisting of m households, each of size n. Suppose that infectives have independent and identically distributed life histories, $H = (T_I, \eta_L, \eta_G)$, where T_I denotes the infectious period of a typical infective, and η_L and η_G are point processes governing times at which *local* and *global* contacts are made, respectively. Each local (global) contact of a given infective is with an individual chosen independently and uniformly from the $n(nm)$ initial individuals in its household (the population).

Becker & Dietz [9] consider the case of highly infectious diseases, and assume that if one individual in a household becomes infected then the whole household becomes infected. Let $\tilde{R}$ be the total number of global contacts emanating from a typical infectious household. Then, provided that the number of households, m is large, the process of infected households can be approximated by a branching process with offspring distribution the distribution of $\tilde{R}$. Thus a major epidemic (one affecting a large number of households) can only occur if $\tilde{R}_0 = \mathrm{E}(\tilde{R}) > 1$. Note that under the above "highly infectious" assumption $\tilde{R}_0 = nR_0$, where now R_0 is the expected number of global contacts made by a typical infective. In general, $\tilde{R}_0 = \mu R_0$, where μ is the expected total size (including the initial infective) of a single household epidemic initiated by one infective, in which global infections are ignored; see Ball et al. [7], where extensions – for example, to unequal household sizes – are discussed.

Spatial Epidemics

A spatial model is often appropriate for plant diseases and also for animal diseases, such as fox rabies (*see* **Epidemic Models, Spatial**). The simplest spatial models usually assume that individuals are located one to each point of a regular lattice and that successive contacts of an infective are with individuals at locations (relative to the infective) chosen independently from a *contact distribution* (see, for example, [19]). The threshold behavior of such epidemics is usually obtained by taking the lattice to be infinite and determining conditions under which a finite initial number of infectives can give rise to an infinite epidemic.

Let R_0 be the expected number of contacts made by a typical infective. For one-dimensional lattices, the epidemic goes extinct with probability one, so no threshold exists. For two-dimensional lattices, there is a critical value of R_0, R_0^{CRIT} say, such that the probability of an infinite epidemic is zero if $R_0 < R_0^{\mathrm{CRIT}}$ and strictly positive if $R_0 > R_0^{\mathrm{CRIT}}$. The existence of R_0^{CRIT} is usually shown by comparing the epidemic with an appropriate percolation process. The value of R_0^{CRIT} depends on the contact distribution. It is

known only in a few very special cases. However, $R_0^{\mathrm{CRIT}} > 1$ and for nearest-neighbor infection models simulations show that $R_0^{\mathrm{CRIT}} \approx 2$.

Note that for both epidemics among a community of households and spatial epidemics, the deterministic and stochastic models will have *different* threshold values, essentially because a deterministic model implicitly assumes that all the group sizes are large. For stochastic models, the threshold values of SIR and corresponding SIS models are now different.

Open Population Epidemics

Consider the general deterministic epidemic, and suppose that susceptibles are recruited into the population at rate ν and all individuals die from natural causes at rate μ. Then the differential equations in (1) become

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} &= -\beta xy - \mu x + \nu, \\ \frac{\mathrm{d}y}{\mathrm{d}t} &= \beta xy - (\gamma + \mu)y, \\ \frac{\mathrm{d}z}{\mathrm{d}t} &= \gamma y - \mu z. \end{aligned} \tag{2}$$

Setting $\mathrm{d}x/\mathrm{d}t = 0$ and $\beta = 0$ shows that the disease-free equilibrium population size is $x_0 = \nu/\mu$. Thus the expected number of infectious contacts made by an infective in an otherwise susceptible population is given by $R_0 = \beta\nu/(\gamma + \mu)\mu$, since now infectives are effectively removed at rate $\gamma + \mu$.

Setting $\mathrm{d}x/\mathrm{d}t = \mathrm{d}y/\mathrm{d}t = 0$ in (2) gives the equilibrium numbers of susceptibles and infectives. When $R_0 \leq 1$, the only equilibrium point is the *disease-free* one $(x^*, y^*) = (\nu/\mu, 0)$. Moreover, this equilibrium is globally asymptotically stable, in the sense that $(x(t), y(t)) \to (x^*, y^*)$ as $t \to \infty$, irrespective of the initial values $(x(0), y(0))$. When $R_0 > 1$, there is a second *endemic* equilibrium point $(x^*, y^*) = (\beta^{-1}(\gamma + \mu), (\gamma + \mu)^{-1}\nu - \beta^{-1}\mu)$, and this too is globally asymptotically stable (unless, of course, $y(0) = 0$); see, for example, Hethcote [15] for details. Thus, if $R_0 \leq 1$ the disease cannot become established in the population, while if $R_0 > 1$ it will become established and remain endemic. A similar conclusion holds for a very broad range of open population deterministic epidemic models, including multipopulation models.

The stochastic version of the above model is far more difficult to analyze. Suppose that the disease is introduced into a susceptible population, which is at its disease-free equilibrium level $x_0 = \nu/\mu$. Then, provided that x_0 is sufficiently large, the early stages of the epidemic can still be approximated by a birth-and-death process. Hence, the epidemic will only have a nonzero probability of taking off if $R_0 > 1$. However, even if it does take off, the epidemic will ultimately go extinct with probability one (cf. [21]), although it may take a very long time to do so. Thus, for practical purposes, endemic behavior is possible. However, simulations and observed data on epidemics show that long-term persistence of infection can only occur if the population is larger than some critical level. This has a long history, going back to the pioneering work of Bartlett [8]. The problem of determining the critical community size, for endemic outbreaks to occur, in terms of the parameters of the underlying model still awaits a satisfactory solution [11]. See Andersson and Bitton [2], pp73–77 for a brief discussion of this stochastic model.

Epidemiology as Legal Evidence

In tort cases concerned with diseases resulting from exposure to a toxic chemical or drug, epidemiologic studies are used to assist courts in determining whether the disease of a particular person, typically the plaintiff, was a result of his or her exposure. This may seem puzzling to scientists, because whenever there is a natural or background rate of an illness one cannot be certain that its manifestation in a specific individual who was exposed to a toxic agent actually arose from that exposure. Indeed, the probability of causation in a specific individual is nonidentifiable [19]. The standard of proof courts utilize in civil cases, however, is the preponderance of the evidence or the "more likely than not" criterion. Thus, scientific evidence that a particular agent can cause a specific disease or set of related diseases in the general population supports an individual's claim that his or her disease came from their exposure. Conversely, scientific studies indicating no increased risk of a specific disease amongst exposed individuals are relied on by defendants, typically producers of the chemical or drug, to support the safety of their product. Similar questions of **causation** arise in cases alleging harm from exposure to hazardous wastes, although the issue in these cases is often whether the exposure was sufficient in magnitude and duration to cause the disease (*see* **Risk Assessment for Environmental Chemicals**).

Epidemiologic studies are also used to determine eligibility for Workers' Compensation, where the issue is whether the employee's disease arose from exposure to an agent in the course of employment [6, p. 831], in regulatory hearings to determine safe exposure levels in the workplace (*see* **Occupational Health and Medicine**), and have even been submitted as evidence in criminal cases [5, p. 153]. We emphasize scientific evidence in tort law, which includes product liability and mass chemical exposure cases, because it is the major area of the law utilizing epidemiologic studies as evidence.

Tort Law

Tort law generally concerns suits for wrongful injury that do not arise from a contract between the parties. Thus, remedies to compensate for injuries from a wide variety of accidents resulting from someone's negligence, e.g. professional malpractice, assault and battery, environmentally induced injury, and **fraud** can be obtained by a successful plaintiff. Product liability is a special area of tort law dealing with the obligations of manufacturers of products to consumers who may suffer personal injury arising from the use of the product.

In any tort claim the plaintiff needs to establish a *prima facie* case by showing that the defendant has a legal duty of care due to the plaintiff and that the defendant breached that duty. In addition, a plaintiff needs to show that (i) she suffered an injury and that the defendant's failure to fulfill its duty of care was the (ii) factual and (iii) legal cause of the injury in question. The law also recognizes defenses that relieve the defendant of liability. The two most prominent ones in tort suits are contributory negligence by the plaintiff and statutes of limitations, which bar suits that are brought after a specified period of time has elapsed from either the time of the injury or the time when the relationship between the injury and the use of the product was known to the plaintiff [8]. In some jurisdictions, especially in Europe [14, p. 834], if the injury results from a defect arising from the product's compliance with a mandatory legal provision at the time it was put on the market, then the manufacturer is not liable. There are substantial differences between jurisdictions as to whether a plaintiff's contributory negligence totally absolves the defendant from liability, reduces it in proportion to the relative fault of the parties, or has no effect on the liability of a defendant whose contribution to the injury was small. In the US, the plaintiff's fault is rarely a complete bar to recovery when the defendant's negligence had a significant role. Similarly, the effective starting date of the limitations period varies among nations and among the states in the US.

When reading actual legal cases that rely on scientific evidence one needs to be aware of the relevant legal rules. For example, although the epidemiologic evidence linking the appearance of a rare form of vaginal cancer in a young woman to her mother's use of diethylstilbestrol during pregnancy is quite strong [1], some states barred plaintiffs from suing because the statute of limitations had expired. Since the cancers were recognized only when the young women passed puberty, typically in the late teens or early twenties, a number of injured women could not

receive compensation. Other states, however, interpreted the limitations period as beginning at the time the plaintiff should have been aware of the connection. In Europe, the European Economic Community (EEC) directive of 1985 provides for a 10-year statute of limitations and allows plaintiffs to file claims within three years after discovering the relationship. Markesinis [14] summarizes the directive and the relevant English and German laws.

Epidemiologic evidence is most useful in resolving the issue of cause in fact, i.e. whether exposure to the product made by the manufacturer, or chemicals spilled onto one's land by a nearby company, can cause the injury suffered by the plaintiff. An alternate formulation of the factual cause issue is whether exposure increases the probability of contracting the disease in question to an appreciable degree. **Case–control studies** were used for this purpose in the litigation surrounding Rely and other highly absorbent tampons [6, p. 840]. Within a year or two after these products were introduced, the incidence of TSS (toxic shock syndrome) amongst women who were menstruating at the time of the illness began to rise sharply. Several studies, cited in Gastwirth [6, p. 918], indicated that the estimated **relative risk** of contracting the disease for users of these tampons was at least 10, which was statistically significant (*see* **Hypothesis Testing**).

In light of the sharp decline in the incidence of TSS after the major brand, Rely, was taken off the market, the causal relationship seems well established and plaintiffs successfully used the studies to establish that their disease was most likely a result of using the product. When only one case–control study, however, indicates an association between exposure and a disease, courts are less receptive. Inskip [12] describes the problems that arose in a British case concerning radiation exposure of workers and leukemia in their children (*see* **Leukemia Clusters**).

There is a rough rule relating the magnitude of the relative risk, R, of a disease related to exposure and the legal standard of preponderance of the evidence, i.e. at least half of the cases occurring amongst individuals exposed to the product in question should be attributable to exposure. As the **attributable risk** is $(R-1)/R$, this is equivalent to requiring a relative risk of at least 2.0. While a substantial literature discusses this requirement (see [20, pp. 1050–1054], [6, Chapters 13 and 14, 24], and [10, pp. 167–170] for discussion and references), courts have been reluctant to adopt it formally, since it would allow the public to be exposed to agents with relative risks just below 2.0 without recourse. The lowest value of R accepted by a court the writer has seen is 1.5, in a case concerning the health effects of asbestos exposure. Courts usually require that the estimated R be statistically significantly greater than 1.0 and have required a **confidence interval** for R but also consider the role of other error rates [10, pp. 153–154]. When a decision must be based on sparse evidence, courts implicitly consider the **power** of a test and may not strictly adhere to significance at the 0.05 level.

The relative risk estimated from typical case–control studies is taken as an average for the overall population. Courts also consider the special circumstances of individual cases and have combined knowledge of the prior health of a plaintiff, the time sequence of the relevant events, the time and duration of exposure, as well as the **latent period** of the disease, with epidemiologic evidence to decide whether or not exposure was the legal cause of a particular plaintiff's disease.

So far, our discussion has dealt with the criteria for factual causality where an injury has already occurred. In some cases concerning exposure to a toxic chemical, plaintiffs have asked for medical monitoring, such as periodic individual exams or a follow-up study. As this is a new development, a specific minimal value of R has not been established.

In product liability law, a subclass of tort, in addition to negligence claims, sometimes one can assert that the manufacturer is subject to strict liability [15, 18]. In strict liability the test is whether the product is unreasonably dangerous, not whether the manufacturer exercised appropriate care in producing the product. Epidemiologic studies indicating a substantial increased risk of a disease can be used to demonstrate that the product is "unreasonably dangerous" from the viewpoint of the consumer.

Some product liability cases concern the manufacturer's duty to warn of dangers that were either known to the manufacturer or could reasonably have been foreseen at the time the product was marketed. In the US, producers are also expected to keep abreast of developments after the product is sold and to issue

a warning and possibly recall the product if **post-marketing** studies show an increased risk of serious disease or injury.

One rationale underlying the duty to warn is informed consent [17, p. 209] (*see* **Ethics of Randomized Trials**). Because asbestos was linked to lung cancer by a major study [23] published in the 1960s, the plaintiff in *Borel vs. Fibreboard Paper Products Corp.*, 493 F. 2d 1076 (5th Cir. 1973) prevailed on his warning claim. The opinion observed that a duty to warn arises whenever a reasonable person would want to be informed of the risk in order to decide whether to be exposed to it.

The time when the risk is known or knowable to the manufacturer is relevant. In *Young vs. Key Pharmaceuticals*, 922 P. 2d 59 (Wash. 1996) the plaintiff alleged that the defendant should have warned about the risk of seizure from the drug given him for asthma. The firm argued that the studies existing in 1979, when the child was injured, were not clinically reliable. Even though subsequent research confirmed those early studies that suggested an increased risk, the court found that the defendant did not have a duty to warn in 1979.

The reverse situation may have occurred in the *Wells* case, 788 F. 2d 741 (11th Cir. 1986). At the time the mother of the plaintiff used the spermicide made by the defendant, two studies had shown an increased risk of limb defects and the court found the firm liable for failing to warn. Subsequent studies, which still may not be definitive, did not confirm the earlier ones, and in a later case the defendant was found not to be liable. While this seems inconsistent from a scientific point of view, from a legal perspective both decisions may be reasonable because the information available at the two times differed.

Government Regulation

Epidemiologic studies are used by regulatory agencies such as the **Food and Drug Administration (FDA)** and Occupational Safety and Health Administration (OSHA) to get manufacturers to recall harmful products or give an appropriate warning. Indeed, the manufacturer of Rely tampons recalled the product after the fourth case–control study linked it to toxic TSS. More recently, case–control studies supported a warning campaign.

In 1982, after a fourth study indicated an association between aspirin use and Reye's syndrome, the FDA proposed a warning label on aspirin containers. The industry challenged the original studies, and the Office of Management and Budget (OMB) asked the FDA [16, 22] to wait for another study. The industry suggested that caretakers of cases would be under stress and might guess aspirin, especially if they had heard of an association, so two new control groups (children hospitalized for other reasons and children who went to an emergency room) were included in the follow-up study [25]. The **odds ratios** (OR) for cases compared with each of these two control groups were about 50, far exceeding those of the school (OR = 9.5) and neighborhood controls (OR = 12.6).

In late 1984 the government, aware of these results, asked for a voluntary warning campaign; a warning was mandatory as of June 1986. The following are the Reye's syndrome cases and fatalities from 1978 to 1989: 1978 (236, 68); 1979 (389, 124); 1980 (555, 128); 1981 (297, 89); 1982 (213, 75); 1983 (198, 61); 1984 (204, 53); 1985 (93, 29); 1986 (101, 27); 1987 (36, 10); 1988 (25, 11); 1989 (25, 11). The cases are graphed in Figure 1. Notice the sharp

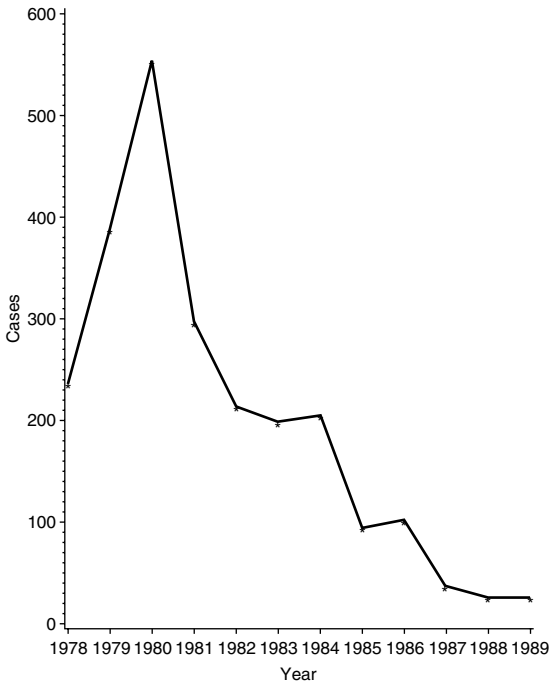

Figure 1 The number of cases of Reye's syndrome for the years 1978–1989

decline between 1983–84 and 1985–86, reflecting the effect of the warning campaign.

Criteria for Admissibility of Studies as Evidence

Courts are concerned with the reliability of scientific evidence, especially as it is believed that lay people may give substantial weight to scientific evidence. In the US, the *Daubert* decision, 113 US 2786 (1993), set forth criteria that courts may use to screen scientific evidence before it goes to a jury. The case concerned whether a drug, Bendectin, prescribed for morning sickness caused birth defects, especially in the limbs. Related cases and the studies are described at length in Green [9]. The *Daubert* decision replaced the *Frye* 293 F. 1013 (DC Cir. 1923) standard, which stated that the methodology used by an expert should be "generally accepted" in the field by the criteria in the Federal Rules of Evidence. The court gave the trial judge a gatekeeping role to ensure that scientific evidence is reliable. Now judges may examine the methodology used and inquire as to whether experts are basing their testimony on peer reviewed studies and methods of analysis before admitting the evidence at trial.

The US Supreme Court decision in *Daubert* remanded the case for reconsideration under the new guidelines for scientific evidence. The lower court, 43 F. 3d (9th Cir. 1995), decided that the expert's testimony did not satisfy the *Daubert* guidelines for admissibility in part because the plaintiff's expert never submitted the **meta-analysis** of several studies, which was claimed to indicate an increased relative risk, for peer review. Similarly, in *Rosen vs. Ciba-Geigy*, 78 F. 3d 316 (7th Cir. 1996), the court excluded expert testimony that a man's smoking while wearing a nicotine patch for three days caused a heart attack. The appeals court said that the expert's opinion lacked the scientific support required by *Daubert* because no study supported the alleged link between short-term use of the patch and heart disease caused by a sudden nicotine overdose. The *Rosen* opinion notes that the trial judge is not to do science but to ensure that when scientists testify in court they adhere to the same standards of intellectual rigor they use in their professional work. If they do so and their evidence is relevant to an issue in the case, then their testimony is admissible, even though the methods used are not yet accepted as canonical in their branch of science.

In two opinions that followed *Daubert, Joiner vs. General Electric*, 522 U.S. 136 (1997) and *Kumho Tire Co. v. Carmichael*, 119 S.Ct. 1167 (1999) the Court expanded the trial judge's role in screening expert testimony for reliability. Now, testimony relying on studies from social science and technical or engineering experience will be subject to review by the judge before the expert is allowed to testify. The *Kumho* opinion noted that the factors mentioned in *Daubert* (e.g. whether the theory or technique on which the testimony is based has been tested, whether it has been subject to peer review and publication, the known or potential error rate) were only a guideline rather than criteria to be strictly applied to prospective expert testimony. In particular, the circumstances of the particular case will have a major role. Commentators [2, 3, 11, 21]) have discussed its implications as well as cases where the circuit courts (covering different regions of the U.S.) have disagreed in their evaluations of similar evidence. Fienberg et al. [4] and Loue [13] discuss the reviewing process, noting some important factors for judges to consider.

Courts have reached different conclusions concerning the admissibility of the method of differential diagnosis, where medical experts conclude that a disease was caused by a particular exposure by eliminating other potential causes. The cases concerning the drug Parlodel and its relationship to stroke, discussed in [7] illustrate the problem. After studies showed that the drug could cause ischemic strokes, some plaintiffs offered expert testimony that these studies showed the drug could cause hemorrhagic strokes too. The Rider v. Sandoz, 295 F. 3d 1194 (11th Cir. 2002) opinion upheld a lower court's rejection of this extrapolation. At the same time it cited favorably Globetti v. Sandoz (111 F. Supp. N.D. Ala 2001) which admitted testimony based on differential diagnosis and also stated that epidemiologic studies are not an absolute requirement. While no human studies had been carried out, animal studies had indicated a risk. The expert was allowed to utilize this information in a differential diagnosis. Thus, the trial judge's assessment of the care and thoroughness with which a differential diagnosis or other scientific study has been carried out by a prospective expert as well as whether the expert has considered all other relevant evidence that is available at the time will be

a major factor in deciding whether the testimony is admissible.

Epidemiology, Overview

Epidemiology and biostatistics together constitute the quantitative foundation for public health and clinical research. Epidemiology has been variably defined [20, 25], but all definitions have as essential components the collection and use of data from populations or groups. Epidemiology might be viewed as formulating study designs to provide unbiased evidence for testing hypotheses by applying methods for gathering and using data from populations or groups of people. The domain of epidemiology includes both observation and experiment, although, ethically, the study of injurious factors is limited to observation. The consequences of exposure to potentially injurious agents can only be assessed by comparing disease risks in persons exposed through natural circumstances, including personal choice, with disease risks in those not exposed. Potentially beneficial agents, like chemopreventive micronutrients, might be evaluated using the same observational approaches or, in a clinical trial, by randomly assigning participants to the agent to be tested or to a placebo or other comparison therapy.

The principles of epidemiologic research are not unique to epidemiology and, in fact, permeate other branches of science concerned with human health and well-being: health services research, psychology, sociology and anthropology. Nor can a sharp point of demarcation be drawn between biostatistics and epidemiology. The most basic distinction places statistical aspects of design and data analysis in the domain of biostatistics and overall design and data collection in epidemiology, but the conducting of contemporary epidemiologic research needs integrated efforts from biostatisticians and epidemiologists, and often from clinicians and basic scientists. In addition, since the findings of much epidemiologic research often have immediate applications to clinical and public health policy, considerable media and public attention is directed to epidemiologic studies, frequently before they have been replicated and their results confirmed.

This article provides an overview of the field of epidemiology, setting a context for the more specific articles in this volume. It addresses the history of epidemiology, the purposes of epidemiologic research, the pathways for using epidemiologic evidence to further public health, and the current scope of the field, which is increasingly fragmented into specific areas of inquiry. The other articles in this book provide detailed reviews of different study designs, analytic methods and specifically focused areas of epidemiology.

History of Epidemiology

The beginning of contemporary epidemiology is often dated to the mid-twentieth century, when many large-scale studies were initiated to assess the causes of the shifting pattern of disease in the developed world observed during the preceding decades: rising mortality from seemingly new chronic diseases, like coronary heart disease and lung cancer, even as mortality from infectious diseases declined [39]. The many landmark studies on this theme that gave rise to current approaches are well known to biostatisticians and epidemiologists alike; for example, the Framingham Heart Study initiated in 1949 [11], and the British physicians' study initiated in 1951 [13]. In addition to these cohort studies, case–control studies were also carried out to characterize more quickly and efficiently the causes of the emerging chronic diseases. For example, the first convincing evidence on smoking and lung cancer was derived from case–control studies reported in the 1940s and early 1950s [52]. Cohort studies were also initiated to characterize the consequences of unique exposures, like the study of Japanese atomic-bomb survivors, which still continues today [43].

The origins of epidemiology, however, can be traced back centuries. Society has continually attempted to find the causes of epidemics of disease, whether the plague centuries ago or the sudden appearance of acquired immune deficiency syndrome, (AIDS), only two decades ago [46]. The search for causes, discussed in the third section, is intrinsically linked to the search for cures and avenues for prevention, and now as in the past, epidemiologic evidence remains central to the development of policies to protect and improve the public's health. An epidemiologic perspective is also central to the provision of care for individual patients who need to be cared for in a population context that recognizes the many factors determining their health and disease status. While "evidence-based" medicine and clinical epidemiology have been only recently touted [18, 40], the role of quantitative inference in clinical

medicine was recognized in the nineteenth century by the French physician, Pierre Louis [28, 46].

One element of epidemiology is the description of the occurrence of disease, generally by person, place and time. The counting of disease events can be traced to Graunt who published his book, *Natural and Political Observations Made Upon the Bills Of Mortality*, in 1662 [6]. In this volume, he analyzed the bills of mortality for London, which included the weekly numbers of deaths and their causes, and the numbers of children christened. From these data, he inferred a lifetable for survival in London at the time. His acquaintance, Sir William Petty, also saw the relevance of counting to medicine and he too attempted to estimate life expectancy at birth [6, 46]. Thirty years after the publication of Graunt's book, Edmund Halley, better known for the comet bearing his name, described a lifetable for Breslau and in doing so he showed a clear understanding of population dynamics.

In the nineteenth century, major developments again took place in London. Wlliam Farr advanced counting to a new level through his work at the General Register Office [15, 46]. Farr held responsibility for health statistics for England and Wales and in that capacity he systematically collected and analyzed data, developing new methods and showing the insights into population health that could be gained from valid descriptive data (*see* **Vital Statistics, Overview**). Farr's contemporary, John Snow, undertook investigations of cholera epidemics in London and also practiced anesthesia, giving chloroform to Queen Victoria for childbirth [44]. Snow's investigations of cholera in London, undertaken by the newly founded London Epidemiological Society, led to the determination that cholera was transmitted via contaminated drinking water. Proof of this hypothesis prompted preventive interventions, including the recommendation to remove the handle of the Broad Street pump, a source of contaminated drinking water.

The further rise of epidemiology to the modern era was based in a scientific framework grounded in the emerging recognition of the role of microorganisms in causing disease and the rise of infectious disease epidemiology. In fact, the first principles for evaluating research findings for evidence of causality are often attributed to Robert Koch, although he had benefited from his teacher, Jacob Henle [14]. Koch applied these principles in his identification of the tubercle bacillus as the cause of tuberculosis.

Epidemiology has also used experimental methods. Early eighteenth-century examples include Lind's small trial of fresh fruit to prevent scurvy and Jenner's experimental use of cowpox vaccination to prevent smallpox. Early in the twentieth century, Goldberger conducted experiments that showed pellagra to result from a dietary deficiency, subsequently shown to be a lack of niacin [2, 32]. The contemporary clinical trial originated in the twentieth century as the concept of randomization of participants was introduced and the power of the design was shown in studies of streptomycin for tuberculosis and of vaccination for polio, for example [27, 31].

The first academic department of epidemiology was founded at the Johns Hopkins University School of Hygiene and Public Health in Baltimore in 1919 with the appointment of Wade Hampton Frost [16]. Frost combined interests in infectious diseases and research methods [30] and he saw the relevance of epidemiology to solving problems in public health. His department and its problem-oriented teaching methods became a model for institutions worldwide. Now, schools of public health throughout the world grant master's and doctoral degrees in epidemiology, as do some medical schools.

By the mid-twentieth century, the stage was set for the rise of modern epidemiology: academic departments were established and the new epidemics of coronary heart disease, chronic lung disease, and cancer motivated new research approaches that could address multicaused diseases with lengthy incubation periods and long natural histories. The prospective cohort study was initially the central design for investigating these diseases. Prospectively conducted cohort studies afforded the opportunity to collect data to test multiple hypotheses concerning disease etiology and the strength of this design was quickly shown by the success of the Framingham and other studies in identifying causes of heart disease and through the rapid confirmation that smoking caused lung cancer and other diseases by the studies of British physicians and other groups, including the one million persons enrolled in the American Cancer Society's Cancer Prevention Study (CPS) [41].

The Framingham study is still considered a model for community-based research. Dawber [11] has

chronicled the origins of the study, which was implemented in the late 1940s to address the rising occurrence of cardiovascular disease. The long-term success of the study can be attributed to the selection of a small and cooperative community, sustained support from the National Institutes of Health (NIH), and to the prescience of the original investigators who established rigorous and standardized protocols for data collection. Data were collected relevant to testing the principal extant hypotheses concerning etiology, which were listed at the study's beginning. As a result, much of our initial understanding of risk factors for cardiovascular diseases was based on evidence from this study. Supplementary studies of other diseases capitalized on the opportunity afforded by having the Framingham population under follow-up, and offspring of the original cohort have now been enrolled in a new cohort study that should be informative on familial factors affecting cardiovascular disease risk. The longitudinal data on multiple risk factors necessitated methodologic advances, since appropriate multivariate methods had not been available. For example, Gordon and colleagues [21] described application of discriminant analysis in a 1959 paper.

The cohort design (*see* **Cohort Study**) remains central to observational epidemiologic research, although elaborations of the design have been made to enhance feasibility while reducing costs. For example, large cohorts, like the Nurses' Health Study participants, have been followed primarily by using mailed questionnaires and matching against central registries to determine vital status. It has even been possible to obtain biologic specimens, including toenails for trace metal analysis and blood for DNA, using this approach. In the US, the NIH has taken the lead in establishing multicenter prospective cohort studies, particularly in the area of cardiovascular disease – for example, the Atherosclerosis Risk in Communities (ARIC) study, the Community Heart Study (CHS), and the Strong Heart Study of heart disease in Native Americans. These multisite studies gain external validity by drawing participants from communities across the US. Data collection is standardized and data are accumulated, evaluated and managed at central coordinating centers.

Opportunities for data linkage have now facilitated the conduct of cohort studies. Using record linkage approaches, lists of exposed individuals can be matched for outcome against death indexes and disease registries (*see* **Record Linkage**). Pioneering cohort studies based on this approach were conducted in Canada, where a mortality register of deaths back to 1950 has been available for matching and establishing vital status and cause of death [36]. The National Health and Nutrition Examination Survey (NHANES) conducted by the National Center for Health Statistics has been given a longitudinal component by linkage against death certificates and additional follow-up data collection [10].

The **case–control** design, discussed in detail elsewhere in this volume, is the other principal observational design for testing hypotheses and has also evolved over the same 50 years. Inherent limitations of this design have led some epidemiologists to consider it inferior to the cohort study [2, 17]. Information obtained by interview from cases and controls may be affected by bias; differential bias across cases and controls may create confusing patterns of association. The results of case–control studies conducted among persons selected through a particular institution, e.g. a hospital or clinic, may also be subject to selection bias [4]. Control selection may also be problematic [46] and design principles and feasibility may be in conflict.

There is now substantial understanding of these problems, however, and a methodologic foundation for the case–control design has been firmly established [1]. Cornfield [9] proposed the odds ratio as an estimate of the relative risk for case–control data and Mantel & Haenszel [29] described methods of stratified analyses in their 1959 paper: "Statistical aspects of the analysis of data from retrospective studies of disease". Miettinen further elaborated the underlying principles and analytic methods [33, 34] as did others [7, 42]. More generally, the links between cohort and case–control designs were noted and case-based sampling designs for cohort studies were proposed that unified the two approaches [26, 38].

The case–control design has proved effective for identifying strong causes of disease, such as smoking and lung cancer, diethylstilbestrol and adenocarcinoma of the vagina, and vinyl chloride and angiosarcoma of the liver. The design has been widely applied in research on the etiology of cancer, primarily by using population-based registries to identify cases and sampling to select representative controls. This design is conceptually equivalent to a case–control study nested within a cohort representing all residents of the registry's catchment

area. One landmark study of this design addressed artificial sweeteners and bladder cancer; the study included 3010 cases and 5783 controls [23]. The case–control approach has now also been applied to assess screening and the risks and benefits of therapy.

The randomized trial, an experimental design, is widely held to be the gold standard of population studies. While experimental designs have been used to test therapeutic interventions for several centuries, the modern clinical trial originated in the twentieth century [27]. The use of randomization was advocated in the late 1940s by Austin Bradford Hill and applied in two seminal trials: a test of the pertussis vaccine and an assessment of the efficacy of streptomycin in treating tuberculosis [12]. The clinical trial has since rapidly evolved to include variations in the design and the development of multicenter approaches that make extremely large trials possible.

The core element is the random assignment of subjects to different therapeutic or preventive options. While randomization does not guarantee comparability of the study groups, it does eliminate the potential bias that may result from an investigator's preconceptions. Randomization makes it impossible to predict the assignment of the next person enrolled in the study. While in observational studies we will often match on variables that are known to influence outcomes, the advantage of randomization over matching is that randomization increases the likelihood of comparability of the groups even for factors that influence prognosis but of which we may be unaware or may be unable to measure. Ideally, randomized trials are conducted "blindly" – that is, the subject is unaware of which regimen he is receiving, and the physician or other health care provider does not know to which therapy the individual has been assigned. This is often accomplished by using a placebo, an inert material that looks and tastes like the active drug. At times, however, blinding may be difficult or impossible to implement, a problem that is most significant when the outcome being studied is a subjective one such as pain. In recent years considerable attention has focused on ethical issues pertaining to the use of placebos since using placebos may often involve not offering a currently available agent that is at least partially effective.

The randomized trial has most often been applied to clinical therapies, but has found increasing value for studying the benefits of community-wide interventions with public health measures.

The Specialization of Epidemiology

With the increasing complexity of epidemiologic research, epidemiologists and their areas of inquiry have become increasingly focused and specific. The bifurcation of the field into "infectious disease epidemiology" and "chronic disease epidemiology" no longer holds. The field has become multidimensional with cells defined by disease (e.g. cancer or heart disease), exposure (e.g. environment or nutrition), methods (e.g. genetic or molecular) and problem domain (clinical or outcome). Increasingly, genetics overlays all lines of inquiry, particularly those directed at disease etiology.

The core methods and principles are comparable across these areas of epidemiology, but each has its own special aspects. Of course, in each area there is a specific biomedical substrate, reflecting the exposures and outcomes of interest and the underlying biological phenomena. Additionally, methods for exposure and outcome assessment may be specific to an area. In studying occupation and health there are specific measurement methods for characterizing workplace exposures and the job itself may be used as an exposure surrogate, sometimes with the application of a job-by-exposure matrix [8]. Studies in the domain of genetic epidemiology use specific study designs, often family-based, and analytic methods that characterize patterns of association of disease risk with genetic markers. Other articles in this volume cover clinical epidemiology, **environmental epidemiology**, genetic epidemiology, **nutritional epidemiology**, **occupational epidemiology**, **pharmacoepidemiology** and **risk assessment**.

Epidemiology, Policy and Public Health

The direct linkage of epidemiologic evidence to making policy intended to advance public health is widely acknowledged. Almost universally, epidemiologists tell the story of John Snow and the Broad Street pump as an illustration of the immediacy of observational findings for solving public health problems. This example is particularly compelling because Snow demonstrated the waterborne transmission of cholera before there was knowledge of the existence of the *Vibrio cholerae* organism. There are numerous other examples, also considered as triumphs of epidemiologic inquiry: establishing cigarette smoking as a

cause of lung cancer and other diseases, identifying powerful and remediable causes of cancer like asbestos exposure and diethylstilbestrol administration during pregnancy, and the characterization of risk factors for AIDS.

As a core discipline of biomedical research, epidemiology is not unique in generating evidence relevant to policy. After all, the ultimate goal of all biomedical research is to advance the health of people. Epidemiology, as a scientific method applied directly in the population context, brings evidence that directly bears on the health of the population and this direct linkage is what distinguishes epidemiology from other branches of biomedical research. As a consequence, epidemiologic findings generally have immediate relevance to setting policies pertinent to health and this relevance often gives prominence to epidemiologic evidence in the diverse processes by which policies are made. This prominence has occasioned targeted review and criticism of specific epidemiologic findings and of epidemiology generally. As epidemiologic research has addressed increasingly complex questions concerning the causes of disease, the risks of environmental factors and the benefits of interventions, the resulting evidence may be subject to uncertainties that cloud decision-making, leading some to question the utility of epidemiologic data.

The community of epidemiologic researchers is divided in its view of epidemiology and policy. At one extreme, some would consider epidemiology as being no different from other branches of science where the rationale for research is often given as advancing knowledge; at the other, epidemiologic research would be construed as justified only if the evidence were to be relevant to advancing public health. Epidemiologists are similarly divided in their view of the role of epidemiologists in policy-making processes. Some eschew such involvement and one respected journal, *Epidemiology*, does not allow authors to offer policy recommendations. Others have called for renewed activism by epidemiologists and engagement with the sweeping social problems that underlie many of the increased risks that epidemiologists have elegantly and repetitively described [37, 45]. Even as debate continues, the use of epidemiology for policy purposes is burgeoning with the rise of the outcomes movement and calls for evidence-based medicine, and the need to apply the explosively expanding knowledge of the human genome in clinical and population contexts.

The paths and processes leading from hypothesis to policy are diverse and often lengthy and ill-defined (see Figure 1 and Table 1). In the area of infectious diseases, findings may lead quickly to action; John Snow acted immediately in response to his own findings on the waterborne transmission of cholera. Continuing in this tradition, investigators addressing infectious disease problems make policy recommendations more often than investigators working in other areas [24]. For some areas of inquiry, evidence

Risk assessment
Jury evaluation

may accumulate slowly, e.g. diet and cancer, and only reach a level of certainty sufficient for policy-making after decades of research. Of course, research and policy-making are interactive and iterative, and policies may change as evidence evolves.

Some of the routes for translating epidemiologic and other data into policy are listed in Table 1. They range from formal and structured, as in the requirements of specific regulations, to informal and unstructured, as in the choices that individuals take for their own lifestyles. For example, the 1996 draft cancer policy guidelines of the US Environmental Protection Agency [51] offer instruction for evaluating and interpreting epidemiologic data. Criteria for causality have been rigorously applied in the reports of the Surgeon General on smoking and health [49, 50]. Gail [19] traced the application of these criteria to the evidence on smoking and lung cancer and showed their utility for organizing the relevant lines of evidence and making certain that alternatives to the causal hypothesis could be satisfactorily addressed. Specific actions may be invoked if the evidence reaches a threshold of certainty, e.g. a causal association is found or a target level of risk is reached. Embedded within these translation routes are processes for identifying and evaluating the relevant evidence (Table 2).

New tools for conducting epidemiologic research, together with the increasing capacity to manage and analyze large databases, have made epidemiologic evidence more informative for answering policy-maker's questions. Large administrative databases, such as the Health Care Financing Administration's Medicare files, can be explored to test hypotheses with immediate policy relevance – outcome of myocardial infarction in relation to hospital volume [47] and patterns of care by race and gender [22, 35], for example. Increasingly powerful multivariable methods for data analysis can detect policy-relevant patterns of association with the confidence that the associations are not spurious, while new models for longitudinal data analysis facilitate the capacity to describe disease and its development in time [48].

For many policy issues, the evidence comes from numerous and sometimes heterogeneous studies. Synthesis of such data for policy purposes has often been accomplished by expert review and consensus, tabular summary, or the application of criteria for causality. These processes have proved effective, particularly for strong associations, but uncertainties in the evidence have undermined conclusions, particularly if conclusions weighted by policy are reached. An example is the epidemiologic evidence on passive smoking, which has been the scientific basis for programs to reduce smoking in public places and repeatedly questioned by the tobacco industry and its consultant scientists. Combining evidence from multiple studies, whether experimental or observational, has proved to be an efficacious approach for synthesis. This combination can be accomplished by meta-analysis, combining summary estimates from individual studies, and pooled analysis, analyzing data jointly from individual participants in multiple studies (*see* **Meta-analysis in Epidemiology**). While the use of meta-analysis has been questioned [3], properly conducted meta-analyses have yielded useful and sometimes unexpected findings [5]. Pooled analysis is a more powerful approach, offering the possibility of controlling, confounding and exploring effect modification at the individual level, but requiring the effort of creating the pooled data set for analysis. The array of alternative approaches for synthesis, ranging from expert opinion to quantitative summary,

has not been rigorously evaluated, but more recent approaches, involving a systematic evaluation and quantitative summary of data, seem preferable.

Summary

The twentieth century has seen a remarkable evolution of epidemiology and also of biostatistics, the companion quantitative science of public health and medicine. Epidemiology has moved from being a problem-solving approach used in the field to a core scientific method of biomedical research. As scientific questions around the public's health have become more complex, the field of epidemiology has itself become more complex with speciation into subareas defined by exposures, outcomes, and the methods and domains of inquiry. Evidence forthcoming from epidemiologic research is given weight in policy development for health care and public health, attesting to the immediacy and relevance of epidemiologic data.

Epilepsy

Approximately 22 of every 1000 people will suffer a seizure (convulsion or fit) sometime during their lives and, of these, 17 will have a recurrence within a comparatively short period (about one year) and be diagnosed with epilepsy; about 10 per 1000 are currently prescribed anti-epileptic drugs (AEDs), and about 5 per 1000 have "active" epilepsy (a seizure within the previous two years). The last is equivalent to a point prevalence for epilepsy of 500 per 100 000 population. With an annual incidence of 40 per 100 000 there are about 65 new cases each day in a population of 60 million.

The epilepsies are one of the oldest documented groups of diseases; they were described and classified in a neo-Babylonian stone "textbook" of medicine (700–600 BC), and effective treatment was claimed by Hippocrates (460–377 BC) who advocated "use of drastic measures including drugs"; various forms of epilepsy are featured in the Bible. Despite this long history, "epilepsy" is poorly understood, a cause being clearly identified in only 50% of cases. This is changing following the introduction of noninvasive, high-definition, computerized scanning techniques, such as magnetic resonance imaging, which can localize lesions deep within the brain. Epilepsy affects all age groups, being particularly associated with birth trauma and infection in the very young, head injury in teenagers and young adults, alcohol in middle age, and vascular disease, cerebral tumors, and pneumonia in the elderly; seizures may be induced by lack of sleep, stress, the menses (catamenial epilepsy), and in some people who are photosensitive, by watching television and playing video games. In some patients seizures may only occur during specific periods (whilst asleep or on wakening), in others randomly.

Towards the end of the nineteenth century Gowers (1845–1915), the first neurologist to study epilepsy scientifically and who initiated the modern era of epilepsy epidemiology, listed about 50 extracts from plants and other chemical compounds (some of them poisons) which had been used during the previous 1400 years to treat epilepsy. Earlier, in 1860, Sieveking had wryly commented that "there is scarcely a substance in the world capable of passing through the gullet of man that has not at one time or another enjoyed the reputation of being antiepileptic". The modern era of pharmacological treatment started with the introduction of bromides (which are quite toxic) by Locock in the 1860s, and culminated by 1976 in the licensing of 37 major drugs under 480 proprietary names worldwide; (see [14]). Today most patients are maintained on one of four AEDs: phenobarbitone (discovered in 1912), phenytoin (1938), carbamazepine (1974), and sodium valproate (1978). During the 10 years following the introduction of sodium valproate few new AEDs were discovered, a situation which has reversed since the late 1980s with 15–20 new agents now under intense investigation, and several already licensed.

Seizures

Most epileptic seizures are spontaneous (unprovoked), short-lived (rarely exceeding 15 minutes in duration), and self-limiting (thus terminate without intervention); however, they are recurrent in some patients and may re-occur over many years either intermittently or in bursts (clusters). An epileptic seizure is thus a transient disturbance of brain function resulting from repeated simultaneous firing (paroysmal discharge) of nerve cells sometimes limited within a specific region of the brain (for example, the temporal lobe or motor cortex), sometimes spreading from a specific region (focus) to the whole brain, and sometimes engulfing the whole brain from onset. This gives rise to a natural subdivision into partial seizures (sometimes secondarily generalized) and primary generalized seizures; partial seizures may or may not be associated with loss of consciousness, leading to further subdivision. In practice there are several different types of both partial and generalized seizures and these have been delineated in a classification system devised by the International League Against Epilepsy (ILAE). Besides a classification of seizure types the ILAE has also devised a classification of the epilepsies (the pathology that underlines the seizures themselves); the former is simpler and ubiquitous (almost mandatory) in studies of epilepsy, the latter is much more complex and, consequently, of less practical use. Both systems require an electroencephalogram (EEG) for precise application. (The EEG is a multi-electrode device which, from the surface of the scalp, records electrical activity integrated over a few million nerve cells situated within different regions of the brain and outputs

multiwave (one from each region, often about 16) continuous traces; these are examined for several specific abnormal patterns characterizing high frequency neuronal discharges.) The majority of patients suffer just one type of seizure, the commonest being primary generalized tonic–clonic and complex partial seizures. With the former the subject loses consciousness, falls to the ground, stiffens (tonic phase), and then suffers violent jerking (clonic phase) of the whole body, which eventually subsides; the subject then regains consciousness but may be confused and tired, and consequently sleeps. With partial complex seizures the subject engages in complicated circular movements of the arms and/or legs and/or fidgety movements with the fingers. A minority of patients manifest seizures of two, or much more rarely, three types. It is important to stress that not all seizures are associated with epilepsy. For example, children under six years of age may suffer a (febrile) convulsion as a result of a high temperature induced by fever; such seizures are not epileptic. However, the induction of a series of epileptic seizures by electrical stimulation of the brain is a therapeutic maneuver for the treatment of some psychiatric disorders [electroconvulsive therapy (ECT)]. Furthermore, some patients may suffer from an illusion that they have had seizures and provide a credible description of them – a psychiatric disorder categorized as "pseudoseizures".

Treatment and Prognosis

In clinical practice patients who experience a seizure are often first seen by a community physician (general practitioner), who will refer most to a neurologist for further investigation, and may, dependent on circumstances, initiate treatment with an AED. Since referral to a specialist often takes about three months, the neurologist will have a longer clinical history upon which to base a firm diagnosis and consequently better grounds for deciding in consultation with the patient whether or not to initiate treatment. In the UK and elsewhere in Europe, drug treatment will start with a comparatively low dose of one of the three or four first line AEDs, with dose escalation only on inadequate seizure control to the point where the patient experiences toxic and unacceptable side-effects. At this point another AED may either be added or substituted. Treatment is sometimes monitored by assaying serum concentrations of the AED as a guide to whether it is actually being taken (many patients – perhaps 40% – may be "noncompliant") and sometimes as a guide to dose or drug changes. Following **observational studies** serum drug concentrations have been grouped into three broad strata: subtherapeutic (inadequate seizure control); therapeutic (seizure control without unacceptable side-effects), and toxic (unacceptable side-effects of the drug). In the US patients may be treated more aggressively, being started on higher doses of AEDs with the objective of quickly achieving optimal (i.e. therapeutic) serum concentrations. However, many patients do remain seizure-free once low dose AEDs are started. In developing areas of the world epileptic seizures are often not treated with AEDs, first because they are unlikely to be available and secondly because many are far too expensive for patients to afford. (Net costs (2003) NHS prescribing (UK) for minimum recommended dosage (cost per year); phenobarbitone (£10); phenytoin (£20); carbamazepine (£77); sodium valproate (£108); and two newer drugs –lamotrigine (£420) and vigabatrin (£655)). Local customs and medical practices may result in patients being treated by traditional methods.

In any group representative of newly diagnosed patients about 75% will become seizure-free for long periods (in excess of two years) within five years of diagnosis, about 10% will continue to experience an occasional seizure or cluster of seizures, and the remaining 15%, despite (multi-) AED therapy (polytherapy), will develop chronic epilepsy experiencing seizures at least once every six weeks and perhaps up to several hundred per day. Although most people with epilepsy reside in the community, some with chronic epilepsy will have an occasional stay in a specialist institution where (re-)establishment of seizure control may be attempted; the more extreme chronic patients will reside there permanently. Some patients for whom AED treatment has failed will request and be assessed for neurosurgery, where part of the brain containing the epileptogenic focus will be removed. Optimistic claims, sometimes startling, of the successful outcome of "epilepsy surgery" have led to increased demands for these procedures over the past decade in Europe and the US though it should be noted that the efficacy of this form of **surgery** has only recently been established in a randomized **clinical trial** (RCT) [40].

Even today, in developed countries, epilepsy is a socially stigmatizing disease which can lead to unemployment and difficulty in finding work, debarment from certain occupations (such as working within the vicinity of potentially dangerous machinery or driving a public service or heavy goods vehicle), restricted social networks, and genuine fear and anxiety. In primitive communities it is still regarded as "possession by a devil or spirits" and treated by traditional methods ("native medicine" (*see* **Alternative Medicine**)). People in the UK who report the occurrence of a seizure (as required by law) to the Driving Vehicles Licensing Authority will have their driving licenses withdrawn until they have demonstrated complete seizure control (usually freedom from seizures of all types for a period of at least one year); those who reduce their doses of AEDs (perhaps because of side-effects or pregnancy) are advised to stop driving for several months. However, driving regulations vary widely from one country to another, and in the US from state to state; most require a period of two years free of seizures, others impose a lifetime ban.

Early Clinical Trials

There have been hundreds, perhaps thousands of studies assessing the efficacy of AEDs mainly through observing numbers of seizures; indeed one of the best known and most quoted references in epilepsy is a monograph by Coatsworth [7] that may claim to be one of the first published comprehensive overviews of treatment. Not only does it predate the first formal **meta-analysis** in epilepsy by 35 years, but it demonstrates some appreciation of exclusion bias for, as Penry states in the Foreword "In keeping with the general philosophy of thorough documentation for better evaluation, a bibliography of publications judged unworthy of profile has been included in addition to the bibliography of profiled articles". Coatsworth garnered articles (either clinical trials which utilize prospectively some form of **experimental design**, or case reports (*see* **Case Series, Case Reports**) of the results of drug treatment retrospectively without initial design) from 64 different journals and published over the period from 1920 to mid-1970. Of the 110 clinical trials, 43% had fewer than 50 patients, 27% more than 100; almost one-half (47%) did not report duration of the study; crucially, three were "multiple group **crossovers**", presumably explaining the only two that were double-blind and one that was single-blind, as well as the three that were randomized! For of these 110 "trials", 106 were single-group studies, with no information about patient evaluation in 74. In Coatsworth's summary:

> the average reported clinical trial may be characterized as a study of one drug given over a variable period to a group of 20 to 29 outpatients of differing seizure types. No controls are used, and the drug is varied in dosage by the needs of the patient. Seizure counts, types of seizure, and side effects are the data collected by an unreported evaluator using the clinical examination and laboratory data as his observational methods. The patients are evaluated before the trial and irregularly during the trial. The results of treatment are reported by the percentage of patients improved. In those studies with fair to good results, the investigator's opinion is that this drug is a valuable addition to the present regimen of antiepileptics.

This situation is apparent even today, for in the early stages of drug development the single-group "before and after" study is used as a screening mechanism for further investigation and, though important for initial safety testing, the results of such studies are sometimes presented with inappropriate conclusions. Patients who suffer seizures (despite AED treatment) are observed over a baseline period (not necessarily of fixed duration) and those with a seizure frequency above a stipulated threshold are all given the new putative AED for a set "test" period. The changes in seizure frequencies between baseline and test periods are then summarized and any reduction interpreted as a demonstration of efficacy. That such reductions may be explained by **regression to the mean**, even in the absence of any treatment effect, is gradually becoming better understood. Indeed, it has been demonstrated, in the form of regression towards the **median**, by Spilker & Segreti [37] who abstracted data from published epilepsy trials that included at least 10 patients and where the baseline and placebo periods were of equal length.

Crossover Trials

The next stage of development (Phase II and early Phase III) consists of two-treatment, two-period **crossover trials** in patients with "drug-resistant" epilepsy. Here again patients are observed over a baseline period (perhaps 8–12 weeks) and those

taking (specific) AEDs and experiencing seizures of predefined types and in excess of a stipulated threshold are randomized to the two sequences of "add-on" treatment with the new agent or "add-on" placebo; treatment periods frequently last up to 12 weeks with an intervening washout period of four weeks. Occasionally the new agent will be substituted for, rather than added to, existing AEDs, in which case the first four weeks of each treatment period may be used for tapering-off the original AEDs while starting the new. The primary responses are seizure counts over the three periods and side-effects over the two treatment periods. Since the variation in seizure counts between patients may be almost two orders of magnitude greater than variation within patients, these designs are much more efficient than the parallel-group design (*see* **Clinical Trials, Overview**). Unfortunately, much of this gain in efficiency is sacrificed in analysis by massive data reduction. Seizure counts are not **normally distributed**, and rather than attempt any form of data **transformation** to achieve this, or the application of any statistical method (such as **Poisson regression** or a mixture model) to allow for it, triallists resort to reporting and comparing the percentages of patients who achieve at least a (rather arbitrary) 50% reduction in seizure frequency by comparison with the baseline period.

Trials of this type are expected to demonstrate an improvement in seizure control on the new agent over that achieved with placebo; however, since there is no active control it is possible that these trials may miss potentially useful agents since the recruitment of "drug-resistant" patients may result in a sample that does not respond to either treatment; this cannot be gauged without the external validity supplied through the inclusion of an internal "active" control. For this and other reasons use of the crossover trial in epilepsy has declined and in the development of some of the newer AEDs abandoned altogether in favor of parallel group studies.

Parallel Group Trials

Traditionally, once a series of crossover trials had been successfully completed in patients who suffered more serious epilepsy, attention switched to the routine clinical treatment of newly diagnosed patients in the community. Such (Phase III) trials are parallel group studies which incorporate an active control; although perhaps originally designed to demonstrate an important clinical advantage of a new AED over established AEDs, experience suggests that this is in fact extremely difficult to achieve, and in practice such studies are now more frequently designed as **equivalence trials** or noninferiority trials. It is of interest that many of the established AEDs, particularly the older ones, have never been subjected to placebo-controlled trials, and it is now regarded as unethical to treat newly diagnosed patients with placebo. The majority of patients in the community experience few seizures and consequently seizure counts are not a useful outcome measure, often being too sparse for sensible analysis. Attention focuses instead on **survival-type analyses** of events associated with seizure remission (that is complete absence of seizures) as much as seizure recurrence.

The interval from **randomization** to first seizure recurrence is popular because it provides an estimate of the percentage of patients who remain seizure-free. However, it has the disadvantage of concentrating upon events that occur early in the follow-up period and thereby makes no allowance for dose adjustment. Alternatives are interval from randomization to first seizure after an initial window of (say) two months during which dose titration may take place to establish seizure control, interval from randomization to a particular type of seizure [e.g. major (tonic–clonic) seizure], or interval from randomization to the nth seizure ($n > 1$), or the nth day on which a seizure occurs. (Interestingly, Shofer & Temkin [36] investigated the **power** of analyses based on time to the nth seizure by comparison with seizure frequency in a **simulation** study of crossover trials where seizure frequencies were quite high and assumed to follow a **negative binomial distribution**. They found that while statistical tests based on seizure frequency itself exhibited the highest power, tests on time to the twelfth seizure for a sample size of 50 approached the power of tests on seizure frequency with a sample size of 20).

However, since the main purpose of AEDs is to eliminate seizures altogether through the establishment of long-term control, analyses now mainly focus on the interval from randomization to the achievement of a defined period of remission (complete absence of seizures of any type); popular choices are six months, one, two, and five years. In epidemiologic studies, and increasingly in clinical trials where some

measure of long-term outcome is required, the proportion of patients in terminal remission at different stages of follow-up is also reported; for example, the proportion of patients free from seizures during the two years immediately before five-year follow-up.

Modified Designs

Problems with the active equivalence design clinical trial in epilepsy have been succinctly summarized by Leber [21] and Gram [9], and these, combined with the ethical problems of withholding effective treatment (*see* **Ethics of Randomized Trials**) have led to suggestions for alternate designs. Pledger & Kramer [29] discuss two of these, including the active low-dose control where the aim is to establish a treatment difference, rather than equivalence, between the randomized groups. Another option is the design proposed by Amery & Dony [3] where all eligible patients are first treated for a set period with the drug under investigation; those who do not show a beneficial response are not followed further while those who do are randomized either to continue treatment or to have the investigational drug substituted by a placebo.

Quality of Life

People with epilepsy suffer social stigmatization as a consequence both of seizures and of taking AEDs; one result of this has been an awareness of the need to study not just the recurrence of seizures but their severity and their social consequences. Several groups have developed scales for assessing seizure severity and for disease-specific **quality of life**; these are now used frequently in clinical trials [39].

International League Against Epilepsy (ILAE)

The ILAE is a confederation of the world's leading experts in epilepsy and allied specialties that has been responsible for setting standards through Guidelines produced by Commissions set up to advise on specific issues. Apart from the classification systems mentioned above these include, among other Guidelines, those for Clinical Evaluation of Antiepileptic Drugs [12, 13], for Therapeutic Monitoring of Antiepileptic Drugs [16], for Antiepileptic Drug Trials in Children [17], and for Epidemiologic Studies on Epilepsy [15, 18]. ILAE has also produced an International Glossary of Antiepileptic Drugs [14], and commentaries on the economic burden of epilepsy [19], and genetic epilepsies [20].

Journals

There are four journals devoted entirely to epilepsy, although papers in this specialty are published regularly in general medical and general neurology journals. The four are *Epilepsia* (official journal of the ILAE; started 1960), *Epilepsy Research* (1987), *Seizure* (journal of the British Epilepsy Association; 1992), and *Journal of Epilepsy* (1988). The standard of statistical presentation in these journals is comparable with most other medical specialties and rarely ventures farther than the use of routine summary measures and associated significance tests; **actuarial methods** first appeared about 20 years ago. In some ways this is surprising since epilepsy is a heterogeneous, recurrent condition in which seizures may not be accurately recorded, and which would appear to offer an ideal opportunity for the application of a range of sophisticated, contemporary statistical techniques such as **multilevel**, **random effects** models, **frailty** models, and stochastic models (*see* **Stochastic Processes**) including **measurement error**; all with recurrence.

However, there are a few exceptions; for example, Hopkins et al. [10] and Milton et al. [28] examine seizure occurrence patterns using **Poisson processes**; the former, as well as Albert [1] look at **Markov processes**. Racine-Poon & Dubois [30] use a **hierarchical random-effects model** to predict maximum plasma carbamazepine concentrations in individual patients. Thall & Vail [38] and Breslow and Clayton [5] present reanalyses of an earlier trial using **generalized linear mixed models** that account for **overdispersion**, heteroscedasticity (*see* **Scedasticity**), and dependence (*see* **Statistical Dependence and Independence**).

Landmark Studies

With many hundreds of papers on epilepsy published over more than a century it is difficult, if not unfair, to identify any as being of such outstanding merit that methodologically they are vastly superior to all

others. While there have been many comparatively useless investigations, there have also been many very fine studies that demonstrate the best principles of design, conduct, and analysis. Those identified below should therefore be viewed as a sample of the better studies, not the only ones.

The first RCTs in epilepsy were published in 1956 [31, 35] but it was another 30 years before comparative trials in the community recruited in excess of 100 patients per treatment [25], and more than another 10 years before the first meta-analysis [24]. The importance of overviews for emerged since the establishment of the Cochrane Epilepsy Group in Liverpool, UK, in 1996 with its database of over 350 trials involving more than 3500 patients. (*see* **Cochrane Collaboration**). Meta-analyses from this Group have been used to illustrate methods for extracting estimates of hazard ratios from published trials [42], and methods for evaluating putative interactions between epilepsy type and treatment outcome [41], as well as to discuss difficulties in the interpretation of the summary statistic, number needed to treat ([11, 22]).

The largest RCT in epilepsy was the Medical Research Council Anti-epileptic Drug Withdrawal Study [26] which recruited over 1000 patients with a history of epilepsy who had been seizure-free for more than two years, and compared the risks of seizure recurrence in those randomized to withdraw AEDs with those randomized to continue; it also provided a predictive model for the risks of seizure recurrence under the two treatment policies that is now used in counseling patients [27].

While the first randomised trial of epilepsy surgery has been mentioned above [40], another innovative trial also published in 2001, was that of treatment of patients suffering prolonged seizures (*status epilepticus*) and unconscious, with lorazepam, diazepam, or placebo. Single drug packs were allocated randomly to ambulances, and trial entry was authorized by paramedical staff using radio contact to a physician at the base hospital under a waiver of informed consent [23]. The trial demonstrated the safety and effectiveness of the two active drugs compared with placebo [2].

The methodologic problems of epidemiologic follow-up studies in epilepsy have been summarized by Sander & Shorvon [33]; besides describing the difficulties of case **ascertainment**, and the problems of diagnosis, classification, and **selection bias**, they include an appendix of prevalence and incidence studies. Three groups have presented a series of papers based on follow-up of extensive cohorts of patients. The first in Minnesota, USA, is a retrospective study of 618 patients diagnosed with epilepsy at the Mayo Clinic between 1935 and 1974 (later extended to 1984) [4]; they report on the remission of seizures, prevalence, incidence, and mortality, as well as the risk of recurrence after an initial unprovoked seizure, a subject which has caused considerable debate over many years as a result of diagnostic and verification problems. The second [8] identified 122 patients with epilepsy out of a population of 6000 from a single general practice in the UK; they reported prevalence and outcome. The third, also in the UK, is the National General Practice Study of Epilepsy [34] in which 1195 patients considered by their general practitioners to have a possible diagnosis of epilepsy or febrile convulsions were followed up prospectively; the study reported risks of seizure recurrence and remission, and also examined mortality.

Equivalence Trials

Frequently, a **clinical trial** is designed to evaluate whether an experimental treatment (e.g. a therapy, preventive agent, or medical device) is sufficiently similar to an accepted or "standard" treatment, by some measure of treatment effect, to justify its use. The experimental treatment is often expected to be equal in effect to the standard, but not superior to it. Hence, such a study is commonly called an *equivalence* trial [5, 7]. The term *similarity* trial [5] has also been suggested, since we cannot actually show treatments to be equivalent but may be able to show that they are sufficiently similar by an appropriate criterion. Furthermore, investigators might not expect the treatments to have exactly equal effects, but they might nevertheless wish to demonstrate that the difference in effects is acceptable, considering the benefits of the experimental treatment, such as fewer side effects, greater convenience of use, or lower cost. In this article, *equivalence* and *similarity* are used interchangeably. Other terms that have been suggested include *active control* [19], *positive control* [19, 24], *δ-equivalence* [22], and *δ-no-worse-than* [22], where δ denotes the difference in the outcome measure between two treatments.

The Question Under Study

Formally, we design the trial to show that the experimental and standard treatments are similar with respect to a suitable parameter Θ, which might represent, for example, a difference or ratio of proportions, a difference or ratio of means, or a ratio of event rates of hazards. Assume Θ is defined so that positive values (or values greater than one, in the case of a ratio) indicate superiority of the standard treatment. Letting subscripts E and S refer to experimental and standard, respectively, Θ might be the difference $p_E - p_S$ in probabilities of disease, or the ratio μ_S/μ_E of geometric means of protective serum antibody levels induced by a vaccine. Because of the variability inherent in biologic experimentation, we cannot demonstrate exact equivalence statistically, even if the treatments are identical. We can, however, estimate Θ as precisely as desired from a large enough study.

Generally, in a study of therapeutic or preventive agents where the **outcome** is a clinical measure of treatment effect such as death or onset of disease (or a **surrogate** thought to be related to the clinical outcome), an equivalence or similarity trial will be designed to show that the standard treatment is not superior by a prespecified quantity Θ_0 or more. Thus, the question of primary interest in such a trial is usually one-sided (*see* **Alternative Hypothesis**); we place no restriction on the possible degree of superiority of the experimental treatment. (Note that the standard can be superior to the experimental treatment by an amount less than Θ_0 and the experimental treatment still be considered acceptable. If this is not the case, the trial is not a similarity trial, and it should be designed to show superiority of the experimental treatment.) For example, if Θ represents a difference $p_E - p_S$ in probabilities of disease and it is considered sufficient to demonstrate that the probability of disease using experimental treatment is not more than 0.15 greater than the probability using standard treatment, then $\Theta_0 = 0.15$.

Choice of a meaningful value for Θ_0 is crucial, since it defines levels of similarity sufficient to justify use of the experimental treatment. Θ_0 must be considered reasonable by clinicians (*see* **Clinical Significance Versus Statistical Significance**) and must be less than the corresponding value for placebo compared to standard treatment, if that is known [24]. Thus, the sample size required (*see* **Sample Size Determination for Clinical Trials**) may be much larger than that for a trial comparing the experimental treatment to placebo [15]. The choice of Θ_0 depends on the seriousness of the primary clinical outcome, as well as the relative advantages of the treatments in considerations extraneous to the primary outcome [7]. Careful choice of design parameters is not, however, unique to a similarity trial; in a trial designed to show superiority, it is important to select a meaningful and realistic value for the minimum effect to be detected [20].

Confidence Intervals and Hypothesis Tests

There are advantages to considering design and analysis of an equivalence trial in terms of **confidence intervals** rather than **hypothesis testing** [7, 15, 18, 25]. The confidence interval approach makes the desired outcome of the trial clear and avoids the mistake of choosing an inappropriate hypothesis (see below). Figure 1 depicts a $100\ (1 - 2\alpha)\%$ confidence interval for Θ around a point estimate $\widehat{\Theta}$. We assume

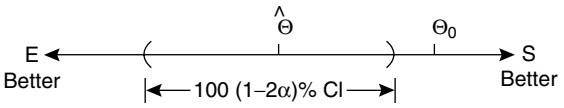

Figure 1 $100(1-2\alpha)\%$ confidence interval for Θ around a point estimate $\widehat{\Theta}$. An upper limit less than Θ_0 allows a conclusion of similarity, or "equivalence". E: experimental treatment; S: standard treatment

equal probability α in each tail. For a specified value of α (e.g. 0.05, 0.025, 0.01), we consider the treatments similar if the upper confidence limit is less than the prespecified quantity Θ_0. Thus, for example, the conventional α of 0.05 corresponds to a two-sided 90% confidence interval. Only a one-sided 100 $(1-\alpha)\%$ interval is really needed. It is appropriate, however, to report a two-sided interval with confidence coefficient $1-2\alpha$, since there is usually interest in the lower limit also. Note, in particular, that a lower limit >0, which indicates superiority of the standard, is consistent with similarity or "equivalence" according to our definition as long as the upper limit is less than Θ_0.

In hypothesis-testing terms, the appropriate null hypothesis is that the standard is superior to the experimental treatment by at least Θ_0; i.e. we test the null hypothesis $H_0 : \Theta \geq \Theta_0$. Rejection of H_0 at significance level α in favor of the one-sided alternative that $\Theta < \Theta_0$ is then sufficient to show similarity. Though such a procedure is correct and is equivalent to the corresponding confidence interval procedure, it encourages consideration of the situation as one of decision making, whereas it is usually one of estimation. A test tells us the strength of the evidence against a specific hypothesis, whereas a confidence interval tells us what values of Θ are consistent with the data.

Design of a similarity or equivalence trial has often been based on the **null hypothesis** $H_0 : \Theta \leq 0$ (or $H_0 : \Theta \leq 1$, for a ratio), as though the purpose of the trial were to demonstrate superiority of the standard treatment. Failure to reject the null hypothesis would then lead to a conclusion of equivalence. Such an approach is *not* appropriate [1, 3, 6, 7, 13, 18, 19, 25, 26], for several reasons. First, it contorts the logic of hypothesis testing; as has long been recognized, we cannot prove statistical hypotheses [9], so we design a study to *reject*, not accept, the null hypothesis [3], i.e. we measure the strength of the evidence *against*, not for, the null hypothesis [1, 2]. Secondly, if a trial has insufficient sample size, large variability, or some other defect due to poor design or conduct, it may fail to reject the null hypothesis of no difference, even if an important difference exists [3, 6, 7, 15, 18, 19, 24–26]. Thus, an inadequately designed or conducted trial may give the desired result, whereas a well designed and well conducted one would not. Furthermore, in a trial designed with high **power**, we may reject the null hypothesis of no difference and thus fail to conclude equivalence, even if the actual magnitude of the difference is unimportant [1, 7, 25, 26]. Hence, the hypothesis of no difference is an inappropriate basis for designing an equivalence trial, and the ***P* value** against that hypothesis is irrelevant to a conclusion of similarity. The size of trial so obtained may be larger or smaller than that based upon a correct approach (see section on sample size).

One-Sided and Two-Sided Questions

As already noted, in an equivalence trial with a clinical outcome, the question of primary interest is usually one-sided, namely can we show that the experimental treatment is not worse than the standard treatment by as much as Θ_0 [3, 18]? We do not wish to show that $\Theta > \Theta'$ for some Θ'. (Note that demonstrating superiority of the experimental treatment – i.e. showing $\Theta < 0$ for a difference or $\Theta < 1$ for a ratio – does not imply a test in the "other" direction from Θ_0, but corresponds to $\Theta_0 = 0$ or 1; if we wish to show superiority of the experimental treatment, then by definition we do not have a similarity trial.)

If we wish to demonstrate that the effects of two treatments do not differ much in either direction, we are interested in whether $\Theta_{01} < \Theta < \Theta_{02}$ for some Θ_{01} and Θ_{02} with $\Theta_{01} < \Theta_{02}$. To show this, the confidence interval for Θ should lie entirely between Θ_{01} and Θ_{02}. Such a situation is two-sided. An important class of two-sided trial is a **bioequivalence** or **bioavailability** trial [1, 13, 25, 26], in which it is desired to show that the biological activity or availability of two treatments is similar in both directions. Comparison of lots of a vaccine might also involve a two-sided question. Consideration of the corresponding hypothesis tests demonstrates, however, that the two-sided equivalence setting is different from the more familiar two-sided test situation (Figure 2(a)). The latter involves a null hypothesis that Θ takes a

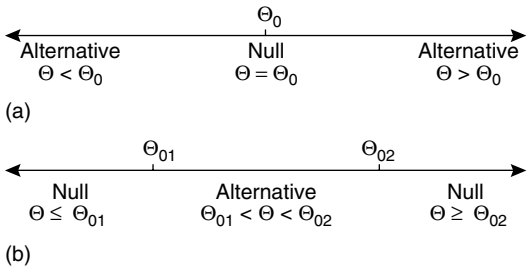

Figure 2 Null and alternative hypotheses for different types of two-sided tests: (a) two-sided alternative; (b) two-sided null

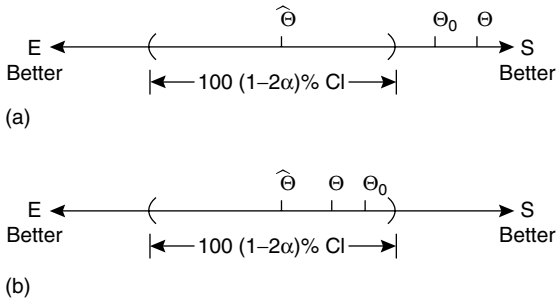

Figure 3 (a) Type I and (b) type II errors in an equivalence or similarity trial. E: experimental treatment; S: standard treatment. Θ denotes the true value, $\widehat{\Theta}$ the point estimate, and Θ_0 the criterion for concluding similarity

single value Θ_0 and an **alternative hypothesis** that Θ differs from Θ_0 in either direction; thus, the *alternative* is "two-sided", since its values lie on both sides of the null value. In the two-sided equivalence situation [Figure 2(b)], however, it is the *null* hypothesis (i.e. $\Theta \leq \Theta_{01}$ or $\Theta \geq \Theta_{02}$) that is two-sided, because it includes values on both sides of the alternative values [1, 23]. This difference has implications for sample size calculation, as indicated below.

Here, we will continue to assume a one-sided situation unless it is specifically stated otherwise.

Type I and Type II Errors

In an equivalence trial, we make a type I error if we falsely conclude similarity; i.e. if we obtain an upper confidence limit $< \Theta_0$ when the true value of Θ is $\geq \Theta_0$ [Figure 3(a)] or, in hypothesis-testing terms, if we reject $H_0 : \Theta \geq \Theta_0$ when H_0 is true. When we base the conclusion on the upper limit of a two-sided $100(1-2\alpha)\%$ confidence interval or on the corresponding one-sided test, the probability of a type I error is $\leq \alpha$.

A type II error is a failure to conclude similarity when the treatments are similar; i.e. obtaining an upper confidence limit $\geq \Theta_0$ when the true value of Θ is $< \Theta_0$ [Figure 3(b)] or failing to reject H_0 when H_0 is false. We denote the probability of a type II error for some specific value of $\Theta < \Theta_0$ by β; $1-\beta$ is then the power of the test or confidence interval procedure for that value of Θ.

It is, of course, desirable to keep both α and β small. However, as is usually the case in clinical trials, it is generally more important to keep α small.

Sample Size

Sample size formulations are available for various types of comparative measures in one-sided similarity trials – e.g. a difference in **normally distributed** means, a difference or ratio of proportions, and a ratio of event rates or hazards. In the descriptions of specific formulations below, Θ refers to the value of the difference or ratio for which we calculate power and Θ_0, as before, denotes the value we wish to rule out. We assume $\Theta < \Theta_0$. The sample size will also depend on the type I and type II error probabilities α and β and, in comparisons of proportions, the assumed true values of the proportions.

For testing the hypothesis of no difference between means from two normal distributions with equal and known variances, we have

$$N = \sigma^2 \left[\frac{1}{k} + \frac{1}{1-k} \right] \frac{(z_\alpha + z_\beta)^2}{\delta^2},$$

where N is the total number of individuals in two groups, σ^2 is the common variance, k and $(1-k)$ are the proportions of the total sample in the two groups, z_α and z_β are upper quantiles of the normal distribution corresponding to α and β, and δ is the minimum difference to be detected [16]. The only change necessary for a similarity trial is to replace δ with $\Theta_0 - \Theta$. Thus, for $\Theta = 0$, we obtain the same sample size for a similarity trial as for the conventional hypothesis of no difference with Θ_0 as the minimum difference to be detected.

If the comparison is based on a ratio of geometric means, as in comparing serum antibody levels, we can take logarithms of the original observations and

proceed as above, if the logarithms are approximately normally distributed.

Various methods have been suggested for analyzing differences [3, 6, 12, 18] and ratios [4, 11] of proportions in an equivalence trial. A **likelihood** score approach has been suggested as the best method overall in these settings [4, 8, 11, 21]. Sample size formulas based on score statistics have been derived for analysis of both differences [8, 21] and ratios [8]. If the null difference is 0 and the null ratio is 1, the two likelihood score sample size formulations of Farrington & Manning [8] are equivalent, and both reduce to a familiar formula for comparing proportions [16].

Table 1 shows sample sizes for some trials in which the outcome is an adverse event, such as the development of disease or a reaction to a treatment or vaccination. Total sample sizes for two equal-sized groups, calculated by the likelihood score method, are given for comparisons based on a difference in proportions ($p_E - p_S$) and on a ratio of proportions (p_E/p_S) [8]. In these examples, the ratio comparison requires larger sample sizes than the difference comparison. Nevertheless, for small proportions, the ratio may be the preferred measure, since it may be more stable than the difference over a variety of settings. Table 1 also shows the sample size obtained from the inappropriate approach of testing the hypothesis of no difference; it can be either larger or smaller than the sample size obtained from the correct calculation. In addition, if the probability of disease is assumed to be higher with the experimental treatment than with the standard treatment, then the sample size required can be much greater than if the probabilities are assumed equal.

Table 1 Total sample size in two equal-sized groups for comparing proportions: $\alpha = 0.05$, $\beta = 0.10$

			Total sample size[a]		
p_E	p_S	p_{E0}^b	Difference		Ratio
0.01	0.01	0.015	14 100	(17 000)[c]	21 100
0.10	0.10	0.200	332	(434)	684
0.40	0.40	0.600	202	(212)	324
0.50	0.40	0.600	826	(212)	1 330
0.60	0.60	0.700	820	(776)	972

[a]Calculated by method of likelihood scores [8].

[b]p_{E0} refers to the value of p_E under the null hypothesis that $p_E - p_S \geq \Theta_0$ (or $p_E/p_S \geq \Theta_0$), where $\Theta_0 = p_{E0} - p_S$ (or p_{E0}/p_S).

[c]Sample size for testing hypothesis of no difference [16], where now p_{E0} is assumed to be the true value of p_E.

If the outcome of interest is an event rate or time to an event (*see* **Survival Analysis, Overview**), one may wish to show similarity via the ratio of event rates or ratio of hazards. Fleming [10] has given a sample size formula for the familiar two-sided situation of a single null value to be ruled out (*not* for a two-sided equivalence trial; see below). The sample size for a one-sided similarity trial can be obtained from Fleming's formula by substituting α for $\alpha/2$. A **Poisson distribution** assumption can be employed for analyzing the ratio of sufficiently small event rates [4].

For a two-sided equivalence trial, where we want to show that $\Theta_{01} < \Theta < \Theta_{02}$, a 100 $(1 - 2\alpha)$% confidence interval with equal tail probabilities provides a test of the hypothesis H: $\Theta \leq \Theta_{01}$ or $\Theta \geq \Theta_{02}$ with significance level $\leq \alpha$ (not 2α) [13, 23]. The power, however, will be lower than for either of the corresponding one-sided trials with the same numbers of individuals. In the symmetric situation where $\Theta_{01} = -\Theta_{02}$ and the assumed value of Θ is 0 (or, for ratios, $\Theta_{01} = 1/\Theta_{02}$ and the assumed value is 1), the sample size for type I error probability α and power $1 - \beta$ in two equal-sized groups is obtained from the formula for the corresponding one-sided problem, with the same z_α but with $z_{\beta/2}$ substituted for z_β [8]. This is a consequence of the null hypothesis, not the alternative, being two-sided; in the more familiar two-sided situation of a single-valued null hypothesis, we would substitute $\alpha/2$ for α, but keep β the same. Sample size formulations have also been given for bioequivalence studies designed as two-period **crossover** trials [1, 26].

Interim Analysis

In monitoring accumulating data from an equivalence trial (*see* **Data and Safety Monitoring**) for possible early stopping, familiar methods can be applied – for example, a confidence interval procedure, corresponding to a group sequential test, requiring an upper limit $< \Theta_0$ before considering termination [14]. Durrleman & Simon [7] have suggested a related procedure. Alternatively, if a trend develops in favor of the experimental treatment, it might be desirable to continue the trial unless the stronger result is obtained that the experimental treatment

is clearly superior to the standard; that is, unless the upper limit of the interim confidence interval is <0.

Special Considerations

Several authors have pointed out problems associated with equivalence trials and requirements for a conclusion of effectiveness of an experimental treatment on the basis of similarity to a standard treatment [15, 19, 24]. Assuming there is no placebo control in the trial, for ethical (*see* **Ethics of Randomized Trials**) or other reasons, the conclusion must rely in part on historical data. From earlier trials, it must be clear that the standard is superior to placebo. It must also be clear, from the equivalence trial itself, not only that the standard and experimental treatments are similar to each other, but also that both are more effective than placebo would have been in that trial. Thus, the equivalence trial should include similar patients and employ similar procedures to those in the trials that previously showed the standard to be effective. The trial should also be large enough to support a conclusion that both treatments are superior to placebo.

Failure to conduct an equivalence trial rigorously according to protocol may obscure important differences between the treatments and contribute to a conclusion of similarity [15, 19, 24]. Thus, the incentive to adhere strictly to the protocol (*see* **Clinical Trials Protocols**), to obtain the desired result, is not present. Appropriate monitoring of protocol adherence is, therefore, especially important in this type of trial.

Most statisticians agree that an **intention-to-treat analysis** is essential when reporting the results of a randomized clinical trial. Such an analysis includes all randomized individuals, in the groups to which they were originally assigned, regardless of the treatment actually received and their level of **compliance** with the treatment regimen. In a trial designed to show superiority, this approach provides a valid test of the null hypothesis of interest, that the experimental treatment has no benefit. That is, the probability of a type I error does not exceed the nominal value. Such may not be the case, however, in an equivalence or similarity trial. To the extent that individuals receive the wrong treatment or are otherwise noncompliant, an intention-to-treat analysis tends to make the treatments appear more similar in effect than they are. An equivalence trial can thus have a type I error probability larger than the nominal value; a conclusion of similarity may therefore require support from other appropriate analyses [17, 19].

Clearly, there are special issues, as noted above, associated with equivalence trials. Nevertheless, such trials – well designed, conducted, and analyzed – are essential in many areas of medicine for properly evaluating new treatments.

Errors in the Measurement of Covariates

Problems involving **covariate** measurement error arise frequently in health research. In retrospective epidemiological studies, for example, it may be difficult or impossible to accurately assess the level of exposure to potential **risk factors** for cancer such as radiation [20], herbicides [25], or dietary fat [22] (*see* **Case–Control Study**). In prospective studies, risk factors of interest may be difficult to observe because of physical location or cost (*see* **Cohort Study**). For example, the degree of narrowing of coronary arteries may reflect risk of heart failure, but physicians may measure the degree of narrowing in carotid arteries instead because of the less invasive nature of this method of assessment. In other settings, the risk factor may be an average value of a quantity over time and any practical way of measuring such a quantity necessarily features measurement error. This was the case in the Framingham Heart Study [15] where one of the risk factors of interest for coronary artery disease was average daily systolic blood pressure. In some settings, interest may lie in assessing associations between **categorical** exposure variables and disease status. Some exposure variables are inherently categorical (e.g. genetic classifications), but categorical covariates also arise when cutpoints are specified for continuous covariates such as systolic blood pressure (SBP) (e.g. SBP <140, $140 \leq$ SBP < 160, $160 \leq$ SBP) (*see* **Categorizing Continuous Variables**). In the latter case, measurement error in the continuous scale results in incorrect category assignments.

When mismeasured covariates are continuous, by convention the problems are said to involve covariate measurement error, whereas mismeasured categorical covariates are said to be misclassified (*see* **Misclassification Error**). In both of these settings, models based on covariates measured with error generally produce biased estimates of parameters characterizing the association between the covariates and the outcome of interest (*see* **Unbiasedness**). A textbook treatment of measurement-error problems is given by Fuller [9] for **multiple linear regression** models and by Carroll et al. [5] for **generalized linear models**.

A comprehensive review of the issues and methodologic advances pertaining to covariate and response measurement error is found in the entry **Measurement Error in Epidemiologic Studies**. Statistical methods for dealing with misclassified categorical variables are reviewed in the entry **Misclassification Error**. In this article, we provide a brief survey of strategies for dealing with mismeasured or misclassified covariates in the context of regression models. An illustrative application is presented using data from a case–control study [3], and the impact of misspecifying the nature of the misclassification distribution is discussed.

Survey of Methods

Let Y be a response variable, $\boldsymbol{Z}$ the vector of covariates free of error, $\boldsymbol{X}$ be the covariates subject to measurement error, and $\boldsymbol{W}$ be the result of attempting to observe $\boldsymbol{X}$ in the presence of measurement error (i.e. $\boldsymbol{W}$ is the mismeasured version of $\boldsymbol{X}$). Suppose that the distribution of Y is dependent on $(\boldsymbol{X}, \boldsymbol{Z})$ through a model denoted by $h(Y, \boldsymbol{X}, \boldsymbol{Z}; \boldsymbol{\beta}_x, \boldsymbol{\beta}_z)$, where the dependence of Y on $\boldsymbol{X}$ and $\boldsymbol{Z}$ is reflected by a linear predictor $\boldsymbol{X}'\boldsymbol{\beta}_x + \boldsymbol{Z}'\boldsymbol{\beta}_z$ and additional **nuisance parameters** are suppressed for convenience. Primary interest lies in the estimation of the vector of regression coefficients $\boldsymbol{\beta} = (\boldsymbol{\beta}_x', \boldsymbol{\beta}_z')'$. Naive use of $\boldsymbol{W}$ in place of $\boldsymbol{X}$ could introduce a considerable bias in the estimation of $\boldsymbol{\beta}_x$, and in many cases $\boldsymbol{\beta}_z$. Mechanisms inducing measurement error can lead to differential or nondifferential measurement error. If the distribution of Y given $(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{W})$ depends only on $(\boldsymbol{X}, \boldsymbol{Z})$, then the measurement-error process is called *nondifferential*, but otherwise it is called *differential*. Nondifferential measurement error can be equivalently stated such that the **conditional** distribution of $\boldsymbol{W}$ given $(\boldsymbol{X}, \boldsymbol{Z}, Y)$ depends only on $(\boldsymbol{X}, \boldsymbol{Z})$. In this case, it is clear that the term "nondifferential" means that the error distribution is not different for those with different values of Y.

Corrections for measurement error typically rely on there being some data available with which to estimate parameters of the error distribution. This may be, for example, a data set of replicated measurements $\boldsymbol{W}$ for a particular value of $\boldsymbol{X}$ to facilitate estimation of **variance components** of the error distribution in the case of continuous covariates. In other contexts, a validation data set may be available with which to estimate misclassification rates

for categorical covariates. Further remarks on the different types of supplementary data including replication, **validation**, and instrumental data are found in **Measurement Error in Epidemiologic Studies**.

Approximate Methods of Correction

A variety of approaches have been proposed to correct for the bias induced by measurement error (e.g. [1, 30, 31, 41]). Two widely used approaches are *regression* **calibration** and **simulation** *extrapolation* [5]. Except for some special models such as linear and loglinear regression models, these approaches only yield approximately **consistent** estimators; the appeal of these approaches lies in their simplicity and ease of implementation.

If $\mu_{xz} = E(Y|\boldsymbol{X}, \boldsymbol{Z})$, then given a link function $g(.)$, a regression model may be formed by specifying

$$g(\mu_{xz}) = \boldsymbol{X}'\boldsymbol{\beta}_{\boldsymbol{x}} + \boldsymbol{Z}'\boldsymbol{\beta}_{\boldsymbol{z}}. \tag{1}$$

It is not possible to estimate $\boldsymbol{\beta}$ from this model using standard methods since $\boldsymbol{X}$ is not available. Given a validation data set, however, an approximate version of the model may be obtained by replacing $\boldsymbol{X}$ with an estimate of its conditional expectation given $\boldsymbol{W}$ and $\boldsymbol{Z}$, which we denote by $m(\boldsymbol{W}, \boldsymbol{Z}; \boldsymbol{\theta})$. That is, if $\hat{\boldsymbol{\theta}}$ denotes an estimate of $\boldsymbol{\theta}$ and $\hat{m}(\boldsymbol{W}, \boldsymbol{Z}; \hat{\boldsymbol{\theta}})$ denotes the estimate of the conditional expectation, the mean specification

$$g(\mu_{xz}) \approx \hat{m}(\mathbf{W}, \boldsymbol{Z}; \hat{\boldsymbol{\theta}})'\boldsymbol{\beta}_x + \boldsymbol{Z}'\boldsymbol{\beta}_z \tag{2}$$

may be used to estimate $\boldsymbol{\beta}$. If only replication data are available, alternative estimates of $\boldsymbol{X}$ may be used in place of $\boldsymbol{X}$, such as the mean value over all replications. **Instrumental** data provide an alternative approach for inserting an estimate of $\boldsymbol{X}$ based on suitable regression models.

The approach of regression calibration was first suggested by Prentice [21] for the **proportional hazard** models in **survival analysis**. A general form of regression calibration was suggested by Carroll & Stefanski [7] and Gleser [10]. Further developments for generalized linear models were discussed in [2, 23], and [24]. More recently, Wang et al. [38] studied this approach in the context of the **Cox model** with **missing** or mismeasured covariate data, where the missing data are estimated on the basis of a validation data set. The method performs surprisingly well given its simplicity, though the estimates of regression parameters may not be consistent in general.

Simulation extrapolation is an attractive simple approach for reducing bias due to measurement error. Estimates based on simulation extrapolation are obtained by adding additional measurement error to the data in a resampling-like step, establishing a trend of measurement error-induced bias as a function of the variance of the added measurement error, and extrapolating back to the case of no measurement error. This approach, proposed by Cook & Stefanski [8], is well suited to additive or multiplicative measurement errors and leads to improved estimates subject to correct model specification [5]. Refinements have been developed in [4] and [34], where the theoretical justification to this approach and the asymptotic distribution of the simulation extrapolation estimates have been investigated.

Methods Based on Estimating Equations

Unbiased estimating equations (*see* **Generalized Estimating Equations**) provide consistent estimates for parameters of interest and it is natural to consider ways to construct unbiased **estimating functions** for problems involving measurement error. The various forms of estimating functions may be formulated under the assumptions of either a so-called functional error model for which the covariates $\boldsymbol{X}$ are treated as fixed constants, or a structural error model for which $\boldsymbol{X}$ are treated as random variables arising from a particular distribution. Two widely used approaches are based on conditional and corrected score functions.

Suppose that given $(\boldsymbol{X}, \boldsymbol{Z})$, Y arises from a distribution in the **exponential family** and (1) holds. When the surrogate $\boldsymbol{W}$ is assumed to have a **normal distribution** with, for example, $\boldsymbol{W} \sim N(\boldsymbol{X}, \Sigma)$, a generalized linear measurement-error model may be formulated by combining these two distributions. Stefanski & Carroll [32] specifically discussed the conditional score method in this context, where the estimating functions are obtained by conditioning on sufficient statistics for some important models such as linear, **logistic**, loglinear, and the inverse-gamma.

Nakamura [17] proposed the use of corrected score functions, illustrating this method with applications to a number of practical models (e.g. Gaussian and **Poisson**), when the measurement error is additive with a distribution. A corrected score function is a

function of the observed data $(\boldsymbol{W}, \boldsymbol{Z}; Y)$ such that its expectation with respect to the conditional distribution of $\boldsymbol{W}|\boldsymbol{X}$ is equal to the score function based on the distribution of $(\boldsymbol{X}, \boldsymbol{Z}; Y)$. More specifically, if $S(\boldsymbol{\beta}; \boldsymbol{X}, \boldsymbol{Z}, Y)$ is the score function from the true model of Y and $(\boldsymbol{X}, \boldsymbol{Z})$, any function $S^*(\boldsymbol{\beta}; \boldsymbol{W}, \boldsymbol{Z}, Y)$ is called *a corrected score function* if

$$\mathrm{E}_{\boldsymbol{W}|\boldsymbol{X}}(S^*(\boldsymbol{\beta}; \boldsymbol{W}, \boldsymbol{Z}, Y)) = S(\boldsymbol{\beta}; \boldsymbol{X}, \boldsymbol{Z}, Y). \quad (3)$$

Estimation of $\boldsymbol{\beta}$ may proceed on the basis of the equation

$$S^*(\boldsymbol{\beta}; \boldsymbol{W}, \boldsymbol{Z}, Y) = 0. \quad (4)$$

The corrected score function approach is a functional method in the sense of [5] and therefore does not require specification of a distribution for $\boldsymbol{X}$. One drawback of this approach, however, is that the corrected score function does not always exist and it is not generally easy to obtain when it does exist. Novick & Stefanski [18] discussed using **Monte Carlo** simulation to obtain corrected score functions for many problems, and this approach is related to the approach of simulation extrapolation.

Likelihood and Pseudo-likelihood Methods

The methods described thus far are often applied to problems with continuous covariates subject to error where few distributional assumptions are required. **Likelihood** based analyses provide an alternative approach for many quite general problems including those with misclassified covariates. Let $P_{Y|\boldsymbol{X},\boldsymbol{Z}}(y|\boldsymbol{x}, z; \boldsymbol{\beta})$ be the model of interest where the error-prone true covariate $\boldsymbol{X}$ is unobserved for some subjects and $\boldsymbol{\beta}$ is the parameter of primary interest. Then $P_{Y,\boldsymbol{W}|\boldsymbol{Z}}(y, \boldsymbol{w}|z; \boldsymbol{\beta}, \boldsymbol{\delta}, \boldsymbol{\lambda})$ is the model for the observed data. With the nondifferential measurement error, we may construct the likelihood from the following factorization

$$P_{Y,\boldsymbol{W}|\boldsymbol{Z}}(y, \boldsymbol{w}|z; \boldsymbol{\beta}, \boldsymbol{\delta}, \boldsymbol{\lambda}) = \int P_{Y|\boldsymbol{X},\boldsymbol{Z}}(y|\boldsymbol{x}, z; \boldsymbol{\beta}) \times P_{\boldsymbol{W}|\boldsymbol{X},\boldsymbol{Z}}(\boldsymbol{w}|\boldsymbol{x}, z; \boldsymbol{\delta}) P_{\boldsymbol{X}|\boldsymbol{Z}}(\boldsymbol{x}|z; \boldsymbol{\lambda})\, \mathrm{d}\mu(\boldsymbol{x}), \quad (5)$$

where $\mathrm{d}\mu(\boldsymbol{x})$ indicates that the integrals are sums if $\boldsymbol{X}$ is discrete and integrals if $\boldsymbol{X}$ is continuous, and $P_{\boldsymbol{W}|\boldsymbol{X},\boldsymbol{Z}}(\boldsymbol{w}|\boldsymbol{x}, z; \boldsymbol{\delta})$ and $P_{\boldsymbol{X}|\boldsymbol{Z}}(\boldsymbol{x}|z; \boldsymbol{\lambda})$ represent the conditional distributions of $\boldsymbol{W}$ given $\boldsymbol{X}$ and $\boldsymbol{Z}$ and of $\boldsymbol{X}$ given $\boldsymbol{Z}$, respectively.

Likelihood approaches to measurement error have received comparatively less attention in the literature, perhaps due to its computationally demanding nature and a possible lack of **robustness** [29]. However, likelihood methods may be more flexible, efficient, or reliable for dealing with some problems involving measurement error [29]. For example, **likelihood ratio** inferences can be considerably better than those based on **bootstrap** or normal approximations (e.g. [5, 29]). Stefanski & Carroll [33] compared estimates obtained from the conditional score function approach and **maximum likelihood** for logistic regression models and found that the latter is more efficient when the measurement error is "large" or the logistic coefficient is "large". Schafer & Purdy [29] studied likelihood analysis of normal linear regression models with mismeasured covariates using the **EM algorithm**.

When a direct likelihood approach is computationally demanding, one may use an approximate but simpler version to replace the likelihood function and proceed with the so-called **pseudo-likelihood** approach [3]. Hanfelt & Liang [11] proposed an approximate approach for generalized linear models with measurement error in covariates. Other work that explores this approach for measurement error, includes [6, 12, 26, 27, 28, 37, 40].

Semiparametric and Nonparametric Methods

One may classify approaches for measurement error problems as being parametric, **semiparametric**, or **nonparametric** by considering the assumptions regarding the distribution of the measurement error. Unlike the approaches described above, one may not need to assume a parametric family for the error distribution, but rather can make simple conditional moment assumptions. Pepe & Fleming [19] used the empirical estimation of the likelihood to deal with the mismeasured covariate problem with validation data when measurement error is described nonparametrically. Stefanski et al. [35] proposed a semiparametric correction for bias caused by measurement error. Jiang et al. [14] discussed semiparametric regression models with random effects and measurement errors. The error distribution is not fully specified except for assumptions on the moment **generating function** of the error. Kulich & Lin [16] developed a class of estimating functions for the regression parameters for the

additive hazards models with covariates subject to measurement error. Tsiatis & Davidian [36] developed a semiparametric method for estimation in the context of the proportional hazards model with **time-dependent covariates** measured with error. Huang & Wang [13] avoid distributional assumption and proposed a nonparametric approach to deal with the Cox model when repeated measurements on the covariates are available.

An Application Involving Misclassification

Misclassified Exposure Variables in Case–Control Studies

We now consider an illustrative example based on a case–control study examining the association between invasive cervical cancer and exposure to herpes simplex virus type 2 (HSV-2) [3]. Exposure to HSV-2 was assessed both by a refined western blot procedure and by a less accurate western blot procedure for cases ($Y = 1$) and controls ($Y = 0$). Primary interest is in evaluating the relationship between Y and the result of the refined western blot test (X), but this test result is only directly observed for less than 6% of the subjects. Data based on the less accurate standard western blot test (W) are available for all subjects. Data reported in [3] are reproduced in Table 1.

If there are n subjects under study, let $Y_i = 1$ if subject i is a case and $Y_i = 0$ otherwise, $i = 1, 2, \ldots, n$. Let X_i and W_i be the result of the refined and standard western blot tests respectively for subject i, and let $V_i = I(X_i \text{ is observed}), i = 1, 2, \ldots, n$. Then $\mathcal{V} = \{i : V_i = 1\}$ is the index set for subjects in the validation sample and $\overline{\mathcal{V}} = \{i : V_i = 0\}$ is the index set of subjects in the nonvalidation sample. The triple $\{Y_i, X_i, W_i\}$ is therefore available if $i \in \mathcal{V}$ but only $\{Y_i, W_i\}$ is observed if $i \in \overline{\mathcal{V}}$. Let $n_{vy} = \sum_{i=1}^{n} I(V_i = v, Y_i = y)$ and $n_v = \sum_{i=1}^{n} I(V_i = v)$, so, for example, n_{11} is the number of cases and n_1 is the total number of subjects in the validation data set.

Table 1 Validation and nonvalidation data from cervical cancer case–control study reported in [4]

	Y	X	W	Frequency
Validation data	1	0	0	13
	1	0	1	3
	1	1	0	5
	1	1	1	18
	0	0	0	33
	0	0	1	11
	0	1	0	16
	0	1	1	16
Nonvalidation data	1		0	318
	1		1	375
	0		0	701
	0		1	535

Consider a prospective logistic model

$$P(Y_i = 1|X_i = x, V_i = v) = \frac{\exp(\beta_0^{(v)} + \beta_1 x)}{1 + \exp(\beta_0^{(v)} + \beta_1 x)}, \tag{6}$$

where $\beta_0^{(0)}$ and $\beta_0^{(1)}$ are the intercepts corresponding to the nonvalidation and validation data sets respectively, and β_1 characterizes the increase in risk of cervical cancer with exposure to HSV-2 according to the refined western blot test. Let $\beta = (\beta_0^{(0)}, \beta_0^{(1)}, \beta_1)'$. Note that

$$\beta_0^{(1)} = \beta_0^{(0)} + \log\left(\frac{P(V_i = 1|Y_i = 1)/P(V_i = 0|Y_i = 1)}{P(V_i = 1|Y_i = 0)/P(V_i = 0|Y_i = 0)}\right), \tag{7}$$

and if $\pi_v = P(Y_i = 1|V_i = v)$ then the second term on the right-hand side can be reexpressed as $\log(\pi_1(1 - \pi_0))/(\pi_0(1 - \pi_1))$ and since $\hat{\pi}_v = n_{v1}/n_v$, it is estimated by $\log(n_{11}n_{00}/n_{10}n_{01})$.

The objective here is to estimate β_1 based on the full data set, taking into account the fact that W is a misclassified assessment of X. Inferences on β_1 may be carried out by considering the likelihood

$$\begin{aligned} L = \prod_{i \in \mathcal{V}} & [P(X_i = x_i|Y_i = y_i, V_i = 1) \\ & \cdot P(W_i = w_i|X_i = x_i, Y_i = y_i, V_i = 1)] \\ & \cdot \prod_{i \in \overline{\mathcal{V}}} \left[\sum_{x_i} P(X_i = x_i|Y_i = y_i, V_i = 0) \right. \\ & \left. \cdot P(W_i = w_i|X_i = x_i, Y_i = y_i, V_i = 0) \right], \end{aligned} \tag{8}$$

where we note that

$$P(X_i = 1|Y_i = y, V_i = v) = \frac{P(Y_i = y|X_i = 1, V_i = v) \cdot P(X_i = 1|V_i = v)}{\pi_v}.$$

The conditional probabilities $\delta_{xy} = P(W_i = 1|X_i = x, Y_i = y, V_i = v)$ characterize the misclassification distribution and we let $\delta = (\delta_{00}, \delta_{01}, \delta_{10}, \delta_{11})'$. The assumption of nondifferential misclassification is imposed when we constrain $\delta_{xy} = \delta_x$, $x, y = 0, 1$.

The likelihood in (8) is a function of $\theta = (\beta', \delta', \lambda')'$, where λ is a vector of additional nuisance parameters required to evaluate $P(X_i = x|V_i = v)$ and $\pi_v = P(Y_i = y|V_i = v)$. We may replace π_v by the empirical estimate n_{v1}/n_v, $v = 0, 1$, and λ may simply comprise the parameters $\lambda_1 = P(X_i = 1|V_i = 1)$ and $\lambda_2 = P(X_i = 1|V_i = 0)$.

Table 2 summarizes parameter estimates and standard errors obtained from likelihood analyses of the validation data alone and the full data set [3]. For both data sets, the likelihood in (8) is constructed under the assumption of differential and nondifferential misclassification. The estimate of the **odds ratio** characterizing the increase in risk of cervical cancer with exposure to HSV-2 based on the full data set is 1.84 (95% CI (0.93, 3.65)) under the assumption of differential misclassification and 2.61 (95% CI (1.64, 4.15)) under the assumption of nondifferential misclassification. These estimates can be contrasted with the findings from a naive analysis of the full data set in which W_i is used in place of X_i, where we obtain an odds ratio estimate of 1.57 (95% CI (1.31, 1.89)). Analyses based on the validation data alone give unbiased estimators of β_1, but with somewhat lower precision.

Misspecification of the Misclassification Distribution

Differential misclassification is a concern in case–control studies since disease status is known at the start of the study and cases and controls can therefore be treated differently. If the true error distribution features differential misclassification, but one assumes $\delta_{xy} = \delta_x$, then the estimator maximizing (8) will not be consistent for β. Some authors have empirically investigated the impact of assuming nondifferential misclassification when it is in fact differential (e.g. [3]) and a detailed study can be carried out using the theory of **misspecified** models [39].

Let $S(\theta)$ be the estimating function obtained from the assumed likelihood (8), and let $\hat{\theta}$ be the solution to $S(\theta) = 0$. If (8) is constructed assuming nondifferential misclassification, the asymptotic bias in $\hat{\beta}_1$ under differential misclassification can be evaluated as follows. Let $E_T(\cdot)$ denote the expectation operator with respect to the true joint distribution involving differential misclassification, given by

$$\prod_{i \in \mathcal{V}} P(W_i = w_i, X_i = x_i|Y_i = y_i, V_i = 1) \cdot \prod_{i \in \overline{\mathcal{V}}} P(W_i = w_i|Y_i = y_i, V_i = 0). \quad (9)$$

This joint distribution may be reexpressed as

$$\prod_{i \in \mathcal{V}} [P(X_i = x_i|Y_i = y_i, V_i = 1) \cdot P(W_i = w_i|X_i = x_i, Y_i = y_i, V_i = 1)] \cdot \prod_{i \in \overline{\mathcal{V}}} \Big[\sum x_i P(X_i = x_i|Y_i = y_i, V_i = 0) \cdot P(W_i = w_i|X_i = x_i, Y_i = y_i, V_i = 0) \Big]. \quad (10)$$

Let $E_T(S(\theta))$ denote the expectation of the estimating function and let θ^* denote the value of θ solving $E_T(S(\theta)) = 0$. Then θ^* represents the value to which the naive estimators of θ converge, so $\beta_1^* - \beta_1$ represents the asymptotic bias in the estimator of β_1 when nondifferential misclassification is incorrectly assumed.

To illustrate, consider the same model adopted in the preceding example and take the design features and true parameter values to be roughly comparable to those reported. Specifically, we set $\beta_0^{(0)} = -1$, $\beta_1 = \log(2)$, $n_{00} = 1600$, $n_{01} = 800$, $n_{10} = 200$, and $n_{11} = 100$. We let $\delta_{00} = 0.3$, $\delta_{10} = 0.6$, and let $\psi_v = \delta_{v1}(1 - \delta_{v0})/(\delta_{v0}(1 - \delta_{v1}))$, $v = 0, 1$. If $\psi_0 = \psi_1 = 1$, then the misclassification is nondifferential, but not otherwise. Figures 1 and 2 illustrate how the asymptotic percent relative bias in β_1 varies as a function of $(\psi_0, \psi_1)'$, where attention is restricted to

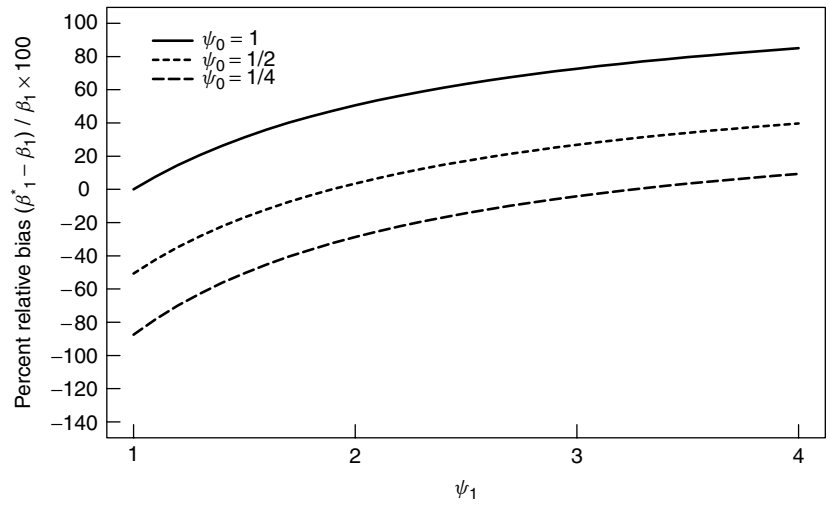

Figure 1 Asymptotic percent relative bias in regression coefficient $(\beta_1^* - \beta_1)/\beta_1 \times 100$ as a function of ψ_0 for specified values of ψ_1

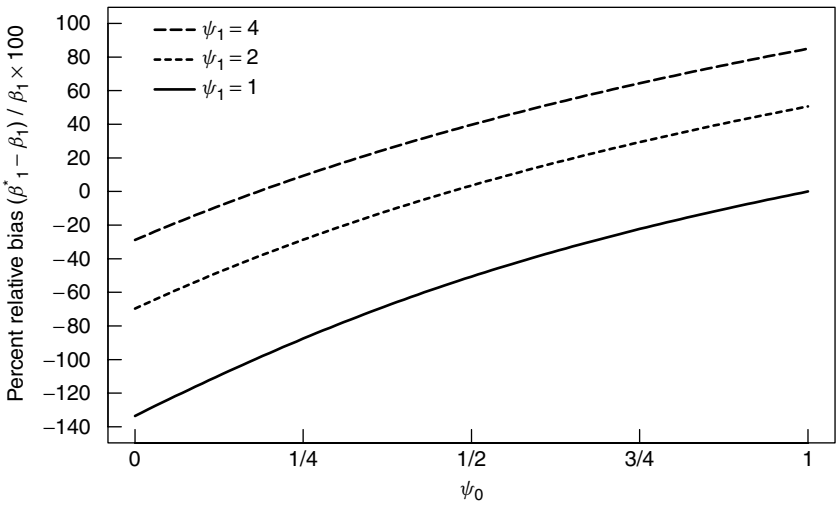

Figure 2 Asymptotic percent relative bias in regression coefficient $(\beta_1^* - \beta_1)/\beta_1 \times 100$ as a function of ψ_1 for specified values of ψ_0

values of ψ_v, $v = 0, 1$ such that the respective misclassification rates are no larger than those implied by δ_{00} and δ_{10}. Note that the resulting bias may be positive or negative in sign, reflecting the fact that bias away from the null value may arise under nondifferential misclassification. Moreover, seemingly small degrees of differential misclassification can lead to appreciable bias.

Errors in Variables

Errors in variables may occur for a variety of reasons; for example, because of limitations of a measuring instrument (e.g. weight) or because of random fluctuations in a physiologic process (e.g. blood pressure). Consider a simple **linear regression** model in which a dependent variable Y is related to an **explanatory variable** X according to $Y = \alpha + \beta X + \varepsilon$, where $\varepsilon \sim \mathrm{N}(0, \sigma^2)$. Observation errors in Y are usually taken to be part of the error specification in the model, while the explanatory variable or covariate, X, is usually assumed to be fixed. Concern is therefore primarily with errors in the measurement of X. Here, we shall refer to the value of the explanatory variable, if it could be measured without error, as the "true covariate" and to the actual value of the variable as the "observed covariate".

If the estimated regression parameters are to be used only for prediction and if the true value of the explanatory variable will never be available, then the usual regression model is appropriate [7, 8]. However, errors in variables can be a problem when the primary interest is in the estimation of the relationship between the dependent variable and the true covariate values.

In uncontrolled experiments, in which the independent variable is allowed to vary freely, the observed covariate is usually assumed to be measured as the true covariate plus an error term. Such errors in measurement cause the estimate of the slope parameter to be biased [3, 7]. The estimate of the slope obtained from the observed covariate, β^*, is related to the slope appropriate for the true covariate, β, according to $\beta^* = \beta\sigma_x^2/(\sigma_x^2 + \sigma_\varepsilon^2)$, where σ_x^2 is the variance of the true covariate in the population and σ_ε^2 is the variance of the errors. In controlled experiments in which the dependent variable is measured at prespecified levels of the explanatory variable, the estimated coefficients are found to be unbiased. This is true because on average, over repeated experiments, the value of the explanatory variable is correct in controlled experiments. The controlled experiment, in which the true covariate is randomly distributed about the observed covariate, has become known as the "Berkson model" in the literature [3].

Generalized Linear Models

A number of strategies for revising estimates of coefficients of mismeasured covariates in a **generalized linear model** have been suggested. Armstrong [1] describes the use of an iteratively reweighted least squares algorithm (*see* **Generalized Linear Model**) to find maximum **quasi-likelihood** estimates, Stefanski [15] describes methods for reducing bias in M-estimates (*see* **Robustness**), and Schafer [14] suggests using the **EM algorithm** and treating the mismeasured covariates as missing variables. Methods of correcting the score function (*see* **Likelihood**) and estimating its efficiency have also been suggested for use when covariates are measured with errors in generalized linear models [9, 17]. It has been found that errors in **confounding** covariates included in the model may lead to incorrect conclusions when testing for treatment effects in unbalanced nonrandomized studies [5] (*see* **Measurement Error in Epidemiologic Studies**). The severity of this problem depends on the size of the error, the degree to which the study is unbalanced, and the strength of the relationship between the confounder and the dependent variable. When confounders are measured with error in randomized studies, treatment effects are underestimated [5]. Pepe & Fleming [10] discuss the use of **nonparametric methods** to estimate coefficients of covariates measured with error when both the true and the observed data are available for a subsample of the population.

Regression Models for Binary Data

Error in the measurement of the explanatory variable in **logistic regression** causes estimates of the **odds ratio** to be biased toward one in most situations [13, 15, 16]. When the majority of the cases have very high or very low risk, however, the odds ratios may be biased away from one [15]. If more than one variable is included in the model, and one or more of these is measured with error, any of the effects may be under- or overestimated, even for variables measured without error [13]. Estimates of regression coefficients from probit models (*see* **Quantal Response Models**), for covariates measured with error according to the Berkson model, have also been shown to be biased [4]. The use of validation information to correct estimates of relative risk has been suggested for probit regression with binary or ordinal

outcomes [18] and for logistic regression when more than one covariate is measured with error [13]. Methods of improving estimates of relative risks have been suggested for situations in which the errors in the covariates are assumed to be normally distributed [6, 15]. Errors in covariates have also been shown to bias the asymptotic levels of test statistics related to treatment in nonrandomized studies when the covariates are unbalanced between treatment groups [15].

Regression Models for Survival Data

Error in the measurement of controlled covariates has been shown to bias regression coefficient estimates in the Cox **relative risk** regression model [12] (*see* **Cox Regression Model**; **Measurement Error in Survival Analysis**). In this model, explanatory variables may depend on time. When the true covariate, $Z(t)$, can be assumed to be normally distributed about the observed covariate, $X(t)$, with variance $h[X(t)]\sigma^2$, the estimated relative risk is $\mathrm{E}\{\exp[\beta Z(t)]\} = \exp\{\beta X(t) + \beta^2 h[X(t)]\sigma^2/2\}$. Error in the measurement of uncontrolled covariates also causes estimates of the relative risk from this model to be biased [11]. The coefficient of the observed covariate, β^*, is related to the coefficient of the true covariate, β, according to $\beta^* = \beta i(\beta)/(i(\beta) + \sigma^2)$, where $i(\beta)$ is the second derivative of the log likelihood and σ^2 is the variance of the errors. The amount of bias in the coefficient of the variable measured with error has been shown to be increased by the presence of a confounder, even when the confounder is measured without error [2]. When only the confounder is measured with error, then one may not fully adjust for it and the coefficient of the covariate of interest will still be biased due to confounding. If both the confounder and the covariate of interest are measured with error, and if the errors in these covariates are correlated, the relative risk may be biased toward or away from one.

J.M. RABOUD

Establishment Surveys With Population Survey–Generated Sampling Frames

Introduction

Though virtually all establishment surveys use stand-alone establishment **sampling frames**, defined as frames that list all establishments in the universe, the stand-alone frame is not a requirement for unbiased **estimation**. When stand-alone frames contain establishment size measures, the Hansen–Hurwitz (HH) pps estimator is typically used to estimate the volume of transactions between establishments and households (*see* **Sampling With Probability Proportional to Size**). This article features a **network sampling** (NS) version of the HH estimator. Because the NS estimator does not use a stand-alone frame, it is a potential competitor of the HH estimator, particularly when stand-alone frames with good quality establishment coverage and size measures are unavailable or are relatively expensive to construct and maintain. The NS estimator uses a population-survey-generated establishment sampling frame – a sample sampling frame that lists the households enumerated in a population **sample survey**, the establishments with whom the survey households have transactions, and the number of transactions each establishment has with survey households. The population-survey-generated frame is constructed with information that is collected from household respondents in the population sample survey.

The survey design of the Consumer Price Index (CPI) is a rare and notable example of an establishment survey design that uses population-survey-generated sampling frames [1]. CPI pricing surveys use population-survey-generated sampling frames that contain the business establishments, which sell commodities to households in the CPI continuing point of purchase surveys, a population sample survey.

This article features a two-stage unbiased NS estimator of X, the sum of the x-variate over transactions between establishments and populations residing in households. The NS estimator and its first- and second-stage **variance components** are presented in the section "NS Estimation". Clusters of establishments with whom survey households have transactions are the first-stage sampling units, and the transactions that those establishments have with all households are the second-stage selection units. The effect of alternative second-stage sampling procedures on the stage 2 **variance** of the NS estimator is also presented in the section "NS Estimation". The well-known two-stage pps HH estimator and variance are presented in the section "HH Estimation" (*see* **Multistage Sampling**). The section "Relative Precision of the HH and NS Estimators" compares the precision of the two estimators in single- and two-stage sample designs under conditions yielding roughly the same expected sample sizes in both types of establishment surveys. Recent research on population-survey-generated sampling frames is cited in the section "Research on Population-survey-generated Frames", and some potential benefits and outstanding challenges of research on population-survey-generating frames are summarized in the final section.

Research on Population-survey-generated Frames

Research on designing establishment sample surveys using population-survey-generated sampling frames has a relatively short history and is in an early developmental stage. The research was motivated by a recommendation of a Panel of the Committee on National Statistics [11] convened by the **National Center for Health Statistics** (NCHS) to review its plans to restructure the national health care provider surveys [3]. The Panel proposed using listings of health care providers servicing households enumerated in the National Health Interview Survey (NHIS) as the sampling frames of health care provider surveys. (The NHIS [2] is a continuing survey of the civilian noninstitutional population.) In view of the difficulties of constructing and maintaining good quality stand-alone frames, especially during periods of rapid institutional structural changes like the ones now occurring in the nation's health care delivery system, the Panel proposed that NHIS-generated establishment frames might provide better quality frames at lower frame construction and maintenance costs.

NCHS [4] presents rough comparisons of the precision of estimates of the volume of dental services between two-stage sample surveys using a stand-alone sampling frame of dentists and an NHIS-generated sample frame of dentists. Difficulties initially encountered in obtaining closed formulas of the variances of establishment survey estimates using population-survey-generated sampling frames were overcome by developing two-stage network sampling estimators [6, 10]). Sirken, Shimizu, and Judkins [9] and Shimizu and Sirken [5] determined the Hansen–Hurwitz versions of the NS estimator and variance presented in the section "NS Estimation". Sirken [7] determined the differences in the sampling efficiencies of the two estimators presented in the section "Relative Precision of the HH and NS Estimators". Sirken and Shimizu [8] determined the Horvitz–Thompson version of the two-stage NS estimator, but it is not included in this article.

Notation

A universe of R establishments has M transactions with a population of N households.

Let M_{ij} denote the number of transactions which household i $(i = 1, 2, \ldots, N)$ has with establishment j $(j = 1, 2, \ldots, R)$, where $M_{ij} \geq 0$. Then

$M_j = \sum_{i=1}^{N} M_{ij}$ = the number of transactions of establishment j with N households and

$M = \sum_{j=1}^{R} M_j$ = the total number of transactions between R establishments and N households.

$\overline{M} = M/N$ = the average number of transactions per household.

Let X_{jk} denote the value of the x-variate for transaction k $(k = 1, 2, \ldots, M_j)$ of establishment j $(j = 1, 2, \ldots, R)$. Then,

$X_j = \sum_{k=1}^{M_j} X_{jk}$ = the sum of the x-variate over the M_j transactions of establishment j,

$X = \sum_{j=1}^{R} X_j$ = the sum of the x-variate over the transactions of R establishments, and

$\overline{X}_j = X_j/M_j$ = the average value of the x-variate over the M_j transactions of establishment j.

NS Estimation

From the perspective of network sampling, a two-stage establishment survey using a population-survey-generated frame is viewed as a two-stage population sample survey in which clusters of establishments having transactions with households $(i = 1, 2, \ldots, N)$ are first-stage selection units, and the M_j transactions of establishment j $(j = 1, 2, \ldots, R)$ that has transactions with household i, $M_{ij} > 0$, are second-stage selection units.

This article assumes that a sample of n households is selected by **simple random sample** (srs) with probabilities $\pi_i = \pi = n/N$ $(i = 1, 2, \ldots, n)$ and with replacement (*see* **Sampling With and Without Replacement**). (However, the NS estimator can be applied to more complex population survey designs than are considered in this article.) Respondents at the N households identify establishments with whom they have transactions and report the number, M_{ij} $(i = 1, 2, \ldots, n)$ $(j = 1, \ldots, R)$, of their transactions with each establishment. (The population-survey-generated frame is constructed with the information provided by household respondents). In the survey conducted with the r_{NS} establishments reported by the N sample households, establishment j $(j = 1, 2, \ldots, r_{\mathrm{NS}})$ reports the values of the x-variate for a sample of $m_j = c_{\mathrm{NS}} \sum_i^n M_{ij}$ from its M_j transactions, where c_{NS} is a positive integer. Two sampling procedures for selecting m_j of the M_j transactions from establishment j $(j = 1, 2, \ldots, r_{\mathrm{NS}})$ are presented and compared:

Procedure (α): Samples of $m_{ij} = c_{\mathrm{NS}} M_{ij}$ transactions are independently drawn from the M_j transactions of establishment j by srs without replacement for each household i $(i = 1, \ldots, n)$ that has transactions with establishment j;

Procedure (β): A single sample of $m_j = c_{\mathrm{NS}} \sum_i^n M_{ij}$ transactions is drawn from the M_j transactions of establishment j by srs without replacement.

The **unbiased** NS estimator of X using stage 2 sampling procedure α is

$$X'_{\mathrm{NS}} = \frac{N}{n} \sum_{i=1}^{n} \sum_{j=1}^{R} M_{ij} \overline{X}'_j(i), \qquad (1)$$

where

$$\overline{X}'_j(i) = \frac{1}{c_{\mathrm{NS}} M_{ij}} \sum_{k=1}^{c_{\mathrm{NS}} M_{ij}} X_{jk} \tag{2}$$

is an unbiased estimate of $\overline{X}_j$ based on the sample of $c_{\mathrm{NS}} M_{ij}$ transactions of establishment j selected for household i. Because households are selected with replacement, the NS estimator counts the quantity $\sum_j^R M_{ij} \overline{X}'_j(i)$ every time the same household i ($i = 1, 2, \ldots, n$) is selected in the sample. Because the same establishment has transactions with multiple households, the NS estimator also counts $M_{ij} \overline{X}'_j(i)$ every time establishment j has transactions with a different sample household.

The variance of X'_{NS} is

$$\mathrm{Var}(X'_{\mathrm{NS}}) = \frac{N^2}{n} \sigma^2_{\mathrm{NS1}} + \frac{N}{n c_{\mathrm{NS}}} \sum_{i=1}^{N} \sum_{j=1}^{R} M_{ij} \times \left(1 - \frac{c_{\mathrm{NS}} M_{ij}}{M_j}\right) \sigma_j^2, \tag{3}$$

where the first and second terms respectively on the right side of (3) are the first- and second-stage variance components, and

$$\sigma^2_{\mathrm{NS1}} = \frac{1}{N} \sum_{i=1}^{N} \left(\sum_{j=1}^{R} M_{ij} \overline{X}_j - \frac{X}{N} \right)^2 \tag{4}$$

is the between-household population variance and

$$\sigma_j^2 = \frac{1}{M_j} \sum_{k=1}^{M_j} (X_{jk} - \overline{X}_j)^2 \tag{5}$$

is the within-establishment population variance for establishment j ($j = 1, 2, \ldots, R$).

An unbiased estimate of the variance of the NS estimator in (3) is

$$\hat{\sigma}^2_{\mathrm{NS}} = \frac{N^2}{n(n-1)} \sum_{i=1}^{n} \left(\sum_{j=1}^{R} M_{ij} \overline{X}'_j(i) - \frac{X'}{N} \right)^2 + \frac{N}{n c_{\mathrm{NS}}} \sum_{i=1}^{n} \sum_{j=1}^{R} M_{ij} \left(1 - \frac{c_{\mathrm{NS}} M_{ij}}{M'_j}\right) \hat{\sigma}_j^2, \tag{6}$$

where

$$\hat{\sigma}_j^2 = \frac{1}{m_j - 1} \sum_{k=1}^{m_j} (X_{jk} - \overline{X}'_j)^2 \tag{7}$$

is an unbiased estimate of σ_j^2 and

$$\overline{X}'_j = \frac{1}{m_j} \sum_{k=1}^{m_j} X_{jk} \tag{8}$$

is the unbiased estimate of the transaction mean $\overline{X}_j$ for establishment j.

The second term on the right side of (3) represents the stage 2 variance using sampling procedure α. The stage 2 variance using sampling procedure β is

$$\left(\frac{N}{n}\right)^2 \mathrm{E} \left[\sum_{i-1}^{n} \sum_{j=1}^{R} M_{ij}^2 \left(\frac{1}{m_j} - \frac{1}{M_j} \right) \sigma_j^2 \right]. \tag{9}$$

Using the inequality $\sum_i M_{ij}^2 \le \left(\sum_i M_{ij}\right)^2$, it is demonstrated below that the stage 2 variance based on sampling procedure α is the upper bound of the stage 2 variance based on sampling procedure β.

$$\begin{aligned}
&\left(\frac{N}{n}\right)^2 \mathrm{E} \left[\sum_{i-1}^{n} \sum_{j=1}^{R} M_{ij}^2 \left(\frac{1}{m_j} - \frac{1}{M_j} \right) \sigma_j^2 \right] \\
&= \left(\frac{N}{n}\right)^2 \mathrm{E} \left[\sum_{j=1}^{R} \left(\frac{\sum_{i=1}^{n} M_{ij}^2}{c_{\mathrm{NS}} \sum_{i=1}^{n} M_{ij}} - \frac{\sum_{i=1}^{n} M_{ij}^2}{M_j} \right) \sigma_j^2 \right] \\
&\le \left(\frac{N}{n}\right)^2 \mathrm{E} \left[\sum_{j=1}^{R} \left(\frac{\left(\sum_{i=1}^{n} M_{ij}\right)^2}{c_{\mathrm{NS}} \sum_{i=1}^{n} M_{ij}} - \frac{\sum_{i=1}^{n} M_{ij}^2}{M_j} \right) \sigma_j^2 \right] \\
&= \left(\frac{N}{n}\right)^2 \sum_{j=1}^{R} \mathrm{E} \left(\frac{\sum_{i=1}^{n} M_{ij}}{c_{\mathrm{NS}}} - \frac{\sum_{i=1}^{n} M_{ij}^2}{M_j} \right) \sigma_j^2 \\
&= \frac{N}{n c_{\mathrm{NS}}} \sum_{i=1}^{N} \sum_{j=1}^{R} M_{ij} \left(1 - \frac{c_{\mathrm{NS}} M_{ij}}{M_j}\right) \sigma_j^2.
\end{aligned} \tag{10}$$

Thus, when feasible, it is more efficient to use sampling procedure β rather than procedure α at the second stage.

HH Estimation

A two-stage establishment sample survey using a stand-alone frame is conducted to estimate X. The stand-alone frame lists R establishments and the number of their respective transactions M_j $(j = 1, 2, \ldots, R)$. At stage 1, a sample of r_{HH} establishments j $(j = 1, \ldots, r_{\mathrm{HH}})$ is selected by pps with replacement, and at stage 2, a fixed size sample of c_{HH} transactions is independently selected from the M_j transactions of establishment j $(j = 1, 2, \ldots, r_{\mathrm{HH}})$ by srs without replacement.

The unbiased HH estimator of X is

$$X'_{\mathrm{HH}} = \frac{M}{r_{\mathrm{HH}}} \sum_{j=1}^{r} \overline{X}'_j, \tag{11}$$

where $\overline{X}'_j = \sum_{k=1}^{c_{\mathrm{HH}}} X_{jk}/c_{\mathrm{HH}}$ is an unbiased estimate of $\overline{X}_j = X_j/M_j$ $(j = 1, 2, \ldots, R)$. The variance of X'_{HH} is

$$\mathrm{Var}(X'_{\mathrm{HH}}) = \frac{M^2}{r_{\mathrm{HH}}}\sigma^2_{\mathrm{HH1}} + \frac{M}{r_{\mathrm{HH}}c_{\mathrm{HH}}} \times \sum_{j=1}^{R} (M_j - c_{\mathrm{HH}})\sigma_j^2, \tag{12}$$

where the first and second terms respectively on the right side of (12) are the first- and second-stage variance components, and

$$\sigma^2_{\mathrm{HH1}} = \frac{1}{M}\sum_{j=1}^{R} M_j \left(\overline{X}_j - \frac{X}{M}\right)^2 \tag{13}$$

is the between-establishment variance, and σ_j^2 is the within-establishment population variance for establishment j $(j = 1, 2, \ldots, R)$ defined in (5).

Relative Precision of the HH and NS Estimators

Let

$$m_{\mathrm{HH}} = c_{\mathrm{HH}} r_{\mathrm{HH}} = \text{the transaction sample size of the HH estimator of } X$$

and

$$m_{\mathrm{NS}} = c_{\mathrm{NS}} \sum_{i=1}^{n}\sum_{j=1}^{R} M_{ij} = \text{the transaction sample size of the NS estimator of } X.$$

Set $c_{\mathrm{NS}} = c_{\mathrm{HH}} = c$ and $r_{\mathrm{HH}} = \sum_{i=1}^{n}\sum_{j=1}^{R} M_{ij}$ and it follows that HH and NS transaction sample sizes are equivalent, $m_{\mathrm{HH}} = m_{\mathrm{NS}}$, and $\mathrm{E}(m_{\mathrm{HH}}) = \mathrm{E}(m_{\mathrm{NS}}) = cn\overline{M}$. (From the viewpoint of survey costs, it is worthy to note that for a fixed transaction sample size, the expected number of distinct establishments is smaller in NS than in HH because multiple households have transactions with the same establishment and often households have multiple transactions with the same establishment.) Under these simplifying conditions, the difference between the variances of the NS and HH estimators of X given in (3) and (12), respectively, can be written as

$$\mathrm{Var}(X'_{\mathrm{NS}}) - \mathrm{Var}(X'_{\mathrm{HH}}) = \frac{N^2}{n}(\sigma^2_{\mathrm{NS}} - \overline{M}\sigma^2_{\mathrm{HH1}}) - \frac{N}{nc}\sum_{j=1}^{R}\rho_j(\alpha)\sigma_j^2, \tag{14}$$

where the first term and second terms, respectively, on the right side of (14) are the differences between the stage 1 and stage 2 variance components of the NS and HH estimators, and

$$\rho_j(\alpha) = (M_j - c) - \left(\frac{1}{M_j}\right)\sum_{i=1}^{N} M_{ij}(M_j - cM_{ij}) = \left(\frac{c}{M_j}\right)\sum_{i=1}^{N} M_{ij}(M_{ij} - 1) \geq 0 \tag{15}$$

is the difference between the HH and NS second-stage finite population corrections for establishment j if the NS estimator is based on sampling procedure α. If the NS estimator is based on sampling procedure β, then $\rho_j(\beta) \geq \rho_j(\alpha)$.

Under the conditions of equivalent transaction sample sizes specified earlier, the NS and HH estimators are equally efficient in stage 1 and stage 2 components, if and only if, the M transactions are distributed over N households such that every household i $(i = 1, 2, \ldots, N)$ has a single transaction. Under these conditions, the NS and HH estimators are equivalent. The direction and magnitude of differences between variances of the NS and HH estimators will vary from survey to survey depending on the kinds and extent of clustering of transactions within households. For example, the first-stage variance component is likely to be less for the HH estimator than for the NS estimator if $\overline{M} = M/N$ is a small fraction and/or if households have multiple transactions

with the same establishments. On the other hand, as evident from (15), the second-stage variance component is less for the NS estimator than for the HH estimator if any of the establishments have multiple transactions with the same households, and the magnitude of their difference depends on the extent of households having multiple transactions with the same establishments.

Summary Remarks

Unbiased estimation can be obtained in establishment surveys that use population survey-generated frames, that is, sample sampling frames that list only the establishments that have transactions with households in a population sample survey. Clearly, population-survey-generated establishment frames definitely deserve consideration whenever stand-alone establishment frames of good quality are unavailable or prohibitively expensive to construct and maintain. However, even when good stand-alone frames are available, population-survey-generated frames may be competitive.

For example, this article compares the sampling variances in two-stage establishment sample survey designs that use a HH estimator and an NS estimator that depend on flawless sampling frames. The HH estimator depends on a stand-alone sampling frame with parametric measures of establishment size, and the NS estimator depends on a population-survey-generated sampling frame showing the total number of transactions of each establishment with survey households. When the transaction sample sizes of the NS estimator and the HH estimator are roughly the same, neither estimator is necessarily more efficient than the other, and the direction and magnitude of the difference between their variances depends on several parameters whose values are likely to vary considerably from survey to survey and between population domains in the same survey. Empirical studies are needed to estimate the values of the parameters.

Empirical studies are also needed to determine the cost and error effects of three major assumptions of the theoretical findings presented in this article: (1) the stand-alone frame and the population-survey-generated frame are flawless in coverage and size measures, (2) the population survey, which yields the population-survey-generated sampling frame is based on an srs design, and (3) the simplifying conditions specified to yield equivalent HH and NS transaction sample sizes. Fortunately, the estimation procedures are **robust** and are applicable to more complex survey designs and less stringent survey conditions than are considered in the article.

Estimating Functions

In common with other areas of statistics, a major activity in biostatistics consists of constructing probabilistic models. These models can be classified very broadly as (i) parametric models and (ii) semiparametric models. In (i) the distributions are specified up to a number of unknown *parameters*, some of which are of scientific interest; the others are commonly called **nuisance parameters**. In (ii) the parameters of scientific interest are modeled directly thus eliminating generally, though not altogether, the effects of the nuisance parameters. For estimation of the unknown parameters two distinct methodologies have been in practice for a long time. The method of **maximum likelihood** was put forward with a statistical justification by Fisher [13], for parametric models in (i) above; the method, however, was also known to **Gauss** a century before. The method of **least squares** was formulated by Legendre [28] and was statistically justified by Gauss [15, 16]. As illustrated below, both methods, maximum likelihood and least squares, have their strengths and weaknesses. It is further demonstrated how the method of *estimating functions* put forward by one of the present authors, Godambe [17], has in recent years provided a unification and extension of the two historical methods of maximum likelihood and least squares. The estimating function methodology eliminates the weaknesses and combines the strengths, of both the maximum likelihood and the least squares methods. This methodology, because of its inbuilt flexibility, provides a versatile tool for applications in diverse areas including biostatistics. The topics particularly covered here are **case–control studies**, prospective and **retrospective** sampling, **overdispersion**, **longitudinal data**, and the like.

The Methods of Maximum Likelihood (ML) and Least Squares (LS)

We assume the **random variate y** has a density function $f(\mathbf{y};\theta)$. The function f is completely specified up to the unknown parameter, θ, assumed for simplicity to be a scalar. The maximum likelihood method (ML) consists of estimating the unknown parameter θ on the basis of the response, $\mathbf{y}$, by the value $\hat{\theta}(\mathbf{y})$ which, for the fixed $\mathbf{y}$, maximizes $f(\mathbf{y};\theta)$ for all variations of θ. Granting regularity conditions the score function (*see* **Likelihood**) is defined as $\partial \log f/\partial\theta$ and the ML estimate, $\hat{\theta}(\mathbf{y})$, is given by solving for θ the *ML equation*

$$\frac{\partial \log f(\mathbf{y};\theta)}{\partial\theta} = 0. \tag{1}$$

If the random variate $\mathbf{y}$ consists of n components $\mathbf{y} = (y_1, \ldots, y_n)$, then under very general conditions, as $n \to \infty$, i.e. asymptotically (*see* **Large-sample Theory**) the solution of the ML equation (1) tends to be an unbiased minimum variance estimate of θ, with the variance $\to 0$; Fisher [13]. That simply means that among the **consistent** estimates of θ, the ML estimate has an asymptotically smallest variance. This is the *strong* property of ML estimation. But now suppose the density f of the random variate $\mathbf{y}$ is specified by two parameters, θ_1 and θ_2, $f = f(\mathbf{y};\theta_1,\theta_2)$, θ_1 being the parameter of interest and θ_2 the nuisance parameter. Now given the response $\mathbf{y}$, what is the ML estimate of θ_1 ignoring θ_2? This question has no answer. Suppose we estimate both parameters θ_1 and θ_2 by the ML method; $(\hat{\theta}_1, \hat{\theta}_2)$. That is, the density $f(\mathbf{y};\theta_1,\theta_2)$ is maximized for the joint variation of (θ_1,θ_2) at $\theta_1 = \hat{\theta}_1(\mathbf{y})$ and $\theta_2 = \hat{\theta}_2(\mathbf{y})$. If now, as before, $\mathbf{y} = (y_1, \ldots, y_n)$ and if the dimensionality of the nuisance parameter θ_2 increases with n, then $\hat{\theta}_1(\mathbf{y})$ may tend to a false value of θ_1 as $n \to \infty$ (*see* **Convergence in Distribution and in Probability**). Suppose, for example, $y_i = (y_{i1}, y_{i2})$, $i = 1, \ldots, n$, and that all ys are distributed independently and normally with the means $\mathrm{E}(y_{i1}) = \mathrm{E}(y_{i2}) = \theta_{2i}$, $i = 1, \ldots, n$, $\theta_2 = (\theta_{21}, \ldots, \theta_{2n})$ and with a common variance θ_1. In this case the ML estimate

$$\hat{\theta}_1(\mathbf{y}) = \frac{1}{4}\frac{\sum_1^n (y_{i1} - y_{i2})^2}{n} \longrightarrow \frac{1}{2}\theta_1.$$

That is, the ML estimate $\hat{\theta}_1$ is inconsistent [40]. This then is a major weakness of ML estimation.

As noted above, the ML method of estimation presupposes a fully parametric model $f(\mathbf{y};\theta)$. However, the least squares (LS) method assumes only a semiparametric model: the mean values of the responses are modeled as functions of the parameter of interest θ. Let $\mathbf{y} = (y_1, \ldots, y_i, \ldots, y_n)$ be the vector of independent random variates with mean values $\mathrm{E}(y_i) = \alpha_i(\theta)$ and variances $\mathrm{E}(y_i - \alpha_i)^2 = \sigma_i^2$, $i = 1, \ldots, n$, where the α_i are some specified functions of the parameter $\theta;\theta$, as before, is assumed a scalar. The

variances σ_i^2 are assumed to be known constants. As usual, the value of the parameter θ is unknown. The LS method consists of estimating θ, on the basis of the response, $\mathbf{y}$, by the value $\hat{\theta}(\mathbf{y})$, which minimizes for the fixed $\mathbf{y}$, $\sum_1^n[(y_i - \alpha_i)^2/\sigma_i^2]$ for all variations of θ. Thus the LS estimate, $\hat{\theta}(\mathbf{y})$, is obtained by solving for θ the *LS equation*

$$\sum_{i=1}^{n}[y_i - \alpha_i(\theta)]\frac{\partial\alpha_i(\theta)/\partial\theta}{\sigma_i^2} = 0. \tag{2}$$

For linear functions α_i, this method of estimation, as previously indicated, was proposed by Legendre [28]. The estimate $\hat{\theta}(\mathbf{y})$, so obtained, was shown by Gauss [16] to have minimum variance in the class of all linear **unbiased** estimates of θ. Usually this is known as the Gauss–Markoff theorem. Thus the Gauss–Markoff theorem gives a *strong* finite sample property of LS estimation. Even if the functions α_i are not linear, granting some regularity conditions, the LS estimate, though no longer unbiased, is *consistent*. The LS method, however, breaks down when the variances σ_i^2 are not "known constants" but are "known (specified) functions" of θ; $\mathrm{E}(y_i - \alpha_i)^2 = \sigma_i^2(\theta)$, $i = 1, \ldots, n$. Now the *LS equation* (2) is to be replaced by

$$\left\{\sum_{i=1}^{n}[y_i - \alpha_i(\theta)]\frac{\partial\alpha_i(\theta)/\partial\theta}{\sigma_i^2(\theta)}\right\} + \left\{2\sum_{i=1}^{n}[y_i - \alpha_i(\theta)]^2 \times \frac{1}{\sigma_i^3(\theta)} \cdot \frac{\partial\sigma_i(\theta)}{\partial\theta}\right\} = 0. \tag{3}$$

Here the second term on the left-hand side of (3), for large samples, is of the order $\sum_1^n \partial \log \sigma_i(\theta)/\partial\theta$. Hence it is easy to see that the solution of (3), unlike that of (2), would provide an *inconsistent* estimate of θ. This then is a major *weakness* of the LS method.

The Method of Estimating Functions (EF)

The two methods of estimation, ML and LS, are characterized by the "estimating equations", (1) and (2), respectively. More generally, we define an *estimating function* as a function of the random variate $\mathbf{y}$ and the parameter of interest θ, $g(\mathbf{y}, \theta)$ say. For every observation $\mathbf{y}$, the solution of the estimating equation $g(\mathbf{y}, \theta) = 0$, namely $\hat{\theta}$, provides an estimate of θ. Thus in (1) and (2) the estimating functions are

$$g_1(\mathbf{y}, \theta) = \frac{\partial \log f(\mathbf{y}; \theta)}{\partial\theta} \quad \text{and}$$

$$g_2(\mathbf{y}, \theta) = \sum_{i=1}^{n}[y_i - \alpha_i(\theta)]\frac{\partial\alpha_i(\theta)}{\partial\theta}\frac{1}{\sigma_i^2}, \tag{4}$$

respectively. Unlike the two methods of estimation, ML and LS, which emphasize the properties of the "estimate", i.e. the solution of the equation $g(\mathbf{y}, \theta) = 0$, the EF method emphasizes the properties of the estimating function g itself. For instance, it is called unbiased if, for all θ, the expectation

$$\mathrm{E}g(\mathbf{y}, \theta) = 0. \tag{5}$$

Thus, although the estimates (solutions) $\hat{\theta}$ obtained from (1) and (2) are generally biased, the corresponding estimating functions g_1 and g_2 in (4) are unbiased: $\mathrm{E}(g_1) = 0$ and $\mathrm{E}(g_2) = 0$. Interestingly, the inconsistency of the solution of the estimating equation, (3), is due to the fact that the corresponding estimating function, namely

$$g_3 = g_2 + \left\{2\sum_{i=1}^{n}(y_i - \alpha_i)^2\frac{1}{\sigma_i^3}\frac{\partial\sigma_i}{\partial\theta}\right\}, \tag{6}$$

unlike g_2, is *not* unbiased.

In EF methodology we deal with EFs g which are unbiased, i.e. they satisfy the property (5). To compare the efficiencies of various unbiased estimating functions g, the *variance* of g, $\mathrm{E}(g^2)$, is not a useful criterion, for trivially $\mathrm{E}(g^2) \equiv 0$ for the unbiased estimating function g which is identically 0 for all values of $\mathbf{y}$ and θ. This difficulty is overcome by using the standardized version of g, namely

$$g_s = \frac{g}{\mathrm{E}\left(\frac{\partial g}{\partial\theta}\right)}. \tag{7}$$

Note that the standardized versions of two unbiased estimating functions, namely g and $k(\theta)g$, $k(\theta)$ being a constant depending on θ, are *identical*. This is necessary for the estimating functions g and $k(\theta)g$ to have the same inferential content. Although the standardization given by (7) is somewhat arbitrary, it has proved to be very versatile, with applications in various fields of statistics. This is illustrated below. Initially, the standardization (7) provides a definition of an *optimal* estimating function.

Definition. For a given model, let $\mathcal{G}$ be an arbitrary class of unbiased estimating functions g, $\mathcal{G} = \{g\}$. In $\mathcal{G}$, the estimating function g^* is said to be optimal if for any other $g \in \mathcal{G}$,

$$\mathrm{E}(g_{\mathrm{s}}^*)^2 \leq \mathrm{E}(g_{\mathrm{s}})^2, \tag{8}$$

for all θ.

Now consider the parametric model $f(\mathbf{y};\theta)$ mentioned previously in relation to ML estimation. Furthermore, in the above definition, let $\mathcal{G}_0$ be the class of all unbiased estimating functions satisfying some regularity conditions. Then in $\mathcal{G}_0$ the optimal estimating function g^* is given by the score function (SF)

$$g^* = \frac{\partial \log f(\mathbf{y};\theta)}{\partial \theta} \tag{9}$$

(see [17]). This is a finite sample optimality of ML estimation in contrast to its asymptotic property [13] mentioned earlier. Actually, the latter follows from the former. Again, as before, we consider the nuisance parameter situation. In the model $f(\mathbf{y};\theta), \theta = (\theta_1, \theta_2)$, let θ_1 be the parameter of interest and θ_2 the nuisance parameter. To estimate θ_1, ignoring θ_2, we consider the class $\mathcal{G}_{\mathrm{c}}$ of unbiased estimating functions g which depend on θ only through θ_1. Now suppose the model f admits a complete **sufficient statistic** $\boldsymbol{t}$ (independent of θ_1) for θ_2 and $f(\mathbf{y}|t;\theta_1)$ denotes the density of $\mathbf{y}$ conditional on t. Then granting some regularity conditions, the optimal estimating function in $\mathcal{G}_{\mathrm{c}}$ is given by the conditional score function

$$g^* = \frac{\partial \log f(\mathbf{y}|t;\theta_1)}{\partial \theta_1}; \tag{10}$$

the definition of "optimality" used being the same as before [18]. The solution of the estimating equation $g^* = 0$, in (10), unlike that of the ML equations, (1), is a consistent estimate generally for problems of the Neyman–Scott [40] type. Thus, EF theory corrects the ML estimation for its major weakness. A similar correction to LS estimation is provided by the EF theory. This is shown in what follows.

As previously indicated, LS estimation presupposes a semiparametric model. We have a random vector of observations, $\mathbf{y} = (y_1, \ldots, y_i, \ldots, y_n)$, with independent components. The mean values, $\mathrm{E}(y_i) = \alpha_i(\theta)$, and the variances, $\mathrm{E}(y_i - \alpha_i(\theta))^2 = \sigma_i^2(\theta), i = 1, \ldots, n; \alpha_i$, and σ_i are some specified functions of the parameter of interest θ. It was noted earlier that LS estimation works well when α_i are linear functions of θ and σ_i are independent of θ. In this case the estimation derived from the LS equation (2) is supported by the Gauss–Markoff theorem. However, when σ_i depends on θ, the LS equation (3) leads to an inconsistent estimate. This inconsistency is due to the fact that the EF g_3 in (6) is *not* unbiased. To correct this situation the EF theory here starts with the *elementary* unbiased EFs $h_i = y_i - \alpha_i(\theta)$ and $\mathrm{E}(h_i) = 0, i = 1, \ldots, n$. Now the linear estimates of the Gauss–Markoff theorem are replaced by the class $\mathcal{G}_l$ of *linear* unbiased EFs,

$$g = \sum_{i=1}^{n} h_i a_i, \tag{11}$$

where a_i can be arbitrary functions of θ. Note that g is linear in h_i and is unbiased, $\mathrm{E}(g) = 0$. Furthermore, it can be shown that in this class $\mathcal{G}_l$ of linear unbiased EFs the "optimum" g^* satisfying the inequality (8) is given by

$$g^* = \sum_{i=1}^{n} [y_i - \alpha_i(\theta)] \frac{\partial \alpha_i(\theta)/\partial \theta}{\sigma_i^2(\theta)}. \tag{12}$$

Note that when the variances σ_i^2 are constants independent of θ, the estimating function g_2 in (4) provided by the LS method is identical to g^* in (12). However, when σ_i^2 depends on $\theta, \sigma_i^2 = \sigma_i^2(\theta)$, g^* in (12) is different from the EF g_3 in (6), provided by the LS method. Not only does the equation $g^* = 0$, unlike the LS equation $g_3 = 0$, provide a consistent solution, but in fact $g^* = 0$ is the ML equation (g^* being the score function) for the **exponential family** of distributions [3, 45]. Actually, since Wedderburn [45], $g^* = 0$ is called the **quasi-likelihood** equation [34] (*see* **Generalized Linear Model**). The optimality of the estimating function g^* in (12) was established in a wider setting of stochastic processes by Godambe [19]; following that reference we call g^* the *quasi-score function*.

The quasi-score function is a *synthesis*, provided by the EF theory, of the two traditionally distinct methods of estimation namely ML and LS. For, note that the EFs g^* in (9), (10), and (12) all satisfy the same criterion of optimality, namely (8); only the competing classes in the three cases $\mathcal{G}_0, \mathcal{G}_{\mathrm{c}}$, and $\mathcal{G}_l$, respectively, are different. These classes are derived from the underlying models. The quasi-score function, that is the optimum EF g^* in (12), has a wider domain of application than either the ML or

the LS methods. The domain of application of g^* is vastly enhanced further by letting the elementary estimating functions h_i in (11) be arbitrary functions of $\mathbf{y}$ and θ, which are *conditionally* unbiased, i.e. unbiased conditional on some partition (σ-field) of the sample space. For, in that case the constants $a(\theta)$ in (11) can be replaced by any functions of $\mathbf{y}$ and θ which are measurable with respect to the σ-field generated by the partition. This provides an enlarged class $\mathcal{G}_{\text{lc}}, \mathcal{G}_{\text{lc}} \supset \mathcal{G}_{\text{l}}$ of the competing estimating functions. The optimal estimating function g^* in $\mathcal{G}_{\text{lc}}$, i.e. the one satisfying condition (8), was obtained by Godambe & Thompson [23]. This covers areas of **stochastic processes** underlying many biostatistical applications.

From the above discussion it should be clear that the optimal EF, g^*, not only provides a point estimate through the equation $g^* = 0$, but it also provides a substitute for a score function (1), in a semiparametric model. Let g be any unbiased EF, and furthermore let the semiparametric model be a union of families of parametric distributions. Then, very generally, we have:

1. $\mathrm{E}(g^* - \mathrm{SF})^2 \leq \mathrm{E}(g - \mathrm{SF})^2$.
2. **correlation** $(g^*, \mathrm{SF}) \geq \mathrm{correlation}(g, \mathrm{SF})$, where the score function, SF, and the expectation, E, correspond to the underlying parametric family of distributions.
3. Moreover, the **confidence intervals** obtained by inverting the distribution of g^* are asymptotically shorter than the corresponding ones based on g [21].

Now for a parametric family of distributions the optimal EF, g^*, is given by the score function as in (9). Also, according to the just stated property, 3, the confidence intervals based on the score function are asymptotically shortest [48].

One important implication of point 3 above, for all statistical (including biostatistical) practice, is that the confidence intervals based on the inversion of the distribution of the optimal EF g^* are preferable to those based on any (unbiased minimum variance) estimate. Even operationally, the distribution of the estimate often is far less tractable than that of an estimating function consisting of independent components. This is often the case in biostatistical applications, as will be seen subsequently.

Case–Control Studies

Case–control or retrospective studies are of great importance in both biostatistics and the social sciences where they are referred to as choice-based sampling studies. In such a study comparisons are made between individuals who have a particular disease or condition, the cases, and individuals who do not have the disease, the controls. In the simplest case, where a single binary risk factor or exposure variable is of interest, one might sample cases from a population having the disease and also controls from the disease-free population. One then ascertains retrospectively whether or not the sampled individuals have been exposed to the risk factor. In the simplest situation this reduces to a comparison of two **binomial distributions** with the **odds ratio** $\theta = [p_1(1 - p_2)/p_2(1 - p_1)]$ the parameter of interest, this being a measure of association between disease and exposure. Here $p_i, i = 1, 2$, is the probability of exposure for cases and controls, respectively. The nuisance parameter complementary to θ may be taken as p_2 and one is interested in an optimal estimating function for θ free of the nuisance parameter p_2. If $\mathbf{y} = (y_1, y_2)$ are the observed number of exposed individuals in the samples of cases and controls, respectively, then $t = y_1 + y_2$ is a complete sufficient statistic for the nuisance parameter p_2. Hence by a result of Godambe [18], mentioned in (10) above, the optimal estimating function for θ is the conditional score $\partial \log f(\mathbf{y}|t;\theta)/\partial\theta$. In this case

$$\frac{\partial \log f(\mathbf{y}|t;\theta)}{\partial\theta} = y_1 - \mathrm{E}(y_1|t;\theta), \qquad (13)$$

which is free of p_2 and clearly unbiased. We note also that while conditioning is important in eliminating the nuisance parameter, the result of Godambe [18] implies unconditional global optimality for this estimating function. We note also that this argument in terms of estimating functions is related to Fisher's use of conditional likelihood for the **2 × 2 table** (*see* **Fisher's Exact Test**).

In practice, there will be a number of **confounding** variables or factors that may conceal or exaggerate the true effect of the risk factor of immediate interest. A common strategy is to stratify the cases and controls into a number of strata $i, i = 1, \ldots, N$, say, on the basis of such confounding variables (*see* **Stratification**). If the odds ratios $\theta = [p_{i1}(1 - p_{i2})/p_{i2}(1 - p_{i1})], i = 1, \ldots, N$, are the same for each stratum,

then we have N 2×2 tables with p_{i1} and p_{i2} being the exposure probabilities for cases and controls in the ith stratum. Here we have a single parameter θ of interest and N nuisance parameters $p_{i2}, i = 1, \ldots, N$. The difficulties involved in maximum likelihood estimation with many nuisance parameters, as mentioned earlier, are well known since Neyman & Scott [40]. This is a classic Neyman–Scott type situation. However, the estimating function approach avoids the inconsistency of the maximum likelihood estimate of θ by conditioning on $t_i = y_{i1} + y_{i2}$, where y_{i1} and y_{i2} are the number of exposed individuals for the cases and controls, respectively, in the ith stratum. The conditioning statistic, t_i, is again complete and sufficient for p_{i2} and the optimal estimating function for θ is obtained by summing terms like (13) for each stratum. Yanagimoto [51] considers combinations of unbiased estimating functions from different strata which, although suboptimal, may be simpler computationally than (13). Yanagimoto suggests the following unbiased estimating equation for stratum i:

$$g_i(\mathbf{y}_i; \theta) = y_{i1}(n_{i2} - y_{i2}) - \theta y_{i2}(n_{i1} - y_{i1}),$$

where $\mathbf{y}_i = (y_{i1}, y_{i2})$ and n_{i1} and n_{i2} are the sample sizes for cases and controls, respectively. The optimal weighted combination of these, minimizing Godambe's criterion (8), is

$$g(\mathbf{y}; \theta) = \sum_{i=1}^{N} w_i g_i(\mathbf{y}_i; \theta),$$

where $w_i = w_i(\theta) = \mathrm{E}(\partial g_i / \partial \theta)\mathrm{var}^{-1}(g_i)$. For $\theta = 1$, Yanagimoto finds $w_i(1) = (n_i + m_i)^{-1}$, yielding the celebrated **Mantel–Haenszel** estimator [32].

The optimality of the conditional score function exemplified above for the binomial distribution applies more generally to canonical exponential families. For example, mortality rates are often modeled under **Poisson** assumptions, and the parameter of interest, the standardized mortality rate θ, may be taken as a ratio of Poisson means for exposed vs. nonexposed. Again, $t_i = y_{i1} + y_{i2}$, the total number of deaths in each stratum, is a complete sufficient statistic for the nuisance stratum parameter and derivation of the optimal estimating function parallels the binomial case. Computationally the situation is simpler in that the conditional score involves the binomial distribution of y_{i1}, given $y_{i1} + y_{i2}$, while (13) above involves the noncentral **hypergeometric**.

Prospective and Retrospective Sampling

Frequently the analysis of case–control studies proceeds by ignoring retrospective sampling and assuming that the data arose prospectively. Prentice & Pyke [42] provided one justification for this by showing that the resulting estimators of the **logistic regression** coefficients are consistent and that the usual standard errors are asymptotically correct. In this respect the advantages of the estimating functions approach have been recently demonstrated by Carroll et al. [6] as follows.

Simple ideas from estimating function theory may be used to generalize the above result of Prentice & Pyke to a variety of other analyses and sampling schemes. For example, the logistic model may be replaced by **robust** models; **measurement error** models may be accommodated; **missing data** patterns of general types, as well as stratified studies, are encompassed. The multiplicative model of Weinberg & Wacholder [46], and other models not necessarily of the logistic form, are also included. In the more general situation just mentioned a somewhat weaker result than that of Prentice & Pyke holds. If the case–control sampling scheme is ignored and asymptotic standard errors are derived as if the study were prospective, then the standard errors are, in general, at worst asymptotically conservative. However, the asymptotic theory based on estimating functions enables one to identify a simple sufficient condition which ensures that prospectively derived standard errors are, in fact, asymptotically correct. This condition can be shown to apply to a variety of examples.

The simple case of the classical logistic model exemplifies the essence of the argument. The estimating equations for prospective sampling are given by

$$\mathbf{0} = \sum_{i=1}^{n} \begin{pmatrix} 1 \\ X_i \end{pmatrix} [D_i - H(\theta_0^* + \theta_1 X_i)], \qquad (14)$$

where D_i is the binary variable for the ith individual, X_i the covariate, and $H(\cdot)$ the usual logistic distribution function. This may be written as

$$\mathbf{0} = \sum_{i=1}^{n} \psi_i(D_i, X_i, \boldsymbol{\theta}^*) = \boldsymbol{\Psi}, \qquad (15)$$

where $\boldsymbol{\theta}^* = (\theta_0^*, \theta_1)'$ is the unknown parameter. Prospectively, the right-hand side of (15) is an unbiased estimating function. Furthermore,

$$\mathrm{E}\psi_i(D_i, X_i, \boldsymbol{\theta}^*) = \mathbf{0} \tag{16}$$

for each i, so that each component is also an unbiased estimating function in the prospective sampling scheme. The asymptotic standard error of the solution to (15) is, by the usual Taylor series argument,

$$\mathbf{B}^{-1}(\boldsymbol{\theta}^*)\mathbf{A}(\boldsymbol{\theta}^*)\mathbf{B}^{-1}(\boldsymbol{\theta}^*),$$

where

$$\mathbf{B}(\boldsymbol{\theta}^*) = n^{-1}\mathrm{E}\left(\frac{\partial \boldsymbol{\Psi}}{\partial \boldsymbol{\theta}^*}\right)$$

and

$$\mathbf{A}(\boldsymbol{\theta}^*) = n^{-1}\mathrm{cov}(\boldsymbol{\Psi}).$$

Moreover, because of (16):

$$\begin{aligned}\mathbf{A}(\boldsymbol{\theta}^*) &= n^{-1}\sum_{i=1}^{n}\mathrm{E}[\psi_i(D_i, X_i, \boldsymbol{\theta}^*)\psi_i'(D_i, X_i, \boldsymbol{\theta}^*)] \\ &= \mathbf{C}(\boldsymbol{\theta}^*), \text{ say.}\end{aligned}$$

Turning now to the retrospective sampling scheme, with $\boldsymbol{\theta}^*$ replaced by $\boldsymbol{\theta} = (\theta_0, \theta_1)'$, where $\theta_0 = \theta_0^* + \log(n_1/n_0) - \log[\Pr(D=1)/\Pr(D=0)]$, where n_i is the sample size for individuals with $D = i, i = 0$ or 1, and $\Pr(D=1)$ is the unknown prospective probability of success. Consider (15) with $\boldsymbol{\theta}^*$ replaced by $\boldsymbol{\theta}$. While $\boldsymbol{\Psi}$ remains unbiased [42], the component estimating functions $\psi_i(D_i, X_i, \boldsymbol{\theta})$ are, in general, not unbiased. Instead of $\mathbf{A}(\boldsymbol{\theta}) = \mathbf{C}(\boldsymbol{\theta})$, we now have, by an elementary calculation,

$$\mathbf{A}(\boldsymbol{\theta}) = \mathbf{C}(\boldsymbol{\theta}) - \mathbf{D}(\boldsymbol{\theta}),$$

with

$$\mathbf{D}(\boldsymbol{\theta}) = n^{-1}\sum_{i=1}^{n}\mathrm{E}[\psi_i(D_i, X_i, \boldsymbol{\theta})]\mathrm{E}[\psi_i'(D_i, X_i, \boldsymbol{\theta})]$$

a positive semi-definite matrix. The positive semi-definiteness of $\mathbf{D}(\boldsymbol{\theta})$ implies that the use of the prospective formula $\mathbf{B}^{-1}(\boldsymbol{\theta})\mathbf{C}(\boldsymbol{\theta})\mathbf{B}^{-1}(\boldsymbol{\theta})$ will, in general, produce inflated standard errors when applied to data collected retrospectively.

This simple argument can be generalized to a wide variety of models and measurement error schemes. A key assumption is that a general version of (15), which is prospectively unbiased, is also retrospectively unbiased. As an informal argument justifying this assertion note that prospective unbiasedness implies $\mathrm{E}\{\psi(D, \mathbf{X}, \boldsymbol{\theta})|\mathbf{X}\} = 0$, for the classical model, i.e.

$$\sum_{d=0}^{1}\psi(d, x, \theta)H^d(x, \theta)[1 - H(x, \theta)]^{1-d} = 0. \tag{17}$$

Similarly, conditioning on the disease outcome variable D, retrospective unbiasedness implies $\mathrm{E}\{\psi(D, \mathbf{X}, \boldsymbol{\theta})|D\} = 0$. Suppose we define

$$k_d = \int \psi(d, x, \theta)H^d(x, \theta)[1 - H(x, \theta)]^{1-d}\tau(x)\,\mathrm{d}x,$$

where $\tau(x)$ is the marginal density of x induced by the case–control sampling scheme. Then it follows from (17) that $k_0 + k_1 = 0$, implying retrospective unbiasedness. Note that k_1 equals the first column of $-\mathrm{E}(\partial\Psi/\partial\theta)$, which is the condition that prospectively derived standard errors are retrospectively asymptotically correct. These results for the classical model can be generalized to a variety of more complex schemes.

Many other applications of estimating functions in biostatistics are similar to this one in that the primary focus is on the generation of point estimates together with asymptotic standard errors. However, a consequence of the optimality of an estimating function is that confidence intervals based directly on it are asymptotically the shortest, as pointed out earlier. Hence, interval estimation based on inversion of appropriately standardized optimal estimating functions should be superior to those based on estimates and standard errors, *even if* these latter are obtained from optimal estimating functions. Special cases of this phenomenon have been demonstrated, e.g. Boos [2] or Sprott & Viveros [43].

In the works of Prentice & Pyke [42] and Carroll et al. [6] discussed above, and others, the parameters estimated belong to a *model* and the sample is supposed to be drawn from the *hypothetical population* generated by the model. However, generally in biostatistical applications the "sample" is drawn from a finite *survey population* consisting of individuals or units. This survey population is supposed to be a random sample from the hypothetical population mentioned above. In many situations the statistician is interested not only in estimating the parameters of

the hypothetical population (model), but also in estimating the survey population parameter *related* to or *induced* by the model [22]. For instance, if the model parameter β represents the regression coefficient in the hypothetical population, then the induced survey population parameter β_s is the regression coefficient in the finite survey population. The estimating function theory provides optimal estimation of both parameters β and β_s *jointly*, on the basis of a sample drawn from the survey population with a specified sampling design. Utilizing this theory, Godambe & Vijayan [24] have obtained, among other things, optimal estimation for the logistic model based on a "sample" drawn with response-dependent retrospective sampling from a survey population. These results, as a special case, become identical to those of the earlier authors when the "sample" is the same size as the "survey population". The authors also provide a proof of the often conjectured large-sample equality of "prospective" and "retrospective" scores for the parameter of interest.

Modeling Overdispersed Data

Data involving counts or proportions occur frequently in medical applications. For example, disease incidence data or mortality statistics usually involve data in the form of counts. In **teratology** the proportion of malformed fetuses in litters, for which the mother has been subjected to a given dose of teratogen, provides data used to model the probability of malformation as a function of dose. The simplest models for such data, namely the Poisson and binomial, respectively, are usually inadequate in that they predict less variation than is exhibited in such data. One source of such **overdispersion** or extravariation is lack of independence. For example, in spatial mortality statistics, counts in contiguous areas will tend to be correlated (*see* **Geographic Epidemiology**), while in teratology the binary responses of members of the same litter tend to be correlated, the so-called litter effect (*see* **Preclinical Treatment Evaluation**). Estimation of regression parameters in the mean of the response variable often will be of primary interest, although in studies of disease association within families, correlation or association parameters will be of substantive interest. In the former case the parameters in the link function for the mean will be the parameters of interest, whereas correlation or association effects will be described by nuisance parameters. Optimal estimating functions for the parameters of interest in the presence of nuisance parameters are therefore of some interest. However, estimation of the nuisance parameters is important in that standard errors and the validity of associated tests and confidence intervals for the parameters of interest will depend on these so-called nuisance parameters.

Consider the generalized linear models with, for example, Poisson errors for counts and binomial errors for proportions. Here often the systematic part of the model is assumed to be "correct" with an appropriate choice of a link function and covariates. Yet the variance of replicate or near replicate observations is considerably greater than that suggested by such simple exponential family models. As Cox [7] points out, maximum likelihood estimates of regression parameters will not be seriously in error if one ignores this so-called overdispersion. However, associated standard errors, and hence tests and confidence intervals based on them, which ignore such overdispersion can be very misleading.

Overdispersion is frequently modeled using a fully parametric mixed Poisson or mixed binomial model. In this approach the means associated with each Poisson count or binomial proportion are assumed to be random variables with specified parametric distributions. Estimation of the parameters in these mixed distributions proceeds by full maximum likelihood. Manton et al. [33], Hinde [26], and Lawless [27] for count data and Crowder [8], Williams [49, 50] for proportions, provide examples of this. Manton et al., for example, deal with an application to modeling spatial variability in lung cancer mortality rates. The mixing distributions most frequently used (i.e. **gamma** for the Poisson (*see* **Contagious Distributions**) and beta for the binomial (*see* **Beta-binomial Distribution**)) are selected for their mathematical tractability rather than scientific plausibility. Sometimes, if the actual mechanism leading to the overdispersion is known, then such fully parametric modeling may be entirely convincing, but in practice this is the exception rather than the rule.

To avoid this criticism, models that specify only second-order properties of the mixing distribution, or equivalently second-order properties of the observed counts or proportions, may be formulated. This leads to a more robust approach based on quasi-likelihood. Many *ad hoc* techniques used historically in the analysis of counts or proportions may now be regarded

as instances of quasi-likelihood. For example, the use of a multiplicative variance inflation factor in probit analysis [[12], Chapter 4] (*see* **Quantal Response Models**), or the treatment of continuous responses by Fisher [14] with variance proportional to the mean as essentially having a Poisson likelihood, can be regarded as primitive instances of quasi-likelihood.

Estimation of Dispersion Parameters

Major interest usually focuses on the regression parameters, the dispersion parameters being of importance only to the extent that they reflect the precision of the regression parameter estimates. For this reason, relatively *ad hoc* methods are used to estimate the dispersion parameters. Sometimes, however, the dispersion parameters are of interest in their own right. Furthermore, in **multivariate multiple regression** problems, association or correlation parameters are also of interest, e.g. in **segregation analysis** in genetics; see Whittemore & Gong [47] or Zhao [52]. Also, Zhao & Prentice [53] note the importance of simultaneous estimation of mean, variance, and covariance parameters in a variety of biostatistical applications. The theory of optimal estimating functions treats all parameters on the same logical footing and shows the way to a formal theory of joint estimation of both regression and dispersion parameters. Less formal approaches have been developed by Nelder & Pregibon [39] and Davidian & Carroll [9]. Wedderburn's quasi-likelihood was originally designed for parameters in the link function. Nelder & Pregibon [39] attempt to obtain a function of both mean and dispersion parameters which has the properties of a log likelihood for both sets of parameters. However, consistent estimation of parameters in the variance function is not achieved in general owing to the lack of the unbiasedness property of the underlying estimating functions. Clearly, then, their extended quasi-score cannot be identified with an optimal estimating function in the sense of this article. The same terminology as used by Nelder & Pregibon is adopted by Godambe & Thompson [23], but in their case the identification of an extended quasi-score with an optimal estimating function is preserved – at the expense of specification of higher-order moments.

More formally, let us assume that we have independent observations, $y_i, i = 1, \ldots, n$, with

$$\mathrm{E}(y_i) = \mu_i, \qquad \mu_i = \mu_i(\beta),$$

$$\mathrm{var}(y_i) = V(\mu_i; \lambda).$$

Standard multiplicative overdispersion, or more complicated structural variance parameters, as in McCullagh & Nelder [[34], Chapter 10], can be accommodated in this formulation. The common approach to this is to note that if the variance parameter λ is known, then the Wedderburn equations,

$$U(y; \beta, \lambda) = \sum \frac{y_i - \mu_i}{V(\mu_i; \lambda)} \frac{\partial \mu_i}{\partial \beta} = 0, \qquad (18)$$

are optimal linear estimating equations for β. A variety of methods for estimating the variance parameters λ have been proposed to supplement (18). Examples of such methods are:

1. moment methods (e.g. [4, 27], and [35]);
2. extended quasi-likelihood [39]; and
3. **pseudo-likelihood** [9].

These methods do not lead jointly to optimal estimating equations in the sense of this article. However, methods based strictly on optimal estimating functions may well be less robust than these methods.

To review them briefly, method (1) involves supplementing (18) with the moment equation for λ, given by

$$\sum_{i=1}^{n} \left[\frac{(y_i - \mu_i)^2}{V(\mu_i; \lambda)} - 1 \right] = 0, \qquad (19)$$

or the bias-corrected version,

$$\sum_{i=1}^{n} \left[\frac{(y_i - \mu_i)^2}{V(\mu_i; \lambda)} - \frac{n-p}{n} \right] = 0, \qquad (20)$$

where p is the dimension of β. Then (19) or (20) and (18) would be solved jointly, possibly in a doubly iterative fashion. The above is for a scalar λ. In the case where λ is a vector, additional quadratic forms could be equated to their expected values to obtain additional equations, as in McCullagh & Nelder [34, Chapter 10].

For method (2), the extended quasi-likelihood of Nelder & Pregibon is given by

$$Q^{+}(\beta, \lambda) = -\frac{1}{2} \sum_{i=1}^{n} D(y_i, \mu_i, \lambda) - \frac{1}{2} \sum_{i=1}^{n} \log[2\pi V(y_i; \lambda)], \qquad (21)$$

where

$$D(y, \mu, \lambda) = -2 \int_y^{\mu} \frac{y - t}{V(t; \lambda)} \, \mathrm{d}t.$$

Q^+ is then maximized jointly in β and λ.

Finally, in the pseudo-likelihood method of Davidian & Carroll, one fixes β at a preliminary estimate, $\beta = \hat{\beta}$ say, and maximizes the normal theory likelihood in λ:

$$l_{pl}(\hat{\beta}, \lambda) = -\sum_{i=1}^{n} \log V(\mu_i; \lambda) - \sum_{i=1}^{n} \frac{(y_i - \mu_i)^2}{V(\mu_i; \lambda)}. \tag{22}$$

An updated estimate of β can be obtained by successive iterations.

The methods of pseudo-likelihood and extended quasi-likelihood correspond to taking the Pearson chi-square statistic and the deviance, respectively, as response variables in the analysis of dispersion (*see* **Chi-square Tests**). Davidian & Carroll [9] prefer pseudo-likelihood, based on asymptotic considerations. However, recent work by Nelder & Lee [38] suggests that extended quasi-likelihood performs better in finite sampling. In the analysis of Taguchi-type experiments, for example, dispersion parameters must frequently be estimated on the basis of rather limited data, so that finite sample performance may be of some practical importance. A similar concern applies to many biostatistical applications.

Godambe & Thompson [23] obtain jointly optimal estimating equations as follows. Let γ_{1i} and γ_{2i}, respectively, denote the **skewness** and **kurtosis** of the ith observation. Also, let $\Delta_i = \gamma_{2i} + 2 - \gamma_{1i}^2$. Define the elementary orthogonal estimating functions for $i = 1, \ldots, n$ as

$$h_{1i} = y_i - \mu_i, h_{2i} = (y_i - \mu_i)^2 - V(\mu_i; \lambda) - \gamma_{1i}[V(\mu_i; \lambda)]^{1/2}(y_i - \mu_i).$$

Then, the optimal combination of h_{1i} and h_{2i} is given by Godambe & Thompson [23] as

$$\sum_{i=1}^{n} \left[\frac{h_{1i} \partial \mu_i / \partial \beta_j}{V(\mu_i; \lambda)} - h_{2i} \times \frac{[V(\mu_i; \lambda)^{1/2} \gamma_{1i} - \partial V / \partial \mu_i] \partial \mu_i / \partial \beta_j}{V(\mu_i; \lambda) \Delta_i} \right] = 0, \tag{23}$$

$j = 1, \ldots, p$, and

$$\sum_{i=1}^{n} h_{2i} \frac{\partial V / \partial \lambda_j}{V^2(\mu_i; \lambda) \Delta_i} = 0, \tag{24}$$

$j = 1, \ldots, k$, where k is the dimension of λ. We remark that within the exponential family, the second term on the left-hand side of (23) vanishes. Thus, the optimum linear and quadratic equations for β coincide in this case.

Godambe & Thompson [23] refer to these as extended quasi-likelihood equations. They are clearly not, however, the same as the equations derived from (21). The adjective "extended" is unnecessary in a sense here, as pointed out by Heyde [25], because if one identifies the quasi-score with the optimal estimating function according to criterion (8), then these are simply the quasi-score equations derived from the class of combinations of the elementary functions h_{1i} and h_{2i}. The other methods are not quasi-score functions in this sense. Nelder [36] has explored the consequences of replacing h_{2i} above by an approximately unbiased elementary estimating function based on the deviance component, d_i, of the ith observation. Under certain approximating assumptions, he shows that deviance-based versions of (23) and (24) are the same as those obtained using (21). Nelder [37], in discussion of Desmond [10], points out that the use of deviance **residuals** absolves the statistician of the need to make assumptions about the form of third and fourth moments (at least to first order). He predicts that with further refinement this may lead to good approximations to jointly optimum estimating equations which do not depend on assumptions about higher-order cumulants.

Other Applications

The aim of this article has been twofold. First, to point out that the methodology of estimating functions produces a unification and extensions of approaches to statistical modeling and inference, both parametric and semi-parametric. Secondly, to illustrate, via selected examples, how this methodology applies in biostatistics. We have limited our discussion here to case–control studies, prospective and retrospective sampling, and overdispersion. There are many other applications not discussed here, in particular to **longitudinal studies** which we outline briefly

in the following paragraphs. Since this is discussed elsewhere, we simply draw the reader's attention to some recent pertinent work.

Many studies in the biomedical sciences involve data which are longitudinal in nature. In such studies a response variable, frequently a health indicator, is measured repeatedly in time for the individuals in the study, together with covariate vectors, including treatment covariates which may influence the response. Frequently, more than one response variable, which may be discrete or continuous or a combination of both, is measured leading to a **multivariate** response vector. Liang et al. [31] give several examples from public health research. Such data structures lead naturally to problems involving the estimation of mean and association parameters for discrete and continuous multivariate regression analysis. There has been a great deal of development in this area recently for non-Gaussian responses, especially as it applies to binary longitudinal data (*see* **Multivariate Methods for Binary Longitudinal Data**). Also, likelihood approaches to multivariate regression modeling of normal data, including longitudinal studies, have been much studied, e.g. Ware [44]. These methods exploit the tractability of the multivariate normal distribution to provide full maximum likelihood solutions. Likelihood analysis for non-Gaussian data is considerably less tractable. Prentice [41], in the context of binary data, emphasizes the difficulties in obtaining computationally simple likelihood analyses for such longitudinal data, except for special cases.

The estimating function methodology is particularly attractive here for two reasons. First, in lieu of specifying a complete likelihood we can simply model the first- and second-order moments of the response in terms of mean, dispersion, and association parameters i.e. construct a semiparametric model. Secondly, this method is more robust to incorrect model assumptions about higher-order moments, e.g. Liang & Rathouz [29]. We do not describe this work here, since an excellent exposition is given in Diggle et al. [11] (*see* **Generalized Estimating Equations**). However, for a more expansive discussion of the connections of GEE methods with the concepts of quasi-score and optimal estimating functions, see [10] and [30].

In the regression models treated in this article we have assumed that covariates are measured without error. However, measurement error in the covariates is often an important consideration in the biomedical sciences, since ignoring it can produce serious bias in the estimation of covariate effects (*see* **Errors in Variables**). Carroll et al. [5] consider a variety of methods for dealing with measurement error in nonlinear models, and in particular make use of estimating functions in their development.

Further examples of areas of application in biostatistics, e.g. **survival analysis**, may be found in Godambe [20], which is a good general reference for both theoretical developments and applied investigations. Additionally, [1] contains contributions from leading researchers in the field.

Estimation, Interval

As the phrase implies, *interval estimation* concerns the use of available data from a study to construct an interval estimator (often called a **confidence interval**) that is used to make a statistical **inference** about the true (but unknown) value of a parameter θ of interest (*see* **Estimation**). More specifically, an exact $100(1-\alpha)\%$ confidence interval is defined in terms of two **random variables**, a lower limit L and an upper limit U, such that $\Pr[L < \theta < U] = 1-\alpha$, where $0 < \alpha < 1$ and where α is typically chosen to take values such as 0.10, 0.05, 0.02, and 0.01. The exact confidence level $(1-\alpha)$ associated with the interval estimator (L, U) can be interpreted in two ways. In an infinite number of repetitions of the study leading to an infinite number of such $100(1-\alpha)\%$ confidence intervals, an exact proportion $(1-\alpha)$ of all such intervals, the *confidence coefficient*, will enclose the true value of the parameter θ. Equivalently, before the study is conducted and hence before any data are collected, the probability is exactly $(1-\alpha)$ that any random interval (L, U) will enclose the true value of the parameter θ. For any particular study, once the data are collected and the confidence interval is computed using the available data, the actual probability is either 0 or 1 that this observed interval [called the realization of the interval estimator (L, U)] actually encloses the true value of θ, and it is not known which of these two values (0 or 1) is correct. For example, if 1.25 and 3.80 are the observed (or realized) values of L and U for a given set of data, a statement like "$\Pr(1.25 < \theta < 3.80) = 0.95$" is statistically incorrect. Also, since it is L and U that are the random quantities (and not the parameter θ), it is inappropriate terminology to say that "θ falls inside the confidence interval". Indeed, the true unknown value of θ is fixed, and it is the interval estimator (L, U) that either encloses or does not enclose the true value of θ.

To consider a simple example, suppose that $Y_1, Y_2, \ldots, Y_n$ constitute a random sample of size n from an $\mathrm{N}(\mu, \sigma^2)$ population, and we wish to use these n observations to construct an exact $100(1-\alpha)\%$ confidence interval for the parameter μ. With $\overline{Y} = n^{-1}\sum_{i=1}^{n} Y_i$ and $S^2 = (n-1)^{-1}\sum_{i=1}^{n}(Y_i - \overline{Y})^2$, then the random variable $T_{n-1} = \sqrt{n}(\overline{Y} - \mu)/S$ has exactly a **Student's *t*-distribution** with $n-1$ degrees of freedom (df), namely $T_{n-1} \sim t_{n-1}$. Hence, if $t_{n-1,1-\alpha/2}$ is the $100(1-\alpha/2)$ percentile point of Student's t-distribution with $n-1$ df, then

$$\begin{aligned} 1-\alpha &= \Pr(-t_{n-1,1-\alpha/2} < T_{n-1} < t_{n-1,1-\alpha/2}) \\ &= \Pr(-t_{n-1,1-\alpha/2} < \sqrt{n}(\overline{Y} - \mu)/S \\ &\quad < t_{n-1,1-\alpha/2}) \\ &= \Pr(\overline{Y} - t_{n-1,1-\alpha/2}S/\sqrt{n} < \mu \\ &\quad < \overline{Y} + t_{n-1,1-\alpha/2}S/\sqrt{n}), \end{aligned}$$

so that $L = \overline{Y} - t_{n-1,1-\alpha/2}S/\sqrt{n}$ and $U = \overline{Y} + t_{n-1,1-\alpha/2}S/\sqrt{n}$. Thus, based on the assumption that we have a random sample of size n from an $N(\mu, \sigma^2)$ population, then $\overline{Y} \pm t_{n-1,1-\alpha/2}S/\sqrt{n}$ is an exact $100(1-\alpha)\%$ confidence interval for μ. If the stated assumption is true, then this is the best $100(1-\alpha)\%$ confidence interval for μ in the sense that it has the shortest expected width.

Making the fully parametric assumption that the available data consist of independent random samples from normal populations allows for the construction of exact confidence intervals in more general settings. In particular, consider using data on n independent subjects to fit the **multiple linear regression** model

$$\mathrm{E}(Y_i | x_{i1}, x_{i2}, \ldots, x_{ik}) = \beta_0 + \sum_{j=1}^{k} \beta_j x_{ij} = \mathbf{x}_i'\boldsymbol{\beta}, \quad i = 1, 2, \ldots, n, \tag{1}$$

where the (univariate) response for the ith subject is Y_i, where the covariate vector for the ith subject is $\mathbf{x}_i' = (1, x_{i1}, x_{i2}, \ldots, x_{ik})$, and where the vector of unknown regression coefficients is $\boldsymbol{\beta}' = (\beta_0, \beta_1, \ldots, \beta_k)$. Under the classical assumptions that the **conditional distribution** of Y_i given $x_{i1}, x_{i2}, \ldots, x_{ik}$ is normal with conditional mean given by (1) and with conditional (homogeneous) variance σ^2, then the **maximum likelihood** (and unweighted **least squares**) unbiased estimator $\hat{\boldsymbol{\beta}} = (\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k)'$ of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$, where $\mathbf{X}' = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ and where the row vector of responses is $\mathbf{Y}' = (Y_1, Y_2, \ldots, Y_n)$. Under the given assumptions, for $j = 0, 1, 2, \ldots, k$, it follows that $\hat{\beta}_j \sim \mathrm{N}(\beta_j, v_{jj}\sigma^2)$, where v_{jj} is the jth diagonal element of the matrix $\mathbf{V} = (\mathbf{X}'\mathbf{X})^{-1}$. With

the unbiased estimator of σ^2 being $\hat{\sigma}^2 = (n - k - 1)^{-1}(\mathbf{Y}'\mathbf{Y} - \hat{\boldsymbol{\beta}}'\mathbf{X}'\mathbf{Y})$, the standardized random variable $(\hat{\beta}_j - \beta_j)/(v_{jj})^{1/2}\hat{\sigma}$ has exactly a t_{n-k-1} distribution. Thus, it follows directly that the exact $100(1-\alpha)\%$ confidence interval for β_j has the specific form $\hat{\beta}_j \pm t_{n-k-1,1-\alpha/2}(v_{jj})^{1/2}\hat{\sigma}$.

However, in contrast to the classical multiple linear regression scenario described above, there are many realistic and important multivariable modeling applications in biostatistics where assumptions like normality of the response variable, homogeneous variance, and even independence among responses are not justified. For example, if the response variable Y_i is dichotomous (e.g. $Y_i = 1$ if subject i has a certain disease, and $Y_i = 0$ if not), then the distribution of Y_i is point-binomial with mean $\mathrm{E}(Y_i|x_{i1}, x_{i2}, \ldots, x_{ik}) = \Pr(Y_i = 1|x_{i1}, x_{i2}, \ldots, x_{ik}) = \pi_i$ and with variance $\mathrm{var}(Y_i|x_{i1}, x_{i2}, \ldots, x_{ik}) = \pi_i(1 - \pi_i)$, so that the variance of Y_i is not the same for all i (i.e. is not homogeneous across subjects) since the mean of Y_i varies with i. In this situation, a useful and popular maximum likelihood approach for modeling π_i as a function of covariates $x_{i1}, x_{i2}, \ldots, x_{ik}$ is **logistic regression**, where we consider the logistic regression model

$$\mathrm{logit}(\pi_i) = \ln \frac{\pi_i}{(1 - \pi_i)} = \beta_0 + \sum_{j=1}^{k} \beta_j x_{ij}. \qquad (2)$$

In contrast to model (1), model (2) describes logit $[\mathrm{E}(Y_i|x_{i1}, x_{i2}, \ldots, x_{ik})]$ as a linear function of the regression coefficients $\beta_0, \beta_1, \ldots, \beta_k$. The theoretical aspects and practical applications of logistic regression methods have been described in several textbooks (e.g. see Breslow & Day [1], Hosmer & Lemeshow [5], and Kleinbaum et al. [6]).

More generally, the logistic regression model is one example of a very broad family of **generalized linear models** for describing discrete and continuous outcome data [7]. The generalized linear model (GLM) family includes, as some special cases, multiple linear regression and **analysis of variance** models under normality, logistic regression and **Poisson regression** models, probit models (*see* **Quantal Response Models**), **multinomial** response models for categorical outcomes, and some commonly used models for **survival data**.

Maximum likelihood methods, which are optimal asymptotically under certain regularity conditions, are typically used to fit generalized linear models; thus, associated interval estimation procedures are generally valid only for large samples. To discuss the use of maximum likelihood-based interval estimation methods, suppose that $L(\mathbf{Y}, \mathbf{X}; \boldsymbol{\theta})$ is a **likelihood** function, where $\mathbf{Y}$ and $\mathbf{X}$ are as defined earlier and where $\boldsymbol{\theta} = (\theta_1, \theta_2, \ldots, \theta_p)'$ is a vector of unknown parameters. For example, $L(\mathbf{Y}, \mathbf{X}; \boldsymbol{\theta})$ would be a product of appropriately defined normal distributions for the multiple linear regression example considered earlier, where $\boldsymbol{\theta}' = (\boldsymbol{\beta}', \sigma^2)$ and $p = k + 2$. And $L(\mathbf{Y}, \mathbf{X}; \boldsymbol{\theta})$, with $\boldsymbol{\theta} = \boldsymbol{\beta}$ and $p = k + 1$, would be a product of point-binomial distributions for the logistic regression situation previously discussed. More generally, $L(\mathbf{Y}, \mathbf{X}; \boldsymbol{\beta})$ could be a **hypergeometric** distribution-based likelihood appropriate for conditional logistic regression [6, Chapter 20], or it could represent a **partial likelihood** appropriate for the **Cox regression model** in **survival analysis** [7, Chapter 13].

The maximum likelihood estimator $\hat{\boldsymbol{\theta}} = (\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_p)'$ of $\boldsymbol{\theta}$ is the vector solution to the set of p maximum likelihood (or score) equations $\partial \ln L(\mathbf{Y}, \mathbf{X}; \boldsymbol{\theta})/\partial\theta_j = 0$, $j = 1, 2, \ldots, p$. In most generalized linear model situations (one notable exception being the multiple linear regression example considered earlier), these maximum likelihood equations are nonlinear in the elements of $\boldsymbol{\theta}$, and so they must be solved by iteratively reweighted least squares. Iteratively reweighted least squares methods produce the large-sample estimated variance–covariance matrix of $\hat{\boldsymbol{\theta}}$ as the $(p \times p)$ matrix $\hat{\mathbf{V}} = [\mathbf{I}(\mathbf{Y}, \mathbf{X}; \hat{\boldsymbol{\theta}})]^{-1}$, where $\mathbf{I}(\mathbf{Y}, \mathbf{X}; \hat{\boldsymbol{\theta}})$ is the observed information matrix with (j, j')th element defined as $-\partial^2 \ln L(\mathbf{Y}, \mathbf{X}; \boldsymbol{\theta})/\partial\theta_j \partial\theta_{j'}$, evaluated at $\hat{\boldsymbol{\theta}}$. Since the estimated variance of $\hat{\theta}_j$ is $\hat{v}_{jj}$, the (j, j)th element of $\hat{\mathbf{V}}$, it follows from maximum likelihood theory that, for large samples, the quantity $(\hat{\theta}_j - \theta_j)/\sqrt{\hat{v}}_{jj}$ is approximately distributed as a standard normal random variable if the assumed statistical model is valid. Hence, an approximate $100(1-\alpha)\%$ large-sample (normal approximation-based) confidence interval for the parameter θ_j is $\hat{\theta}_j \pm Z_{1-\alpha/2}\hat{v}_{jj}$.

It is also possible to construct a confidence interval for θ_j using the principles underlying **likelihood ratio tests**. In particular, let $\boldsymbol{\psi}_{\theta_j} = (\theta_1, \theta_2, \ldots, \theta_{j-1}, \theta_{j+1}, \ldots, \theta_p)'$ be the $(p-1) \times 1$ column vector of all parameters in $\boldsymbol{\theta}$ except for θ_j. Then, if $\hat{\boldsymbol{\psi}}_{\theta_j}$ is the maximum likelihood estimator of $\boldsymbol{\psi}_{\theta_j}$ with θ_j fixed

(so that $\hat{\boldsymbol{\psi}}_{\theta_j}$ will, in general, be a function of θ_j), then the log likelihood ratio statistic

$$2 \ln L(\mathbf{Y}, \mathbf{X}; \hat{\boldsymbol{\theta}}) - 2 \ln L(\mathbf{Y}, \mathbf{X}; \theta_j, \hat{\boldsymbol{\psi}}_{\theta_j})$$

has an approximate χ_1^2 distribution (**chi-square distribution** with one **degree of freedom**) for large samples if the assumed model is valid. Then, the set of all values of θ_j satisfying

$$2 \ln L(\mathbf{Y}, \mathbf{X}; \hat{\boldsymbol{\theta}}) - 2 \ln L(\mathbf{Y}, \mathbf{X}; \theta_j, \hat{\boldsymbol{\psi}}_{\theta_j}) \leq \chi^2_{1,1-\alpha}$$

constitutes an approximate large-sample $100(1 - \alpha)\%$ confidence interval for θ_j. It is important to note that such likelihood ratio-based confidence intervals often perform better for small samples than do the normal approximation-based intervals discussed earlier. The partially maximized log likelihood $\ln L(\mathbf{Y}, \mathbf{X}; \theta_j, \hat{\boldsymbol{\psi}}_{\theta_j})$ is called the **profile log likelihood** for θ_j. All of these methods can be generalized to produce confidence sets for a vector of parameters (e.g. [7]).

There are several other general methods for constructing interval estimators of unknown parameters. For example, for correlated response data as encountered in **longitudinal studies** where the same response variable is measured more than once on each subject, **generalized estimating equations** (GEE) methods based on **quasi-likelihood** theory can be used to develop interval estimators that involve the use of a **robust** estimator of the variance–covariance matrix of the parameter estimates (e.g. [2]). There are numerous **nonparametric methods** available for developing interval estimators (e.g. [4] and [9]), and there are so-called exact confidence interval methods based on the use of certain network algorithms (e.g. [8]) (*see* **Exact Inference for Categorical Data**). And, last but not least, **computer-intensive bootstrap** interval estimation methods [3] have become very popular in recent years.

In most practical situations it is possible to consider the use of several different types of interval estimators, some involving more assumptions than others. It is generally good advice to use various alternative interval estimation methods in such situations, these methods hopefully ranging from being fully parametric to being fully nonparametric in nature. Only when global statistical conclusions about the parameters of interest vary distinctly from method to method would one have to be seriously concerned about the appropriateness of any assumptions that have been made. When in doubt, it is best to use interval estimation methods that possess good statistical properties not depending directly on the validity of unverifiable assumptions.

Estimation

The object of estimation is to use available data to estimate or guess the values of unknown quantities. The unknown quantities, which are called *parameters*, may be familiar population quantities such as the population **mean** μ, population proportion p, population **variance** σ^2, and population **median** ν. In other situations the parameters are part of more elaborate statistical models, such as the coefficients $\beta_0, \beta_1, \ldots, \beta_p$ in a **linear regression** model

$$Y = \beta_0 + \sum_{j=1}^{p} x_j \beta_j + \varepsilon,$$

which relates a response variable Y to **covariates** or **explanatory variables**, $x_1, x_2, \ldots, x_p$.

For instance, we may be interested in the mean diastolic blood pressure $\mu = \mathrm{E}(Y)$ of a target population, in which case the sample mean $\overline{Y}$ is a familiar estimator, or we may model the blood pressure as a function of the predictor $x =$ age, and a random error ε, in a linear model such as $Y = \beta_0 + \beta_1 x + \varepsilon$. In this case natural estimators of the parameters β_0 and β_1 are the **least squares** estimators

$$\hat{\beta}_1 = \frac{\sum (x_i - \overline{x}) Y_i}{\sum (x_i - \overline{x})^2}, \quad \hat{\beta}_0 = \overline{Y} - \hat{\beta}_1 \overline{x}.$$

The field of biostatistics is, to a large extent, concerned with developing estimators for parameters in different types of medical and public health studies and to give measures of the accuracy of these estimates. Another important concern is to select **efficient**, or, if possible, optimal estimators of a parameter vector $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$ from classes of reasonable estimators.

Let $P = P(\mathbf{y})$ denote the probability distribution of the data $\mathbf{Y} = (Y_1, Y_2, \ldots, Y_n)$. In the discrete case, P is the probability function of $\mathbf{Y}$, and in the continuous case it is the distribution function of $\mathbf{Y}$. The postulated relationship between P and $\boldsymbol{\theta}$ is crucial for estimation. Two commonly used approaches are as follows:

1. In *parametric* models, a vector $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$ determines P. Thus, suppose $\boldsymbol{\theta} = (\theta_1, \theta_2) = (\mu, \sigma^2)$; then, if the distribution of the response Y is **normal**, $\boldsymbol{\theta}$ determines P, that is, $P(\mathbf{y}) = P(\mathbf{y}, \boldsymbol{\theta})$.
2. In the $\boldsymbol{\theta} = (\mu, \sigma^2)$ example, if it is not possible to assume normality or any other specified distribution for $\mathbf{Y}$, then $\boldsymbol{\theta}$ does not determine P. In such cases it is often useful to express $\boldsymbol{\theta}$ as a function of P, that is, $\boldsymbol{\theta} = \boldsymbol{\theta}(P) = [\mu(P), \sigma^2(P)]$. In general, such representations are not unique. For a given $\boldsymbol{\theta}$ in a study we will see in what follows that it is possible to have $\boldsymbol{\theta} = h_1(P)$ and $\boldsymbol{\theta} = h_2(P)$ for different h_1 and h_2. Another parameterization in the (μ, σ^2) example consists of introducing the parameter $\boldsymbol{\theta} = (\mu, \sigma^2, F_\varepsilon)$, where F_ε is the unknown distribution of $\varepsilon = Y - \mu$. Under general conditions this $\boldsymbol{\theta}$ determines P. In such cases, where at least one of the unknowns in θ is real and at least one is a function, the model is called *semiparametric*. In the simple linear model for blood pressure vs. age, if ε is normal $(0, \sigma^2)$ and the equation $Y = \beta_0 + \beta_1 x + \varepsilon$ is assumed, then the distribution of Y is determined by $\boldsymbol{\theta} = (\beta_0, \beta_1, \sigma^2)$ and the model is parametric. However, we can define β_0 and β_1 to be the coefficients in the best linear predictor of Y, that is, they minimize $\mathrm{E}[Y - (b_0 + b_1 X)]^2$. In this case $\beta_1 = \mathrm{cov}(X, Y)/\mathrm{var}(X)$, $\beta_0 = \mathrm{E}(Y) - \beta_1 \mathrm{E}(X)$, $\sigma^2 = \mathrm{var}[Y - (\beta_0 + \beta_1 X)]$, and $(\beta_0, \beta_1, \sigma^2)$ does not determine the distribution F of (X, Y). This second approach has the advantage that it is not necessary to assume a linear model. Instead, the goal is to estimate the coefficients of the best *linear* predictor $\beta_0 + \beta_1 X$ of Y. In this case β_0, β_1, and σ^2 are functions of the distribution P of (X, Y). In some cases it is useful to consider the semiparametric model where the full parameter is $\boldsymbol{\theta} = (\beta_0, \beta_1, \sigma^2, F_X, F_{\varepsilon,x})$. Here F_X is the distribution of X and $F_{\varepsilon,x}$ is the **conditional distribution** of $\varepsilon = Y - (\beta_0 + \beta_1 X)$ given $X = x$. Under general conditions, this expanded $\boldsymbol{\theta}$ determines P.

Note that the notational scheme $\boldsymbol{\theta} = \boldsymbol{\theta}(P)$ also works in the parametric case; however, when appropriate, parametric modeling with $P = P_{\boldsymbol{\theta}}$ often leads to simple analysis and efficient estimators. Parametric models are often natural for studies where the distributions are binomial, **multinomial**, **hypergeometric**, **negative binomial** or, more generally, can be derived

by probabilistic calculations from an experimental situation. The semiparametric approach is appropriate when population means, regression coefficients, variances, and other population quantities are of interest but it is not possible to assume normality of distributions or linearity of mean relationships.

The next sections discuss some of the standard methods of estimation including some of the theory. Books that treat these topics in detail include Bickel & Doksum [1], Lehmann [6], and Bickel et al. [2]. Books that focus on estimation in biostatistics include Kalbfleisch & Prentice [4], Lawless [5], and Cox & Oakes [3].

Methods of Estimation

We consider several techniques for estimating a vector parameter $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$ or, more generally, a vector $[q_1(\boldsymbol{\theta}), \ldots, q_r(\boldsymbol{\theta})]$ of functions of $\boldsymbol{\theta}, r \leq m$. The first three classes of estimates are for parameters that can be expressed as $\boldsymbol{\theta} = \boldsymbol{\theta}(P)$. The fourth and fifth are parametric with $P = P_{\boldsymbol{\theta}}$.

The Frequency Plug-in Method

Suppose we obtain a sample of n independent identically distributed responses and classify each response into one of d distinct categories. Let p_j denote the probability of the jth category and let N_j denote the number of responses that fall in the jth category. Then the distribution of $N_1, \ldots, N_d$ is multinomial $(n, p_1, \ldots, p_d)$ and $p_j = \mathrm{E}(N_j)/n$. The frequency plug-in estimator $\hat{p}_j$ of p_j replaces the unknown frequency $\mathrm{E}(N_j)$ with the observed frequency N_j, that is, $\hat{p}_j = N_j/n$. For functions $\theta_s = h_s(p_1, \ldots, p_d)$ the plug-in estimators are $\hat{\theta}_s = h_s(\hat{p}_1, \ldots, \hat{p}_d), s = 1, \ldots, m$.

Examples are provided by multiway **contingency tables**. For instance, using different subscripting, suppose N_{ijk} denotes the number of high blood pressure patients in a study that fall in the category (i, j, k) based on the following three classifications:

1. treatment membership ($i = 0$, control; $i = 1$, treatment),
2. reduction in blood pressure ($j = 0$, zero or negative; $j = 1$, moderate; $j = 2$, high),
3. age group ($k = 0$, <30; $k = 1$, 30–40; $k = 2$, 41–50; $k = 3$, 51–60; $k = 4$, >60).

Let p_{ijk} be the probability of the category (i, j, k), then $\hat{p}_{ijk} = N_{ijk}/n$. Moreover, the contrast parameters

$$\theta_k = \sum_{j=1}^{2} j(p_{1jk} - p_{ojk}), \quad k = 0, 1, \ldots, 4,$$

which measure the expected improvement in blood pressure score due to the treatment for age group k, has the plug-in estimators

$$\hat{\theta}_k = \sum_{j=1}^{2} j(\hat{p}_{1jk} - \hat{p}_{ojk}), \quad k = 0, 1, \ldots, 4.$$

Returning to the general notation $p_j, N_j, j = 1, \ldots, d$, consider the case where $p_j = p_j(\boldsymbol{\theta})$ depends on some parameter $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m), m \leq d$. For example, suppose θ denotes the probability of alleles A_1 at a certain locus and suppose A_2 has frequency $(1 - \theta)$. In the **Hardy–Weinberg** model the three genotypes $A_1\ A_1$, $A_1\ A_2$, and $A_2\ A_2$ have probabilities

$$p_1 = \theta^2, \qquad p_2 = 2\theta(1 - \theta), \qquad p_3 = (1 - \theta)^2.$$

In this case, θ can be written as $\theta = \sqrt{(p_1)}$, or $\theta = 1 - \sqrt{(p_3)}$, or $\theta = p_1 + \frac{1}{2}p_2$. Thus plug-in estimators are not unique and three plug-in estimators are $\sqrt{(\hat{p}_1)}, 1 - \sqrt{(\hat{p}_3)}$, and $\hat{p}_1 + \frac{1}{2}\hat{p}_2$. In general, plug-in estimators of $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m), m \leq k$, are obtained by solving the equations $p_j(\boldsymbol{\theta}) = \hat{p}_j, j = 1, \ldots, k$, for $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$. Let the solution be $\hat{\boldsymbol{\theta}} = (\hat{\theta}_1, \ldots, \hat{\theta}_m)$, then the plug-in estimator of $(q_1(\boldsymbol{\theta}), \ldots, q_r(\boldsymbol{\theta}))$ is $(q_1(\hat{\boldsymbol{\theta}}), \ldots, q_r(\hat{\boldsymbol{\theta}}))$.

The Method of Moments

Another plug-in method is the **method of moments**. For a vector $\mathbf{X} = (X_1, \ldots, X_k)$, of observations, let the moments be

$$m_{jkrs} = \mathrm{E}(X_r^j X_s^k), \quad j \geq 0, k \geq 0, r, s = 1, \ldots, k.$$

For independent identically distributed $\mathbf{X}_i = (X_{i1}, \ldots, X_{ik}), i = 1, \ldots, n$, we define the empirical or sample moment to be

$$\hat{m}_{jkrs} = \frac{1}{n} \sum_{i=1}^{n} X_{ir}^j X_{is}^k, \quad j \geq 0, k \geq 0, r, s = 1, \ldots, k.$$

If $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$ can be expressed as a function of the moments, then the method of moment estimate $\hat{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$ is obtained by replacing m_{jkrs} by $\hat{m}_{jkrs}$. For instance, when $k = 1$, the method of moments estimator of $\boldsymbol{\theta} = (\mu, \sigma^2) = [\mathrm{E}(X), \mathrm{E}(X^2) - \mu^2]$ is $[\overline{X}, (1/n)\sum X_i^2 - \overline{X}^2]$, where $\overline{X} = n^{-1}\sum X_i$. In the example where β_0 and β_1 are the parameters of the best linear predictor of X and Y,

$$\beta_1 = \frac{\mathrm{cov}(X, Y)}{\mathrm{var}(X)} = \frac{\mathrm{E}(XY) - \mathrm{E}(X)\mathrm{E}(Y)}{\mathrm{E}(X^2) - \mathrm{E}^2(X)},$$
$$\beta_0 = \mathrm{E}(Y) - \beta_1 \mathrm{E}(X).$$

Thus the method of moment estimators are

$$\hat{\beta}_1 = \frac{n^{-1}\sum X_i Y_i - \overline{X}\,\overline{Y}}{n^{-1}\sum X_i^2 - (\overline{X})^2}, \qquad \hat{\beta}_0 = \overline{Y} - \hat{\beta}_1 \overline{X}.$$

For a parametric example consider a study where the survival time T is modeled to have a **gamma distribution** with density

$$\left[\frac{\lambda^\alpha}{\Gamma(\alpha)}\right] t^{\alpha-1} \exp\{-\lambda t\}, \quad t > 0,\ \alpha > 0,\ \lambda > 0.$$

In this case $\theta = (\alpha, \lambda)$, $\mu_1 = \mathrm{E}(T) = \alpha/\lambda$, and $\mu_2 = \mathrm{E}(T^2) = \alpha(1 + \alpha)/\lambda^2$. Solving for θ gives

$$\alpha = \left(\frac{\mu_1}{\sigma}\right)^2, \quad \hat{\alpha} = \left(\frac{\overline{X}}{\hat{\sigma}}\right)^2,$$
$$\lambda = \frac{\mu_1}{\sigma^2}, \qquad \hat{\lambda} = \frac{\overline{X}}{\hat{\sigma}^2},$$

where $\sigma^2 = \mu_2 - \mu_1^2$ and $\hat{\sigma}^2 = n^{-1}\Sigma X_i^2 - \overline{X}^2$. In this example the method of moment estimator is not unique. We can express θ as a function of μ_1 and $\mu_3 = \mathrm{E}(T^3)$ and obtain a method of moment estimator based on $\hat{\mu}_1$ and $\hat{\mu}_3$.

Weighted and Generalized Least Squares Estimators

Suppose Y is a response such as blood pressure whose distribution depends on the levels $x_1, \ldots, x_p$ of p predictor variables such as $X_1 =$ level of treatment, $X_2 =$ age, $X_3 =$ dietary salt intake, etc. Suppose $\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_p)$ is the vector of coefficients of the best linear predictor, that is, $\boldsymbol{\beta}$ minimizes

$$\mathrm{E}\left[\left(Y - \sum_{j=0}^{p} b_j X_j\right)^2 w(\mathbf{X}, Y)\right],$$

where $X_0 = 1$, $\mathbf{X} = (X_0, X_1, \ldots, X_p)$, and $w(\mathbf{X}, Y)$ is a given weight function exemplified in what follows. Here $\boldsymbol{\beta} = \boldsymbol{\beta}(P)$ depends on the probability distribution P of $(\mathbf{X}, Y)$. To estimate $\boldsymbol{\beta}(P)$ we replace P by the empirical probability distribution P_n which gives probability n^{-1} to each observed sample point $(x_{i1}, \ldots, x_{id}, y_i) = (\boldsymbol{x}_i, y_i)$, $i = 1, \ldots, n$. This leads us to seek the minimizer $\hat{\boldsymbol{\beta}}$ of

$$\sum \left(y_i - \sum_{j=0}^{p} b_j x_{ij}\right)^2 w_i,$$

where $w_i = w(x_i, y_i)$ and $x_{i0} = 1$. The solution is $\hat{\boldsymbol{\beta}} = (\mathbf{X}_\mathrm{D}^\mathrm{T}\mathbf{W}\mathbf{X}_D)^{-1}\mathbf{X}_\mathrm{D}^\mathrm{T}\mathbf{W}_\mathbf{y}$, where $\mathbf{X}_\mathrm{D}$ is the $n \times (p + 1)$ design matrix (x_{ij}), $\mathbf{y} = (y_1, \ldots, y_n)^\mathrm{T}$, $\mathbf{W} = \mathrm{diag}(w_1, \ldots, w_n)$ and $\mathbf{X}_\mathrm{D}$ and $\mathbf{W}$ are assumed to have ranks $p + 1$ and n, respectively. This $\hat{\boldsymbol{\beta}}$ is called the *weighted least squares estimator*.

The weights w_i are determined by the application. For example, consider a study where a health indicator such as CD4 blood cell count is taken at time points $t_0 < t_1 < \cdots < t_k$ for HIV infected subjects. After adjusting for changes in blood cell counting technology, the mean of the fourth root of such blood cell counts decreases linearly over time [7]. That is, the slope is constant. For the ith subject the responses are the local slopes

$$Y_{ij} = \frac{\{CD4 \text{ at time } t_{i,j}\}^{1/4} - \{CD4 \text{ at time } t_{i,j-1}\}^{1/4}}{t_{i,j} - t_{i,j-1}},$$
$$j = 1, \ldots, k_i, i = 1, \ldots, m,$$

where $k_i =$ number of measurements for subject i. The predictors considered are $x_{i1} =$ age and $x_{i2} = \{\text{CD8 at first visit time} = t_{i,0}\}^{1/4}$, where CD8 is another blood cell count health indicator. The shorter the time interval length $\Delta_{ij} = t_{i,j} - t_{i,j-1}$ is, the more variable Y_{ij} is. The standard deviation of Y_{ij} is close to being proportional to Δ_{ij}^{-1}; thus a reasonable weighted least squares estimator $\hat{\boldsymbol{\beta}} = (\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2)$ is the minimizer of

$$\sum_{i=1}^{m}\sum_{j=1}^{k_i}[y_{ij} - (b_0 + b_1 x_{i1} + b_2 x_{i2})]^2 \Delta_{ij}.$$

Returning to the general design matrix notation, the *generalized least squares estimator* is defined as

the minimizer of

$$(\mathbf{Y} - \mathbf{b}\mathbf{X}_D)^{\mathrm{T}}\mathbf{W}(\mathbf{Y} - \mathbf{b}\mathbf{X}_D)$$

where $\mathbf{b} = (b_0, b_1, \ldots, b_p)^{\mathrm{T}}$ and $\mathbf{W}$ is an $n \times n$ matrix not necessarily diagonal. Again, it is assumed that $\mathbf{X}_D$ has rank $p + 1$ and $\mathbf{W}$ has rank n, in which case the estimator is given by the same formula as before.

Maximum Likelihood Estimators

The idea of **maximum likelihood** is to find the value $\hat{\boldsymbol{\theta}}(\mathbf{y})$ of $\boldsymbol{\theta}$ which is "most likely" to have produced the data $\mathbf{y} = (y_1, \ldots, y_n)$. These estimators $\hat{\boldsymbol{\theta}}(\mathbf{y})$ are defined for *regular parametric models*, that is, for models where in the discrete case the set of $\mathbf{y}$, where the probability function $p(\mathbf{y}, \boldsymbol{\theta}) = \Pr(\mathbf{Y} = \mathbf{y})$, is nonzero does not depend on $\boldsymbol{\theta}$, and in the continuous case $\mathbf{Y}$ has a density $p(\mathbf{y}, \boldsymbol{\theta})$. It is also assumed that $p(\mathbf{y}, \boldsymbol{\theta}) < \infty$ for all $\mathbf{y} \in R^n$ and all $\boldsymbol{\theta}$ in Θ, where the parameter set Θ of possible $\boldsymbol{\theta}$ is a subset of R^k for some k. If $\mathbf{y} = (y_1, \ldots, y_n)$ are data values obtained in a study, the **likelihood** function $L_{\mathbf{y}}(\boldsymbol{\theta})$ is defined as the function of $\boldsymbol{\theta}$ given by $L_{\mathbf{y}}(\boldsymbol{\theta}) = p(\mathbf{y}, \boldsymbol{\theta}), \boldsymbol{\theta} \in \Theta$. A *maximum likelihood estimator* (mle) of $\boldsymbol{\theta}$ is a value $\hat{\boldsymbol{\theta}} = \hat{\boldsymbol{\theta}}(\mathbf{y})$ which satisfies $L_{\mathbf{y}}(\hat{\boldsymbol{\theta}}) = \max\{L_{\mathbf{y}}(\boldsymbol{\theta}) : \boldsymbol{\theta} \in \Theta\}$. The maximum likelihood estimator of $[q_1(\boldsymbol{\theta}), \ldots, q_r(\boldsymbol{\theta})]$ is defined as $[q_1(\hat{\boldsymbol{\theta}}), \ldots, q_r(\hat{\boldsymbol{\theta}})]$. The maximum likelihood estimator $\hat{\boldsymbol{\theta}}$ is obtained as the solution to the *likelihood equations*

$$\frac{\partial}{\partial \theta_j} l_{\mathbf{y}}(\boldsymbol{\theta}) = 0, \quad j = 1, \ldots, m,$$

where $l_{\mathbf{y}}(\boldsymbol{\theta}) = \log L_{\mathbf{y}}(\boldsymbol{\theta})$.

For example, if $Y_1, \ldots, Y_n$ are independent, identically distributed with normal (μ, σ^2) distribution, then

$$l_{\mathbf{y}}(\boldsymbol{\theta}) = -\tfrac{1}{2}n \log(2\pi) - n \log \sigma - \tfrac{1}{2}\sigma^{-2} \sum (y_i - \mu)^2$$

and the maximum likelihood estimators are easily shown to be $\hat{\mu} = \overline{y}$ and $\hat{\sigma}^2 = n^{-1} \sum (y_i - \overline{y})^2$. In the trinomial Hardy–Weinberg example with $p_1 = \theta^2$, $p_2 = 2\theta(1 - \theta)$, $p_3 = (1 - \theta)^2$, we have

$$L_{\mathbf{n}}(\theta) = p(\mathbf{n}, \theta) = P(\mathbf{N} = \mathbf{n}, \theta) = \frac{n!}{n_1! n_2! n_3!} \theta^{2n_1} [2\theta(1 - \theta)]^{n_2} (1 - \theta)^{2n_3},$$

where $n = n_1 + n_2 + n_3$. Solving the likelihood equation $l'_{\mathbf{n}}(\boldsymbol{\theta}) = 0$, we find the mle $\hat{\theta} = \hat{p}_1 + \frac{1}{2}\hat{p}_2$, which we recognize as the third plug-in method estimator in the section on the Frequency Plug-in Method above.

Bayesian Estimators

In **Bayesian** models a distribution $\pi(\theta)$, called a **prior distribution**, is introduced for the parameter $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$. In the discrete case, $\pi(\boldsymbol{\theta})$ is the probability function of $\boldsymbol{\theta}$ and in the continuous case it is the density. The probability function (discrete case) or density (continuous case) of the data $\mathbf{Y} = (Y_1, \ldots, Y_n)$ now represents the conditional distribution of $\mathbf{Y}$ given $\boldsymbol{\theta}$, and is written $p(\mathbf{y}|\boldsymbol{\theta})$. The conditional distribution of $\boldsymbol{\theta}$ given the data $\mathbf{y}$ is called the *posterior distribution* of θ and by **Bayes' Theorem**, it is given by

$$\pi(\boldsymbol{\theta}|\mathbf{y}) = c\pi(\boldsymbol{\theta}) p(\mathbf{y}|\boldsymbol{\theta}),$$

where $c^{-1} = \sum_k \pi(k) p(\mathbf{y}|k)$ in the discrete case and $c^{-1} = \int \pi(t) p(\mathbf{y}|t)\, \mathrm{d}t$ in the continuous case. One approach to Bayesian estimation consists of selecting the value $\hat{\boldsymbol{\theta}} = \hat{\boldsymbol{\theta}}(\mathbf{y})$ that makes the observed $\mathbf{y}$ most "probable" according to the posterior distribution $\pi(\boldsymbol{\theta}|\mathbf{y})$, that is, it is a value of $\boldsymbol{\theta}$ that maximizes $\pi(\boldsymbol{\theta}|\mathbf{y})$. Another approach is to use the value $\boldsymbol{\theta}_B$ that minimizes the posterior **mean square error**. That is,

$$\boldsymbol{\theta}_B = \arg\min \mathrm{E}[(\boldsymbol{\theta}_B - \boldsymbol{\theta})^2|\mathbf{y}] = \mathrm{E}(\boldsymbol{\theta}|\mathbf{y}) = \text{the posterior mean.}$$

Unbiased Estimation. Residual Sum of Squares

The error in using the observable $\hat{\theta}$ to estimate the unknown θ is $\hat{\varepsilon} = \hat{\theta} - \theta$. In many cases it is possible to adjust estimators so that their long-run average error is zero, that is, so that $\mathrm{E}(\hat{\varepsilon}) = 0$. Such estimators are called **unbiased**. For example, consider the parameter $\sigma^2 = \mathrm{var}(Y)$. Suppose $Y_1, \ldots, Y_n$ are independent identically distributed, then we arrived earlier at the estimator $\hat{\sigma}^2 = n^{-1} \sum (Y_i - \overline{Y})^2$. With a little algebra it can be shown that $\mathrm{E}(\hat{\sigma}^2) = [(n - 1)/n]\sigma^2$, and $\hat{\sigma}^2$ is not unbiased. There is a debate as to whether unbiased estimation is desirable. However, a nearly universal tradition has developed

where variances are unbiasedly estimated. In our case, this amounts to adjusting $\hat{\sigma}^2$ by multiplying it by $(n-1)/n$. That is, σ^2 is unbiasedly estimated by

$$S^2 = (n-1)^{-1} \sum (Y_i - \overline{Y})^2.$$

As another example, consider the linear model

$$Y_i = \beta_0 + \sum x_{ij}\beta_j + \varepsilon_i, \qquad \mathrm{E}(\varepsilon_i) = 0,$$

$$\sigma^2 = \mathrm{var}(Y_i) = \mathrm{var}(\varepsilon_i).$$

Here $\varepsilon_1, \ldots, \varepsilon_n$ are independent identically distributed. When the design matrix $\mathbf{X}_\mathrm{D} = (x_{ij})$ has rank $p+1$, the unbiased estimator of σ^2 is $RSS/[n-(p+1)]$, where RSS = residual sum of squares is defined by

$$\mathrm{RSS} = \sum_i \left[Y_i - \sum_j x_{ij}\hat{\beta}_j \right]^2$$

(*see* **Multiple Linear Regression**). Here $\hat{\beta}_0, \ldots, \hat{\beta}_p$ are the unweighted [$\mathbf{W}$ = weight matrix = diag(1, $\ldots$, 1)] least squares estimators of $\beta_0, \ldots, \beta_p$.

Standard Errors

It is crucial to provide a measure of the accuracy of estimators. The *error* in using $\hat{\theta}$ to estimate θ is $\hat{\varepsilon} = \hat{\theta} - \theta$. Suppose that $\hat{\varepsilon}$ has an expected value close to zero in the sense that $\sqrt{n}\mathrm{E}(\hat{\varepsilon}) \to 0$ as $n \to \infty$. Then a measure of how close the distribution of the error is concentrated near zero is given by the standard deviation $\sigma_0 = \mathrm{sd}(\hat{\varepsilon}) = \mathrm{sd}(\hat{\theta})$ of $\hat{\varepsilon}$. In the parametric case σ_0 is a function $\sigma_0(\theta)$ of θ and in the general case it is a function $\sigma_0(P)$ of the probability distribution P. Thus we can use the estimation methods provided earlier to estimate σ_0. Such an estimate $\hat{\sigma}_0$ of σ_0 is called the **standard error** of $\hat{\theta}$, and it is written as $\mathrm{se}(\hat{\theta})$.

For example, if $Y_1, \ldots, Y_n$ are independent identically distributed, then for estimating the mean μ, $\mathrm{sd}(\overline{Y}) = \sigma/\sqrt{n}$ and $\mathrm{se}(\overline{Y}) = S/\sqrt{n}$, where $S^2 = (n-1)^{-1}\Sigma(Y-\overline{Y})^2$. In the trinomial Hardy–Weinberg case, $\hat{\theta} = \hat{p}_1 + \frac{1}{2}\hat{p}_2$ and it can be shown that $\mathrm{var}(\hat{\theta}) = (2n)^{-1}\theta(1-\theta)$. It follows that $\mathrm{se}(\hat{\theta}) = [(2n)^{-1}\hat{\theta}(1-\hat{\theta})]^{1/2}$.

In the linear model $Y_i = \beta_0 + \Sigma x_{ij}\beta_j + \varepsilon_i$, with $\sigma^2 = \mathrm{var}(\varepsilon_i)$, the covariance matrix of the (unweighted) least squares estimator $\hat{\boldsymbol{\beta}}$ is $\mathrm{cov}(\hat{\boldsymbol{\beta}}) = (\mathbf{X}_\mathrm{D}^\mathrm{T}\mathbf{X}_D)^{-1}\sigma^2$. The standard error of $\hat{\beta}_j$ is then $\sqrt{v_j}S_p$, where v_j is the jth diagonal element of $(\mathbf{X}_\mathrm{D}^\mathrm{T}\mathbf{X}_\mathrm{D})^{-1}$ and $S_p^2 = \mathrm{RSS}/n - (p+1)$ is the unbiased estimator of σ^2.

Comparison of Estimators: Efficiency

For any given unknown $q(\boldsymbol{\theta})$ there are many possible estimators. The preferable estimator is the one that makes the most efficient use of the data; that is, the estimator $T(\mathbf{Y})$ of $q(\boldsymbol{\theta})$ should be such that the distribution of the error $\hat{\varepsilon} = T(\mathbf{Y}) - q(\boldsymbol{\theta})$ is as closely as possible concentrated near zero. There are many ways of making this idea precise. The most common is to try to minimize the long-run squared error, that is, to minimize the *mean squared error (mse)*:

$$M(T;\boldsymbol{\theta}) = \mathrm{E}[T(\mathbf{Y}) - q(\boldsymbol{\theta})]^2.$$

The mse can be decomposed into a "systematic error" represented by the square of the bias $B(T;\boldsymbol{\theta}) = \mathrm{E}[T(\mathbf{Y}) - q(\boldsymbol{\theta})]$ and the intrinsic variability represented by the variance $V(T;\boldsymbol{\theta}) = \mathrm{var}(T(\mathbf{Y}))$. Thus

$$M(T;\boldsymbol{\theta}) = B^2(T;\boldsymbol{\theta}) + V(T;\boldsymbol{\theta}).$$

For instance, suppose $Y_1, \ldots, Y_n$ are independent identically distributed random variables that represent the survival times of n patients in a medical study. If the distribution is **exponential**, we can write the survival function $S(y) = P(Y > y)$ as $\exp\{-y/\theta\}$, where θ is the mean survival time $\mathrm{E}(Y)$. It is easy to see that the mle of θ is $\overline{Y} = n^{-1}\Sigma Y_i$. Thus the mle of $q(\theta) = \exp\{-y/\theta\}$ is

$$T(\mathbf{Y}) = q(\overline{Y}) = \exp\left\{\frac{-y}{\overline{Y}}\right\}.$$

Since $2\sum_1^n Y_i/\theta$ has a **chi-square distribution** with $2n$ **degrees of freedom** (χ^2_{2n}), **numerical integration** will yield the systematic error (bias) and variance of $T(\mathbf{Y})$. On the other hand, good approximations can be obtained from the expansion

$$q(\hat{\theta}) \cong q(\theta) + q'(\theta)[\hat{\theta} - \theta] + \tfrac{1}{2}q''(\theta)[\hat{\theta} - \theta]^2$$

and the first four moments of the χ^2_{2n} distribution. Such computations yield insight into the components of the mse of $T(\mathbf{Y})$. However, it is useful to have general results to check whether a given estimator

can be improved upon. One such result for parametric models is the **information** *inequality*

$$\text{var}[T(\mathbf{Y})] \geq \frac{[\psi'(\theta)]^2}{I(\theta)}, \tag{1}$$

where $\psi(\theta) = \text{E}[T(\mathbf{Y})]$ and

$$I(\theta) = \text{E}\left\{\left[\frac{\partial}{\partial\theta}\log p(\mathbf{Y},\theta)\right]^2\right\} \tag{2}$$

is the *Fisher information* of the model with probability function (discrete case) or density function (continuous case) $p(\mathbf{Y},\theta)$. If $Y_1,\ldots,Y_n$ are independent, identically distributed, then $I(\theta) = nI_1(\theta)$, where $I_1(\theta)$ is the expression (2) with $\mathbf{Y}$ replaced by Y_1. In this case it can be shown (e.g. [6]) under general conditions that if $\hat{\theta}$ is the mle, then $n^{1/2}[q(\hat{\theta}) - q(\theta)]$ is asymptotically normal with mean zero and variance $[q'(\theta)]^2/nI(\theta)$. That is, in the limiting distribution, $\sqrt{n}$ (bias) is zero and n (var) reaches the lower bound in (1). (However, it should be remembered that the variance in the limiting distribution is not always equal to the limit of the variance.) This analysis is used to conclude that in the preceding sense, the mle $q(\hat{\theta})$ is an asymptotically optimal (most *efficient*) estimator of $q(\theta)$. (There are other asymptotically optimal estimators, e.g. Bayes estimators.) Note that from the above it can be concluded that the standard error of $q(\hat{\theta})$ is $|q'(\hat{\theta})|/[nI(\hat{\theta})]^{1/2}$. The above considerations can be extended to the case of multiple parameters $\theta_1,\ldots,\theta_m$, (e.g. [6]) and to semiparametric models, (e.g. [2]).

Ethics of Randomized Trials

Ethical concerns about human experimentation have been of concern for thousands of years [3, 16]. However, since the Nazi atrocities [12] in the name of medical research, there has been a resurgence of ethical concerns. This has resulted in enactment of codes, guidelines, and laws, including the Nuremberg Code [15], the Declaration of Helsinki [5], and Federal Regulations [7]. In addition, there has been ongoing concern for the ethical dimensions of the patient and physician relationship; as evidenced, for example, by the Hippocratic oath [14]. The ethics of randomized clinical trials (RCTs) deal with a subset of concerns about human experimentation. This article addresses both general and specific ethical concerns.

Philosophical Basis

There are no universally accepted ethical principles to guide experimentation and RCTs in humans, neither through religious revelation and dogma nor through any philosophical system. However, all thoughtful commentators agree that there is a need for guidance. Even in more recent times, there have been examples of behavior that most commentators consider unethical. For example, the Tuskegee study [8] withheld the newly discovered cure for syphilis and continued to observe the natural history of syphilis on humans without obtaining their consent.

In addition to religious revelation, there are two primary approaches to human ethics. During the eighteenth and nineteenth centuries, David Hume, Jeremy Bentham, and John Stuart Mill, among others, developed Utilitarian philosophy as a method of determining appropriate standards for human behavior [2]. This philosophy is sometimes summarized as obtaining the greatest good for the greatest number, or maximizing the sum of human happiness. Utilitarian philosophies advocate acts that result in increasing some measure of utility for the entire human population. At one end of the Utilitarian spectrum each act is assessed for the results for the entire human population (possibly including those yet unborn). Other Utilitarian philosophers argue that it is impracticable to evaluate each act; principles that approximately result in optimal utility should be used. Under most Utilitarian philosophies, RCTs result in good for the greater number of individuals and are justified.

Other, deontologic ethical systems advocate general principles that are appropriate for human behavior. For example, Beauchamp & Childress [2] present four principles for biomedical ethics. The principle of *autonomy* states that there is inherent value in allowing each individual to act as an independent being. The principle of *beneficence* states that one should act for the good of others. The principle of *nonmalfeasance* states that one should avoid doing harm to others. The principle of *justice* states that one should act in a just manner. In the clinical trial area, Pappworth [13] suggests the principle of equality: the investigator should be willing to participate or have family members participate under similar conditions.

Specific codes for the physician have a long history, including the Hippocratic oath [14]. Current important codes for the medical community include the Nuremberg code [15] and the Declaration of Helsinki of the World Medical Congress [5]. Both agree that subjects should be informed of experimentation, that the physician's first responsibility is to her/his patient, and that experiments must not expose subjects to undue risk that is not commensurate with the gain from the experiment. These principles may also be argued from the ethical principles given above [2]. Specific possible implications and dilemmas of current ethical standards are now considered.

Informed Consent

Informed consent was first introduced as a term in case law in 1957 [6], but was emphasized (without the terminology) in the Nuremberg Code [15]. The roots go back at least as far as 1900, when the Prussian minister for religious, educational, and medical affairs issued a directive that the subject had to give "unambiguous consent" after a "proper explanation of the possible negative consequences . . ." [19]. In most countries, informed consent is now a matter of law. In practice, the issue of informed consent is a difficult one, since communication about complex scientific, biologic, medical material is problematic even in the best of circumstances. There are exceptions to requiring informed consent of the experimental subject. In some countries, for minors and individuals who cannot reasonably give an informed consent, those with power of attorney are allowed to give consent. In

other circumstances, where time and situation do not permit informed consent (e.g. during cardiac arrest) separate rules have been developed in some countries to allow research (including RCTs) after appropriate review. Zelen [20] has proposed a design for a standard therapy against a new therapeutic arm. He argues that it is ethical to randomize before talking to the subjects; only those randomized to the new therapy need to give informed consent, since the others would have received the standard therapy if there had been no trial. The ethics of the design *vis-à-vis* informed consent have been considered questionable.

Review of Ethics

A second procedure for protecting patient and subject safety is to require an independent body to review and approve a study before it can begin. In the United States, this independent body is an institutional review board (IRB). For trials under the purview of the US **Food and Drug Administration** (FDA), such boards must satisfy a number of federal regulations (that carry the force of the enabling law [7]). In addition, experiments involving new drugs, biologics (that is, drugs that are compounds naturally occurring in the human body), and devices must have the experimental protocol approved by the FDA as well as an IRB before implementation. In approving experiments with new compounds, both law and the Declaration of Helsinki [5] mandate that appropriate **preclinical** (basic science and animal) studies be performed before beginning human experimentation.

Physician–Scientist Conflict

The most difficult and extensively argued ethical debate about clinical trials and medical experimentation is the real or perceived conflict between the physician's duty to put the patient's welfare and treatment first and the scientist's desire to obtain adequate and well-controlled experimental data. In a RCT the physician has delegated to a statistical, or random, assignment his role of collaboratively deciding with the patient the best diagnostic or therapeutic approach (*see* **Randomization**; **Randomized Treatment Assignment**). To some this is viewed as a potentially morally unacceptable role for the physician; for example, Hellman & Hellman [11] mention that the conflicting physician roles arise "from the classic conflict between rights-based moral theories and utilitarian ones". Some argue that randomization is appropriate if the physician is in *equipoise*; that is, the physician truly has no preference as to the best treatment. It has also been argued that it is enough that there be "clinical equipoise" [10]; that is, "if there is genuine uncertainty within the expert medical community – not necessarily on the part of the individual investigator – about the preferred medical treatment". A large group of **AIDS** researchers has advocated the use of "the uncertainty principle" [4]:

> Patients and physicians can be encouraged to participate in randomized clinical trials by adhering to the uncertainty principle and understanding the limited circumstances in which randomization may not be appropriate. By the uncertainty principle, we mean the principle that a trial should be open only to patients for whom the choice of a treatment remains substantially uncertain.

In addition, if a treatment is known but the consequences of no treatment are reversible and moderate – for example, a headache, with the possibility of rescue medication – one can argue under certain circumstances that the risk–benefit ratio still allows a randomized trial.

Approximate equipoise may be considered a reasonable requirement to *begin* a trial. However, as any small amount of additional evidence becomes available an exact individual equipoise would be lost. Thus complete equipoise cannot reasonably be maintained throughout a RCT, even though it holds at the beginning of the trial. For this reason, RCT investigators must address the potential conflict between a health researcher's or physician's responsibilities to her or his patient and the physician's responsibilities as a scientist. If a physician has an overriding obligation in every circumstance to recommend the "best therapy", no matter how lacking or slender the scientific evidence, then most RCTs are probably unethical. Arguably, such a stance is not good for society as a whole; but proponents of this view argue that ethical considerations of the patient–physician relationship, or implied contract, must take precedence. On the other hand, if, lacking a reasonable standard of evidence about the risk–benefit ratio of a proposed therapy, it is reasonable to perform human experimentation, then many RCTs are appropriate and ethical. Trials may then continue until a reasonable standard of evidence shows that one of the assigned treatments is efficacious or harmful. Of course, such

trials must have appropriate informed consent. Where informed consent is inappropriate (e.g. with some mental states) or impossible (e.g. in a subject undergoing a cardiac arrest), there is an even greater need for independent review of its ethics. Other RCTs may be appropriate when the risk to the subjects is small compared to the potential gain from the experiment.

Many countries have decided *de facto* that RCTs are ethical if the objective level of scientific evidence about a potential therapy is lacking. In these countries drug, biologic, or device laws restrict the physician's choices until a new therapeutic or diagnostic method has adequate scientific evaluation. Depending upon one's focus, the medical declarations seem to favor either RCTs or the primacy of the physician–patient relationship. For example, the widely quoted and used Declaration of Helsinki [5] notes:

> The Declaration of Geneva of the World Medical Association binds the physicians with the words. "The health of my patient will be my first consideration." The International Code of Medical Ethics declares that, "A physician shall act only in the patient's interest when providing medical care which might have the effect of weakening the physical and mental condition of the patient".

Yet the Declaration of Helsinki also goes on to give principles for medical experimentation and notes that the research "cannot be legitimately carried out unless the importance of the objective is in proportion to the inherent risk to the subject". The tension between what has been called the "clinical imperative" and research seems unlikely to be totally resolvable. For this reason, safeguards about independent review of research proposals and informed consent must be taken most seriously. All individuals, including statisticians, involved in such clinical research have an obligation to insure an ethical RCT (to the extent that they may reasonably be expected to understand the ethical issues).

The theme of the clinical imperative versus the need of society for reasonable evidence of efficacy and safety for medical diagnostic and therapeutic methods has analogs in other areas. Similar balancing of needs between the individual and society exist for eminent domain (the government's right to take property for public use, usually with compensation), mandatory immunization, mandatory service in the armed services, restrictions on smoking, reportable diseases, quarantine, and so on. However, in medical research the issue is more difficult, because of the dual role and commitment of the physician/scientist.

Placebo Treatment Arms

Another related major area of ethical concern in clinical trials is the use of placebo treatment arms (*see* **Blinding or Masking**). Some commentators assert that when there is a known therapy of value, it is unethical to use a placebo (see, for example, [17]). Many scientists involved in RCTs feel that placebos may ethically be used when any adverse outcomes are reversible and the potential gain from the experiment justifies the risk or discomfort to the experimental subjects. For example, trials of analgesics for headache pain or upset stomach and antihypertensive drug trials often use placebos with rescue allowed or required for severe or protracted pain or blood pressures above fixed levels. Because of the many well-known difficulties with active control trials, it has been suggested that "if it is ethical to use a placebo it is unethical not to use one" [9]. There is a consensus that placebos are not ethical in most circumstances when there is a known beneficial treatment that prevents a serious irreversible adverse outcome: in this case active control trials are used.

Trial Monitoring

There is an ethical consensus that trials with a serious, irreversible endpoint must not continue when one treatment of a trial is shown to be superior. The Nuremberg Code [15] states:

> During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probable cause to believe, in the exercise of the good faith, superior skill and careful judgment required of him that a continuation of the experiment is likely to result in injury, disability, or death to the experimental subject.

The Declaration of Helsinki [5] states that "Physicians should cease any investigation if the hazards are found to outweigh the potential benefits". In RCT practice, this means that trials with serious, irreversible endpoints must stop when one therapy is "proven" to be superior. This had led to boards or committees, often called Data and Safety Monitoring Boards (DSMBs), that evaluate the study data as the

accumulate. As a result there is a substantial literature on stopping rules for clinical trials (*see* **Data and Safety Monitoring**). Because investigators delegate their ethical responsibility to monitor accumulating data for patient harm or benefit, the ethical responsibility and pressure is assumed by such boards. By current guidelines, the DSMBs consider a therapy not proven to be efficacious or harmful when the trial data are very close to reaching a stopping criteria but have not reached a stopping criteria, but consider the result as decisive with a small amount of additional data that are sufficient to satisfy such a criterion (with all other factors supporting this interpretation). It should be emphasized that the statistical stopping rules are only guidelines; a DSMB must consider all relevant information (including, but not restricted to, other trials of the same treatment or related treatments, biologic reasoning and plausibility, and other possible explanations, such as imbalance between treatment arms, unblinding, and so on).

Experimental Design

The Nuremberg Code [15] asserts that "The experiment should be such as to yield fruitful results for the good of society ...". It has been argued that this implies that an experiment must have a sound **experimental design**, including appropriate statistical analysis plans and adequate statistical power. Others feel that pilot studies do not need to have enough statistical power to meet the usual standards of proof under important **alternative hypothesis**. As a member of the research team in a RCT, the biostatistician should insure an appropriate experimental design.

Professional Conduct

Both the **American Statistical Association** [1] and the **Royal Statistical Society** [18] publish guidelines for the practice of statistics. Both guidelines address the need to respect privacy, although the majority of the points made refer to more general statistical practice. The Declaration of Helsinki [5] states that "In publication of the results of his or her research, the physician is obliged to preserve the accuracy of the results". All of the ethical strictures on the collection, analysis and reporting of data [1, 18] hold for RCT data (*see* **Data Management and Coordination**). This is particularly important, since there are often powerful scientific career or financial pressures on biostatisticians involved in the conduct, analysis, presentation, and review of RCT results.

Ethnic Groups

The word "ethnic" is defined in *Webster's Unabridged Dictionary* as "designating or of any of the basic divisions or groups of mankind, as distinguished by customs, characteristics, language, etc.". Technically, the word "racial" has a more biological or genetic definition. However, by custom, these terms have come to be used interchangeably. Since the issues related to study design and data analysis are the same for either "ethnicity" or "race", this distinction is not important for the present discussion. In most contexts, an individual's ethnicity is either self-declared or assigned on the basis of nativity, ancestral origin, or some other observable characteristic.

Ethnicity is an important variable in human studies because of the substantial differences in risk among ethnic groups for many chronic diseases, both infectious (e.g. hepatitis B, AIDS) and noninfectious (e.g. heart disease, cancer). These ethnic disparities may be explained by differences in the prevalence, intensity or type of exposures to environmental or behavioral factors, such as cigarette smoking or diet, that are causally related to the disease. They may also be due to certain inherited genetic variations (*see* **Genetic Epidemiology**) acting as modifiers of these associations (e.g. in genes involved in metabolic activation or detoxification of drugs and carcinogens), or they may result from an increased prevalence of a major susceptibility gene in a particular ethnic group (e.g. the breast cancer 1 gene in Ashkenazi Jews). Therefore, ethnicity may be considered as either a **confounder** or as an **effect modifier** in research studies.

However, ethnicity is generally not a simple variable to manage. It is usually classified as a **nominal** variable, although division into degrees of adherence to cultural traditions or extent of genetic admixture is sometimes possible. Data sources often agglomerate distinct ethnic groups into assemblages that are not meaningful for a particular study, yet cannot be disaggregated. For example, the US census combines Asians with Pacific Islanders, each of which is itself a heterogeneous mix of genetic and cultural groups. Assessment of ethnicity can lead to substantial **misclassification**, because individuals of mixed ancestry may only partially identify their origins, or, if the characterization is based on appearance, it may be misassigned. A further problem when using existing data sources in an analysis is lack of comparability in definition between two or more sources of ethnic information. For example, the computation of cancer incidence rates utilizes data from tumor registries (*see* **Disease Registers**) for the numerators and **census** data for the denominators; the basis for classifying individuals in these two sources often varies.

Despite the difficulties in accurately assigning ethnicity, research studies can often be enhanced by including different ethnic groups. For example, by doing so, the extent of variation in exposure variables is generally increased, and this can be helpful to the research in appropriately combined analyses. An examination of similarities and differences across ethnic groups may also offer new clues to etiology, and may help to elucidate the role of genetic factors in disease occurrence. Furthermore, ethnic-specific analyses are sometimes important for public health, economic, or other nonbiological reasons.

The way ethnicity is dealt with in study design and data analysis depends on whether it is considered as a confounder or an effect modifier, and on the sample composition. To begin with, if few in number, subjects of some ethnic backgrounds may be excluded altogether. Sample size requirements for the ethnic groups studied will differ depending on whether ethnicity is considered as an adjustment variable or an interaction variable. Also at the design stage, a matched **case–control** design or oversampling may be used to ensure balanced representation of smaller ethnic groups, a desired feature even if ethnicity is merely an adjustment variable. If an unmatched design is preferred, or in a prospective study, ethnicity is usually adjusted for in the analysis, either by **stratification** or by introducing dummy variables in a **multivariate analysis**. However, the danger of **overmatching** or overadjusting must be considered when ethnicity is thought to be on the same etiologic pathway as the dependent variable. An unmatched design must also be used if a residual association with ethnicity is to be tested for, after adjustment for other independent risk factors.

In summary, ethnicity is an important variable for classifying individuals in biomedical research. It is often an indicator of group exposure or genetic differences that may be important in disease causation. It is also a major confounding factor, which can be adjusted for either in the design or analysis stage of a study.

Eugenics

The study of human biology as an intellectual and academic discipline expanded vigorously during the late nineteenth century, largely in response to the publication of Charles Darwin's *On the Origin of Species by Means of Natural Selection* in 1859 and *The Descent of Man* in 1871. Two significant consequences of the introduction of evolutionary theory were the birth of the Eugenics Movement and the emergence of the concept of social Darwinism. The Eugenics Movement was founded by **Francis Galton**, **Karl Pearson**, and their colleagues at the Galton Laboratory for National Eugenics in London. These investigators concentrated their inquiries on the perpetuation of traits that they held to be preferable in the human species. These traits, under the idea of social Darwinism, included personal qualities of "talent" and "natural ability" observed more frequently in classes of persons regarded as socially "fit". Excluded were the many undesirable traits that abounded among lower social classes that were regarded as socially "unfit". Galton coined the term "eugenics" in 1883, deriving it from Greek roots meaning "good in birth", and intending the word to describe a scientific inquiry into describing and improving the genetic endowment of man [13].

The theory and practice of eugenics quickly expanded to the US. In 1910 the leading American eugenicist, Charles B. Davenport, founded the Eugenics Record Office (ERO) at Cold Spring Harbor, New York, and installed Harry H. Laughlin as the director. The ERO became the center of eugenic research in the US and was generously funded from numerous sources, including the fortunes of the Rockefeller, Harriman, and Carnegie families [13]. American eugenic research followed two distinct but related lines of inquiry: first, the documentation of the transmission of biological and social traits in succeeding generations of particular families, and, secondly, the development of social and scientific policies and legislation that would support biological solutions to the unwanted perpetuation of undesirable human traits.

The activities of both the British and the American schools of eugenics proceeded in tandem with the development of eugenic theory in Germany. The unique nature of German eugenics as a social force rested in large measure on the position of most eugenicists as members of the respected and revered university-based academic elite. Although many supporters of German eugenics were not affiliated with university communities [15], the strength of the movement was solidly established in the German universities – a fact that afforded credibility and acceptability to professional writings and public policies about the inequalities of man [10].

As the study of eugenics expanded, several lines of inquiry were pursued at different times, in various locations. These more circumscribed areas of research included, early on, intense investigations of the physical traits of man, accompanied by interpretations about the relationship between physical attributes and social qualities. Somewhat later, numerous social traits received close attention and analysis, as did mental traits, including intelligence, mental retardation, and several types of mental illness. As the Eugenics Movement reached its peak, underlying theories and historical policies became the justification for "directed medical killing" [14], barbarous medical experimentation [17], and racial genocide [16].

Physical Traits

Curiosity about hereditary physical differences among human beings has been documented since the writings of the ancient Greeks, including Hippocrates, who noted, for example, the familial nature of baldness, blue eyes, and "long" heads [20]. As scientists raced to investigate the implications of social Darwinism in the last decades of the nineteenth century, they amassed enormous sets of data on the size of the brain in humans and primates and were able to conclude that the larger brains "in men than women, in eminent men than in men of mediocre talent", reflected the superior intelligence of talented men. The practice of weighing brains evolved in the late nineteenth century into more sophisticated measurements of myriad body parts as the science of **anthropometry** emerged. Calipers became standard investigative tools as investigators sought to correlate physical characteristics with social traits, and anthropometry enjoyed a period of dubious glory in the late nineteenth century with the studies of the Italian anthropologist Cesare Lombroso, who concluded that "[c]riminals are the apes in our midst, marked by anatomical stigmata of atavism", such that criminality and guilt could be reasonably predicted from

physical measurements in certain groups including the handicapped and Gypsies [11]. These early methods found new applications in the 1930s and 1940s when the Nazis used anthropometry to support racial classifications and segregation.

Social Traits

The leap from anthropometry and criminality to a plethora of other social characteristics was a short one. At the time when Lombroso was measuring the bodies of criminals and promoting the elimination of these persons from society, eugenicists in the Galton Laboratory were noting the concentration of talent among the educated classes of the British population. Decades before the rediscovery of **Mendel's laws** of single gene inheritance, Galton, in 1869, published his concepts of eugenics and the origins of "natural ability" under the title, *Hereditary Genius: An Inquiry into Its Laws and Consequences* [13]. British investigators noted two centuries of numerous blood relatives in the ranks of jurists and statesmen, artists and musicians, politicians and military leaders, and scientists and humanists. These observations were used to support conclusions about the hereditary superiority of these more accomplished classes of human beings.

While the Galton Laboratory collected data on those who excelled, eugenicists on both sides of the Atlantic were documenting the familial nature of a number of less attractive social traits in the human population. The most notable account of social pathology was the study of seven generations of the Juke family of New York, published by Richard Dugdale in 1877, and confirmed in a follow-up study some 40 years later [8]. The Jukes were documented to be a family of criminals, prostitutes, and social misfits, characterized by personal traits of "feeblemindedness, indolence, licentiousness, and dishonesty". Similar studies of other social traits expanded the reach of genetics and social Darwinism to alcoholism, pauperism, insanity, and communicable social diseases. The possibility that traits of social degeneracy could be related to the dismal living circumstances of legions of families in the early twentieth century was either unrecognized or ignored as the proponents of eugenic theory looked to future control of the propagation of these unfortunate human groups.

From an analytic point of view, the major difference between British and American approaches was the biometric approach of the British in their analysis of metric traits, contrasted to the intense compulsion of the Americans to document a monogenic etiology of familial social traits. Of importance to the followers of Galton were principles of **correlation** and **regression to the mean**, both of which added strength to ideas of hereditary social degeneracy and decline. American eugenics, however, found support in suggestions that complex traits, or qualities, could be determined by simple modes of single gene inheritance. Thus, for example, the tendency of seafaring fathers to have seafaring sons was attributed to a single gene for a trait that was designated thalassophilia, as was nomadism, or the impulse to wander, among the Comanches, the Gypsies, and the Huns.

Mental Traits

In addition to physical and social traits, the familial nature of mental traits was also scrutinized by researchers in eugenics as well as by investigators in psychology and education. Early measures of intelligence were developed by Alfred Binet, a French psychologist, and later refined by British and American investigators, to produce the intelligence quotient (IQ), a measure initially assumed to represent an innate, immutable quality of individual mental acuity. Early studies of intelligence in twins, with application of methods of factor analysis, added credence to claims of the genetic determination of intelligence, an idea supported by the widely read, but fraudulent, reports of Cyril Burt, who claimed to have studied 53 twin pairs who in fact had never existed. Significant applications of intelligence testing in the American military suggested that most white American males were of very low intelligence, and tests used in American immigration procedures purported to prove that immigrants from southern Europe and eastern Mediterranean countries were of consistently lower intelligence than immigrants from northern Europe. More recent studies continue to support claims of substantial genetic differences among races in the development of intelligence [12].

Tests of mental capacity were also used to define the mental status of persons who were mentally retarded, and individual scores were used to assign

the retarded to groups of morons, imbeciles, or idiots, depending on the degree of mental deficiency. (This language was later replaced by less pejorative terms of mild, severe, and profound retardation.) Retarded children born to parents of limited mental capacity lent credence to claims of the predominantly hereditary nature of mental deficiency, although some studies continued to indicate the significant role of environmental influences in the development of mental abilities. Complex and conflicting evidence for monogenic, polygenic, and environmental contributions to the phenotypes of mental retardation led to exhaustive studies by Lionel Penrose in the 1930s into the sources of retardation among the patients at the Royal Eastern Counties' Institution in Colchester, England. Penrose confirmed the hereditary nature of some monogenic diseases, including phenylketonuria, congenital hypothyroidism, Huntington's disease and others. He also noted the similarities among patients with Down's syndrome and the increased frequency of these children born to older mothers. But, he noted, most patients appeared to suffer from retardation that arose in combinations of environmental, pathological, and genetic factors, and he cautioned against facile labeling of patients without firm justification.

In contrast to the diverse etiologies of mental retardation, mental illness includes a number of organic pathological processes that underlie such diseases as schizophrenia, depression, and manic-depression. While early family studies of these illnesses noted significant clustering in certain families, suggesting single gene inheritance, later introduction of sound epidemiologic principles and correction for ascertainment bias have reduced the figures for disease frequency and recurrence risks and have implied multifactorial etiologies for these disorders [13]. Mental illnesses have also been the subject of twin studies (*see* **Twin Analysis**) that have generally verified a significant genetic contribution to disease phenotypes, as well as a greater risk to closely related persons who share similar environments [20].

Providing care for the mentally retarded and mentally ill has progressed hesitantly over much of Western history. In ancient times, the burden of caring for defective infants was often eliminated when the infants were exposed and abandoned. In later centuries, placing the backward child in the care of an incompetent nurse often hastened the end of the child's existence [7]. Society later assumed the responsibility of caring for these unfortunate persons, although early institutional care consisted of little more than providing separate warehouses for male and female patients. As the Eugenics Movement gathered momentum, however, proponents of improving the genetic endowment of man advocated more permanent methods of genetic control among the mentally disabled, particularly surgical sterilization of both men and women whose continuing fertility could result in further generations of mentally deficient persons. These suggestions became the subject of legislation in some 28 American states before 1931, and tens of thousands of mental patients were forcibly sterilized under these statutes [18]. The propriety of sterilization programs for eugenic purposes was reinforced in 1927 when the United States Supreme Court upheld a Virginia sterilization statute by noting that "three generations of imbeciles are enough" [5]. These programs continued into the 1960s, long after the Supreme Court reexamined the issue of reproductive rights in 1942 and found the right to procreate to be a fundamental right, deserving of the strictest constitutional protection [19]. Finally, during the years of legislatively sanctioned sterilization programs, voluntary sterilization was generally encouraged among families in the general public who had mentally retarded or otherwise severely deficient children or were at risk of having such children in the future.

Racial and Ethnic Traits

From its inception the Eugenics Movement was dedicated to the proposition of ranking and valuing human groups on the basis of racial and ethnic characteristics, although distinctions among racial, ethnic, and even national origins were often indistinct. Pearson, for example, noted that Jewish youth in London's East End were quite as intelligent as Gentiles but tended to be physically inferior and somewhat dirtier. Davenport regarded the Poles, the Irish, the Italians, and the "Hebrews" as distinct racial groups. He further concluded that the Poles were "independent and self-reliant though clannish", that the Italians were prone to "crimes of personal violence", and that the Hebrews were "intermediate between the slovenly Serbians and Greeks and the tidy Swedes, Germans, and Bohemians" though given to "thieving". These types of quasi-cultural distinctions were ultimately compiled, along with exhaustive biological

traits, by the German eugenicists Erwin Baur, Eugen Fischer, and Fritz Lenz, who noted, for example, that the "Mediterranean" race was typified by "narrow, long skulls, like the Nordic, but smaller and somewhat wider and steeper forehead", very dark brown to black hair and eyes, and significantly brownish skin; furthermore, this group had "neither the quiet industry of the Mongoloid race nor the initiative and energy of the Nordic people". With respect to Germanic peoples, these authors further noted that the "sturdy, blond race" of Westfalen and Schwaben could be distinguished by their clumsiness, stubbornness, rigidity, and sedentary nature, compared with the "slim, blond race" of more Nordic descent that was more inclined toward thought, discovery, nature, and beauty of form [3]. Both American and European eugenicists consistently agreed that the Negro race represented the nether end of the human racial scale, while the white, Anglo-Saxon, Protestant population of northern Europe represented the fortunate epitome of human evolution. These and thousands of other distinctions, delineated in professional publications and in the popular press, gave substance to human differences and were the foundation for further judgments about the relative value of various groups in the human "hierarchy" [13].

Racial and ethnic distinctions, whether based in fact or fiction, became the foundation for vigorous campaigns to limit immigration, particularly from southern and eastern Europe into the US. Davenport was concerned that the influx of immigrants from these areas, their tendency to have large families, and their subsequent marriage into the American population, would result in making the American population "darker in pigmentation, smaller in stature, more mercurial ... more given to crimes of larceny, kidnapping, assault, murder, rape, and sex-immorality". So fervent was this fear of racial decline that a strong lobby, led by Laughlin, developed for the single purpose of restricting immigration into the US by establishing quotas for immigration from individual European countries. The immigration lobby succeeded in introducing federal legislation that resulted in the Immigration Act of 1924, overwhelmingly passed by Congress and signed by President Calvin Coolidge, who was already on record as noting that "America must be kept American. Biological laws show ... that Nordics deteriorate when mixed with other races" [13] (*see* **Admixture in Human Populations**).

Excesses of National Socialism in Germany

The development of eugenics in Germany during the 1930s and 1940s was the result of a confluence of social and political forces that had been developing for several decades. On the practical side, for example, the German economy had never recovered from the crippling penalties imposed at the end of World War I, and German eugenicists were careful to emphasize, at every opportunity, the interminable and substantial costs of housing and caring for persons with inherited or acquired disabilities and diseases. On the theoretical and intellectual side, from a negative perspective, the university community read and absorbed the early writings of Adolf Jost, who argued that the German "Volk", as a racial–cultural entity, should have the right to kill some individuals in order to preserve the health of the body of the whole Volk. Somewhat later, Karl Binding and Alfred Hoche, a jurist and a psychiatrist, argued that the state had a right, and perhaps even a duty, to end the lives of people whose "lives were not worthy of life" [4]. Finally, among the innumerable racist and eugenic arguments included in *Mein Kampf* were declarations that the fiscal woes of Germany could, in large measure, be ascribed to the Jews, and that a person's right to life ends when he is no longer capable of fighting for his own health. From a positive perspective, both academic eugenicists as well as the Nazis argued the physical and mental superiority of the Nordic, or "Aryan", race and proposed programs that would encourage qualified individuals and couples to produce children who would be a credit to their German Vaterland.

The academic thrust of eugenics was well established by the time the Nazis assumed power in 1933. Thereafter, the government implemented programs that for the first time legally separated undesirable persons from the body of society through restrictive social legislation about marriage and occupational licenses. Separations from society continued to escalate through legislation and clandestine directives until, in the world of medicine, the mentally retarded and the mentally ill who were cared for in public institutions were targeted for destruction. These patients had such severe disabilities that they were not expected to return to productive lives in German society: these were the "lebensunwertig", the lives "not worthy of life" [1]. As these groups disappeared, the next step was the

annihilation of institutionalized Jews who, though mentally ill, had favorable prognoses for recovery. Medical and anthropological interests soon reached into the concentration camps that filled rapidly with the unwanted in German society, including political detainees, Jews, Gypsies, homosexuals, convicted criminals, and, later, prisoners of war. These vast assemblies provided material for anatomy collections and descriptive studies at major universities and for numerous medical experiments, including investigations of sterilization methods, infectious diseases, the effects of poisons, and the effects of high altitude and extreme cold. The meticulous system of documentation in the German bureaucracy later provided exhaustive information about the nature and extent of Nazi biomedical research and experimentation [6].

The atrocities committed during the Third Reich were the subject of criminal prosecution during the Nuremberg trials, and many of the more prominent leaders of National Socialism were sentenced to death or to long prison terms. While most of the current community of bioethics and medical research continues to acknowledge revulsion at the horrors of Nazi research and experimentation, professionals in many disciplines remain divided over the issue of using various sets of Nazi data in contemporary studies. One conflict that may never enjoy a resolution is whether using these data, on the one hand, gives tacit approval to the barbarous circumstances under which the data were collected, or, on the other hand, gives acknowledgement and value to the lives of the subjects who perished in the experiments [2, 9].

Contemporary Perspective

The Eugenics Movement has a long record of intellectual and racist elitism that in recent decades has lost much of its earlier support. The Movement was founded and nourished by intellectual leaders in Europe and the US, and it enjoyed strong support from persons of political, financial, and social advantage. Early contributions and support from such disciplines as biometrics, genetics, anthropology, evolutionary biology, medicine, psychology, and sociology provided credence to concepts that eventually became major contributing factors to vast programs of social and racial genocide. As the world discovered the unspeakable truth of the Holocaust, the word "eugenics" acquired a tone of terror in the interrelationships of man, a tone that constantly implied the obscene violation of human rights. Only recently, however, have researchers in genetics and bioethics begun to distinguish between eugenics imposed by government and eugenics practiced by individual choice. The former was the source of forced sterilizations, legislation designed to protect "racial purity", programs of "directed medical killing", and ultimately the practice of mass murder. The latter, however, is an integral part of contemporary programs of nondirective **genetic counseling** that are dedicated to moral and legal principles of personal autonomy and individual choice in issues of human reproduction. Eugenics has come full circle, from genuine, though misguided, concern about the health of the human race, through brutal programs of cleansing society of its undesirable elements, to a new concern for human health that allows personal choice about bearing children with genetic impairments.

European Federation of Statisticians in the Pharmaceutical Industry (EFPSI)

The Federation is open to nationally constituted groups of statisticians who are working in or for the pharmaceutical industry (see www.EFSPI.ORG). Thus, EFSPI is engaged in statistical aspects of research, development, production, and **post-marketing surveillance** of drugs, biologics, and medical devices. The objectives of the Federation are (according to the EFSPI constitution):

1. to promote professional standards of statistics and the standing of the statistical profession in matters pertinent to the European pharmaceutical industry
2. to offer a collective expert input on statistical matters to national and international authorities and organizations.
3. to exchange information on and to harmonize attitudes to the practice of statistics in the European pharmaceutical industry and within the member groups

The Federation was constituted and officially launched in August 1992. There are now eleven member groups representing:

Belgium – BVS/SBS	(Belgishe Verening voor Statistiek/Societe Belge de Statistique) – Biostatistics Section
Denmark – DSBS	(Dansk Selskab for Biofarmaceutisk Statistik)
Finland – SSL	(Statistikot Suomen Lääketeollisuudessa)
France – SFdS	Societé Francaise de Statistique – Biopharmacy and Health Group
Germany – APF	(Arbeitsgruppe Pharmazeutische Forschung at German region of International Biometric Society)
Italy – BIAS	(Biometristi dell'Industria-Farmaceutica Associati)
Netherlands – PSDM	(Workgroup Pharmaceutische Statistiek en Datamanagement van Verenining voor Statistiek – Biometrische Sectie)
Spain – ABC if	(Asociacion de Biometria Clinica para la Investigacion Farmaceutia.
Sweden – FMS	(Foreningen for Medicinsk Statistik)
Switzerland – BBS	(Basler Biometrische Sektion of International Biometric Society)
UK – PSI	(Statisticians in the Pharmaceutical Industry)

Thus, 11 European countries, with a total membership of over 2000, statisticians are represented via EFSPI and can be reached by mailings organized by the respective national groups. Links to the individual member organizations can be found via EFSPIs website at www.EFSPI.ORG.

EFSPI has established a number of special interest groups (including one in nonclinical statistics). EFSPI working parties are set up when appropriate to consider specific topical issues. The question of certification of statisticians and the interpretation of the term "qualified and experienced statistician", a description used in regulatory guidelines, have been considered. The initial results of the working party were published in 1999 in *Drug Information Journal* [1].

The main activities of the Federation, however, have been concerned with guidelines for, and other regulatory aspects (*see* **Drug Approval and Regulation**) of, statistical issues in **clinical trials**. In recent years, this has involved EFSPI input to a number of guidelines including those issued by the Committee for Proprietary Medicinal Products (CPMP) of the European Community and by the **Food and Drug Administration (FDA)** in the US. These have included guidance documents on good clinical practice [2] and on biostatistical methodology in clinical trials, in general or within specific therapeutic areas. Examples are guidance documents on "Bioavailability and Bioequivalence" and on Points to Consider documents on more specific statistical topics such as for example, "Superiority, Noninferiority and Equivalence", "Validity and Interpretation of Meta-Analysis, and one Pivotal Study", "Missing Data and

Multiplicity Issues in Clinical Trials" and "Baseline Covariates" [3] and [4]. In addition, input has been made to guidelines developed under the International Conference on Harmonization (ICH), which has included guidelines on the structure and content of clinical trial reports, on statistical principles for clinical trials, and on the choice of control group. In each case, review comments have been harmonized between the member EFSPI groups and sent to the regulatory agencies and industry associations as a joint statement.

Activities of EFSPI have been presented at the **International Statistical Institute's** (ISI) 49th Session in Florence and 52nd in Helsinki and at Drug Information Association (DIA) meetings, since 1993 in both clinical and nonclinical areas. In collaboration with DIA, EFSPI contributes to suggestions of topics for the clinical and nonclinical DIA workshops.

Cooperation has been achieved with a number of other organizations, including:

1. the EFPIA (European Federation of Pharmaceutical Industries Association), concerning European regulatory issues
2. the FDA and the PhRMA (Pharmaceutical Research and Manufacturers Association) biostatistics subsection, in the US, concerning regulatory harmonization
3. the DIA concerning scientific publications and conferences
4. the ISCB (**International Society for Clinical Biostatistics**).

EFSPI now has a website `www.EFSPI.ORG`.

European Organization for Research and Treatment of Cancer (EORTC)

The main aim of the European Organisation for Research and Treatment of Cancer (EORTC), which is based in Brussels, is to conduct, develop, coordinate, and stimulate multidisciplinary research in Europe on the experimental and clinical bases of cancer treatment, with the final goal being to develop optimal treatment strategies in order to improve the standards of cancer treatment. It is a scientifically driven organization consisting of a unique pan-European network involving more than 2000 clinical investigators and scientists in some 300 hospitals, laboratories, and research institutions in 31 different countries. In 2003, approximately 6000 new patients were entered into the 130 trials handled at the EORTC Data Center, with more than 800 patients being entered in intergroup trials carried out with other regional, national, or international research groups.

The EORTC was founded in 1962, as an international nonprofit organization under Belgian law, by workers in the main cancer research institutes of the European Common Market countries and Switzerland. In order to provide a central coordination of its **clinical trials**, an EORTC Coordinating Office was established in 1969. Through the efforts of Henri Tagnon and Marvin Zelen and the support of the US National Cancer Institute (*see* **National Institutes of Health (NIH)**), this was transformed into the EORTC Data Center, which was formally launched in January 1974. Located at the Institut Jules Bordet in Brussels, Belgium, it was set up with the help and expertise of a number of American statisticians, including Al Bartolucci, Jim Williams, and Steve George. The last two served as the initial (temporary) directors and principal statisticians. Upon the departure of Steve George in the summer of 1975, Maurice Staquet took over as director, and its first permanent full-time statistician, Richard Sylvester, joined the staff. In 1979, he was named Assistant Director for Biostatistics, a post that he still holds. In 1984, members of the EORTC Data Center edited *Cancer Clinical Trials: Methods and Practice* [1], a very successful book dealing with the methodology of designing, conducting, and analyzing cancer clinical trials.

In 1990, the EORTC Data Center moved to the Brussels campus of the medical school of the Université Catholique de Louvain. A year later in 1991, Françoise Meunier was appointed as Director of the EORTC Central Office/Data Center. In 1995, she was appointed as Director General of the EORTC and Patrick Therasse was appointed as Director of the EORTC Data Center.

Since its inception, the primary role of the EORTC Data Center has been to provide state-of-the-art statistical, medical, **data management**, **quality control**, and computer expertise to some 20 EORTC Clinical Research Groups for the **phase I**, **phase II** and large, **multicenter** phase III clinical trials that they carry out. It has also assumed a major role in **teaching statistics** and the methodology of cancer clinical trials, and has developed Fellowship Programs for the training of statisticians and other scientists.

As of January 2004, there were nine biostatisticians working at the Data Center. Traditionally, its statistical research activities have been applied in nature. In recent years, it has greatly expanded its statistical activities through the development of an applied statistical research program dealing with problems in treatment **outcome research** and **frailty** models, designs for phase II/III trials, nonproportional hazard models (*see* **Survival Analysis, Overview**), design and analysis of **Quality of life** quality of life studies, independent data monitoring committees and interim analyses (*see* **Data Monitoring Committees**), and the design and analysis of biomarker studies (*see* **Molecular Epidemiology**). Statistical methodology and results are discussed in its twice-monthly Stats Club meetings.

Event History Analysis

Introduction

Event history analysis deals with data obtained by observing individuals over time, focusing on events occurring for the individuals. Thus, typical outcome data consist of *times of occurrence* of events and of *types of events* that occurred. Frequently, an event may be considered as a *transition* from one state to another and, therefore, *multistate models* will often provide a relevant modeling framework for event history data. Multistate models are discussed from several points of view in the books by Andersen et al. [10], Blossfeld & Rohwer [18], Courgeau & Lelièvre [26] and Hougaard [45, Chapters 5-6] and Kalbfleisch & Prentice [48, Chapter 8]; see [14, 22, 44] for recent survey papers.

Survival Data

The simplest multistate model is the two-state model for **survival** data with one transient state "0: alive" and one absorbing state "1: dead"; see Figure 1. In general, an *absorbing* state is a state from which further transitions cannot occur, while a *transient* state is a state that is not absorbing. The observation for a given individual will here in the simplest form, consist of a random variable, say T, representing the time from a given origin (time 0) to the occurrence of the event "death". The distribution of T may be characterized by the probability distribution function $F(t) = \text{Prob}(T \leq t)$ or, equivalently, by the survival distribution function $S(t) = 1 - F(t) = \text{Prob}(T > t)$. It is seen that $S(t)$ and $F(t)$, respectively, correspond to the probabilities of being in state 0 or 1 at time t. If every individual is assumed to be in state 0 at time 0, then $F(t)$ is also the *transition probability* from state 0 to state 1 for the time interval from 0 to t. In continuous time, the distribution of T may also be characterized by the **hazard rate** *function*

$$\alpha(t) = \frac{-\,\mathrm{d}\log S(t)}{\mathrm{d}t} = \lim_{\Delta t \to 0} \frac{\text{Prob}(T \leq t + \Delta t \mid T \geq t)}{\Delta t}, \quad (1)$$

that is,

$$S(t) = \exp\left(-\int_0^t \alpha(u)\,\mathrm{d}u\right) \quad (2)$$

(*see* **Survival Distributions and Their Characteristics**).

Thus, $\alpha(\cdot)$ is the *transition intensity* from state 0 to state 1, that is, the instantaneous probability per time unit of going from state 0 to state 1.

In general, event history analysis deals with inference for transition intensities and transition probabilities in multistate models. This includes **estimation** and **hypothesis tests** for these quantities and analysis of **regression** models where these quantities are related to (possibly time-dependent) **explanatory variables** observed for the individuals under study. Most frequently, multistate models are defined by their transition intensities from which transition probabilities may or may not be derived depending on the modeling assumptions. This latter activity is some times denoted *"survival synthesis"*.

A typical feature of event history analysis is the inability to observe complete event histories, for example, by the end of the observation period all individuals under study may not have reached an absorbing state. In survival analysis, this would correspond to individuals still being alive by the end of the study, and this kind of *incomplete observation* is known as *right* **censoring**. Furthermore, all individuals may not have been observed from the same time origin. This kind of incomplete observation where individuals are only observed conditionally on not having reached an absorbing state by the time of initiation of the study is known as *left*-**truncation**. Restricting attention to right censoring, a crucial problem is whether the available incomplete data enables one to make a valid inference on parameters in the multistate model for the complete data. The condition for this is known as *independent* right censoring (*see* **Censored Data**).

Multistate Models

In this section, we will present a number of different multistate models. We will begin with a few heuristic

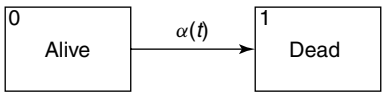

Figure 1 The two-state model for survival data

definitions that may all be made rigorous within the framework of so-called *marked point processes* [10, Chapter III; 16].

A *multistate process* is a **stochastic process** $(X(t), t \in \mathcal{T})$ with a finite *state space* $\mathcal{S} = \{1, \ldots, p\}$ and with right-continuous sample paths: $X(t+) = X(t)$. Here, $\mathcal{T} = [0, \tau]$ or $[0, \tau)$ with $\tau \leq +\infty$. The process has *initial distribution* $\pi_h(0) = \text{Prob}(X(0) = h)$, $h \in \mathcal{S}$. A multistate process $X(\cdot)$ generates a *history* $\mathcal{X}_t$ (a σ-algebra) consisting of the observation of the process in the interval $[0, t]$. Relative to this history, we may define *transition probabilities* by

$$P_{hj}(s, t) = \text{Prob}(X(t) = j \mid X(s) = h, \mathcal{X}_{s-}) \quad (3)$$

for $h, j \in \mathcal{S}, s, t \in \mathcal{T}, s \leq t$ and *transition intensities* by the derivatives

$$\alpha_{hj}(t) = \lim_{\Delta t \to 0} \frac{P_{hj}(t, t + \Delta t)}{\Delta t} \quad (4)$$

which we shall assume exist. Some transition intensities may be 0 for all t. Graphically, multistate models may be illustrated using diagrams with boxes representing the states and with arrows between the states representing the possible transitions, that is, the nonzero transition intensities [10, Section I.3; 43]. A state $h \in \mathcal{S}$ is *absorbing* if for all $t \in \mathcal{T}, j \in \mathcal{S}, j \neq h, \alpha_{hj}(t) = 0$; otherwise h is *transient*. The *state probabilities* $\pi_h(t) = \text{Prob}(X(t) = h)$ are given by

$$\pi_h(t) = \sum_{j \in \mathcal{S}} \pi_j(0) P_{jh}(0, t). \quad (5)$$

Notice that the $P_{hj}(\cdot, \cdot)$ and thereby the $\alpha_{hj}(\cdot)$ depend on both the probability measure Prob and on the history though this dependence has been suppressed in the notation. If $\alpha_{hj}(t)$ only depends on the history via the state $h = X(t)$ occupied at t, then the process is **Markovian**. Sometimes, one is interested in considering an extended history that also includes observed **covariates**. If only time-fixed covariates Z are studied, then the observed history is $\mathcal{F}_t = \mathcal{X}_t \vee \mathcal{Z}_0$, whereas **time-dependent covariates** $Z(t)$ give rise to an extended history of the form $\mathcal{F}_t = \mathcal{X}_t \vee \mathcal{Z}_t$ where, in both cases, $\mathcal{Z}_t$ is the history generated by the covariates in $[0, t]$. We shall here focus on the *purely endogenous* case where $\mathcal{Z}_t \subset \mathcal{X}_t \vee \mathcal{Z}_0$; that is, the covariates are either all time-fixed or the random development of the time-dependent covariates is fully specified by the history of the process itself (see, however, the section " Partial model Specification" for cases with time-dependent covariates that are not endogenous).

The Two-state Model for Survival Data

This model, illustrated in Figure 1, has $p = 2$ states and only one possible transition from state 0 to state 1. The corresponding transition intensity $\alpha_{01}(t)$ is given by the hazard rate function $\alpha(t)$, while $\alpha_{10}(t) = 0$ for all t, that is, state 1 is absorbing. The initial distribution is degenerate in 0: $\pi_0(0) = 1$ and the process is Markovian. Covariates may be entered into the model using a regression model for $\alpha(\cdot)$.

The Competing Risks Model

This model (*see* **Competing Risks**) has one transient state "0: alive" and a number, k, of absorbing states, state $h, h = 1, \ldots, k$ corresponding to "death from cause h". Thus, there are $p = k + 1$ states. The model is illustrated for $k = 2$ in Figure 2.

The transition intensities $\alpha_{0h}(t)$ for $h = 1, \ldots, k$ are given by the cause-specific hazard functions:

$$\alpha_h(t) = \lim_{\Delta t \to 0} \frac{\text{Prob}(\textit{Dead from cause } h \textit{ by } t + \Delta t \mid T \geq t)}{\Delta t} \quad (6)$$

where T is the survival time. The initial distribution is degenerate in 0, the only transient state of the model, that is, $\alpha_{hj}(t) = 0$ for all $h \neq 0$ and all j.

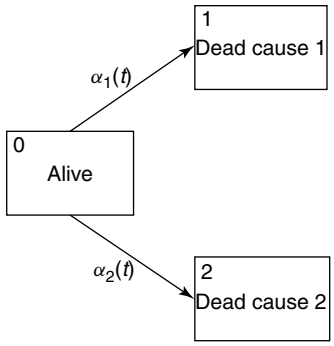

Figure 2 Competing risks model for mortality from 2 causes

The transition probabilities are given by the survival function

$$P_{00}(0,t) = S(t) = \text{Prob}(T > t) = \exp\left(-\int_0^t \sum_{h=1}^{k} \alpha_h(u)\,\mathrm{d}u\right), \quad (7)$$

and the cumulative incidence functions

$$P_{0h}(0,t) = \int_0^t S(u-)\alpha_h(u)\,\mathrm{d}u, \quad h = 1,\ldots,k. \quad (8)$$

Like the simple two-state model ($k = 1$), the competing risks model is Markovian and covariates may be included into the model via regression models for the cause-specific hazards. This model was studied by Andersen et al. [9].

The Illness–death Model

This model (*see* **Aalen–Johansen Estimator**) is illustrated in Figure 3. Often, the time t is the age of the individual, and usually individuals will be assumed to be in state 0 at $t = 0$.

However, individuals will not always be observed from $t = 0$ as shall be further discussed in the sections "Counting Process Representation, Likelihood" and "Statistical Model Specification". The mortality $\alpha_{12}(t)$ of the diseased (the *lethality*) may sometimes depend on duration d since entry to state 1 in addition to the dependence on "age" t. (Notice that, despite the notation, $\alpha_{12}(t)$ then depends on the *random* time of the most recent transition into 1.) If $\alpha_{12}(t)$ does not depend on d the process is Markovian, otherwise it is a **semi-Markov process**, an example of a purely endogenous process.

In Figure 3, we have indicated the possibility of *reversibility*: the transition back from state 1 to 0 is possible. It will turn out that the simple unidirectional model where $\alpha_{10}(t) = 0$ is rather easier to analyze statistically. Thus, the transition probabilities in this model have simple explicit expressions:

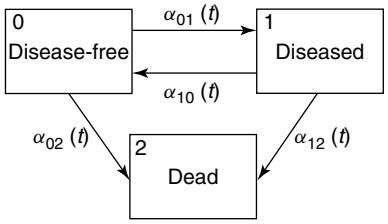

Figure 3 The illness–death or disability model

$$P_{00}(s,t) = \exp\left(-\int_s^t (\alpha_{02}(u) + \alpha_{01}(u))\,\mathrm{d}u\right) \quad (9)$$

and (in the Markovian case)

$$P_{01}(s,t) = \left(\int_s^t P_{00}(s,u-)\alpha_{01}(u)P_{11}(u,t)\,\mathrm{d}u\right) \quad (10)$$

where

$$P_{11}(s,t) = \exp\left(-\int_s^t \alpha_{12}(u)\,\mathrm{d}u\right).$$

More generally, the lethality $\alpha_{12}(\cdot)$ may depend on both age and duration. If we then define

$$\alpha_{12}(t,d) = \lim_{\Delta t \to 0} \frac{\text{Prob}\begin{pmatrix} X(t+\Delta t) = 2 | X(t) = 1, \\ 0 \to 1 \text{ transition at } t - \mathrm{d} \end{pmatrix}}{\Delta t},$$

$P_{11}(u,t)$ in (10) should be replaced by $\exp(-\int_u^t \alpha_{12}(s, s-u)\,\mathrm{d}s)$. The illness–death model is one of the most important multistate models and it was discussed in early papers by Fix & Neyman [31] and Sverdrup [71].

Repeated Events

If interest focuses on repeated occurrences of a given event, for example, hospital admissions, childbirths, infections and so on. then a model as illustrated in Figure 4 (where transitions to an absorbing "Dead" state have been omitted) may be considered. In applications of such a model, an interesting functional is often the expected number of occurrences of the event over the time interval $[0, t]$; see [24] and **Repeated events**.

Interaction Between Life History Events

This Markov model, illustrated in Figure 5, describes the joint behavior of two life events A and B; if $\alpha_{0B} = \alpha_{A,AB}$ but $\alpha_{0A} \neq \alpha_{B,AB}$, A is called *locally dependent on* B but B is not locally dependent on A. The temporal order of events allows for this

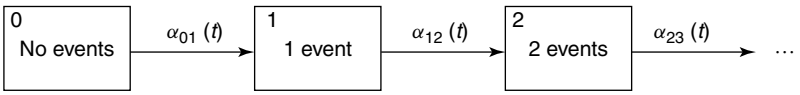

Figure 4 A model for repeated events

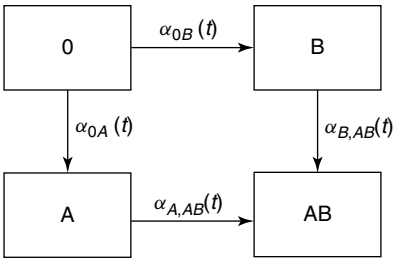

Figure 5 Interaction between life history events

asymmetric concept of dependence, which yields more information for drawing causal inference (*see* **Causal Direction, Determination**; **Causation**) than the standard symmetric association concepts from **cross-sectional studies**. Similar duration dependence as in the illness–death process might be added. A model of this type was discussed by Aalen et al. [6] for a study of interaction between menopause and a certain chronic skin disease; see also [18, 26].

Bone Marrow Transplantation

A model combining most of the above features has been studied in detail (e.g. [56, 58, 60]) as describing some of the possible states of a leukemia patient following bone marrow **transplantation**; see Figure 6.

Patients have been given various kinds of therapy to temporarily keep the disease down, they are said to be in *remission*. In our context these patients are followed since bone marrow transplantation ($t = 0$), initially considered in state 0. Two different types of complications are considered: acute graft-versus-host disease (A), chronic graft-versus-host disease (C), and a special state AC is defined for those patients acquiring both A and C. Patients are followed until relapse of the leukemia (R) or death (D) while still in remission. Relapsed patients are not followed further in this context. If all transition rates depend only on time t since transplantation, we have again a Markov process, but various kinds of duration dependence (semi-Markov process models) may also be relevant.

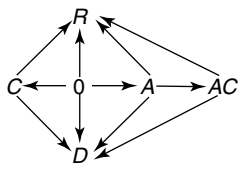

Figure 6 A model for events following bone marrow transplantation: Acute and chronic graft-versus-host disease, relapse and death

Counting Process Representation, Likelihood

Assume that multistate processes $X_i(t)$, such as described in the section "Multistate Models", are observed over intervals $[0, \tau_i]$ for individuals $i = 1, \ldots, n$. Assume, first that τ_i is a fixed (i.e. non-random) time of termination of observation for individual i. Random right-censoring (see the section "Survival Data") and delayed entry are treated below. Since $X_i(t)$ is constant between transitions, it is equivalent to record $X_i(0)$ and the *counting processes*

$$N_{hj}^i(t) = \#\,(\text{direct transitions } h \to j \text{ in } [0,t] \text{ for } i), \tag{11}$$

described by the times T_{hj}^{ik} of these transitions, where

$$0 < T_{hj}^{i1} < \cdots < T_{hj}^{iN_{hj}^i(\tau_i)} \leq \tau_i \tag{12}$$

(*see* **Counting Process Methods in Survival Analysis**).

Let $N_{hj}(t) = \sum_{i=1}^n N_{hj}^i(t)$. It will turn out to be useful to also introduce $Y_h^i(t) = I\{X_i(t-) = h\}$ and

$$Y_h(t) = \#\,(\text{individuals "at risk" in state } h \text{ at time } t-) = \sum_{i=1}^n Y_h^i(t).$$

Note that, for $t > \tau_i$, $N_{hj}^i(t) = N_{hj}^i(\tau_i)$, and $Y_h^i(t) = 0$; these can thus be considered to be defined on $(0, \infty)$.

For individual i, denote the initial distribution $(\pi_h^i(0))$, the density of time-fixed covariates $f(Z_i)$, and the transition intensities $\alpha_{hj}^i(t)$, then the **likelihood** is (see [10, Section III.2])

$$\prod_{i=1}^{n} f(Z_i)\pi_{X_i(0)} \prod_{h\neq j} \prod_{k=1}^{N_{hj}^i(\tau_i)} \alpha_{hj}^i(T_{hj}^{ik}) \times \exp\left(-\int_0^{\tau_i} \alpha_{hj}^i(t) Y_h^i(t)\, \mathrm{d}t\right). \quad (13)$$

It is very common to condition on Z_i and on the initial values $X_i(0)$ (the distribution of which may often be degenerate anyway), and consequently omit the factors $f(Z_i)\pi_{X_i(0)}$ from the likelihood. We shall do so without further comment in the sequel.

Recall from above that the notation $\alpha_{hj}^i(t)$ represents possible dependence of the transition intensity on the whole history $\mathcal{X}_t^i$ of the process. Thus, $\alpha_{hj}^i(t)$ may well contain covariates and other random elements, as already exemplified.

Two patterns of incomplete observations are particularly easily tractable, because they lead to only minor modification of this likelihood: **Delayed entry** where individual i enters at some time V_i, and *right-censoring* where nothing is known about i after some time U_i. Both V_i and U_i may be random although either only dependent on the previous history of the process or independent of the process (see e.g. [10, Chapter 3], for precise specification of this and further discussion). The reason for the particular tractability of these mechanisms is that the "at risk" indicator $Y_h^i(t) = I\{X_i(t-) = h\}$ in the likelihood just needs to be amended to

$$Y_h^i(t) = I\{X_i(t-) = h,\ V_i < t \leq U_i\}. \quad (14)$$

(*see* **Counting Process Methods in Survival Analysis**).

Statistical Model Specification

As indicated in the introduction, the first purpose of event history analysis is to gain insight into the dynamics of the processes by quantifying *transition intensities* and perhaps assessing their dependence on covariates, possibly using various stratifications. Sometimes, additional functionals are useful, particularly various types of *transition probabilities* obtained by integrating certain functions of the transition intensities. A final purpose may be **prediction**, both as illustration of the dynamics and for concrete practical purposes.

Markov Processes

The most important class of models is the (continuous time) *Markov process* $X(t)$ on the finite state space $\mathcal{S} = \{1, \ldots, p\}$, where the dependence of $\alpha_{hj}^i(t)$ on the history $\mathcal{X}_t$, introduced at the beginning of the section "Multistate Models", is only via the current state of $X(t)$ (and possibly via time-fixed covariates). Statistical models are usually obtained by specifying the class of transition intensities $(\alpha_{hj}^i(t))$ for each individual i.

Parametric Models for Transition Intensities. The simplest class of models is obtained by keeping the transition rates *constant*: $\alpha_{hj}^i(t) = \alpha_{hj}^i$. *Piecewise constant* intensities

$$\alpha_{hj}^i(t) = \alpha_{hj}^{i(l)}, \quad t_{l-1}^{hj} < t \leq t_l^{hj}, \quad \text{all } t_0 = 0, \quad (15)$$

form the next step up and this choice is of widespread use, particularly in large studies in econometrics, epidemiology, sociology and demography [10, Section VI.1; 21, 43, 62].

Transition probabilities for the constant and piecewise constant Markov process models are explicit functions of the transition intensities (e.g. [20]), allowing direct "plug-in" **maximum likelihood** estimation, as well as calculation of standard error estimates via the **delta method**.

Although the piecewise constant model is often sufficient to describe the dependence of intensities on time, other possibilities exist. Certain mathematical functions of time may generate the model, such as the Gompertz–Makeham model for mortality (*see* **Aging Models**)

$$\alpha(t) = \alpha + \beta\gamma^t \quad (16)$$

but except for mortality studies in **actuarial** and some **demographic** contexts, such parametric models are used rather little. One reason for this may be the powerful development of methodology for "**nonparametric**" statistical inference, where $\alpha_{hj}(t)$ is left unspecified (*see* **Semiparametric Regression**).

Freely Varying ("Nonparametric") Transition Intensities. Assume first that the transition intensities are the same for all individuals but that they

are allowed to vary freely with time: $\alpha_{hj}^i(t) = \alpha_{hj}(t)$. Statistical inference is then conveniently phrased in terms of the counting process approach pioneered by Aalen [1, 2]; see Andersen et al. [10] for a detailed exposition. Estimators (which may be given a **nonparametric maximum likelihood** interpretation) of the integrated intensities

$$A_{hj}(t) = \int_0^t \alpha_{hj}(u)\,\mathrm{d}u \tag{17}$$

are obtained as the *Nelson–Aalen estimators* (*see* **Nelson–Aalen Estimator**).

An elaborate mathematical theory based on stochastic integrals and martingales is available to study exact and asymptotic properties of these estimators (*see* **Counting Process Methods in Survival Analysis**).

When estimates are desired of the transition intensities $\alpha_{hj}(t)$ themselves rather than their integrals, *smoothing* techniques are necessary (e.g. [10, Section IV.2]) (*see* **Smoothing Hazard Rates**).

An important feature of the nonparametric approach is its elegant generalization (due to Aalen and Johansen [7]) to estimating *transition probabilities*. The basic tool is the (matrix) *product-integral* (*see* **Product-integration**).

Define $\alpha_{hh}(t) = -\sum_{j \neq h} \alpha_{hj}(t)$ and the intensity matrix function $A(t) = ((\alpha_{hj}(t)))$; then the matrix $P(s,t) = ((P_{hj}(s,t)))$ of transition probabilities

$$P_{hj}(s,t) = \mathrm{Prob}(X_i(t) = j | X_i(s) = h) \tag{18}$$

is given by

$$P(s,t) = \Pi_s^t (I + A(\,\mathrm{d}u)). \tag{19}$$

The *Aalen–Johansen* estimator of $P(s,t)$ is obtained by plugging the matrix of Nelson–Aalen estimators $((\hat{A}_{hj}(t)))$ into this formula:

$$\hat{P}(s,t) = \Pi_s^t (I + \hat{A}(\,\mathrm{d}u)). \tag{20}$$

(*see* **Aalen–Johansen Estimator**).

For the simple two-state model for survival data, $\hat{P}_{00}(0,t)$ reduces to the classical **Kaplan–Meier** [49] **estimator** $\hat{S}(t) = \prod_{T_i \leq t}(1 - \mathrm{d}N_{01}(T_i)/Y_0(T_i))$ of the survival function $S(t)$.

As documented in detail by Anderson et al. [10, Section IV.4], there is a well-developed theory, again based on stochastic integrals and martingales, about the asymptotic properties of the Aalen–Johansen estimator.

Markov Regression Models. For Markov models with several states, there will often be too little empirical basis for estimating freely varying transition intensities between all states for all subgroups, so that more **parsimonious** regression models are required. The most frequently used regression models in event history analysis have a multiplicative structure with a baseline $h \to j$ transition intensity $\alpha_{hj0}(t)$, assumed common for all individuals. For an individual, i, with time-fixed covariates $Z_i = (Z_{im})$, the transition intensity is then modeled as

$$\alpha_{hj}^i(t) = \alpha_{hj0}(t) \exp\left(\beta_{hj}' Z_i\right), \tag{21}$$

where the effect of a covariate Z_{im} is described by factors of proportionality $\exp(\beta_{hjm})$. In (21), the baseline hazard may be completely unspecified as in the Cox [27] **proportional hazards** model for survival data (*see* **Cox Regression Model**), or it may be assumed to be piecewise constant leading to **Poisson regression** models. In both cases, inference may be based on the likelihood (13), which for the Cox model leads to the so-called Cox's **partial likelihood** [10, Section VII.2; 28]. The choice between Cox and Poisson models is frequently a matter of convenience, though the latter may be advantageous in large studies where a sufficiency reduction of data into tables of event counts and **person-years** within groups of (categorical) covariates is feasible (e.g. [21, Chapter 31]). In contrast, application of the Cox model requires one data record per individual for each transition.

In (21), the notation suggests that separate baseline hazards and regression coefficients are assumed for each possible transition. If that is the case, then the parameters may be estimated by fitting separate Cox or Poisson models for each transition. However, more parsimonious models may be obtained by assuming some baseline transition intensities proportional (e.g. [56, 58]) or by assuming some covariates to have the same effect on several transitions (e.g. [10, p. 494]). Also, models in which the proportional hazards assumption is relaxed may be considered. In the Poisson case, this is simply an interaction between time and the covariate giving rise to nonproportionality whereas, for the Cox model, the less restrictive model is known as the *stratified* Cox model.

Andersen and Keiding [14] described how such flexible Cox models may be formulated in a way

that shows how standard computer **software** may be applied. In a similar way, Poisson regression models may be analyzed using standard **generalized linear models** software (e.g. [68, 72]).

Another regression model for survival data that readily extends to multistate models is Aalen's [3, 4] nonparametric additive model:

$$\alpha_{hji}(t) = \alpha_{hj0}(t) + \beta_{hj}^{'}(t)Z_i \qquad (22)$$

(see also [10, Section VII.4]; **Aalen's additive regression model**). In this model, both the baseline transition intensities $\alpha_{hj0}(t)$ and the regression functions $\beta_{hjm}(t)$ are left unspecified and nonparametric estimates may be obtained using a generalized **least squares** procedure. Aalen et al. [5] presented a review of this model and its use in multistate models.

"Survival synthesis", that is, combination of the regression estimates for the transition intensities into transition or state probability estimates, may be performed using the product-integral as described by Andersen et al. ([10, Section VII.2.3]; see also [19]). However, except for the simple case of survival data no standard software exists for these computations.

Beyond Markov Processes

The most important deviations from the Markov property in practice are various kinds of **duration dependence**, where transition intensities depend on other time origins than $t = 0$, typically the time at entry to the present state. There are two main approaches to handling these.

As long as transition intensities depend only on one time origin each (e.g. all intensities depend only on duration in the present state), a model for the multistate process may be obtained by combining independent submodels for each transition intensity. These may, in turn, be modeled as constant or piecewise constant or by non- or semiparametric models, and as long as there is a unidirectional flow in the model, transition probabilities are still straightforward explicit functionals that may be estimated by plugging in the intensity estimates. Variance calculations may, however, become less direct.

More elaborate models will include several time origins (such as both age, disease duration, calendar time), often in piecewise constant intensity (Poisson) models or semiparametric regression models such as the Cox model.

In the Poisson models, the various time variables all enter the models as explanatory factors in a symmetrical way (and also symmetrical with respect to the other covariates of the model). However, in Cox models, one of the time variables must be chosen as the "baseline" time variable while the others may be included as time-dependent covariates. The choice of baseline time variable may be governed by several considerations. First, the effect of the baseline time variable is given by the unspecified baseline hazard and, therefore, no regression coefficients are estimated for this variable. Thus, a time variable whose effect is of particular interest may not be the obvious choice as the baseline time variable. On the other hand, if a time variable is suspected to have an irregular effect that may not be easy to model parametrically via a time-dependent covariate, then this time variable may conveniently be chosen as the baseline time variable (e.g. [21, Chapter 31]).

Hypothetical Calculations in Multistate Models

As mentioned earlier, there is often considerable interest in studying the consequences of the estimated transition intensities by calculating summary measures such as transition probabilities. When a full model has been estimated, this can be done not only for the model observed "in this world". Rather, the consequences of an assumed (or fitted) multistate model may be usefully further illustrated by calculating transition probabilities in hypothetical models obtained by changing some of the parameters. An elaborate example of this was given by Keiding et al. [56] for the bone marrow transplantation context; see also [60]. Similar calculations have in fact been performed in the competing risks model ever since the first discussion by Bernoulli [17] of the effect on population mortality of removing smallpox through **vaccination**. The interpretational justification of such calculations was discussed by Gail [34], Prentice et al. [69], Kalbfleisch and Prentice [48, Chapter 7] and Andersen et al. [9].

Partial Model Specification

We have so far assumed that the multistate model was completely specified through statistical modeling of all transition intensities and a specific probability mechanism for the combination of these into transition probabilities. In a series of papers, [25, 65,

66, 67], Pepe and her colleagues have developed estimates of certain functionals in multistate models without assuming a full probability structure. One example is the *prevalence* of a transient condition indicated by state c defined as

$$\frac{P_{0c}(0,t)}{\sum_{j\in\mathcal{T}} P_{0j}(0,t)},$$

where $\mathcal{T}$ is the set of transient states and 0 is a fixed "initial" state. The idea is to estimate numerator and denominator separately by simple linear combinations of Kaplan–Meier estimates. Easily applicable variance estimates are then available, which in one recent application [59], showed that the precision of the Pepe approach was close to the more elaborate (and restrictive) complete Markov model.

Datta and Satten [29], Satten and Datta [70], and Glidden [37] studied the product-integral of the Nelson–Aalen estimator and showed that, also for non-Markovian processes, this combined with the initial distribution $\pi_h(0)$ provides consistent and asymptotically normal estimators for the state probabilities $\pi_h(t)$ (see the section, "Multistate Models").

Andersen et al. [15] showed how regression models for transition probabilities $P_{hj}(s,t)$ or state probabilities $\pi_h(t)$ may be obtained directly in multistate Markov models using **jackknife** pseudo-observations. In fact, their approach may be extended to state probabilities in non-Markovian models using the results of Glidden [37].

Another example of partial model specification occurs when the model contains time-dependent covariates that are not purely endogenous. In fact, for time-fixed covariates, we just (see the section "Multistate Models") conditioned on their observed values without specifying their distribution $f(Z_i)$, but for time-dependent covariates, such a conditioning is more tricky. Formally, the likelihood will contain factors for the stochastic development of $Z_i(t)$, given the history $\mathcal{F}_{t-} = \mathcal{X}_{t-} \vee \mathcal{Z}_{t-}$ and the likelihood (2) is not the full likelihood but only a partial likelihood for the parameters for the transition intensities $\alpha^i_{hj}(t)$. This means that inference for the transition *intensities* may be based on this partial likelihood, whereas the transition *probabilities* will typically depend also on the parameters in the model for $Z_i(t)$.

Thus, if the model contains time-dependent covariates that are not purely endogenous, then transition probabilities cannot be estimated using only a partial model specification. A joint model for the multistate process $X_i(t)$ and the time-dependent covariates $Z_i(t)$ is needed. When $Z_i(t)$ only takes a finite number of values, this joint model could, again, be a multistate model where $Z_i(t)$ is now endogenous (e.g. [8, 13]). Examples of more general joint models were presented by Wulfsohn & Tsiatis [73] and Henderson et al. [40] (see **Joint Modeling of Longitudinal and Event Time Data**).

Kalbfleisch and Prentice [48, Chapter 9] studied intensities obtained from conditioning on a smaller history than that generated by the process itself, particularly within the repeated events framework.

Observational Patterns

As emphasized in the introduction, event history data are rarely observed completely. Some patterns of incomplete observation are more easily handled than others, and this final section aims at introducing some of the more important classes. As mentioned above (see the section "Counting Processes Representation, Likelihood"), independent delayed entry and right censoring only modify the likelihood slightly and the statistical methods then all go through.

Interval Censoring

An important class of incomplete observational patterns consists in the times of some (but often not all) transitions not being known exactly but only up to an **interval**, for example, between visits to a clinic or between censuses. (The *number* of transitions is usually assumed to be known precisely.) A classical approach in demography [41] is to approximate the "exposure"

$$S^i_h = \int_{V_i}^{U_i\wedge\tau_i} Y^i_h(t)\,\mathrm{d}t; \tag{23}$$

another to impute values in the observation interval for the time at risk. Systematic studies of nonparametric maximum likelihood estimation under interval censoring of the healthy $\rightarrow$ diseased transition in the unidirectional illness–death model are by Frydman [32, 33], Joly et al. [46], and Gaüzère [35]. Kay [50] and Andersen et al. [12] exemplified interval-censored observation in the reversible illness–death model, using piecewise constant intensity models. A

particular example is **panel data**; see for example, [36] and the references therein. Interval censoring in multistate models was discussed by Commenges [23], (*see* **Interval Censoring**).

Conditioning in Multistate Models

Many observational patterns in event history analysis may be described by **conditional** distributions in simpler models, which often describe "direct" observations that are practically unobtainable. A prime example is left truncation; another, *right truncation* with widespread use in studies of AIDS patients whose development is often observed conditional on having contracted the disease before the study entry. For general discussions, see [47, 54, 39]. A more elaborate application of such retrospective observational plans obtained by conditioning in an underlying "prospective" Markov process model was documented by Aalen et al. [6] for the four-state interaction of life history events example described above (Figure 6). These authors relied heavily on the concise but important general framework of Hoem [42]. We shall here briefly outline how this methodology works for a simple example of retrospective incidence estimation, obtained from the Markov illness–death model without recovery illustrated in Figure 4. Assume that we study a random sample of individuals alive at same fixed age u; for those who had by then contracted the disease the age at which this happened is recorded. The observed multistate model has state space $\mathcal{K} = \{0, 1\}$ and transition probabilities

$$Q_{hj}(s,t) = \text{Prob}\{X(t) = j \mid X(s) = h, X(u) \neq 2\} \tag{24}$$

for $h, j \in \{0, 1\}$ and $0 < s < t < u$. We get

$$Q_{hj}(s,t) = P_{hj}(s,t)\frac{P_{j\mathcal{K}}(t,u)}{P_{h\mathcal{K}}(t,u)}, \tag{25}$$

where $P_{hj}(s,t)$ are the transition probabilities in the original illness–death process and $P_{h\mathcal{K}} = P_{h0} + P_{h1}$. Hoem [42] used the term *purged* for the conditional Markov process on $\mathcal{K}$ with transition probabilities $Q_{hj}(s,t)$. The transition intensity of the purged process is

$$\lambda_{01}(t) = \alpha_{01}(t)\frac{P_{11}(t,u)}{P_{1\mathcal{K}}(t,u)} \tag{26}$$

and it may be proved that if the mortality of the diseased is never smaller than that of the healthy, that is, $\alpha_{02}(t) \leq \alpha_{12}(t)$ for all $t \leq u$, then $\lambda_{01}(t) \leq \alpha_{01}(t)$, with equality if and only if $\alpha_{02}(t) \equiv \alpha_{12}(t)$. This documents the intuitively obvious result, that the retrospective study will underestimate the disease incidence because of *survivor selection*. Andersen and Green [11] used such methodology to study robustness of diabetes incidence estimates in a situation where diabetics were only observed conditionally on not emigrating before a certain age.

The Prevalent Cohort Study. An important sampling frame for the illness–death model without recovery is the *prevalent cohort study* in which a cross-sectional sample of diseased is taken at a fixed calendar time; *see* **Biased Sampling of Cohorts**. Keiding [52], (cf. Lund [63]), discussed the conditions for correct inference on mortality $\alpha_{12}(t)$ based on follow-up of the diseased, studied under left truncation, and compared to inference based on the **length-biased** durations, which include the retrospective time from disease onset, as well as to the *forward recurrence time* from sampling to death, assuming **stationarity**.

Retrospective estimation of incidence based on the disease onset information of the survivors and independent lethality information was exemplified by Keiding et al. [55] (cf. Ogata et al. [64]).

Some Other Partial Information Designs

Sometimes interval-censoring is extreme – in a cross-sectional study, it is for all individuals where it is only known whether or not an event has happened at age of sampling. Such *current-status data* were discussed in detail by Diamond & McDonald [30], Keiding [51] and Keiding et al. [53]; and there is an elaborate recent mathematical–statistical development in this area; see, for example, [38] and Lin et al. [61] (*see* **Interval Censoring**). For *time to pregnancy* data, Keiding et al. [57] proposed using the *current duration* elapsed so far; under suitable stationarity conditions, this distribution can be considered a backward recurrence time; (*see* **Time to Pregnancy**).
