The Physicians' Health Study was the first randomized trial to demonstrate a benefit of aspirin in reducing the risk of a first myocardial infarction. This finding was not supported by the smaller British Doctors Trial [27], but has been confirmed in two more recently reported primary prevention trials, the Thrombosis Prevention Trial [37] and the Hypertension Optimal Treatment trial [13]. An overview (*see* **Meta-analysis of Clinical Trials**) of all four available trials shows a highly significant ($P < 0.00001$)

33% reduction in risk of a first myocardial infarction attributed to aspirin [14], while there are still too few strokes and deaths upon which to draw firm conclusions.

With regard to β-carotene, the Physicians' Health study was by far the longest randomized trial of this agent – at 12 years of treatment and follow-up, it was two to three times longer than any other randomized trial of β-carotene. Since the Physicians' Health Study in 1982, three other trials of shorter duration have been designed and completed. The Chinese Cancer Prevention Study, conducted among a nutritionally deficient rural population, found a statistically significant 9% decrease in total mortality, a 13% decrease in total cancer mortality, and a 21% decrease in gastric cancer deaths, and a non-significant 10% decrease in cerebrovascular mortality among those assigned to a combined daily treatment of β-carotene (15 mg), vitamin E (30 mg), and selenium (50 μg) [4]. In the six-year Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ATBC), conducted among male Finnish smokers, the risk of cancer was not lower among the men on active treatment (50 mg of alpha-tocopherol, or 20 mg of β-carotene, or both) compared with those in the placebo arm. In fact, β-carotene use was associated with statistically significant increases in lung cancer (18%), total mortality (8%), and mortality from ischemic heart disease (12%) [36]. The Beta-Carotene and Retinol Efficacy Trial (CARET), conducted among men and women at high risk of lung cancer, was stopped prematurely, with an average of just four years of treatment and follow-up, because preliminary results showed an increased risk of lung cancer, death from lung cancer, and death from cardiovascular disease in the active treatment group [25]. It must be noted that the possible increased risk did not reach the prespecified O'Brien–Fleming boundary ($P < 0.007$) for early termination (*see* **Data and Safety Monitoring**). Thus, the null results from the Physicians' Health Study are the most accurate, least biased, and least confounded results of β-carotene in primary prevention to date.

Other Benefits of the Physicians' Health Study

The Physicians' Health Study was the first large-scale study ever to collect by mail and store a large number of blood samples. Approximately 15 000 randomized physicians (68%) contributed blood samples at baseline, which were stored as aliquots in liquid nitrogen. This bank of blood samples has offered the opportunity to conduct large-scale blood-based epidemiologic studies using a prospective, nested, case–control design. Completed studies include investigations on the influence of a variety of potential markers on risk of coronary heart disease, including homocysteine [35] and inflammatory markers such as C-reactive protein [30], fibrinogen [22], and soluble intercellular adhesion molecule-1 [31]. The stored blood samples have also allowed for the rapid evaluation of hypotheses generated from the identification of possible genetic markers. For example, a 1992 case–control study [7] suggested an association between a polymorphism of the angiotensin-converting-enzyme (ACE) gene and the occurrence of myocardial infarction. Prospective blood-based data from the Physicians' Health Study reported shortly thereafter, however, showed that the presence of the D allele of the ACE gene conferred no appreciable increase in the risk of ischemic heart disease or myocardial infarction [21].

In addition to blood-based epidemiologic investigations, the Physicians' Health Study has been an excellent cohort for testing a variety of timely and important hypotheses from observational data. These range from a positive association between smoking and risk of cataract [9] to an inverse association between exercise and risk of type 2 diabetes [23] and stroke [20], as well as the investigation of a number of dietary factors (fish consumption [2, 3, 24], vitamins B_6 and folate [8], and moderate alcohol consumption [1, 6, 11]) on risk of various diseases.

The Physicians' Health Study has also provided an opportunity to explore the decreases in mortality from cardiovascular disease that began in the mid 1960s. In 1982, when the study began, 28% of American men and 19% of US physicians smoked, though only 11% of Physicians' Health Study participants reported being current smokers. That difference could be one reason for the low rate of incidence of cardiovascular events observed in the Physicians' Health Study. With respect to case fatality rates for myocardial infarction, among participants in the Physicians' Health Study, the average time from onset of symptoms of myocardial infarction to emergency medical care was 1.8 hours, while the population

average was 4.8 hours [32]. Shifting the population average toward that observed among Physicians' Health Study participants could significantly decrease mortality and morbidity from myocardial infarction.

Finally, a number of methodological advances have been tested in the Physicians' Health Study. The use of a prerandomization run-in, for example, enhanced the validity and made the trial more efficient – **compliance** with pill taking increased up to 40% and duration of follow-up decreased 7%. In addition, enrolling 11 152 fewer subjects in the trial resulting from the use of the run-in led to substantial cost savings [19] (*see* **Cost-effectiveness in Clinical Trials**). The Physicians' Health Study also demonstrated the advantages of the 2×2 factorial trial, a research design allowing for the independent and simultaneous evaluation of two hypotheses. Finally, the trial showed the feasibility of conducting a large-scale randomized trial entirely by mail at a fraction of the usual cost for randomized trials.

Conclusion

The Physicians' Health Study has made and should continue to make important substantive and methodologic contributions to the investigation of the causes and prevention of cardiovascular disease, cancer, and other chronic diseases.

Pillai's Trace Test

Pillai in 1955 [24] proposed the trace test for the following three testing problems: (i) equality of mean vectors of lp-variate normal distributions with the common but unknown **covariance matrix** (*see* **Multivariate Normal Distribution**); (ii) independence between two sets of variates distributed jointly as a normal distribution with unknown mean vector; and (iii) equality of covariance matrices of two p-variate normal distributions with unknown mean vectors.

In all these problems the test statistic can be expressed as $V^{(s)} = \text{trace}(\mathbf{B})$, where $\mathbf{B} = \mathbf{S}_1(\mathbf{S}_1 + \mathbf{S}_2)^{-1}$, $\mathbf{S}_1$ and $\mathbf{S}_2$ being $p \times p$ matrices, s being the number of nonzero characteristic roots of B (*see* **Eigenvalue**). The problem (i) can be seen to be equivalent to the **multivariate analysis of variance** (MANOVA) problem, and, in that case, $\mathbf{S}_1$ and $\mathbf{S}_2$ denote the sums of squares and cross-products matrices "due to hypothesis" and "due to error", respectively. For problem (ii), $\mathbf{S}_1 = \mathbf{S}_{12}\mathbf{S}_{22}^{-1}\mathbf{S}_{21}$, $\mathbf{S}_2 = \mathbf{S}_{11} - \mathbf{S}_{12}\mathbf{S}_{22}^{-1}\mathbf{S}_{21}$, where $\mathbf{S}_{ij}$, $i, j = 1, 2$, is the partitioned sums of squares and cross-products matrix corresponding to the two sets of variates, based on a random sample from the distribution. For problem (iii), $\mathbf{S}_1$ and $\mathbf{S}_2$ are the sums of squares and cross-products matrices based on **random samples** from the two distributions with **degrees of freedom** (df) ν_1 and ν_2, respectively.

The trace test has also been considered by Bartlett [3] for (ii), and Nanda [20] has considered the distribution of this statistic when $\mathbf{S}_1$ and $\mathbf{S}_2$ are independent central **Wishart** matrices.

We assume $s = p$; if $s < p$ for (i), then the parameters can be modified appropriately. The null distribution of $V^{(s)}$ takes the same form in each of these three problems. Nanda [20] has derived the distribution of $V^{(s)}$ when s = 2,3, and $|\nu_1 - p| = 1$. Pillai [24] has suggested approximation of the null distribution of $V^{(s)}/s$ by $B[s(2m + s + 1), s(2n + s + 1)]$, where $m = (|\nu_1 - p| - 1)/2$, $n = (\nu_2 - p - 1)/2$ (*see* **Beta Distribution**), and recommended this approximation when $m + n > 30$; this amounts to approximating the cut-off points of the test statistic based on the upper percentage points of the ***F* distribution**. Pillai & Mijares [32], and Mijares [17] have tabulated upper 5% and 1% points of $V^{(s)}$ based on this approximation for small s and various m and n; see also Pillai [25, 26]. Pillai & Jayachandran [30] have obtained the **moment generating function** of $V^{(s)}$ and derived explicit expression for its cumulative distribution function for $s = 3$, $m = 1, 2, 3$ and $s = 4$, $m = 0, 1$, along with the corresponding values of the exact upper 5% and 1% points for several n. Mikhail [18] has derived the exact null distribution of $V^{(2)}$. Davis [4, 5] has also obtained the null distribution for $m = 2, 3$, and studied the accuracy of Pillai's beta approximation. The exact null distribution of $V^{(s)}$ is obtained by Krishnaiah & Chang [13] in the general case. Exact percentage points of $V^{(s)}$ are tabulated by Schuurmann et al. [35]; see also Anderson [1].

The limiting distribution of $\nu_2 V^{(s)}$, as $\nu_2 \to \infty$, is the **chi-square distribution** with $\nu_1 p$ df. The asymptotic expansion for the null distribution of $V^{(s)}$ is derived by Muirhead [19] and Fujikoshi [6].

Khatri & Pillai [11] derived the first two **moments** of $V^{(s)}$ in the noncentral case for MANOVA (linear alternative).

Pillai & Jayachandran [31] derived the noncentral distribution of $V^{(s)}$ for (i) and (ii) for the 2-root case, and tabulated the **power** functions for $p = 2$. Pillai [27] has obtained the moment generating function in the noncentral case for (i) and (ii), and later Khatri & Pillai [12] derived the noncentral distribution in a series form for (i). Pillai & Al-Ani [28] derived the noncentral distribution in the 2-root and 3-root cases for (iii). See also Pillai & Sudjana [33] for some numerical studies on the nonnull distribution.

Fujikoshi [6] has obtained asymptotic expansion of the nonnull distribution of $V^{(s)}$ for MANOVA and the test of independence (with local alternatives) when ν_2 is large; later, Fujikoshi [7] obtained a similar expansion in terms of noncentral chi-square distributions when ν_1 is large. For similar asymptotic expansions for the nonnull distribution, see Lee [14, 15].

Kiefer & Schwarz [10] have shown that Pillai's trace test is **Bayes** and admissible (*see* **Decision Theory**) for the MANOVA problem. It follows from the results of Olkin & Perlman [21] that this trace test is **unbiased** for problems (i) and (ii). Perlman [23] has shown that the power function of this test enjoys the monotonicity property in the respective noncentral parameters in both cases, if the cutoff point is not too large; for details, see Perlman [23]. It follows from the result of Anderson & DasGupta [2]

that the one-sided trace test for (iii) enjoys the monotonicity property of its power function when the **alternative** is one-sided; Giri [8] has shown that the one-sided trace test is locally best invariant (*see* **Hypothesis Testing**) for (iii). The locally best property of the trace test among all invariant tests is shown by John [9] for (i), (ii), and (iii). Schwarz [36] has studied the trace test and shown that it has the local **minimax** property for (i) and (ii).

Mikhail [18] found that the trace test has better power than that of any other standard test for the MANOVA problem when $p = 2$. Pillai & Jayachandran [30] compared the trace test with other standard tests for the MANOVA problem, and found that the trace test has the maximum power for small deviations from the null hypothesis when $p = 2$.

Schatzoff [34] calculated the expectation of the observed significance value of the trace test under different alternatives for the MANOVA problem, and found that the trace test is quite sensitive. On the basis of permutation distributions (*see* **Randomization Tests**), Mardia [16] has shown that the trace test is moderately robust for problem (i), but highly sensitive for (iii). On the basis of a Monte Carlo study, Olson [22] found that the trace test is most robust among the standard tests for the MANOVA problem with respect to deviations from normality and homogeneity of covariance matrices. Pillai & Sudjana [33] carried out some robustness study of the trace test for (i) and (iii) in the 2-root case; a **robustness** study for (ii) has been carried out by Pillai & Hsu [29].

SOMESH DASGUPTA

Pinel, Philippe

Born: April 20, 1745, in Jonquières, France.
Died: October 25, 1826, in Paris, France.

Phillipe Pinel received his training in medicine from the schools at Toulouse and Montpellier. In 1778 he went to Paris where he eventually became associated with a group of thinkers known as the Idéologues who took their inspiration, in part, from the work of the mathematician, the Marquis de Condorcet. Condorcet believed that the "calculus of probabilities" was the key to extending a scientific understanding to problems dealing with human society – what eighteenth-century thinkers referred to as the "science of man".

With the changing political climate following the French Revolution, Pinel was able to find positions in the Parisian hospitals that treated the mentally ill. In 1793 he was appointed to Bicêtre and in 1795 he was appointed to an analogous position at Salpêtrière, then a repository for the inveterately insane. From this institutional base, Pinel was able to test the success of "moral treatment" of the insane, which involved removing their physical restraints and treating them in a more humane manner. Also, Pinel was able to use the hospital setting to observe large numbers of patients, thereby facilitating statistical comparison. In a speech read before the Institut de France in 1807, Pinel [2] reported on a statistical "experiment" that he conducted to demonstrate that "moral treatment" was superior to the traditional treatment (which involved bleeding and other more "physical" interventions by the physician). As discussed in Goldstein [1], Pinel used no control group of patients who had been treated by the traditional means; however, he did establish a 93% rate of cure for maniacs and melancholics treated by "moral" methods. Two years later Pinel [3] presented a more detailed analysis of his statistical findings in *Traitè Medico-Philosophique sur l'Alienation Mentale*, in which he declared that the "fundamental principle of the calculus of probabilities" entails acquiring knowledge of the number of cases "favorable and contrary".

Thus, Pinel is important not only for the history of **psychiatry**, but also for the **history of biostatistics**. By placing emphasis on more humanitarian treatment of the insane, his work marks a major shift toward more "enlightened" treatment of the mentally ill. By placing emphasis on statistical comparison to prove efficacy, he foreshadowed a methodological approach that would become increasingly important throughout the course of the nineteenth and twentieth centuries.

Pitman Efficiency

The Pitman efficiency is an index for comparing test procedures or estimators. It is of special importance for comparing procedures in large samples. Given two procedures, $\mathcal{P}_1$ and $\mathcal{P}_2$, with a particular definition of "goodness" of the procedures, if $\mathcal{P}_1$ requires n_1 observations and $\mathcal{P}_2$ requires n_2 observations to achieve the same level of "goodness", the **efficiency** of $\mathcal{P}_1$ relative to $\mathcal{P}_2$ is rel. eff. $(\mathcal{P}_1, \mathcal{P}_2) = n_2/n_1$. This is the basic idea in the Pitman relative efficiency index. We illustrate this first with two examples.

Example 1

Suppose that $X_1, \ldots, X_n$ are independent identically distributed (iid) **random variables** (a **random sample**) from a **lognormal distribution** $\ln(\mu, \sigma^2)$ (i.e. $\log X_1 \sim \mathrm{N}(\mu, \sigma^2)$). The expected value of X_1 is $\xi = \exp(\mu + \sigma^2/2)$. Assume that μ is unknown and σ^2 is known. An unbiased estimator of ξ is the sample mean $\overline{X}_n$, having a variance $\mathrm{var}\{\overline{X}_n\} = [w_1(\mu, \sigma^2)]/n$, where $w_1(\mu, \sigma^2) = \mathrm{var}\{X_1\} = \xi^2[\exp(\sigma^2) - 1]$. The **maximum likelihood** estimator (MLE) is $\hat{\xi}_n = \exp(\overline{Y}_n + \sigma^2/2)$, where $Y_i = \log X_i (i = 1, \ldots, n)$, $\overline{Y}_n = (1/n)\sum_{i=1}^{n} Y_i$. The MLE, $\hat{\xi}_n$, is a **biased** estimator of ξ, having the **mean square error** (MSE)

$$\begin{aligned}\mathrm{MSE}\{\hat{\xi}_n\} &= \xi^2\left[\exp\left(\frac{2\sigma^2}{n}\right) - 2\exp\left(\frac{\sigma^2}{2n}\right) + 1\right] \\ &= \frac{\sigma^2}{n}\xi^2\left(1 + \frac{7}{4}\frac{\sigma^4}{n} + \cdots\right) \\ &= \frac{\sigma^2}{n}\xi^2 + O\left(\frac{1}{n^2}\right).\end{aligned}$$

Let n_1 be the value of n for which $\mathrm{MSE}\{\hat{\xi}_n\} = c$ and let n_2 be the value of n for which $\mathrm{var}\{\overline{X}_n\} = c$. For small values of c we need large values of n_1 and n_2, and the index of relative efficiency of the MLE vs. $\overline{X}_n$ is approximately

$$\frac{n_2}{n_1} \approx \frac{\exp(\sigma^2) - 1}{\sigma^2} = 1 + \frac{\sigma^2}{2} + \frac{\sigma^4}{6} + \cdots.$$

This shows that $\overline{X}_n$ is very inefficient, compared with the MLE, if σ^2 is large. This result is intuitively clear, since $\overline{X}_n$ is not a **sufficient statistic** for this family of distributions.

Example 2

Consider a random sample $X_1, \ldots, X_n$, from a **normal distribution**, $\mathrm{N}(\mu, \sigma^2)$, with known variance σ^2 and unknown mean μ. In quality control problems we are often interested in testing whether $p = \Pr\{X_1 \geq \xi_0\}$ is greater than some value p_0. Both p_0 and ξ_0 are specified constants. This problem is equivalent to that of testing the **null hypothesis** $\mathrm{H}_0 : \mu \geq \mu_0$ against the **alternative** $\mathrm{H}_1 : \mu < \mu_0$, where $\mu_0 = \xi_0 - Z_{1-p_0}\sigma$ and where Z_{1-p_0} is the $(1 - p_0)$th **quantile** of $\mathrm{N}(0, 1)$. It is well known that the uniformly **most powerful** (UMP) test of H_0 vs. H_1, at level of significance α, is given by the test function

$$\phi_1(\overline{X}_n) = \begin{cases} 1, & \text{if } \overline{X}_n \leq \mu_0 - Z_{1-\alpha}\sigma/\sqrt{n}. \\ 0, & \text{otherwise.} \end{cases}$$

The **power** of this test is given by the function,

$$\psi_n^{(1)}(\mu_1) = \Phi\left(\frac{\mu_0 - \mu_1}{\sigma}\sqrt{n} - Z_{1-\alpha}\right), \quad \text{for } \mu_1 \leq \mu_0,$$

where $\Phi(\cdot)$ is the standard normal distribution function. Clearly, for each $\mu_1 < \mu_0$, $\lim_{n\to\infty} \psi_n(\mu_1) = 1$. Moreover, $\psi_n^{(1)}(\mu_1)$ is a strictly increasing function of n, and the value of n for which $\psi_n^{(1)}(\mu_1) \geq 1 - \beta$ is

$$n_1 = \min\left\{n : n \geq \frac{(Z_{1-\alpha} + Z_{1-\beta})^2}{(Z_{1-p_1} - Z_{1-p_0})^2}\right\}.$$

Note that in terms of the original testing problem, μ_1 corresponds to $p_1 = P_{\mu_1}\{X \geq \xi_0\}$, or $\mu_1 = \xi_0 - \sigma Z_{1-p_1}$. Obviously, if $p_1 < p_0$, then $\mu_1 < \mu_0$.

An alternative test procedure is to count the number, K_n, of items in the sample having values greater than ξ_0 (number of conforming items). K_n has a **binomial distribution** $B(n, p)$. We consider the test of the null hypothesis $\mathrm{H}_0 : p \geq p_0$, against the alternative $\mathrm{H}_1 : p < p_0$. The UMP test, based on K_n, of level α, is

$$\phi_2(K_n) = \begin{cases} 1, & \text{if } K_n < C_\alpha, \\ \gamma_\alpha, & \text{if } K_n = C_\alpha, \\ 0, & \text{if } K_n > C_\alpha, \end{cases}$$

in which $C_\alpha = B^{-1}(\alpha; n, p_0)$, and $\gamma_\alpha = [\alpha - B(C_\alpha - 1; n, p_0)]/[b(C_\alpha; n, p_0)]$. Here $B^{-1}(\alpha; n, p_0)$ denotes the α-quantile of $B(n, p_0)$; $B(C_\alpha; n, p_0)$ and

$b(C_\alpha; n, p_0)$ are the cumulative distribution function (cdf) and probability density function (pdf) of $B(n, p_0)$, respectively, at C_α. The power function of ϕ_2 is

$$\psi_n^{(2)}(p_1) = P_{p_1}\{K_2 < C_\alpha\} + \gamma_\alpha P_{p_1}\{K_2 = C_\alpha\}$$
$$= B(C_\alpha - 1; n, p_1) + \gamma_\alpha b(C_\alpha; n, p_1).$$

In large samples,

$$C_\alpha \doteq np_0 - Z_{1-\alpha}[np_0(1-p_0)]^{1/2}$$

and

$$\psi_n^{(2)}(p_1) \cong \Phi\left(\sqrt{n}\frac{p_0 - p_1}{[p_1(1-p_1)]^{1/2}} - Z_{1-\alpha}\left[\frac{p_1(1-p_1)}{p_0(1-p_0)}\right]^{1/2}\right).$$

Let n_2 denote the smallest n needed so that $\psi_n^{(2)}(p_1) \geq 1 - \beta$. We have

$$n_2 \doteq \frac{(Z_{1-\alpha}[p_0(1-p_0)]^{1/2} + Z_{1-\beta}[p_1(1-p_1)]^{1/2})^2}{(p_0 - p_1)^2}.$$

The ratio of n_2 to n_1 gives the relative efficiency of $\phi_1(\overline{X}_n)$ vs. $\phi_2(K_n)$. This is given by

$$\frac{n_2}{n_1} \simeq \frac{(Z_{1-\alpha}[p_0(1-p_0)]^{1/2} + Z_{1-\beta}[p_1(1-p_1)]^{1/2})^2}{(Z_{1-\alpha} + Z_{1-\beta})^2} \times \frac{(Z_{1-p_1} - Z_{1-p_0})^2}{(p_0 - p_1)^2}.$$

For $\alpha = \beta = 0.05$ and $p_0 = 0.95$, we obtain the relative efficiency values shown in Table 1. These results are not surprising, since the binomial testing is a **nonparametric** (distribution-free) method, while the test ϕ_1 is based on the minimal sufficient statistic, $\overline{X}_n$ for the normal model.

Pitman [5] introduced an index of **asymptotic relative efficiency** for tests and for estimators. An exposition of the theory can be found in Lehmann's book on estimation [4] and in Pitman's book [6]. A more general approach was given by Hoeffding & Rosenblatt [3]. We now present the essential results.

Table 1

p_1	n_2/n_1
0.945	4.33
0.94	4.21
0.935	4.10
0.93	4.00
0.925	3.91
0.92	3.82

Asymptotic Relative Efficiency of Test Procedures

Let $X_1, X_2, \ldots$ be a sequence of iid random variables having a common cdf $F_\theta(x)$, which depends on a real parameter θ. Let $T_n = t(X_1, \ldots, X_n)$ be a real-valued statistic, such that

$$Z_n = \frac{T_n - \mu_n(\theta)}{\sigma_n(\theta)} \xrightarrow[n \to \infty]{\text{d}} \text{N}(0, 1)$$

(*see* **Convergence in Distribution and in Probability**). It is often the case that $\sigma_n(\theta) = c(\theta)w_n$, where $c(\theta) > 0, w_n > 0$ and $w_n \downarrow 0$ and $n \to \infty$. Typically, $w_n = n^{-\alpha}$ or $w_n = (n \log n)^{-\alpha}$ for $\alpha > 0$. Moreover, $\mu_n(\theta) \to \mu(\theta)$ as $n \to \infty$. The problem is to test $\text{H}_0 : \theta \leq \theta_0$ against $\text{H}_1 : \theta > \theta_0$ at level of significance α (*see* **Level of a Test**). Consider a sequence of test procedures, which reject H_0 whenever $(T_n - \mu(\theta_0))/\sigma_n(\theta_0) \geq k_n$, where $k_n \to Z_{1-\alpha} = \Phi^{-1}(1-\alpha)$. The power functions corresponding to this sequence of tests are, for some $\theta > \theta_0$,

$$\psi_n(\theta; T_n) = P_\theta\{T_n \geq \mu(\theta_0) + k_n\sigma_n(\theta_0)\}$$
$$\cong \Phi\left(\frac{\mu(\theta) - \mu(\theta_0)}{c(\theta_0)w_n}\frac{c(\theta_0)}{c(\theta)} - Z_{1-\alpha}\frac{c(\theta_0)}{c(\theta)}\right).$$

We assume the following:

1. $\mu(\theta)$ has a continuous derivative, $\mu'(\theta)$, in a neighborhood of θ_0 and $\mu'(\theta) > 0$;
2. $c(\theta)$ is continuous in a neighborhood of θ_0, and $c(\theta_0) > 0$.

Notice that under these assumptions, for $w_n \downarrow 0$ as $n \to \infty$, for a fixed θ in the required neighborhood of θ_0, $\lim_{n\to\infty} \psi_n(\theta; T_n) = 1$. Thus, the above large sample test is **consistent**. We consider its limiting power, for a sequence of alternatives $\theta_n \to \theta_0$. More specifically, let $\theta_n = \theta_0 + \delta w_n$ with $\delta > 0$. Then, for

large values of n, $\mu(\theta_n) \approx \mu(\theta_0) + \delta w_n \mu'(\theta_0)$ and $c(\theta_0)/c(\theta_n) \to 1$. The asymptotic power is

$$\lim_{n\to\infty} \psi_n(\theta_n; T_n) = \Phi\left(\frac{\delta\mu'(\theta_0)}{c(\theta_0)} - Z_{1-\alpha}\right) = \psi^*,$$

where $0 < \psi^* < 1$.

The function

$$J(\theta; T) = \frac{[\mu'(\theta)]^2}{[c(\theta)]^2}$$

is called the *asymptotic efficacy* of T_n (see [6, p. 351]). Let $\{V_n\}$ be an alternative sequence of test statistics, having asymptotic efficacy $J(\theta; V) = [\eta'(\theta)]^2/[d(\theta)]^2$. Consider the case in which $w_n = n^{-1/2}$ for *both* $\{T_n\}$ and $\{V_n\}$. In this case, the sample size n' required for attaining the same limiting power ψ^* is such that

$$\lim_{n\to\infty} \frac{n}{n'(n)} = \frac{J(\theta_0; V)}{J(\theta_0; T)} = \left(\frac{\eta'(\theta_0)}{\mu'(\theta_0)}\right)^2 \frac{c^2(\theta_0)}{d^2(\theta_0)}.$$

This limit is called the Pitman asymptotic relative efficiency (ARE) of $\{V_n\}$ compared with $\{T_n\}$, and denoted by $\text{eff}(\theta_0; V_n, T_n)$. More generally, if $w_n = n^{-\alpha}$, $\alpha > 0$, then the Pitman ARE is

$$\text{eff}(\theta_0; V_n, T_n) = \left(\frac{J(\theta_0, V)}{J(\theta_0, T)}\right)^{1/2\alpha}.$$

Note that if Z_n and $W_n = (V_n - \eta_n(\theta))/v_n(\theta)w_n$ do not have the same asymptotic distribution then the ARE index is not defined.

Example 3

Let $X_1, X_2, \ldots, X_n$ be a random sample from a distribution $G(x;\theta) = F(x - \theta)$, where θ is the **median** of $G(x;\theta)$; that is, $\theta = G^{-1}(\frac{1}{2};\theta)$. We assume that $F(x)$ is symmetric around zero; that is, $F^{-1}(\frac{1}{2}) = 0$. We further assume that $F \in \Omega_s$, where Ω_s is the family of symmetric distributions, which are absolutely continuous, with pdf $f(x)$, having a continuous derivative $f'(x)$. Let $R_j (j = 1, \ldots, n)$ be the **ranks** of $Y_j = |X_j|$ and let $s(x) = I\{x > 0\}$ be the sign of x. A **score** statistic for testing the hypothesis $\text{H}_0 : \theta \le 0$ vs. $\text{H}_1 : \theta > 0$ is

$$\overline{V}_n = \frac{1}{n}\sum_{j=1}^{n} \phi\left(\frac{R_j}{n+1}\right) s(X_j),$$

where $\phi(\cdot)$ is a score function; that is, $\phi(u)$ is nondecreasing on (0, 1) $\phi(u) \ge 0$ and $\int_0^1 \phi(u)\,\text{d}u < \infty$. A large class of nonparametric test statistics can be expressed as such score functions. As shown by Hettmansperger [2, p. 105], the efficacy of V_n, for $\theta_0 = 0$, is

$$J(0, V_n) = \frac{\left[\int_0^1 \phi(x) \dfrac{f'\{F^{-1}[(x+1)/2]\}}{f\{F^{-1}[(x+1)/2]\}}\,\text{d}x\right]^2}{\int_0^1 \phi^2(x)\,\text{d}x}.$$

Using this function, one can obtain the Pitman ARE of two different score statistics, when $f(x)$ is a specified density, symmetric around zero.

Asymptotic Relative Efficiency of Estimators

Let $\mathcal{F}$ be a family of distributions depending on a real parameter θ. Consider the problem of estimating a real parameter $w(\theta)$. Given a random sample $\mathbf{X}_n = (X_1, \ldots, X_n)$, let $\hat{w}_1(\mathbf{X}_n)$ and $\hat{w}_2(\mathbf{X}_n)$ be two estimators of $w(\theta)$. We assume that:

1. $E_\theta\{\hat{w}_i(\mathbf{X}_n)\} = w_{i,n}(\theta), i = 1, 2$; and
2. $V_\theta\{\hat{w}_i(\mathbf{X}_n)\} = \sigma^2_{i,n}(\theta), i = 1, 2$.

The efficacy of $\hat{w}_i(\mathbf{X}_n)$ is defined as

$$J_n(\theta; \hat{w}_i) = \frac{[w'_{i,n}(\theta)]^2}{\sigma^2_{i,n}(\theta)}.$$

The relative efficiency of $\hat{w}_2$ compared with $\hat{w}_1$ is defined as (see [1])

$$\text{RE}_n(\theta; \hat{w}_2, \hat{w}_1) = \frac{J_n(\theta; \hat{w}_2)}{J_n(\theta; \hat{w}_1)}.$$

The asymptotic relative efficiency is

$$\text{ARE}(\theta; \hat{w}_2, \hat{w}_1) = \lim_{n\to\infty}\left[\frac{J_n(\theta; \hat{w}_2)}{J_n(\theta; \hat{w}_1)}\right].$$

If both estimators are asymptotically unbiased, in other words, $w_{i,n}(\theta) \to w(\theta)$ as $n \to \infty, i = 1, 2$ and if $\sigma^2_{i,n}(\theta) = [\sigma^2_i(\theta)]/n + o(1/n)$ as $n \to \infty$, then

$$\text{ARE}(\theta; \hat{w}_2, \hat{w}_1) = \frac{\sigma^2_1(\theta)}{\sigma^2_2(\theta)}.$$

If the family $\mathcal{F}$ satisfies the Cramér–Rao regularity conditions (see [7]), the mean square error of an estimator $\hat{w}(\theta)$ is often compared to the **Cramér–Rao** lower bound for variances of unbiased estimators of $w(\theta)$, and the relative efficiency is defined as

$$\mathrm{RE}_n(\theta; \hat{w}) = \frac{w'(\theta))^2}{nI(\theta)\mathrm{MSE}_\theta\{\hat{w}\}},$$

where $I(\theta)$ is the Fisher **information** function. Thus, if $\mathrm{MSE}_\theta\{\hat{w}\} = \sigma^2(\theta)/n + o(1/n)$ as $n \to \infty$, then $\lim_{n\to\infty} \mathrm{RE}_n(\theta; \hat{w}) = [w'(\theta)]^2/I(\theta)\sigma^2(\theta)$.

Example 4

Consider the problem of Example 1, for estimating the mean ξ of a lognormal distribution $\ln(\mu, \sigma^2)$, with σ^2 known. Here, $w(\mu) = \exp(\mu + \sigma^2/2)$, and the Fisher information is $I(\mu) = \sigma^2$. Thus, the relative efficiency of the unbiased estimator $\overline{X}_n$ is

$$\mathrm{RE}_n(\mu; \overline{X}_n) = \frac{[\exp(\mu + \sigma^2/2)]^2\sigma^2}{nV\{\overline{X}_n\}} = \frac{\sigma^2}{\exp(\sigma^2) - 1}.$$

In this case $\mathrm{RE}_n(\mu, \overline{X}_n) < 1$ for all σ^2, and $\mathrm{RE}_n(\mu, \overline{X}_n) \to 0$ as $\sigma^2 \to \infty$.

If the distribution of X depends on k parameters, $\theta_1, \ldots, \theta_k, k > 1$, the definition of relative efficiency of estimators of $w(\theta_1, \ldots, \theta_k)$ is more complicated. The reader is referred to Zacks [8].

Placebos

History of Placebo

The placebo, which originates from Latin meaning "I shall please", was used for centuries as therapy for patients whom physicians were unsure of how to treat or for whom no useful treatment was available [26]. Attitudes towards therapies in Western cultures have shifted dramatically over the last four decades. Principles of safety, efficacy, and informed consent of participants are now well entrenched (*see* **Ethics of Randomized Trials**); the randomized controlled trial (*see* **Clinical Trials, Overview**) dominates as the method for evaluating therapy and patients are increasingly involved in decisions about their care [38]. The role of the placebo has evolved in response to all of these factors. In research, the notion of placebo control arose to account for those beneficial or harmful effects not directly attributable to the therapy of interest. Despite some dissent, placebos and placebo-controlled trials remain the benchmark by which all new drugs are evaluated and regulated [50]. In clinical care, any part of an encounter can have some therapeutic value and influence the patient's response, including taking a history, stating a diagnosis, or making repeated measurements (e.g. blood pressure) or assurances about prognosis. Knowledgeable clinicians are interested in determining which parts of the placebo effect they should implement to optimize their patients' health.

Definitions

Many, similar definitions for "placebo", "placebo effect", and "placebo response" exist. Here, we use the word *placebo* to mean an inert substance or sham procedure designed to appear identical to the active substance or procedure but without known therapeutic effect. *Placebo effect* or *placebo response* is the psychophysiologic effect associated with placebos, thought to be primarily operative through the expectations or symbolic meaning of the administered therapy [5, 36, 39]. This implies both positive and negative effects, although the latter are often referred to as the *nocebo effect* [19]. More recently, the placebo effect has been further characterized as a *true* placebo effect versus a *perceived* placebo effect. The perceived placebo effect, which is the effect commonly quoted and discussed in the literature, includes the true placebo effect plus other nonspecific effects, including the natural course of disease, **regression to the mean**, unidentified co-intervention effects, and other time-dependent effects [15, 39]. The natural course of any disease or symptom will change in severity over time and may resolve on its own (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**). Regression to the mean, where a follow-up measurement of a patient's disease or symptoms gives a more normal reading, is a well-recognized phenomenon. Patients enrolled in a trial may influence clinical outcomes by implementing unidentified parallel interventions (co-intervention), for example, by starting a weight-loss program while in a trial of a diabetes drug. Time-dependent effects might include the increasing skill of the investigator in measuring study endpoints, or the decreasing "white coat hypertension" effect as patients become used to having their blood pressure measured. Since these nonspecific effects are inherent in any therapy (i.e. active intervention, placebo, or no-treatment groups), it has been argued that we should be focusing on the true placebo effect as a measurement target [15, 23].

Magnitude of the Placebo Effect

For decades, the placebo response has been assumed to be similar across disease categories at approximately 35% improvement from baseline [3]. This figure has been applied equally to the proportion of patients improving and to the degree of improvement per patient per outcome. More recently, doubt has been cast on the constant placebo response as evidence accumulates that both the true and perceived placebo effects are variable [15, 36, 55]. A review of 75 trials of antidepressant medications revealed that the placebo response rate varied from 12.5 to 51.8% and had increased over time [55]. A recent systematic review of randomized trials with placebo and no-treatment arms (*see* **Meta-analysis of Clinical Trials**), concluded that there was evidence of a mild true placebo effect for some subjective outcomes (e.g. pain and anxiety) but not for more objective outcomes (blood pressure, weight loss, asthma outcomes) [23]. For example, placebo was associated with a reduction in **pain** by a mean of 0.65 cm

on a 10 cm visual analog scale, as compared with no treatment. The authors measured the difference in outcomes between the two arms at the end of the treatment period rather than the change in outcomes from baseline, thus attempting to control for the nonspecific effects and determine the true placebo effect [22]. Their concluding caution against the use of the placebo and its effects for therapeutic purposes outside of a controlled clinical trial raised a storm of criticism. Although the validity of the findings were questioned, in terms of widely varying populations and diseases, heterogeneity and low statistical **power** [1, 46], wrong choice of placebo [27], and contamination of the "no-treatment" arms [14], in our opinion, it is really the generalizability of the findings that is in question (*see* **Validity and Generalizability in Epidemiologic Studies**). Within randomized controlled trials, where patients acknowledge by their consent that they know they may not receive an active treatment, the perceived (total) placebo effect may be more muted than in clinical practice. Furthermore, even within randomized trials, unblinding can occur and **bias** clinician and patient – a situation bound to happen with a no-treatment arm. Finally, and most important, a finding that placebo therapies and no-treatment arms do not differ does not negate the possibility that a true placebo effect occurred (and occurred equally) in both groups.

It is important to keep in mind that placebos are not risk free. Placebos may be harmful if they delay access to effective therapy for the disease under investigation, if their nonspecific symptomatic effects mask a condition that has effective treatment or via direct nocebo effect [1]. Where placebos are used without patient consent, any revelation of the deception may seriously undermine patient–physician relationship, which is itself a powerful source of "placebo effect".

Influences on the Placebo Effect

The attitude and behavior of the clinician toward the treatment and the patient, the attitude of the patient toward her own health and the treatment, as well as external, cultural, family, and media influences, all influence the placebo effect [5, 13, 22, 28, 35, 36]. Treatment variables including appearance, invasiveness, impressiveness, perceived plausibility, past experience, and cost all appear to play a role.

Provider factors can produce major placebo effects and, although not well studied, are considered integral to the "art of medicine". The white coat of the clinician, the stethoscope, the interest, empathy, authority, and compassion displayed in the interview with the patient and the motivation and skillfulness with which a diagnosis or therapeutic path is pursued, each may influence the patient [5, 36, 39]. In a study of 200 British patients presenting to a physician with abnormal symptoms for which no firm diagnosis could be made, the patients were randomly assigned to a negative or positive consultation, and placebo treatment or no treatment [7]. The positive consultation consisted of a firm diagnosis and reassurance that the patient would be better in a few days while in the negative consultation, the physician confessed uncertainly. Two weeks later, 64% of those who received a positive consultation reported improvement compared with 39% of those who received a negative consultation. The percentage of the placebo treated group who improved was not significantly different than the percentage in the untreated group.

Patient expectations, prior experiences with similar therapies, severity of current complaints, and suggestibility likely play a role in the placebo effect but have not been rigorously studied [2, 17, 29, 34, 36, 41, 42]. In a 10-week study of exercise, 48 healthy young adults were randomized to a control aerobics training program or an exercise program with constant reminders of the aim to improve both aerobic capacity and psychological well-being [13]. After 10 weeks, significant increases in fitness levels were seen in both groups, however, self-esteem and psychological well-being were only significantly improved in the experimental group, not the control group. Cultural differences in placebo responsiveness have also been explored. A review of 117 studies of ulcer treatment, and 37 studies of treatment for anxiety, showed Germany had the highest placebo healing rates for ulcers, but experienced only moderate placebo rates for treatments of anxiety. In comparison, Italy had the lowest placebo effects for anxiety, while Brazil had the lowest rates for ulcers [35]. Similarly, a retrospective analysis of deaths attributed to lymphatic cancer found that Chinese-Americans who were born in "Earth years", and therefore deemed by Chinese medical history to be especially susceptible to diseases involving lumps, nodules, or tumors, had a lower mean age of death than those born in other years. No

such relationship could be seen in Caucasian controls who died of similar causes [35, 36].

Patients who enter into trials compared with those who do not and patients who adhere to their treatment, whether placebo or not, compared with those who do not (*see* **Compliance Assessment in Clinical Trials**), may have different outcomes. In a large study of beta-blockers to prevent a recurrence of a myocardial infarction, it was found that those who took more than 80% of their medications had a lower mortality rate compared to poor adherers whether they received beta-blockers or placebo [35, 39]. A **Cochrane** methods review pilot looked at patients enrolled in phase III randomized controlled trials (*see* **Clinical Trials, Overview**) versus patients who were similar but not enrolled. In 23 out of 25 reports, better outcomes were documented for patients within the trials compared to those who were not. Overall, there were lower mortality and lower rates for complications of therapy [21]. An analysis of the CAMIAT (Canadian Amiodarone Myocardial Infarction Arrhythmia Trial) study [24] showed that adherence to placebo or amiodarone, both predicted mortality. Patients who received placebo and were considered noncompliant had over a two-fold increased risk of sudden cardiac death, cardiac mortality, and all-cause mortality compared to those placebo patients who were compliant.

Drug and treatment characteristics, apart from the pharmacology of the active ingredient(s), can have powerful placebo effects. Studies suggest that subjects react to the "meanings" or suggestion of the color and quantity of drugs. Red suggests "hot" or "danger", blue suggests "down" or "quiet", and a quantity of two means "more than one" [6, 12, 35]. A group of medical students were told that they were participating in a single-blinded study (*see* **Blinding or Masking**) on the psychological and physiologic effects of two drugs, a sedative and a stimulant, and received one or two placebo capsules of either blue or pink without attribution of any effect [6]. The consent form they were asked to sign gave a brief description of the stimulant or sedative side effects they may expect to experience. Study results showed that the students tended to experience stimulant reactions to the pink capsules, while the blue capsules produced depressant effects. Two capsules tended to produce a greater effect than one for both psychological changes (e.g. drowsiness) and physiologic changes (e.g. pulse) [37]. In other words, analgesia associated with an injection of saline solution was reversed with an opiate antagonist such as naloxone and enhanced with an opiate agonist such as proglumide, which suggests that these patients were experiencing a physiologic response such as the release of endogenous opioids [4, 35]. Furthermore, the placebo response can be shown to produce a typical **pharmacokinetic** profile of activity [56].

Surgery and other mechanical or invasive procedures have been thought to produce exaggerated placebo responses, ever since the original studies of sham internal mammary artery ligation for the treatment of angina, where 80% of patients in the sham treatment arm reported substantial improvement [9]. More recently, the value of an extremely common procedure, arthroscopic lavage and debridement in patients with osteoarthritis of the knee, was questioned when it was found no better than sham surgery for outcomes of pain and physical function [37]. Reviews of trials examining placebo or comparing different placebo routes indicate that injections are more powerful than pills, and devices or procedures, such as sham ultrasound or sham acupuncture seem to be associated with stronger placebo effects than oral placebos [15, 28]. However, the extent to which the response is influenced by the procedure administrator versus the procedure itself remains unclear.

Ethics of Employing Placebo in Research

Many questions have been raised about the ethics of using placebos in human research. Strong critics of the placebo argue that it is not ethical to assign subjects to any intervention that has even the potential of being less efficacious than current therapy (*see* **Ethics of Randomized Trials**). The opposing view asserts that very few "standard" treatments have been proven effective by today's research standards, that placebo-controlled trials are a necessary first step with the smallest sample size to establish whether further research with a drug or treatment is warranted and that patients tend to improve within these trials regardless of allocation because of the close attention and follow-up. Certain situations, such as life-threatening conditions where a proven effective treatment exists, are agreed to be inappropriate for placebo-only allocation [50]. One of the areas of medicine where the use of placebo has been debated widely is in depression. Critics worried that randomization to placebo might lead

to serious harm including suicide. When this was reviewed, not only were completed and attempted suicide rates similar for placebo, standard antidepressants (imipramine, amitriptyline, trazodone), and the investigational antidepressants (fluoxetine, sertraline, paroxetine), but also the clinical responses were not very different among the three groups either [30]. Another large review noted that the response to placebo in depressed patients was highly variable (10–50%) between trials, and has increased over the years with increasing trial length [55]. All of these factors suggest that the use of active treatment controls instead of placebo would make accurate evaluation of interventions difficult.

Although it has been well argued that research subjects, by way of informed consent, indicate their willingness to freely participate in a placebo-controlled trial, there is some evidence that patients may not be fully informed about risks and benefits of the treatment options [25, 43]. Studies of consent documents have shown that they sometimes overstate the benefits and understate the risks of research protocols and are frequently written beyond the reading level of patients [11, 33, 49]. Even when consent forms are accurate and appropriate, patients may confuse treatment in a clinical trial with that of individualized medical care, overestimate the benefits of participating in a trial, and underestimate the risks they may be involved in [20]. A recent survey of patients participating in cancer trials showed that while they were satisfied with the consent form and considered themselves well informed, a large percentage of these patients did not recognize that the treatment being described was not a standard therapy, that there was potential risk to themselves, and that the study drug was unproven [25]. This research suggests that some of the placebo effect is already evident at this early stage before any treatment is actually given – the trust in trial clinicians, the hope for therapeutic benefit, and so on may color the patient's memory of consent.

Guidelines for the Use of Placebos in Research

Several prominent guidelines provide some direction for the use of placebos in research. All agree on basic principles such as noncoercion and fully informed consent for participants. In other matters, the guidelines differ somewhat. The Declaration of Helsinki has the strictest guidelines and is often cited by critics of the placebo. First ratified by the World Medical Association (WMA) in 1964, it cites "The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic, or therapeutic methods exists" [57]. However, its stand has been criticized as too strict as "best ... methods" may not be the same as "best available" or "most cost-effective" comparators [40] and many standard therapies have not been rigorously compared to determine which is the best. The International Conference on Harmonization (ICH), a committee with representatives from the drug industry and regulatory authorities internationally, has published ICH E10 – Guideline for Choice of Control Group and Related Issues in Clinical Trials [53]. These **guidelines**, citing the unique scientific usefulness and general safety of placebos, allow the use of placebo controls even when effective treatment exists unless subjects would be exposed to an unacceptable risk of death or permanent injury or if the toxicity of standard therapy is so severe that "many patients have refused to receive it". ICH E10 advocates the use of modified study designs whenever possible, such as add-on studies, **factorial designs**, or "early escape" from ineffective therapy [53].

Various national regulatory and research bodies have formulated their own guidelines. The Tri-Council Policy Statement (TCPS) from Canada's three main research granting agencies, requires that grant recipients abide by the Declaration of Helsinki, prohibiting the use of placebo-controlled trials if there is an existing effective therapy available. However, it allows for broad exemptions, for example, for exceptional circumstances where effective treatment is not available to patients due to cost constraints or short supply, use in refractory patients, for testing add-on treatment to standard therapy, where patients have provided an informed refusal of standard therapy for a minor condition for which patients commonly refuse treatment, or when withholding such therapy will not lead to undue suffering or the possibility of irreversible harm [51]. The US **Food and Drug Administration's** Code of Federal Regulations (CFR), revised in April 2002, accepts placebo-controlled trials and does not stipulate any restrictions but strongly advocates the need for informed

consent [10, 18]. The primacy of informed patient consent in placebo-controlled trials has spurred a number of critiques [25, 32, 48], challenges [52], and recommendations to improve processes of obtaining consent [11, 31, 44, 47, 54].

Patients themselves have become involved. The National Depressive and Manic-depressive Association, a large patient-directed illness-specific organization in the United States, recently developed a consensus development panel to discuss the controversy regarding the use of placebo [8]. In their guidelines, they acknowledge that mood disorders are episodic, chronic conditions that are associated with considerable morbidity and have no curative or fully preventative treatments. Despite the Declaration of Helsinki, it was agreed that mood disorder research was not at the point where noninferiority trials (trials designed only to rule out that the new therapy is worse than the control) (*see* **Equivalence Trials**) involving active controls could be considered scientifically valid designs. Therefore, the guidelines cite "placebo is justified when testing a new antidepressant with a novel mechanism of action that has a substantial probability of efficacy with an acceptable adverse effect risk. However, placebo is also ethical in studies of new drugs in a class because the newer members may offer important advantages over the original drug."

Despite the guidelines that currently aid researchers regarding the use of placebos in research, there are ongoing issues that need to be addressed. One could debate the "proof" of efficacy compared to placebo for many drugs in current use, such that the counterargument has been made that it might be unethical to insist on the use of these drugs in control groups. The Declaration of Helsinki's view on placebo was established in an attempt to deter pharmaceutical companies and research organizations from exploiting people in poorer populations, who may not have access to proven treatments. This concern is not relevant in many countries. Advocating the use of placebos only when no standard treatment exists leaves the efficacy of drugs in certain patient groups largely unknown. Many clinicians need to know whether a therapy is "better than nothing" and could therefore be an alternative for patients who do not respond to the conventional treatment or cannot tolerate it [45]. In chronic diseases such as hypertension, diabetes, and vascular disease, combinations of therapies are increasingly prevalent. It is likely a more efficient assessment of a new drug to test it against placebo initially before embarking on multiple, more complicated, larger sample size, drug add-on trials.

Innovations to Improve Research Involving Placebo

Apart from improving the process of informed consent as described above, several themes of innovative trial design are developing. All attempt to minimize patient exposure to placebo only or increase the efficiency of the design to lower sample size. The first design, now commonly used, is the add-on trial where one group gets both the standard therapy and the new therapy while the other group gets the standard therapy only. The difference between the mean response of the combination standard/new therapy group and the mean of the standard therapy group alone is a reasonable estimate of effect of the new therapy provided the two therapies do not interact with each other.

The second design was developed for antidepressant drug trials to address the high placebo response rates [55]. This two-phase randomized **crossover** method initially randomizes more patients to placebo than active therapy and, in the second phase, crosses over only placebo nonresponders [16]. It is intended to minimize the overall placebo response rate and thus the sample size required to show a clinically important difference (*see* **Sample Size Determination for Clinical Trials**).

The third design avoids the bias of patient selection according to placebo response. A 2^2 factorial design involving standard and new therapies has four groups: double placebo, new therapy, standard therapy, and combination standard therapy/new therapy. With a $1:1:1:1$ allocation ratio, there are two estimates of the efficacy of the new therapy–the difference between the new therapy group mean and the double placebo group mean, and the difference between the combination standard therapy/new therapy group mean and the standard therapy group mean. These two estimates are pooled together to measure the overall efficacy of the new therapy by computing the mean of the two estimates. These two estimates should be similar to each other provided the new therapy does not **interact** with the standard therapy. However, one half of the patients are given either the double placebo or the new therapy of yet unproven efficacy. This may present an ethical problem if the

standard therapy has excellent efficacy and clinicians are reluctant to deny patients access to it. If the investigator were to drop these two groups from the third design, the result is the first, add-on design, and the measure of interaction between the two therapies has to rely on theory, not data.

A fourth design is possible where there are two known-to-be effective therapies available and where some clinicians might use the first standard, some might use the second standard, and some might use both standards together. Here, a 2^3 factorial design should be considered: triple placebo, new therapy, first standard therapy, second standard therapy, double combination of new therapy and the first standard therapy, double combination of the new therapy with the second standard therapy, double combination of the first standard and second standard therapies, triple combination of the new therapy, the first standard therapy and the second standard therapy with 8 groups and an equal allocation ratio. The design would provide four estimates of the efficacy of new therapy, namely: (1) the difference in the mean of new therapy group and the mean of the triple placebo group, (2) the difference in the mean of the double combination of new therapy and first standard group and the mean of the first standard group, (3) the difference in the mean of the double combination of the new therapy and second standard therapy and the mean of the second standard group and (4) the difference between the mean of the triple combination of new therapy, first standard therapy and second standard therapy and the mean of the double combination of the first and second standard therapies. These four estimates should be similar to each other provided the new therapy does not interact with either of the first or second standard therapies, an assumption that can be checked.

Finally, if the two ethically challenged groups, placebo and new therapy, are dropped from the fourth design, then the remaining fractional factorial design has six groups that permit three estimates of efficacy of the new therapy, namely, (2), (3), and (4). Again these three estimates should be similar to each other provided the two standard therapies do not interact with new therapy, and these three estimates should be similar to the one estimate of the efficacy of the new therapy that it is not possible to obtain from the six groups, namely (1). This six-group fractional factorial design still permits the efficacy of the new therapy to be estimated by pooling together the three estimates with the mean of (2), (3), and (4). Provided the interaction assumption is reasonable, this three-term mean should provide adequate evidence of the efficacy of the new therapy. This fifth design should be ethically acceptable since no patient is being denied the benefit of a known therapy.

Summary

The placebo's role in medicine has been and continues to be in transition. For decades, the dispute regarding the placebo revolved around its ability (or not) to induce psychological or physiological effects. More recently, the debate has focused on the utilization of the placebo-controlled trial, its usefulness, and whether, despite informed consent, it impinges on patient autonomy and the practice of beneficence. There are currently several international guidelines that direct the researchers on the use of placebos; however, there are prominent differences between them. The future is likely to bring developments in trial designs where a new therapy's effect can be compared to placebo yet no individual subject is exposed only to placebo, designs that lower the placebo response rate so that treatment effect may be ascertained more efficiently, and designs that allow further exploration and exploitation of factors influencing the placebo effect.

Point Processes

Point processes provide the appropriate mathematical models for describing a countable set of points randomly located in some space; renewal and Poisson processes on a line are the simplest and best-known examples. There is a rich variety of applicable point process models of relevance in many fields. As discussed in [17], the origins of point process theory lie in the areas of **life tables** and renewal theory, counting problems starting from work of **S.D. Poisson** and leading to applications in particle physics and population processes (*see* **Population Growth Models**), and communication engineering.

Illustrative examples of point processes include: times of emission of pulses in a nerve fiber; times of arrival of patients at an intensive care unit; survival times of patients following onset of a disease; locations of trees in a forest, ants' nests in a region, particles in space, or a specified type of cell in a section (or volume) of tissue; locations and instantaneous directions of movement of insects, spermatozoa, etc. in a region; times of occurrence, locations and magnitudes of earthquakes in a given region.

It may be helpful to read the present article in conjunction with those on **renewal processes** and **Poisson processes**. Especially in the latter, many key point process ideas are introduced, often in a simple intuitive way using appealing examples. Here, we sketch in a more formal way the foundational ideas, in the hope that the reader may be assisted and motivated to read the literature. Even those parts of the point process literature that look forbiddingly mathematical are often based on very simple ideas which a nonmathematician may well be able to grasp without needing to understand all the detailed mathematics. Further aims, especially in later sections, are to show some of the rich variety of point process and **stochastic process** models that can be built from more basic point processes, and to discuss some aspects of statistical inference for point process data.

Representing Realizations

The intuitive paradigm of a point process realization should mostly be, as above, a (finite or) countable set $\mathbf{x} = \{x_i\}$ of (distinct) points randomly located in some *state space* S. This space would commonly be one-dimensional, often representing time, or two- or three-dimensional. In principle, dealing with earthquakes would require a time dimension, three spatial dimensions for the location of the epicenter, and a further dimension for the magnitudes. Thus, for many applications, the state space S will be a Euclidean space, and essentially, this is assumed in the present article. More general spaces can be used, and indeed are required to deal with aspects of point process theory and some applications, for example in stochastic geometry and **stereology** (see [5] and [9]); some of these applications are discussed in a later section.

Two other points of view concerning realizations are possible. The first, applicable only when the space is one-dimensional and ordered, like the real line, involves representing the realization as the sequence of "intervals" between successive points and telling where these points should be located in relation to the origin. Renewal processes are usually defined in this way. The second involves viewing the realization as a counting measure $N(\cdot)$. (A *measure* is a function defined for sets, taking nonnegative real values or the value $+\infty$, and additive, even countably so, over disjoint sets. In respect of the latter property a measure behaves like **probabilities**. A measure is called a *counting measure* if its values are nonnegative integers or $+\infty$ (*see* **Counting Process Methods in Survival Analysis**).) The connection between this and the initial view is that $N(B) = \#\{x_i \in B\}$, the number of points from the set $\{x_i\}$ which lie in B, considered for suitable subsets B of the space. Such subsets should include at least all possible bounded sets which are intervals (on a line), rectangles or disks (in a plane), or boxes or balls (in space), as well as unions and intersections of these. In addition, it is usual to assume that $N(B)$ is finite whenever the set B is bounded. Such an assumption, often called *local finiteness*, is likely to be satisfied in most applications.

The counting (measure) view of realizations, although maybe not the most intuitive, is not without practical relevance, in that suitable counts will often provide an appropriate description of the data. Moreover, this view is necessary for developing a nice mathematical theory of point processes in general spaces, in particular because it facilitates the treatment of possible "multiple" points. (In the set view of realizations the points x_i must, strictly speaking, be distinct.)

A disadvantage of adopting the counting viewpoint is that the resultant theory depends heavily on the theory of measure and integration, which is often regarded as difficult, and not common knowledge among those interested in applications of point processes. Nevertheless, many of the ideas of point process theory can be explained with minimal dependence on measure and integration theory, sometimes by resorting to the more heuristic "set" view of realizations. This is the approach adopted in the present article. For a more mathematical approach consult the references listed at the end of this article, especially [24].

Describing Point Processes

To describe a point process we need, in principle, all probabilities such as $\Pr(N(B) = n), n = 0, 1, \ldots$, for suitable sets B, and also all joint probabilities

$$\Pr(N(B_1) = n_1, N(B_2) = n_2), \quad n_1, n_2 = 0, 1, \ldots,$$

for suitable B_1 and B_2. For fixed B, the collection of probabilities

$$\{\Pr(N(B) = n) : n = 0, 1, \ldots\}$$

is one of the *one-dimensional distributions* of the process. Similarly, for fixed B_1 and B_2 the collection

$$\{\Pr(N(B_1) = n_1, N(B_2) = n_2) : n_1, n_2 = 0, 1, \ldots\}$$

of joint probabilities is one of the *two-dimensional distributions* of the point process.

In general, for a fixed positive integer k and (Borel) subsets $B_1, \ldots, B_k$ of the state space we need

$$\{\Pr(N(B_1) = n_1, \ldots, N(B_k) = n_k) : n_1, \ldots, n_k = 0, 1, \ldots\}.$$

This is simply the joint distribution of $N(B_1), \ldots, N(B_k)$, the numbers of points in the sets $B_1, \ldots, B_k$. These joint distributions, for all possible k and subsets $B_1, \ldots, B_k$, are called the *finite-dimensional distributions* of the point process. For a given point process, they must be mutually consistent; for instance, the marginals of any two-dimensional distribution must coincide with the separate one-dimensional distributions for the specified sets B_1 and B_2. Furthermore, for example, since for disjoint B_1 and B_2 the counts must be additive in the sense that $N(B_1 \cup B_2) = N(B_1) + N(B_2)$ (with probability one), the family of one-dimensional distributions of a point process must be an "additive" family of probability distributions. Such additivity and consistency conditions, though in a sense simple, are highly restrictive: they put severe limitations on the structure of the possible finite-dimensional distributions for a point process, and in general make it a nontrivial task to specify (a new) point process model.

If a suitable consistent, additive family of potential finite-dimensional distributions can be found, then we have specified a point process. (Some would regard this conclusion as resting on a variant of a stochastic process existence theorem usually attributed to Kolmogorov.) Thus the properties of a point process can be regarded as being determined by the collection of all its finite-dimensional distributions.

At least when the state space is Euclidean, i.e. $S = \mathbb{R}^d$ for some positive integer d, a point process is called *(strictly) stationary* if its probabilistic properties are invariant under translation: specifically, if for every u in the state space S, every positive integer k, every collection of subsets $B_1, \ldots, B_k$ of the state space, and every collection $n_1, \ldots, n_k$ of nonnegative integers, we have

$$\Pr(N(B_1) = n_1, \ldots, N(B_k) = n_k) = \Pr(N(B_1 + u) = n_1, \ldots, N(B_k + u) = n_k),$$

where $B + u = \{x + u : x \in B\}$ denotes the set of all points obtained by translating B by u. Thus for a stationary point process the distribution, and hence expected value, of the number of points falling in any translate of a given set B is the same as that for the set B. One consequence is that $\mathrm{E}N(B) = \mu|B|$, where $|B|$ denotes the Lebesgue measure (length, area, volume, etc.) of B and μ, called the *intensity*, denotes the expected number of points falling in any set U having $|U| = 1$ (that is, any set having unit length, area or volume, as appropriate). Also, for any stationary point process, it can be shown that the limit

$$\rho = \lim_{h \to 0+} \frac{\Pr\big(N(B_h) > 0\big)}{h^d},$$

where $B_h = (0, h]^d$, exists and $0 \le \rho \le \infty$. The quantity ρ is often called the *rate* of the point process, though this terminology is not standardized in the literature. Note that $\rho \le \mu$ since $\Pr\big(N(B_h) >$

$0) \leq \mathbb{E}N(B_h)$ for all h. For spatial point processes ($d \geq 2$) one may also be interested in *isotropy*, a concept analogous to stationarity, defined by all the finite-dimensional distributions being invariant under rotations.

A point process is called *simple* if, with probability one, its realizations have no multiple points, i.e. if $\Pr(N(\{x\}) = 0 \text{ or } 1 \text{ for every } x \in S) = 1$. From any point process N it is possible to derive an associated simple point process N^* by "forgetting" all multiplicities in the original process N. The process N^* is stationary whenever N is stationary, and therefore has an intensity μ^*. Clearly, $\mu^* \leq \mu$. Furthermore, for a point process N that is both simple and stationary $\rho = \mu\ (= \mu^*)$, a result often known as Korolyuk's theorem.

A point process is termed *mixing* if events defined in terms of the numbers of points in widely separated sets are close to independent. (For a formal definition see, for example, [17].) Some such property is needed to ensure consistent estimation of the intensity of a stationary point process; many use the related notion of ergodicity (cf. [25] or [43, p. 194]).

It is important to be able to look at the distribution of a point process when we view that process from an arbitrary point in the process. The *Palm distribution* of a point process is, more formally, the conditional distribution of the process given that, for example, there is a point of the process at x. For a stationary point process this conditioning can be reduced to the demand that there be a point at the origin. Such conditioning requires care because the conditioning event is clearly one of probability zero, and a rigorous introduction is beyond the scope of the present article. For a stationary point process on the real line it is by means of the Palm distribution that we must approach, for example, the distribution of the times between successive points ("intervals") when starting from a description of the process in terms of its finite-dimensional distributions. There is also an inversion formula which allows the latter distributions to be expressed in terms of the Palm distribution. The simplest consequence of this is that the intensity of a stationary simple point process is equal to the reciprocal of the mean time between successive points. For a development of these ideas see [41, Chapter 4] or [45]. For a stationary isotropic point process the Palm distribution is needed at least in order to define formally the nearest-neighbor distribution function and the K-function which play an important role in statistical inference for such processes (see the section "Statistical Inference" later in this article).

Some Basic Point Processes

A *homogeneous Poisson process* in a Euclidean space $S = \mathbb{R}^d$ can be defined by the following two requirements:

1. $N(B) \sim \text{Poi}(\lambda|B|)$, where $|\cdot|$ denotes Lebesgue measure (length, area or volume) on $\mathbb{R}^d$ and B denotes any bounded subset of the state space S.
2. $N(B_1), \ldots, N(B_k)$ are mutually independent random variables whenever $B_1, \ldots, B_k$ are pairwise disjoint bounded subsets of S.

A point process satisfying the latter condition is often called *completely random*. Observe that requirements 1 and 2 together specify the form of all finite-dimensional distributions and ensure the process is (strictly) stationary. In addition, requirement 1 ensures that λ is the intensity of the process.

Any homogeneous Poisson process has the fundamental property that, given the number of points in a bounded subset of the state space, these points are distributed independently and uniformly over the subset. This "conditional" property is an important tool in proving other results about homogeneous Poisson processes and about processes derived from them.

The point process that results from such conditioning of is a particular type of *Bernoulli process* (also called sample process or binomial process).

In general, such a process is defined on a compact (i.e. closed and bounded) set W by requiring that all its realizations have the same fixed total number of points and that these points are distributed independently and identically over W according to some specified probability distribution. Such processes are straightforward to simulate.

A Poisson process with *intensity function* $\lambda(u)$, where $\lambda(u)$ is nonnegative for all u in S and $\int_B \lambda(u)\,\mathrm{d}u$ is finite for all bounded sets B, is defined as for a homogeneous Poisson process but with requirement 1 replaced by

1. $N(B) \sim \text{Poi}(\int_B \lambda_u\,\mathrm{d}u)$, for any bounded subset B of the state space S.

Such a process is also called an *inhomogeneous* or *nonhomogeneous Poisson process*, a terminology which is not meant to exclude homogeneous Poisson processes as the special cases for which the intensity function is in fact constant. The class of inhomogeneous Poisson processes includes, for example, processes for which $\lambda(u)$ – or perhaps preferably, $\ln \lambda(u)$ – exhibits some trend with u, is a periodic function, or is dependent on the values of some associated explanatory variables. For processes on the real line, viewed as a time axis, the intensity function is commonly referred to as the instantaneous intensity function.

In practice, many point processes will be defined most simply by means other than direct specification of their finite-dimensional distributions. When $S = [0, \infty)$ we can define an *(ordinary) renewal process* by the set $\{L_1, L_1 + L_2, L_1 + L_2 + L_3, \ldots\}$ of random points, where $L_1, L_2, L_3, \ldots$ are independent and identically distributed (lifetime) random variables. If L_1 is allowed a distribution different from that of the other random variables the process is called a *modified renewal process*. Counting properties of a renewal process are less simple to describe, except when the common distribution of $L_1, L_2, L_3, \ldots$ is an **exponential distribution**, in which case the process reduces to a homogeneous Poisson process on $[0, \infty)$.

A wide variety of types of point process can be defined in terms of simpler point processes, such as Poisson or renewal processes. Their finite-dimensional distributions could, in principle, then be derived, although this may be difficult or tedious in practice, and unnecessary in full detail. Sometimes it is possible to work with probability **generating functions** or **moment generating functions** of relevant finite-dimensional distributions, and at other times with certain summary measures or **moments**.

Three broad classes of point processes can be constructed from Poisson processes by introducing further randomness. One of these is the class of *compound Poisson processes*. Such a process is obtained from a Poisson process, homogeneous or inhomogeneous, by replacing each point, independently of the other points, by a random number of new points all of which are placed at the associated point of the original process. In general a process of this type would have points with multiplicity greater than one. Another class is that of *mixed Poisson processes* (cf. [22]), which are defined by allowing the parameter λ of a homogeneous Poisson process to have a specified distribution (*see* **Contagious Distributions**). Such processes provide one of the simplest classes of processes which are not mixing; essentially the lack of mixing is a consequence of the dependence of the number of points in even widely separated sets on the common value of λ. The third class is that of *doubly stochastic Poisson processes* or *Cox processes*. Such a process is obtained from an inhomogeneous Poisson process by allowing its intensity function to be a realization of some other stochastic process, which might be thought of as representing an underlying (usually unobservable) environmental heterogeneity. One type of Cox process on $S = \mathbb{R}$ is obtained taking the stochastic process governing the intensity function to be a continuous-time **Markov chain** with finitely many states. Such processes are also called *Markov modulated Poisson processes* [40]. In the simplest case, the Markov chain has just two states, where these correspond to a high level and a low (or even zero) level for the intensity function. Both the mixed Poisson and Cox process models allow for **overdispersion** (relative to a Poisson process), in that the counts may have a variance greater than their mean.

Product Densities

For point process properties, an approach which many find both intuitively appealing and useful is to consider the so-called *product densities* of the process. These are defined, under further conditions which will be mentioned in the next section, for a point process which is simple. They can be described in terms of differentials as follows: the first-order product density is given, for any u in the state space S, by $m_1(u)\,\mathrm{d}u = \Pr(N(\mathrm{d}u) = 1)$, where the right-hand side can be thought of as the probability of the event "a point at u". In the case of a Poisson process with intensity function $\lambda(u)$ we have $m_1(u) = \lambda(u)$. For a general point process $m_1(u)$ itself is called the *intensity function* of the process.

The second-order product density is given, for any distinct u_1, u_2 in the state space S, by

$$m_2(u_1, u_2)\,\mathrm{d}u_1\,\mathrm{d}u_2 = \Pr(N(\mathrm{d}u_1) = 1, N(\mathrm{d}u_2) = 1),$$

where the right-hand side is the probability of the event "a point at each of u_1 and u_2". In general, for any positive integer k and any distinct $u_1, \ldots, u_k$

in the state space, the kth-order product density is given by

$$m_k(u_1, \ldots, u_k)\, \mathrm{d}u_1 \ldots \mathrm{d}u_k = \Pr(N(\mathrm{d}u_1) = 1, \ldots, N(\mathrm{d}u_k) = 1).$$

For a stationary point process we must have $m_1(u) = \mu$, the intensity of the point process, and $m_2(u_1, u_2)$ must be a function just of $u_2 - u_1$, or even just of the (Euclidean) distance $\mathrm{d}(u_1, u_2)$ between u_1 and u_2 when the process is also isotropic.

In the case of a homogeneous Poisson process with intensity λ we have $m_k(u_1, \ldots, u_k) = \lambda^k$ for all k and distinct $u_1, \ldots, u_k$, and the covariance density is identically zero. For a renewal process, on $S = [0, \infty)$, it can be shown that

$$m_k(u_1, \ldots, u_k) = h_1(u_1)h(u_2 - u_1) \ldots h(u_k - u_{k-1})$$

for all k and distinct $u_1, \ldots, u_k$, where h is the (ordinary) renewal density and h_1 the modified renewal density, which takes account of the fact that the origin need not be a renewal point (*see* **Renewal Processes**).

Since $m_1(u)\, \mathrm{d}u = \Pr(N(\mathrm{d}u) = 1) = \mathrm{E}N(\mathrm{d}u)$, it follows that $\mathrm{E}N(B) = \int_B m_1(u)\, \mathrm{d}u$ gives the expected number of points in B. Similarly,

$$\mathrm{E}N(B)[N(B) - 1] = \int_B \int_B m_2(u_1, u_2)\, \mathrm{d}u_1\, \mathrm{d}u_2$$

yields the second factorial moment of $N(B)$. These ideas lead to consideration of moment measures.

Moment Measures

For any point process N, a set function $M_1(\cdot)$ can be defined for (Borel) subsets B of S by $M_1(B) = \mathrm{E}N(B)$. This inherits the nonnegativity and additivity properties of N and so is itself a measure, variously called the *mean measure*, the *intensity measure* or the *first moment measure* of N. This and higher-order equivalents provide for a point process the analogs of the ordinary moments of a random variable.

The simplest aspects of the dependence structure of a point process are embodied in its *second moment measure* $M_2(\cdot)$. This is defined for subsets B_1 and B_2 of the state space starting from its value $M_2(B_1 \times B_2) = \mathrm{E}N(B_1)N(B_2)$ for the "rectangle" $B_1 \times B_2$ in S^2, the Cartesian product of the state space with itself, and extending in a standard manner to a measure $M_2(\cdot)$ on S^2. Since $M_2(B_1 \times B_2) = M_2(B_2 \times B_1)$, $M_2(\cdot)$ is a symmetric measure. In a similar way, starting from $C(B_1 \times B_2) = M_2(B_1 \times B_2) - M_1(B_1)M_1(B_2)$ we can define the *covariance measure* of the point process N. (Observe that C, although being additive for disjoint sets, may take negative values.) Putting $B_1 = B_2 = B$ gives $M_2(B \times B) = \mathrm{E}\{N(B)^2\}$, and also the *variance function*, a set function, defined by $\mathrm{var}N(B) = C(B \times B)$. When the state space is the real line and $B = (0, t]$, it is the function $V(t) = \mathrm{var}N((0, t])$ which is usually called the variance function.

A disadvantage of the moment measures is that the second and all higher-order moment measures of any point process have "diagonal concentrations" [17, Section 5.4]. At least for simple point processes, this disadvantage can avoided by introducing *factorial moment measures*, which are the point process analogs of factorial moments for a random variable. The first factorial moment measure coincides with the mean measure, while the second factorial moment measure $M_{[2]}(\cdot)$ can be defined by

$$M_{[2]}(B_1 \times B_2) = M_2(B_1 \times B_2) - M_1(B_1 \cap B_2)$$

for subsets B_1 and B_2 of S. Observe that when B_1 and B_2 are disjoint the right-hand side reduces to $M_2(B_1 \times B_2)$, but that when $B_1 = B_2 = B$ (say) it reduces to the second factorial moment of $N(B)$. In some circumstances when $S = \mathbb{R}^d$ for some d, the factorial moment measures can be defined by densities with respect to Lebesgue measure (length, area, volume, etc.) in the appropriate dimensional Euclidean space, these being the product densities introduced heuristically in the previous section.

A useful result for moment measures is *Campbell's theorem* (see [17, Section 6.4] or [27, Section 3.2]), the simplest version of this being that for a wide class of functions g and subsets B of the state space

$$\mathrm{E}\left\{\int_B g(u)N(\mathrm{d}x)\right\} = \int_B g(u)M_1(\mathrm{d}u).$$

An alternative, possibly more immediately meaningful expression of this is

$$\mathrm{E}\left\{\sum_{i:X_i \in B} g(X_i)\right\} = \int_B g(u)m_1(u)\, \mathrm{d}u,$$

where $\{X_i\}$ is the set of random points corresponding to the point process N and $m_1(u)$ its intensity

function. The latter integral simplifies to $\mu \int_B g(u)\,\mathrm{d}u$ whenever the point process is stationary with intensity μ. Campbell's theorem can be extended to results for higher-order moment measures, and also to results involving the Palm distribution; see, for example, [45, Chapter 4].

Operations on Point Processes and Associated Limit Results

There are a number of operations by which new point processes can be generated from a process or processes already defined. Useful tools for dealing with these operations – generating functionals – will be discussed in a later section.

Superposition

For two point processes N_1 and N_2, not necessarily independent, a new process, N, their *superposition*, can be defined by $N = N_1 + N_2$, where this is to be interpreted as $N(B) = N_1(B) + N_2(B)$ for subsets B of the state space (or in intuitive terms as the pooling of the sets of points for the two processes). When the processes are independent, the distribution of the superposition can be viewed as a convolution of the distributions of the summand processes. In particular, the superposition of two independent homogeneous Poisson processes with respective intensities λ_1 and λ_2 is another homogeneous Poisson process, with intensity $\lambda = \lambda_1 + \lambda_2$. By iteration, the superposition of several point processes can be considered and, under appropriate conditions, the superposition of a countable number of point processes (the latter being needed, for example, in "Cluster processes"; see below).

Random Deletion

Given a point process N, consider the operation of *random deletion* or *random thinning* (sometimes called Bernoulli deletion) whereby, given a realization of N, each point in that realization is deleted with probability $1 - p$ and retained with probability p, independently of all other points in the realization. The intensity function for the process of retained points is then clearly $pm_1(u)$, where $m_1(u)$ is the corresponding intensity for the original process N. Thus, if N is stationary with intensity μ, then the process of retained points is stationary, with intensity $p\mu$. If N is a homogeneous Poisson process, then so is the new process; furthermore, so is the process of deleted points, and these two processes are independent.

Random Translation

For any point process N the operation of *random translation* can be defined as follows: given a realization of N, each point in that realization is shifted, independently of all other points in the realization, the shift having some specified distribution function on S, where this distribution is the same for each point in the original realization. (The shifts are thus assumed independent and identically distributed.) If the original point process is stationary, then so also is the resultant randomly translated process; furthermore, if N is homogeneous Poisson, then so is the resultant process and their intensities are the same.

Cluster Processes

Here each point of an "input" point process is replaced by the points of some subsidiary point process or cluster, and the superposition of all these clusters is then the "output" process or *cluster process*. In the simplest situation the input might be a homogeneous Poisson process with specified intensity and the clusters independent and identically distributed point processes, each with its origin translated to the associated point of the input process (often called the cluster center). Then, when $S = \mathbb{R}$, two particular types of cluster structure are: (i) a finite renewal process with the number of points either fixed or following a specified distribution, and the interval (lifetime) distribution also specified; or (ii) a process in which the number of points is either fixed or follows a specified distribution, and these points are placed independently and identically according to a specified distribution on S. The resultant cluster processes are respectively termed *Bartlett–Lewis* and *Neyman–Scott (cluster) processes*. Processes of the latter type can also be considered for Euclidean state spaces $S = \mathbb{R}^d$. Compound Poisson processes are special cases in which all the points of a given cluster are placed at the cluster center.

State Space Transformation

In this case the operation is not defined directly on a process or processes, but initially as a mapping

which transforms points of the state space S into points of a new state space S^*. Such a mapping then transforms the set of points of any given point process realization in S into a corresponding realization in S^*. Under this type of operation an inhomogeneous Poisson process on S is transformed into another such process on S^* [27, Section 2.3]. However, if the initial process were a homogeneous Poisson process the homogeneity would not in general be preserved.

Limit Results

Associated with the operations of superposition, random deletion and random translation are certain limit results concerning point processes. The simplest is that the superposition of a large number of independent and suitably sparse point processes is approximately a Poisson process.

For point processes in Euclidean state spaces, the simplest limit theorem for deletions is as follows: suppose that points of an initial point process are subject to Bernoulli deletions, with retention probability p for any individual point, and that the scale is contracted so as to balance the deletions and preserve the intensity. From suitable initial point processes, it is possible to prove convergence as $p \to 0$ to a homogeneous Poisson process.

Among limit results for random translations, arguably the simplest allows the points of a suitable initial point process to move with independent and identically distributed random velocities, and yields convergence to a homogeneous Poisson process after a long time.

Substantial generalizations of these basic results can be considered, and once again generating functional methods can be used. Here, we have not attempted even a definition of what is meant by convergence of point processes: for this and other details see, for example, [17, Chapter 9].

Generating Functionals

Various **generating functions** (probability generating functions, **moment generating functions** or Laplace transforms, and **characteristic functions**) are useful tools in the study of random variables; probability generating functions are especially helpful with nonnegative integer-valued random variables. All the above generating functions have "functional" relatives that are useful in the study of point processes, as a means of compactly summarizing information about point processes and enabling that information to be manipulated. We mention here only one type of functional. (A functional is a function whose argument is itself a function, rather than a real number or vector of real numbers.)

The *probability generating functional* G of a point process N can be defined, for functions h mapping the state space S to values in [0, 1] and equal to one outside some bounded set, by $G[h] = \mathrm{E}\left(\exp\left\{\int_s \ln h(u) N(\mathrm{d}u)\right\}\right)$. This can be considered heuristically as

$$G[h] = \mathrm{E}\left(\prod_{u \in S} h(u)^{N(\mathrm{d}u)}\right) = \mathrm{E}\left(\prod_{u : N(\{u\}) > 0} h(u)^{N(\{u\})}\right).$$

The middle expression allows us to think of G as the joint probability generating function of all the random variables $N(\mathrm{d}u), u \in S$. Working heuristically with this form, property (ii) of a homogeneous Poisson process with intensity λ, and the form of the probability generating function of a Poisson-distributed random variable, we find that the probability generating functional of a homogeneous Poisson process with intensity λ is

$$\begin{aligned} G[h] &= \prod_{u \in S} \mathrm{E}(\exp\{[h(u) - 1]\lambda \, \mathrm{d}u\}) \\ &= \exp\left\{\lambda \int_s [h(u) - 1] \, \mathrm{d}u\right\}. \end{aligned}$$

Consider now the superposition N of two independent point processes N_1 and N_2 having respective probability generating functionals G_1 and G_2. Then the probability generating functional of the superposition N is given by $G[h] = G_1[h]G_2[h]$. The probability generating functional of the process obtained from N by random deletions, as described earlier is $G[1 - p + ph]$, where G is the probability generating functional of N. Using these ideas it is possible to give proofs of the assertions about Poisson processes made in the previous section; see, for example, [17, Section 8.2].

Markov Point Processes and Some Related Processes

A wide class of point processes on some bounded subset S of a Euclidean space can be defined by

specifying their densities, i.e. likelihood ratios, with respect to a homogeneous Poisson process of unit intensity defined on S. Among these processes are some, known as *Markov point processes*, which allow the introduction of a form of spatial dependence that is local or Markov (see [14, Section 8.5.5], [20, Section 4.9] or [45, Section 5.5]). For the simplest such processes, the densities (with respect to the unit Poisson process) have a representation as a canonical **exponential family** (see, for example, [31, Chapter 2] and references cited there), with a small number of parameters. Since **maximum likelihood** estimation is in principle straightforward for canonical exponential families, inference for such Markov point processes should also be so. The main difficulty is that the **likelihood function** for such a Markov point process family would usually involve the (parameter-dependent) normalizing constant, for which an explicit closed form is generally impossible. In such a case, the conventional approach to maximum likelihood estimation, based on solving the likelihood equation(s), is not feasible. However, recent advances in computing power and statistical technology have made it possible to bypass calculation of the normalizing constant and conventional maximum likelihood estimation by using the approach known as **Markov chain Monte Carlo**, which involves large-scale **simulation**. For an introduction to these ideas, see [21].

The simplest nontrivial example of such a Markov point process family is the family of *Strauss processes*. These can be defined by densities (with respect to the unit Poisson process) which are proportional to $\beta^{n(\mathbf{x})}\gamma^{t(\mathbf{x})}$, where $\mathbf{x}$ here denotes a particular realization (i.e. a set of finitely many points from S), $n(\mathbf{x})$ is the number of points in $\mathbf{x}$ and $t(\mathbf{x})$ counts the number of r-neighbors of $\mathbf{x}$, that is the number of pairs of points in $\mathbf{x}$ that are within a prespecified distance r of each other. The parameter β, which must be nonnegative, relates to the intensity of the process, while γ is an interaction parameter and must satisfy $0 \leq \gamma \leq 1$. When $\gamma = 1$ the process reduces to a homogeneous Poisson process with intensity β. The case $\gamma = 0$ corresponds to a simple inhibition process, often called a *hard core process*, in which Poisson realizations are conditioned to have no pairs that are r-neighbors. Cases with $0 < \gamma < 1$ yield processes exhibiting less strict inhibition. Another such family, consisting of so-called *triplets processes* [21], can be generated in a similar way by bringing in a further statistic $w(\mathbf{x})$ which counts the number of triples of points that are mutual r-neighbors. The resultant exponential family has a three-dimensional canonical statistic $(n(\mathbf{x}), t(\mathbf{x}), w(\mathbf{x}))$. Such processes can, like the Strauss process, be fitted by Markov chain Monte Carlo methods [21]. Similar comments apply to the *area interaction* processes introduced in [6].

Another class of point processes including Strauss processes is the class of *pairwise interaction processes*, defined by densities (with respect to the unit Poisson process) which are proportional to $\beta^{n(\mathbf{x})} \prod_{i \neq j} h(d(x_i, x_j))$ where $d(x_i, x_j)$ denotes the usual Euclidean distance between x_i and x_j, and h an interaction function, which must be a suitable bounded function. Pairwise interaction processes are a special case of the much wider class of *Gibbs processes* [14, 45], which have their origins in statistical mechanics.

Important in the simulation of the processes discussed in this section, and in Markov chain Monte Carlo methods of inference for such processes, is a class of spatio-temporal stochastic processes known as *spatial birth and death processes* [7, 45]. These are continuous-time pure jump **Markov processes** whose state space is the set of all possible realizations of point processes on S (that is, all finite subsets of S which is assumed, as above, to be a bounded subset of a Euclidean space), and whose only possible transitions are either the "birth" of a new point, or the "death" of a point in the preceding point process realization. (Note that a spatial birth and death process is Markov as regards time). The essence of the connection with simulation is that, under certain conditions, the limiting distribution of a spatial birth and death process is a Markov point process as introduced above. A consequence of this is that realizations of such a Markov point process can be generated as observations on the relevant spatial birth and death process after it has been running for a long time [21, 36].

Statistical Inference

The remarks that follow do scant justice to a difficult area which has been the subject of much recent growth, but may serve as an introduction.

Any statistical analysis of point process data should be backed by suitable **graphical displays**.

Where feasible these should include a plot of the point process realization; in itself, this may show some form of interaction between points. For example, there may be a tendency to **clustering** (in a biological application, perhaps as a result of local reproduction), or to *inhibition* (possibly arising from competition for space or nutrients); *regularity* is likely to be observed when there is inhibition with a minimum permissible distance between points and a sufficiently high intensity. Other plots of data summaries are possible. Some of these may play a purely descriptive or summary role; others may be relevant in fitting particular point process models, or assessing the **goodness of fit** of such models. Whatever the approach, it should be driven primarily by the needs of the person who collected the data.

Assume that the data are a partial realization of a stationary point process: for example, only those points within a bounded window W may be observed. The prime interest may lie in estimation of the intensity. In a forestry application, this may give valuable information, for example on the overall quantity of wood in the forest. However, in such an application it may be necessary to use a more complex model: one that introduces supplementary information on the sizes of individual trees, represented as a mark (see the next section) attached to each point in the point process, may lead to better information on the overall quantity of wood.

If stationarity does not seem a reasonable assumption, then it may be of interest to estimate the intensity function of the process. Here nonparametric *kernel density estimation* techniques could be used (*see* **Density Estimation**); or, based on an inhomogeneous Poisson process model, a specific parametric form could be fitted for the intensity function. These approaches are discussed, for example, in [14, Sections 8.2.4, 8.5.1] and [44, Section 13.3]. Graphical displays in the form of a plot or contour plot of the estimated intensity function could be provided, respectively, for real line or planar data.

In the case of data which are a partial realization of a stationary isotropic point process, three other functions are often considered (see [14, Sections 8.2.6, 8.4] or [20, Chapter 2]). One is $F(r) = \Pr(d(u, \mathbf{x}) \leq r), r > 0$, the distribution function of the distance $d(u, \mathbf{x})$ from an arbitrary point u in S to the nearest point of the process; this is often called the *empty space function*. Another is $G(r) = \Pr(d(x, \mathbf{x}\backslash\{x\}) \leq r), r > 0$, the distribution function of the distance $d(x, \mathbf{x}\backslash\{x\})$ from an arbitrary point x of $\mathbf{x}$ to the nearest other point of the process $\mathbf{x}$. This is the *nearest-neighbor distribution function* of the process. Finally, there is the so-called (Ripley) *K-function* [38] or *reduced second moment function* which can be defined for $r > 0$ by

$$K(r) = \mu^{-1}\mathrm{E}(\text{number of further points of } \mathbf{x} \text{ within distance } r \text{ of an arbitrary point of } \mathbf{x}),$$

where μ is the intensity of the process. To define the latter two functions formally requires consideration of the Palm distribution of the process; the expectation defining the K-function is in fact an expectation with respect to the Palm distribution of the process.

For a homogeneous planar Poisson process with intensity λ it follows that $F(r) = G(r) = 1 - \exp\{-\lambda\pi r^2\}$ and $K(r) = \pi r^2$, $r > 0$. For a clustered point process, $F(r)$ for small r will be less than the corresponding value for a homogeneous Poisson process, while $G(r)$ and $K(r)$ for values of r close to the range of clustering will each be greater than the corresponding Poisson value. For a point process showing inhibition, $F(r)$ for values of r larger than the range of inhibition will exceed the homogeneous Poisson equivalent, while $G(r)$ and $K(r)$ for values of r close to the range of inhibition will each be less than the corresponding Poisson value.

Since $F = G$ for a homogeneous Poisson process, various proposals for assessing Poissonness of a given point process, or as some would say *complete spatial randomness* (often abbreviated to CSR, see [20] or [14]) of that process, are based on comparing F with G. For example, Diggle [19] considered the statistic $\sup_r |F(r) - G(r)|$. Van Lieshout and Baddeley [30] suggested the function $J(r) = [1 - G(r)]/[1 - F(r)]$, defined for r such that $F(r) < 1$, as a useful summary measure to indicate the strength and range of interpoint interactions in a point process. A homogeneous planar Poisson process with intensity λ satisfies $J(r) \equiv 1$. Furthermore, $J(r) < 1$ indicates clustering and $J(r) > 1$ inhibition or regularity, while for many point processes $J(r)$ is constant for r beyond the range of spatial interaction.

The immediately preceding remarks refer to the "true" functions being considered, whereas in practice these functions would usually be estimated from some point process realization. Estimation of the functions F, G, and K on the basis of the points in a bounded window raises special problems of *edge*

effects, which have been discussed by Baddeley [4]. Such effects are of two main types: sampling bias that is size-dependent and related to the well-known problem of **length-biased** sampling (for example, widely separated nearest-neighbor pairs are less likely to be represented in a fixed bounded sampling window), and **censoring** effects (which arise, for example, because the nearest point to a given point inside the window may be outside the window and therefore unobserved). Ways of dealing with these effects are discussed by Ripley [39] and Baddeley [4]. For example, extensions of Campbell's theorem play a key role in assessing bias in the estimation of F, G, and K.

Estimates $\hat{F}$, $\hat{G}$, and $\hat{K}$ can be plotted separately, along with their respective Poisson equivalents based on the estimated intensity. These plots can be used to assess the fit of a homogeneous Poisson process model. Such assessment may be assisted by use of **Monte Carlo** tests (cf. [20]). Here, for example based on F, one would simulate 99 independent realizations from the homogeneous Poisson model with the estimated intensity, and then construct the upper and lower envelopes for F,

$$U_F(r) = \max_i \hat{F}_i(r), \qquad L_F(r) = \min_i \hat{F}_i(r),$$

where the maximum and minimum are taken over the estimates $\hat{F}_i$ of F from each of the 99 simulations. The functions U_F and L_F are then plotted with $\hat{F}$ and its Poisson equivalent. To the extent that $\hat{F}$ lies between U_F and L_F the Poisson model is regarded as acceptable. (Note that, while $(L_F(r), U_F(r))$ gives a 98% **confidence interval** for $F(r)$ for any specified value of r, it cannot be asserted that the same confidence coefficient applies for all values of r in some interval – this is a problem of **simultaneous confidence intervals**.) A similar approach based on G, K, or J could be used; each function embodies somewhat different information from the others, so the plots should be complementary.

Variations on the above plots are possible. For example, one could use a probability plot of P–P type (*see* **Graphical Displays**) where $\hat{F}(r)$ is plotted against the corresponding Poisson equivalent $\hat{F}_{\mathrm{Poi}}(r)$ for each r, and also plot the pairs $(L_F(r), \hat{F}_{\mathrm{Poi}}(r))$ and $(U_F(r), \hat{F}_{\mathrm{Poi}}(r))$ to give corresponding envelope functions. In the case of the K-function it has been found useful to plot either $\hat{K}(r) - \pi r^2$ against r, or $[\hat{K}(r)/\pi]^{1/2} - r$ against r; (see, for example, [14] or [20]).

Indications of deviations from Poissonness shown in plots like those discussed above provide clues as to what type of non-Poisson model may be appropriate. A more detailed description of any observed clustering or inhibition could be attempted by the formulation and fitting of a more complex model (cf. [14, Section 8.5]): for example, this might be some simple Poisson cluster process or a Strauss process. The choice of a suitable model and its fitting may not be entirely simple matters and it is likely that, at least at this stage, the investigator would need to consult with a statistician knowledgeable about point processes. The parameters of a reasonably fitting model provide a summary of the original data: for a homogeneous Poisson process this summary would involve just the intensity; for a Strauss process, as described in the previous section, the parameter β is related to the intensity of the process, while γ describes interactions between neighboring points. Since the case $\gamma = 1$ reduces to a Poisson process, it is in principle possible to assess Poissonness parametrically within the family of Strauss processes by testing the hypothesis $\gamma = 1$.

One of the problems that has impeded development of inference for point process models is the difficulty, and in most cases impossibility, of writing down an expression for the likelihood function. A notable exception is that the likelihood can be written down explicitly for any (inhomogeneous) Poisson process on a line which has been observed over a fixed time interval $(0, T)$; (see [28] or [42]). As indicated in the previous section, there is much current interest (see, for example, [21] and [36]) in the use of Markov chain Monte Carlo methods. These enable likelihood-based inference to be implemented for parametric point process models even when a likelihood function cannot be written down explicitly. There is also the possibility of using pseudo-likelihood methods, in which the likelihood function is replaced by another closely related function that is then used as if it were the likelihood; see [5, 8], and the references therein.

Marked Point Processes and Other Related Processes

As we have indicated above, when modeling the location of earthquakes in a region, or trees in a forest, it may be appropriate to introduce a further random quantity, often called a *mark*, associated

with each point in an underlying point process. The resultant process is known as a *marked point process*, and can be considered as a point process on the product space $S \times M$ consisting of all pairs (x, y) where x is from the original state space S and y from a space M consisting of all possible marks. For the two examples indicated above, the mark space would be taken as $M = (0, \infty)$, though other choices for M are possible. For example, a compound Poisson process can be viewed as a marked (Poisson) point process with M the set of nonnegative integers. Although the general theory of point processes does not strictly need extension to cover marked point processes, the special structure of the new state space leads to related special structure in, for example, moment measures and product densities; see, for example, [45, Chapter 4]. There is, in particular, a version of Campbell's theorem for marked point processes (see also [44, Section 14.2]).

The case of a point process where there are two types of point, for example two types of tree in the forest, can be covered by using a two-point mark space, e.g. $M = \{1, 2\}$. In addition, this setting allows joint consideration of the point process of "retained" points and the point process of "deleted" points in the random deletion context discussed earlier. For Bernoulli deletions it is even easy to write down an expression for the joint probability generating functional of the two processes (probability generating functional of the marked point process) in terms of the probability generating functional of the original process. If the mark space is a finite set, without loss of generality $M = \{1, 2 \ldots, s\}$, then the marked point process is often called a *multitype* or *multivariate point process* (see [12, Chapter 5] or [20, Chapter 6]).

The theory of marked point processes is often helpful in providing language and a unifying framework within which other processes can be considered. **Markov and semi-Markov processes** with finitely many states can be viewed as multitype point processes [12, Section 3.2], although most properties of such processes can be conveniently derived without using this connection. Alternating renewal processes are a special case of semi-Markov processes in which there are two types of mark and two types of lifetime, alternating over time. Shot noise processes (cf. [12, Section 5.6] or [42, Chapter 4]) can also be viewed as marked point processes, where in this case the mark attached to each point is a possibly random multiple (independent and identically distributed for each point) of a fixed function, e.g. a negative exponential function with fixed decay parameter, which represents a 'blip' of electric current associated with that point. The actual shot noise process, which is not a point process, is the superposition (sum) of all the "blips" of current.

Marked point processes provide a framework for treating many probability models of interest in stochastic geometry and stereology. For example, consider a stochastic process whose realizations are a (finite or) countable number of line segments in the plane, with each segment specified by a random location, orientation and length. Such a process can be viewed as a marked point process in which the points of the underlying point process give the locations of the midpoints of the line segments, while two marks attached to each such point record respectively the orientation and length of the line segment to be associated with that point. (An example involving positions and orientations of flies on a leaf is quoted in [44, p. 265].) The simplest such model involving line segments assumes that the underlying point process is a homogeneous Poisson process in the plane. Another type of model can be built from an underlying homogeneous Poisson process in the plane by supposing that each point is independently marked with a positive number drawn from some specified distribution, the same for each point. Then each point of the underlying process is replaced by a disk centered at that point and having radius determined by the mark associated with that point. The union of all such disks then constitutes a realization of the desired process which, of course, is not itself a point process; it is an example of a random set process. Both these types of process are examples of *Poisson grain models* or *Boolean models*; (see, for example, [44, Appendix F] or [45, Chapter 3]). One application of such models is to modeling the distribution of cells over a region.

Rather than consider a process of line segments, it is sometimes of interest to consider a process of lines (infinite in length); see [17, Section 10.6] or [27, Chapter 7] for some discussion of such processes.

Martingale Theory of Point Processes

A different approach to point processes is needed for dealing with processes, such as arise in the study of queueing or communication systems or in **survival**

analysis, which evolve dynamically over time and in a manner that may depend on the past history of the process. For a point process N_t, where t represents time and $N_t = N((0, t])$ in our previous notation, the *stochastic intensity function* $\lambda(t|\mathcal{H}_{t-})$ can be defined heuristically by

$$\lambda(t|\mathcal{H}_{t-})\,\mathrm{d}t = \Pr(N(\mathrm{d}t) = 1|\mathcal{H}_{t-}),$$

where $\mathcal{H}_{t-}$ is a history of N_t up to but not including time t. Using the mathematically well-developed theory of martingales (*see* **Counting Process Methods in Survival Analysis**), the *martingale theory of point processes* provides an approach to formalizing the notion of a stochastic intensity and to solving a wide variety of problems by means of the stochastic calculus that results. It is beyond the scope of the present article to enter into details of this extensive and technically rather difficult theory; see [2, 11] and [42], the latter comprehensive work being focused on applications to survival analysis.

Guide to the Literature

The annotated references that follow may be of some assistance. An expanded version of the present article with similar aims but introducing some more advanced topics can be found in Milne [35]. For those interested primarily in spatial data, especially in biological applications, [20] is highly recommended and [32] and [33] may prove useful. The examples in parts of [14, 38, 39] and [44] are also good, and in all these books there is some discussion of theory; [23, Chapter 5] offers a succinct overview of the theory of point processes and is well motivated by examples; [27] is a masterly survey of the many beautiful properties and applications of Poisson processes and a good introduction to many aspects of general point process theory. More detailed exposition of various aspects of the theory can be found in [10, 16], Grandell [12, 22, 37] and [43]. A much more comprehensive, yet readable, presentation of the mathematical theory is given in [17] and Daley & Vere-Jones [18]. A systematic and careful development of the mathematical foundations of point process theory is in [26] and [34], though these works are usually considered difficult, even by probabilists.

Point process theory, with a view to applications in stochastic geometry, is dealt with in [1, 44], and [45]. A good introduction to stochastic geometry, including its connections with point process theory, is provided in [3].

For those interested especially in statistical inference from point process data [13, 14, 20, 38, 44] and [45] contain examples as well as an introduction to relevant theory; in particular, [14, Section 8.6] and [20, Chapters 6, 7] deal with aspects of inference for multitype point process data.

Pre-1973 references are well covered in [15]. There are many references and an excellent coverage of both theory and applications of point processes, as at 1971, in [29].

Poisson Distribution

The Poisson distribution arises as a limiting form of **binomial distribution**. It is named after the French mathematician, **Siméon Denis Poisson** (1781–1840), but was introduced earlier in 1718, by **A. De Moivre**, who presented the limiting result in approximate form.

The Poisson distribution is also important in its own right; for instance, when rare events of some sort occur randomly in time or space. The variable of interest is the number of events observed in a continuous interval. The interval may be an interval of time, but it may also refer to some other measure of length, or it may be an area or volume segment.

The Poisson distribution is used in many areas of medical research and, in particular, in toxicology, bacteriology and epidemiology. Examples include the number of abnormal cells in a fixed area of a histological slide, the count of bacteria surviving treatment in a fixed volume of bacterial suspension, the number of white blood cells in a drop of blood, the number of new breast cancer cases registered per month by the National Cancer Registry or the number of live births in Greater London during the month of January.

In this article we use nontechnical and heuristic arguments. More detailed information can be found in [3] and [4].

Assumptions

For count data to follow a Poisson distribution three conditions need to be met:

1. In any very small interval (smaller, say, than a millisecond or a cubic nanometer) the probability of an event occurring is proportional to the size of the interval.
2. The probability that the interval contains two or more events gets smaller as the interval gets smaller and can, therefore, for all practical purposes, be ignored.
3. What happens in any small interval is independent of what happens in any other small interval that does not overlap the first.

These conditions imply that events occur over time or space at a constant rate on average, each event occurring independently and at random.

Probability Distribution

We give a heuristic derivation of the Poisson probability distribution using the context of white blood cell counts.

Suppose that Ms Smith has on average 6000 white blood cells in a cubic millimeter of blood. It is reasonable to assume that the probability of finding a white cell in a small drop of blood is proportional to the size of the drop and that, for a sufficiently small drop, the probability of finding two or more white cells is negligible. Since cells move independently, the presence of a white cell in one small drop of blood is not expected to affect the presence or absence of a white cell in any other nonoverlapping drop of the same size. A drop of 0.0005 cubic millimeter ($V = 0.5 \times 10^{-3}\text{mm}^3$) of blood from Ms Smith is examined. If several such drops were examined, some of them would, by random variation alone, contain no white blood cells, others would contain one, or two, and some would contain as many as, say, eight white blood cells. We would expect the average number of white blood cells to be three when the average is taken over a large number of drops of size 0.0005 cubic millimeters ($0.5 \times 10^{-3}\text{mm}^3 \times 6000\text{cells/mm}^3 = 3$ cells). We write $\mu = 3$.

We make a hypothetical split of the 0.0005 cubic millimeter drop of blood into yet smaller subdrops, say, $n = 60$ or 100 or 300 subdrops of equal size. The size of each subdrop ($V/n\text{mm}^3$) gets smaller when the number n gets larger. When the subdrops are sufficiently small, most of them will contain no white blood cells, some will contain one and it is very unlikely that any subdrop will contain more than one white blood cell. The small subdrops are approximating a sequence of n binomial trials, in each of which there is a probability μ/n of finding a white blood cell and a probability $1 - (\mu/n)$ of not finding one. The probability that in the whole series of n subdrops there are exactly x white blood cells is given by the binomial probability

$$\frac{n(n-1)\cdots(n-x+1)}{x!}\left(\frac{\mu}{n}\right)^x\left(1-\frac{\mu}{n}\right)^{n-x}. \quad (1)$$

The assumptions underlying this binomial probability get more accurate as n increases. What happens when n increases indefinitely? We can replace $n(n-1)(n-2)\cdots(n-x+1)$ by n^x, since x will be negligible in comparison with n. We can also replace $[1-(\mu/n)]^{n-x}$ with $[1-(\mu/n)]^n$ since $[1-(\mu/n)]^x$ will

approach one as n increases. It is a standard mathematical result that $[1 - (\mu/n)]^n$ approaches $e^{-\mu}$ when n increases indefinitely, e being the base of the natural (or Napierian) logarithms ($e = 2.718\ldots$). Thus, when n increases indefinitely, the binomial probability in (1) takes the form

$$\frac{n^x}{x!}\left(\frac{\mu}{n}\right)^x e^{-\mu},$$

which equals

$$P_x(\mu) = \frac{\mu^x e^{-\mu}}{x!}, \quad x = 0, 1, 2\ldots. \qquad (2)$$

and defines the Poisson probability distribution.

Interestingly, the limiting approximation derived by De Moivre did not involve the Napierian e, since this was not introduced until the days of Euler (1707–1783).

Table 1 illustrates how the binomial distribution approaches the Poisson when n gets larger and the binomial probability $\pi = \mu/n$ gets smaller, while the mean $\mu = n\pi$ is kept constant.

Matsunawa [5] gives accuracy bounds for the Poisson–binomial approximation. A rule of thumb is that the Poisson approximation to the binomial is good if $n \geq 20$ and $\pi \leq 0.05$ and very good if $n \geq 100$ and $\pi \leq 10$.

The Poisson probabilities in (2) can also be derived from a **Poisson process** by solving a set of differential equations.

Table 1 Probabilities for three binomial distributions with $n\pi = 3$ and for the Poisson distribution with mean 3

Number of events x	$\pi = 0.05$ $n = 60$	$\pi = 0.03$ $n = 100$	$\pi = 0.01$ $n = 300$	Poisson mean $\mu = 3$

Properties

A Poisson random variable X takes the values $x = 0, 1, 2, \ldots$ with probabilities defined by (2). Thus, $P_0 = e^{-\mu}$, $P_1 = \mu e^{-\mu}$, $P_2 = \frac{1}{2}\mu^2 e^{-\mu}$, etc. with $P_1 + P_2 + \cdots = 1$. The whole distribution is characterized entirely by the one parameter μ. The **moment generating function** is of the form $E(e^{tx}) = \exp[\mu(e^t - 1)]$, with the first two moments $E(X) = \mu$ and $E(X^2) = \mu^2 + \mu$. Both the mean $E(X)$ and the variance $\text{var}(X) = E(X^2) - [E(X)]^2$ are thus equal to μ.

The shape of the distribution for $\mu = 1$, 3, 7 and 15 is shown in Figure 1. For small values of μ the distribution is skewed, and it gets more symmetric as μ increases. For $\mu \geq 10$, the distribution is close to symmetric.

Normal Limit

When μ increases indefinitely the Poisson distribution approaches the **normal distribution** with mean μ and variance μ. De Moivre derived the normal limit to the binomial distribution, from which the result for the Poisson distribution follows. Using a continuity correction, the probability that a Poisson random variable takes the integer value x is approximated by the probability that a normally distributed random variable takes values between $x - 0.5$ and $x + 0.5$. The probability that a Poisson variable with mean μ takes values greater than, or equal to, x is correspondingly approximated by the tail area of a normal distribution beyond the standardized normal deviate $z = (|x - \mu| - 0.5)/\sqrt{\mu}$.

Variance-stabilizing Transform

The square root **transformation** $Y = \sqrt{X}$ of a Poisson random variable X stabilizes the variance, with $\text{var}(Y) = \frac{1}{4}$ for all values of μ (*see* **Delta Method**; **Power Transformations**). This allows checking the Poisson assumption, and for Poisson random variables with large enough means one can get approximate results using methods appropriate for normally distributed random variables with constant variance.

Sum of Poisson Variables

The Poisson distribution has a reproductive property: let $X_1, X_2, \ldots, X_k$ be k independent Poisson

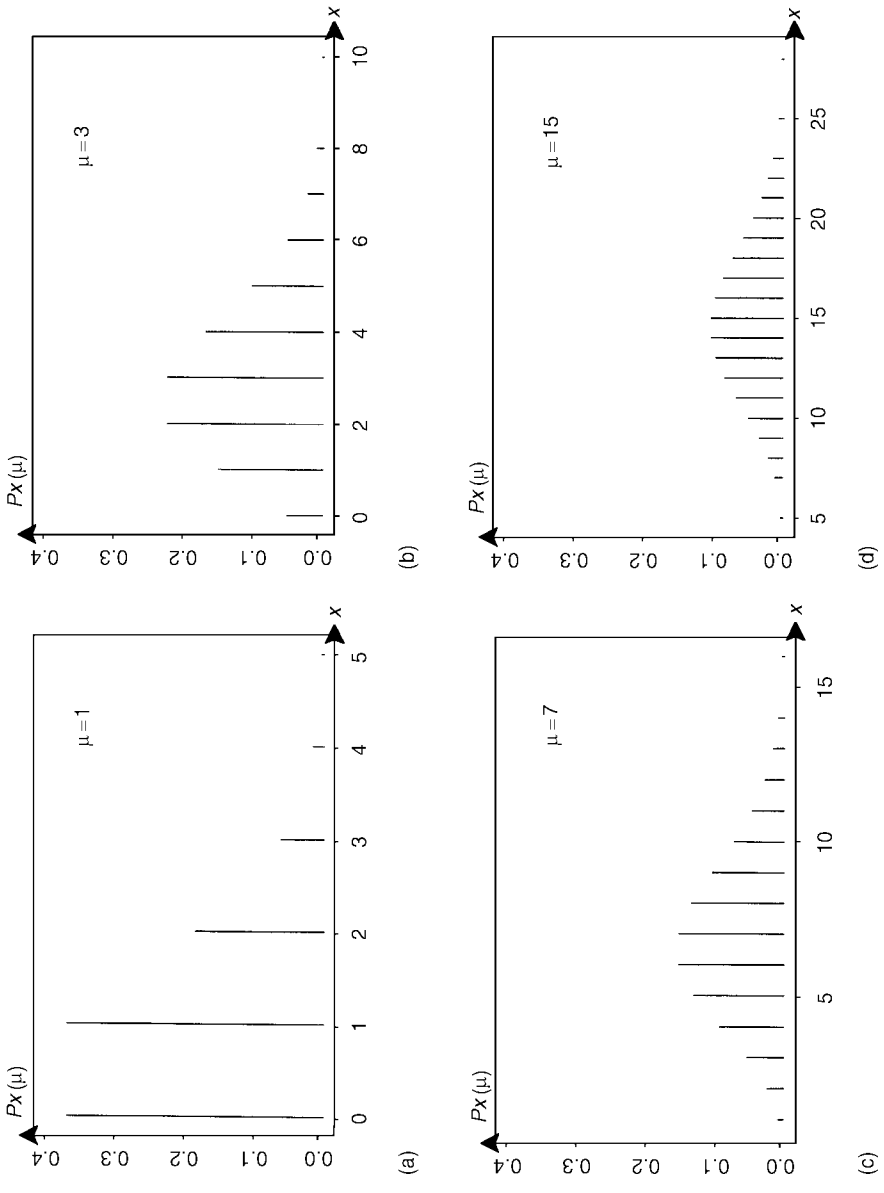

Figure 1 Poisson distribution for various values of the mean μ

random variables with parameters $\mu_1, \mu_2, \ldots, \mu_k$, respectively. Then the sum $X_1 + X_2 + \cdots + X_k$ is also a Poisson random variable with parameter $\mu_1 + \mu_2 + \cdots + \mu_k$.

Binomial and Multinomial

Let X_1 and X_2 be two independent Poisson random variables with parameters μ_1 and μ_2, respectively. The conditional distribution of X_1, given $X_1 + X_2 = n$, is binomial with index n and probability $\mu_1/(\mu_1 + \mu_2)$. Correspondingly, for k independent Poisson variables $X_1, X_2, \ldots, X_k$ with parameters $\mu_1, \mu_2, \ldots, \mu_k$, the conditional distribution, given $X_1 + X_2 + \cdots + X_k = n$, is multinomial with index n and probabilities $\mu_s/(\mu_1 + \mu_2 + \cdots + \mu_k)$, $s = 1, 2, \ldots, k$. This relation between sampling distributions is central to the theory of a **loglinear model** for **categorical data analysis**.

Hypergeometric

Let X_{11}, X_{12}, X_{21}, and X_{22} be four independent Poisson random variables with parameters μ_{11}, μ_{12}, μ_{21} and μ_{22}, respectively. They may be viewed as cell counts in a **2 × 2 contingency table**. Conditional on both margins $X_{i1} + X_{i2} = m_i$ and $X_{1j} + X_{2j} = n_j$, $i, j = 1, 2$, the random variable X_{11} follows a noncentral **hypergeometric distribution** with noncentrality parameter $\theta = \mu_{11}\mu_{22}/\mu_{12}\mu_{21}$. This conditional distribution is used in matched case control studies and in conditional logistic regression. For $\theta = 1$, i.e. when the odds ratio in the 2×2 frequency table is unity, the distribution reduces to the standard hypergeometric distribution.

Heterogeneity

In empirical studies, observed counts often exhibit larger variance than would be expected from the Poisson assumption. One mechanism generating this larger spread is heterogeneity in the average event rate over the population under study. Such **overdispersion** relative to the Poisson was noted already in 1920 by Greenwood & Yule [2], who suggested a model where the mean μ is not constant, but a random variable with a **gamma distribution** (*see* **Accident Proneness**). This leads to a two-parameter **negative binomial distribution** for the count. Mixing distributions other than the gamma distribution have been discussed, as well as distribution-free approaches and quasi-likelihood methods for handling overdispersion. If sources of heterogeneity in the Poisson means are known and measured, then **Poisson regression** methods are appropriate.

Test for Heterogeneity

For a set of k observed counts $X_1, X_2, \ldots, X_k$, it may be of interest to test the hypothesis that they are drawn at random from a single Poisson distribution, as opposed to being drawn from several Poisson distributions with different means. A reasonable test statistic for detecting heterogeneity would compare the spread of the observed counts relative to their average. Let $\overline{X} = \sum_{i=1}^{k} X_i/k$ denote the sample mean. Under the null hypothesis of common mean μ the Poisson *heterogeneity* or *dispersion* test statistic:

$$T = \frac{\sum_{i=1}^{k}(X_i - \overline{X})^2}{\overline{X}} \tag{3}$$

is approximately distributed as a **chi-square distribution** with $k - 1$ degrees of freedom (*see* **Chi-square Tests**). The heterogeneity test in (3) was first introduced by "Student" in 1907 (*see* **Gosset, William Sealy**). Armitage & Berry [1] justify it from two different points of view: for normally distributed observations with constant variance the sum of squares divided by the variance follows a χ^2 distribution. Here $\hat{\mu} = \overline{X}$ is an estimator for the variance under the null hypothesis. One may also view (3) as the usual χ^2 test statistic $T = \sum_{i=1}^{k}(X_i - \hat{\mu}_i)^2/\hat{\mu}_i$, with X_i the observed count and $\hat{\mu}_i = \overline{X}$ the corresponding expected count under the null hypothesis.

In practice, it may be easy to show that a given sample of counts does not originate from a Poisson distribution. The result is useful, since it reveals the presence of some kind of nonrandomness. If the Poisson distribution is rejected, then a distribution involving two (or more) parameters is needed to describe the data. It may, however, take a very large sample to distinguish between, for example, the negative binomial and some other two-parameter distributional form. In general, one should view determination of a specific mechanism for nonrandomness as a biological, rather than a statistical, problem (*see* **Contagious Distributions**).

Poisson Processes

The **Poisson distribution** has often been rediscovered, but goes back to the work of the French mathematician S.-D. Poisson (1837). It arises as a limiting form of the **binomial distribution**, when a rare event is observed occasionally in a large number of repetitions. Thus, suppose that there are a number n of repetitions of some random experiment, the repetitions being statistically independent. Suppose that there is some outcome of the experiment which we describe as a "success", and which has a constant probability p. The probability that there are exactly r successes in the n trials is then given by the binomial probability

$$b(n, p; r) = \binom{n}{r} p^r q^{n-r}, \quad r = 0, 1, 2, \ldots, n. \tag{1}$$

If n is large and p is small, in such a way that the mean number of successes $\mu = np$ is moderate, then $b(n, p; r)$ is well approximated by the Poisson probability

$$\pi_r(\mu) = \frac{\mu^r \mathrm{e}^{-\mu}}{r!}. \tag{2}$$

In fact, it is simple to prove that, as n tends to infinity for fixed μ,

$$b\left(n, \frac{\mu}{n}; r\right) \longrightarrow \pi_r(\mu). \tag{3}$$

A famous example of the occurrence of the Poisson distribution (2), is the stream of particles emitted from a piece of radioactive material and detected in a Geiger counter. One can think of each atom as being an independent trial, with a very small probability of emission in a given interval of time. There are many atoms, and the total number of particles emitted in a time interval will thus have the distribution of (2), where μ is the mean number of emissions in that interval and will normally be proportional to the length of the interval.

This is an example of a Poisson process occurring in one (time) dimension. If we mark out along a time axis the instants at which particles are emitted, then we have a random set of points with the property that, if $N(a, b)$ denotes the number of points between a and b, then for any $a < b$,

$$\Pr[N(a, b) = r] = \pi_r(\mu), \quad r = 0, 1, 2, \ldots, \tag{4}$$

where

$$\mu = \lambda(b - a). \tag{5}$$

Moreover (and this is an essential part of the definition) the random variables $N(a, b)$ for disjoint intervals (a, b) are independent (where disjoint means that no two overlap).

Many other random series of points, such as mutations at a chromosome locus (*see* **Gene**), or arrivals at a queue, are found to be, more or less exactly, Poisson processes in this sense. In many cases, however, the rate λ is not constant, and then (5) must be generalized to

$$\mu = \int_a^b \lambda(t)\, \mathrm{d}t, \tag{6}$$

where $\lambda(t)$ represents the instantaneous rate of occurrence at time t. The best way to visualize this is that $\lambda(t)h$ is, for small h, the probability that at least one of the random points occurs between t and $t + h$.

The one dimension need not be time, but could be spatial, and there is an obvious generalization to two or more dimensions. For instance, the stars visible in the sky, or the (centers of the) spots of a skin rash, might be modeled as random sets of points in two dimensions. The general structure is simple, although there are technical mathematical niceties which are here ignored. We have a space S, which might be ordinary space of some dimension but could be more complicated. The object of interest is a random set of points in S, sufficiently dispersed that for typical subsets A of S the number of these points falling in A is a finite random variable $N(A)$. (Think of S as the plane, and the sets A as being bounded sets like circles, triangles, and rectangles.) The random set of points is then called a Poisson process if

1. the random variable $N(A)$ has a Poisson distribution (2), where $\mu = \mu(A)$ depends on A
2. for disjoint sets $A_1, A_2, \ldots, A_n$, the random variables $N(A_j)(j = 1, 2, \ldots, n)$ are independent.

In most cases the mean

$$\mu(A) = \mathrm{E}[N(A)] \tag{7}$$

is given in terms of a rate function $\lambda(x)$ on S by

$$\mu(A) = \int_A \lambda(x)\, \mathrm{d}x (A \subseteq S), \tag{8}$$

but it can be a general (nonatomic) measure on S.

The simple structure of the Poisson process leads to a number of properties which are extremely powerful in modeling random sets of points. Suppose, for instance, that we have two independent Poisson processes on the same S, and that the numbers of their points falling in a set A are, respectively, $N(A)$ and $N'(A)$. Then superposing these two sets gives a new random set, which also turns out to be a Poisson process. The number of points of the new process falling in A is $N(A) + N'(A)$, which has expectation $\mu(A) + \mu'(A)$.

Again, a mapping from one space to another preserves the Poisson property. If we have a Poisson process on a space S, and a mapping f from S to another space S^*, then f maps the random set of points into (usually) a Poisson process on S^*, and the expectation measure maps in a simple way. The only thing that can go wrong is that the induced measure on S^* may have atoms, in which case f may pile points on top of one another.

Often the random points of the Poisson process come with numerical values attached to them; the stars have their magnitudes, the arrivals at a queue their service requirements. This leads to the concept of a marked Poisson process, where a mark, which may be numerical or more complicated, is associated with each point. If the marks of different points are independent random variables (with distributions depending on the positions of the points), there is a powerful product space representation from which detailed calculations can be made. Thus, a point of the process at x, with a mark m, can be plotted as a random point (x, m) in the product space $S \times M$, where M is the space of possible marks. Then it can be shown that this random set of points is a Poisson process on the product space, and there is an explicit formula for the expected number of points in a given subset.

Suppose that a swarm of bees attacks an unfortunate victim. It might be that the instants of successive stings form a (one-dimensional) Poisson process, and that the amount of venom in each sting is a random quantity independent from bee to bee whose distribution might depend on the time of the sting. Then we have a marked Poisson process, and the product space representation is two-dimensional, each bee being represented by a point whose coordinates are the time at which it stings and the amount of venom. The victim might be interested in the total amount of venom he receives. This is an example of a Poisson sum of the form

$$\sum g(x), \tag{9}$$

where the sum is taken over all the points x of a Poisson process on S, and g is a real-valued function on S. A result known as Campbell's theorem, after the work of N.R. Campbell (1909), gives an explicit formula for the **moment generating function** of the sum (9). This and details and proofs of the properties already cited may be found in [2].

All the results so far described apply whatever the dimension of the space S. For some problems S can be quite a complicated geometrical object. For example, some fibrous substances (such as paper) when viewed microscopically resemble a random array of lines in three-space, and this can be represented as a random set of points in a four-dimensional manifold. However, there are properties which are peculiar to Poisson processes on the line. A one-dimensional Poisson process can always be mapped, by an increasing function, into a Poisson process which is homogeneous in the sense that it satisfies (4) and (5) for some λ. A homogeneous Poisson process is a renewal process in the sense that the intervals between successive points are independent and identically distributed, their common probability density being

$$\lambda \exp(-\lambda x), \quad x > 0. \tag{10}$$

This property is characteristic of the one-dimensional homogeneous Poisson process, and has no analogue in higher dimensions.

One useful aspect of this special case is that, in one dimension, it is easy to construct an alternative model for a random set of points (or **point process** as it is then usually called) which is not Poisson. It is only necessary to change the interval distribution from (10), or to introduce some dependence between successive intervals. It is much more difficult, in more than one dimension, to devise usable models for non-Poisson point processes. There are, however, variants of the Poisson process which can sometimes provide useful models.

One of these is the Poisson cluster process, in which each of the points of a Poisson process gives rise to a random number of daughters, the daughters being dispersed about the parent point in a random way (think of seedlings around trees). Another is the Cox process, which is a Poisson process whose rate function is itself a random process. These are, in principle, very general classes of point processes,

but the generality is paid for in great complexity of calculation. At the same time, they have special properties which limit their usefulness; for instance, a Cox process is always overdispersed in the sense that the variance of the number of points in any set always exceeds its mean (there is equality for a Poisson process), so that no Cox process could be a realistic model for a random set which was underdispersed.

The other significant aspect of the theory of Poisson processes, which is not covered in [2], is that of **limit theorems** and approximations. The Poisson distribution started from a limit result (3), and there are many situations where modifying a non-Poisson process leads approximately or asymptotically to a Poisson process. The best starting point of this aspect is [1].

Poisson Regression in Epidemiology

Various authors [3, 9, 11, 12] have noted that **Poisson regression** can be used to analyze cohort survival data (*see* **Cohort Study**). This formulation also leads to a unification of **risk** estimation based on internal comparison of rates among members of a cohort with various exposure levels and classical epidemiologic methods based on external rates that yield standardized mortality ratios or standardized incidence ratios [2, 5] (*see* **Standardization Methods**).

Poisson regression is an important alternative to **partial-likelihood**-based analysis of the **proportional hazards** model (*see* **Cox Regression Model**) and to parametric analyses of such models (*see* **Survival Analysis, Overview**) for two main reasons. First, it provides an efficient and intuitive method for dealing with cumulative exposures and other **time-dependent covariates** and for allowing risk to depend on multiple time scales (e.g. attained age, time since exposure, or calendar time). Secondly, it facilitates the consideration of a broad range of risk models including those that allow for the direct parametric description of baseline rates, absolute excess rates, and **relative risks**.

Breslow & Day [4] offer a general discussion of the use of Poisson regression in the analysis of cohort survival data. Some of the most extensive applications of these methods have involved studies of radiation effects on mortality and cancer incidence in the atomic bomb survivors [14].

Poisson Regression of Survival Data

The data from cohort survival studies typically consist of information on whether or not the event of interest occurred, the event or censoring time, t, and a vector of possibly time-dependent covariates, $\mathbf{z}$, for each cohort member. Since interest centers on **hazard rates** it is natural and useful for the purposes of analysis or summarization to reorganize such data into an event–time table defined by a cross-classification over a set of time intervals and covariate categories. The data for each cell in such a table include the total number of events, c_{is}, the total time (person-years) at risk, R_{is}, and representative values of the covariates, z_{is} for time period i and category s. For each cell the ratio of the number of events to the time at risk is a crude hazard rate. The analysis involves **regression** methods to smooth these rates as a function of time and other **covariates**.

When such tables are produced as simple summaries of a data set, it is common to limit the number of time periods and other factors used to define the table. However, for modeling rates it is appropriate to use detailed tables with many cells based on a relatively fine **stratification** over time and other factors. For example, a rate table to be used in an analysis of an occupational cohort study (*see* **Occupational Epidemiology**) might be defined in terms of age, year, age at first exposure, sex, and cumulative exposure with hundreds or even thousands of cells. An event–time table for a **clinical trial** might involve follow-up time, age at entry, sex, and treatment. Although not usually necessary in practice, the methods can be applied to a table based on individual subjects where the only grouping is on time. This suggests the close connection between the use of Poisson regression methods for the analysis of rates and the Andersen–Gill **counting process** method [1] for analysis of hazard functions.

If it is assumed that the hazard, λ_{is} is constant within each cell, then the expected number of events in the cell is given by

$$\mathrm{E}(c_{is}) = R_{is} \times \lambda_{is}.$$

In terms of a parametric function, $\lambda(t_i, z_{is}, \theta)$ for the rates, the log **likelihood** for the survival data under the piecewise constant hazard assumption is

$$\sum_{l,s} c_{is} \ln(\lambda(t_l, z_{is}, \theta)) - R_{is} \times \lambda(t_i, z_{is}, \theta),$$

which is equivalent to the log likelihood that would arise if the event counts in the table were independent **Poisson** random variables. Thus, Poisson regression can be used to estimate the parameters in this model.

With this approach, modeling rates in terms of time is straightforward since, in contrast to Cox regression, there is no distinction between time-dependent and time-independent covariates. This is because the time-dependent computations are carried out when the event – time table is constructed and are not repeated each time a model is fitted.

Using External Rates or Expected Cases

In some situations one has external data on the expected rates λ_q^e stratified by time and other factors (e.g. age, calendar time period, and sex but not exposure or treatment related factors). In this case, it is possible to compute the expected number of cases for each cell in the table as $C_{is}^e = R_{is} \times \lambda_q^e$, where $q = q(is)$ denotes the external rate strata corresponding to cell is. In this case, Poisson regression can be used to model the relative hazard, ρ_{is}, since

$$\mathrm{E}(c_{is}) = C_{is}^e \times \rho_{is} = R_{is} \times \lambda_q^e \times \rho_{is}.$$

When **person-years** are replaced by expected numbers of cases, this type of analysis is known as the subject-years method or standardized mortality ratio (SMR) regression [4].

Models for Rate Regression

Following the pioneering work of Cox [8], the most commonly used hazard function model is the **log-linear** proportional hazards model

$$\lambda(t, z, \theta) = \lambda_0(t, \alpha) \times \exp(\beta z). \tag{1}$$

Here λ_0 is a baseline hazard for an individual with covariate $z = 0$.

Other models are also important, however. For example, in **dose–response** studies it is often useful to consider models in which the **excess relative risk** is a linear function of dose d; that is

$$\lambda(t, z, \theta) = \lambda_0(t, \alpha) \times (1 + \beta d).$$

Preston [16] has described a flexible general class of parametric **additive hazard models** of the basic form

$$\lambda_0(t, \alpha, z_0) + \lambda_{\mathrm{EAR}}(t, \beta, z_1) \tag{2}$$

and

$$\lambda_0(t, \alpha, z_0)[1 + \lambda_{\mathrm{ERR}}(t, \beta, z_1)], \tag{3}$$

in which λ_0 represents the baseline or background rates and λ_{EAR} and λ_{ERR} describe the excess absolute or excess relative risks. In these models baseline rates are usually assumed to be loglinear functions of the covariates while the excess risks are modeled as linear or products of linear and loglinear functions of the covariates.

One reason for the popularity of the Cox regression model is that it allows one to focus (perhaps too much) on the **relative risk** while treating the baseline hazard as completely unspecified. A similar simplification is possible in the analysis of **relative risk models** for rates using Poisson regression. This is accomplished by the inclusion of a **multiplicative** parameter for each time interval leading to models such as

$$\tau_i \exp(\beta z) \quad \text{or} \quad \tau_i(1 + \beta d). \tag{4}$$

This approach can also be extended to allow stratification over additional factors, in which case the model is similar to the stratified Cox regression model. Preston et al. [17] describe an efficient **algorithm** for models with large numbers of stratum parameters.

Parameter Estimation and Inference

Parameter estimates for Poisson regression models are computed using **maximum likelihood** methods. Models in which the rates depend on the parameters through a linear function βz, are **Generalized Linear Models (GLM)**. Parameter estimates for GLMs can be computed using iteratively reweighted **least squares** with person-years (or cases for subject-years analysis or standardized mortality/incidence ratio regression) as an "offset". These methods are available in all of the major statistical packages including GLIM, SAS, and S-PLUS (*see* **Software, Biostatistical**). However, the more general rate function models such as (3) and (4) are not GLMs. In this case, it is necessary to make use of special software to define the likelihood and possibly its derivatives. The Epicure package [17] is designed to work with models in the general class described by (1)–(4) above.

Inference about parameters of interest can be carried out using the standard asymptotic methods, including Wald, score, and **likelihood ratio tests**. However, because of the nonlinear nature of the models and, in many applications, the limited information on **excess risks**, asymptotic **standard errors** and hence **hypothesis tests** and **confidence intervals** based on Wald tests can be misleading. Score or likelihood ratio tests and **profile-likelihood**-based confidence intervals should be emphasized when working with additive hazard models.

An important issue concerns the assessment of **goodness of fit** for Poisson regression models derived from detailed event–time tables. Because rate modeling often involves relatively rare events and event–time tables with many cells, the rates or the number of events in each cell of the table can be quite small. In this case, neither the global deviance nor the Pearson **chi-square statistic** provides reasonable guidance as to goodness of fit. The total deviance is often much smaller than the putative **degrees of freedom** (the number of cells in the table minus the number of free parameters in the model). Pregibon [15] developed generalized regression **diagnostics** that can be used for regression models in exponential families. While such diagnostics may be useful in looking for lack of fit and other problems with fitted models [10], they should be interpreted with caution since the underlying data are not independent Poisson counts. In view of these issues, the most effective general method for the assessment of goodness of fit when using Poisson regression to analyze rates is to make use of likelihood ratio tests designed to detect specific departures from models of interest, such as time dependence or nonlinearity, or to make use of **Akaike's criterion** or related statistics to compare alternative (possibly nonnested) models.

Creating Event–Time Tables

The creation of an adequate event–time table is often the most difficult aspect of carrying out analyses of rates using Poisson regression. Among other features, an ideal program for the construction of event–time tables would:

1. allow for categorization on multiple time scales (age, year, length of follow-up, etc.), as well as multiple time-independent and time-dependent factors with variable length intervals in each of these scales;
2. allow for late entry, disjoint follow-up intervals, and multiple events;
3. include procedures for the computation of and categorization on time-dependent quantities;
4. allow computation and storage of counts for multiple event types along with representative values (often time-at-risk weighted means) for covariates of interest for each cell in the table;
5. have efficient procedures for handling the large, sparse tables that can arise when one stratifies on multiple time scales;
6. be able to deal with the data structures that can arise in describing complex exposure histories; and
7. facilitate the incorporation of external rates.

Several computer programs are currently available for the creation of event–time tables. However, many of these programs, e.g. OCMAP [6] and O/E [13], are designed for specific applications and are of limited use in more general problems. Procedures for the creation of such tables in the major statistical programs are extremely limited or nonexistent. The DATAB module in Epicure [17] and "Person-years" [7] are probably the most flexible general-purpose programs for event–time tabulation available at this time. Hopefully, there will be major improvements in this area over the next few years.

Summary

Poisson regression is a powerful tool for the analysis of rates from cohort survival studies that facilitates simple, straightforward analyses of temporal patterns, baseline risks, excess relative or **absolute risks**, and other aspects of hazard functions that may be difficult to assess with other methods. The application of Poisson regression requires that data on individual subjects be organized into event–time tables stratified on time and other factors of interest and, for the most interesting models, specialized software capable of dealing with nonlinear Poisson regression models is also required. The tools needed to conduct these analyses are available today but it is likely that they will be more fully developed in the years to come.

Poisson Regression

For response variables that have counts or frequencies as outcomes it is often reasonable to assume an underlying **Poisson** distribution and describe the impact of **explanatory variables** on their means by some **regression** function. Poisson regression models, as a widely applicable class of models particularly useful in biostatistics, emerged in the late 1970s; see, for example, [6, 11, 21–25, 28, 29, 31], and [32].

As an example consider the data given in Table 1, taken from [27]. Randomly chosen household members from a **probability sample** of Oakland, CA, were asked to note which stressful events had occurred within the last 18 months and to report the month of occurrence of these events. A scattergram of the data indicates a decline of recalls as events lie farther in the past, possibly due to the fallibility of human memory (see Figure 1). To define a Poisson regression model, assume that (i) the number of recalls is a random variable Y distributed as Poisson with mean μ, and (ii) μ is some function of X, the number of months before interview. Plotting logarithms of frequencies against months suggests a linear relationship

$$\log \mu = \alpha + \beta x.$$

For this **loglinear model**, the mean satisfies the exponential relationship,

$$\mu = \exp(\alpha + \beta x) = e^{\alpha}(e^{\beta})^{x}.$$

A one-unit increase in X has a multiplicative effect of e^{β} on μ, i.e. the mean of Y at $x + 1$ equals the mean of Y at x multiplied by e^{β}.

Most of the widely available software packages are capable of fitting **generalized linear models**, and can be used to obtain **maximum likelihood** estimates for the parameters of Poisson regression models as well. For these data one finds $\hat{\alpha} = 2.803$ and $\hat{\beta} = -0.0838$; hence

$$\hat{\mu} = 16.5 \times 0.920^{x},$$

indicating a negative trend in time.

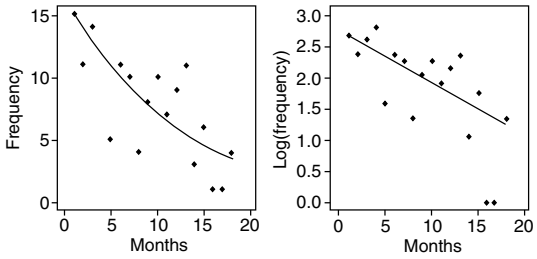

Figure 1 Scattergram of observed frequencies and their logarithms against months before interview. Solid lines represent fitted means and respective values for the linear predictor for the Poisson regression model mentioned in the text

Using the relationship between the **multinomial** and conditional Poisson distributions, this is shown to be equivalent to an exponential decay model for the probability of remembering an event. For a more detailed discussion, see [27] or [33].

Definition

To define the basic version of a Poisson regression model, suppose that we have observations $y_1, \ldots, y_n$ for the response variable $Y_1, \ldots, Y_n$, assumed to be independently distributed Poisson variates with means $\mu_1, \ldots, \mu_n$, i.e.

$$f(y_i|\mu_i) = \frac{\mu_i^{y_i}}{y_i!}\exp(-\mu_i). \qquad (1)$$

The systematic component of the model is specified by some regression function η, depending on regression parameters $\beta_1, \ldots, \beta_k$, with each component relating values $x_{i1}, \ldots, x_{ik}$ of explanatory variables to respective means, i.e.

$$\mu_i = \eta_i(\beta) = \eta_i(x_{i1}, \ldots, x_{ik}; \beta_1, \ldots, \beta_k). \qquad (2)$$

Table 1 Distribution by months prior to interview of stressful events reported from subjects: 147 subjects reporting exactly one stressful event in the period from 1 to 18 months prior to interview. Reprinted from [27, p. 3] by permission of Academic Press, Inc.

Months	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
Number	15	11	14	17	5	11	10	4	8	10	7	9	11	3	6	1	1	4

Often, this relationship is such that some monotone transformation g of the means is connected to a *linear predictor* of explanatory variables,

$$g(\mu_i) = \sum_{j=1}^{k} x_{ij}\beta_j.$$

In this situation g is called the *link function* and the model defined in this manner is an instance of a **generalized linear model** (see [35] and [36] or, for an introductory text, [18]). For $\eta_i(\beta) = \exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right)$ we have the familiar loglinear model,

$$\log \mu_i = \sum_{j=1}^{k} x_{ij}\beta_j.$$

For the model specified by the stochastic component (1) and regression function (2), the log **likelihood** function is written as

$$\ell_y(\beta) = \sum_{i=1}^{n} \{y_i \log[\eta_i(\beta)] - \eta_i(\beta) - \log(y_i!)\}. \quad (3)$$

It may be worthwhile noting that this reduces to a k-parameter **exponential family** log likelihood,

$$\ell_y(\beta) = \sum_{j=1}^{k} \left(\sum_{i=1}^{n} x_{ij} y_i\right) \beta_j - \sum_{i=1}^{n} \exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right) - \sum_{i=1}^{n} \log(y_i!), \quad (4)$$

with jointly **sufficient statistics** $\sum_{i=1}^{n} x_{ij} y_i$, $j = 1, \ldots, k$, if the model is log linear.

Some Special Cases

Loglinear Models for Contingency Tables

Suppose, in obvious notation, y_{ij} with indices $i = 1, \ldots, I$ and $j = 1, \ldots, J$ form a two-dimensional **contingency table**, according to some classifying factors A and B having I and J categories, respectively. A common method for analyzing data of this kind is to assume that cell frequencies Y_{ij} are independently distributed as Poisson and to use loglinear models, where in an **analysis-of-variance**-like fashion logarithms of expected cell frequencies μ_{ij} are assumed to be sums of several effects, e.g. for the **multiplicative model**,

$$\log(\mu_{ij}) = \beta_o + \beta_i^A + \beta_j^B, \quad (5)$$

subject to some constraints on the βs. Sums of independent Poisson variates are again distributed as Poisson with means equal to the sum of respective means. Row totals Y_{i+}, column totals Y_{+j}, and grand total Y_{++} are, therefore, Poisson variates with means $\mu_{i+} = \mu_{i1} + \cdots + \mu_{iJ}$, $\mu_{+j} = \mu_{1j} + \cdots + \mu_{Ij}$, and $\mu_{++} = \sum_{i,j} \mu_{ij}$, respectively. Under the assumption of the multiplicative model these quantities are related by

$$\mu_{ij} = \frac{\mu_{i+}\mu_{+j}}{\mu_{++}},$$

showing that the joint distribution of the contingency table is, in a multiplicative manner, completely determined by the marginal distributions.

The Poisson model assumption implies that marginals are random. If, instead, the total is fixed by the sampling design, it may be more appropriate to assume a multinomial distribution for the table. Formally, the multinomial model can be inferred from the Poisson model by conditioning on the total y_{++} (*see* **Conditional Probability**). For the probability π_{ij} of an observation falling into row i and column j, we then have $\pi_{ij} = \mu_{ij}/\mu_{++}$, and from assuming the multiplicative model (5), it follows that

$$\pi_{ij} = \pi_{i+}\pi_{+j}, \quad (6)$$

where π_{i+} and π_{+j} are the marginal probabilities of an observation falling into row i and column j, respectively. Hence, row and column variables A and B are independently distributed.

Likewise, if row totals are fixed, then each row may be assumed to be multinomially distributed. Again, this can be inferred from the Poisson model by conditioning on the row totals, and the multiplicative model (5) implies identical distributions for the rows – a condition usually called *homogeneity*. It may be worthwhile noting that maximum-likelihood estimates for the parameters in the Poisson models are identical to those obtained for some other sampling designs, such as the multinomial designs just mentioned, making this class of model particularly interesting and useful.

Loglinear models for two- and higher-dimensional contingency tables, used to describe the association and interaction structure connecting the variables, are

Table 2 Number of recurrences of superficial bladder cancer for 31 male patients with grade 2, stage T_1, solitary primary tumors and respective times under observation (in months) by size of primary tumor. Subset of data analyzed in [38]

Size	Recurrences	Time under observation
$\leq$3 cm	1	2, 3, 6, 8, 9, 10, 11, 13, 14, 16, 21, 22, 24, 26, 27
	2	7, 13, 15, 18, 23
	3	20
	4	24
>3 cm	1	1, 5, 17, 18, 25
	2	18, 25
	3	4
	4	19

discussed in the article on **Loglinear Model**. Usually, the goal is to find a **parsimonious** model that fits the data well and allows meaningful substantive interpretation. Most commonly, this search is restricted to **hierarchical models**.

Multiplicative Rate Models

If occurrences of some kind of event are counted over time, then often interest lies in the rate at which events occur. The rate describes the instantaneous risk for an event to happen at a given point in time. To be more specific, the probability of observing exactly one event in the interval ranging from t to $t+h$, divided by its length h, is assumed to tend to some value $\lambda(t)$, as h tends to 0. $\lambda(t)$, as a function of time t, is called the *rate* or *intensity function*.

An important special case, termed the **Poisson process**, assumes that waiting times between successive events are independent and **exponentially distributed** with common mean $1/\lambda$. Here, the rate function is constant over time, $\lambda(t) \equiv \lambda$. Furthermore, the number $Y(t)$ of events that occur up to time t is distributed as Poisson with mean $\mu = \lambda t$. Note that the mean of $Y(t)/t$ equals the rate λ. This suggests a Poisson regression approach

$$\log \lambda = \log\left(\frac{\mu}{t}\right) = \alpha + \beta x$$

for modeling the dependence of the rate function on an explanatory variable X. This can be rewritten as

$$\log \mu = \alpha + \beta x + \log t,$$

with $\log(t)$ as an *offset*, i.e. a variable in the linear predictor, the corresponding regression parameter of which is set equal to 1. Observe that this defines a multiplicative model for the rate function,

$$\lambda = \mathrm{e}^{\alpha}(\mathrm{e}^{\beta})^{x}, \tag{7}$$

with a *baseline rate* $\lambda_0 = \exp(\alpha)$ and proportionality factor $\exp(\beta x)$.

For illustrative purposes a subset of the data analyzed in [38] is reprinted in Table 2. For 31 male patients, who have been treated for superficial bladder cancer, the number of recurrent tumors has been recorded for some time after removal of the primary tumor. Defining X to be 1 for larger primary tumors (>3 cm) and 0 otherwise, and assuming a Poisson process with rate (7), yields parameter estimates $\hat{\alpha} = -1.95$ and $\hat{\beta} = 0.385$. The (baseline) rate for smaller tumors is (estimated as) 0.142, the rate for larger tumors being 1.47 times larger. In terms of waiting times between recurrences, means are estimated as 7.06 and 4.80 months, respectively.

Now suppose that we have recorded, for n individuals, time under observation, t_i, and the number y_i of events occurred. Observation times are assumed to be nonrandom and counts to be mutually independent. We also have a set of explanatory variables $x_{i1}, \ldots, x_{ik}$ available for each subject. Under the assumption of *proportional rates*, $\lambda_i = \lambda_0 \exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right)$, we have

$$\mu_i = \lambda_i \times t_i = \lambda_0 \exp\left[\log(t_i) + \sum_{j=1}^{k} x_{ij}\beta_j\right]$$
$$= \lambda_0 t_i \prod_{j=1}^{k} \exp(x_{ij}\beta_j), \tag{8}$$

i.e. a loglinear model for the mean of the Poisson process, involving the logarithm of observation times as an "explanatory" variable, with the associated regression parameter fixed at a value of 1.

If the process is such that it can be characterized by a time-varying rate function $\lambda(t)$, it is called a *nonhomogeneous Poisson process*. Writing

$$\Lambda(t) = \int_0^t \lambda(u)\,\mathrm{d}u$$

for the *integrated rate* or *intensity function*, the number of occurrences of the event in period until time point t is again distributed as Poisson, but with mean equal to $\Lambda(t)$. Note that events in nonoverlapping time intervals are independent, but waiting times between successive events are, contrary to the homogeneous process with constant rate, neither identically distributed nor independent. In this situation model (8) can be modified, using a *baseline rate* function $\lambda_0(t|\alpha)$, possibly depending on some additional parameter α, to give

$$\mu_i = \exp\left\{\log[\Lambda_0(t_i|\alpha)] + \sum_{j=1}^{k} x_{ij}\beta_j\right\}.$$

Choosing $\Lambda_0(t|\alpha)$ to be t, t^α, or $\exp(\alpha t)$ corresponds to an exponential, a **Weibull**, or an **extreme value** intensity function, respectively, and results in a loglinear model for the Y_is. Disregarding constant terms, the likelihood function for this model is

$$L(\alpha, \beta) = \prod_{i=1}^{n}\left[\Lambda_0(t_i|\alpha)\exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right)\right]^{y_i} \times \exp\left[-\Lambda_0(t_i|\alpha)\exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right)\right]. \quad (9)$$

If times for occurrences of each event were known, a multiplicative term, depending on the parameter α, would be added to (9); see [32].

There is a close connection to **relative risk models**, which are very frequently used in epidemiology. This class of models assumes that risk factors interact in a multiplicative way. See [9] and [12], and, for a critical review, [26].

Proportional Hazard Models for Censored Survival Times

Now suppose that individuals are under observation until either a single event of interest occurs or the period of observations ends for some other reason. For each subject the data are of the form (y_i, c_i), where y_i is the time under observation, and c_i is an indicator variable for **censoring**, taking the value 1 if the event has occurred at time y_i, and the value 0 if the event has not occurred until time y_i. This is a similar situation to the one in the previous example, but with one terminal event that stops the process; interest, however, lies in the analysis of the *survival times* y_i (*see* **Survival Analysis, Overview**).

The distribution of the survival time can be uniquely described by the rate function, in the context of survival analysis usually called **hazard rate** or *force of mortality*. As before, a common approach assumes **proportional hazard** rates,

$$\lambda(y_i|\alpha, \beta) = \lambda_0(y_i|\alpha)\exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right),$$

with a *baseline hazard* $\lambda_0(y_i|\alpha)$.

Assuming a noninformative censoring mechanism (and continuous survival times), the kernel of the likelihood function is $\prod_{i=1}^{n} f(y_i)^{c_i} \times S(y_i)^{1-c_i}$, where $f(y_i)$ denotes the density for the ith survival time, and $S(y_i) = 1 - F(y_i)$, the *survival function*, i.e. the probability for the ith survival time to exceed y_i. The ratio $f(y_i)/S(y_i)$ is identical to the hazard function. For proportional hazard rates, the likelihood function can therefore be expressed as

$$L_{y,c}(\alpha, \beta) = \prod_{i=1}^{n}\left[\Lambda_0(y_i|\alpha)\exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right)\right]^{c_i} \times \exp\left[-\Lambda_0(y_i|\alpha)\exp\left(\sum_{j=1}^{k} x_{ij}\beta_j\right)\right],$$

where $\Lambda_0(y_i|\alpha) = \int_0^{y_i} \lambda_0(u|\alpha)\,\mathrm{d}u$ denotes the cumulative baseline hazard rate. Writing, as we did before, $\mu_i = \exp\left\{\log[\Lambda_0(y_i|\alpha)] + \sum_{j=1}^{k} x_{ij}\beta_j\right\}$, $L(\alpha, \beta)$ is the likelihood function for n independent Poisson variates C_i with means μ_i. Aitkin & Clayton [2] used

this fact to bring survival analysis into the framework of generalized linear models (see also [7, 28], and [31]).

If no assumptions on the functional form of the baseline hazard function are made, then this is Cox's proportional hazards model [13, 14] that can be fitted by maximizing a "**partial likelihood**" (*see* **Cox Regression Model**). Another **semiparametric model**, due to Breslow [7], assumes a piecewise exponential distribution for the survival times, the baseline hazard function in this case is constant over prespecified intervals of time (*see* **Grouped Survival Times**). To be more specific, suppose that the time axis is split into intervals $(a_{p-1}, a_p]$, $p = 1, \ldots, P$, with $0 = a_0 < a_1 < \cdots < a_p < a_{p+1} = \infty$. The baseline hazard can now be written as

$$\lambda_0(y|\alpha) = \exp(\alpha_p), \quad \text{if } a_{p-1} < y \leq a_p.$$

To simplify notation, for individual i and interval $(a_{p-1}, a_p]$ the proportional hazard assumption can be expressed in terms of a constant λ_{ip}, where

$$\lambda_{ip} = \exp\left(\alpha_p + \sum_{j=1}^{k} x_{ij}\beta_j\right). \tag{10}$$

Define P_i to be such that y_i is contained in interval $(a_{P_{i-1}}, a_{P_i}]$ and e_{ip} to be the exposure time of individual i in the pth interval, i.e.

$$e_{ip} = \begin{cases} a_p - a_{p-1}, & \text{if } p = 1, \ldots, P_i - 1, \\ y_i - a_{P_{i-1}}, & \text{if } p = P_i \end{cases}.$$

Also, introduce an extended censoring indicator variable to be

$$c_{ip} = \begin{cases} 1, & \text{if } p = 1, \ldots, P_i - 1, \\ c_i, & \text{if } p = P_i. \end{cases}$$

Disregarding constant terms, the likelihood function is then

$$L_{y,c}(\alpha, \beta) = \prod_{i=1}^{n} \prod_{p=1}^{P_i} (\lambda_{ip} e_{ip})^{c_{ip}} \exp(-\lambda_{ip} e_{ip}),$$

where λ_{ip} is defined by (10). Since this is a Poisson likelihood for the "counts" c_{ip}, the *piecewise exponential model* reduces to a loglinear model. If intervals are chosen such that their endpoints correspond to observed times of death, i.e. t_is with $c_i = 1$, then maximum likelihood estimates for the regression parameters β are found to be close to those obtained from the Cox model; see [3] and [39].

For an example consider the data printed in Table 3. For 33 patients treated for papillary thyroid carcinoma, survival time, censoring indicator, age, and gender are reported. This is a small subset of the data analyzed in [30]. For cutpoints $a_1 = 0.5$, $a_2 = 1$,

Table 3 Survival times: *time* in years, censoring indicator *cens* (= 0 for censored), *gender* (1 for male), and *age* for 33 patients treated for papillary thyroid carcinoma. Subset of data analyzed in [30]

Time	Cens	Gender	Age	Time	Cens	Gender	Age
27.42	0	1	21	2.33	0	1	76
8.50	1	2	31	1.33	0	1	46
0.13	1	1	62	0.08	1	2	84
0.83	1	1	53	2.83	0	2	69
5.92	0	2	52	2.25	1	2	90
1.92	0	2	67	0.25	1	2	52
0.92	1	1	73	3.42	0	2	71
11.67	0	2	56	1.92	1	2	75
0.17	1	1	57	3.00	1	1	69
5.00	1	2	71	1.00	1	1	75
0.08	1	1	53	8.50	1	2	73
0.08	1	2	53	4.17	0	2	36
0.92	1	2	48	3.50	1	1	38
5.08	1	2	65	1.25	1	2	69
5.42	1	2	49	0.33	1	2	77
0.25	0	1	61	0.67	1	1	87
0.17	1	1	71				

$a_3 = 2$, and $a_4 = 3$, the piecewise-constant baseline hazard function is, up to a constant, estimated as

$$\lambda_0(y) = \begin{cases} 0.45, & \text{if } y \leq 0.5, \\ 0.36, & \text{if } 0.5 < y \leq 1, \\ 0.11, & \text{if } 1 < y \leq 2, \\ 0.16, & \text{if } 2 < y \leq 3, \\ 0.20, & \text{if } 3 < y. \end{cases}$$

Regression parameters, estimated for gender and age, are -0.70 and 0.04, respectively.

Log-nonlinear Models

While loglinear models do have some desirable properties, it may not always be possible to find a parameterization such that the regression function is linear on the log scale. An example of this is given in [20], using a log-logistic regression function. The data come from a **radioimmunoassay**, a widely used technique to measure the quantity of a given biological substance by identifying the amount of a radioactive labeled antibody from a reagent by subsamples of increasing concentration. The response variable is the amount of radioactive material remaining measured in counts per minute. If these are very large, a normal distribution for the counts may be assumed, but if this is not the case, an underlying Poisson distribution seems to be more appropriate. For counts $y_1, \ldots, y_n$ and concentrations $x_1, \ldots, x_n$ a regression function of the form

$$\eta_i(\beta_1, \ldots, \beta_4) = \beta_1 + \frac{\beta_2}{1 + \exp\{-[\beta_3 + \beta_4 \log(x_i)]\}} \quad (11)$$

can be used to describe the relationship between mean counts and concentrations. Note that this model cannot be transformed into a loglinear one.

Other examples of log-nonlinear models arise frequently in the analysis of contingency tables, when specific structure in the data suggests inclusion of nonlinear **interaction** effects into the regression function. See, for instance, [1, pp. 287–293].

Likelihood Inference

When adopting a modeling approach it seems to be natural to estimate the parameters of a model by maximizing the likelihood function, or, equivalently, its logarithm. The likelihood function contains all the relevant information about the mechanism that generated the data as well as the data actually observed. The larger its value the stronger the support given, by the data, to the corresponding value of the parameters. When dealing with Poisson regression models, maximum-likelihood estimation is, by far, the most often used method to obtain estimates for the unknown parameters.

Poisson regression models as defined above are instances of curved exponential family models; even if the model is loglinear, it is an exponential family model. So a much more general theory applies to this class of models. Here, only the special case will be considered. Readers interested in a general and detailed treatment are referred to, for example, Barndorff-Nielsen & Cox [5].

To maximize the log likelihood function one usually calculates partial derivatives with respect to all the parameters, sets them equal to 0, and solves this system of equations for the unknowns. For a Poisson regression model with log likelihood (3), the *estimating equations*

$$u_j(\beta) = \sum_{i=1}^{n} \frac{\partial}{\partial \beta_j} \eta_i(\beta) \frac{1}{\eta_i(\beta)} [y_i - \eta_i(\beta)] = 0$$

need to be solved. If the model is loglinear, then this simplifies to

$$u_j(\beta) = \sum_{i=1}^{n} x_{ij} \left[y_i - \exp\left(\sum_{h=1}^{k} x_{ih} \beta_h \right) \right] = 0.$$

A generally applicable method for obtaining estimates numerically is provided by the *Fisher scoring algorithm* (*see* **Optimization and Nonlinear Equations**). In the present case, this is seen to be an *iteratively reweighted least squares procedure*, where, in each step of the iterative algorithm, a weighted **least squares** problem is to be solved. As a particular consequence to this fact, methods developed for diagnosing linear regression models can be modified for generalized linear models. To define *leverage* and *influence* one only needs to refer to respective quantities calculated from the last iteration step (*see* **Diagnostics**). Formulas needed to do so are lengthy to write down, but most of the widely used software packages provide, at least as an option, the figures. For more on diagnostics for generalized linear models

see [15]. Software packages found useful for fitting Poisson regression models include GLIM [20] and **S-PLUS** [10].

Not much is known about existence and uniqueness of maximum likelihood estimators in the general case. For loglinear models, however, if all observed sufficient statistics involved are larger than 0, then maximum likelihood estimates for the means, i.e. $\hat{\mu}_i = \eta_i(\hat{\beta})$, do exist and are unique, which is also true for $\hat{\beta}$, if the design matrix is of full rank. For a more detailed discussion, see [1] and the references therein.

A statistic capable of measuring the amount of support given by the data to a particular value of the parameter compared to its maximum likelihood estimate is the *deviance*, defined as minus two times the logarithm of the *normed likelihood*:

$$\begin{aligned} D_y(\beta) &= -2\log\left(\frac{L_y(\beta)}{L_y(\hat{\beta})}\right) \\ &= -2[\ell_y(\beta) - \ell_y(\hat{\beta})] \\ &= -2\sum_{i=1}^{n}\left\{y_i \log\left[\frac{\eta_i(\beta)}{\eta_i(\hat{\beta})}\right] \right. \\ &\qquad \left. - [\eta_i(\beta) - \eta_i(\hat{\beta})]\right\}. \end{aligned}$$

The deviance cannot be negative. It provides a measure of distance between the model described by β and the model characterized by the most likely parameter $\hat{\beta}$ and can, thus, be used to construct likelihood regions. Assuming β to be the "true" parameter, the deviance has an asymptotic χ^2 distribution with k degrees of freedom, where k is the dimension of the parameter β. This admits an interpretation of likelihood regions as confidence sets.

To obtain a measure of **goodness of fit** similar to the residual sum of squares in normal linear regression, the likelihood for the *maximal model* that perfectly fits the data can be compared to the likelihood of the model under consideration. This statistic is usually written as

$$\mathrm{dev}_y = 2\sum_{i=1}^{n}\left\{y_i \log\left[\frac{y_i}{\eta_i(\hat{\beta})}\right] - [y_i - \eta_i(\hat{\beta})]\right\}, \tag{12}$$

and termed *deviance* as well. Assuming the null model to be correct, the expected value for the latter statistic is approximately equal to the number of residual **degrees of freedom**, i.e. the number of observations minus the number of parameters in the model.

The deviance is a very important tool in searching for a "good", i.e. a parsimonious and well fitting, model, as it can be used to compare nested **hierarchical** models. Suppose we have a model with parameter β and a smaller one with a parameter γ, which can be obtained from β by setting r components to 0. Then, assuming the smaller model to be the correct one, the difference of deviances (12) is asymptotically χ^2 distributed with r degrees of freedom. Note that this is a **likelihood ratio test** for the smaller model with the null hypothesis against the larger model as the alternative.

The deviance is a useful measure of discrepancy, frequently supposed to have an approximate χ^2 distribution. However, this is to be taken with care, as χ^2 is not, in general, guaranteed to be a large sample distribution of (12). The deviance itself can be approximated by

$$X^2 = \sum_{i=1}^{n}\frac{[y_i - \eta_i(\hat{\beta})]^2}{\eta_i(\hat{\beta})}, \tag{13}$$

which is known as the *Pearson goodness-of-fit statistic* (*see* **Chi-square Tests**).

Another way of performing significance tests of hypotheses about single parameters is by applying a *Wald test* (*see* **Likelihood**). This uses the approximate normality of the maximum likelihood estimates and computes, as the test statistic, the ratio of the estimate of the parameter of interest and its asymptotic standard error. The formula is complex, but, again, many statistical packages provide the figures for the Wald test, sometimes under the heading *t-test*, as well as observed significance values. For more detailed accounts on likelihood inference for a generalized linear model with some emphasis on the Poisson regression model see [1, 19, 34] and [35] and the references therein.

An obvious way of defining **residual** quantities is to use square roots of contributions to the sums in (12) or (13), and attach the appropriate signs. Denoting raw residuals by $r_i = y_i - \eta_i(\hat{\beta})$, we have

$$\begin{aligned} r_i^{\mathrm{D}} = \mathrm{sgn}(r_i)(-2\{y_i \log\left[\frac{y_i}{\eta_i(\hat{\beta})}\right] \\ - [y_i - \eta_i(\hat{\beta})]\})^{1/2} \end{aligned} \tag{14}$$

for the *deviance residuals* and

$$r_i^{\mathrm{P}} = \frac{y_i - \eta_i(\hat{\beta})}{[\eta_i(\hat{\beta})]^{1/2}} \tag{15}$$

for the *Pearson residuals*. In any case, large residuals indicate large contributions to the respective goodness-of-fit statistics. Both deviance and Pearson residuals can (and should) be standardized. This requires computation of leverages for all observations. See [37] and [15] for more on residuals in generalized linear models.

For the time trend model fitted to the Stress Recall Data one calculates a deviance of 24.57 with 16 degrees of freedom. The deviance is 1.5 times larger than its approximate expected value, indicating a moderate amount of *overdispersion* (see [8, 16], and [17] for more on the phenomenon of overdispersion in Poisson regression models). Compared to a model with only the constant term included, we see a difference of deviances of 26.67. Referring to its approximate **chi-square distribution** (with 1 degree of freedom) clearly confirms the time trend. The regression parameter for the explanatory variable "months before interview" has been estimated as -0.0837, with an asymptotic standard error of 0.017, resulting in a t-value of -4.99, which is definitely large enough to reject the hypothesis of no time trend. The smallest deviance residual is -1.99, the largest 2.04, and there is no obvious pattern suggesting any specific inadequacies in the model.

GILG U.H. SEEBER

Poisson, Siméon–Denis

Born: June 21, 1781, in Pithiviers, Loiret, France.
Died: April 25, 1840, in Paris, France.

Poisson's formative years were spent in the provinces where he came of modest family. Encouraged by a dedicated teacher at the École Centrale at Fontainebleau, he was admitted to the École Polytechnique in Paris in 1798, where, through the backing of **Laplace**, he was appointed to the academic staff in 1800. He stayed at the École Polytechnique, replacing Fourier as professor in 1806, while gaining other posts, notably a professorship at the Faculty of Sciences at the Sorbonne in 1816. He had been elected to the Paris Academy of Sciences in 1812. Through his life, characterized by hard work and dedication to scientific research and the teaching of science, Poisson accommodated himself to the various changes of political regime. In his research he treated a very broad range of subjects in a great number of publications, of which those on **probability** and its applications are relatively few [4], the most important being the book, published close to the end of his life: *Recherches sur la Probabilité des Jugements en Matière Criminelle et en Matière Civile* (1837).

In the *Recherches*, the **Poisson distribution** is derived as the limit of the distribution function of the (Pascal) distribution with mass function:

$$\binom{m+t-1}{m-1} p^m q^t, \quad t = 0, 1, 2, \ldots,$$

as $m \to \infty$, $q \to 0$ in such a way that $qm \to \omega =$ const. > 0 [5].

Indeed, the Poisson mass function $e^{-\omega}\omega^t/t!$, $t = 0, 1, 2, \ldots$, occurs significantly earlier than in Poisson's work [1–3]. However, he considered the **"Cauchy" distribution** with density $f(x) = 1/\pi (1 + x^2)$, $-\infty < x < \infty$, some 20 years before Cauchy. The use of the notion of a **random variable**, of the cumulative distribution function, and the definition of the density as its derivative, may be original with Poisson [4].

Apart from his many scientific articles and memoirs, Poisson was heavily involved in administration and pedagogical activity. He had the habit of saying "Life is good for only two things: to study mathematics and to teach it."

E. SENETA

Polya Process

The Polya process is a nonstationary birth process (*see* **Stochastic Processes**). Let $X(t)$ be the number of individuals present at time t, with $X(0) = 0$ at $t = 0$. The transition (conditional) probabilities of $X(t)$,

$$P_{0k}(0, t) = \Pr[X(t) = k | X(0) = 0],$$

satisfy the following differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}t} P_{00}(0, t) = -\lambda_0(t) P_{00}(0, t) \tag{1a}$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t} P_{0k}(0, t) = -\lambda_k(t) P_{0k}(0, t) + \lambda_{k-1}(t) P_{0,k-1}(0, t), \tag{1b}$$

for $k = 1, 2, \ldots$, where

$$\lambda_k(t) = \frac{1 + \lambda k}{1 + \lambda t}, \quad \text{for } k = 0, 1, \ldots, \tag{2}$$

is a function of both the number k and time t. The probability **generating function** of $X(t)$, as derived in [2], is

$$G_X(s, t) = [1 + \lambda t - \lambda t s]^{-1/\lambda},$$

which leads to the formula for $P_{0k}(0, t)$:

$$P_{0k}(0, t) = \binom{1/\lambda + k - 1}{k} \left(\frac{1}{1 + \lambda t}\right)^{1/\lambda} \times \left(\frac{\lambda t}{1 + \lambda t}\right)^{k}, \tag{3}$$

for $k = 0, 1, \ldots$. Formula (3) is a **negative binomial distribution** with parameters $1/\lambda$ and $1/(1 + \lambda t)$. The expectation and the variance of $X(t)$ are, respectively,

$$\mathrm{E}[X(t)] = t \quad \text{and}$$
$$\mathrm{var}[X(t)] = t[1 + \lambda t].$$

The Polya process is closely related to the Polya distribution generated by the **Polya urn** scheme [3–5, 7]. Suppose that an urn contains $(a + b)$ balls, of which a balls are red and b balls are black. A ball is drawn at random from the urn, its color noted. The ball is replaced and c balls of the same color are added. After the first draw, there are $(a + b + c)$ balls in the urn. The procedure is repeated.

Among n draws, the number of times resulting in red balls, $X(n)$, has the following probability distribution:

$$P_{\mathrm{k,n}} = \binom{n}{k} \frac{\left\{\begin{array}{c} a(a + c)(a + 2c) \ldots [a + (k - 1)c] \\ \times b(b + c)(b + 2c) \ldots [b + (n - k - 1)c] \end{array}\right\}}{\left\{\begin{array}{c} (a + b)(a + b + c)(a + b + 2c) \\ \times \ldots [a + b + (n - 1)c] \end{array}\right\}}, \tag{4}$$

for $k = 0, 1, \ldots, n$. The expectation and the variance of $X(n)$ are, respectively,

$$\mathrm{E}[X(n)] = np \quad \text{and}$$
$$\mathrm{var}[X(t)] = \frac{npq[1 + nr]}{[1 + r]},$$

where $p = a/(a+b)$, $q = b/(a+b)$, and $r = c/(a+b)$. If $c = 0$, then (4) is a **binomial distribution**; if $c = -1$, then (4) is a **hypergeometric distribution**.

The constant c is a "contagion" factor of the distribution (*see* **Contagious Distributions**). If red balls stand for infection, then the occurrence of an infection (drawing a red ball) increases the amount of infection in the population, and increases the probability of having an infected case (a red ball) in the future. Drawing a black ball will have the opposite effect. The number c can be either positive or negative. If c is positive, then the contagion is positive; if c is negative, then the contagion is negative (such as immunity). The Polya process and Polya distribution have applications in studying contagious diseases, in the theory of cosmic radiation [1], and in the analysis of accident, insurance, and sickness statistics [6].

Polya [3, 7] has shown that, within a time interval $(0,t)$, if $n \to \infty$, $p \to 0$, and $r \to 0$, so that $np \to t$ and $nr \to \lambda t$, then formula (4) in the Polya distribution approaches formula (3) in the Polya process as a limit.

Polya's Urn Model

The Polya urn model was introduced by Eggenberger & Polya [2]. The urn initially contains balls of two colors (W white balls and R red balls). A ball is drawn at random. After each drawing, the chosen ball is returned together with s balls of the same color. The process is repeated n times. Let X be the number of times a red ball is drawn. The exact distribution of X can be found in Johnson & Kotz [3, p. 177] and can be approximated by the well-known Polya distribution [4, p. 64]. It is interesting to note that when $s = 0$, X is a simple **binomial** random variable, and when $s = -1$, X is a **hypergeometric** random variable.

This simple urn model can be generalized. For example, after each draw, t balls of color opposite to that chosen are also added. Furthermore, s and t may be negative, and s and t may be random variables. For these general cases, the properties of X have been studied through the theory of **branching processes** [1] (*see* **Polya Process**).

This model applies to many practical situations in medical studies. The case in which s and t are random variables has an interesting and important application to **sequential methods in clinical trials** (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). Specifically, in comparing two treatments A and B, suppose that eligible patients occur singly and must be treated when they arrive. For each patient's treatment assignment, a ball is selected at random from the urn with replacement. If it is white, assign this patient to Group A; otherwise, assign this to Group B. When the response of a previous patient to treatment A is a success, we add s white balls and t red balls to the urn. However, if the response is a failure, we add s' whites and t' reds to the urn. In practice, $\{s, t, s', t'\}$ are chosen so that this type of randomized Polya urn scheme tends to put more patients on the better treatment, but also provides reliable data to evaluate the treatment difference due to its random nature. The urn scheme can also be modified to deal with the case in which more than two treatments are involved in the study [5], using an urn and balls with more than two colors.

Polygenic Inheritance

Many quantitative, metric, or continuous traits do not show simple Mendelian transmission (*see* **Mendel's Laws**) and their expression is believed to be controlled by polygenes. Strictly speaking, polygenic inheritance refers to the mode of inheritance of characters or traits whose genetic component is determined by polygenes (i.e. many **genes**) with individually small effects, as opposed to monogenic (i.e. single gene) or oligogenic (i.e. a few genes) inheritance.

Plate [26] appears to be the first to use the term "polygenic". Fisher [8] and Mather [21] greatly enriched the meaning of "polygenic inheritance". The main properties of polygenic inheritance were summarized elegantly by Lerner [20], as follows: (i) most metric and meristic (polychotomous, or categorical) traits are affected by a number of genetic loci; (ii) the effects of allelic substitution at each of the segregating loci are usually relatively small and interchangeable, in the sense that identical phenotypes may be displayed by a great variety of **genotypes**; (iii) the phenotypic expression of polygenic traits is subject to considerable modification by environmental influences; (iv) most populations have great reserves of genetic variability, often carried in the gene pool in balanced systems; (v) there is nothing biochemically exceptional about genes controlling polygenic inheritance; (vi) polygenic traits show a continuous rather than a discontinuous distribution.

However, it should be noted that, for dichotomous or binary traits, which are either present or absent in any one individual, a combination of polygenes and environmental factors can determine an underlying or latent risk or liability toward the trait (*see* **Genetic Liability Model**). The values of the liability may or may not be directly observable, and individuals having the trait are those whose liability values exceed a threshold that is sometimes unknown.

Historical Background

Around the turn of this century with the rediscovery of Mendel's work, the field of human heredity was deeply divided and witnessed bitter confrontation between the biometricians, represented by **Karl Pearson** and W.F.R. Weldon, and the Mendelians, led by the Cambridge geneticist William Bateson. The biometricians held that the observed correlations between relatives in large populations were incompatible with Mendelian inheritance [25], and the Mendelians seem to have considered discontinuous genetic variation as incompatible with anything but obviously discontinuous phenotypic variation. A series of experimental and theoretical discoveries made during the 1910s and 1920s eventually led to the settlement of the arguments between the two schools.

Shull [29] demonstrated the rapid fixation of one or another random combination of quantitative traits in self-fertilized lines of maize and interpreted this as due to automatic fixation of Mendelian units. Johannsen [16] showed that heritable and nonheritable agencies were jointly responsible for the variation in seed weight, and that their effects were of the same order of magnitude. The effects of discontinuity of the genotype could be smoothed out and continuous variation realized in the phenotype by the action of the environment. Nilsson–Ehle [23] found that similar factors with smaller individual effects could account for continuous quantitative variation if enough of them were segregating. Each factor would be inherited in the Mendelian way, and its change would be discontinuous. Yet with a number of such factors, having similar and cumulative action, many different dosages would be possible. Continuity would be completed by the blurring effect of noninheritable agencies. These findings were also independently documented by East around the same period [4, 5]. Nilsson–Ehle and East both recognized that their findings were consistent with the cumulative effects of many genes, each with a small effect for a continuous phenotypic variable, and thus laid the one cornerstone of the "polygenic" theory of continuous variations. Sax [28] further established the Mendelian nature of quantitative traits by demonstrating linkage of minor quantitative differentials with marker genes. Yule [37] showed mathematically that Mendelian variation could be retained indefinitely in a randomly breeding population. It was on the basis of these works that **Ronald A. Fisher** was able to synthesize the idea of continuous phenotypic variation of the biometricians with the genetic discontinuity of the Mendelian mechanism of inheritance. He showed [8] how **Galton's** own data could be reconciled with Mendelian inheritance. There were three main aspects to Fisher's argument. First, following

the experimental results of East and Nilsson–Ehle, Fisher adopted the polygenic model in which a large number of genes (infinitely many in Fisher's analysis) of individually small effect were responsible for continuous variation and family resemblance in humans. Secondly, Fisher questioned the generalization drawn from Mendel's experiments that all hybrids for a given character would resemble one or the other parent (i.e. he relaxed the assumption of complete dominance). Thirdly, he allowed in various ways for the effects of **assortative mating**. His model predicts very well the pattern in the correlations between different kinds of relatives.

Polygenic Models

Polygenic models, also called **variance component models** or random effects models, are widely used in the field of animal and plant breeding (see, for example, [13, 14]). In human genetics, polygenic models can be used to identify, among other traits associated with the definition of disease, the subset that have a significant genetic component in their etiology [15, 30]. Moreover, a good, well-tested polygenic model can be utilized in **genetic counseling** [19]. Polygenic models also have the merit that the parameterization is straightforward: various cultural, environmental and complex genetic effects can be easily incorporated into the models. Another attraction of the models is their mathematical tractability when **multivariate normality** is assumed.

Under the polygenic model, the phenotype is the result of the joint action of infinitely many genes, each with a small contribution to the phenotype, and of the environment. In mathematical terms, the polygenic models assume that the phenotypic value y is the additive combination of genotypic value v and independent environmental effect e, namely

$$y = v + e.$$

In general, y can be an arbitrary function of v, but such a model would be too complex to be useful in reality.

The polygenic value v can be further decomposed into various components. For example, v can be decomposed into the mean value μ in the reference population, the additive component a, which is the combination of main effects of all loci, and the dominance effect d, which is the combination of the interactions between homologous genes at each loci (see [1]), i.e.

$$v = \mu + a + d,$$

where a and d are usually assumed to be normal. In practice, phenotypes often have to be transformed to approximate normality prior to analysis.

Let y_i and y_j be random variables defining the trait values of individuals i and j, respectively. Also, let σ_a^2 be the additive genetic variance, σ_d^2 the variance due to dominance, and σ_e^2 the environment variance. Denote ϕ_{ij} as the kinship coefficient for i and j (*see* **Inbreeding**). Then, under the formulation of Fisher, the covariance between the phenotypes for any two individuals, i and j, in a given pedigree, is

$$\mathrm{cov}(y_i, y_j) = 2\phi_{ij}\sigma_a^2 + \Delta_{ij}\sigma_d^2 + \delta_{ij}\sigma_e^2.$$

A multivariate normal distribution with this covariance structure is usually assumed. Under some fairly stringent conditions, Lange [17] proved a **central limit theory** for pedigrees.

In vector notation, and denoting $\mathbf{\Phi} = (\phi_{ij})$ and $\mathbf{\Delta} = (\Delta_{ij})$, the above model can be rewritten as

$$\mathbf{y} = \mu\mathbf{1} + \mathbf{a} + \mathbf{d} + \mathbf{e}, \tag{1}$$

where $\mathbf{1}$ is an $n \times 1$ vector of 1s, $\mathbf{a} \sim \mathrm{N}(\mathbf{0}, 2\sigma_a^2\mathbf{\Phi})$, $\mathbf{d} \sim \mathrm{N}(\mathbf{0}, \sigma_d^2\mathbf{\Delta})$, and $\mathbf{e} \sim \mathrm{N}(\mathbf{0}, \sigma_e^2\mathbf{I})$.

Components $\mathbf{a}$, $\mathbf{d}$, and $\mathbf{e}$ are taken to be independent so that the variance of the phenotype $\mathbf{y}$ is simply the sum of the variances of the components.

A number of other assumptions are usually made to limit the complexity of the model. These include **Hardy–Weinberg equilibrium** and linkage equilibrium (*see* **Linkage Disequilibrium**) for all loci, no epistasis (*see* **Genotype**), and absence of **gene–environment interaction**, of **assortative mating**, and of correlated environments among relatives. Note that some of the assumptions can be relaxed without substantially complicating the mathematics. For example, the assumption of no correlated environments can be lifted by adding a common environment component $\mathbf{c}$ to the model with $\mathbf{c} \sim \mathrm{N}_n(\mathbf{0}, \sigma_d^2\mathbf{C})$, where the element c_{ij} of $\mathbf{C}$ is 1 if i and j share the same environment, and 0 otherwise.

Thus, a general polygenic model is

$$\mathbf{y} = \mu\mathbf{1} + \mathbf{z}_1 + \mathbf{z}_2 + \cdots + \mathbf{z}_k + \mathbf{e}, \tag{2}$$

where the $\mathbf{z}_i$s are k random components, with $\mathbf{z}_i \sim \mathrm{N}_n(\mathbf{0}, \sigma_i^2\mathbf{\Sigma}_i)$; $\mathbf{e}$ is the environmental effect, with $\mathbf{e} \sim$

$N_n(\mathbf{0}, \sigma_e^2\mathbf{I})$. $\mathbf{z}_1, \ldots, \mathbf{z}_k$ and $\mathbf{e}$ are assumed mutually independent. The $\mathbf{\Sigma}_i$s are known and are at least semi-positive-definite. Without loss of generality, we can assume the $\mathbf{\Sigma}_i$s are invertible since we can always reparameterize the model so that, say, $\tilde{\mathbf{\Sigma}}_i = \mathbf{\Sigma}_i + (\varepsilon/\sigma_i^2)\mathbf{I}$, which is invertible, and $\sigma_e'^2 = \sigma_e^2 - \varepsilon$, where ε is small enough so that $\sigma_e^2 - \varepsilon > 0$. Note that here we have assumed a constant mean μ for all individuals. This is for convenience only. In general, the model can include some **fixed effects** such as sex and generation effects, or some **covariates** like age. Incorporation of fixed effects and covariates is straightforward.

Parameter Estimation

Maximum likelihood is the method of choice in parameter estimation for polygenic models because of its theoretical soundness. There are two approaches to maximum likelihood estimation: Fisher's method of scoring and the **EM algorithm**. Most recent theoretical developments in this area are aimed at reducing the computational burdens of likelihood estimation for variance components. In animal breeding genetics, the maximum likelihood method and its related method, **restricted maximum likelihood**, has been applied to estimation in polygenic models, often taking advantage of relatively simple structure in animal breeding data [9, 13, 14, 22]. In human genetics (*see* **Human Genetics, Overview**), the method of scoring is often the method of choice when pedigrees are not too large or complex. Otherwise, the EM method is often used.

The Method of Scoring

Lange et al. [19] provide an excellent exposition on the use of scoring method in parameter estimation for polygenic models. Consider the model in (1). Let $\mathbf{\Omega} = 2\sigma_a^2\mathbf{\Phi} + \sigma_d^2\mathbf{\Delta} + \sigma_e^2\mathbf{I}$, and $\boldsymbol{\gamma} = (\mu, \sigma_a^2, \sigma_d^2, \sigma_e^2)'$. Let $\mathbf{y} = (y_1, \ldots, y_n)'$ be the observed trait values. Individuals with missing values are deleted prior to analysis.

The log likelihood for the pedigree is then

$$L = -\tfrac{1}{2}\log|\mathbf{\Omega}| - \tfrac{1}{2}(\mathbf{y} - \mu\mathbf{1})'\mathbf{\Omega}^{-1}(\mathbf{y} - \mu\mathbf{1}),$$

since

$$\frac{\partial \mathbf{\Omega}^{-1}}{\partial\theta} = -\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\theta}\mathbf{\Omega}^{-1},$$

$$\frac{\partial L}{\partial\mu} = \mathbf{1}\mathbf{\Omega}^{-1}(\mathbf{y} - \mu\mathbf{1}),$$

and

$$\frac{\partial L}{\partial\sigma_k^2} = -\frac{1}{2}\mathrm{tr}\left(\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\right) + \frac{1}{2}\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\mathbf{\Omega}^{-1}(\mathbf{y} - \mu\mathbf{1}),$$

where

$$\frac{\partial\mathbf{\Omega}}{\partial\sigma_a^2} = 2\mathbf{\Phi}, \quad \frac{\partial\mathbf{\Omega}}{\partial\sigma_d^2} = \mathbf{\Delta}, \quad \text{and } \frac{\partial\mathit{\Omega}}{\partial\sigma_e^2} = \mathbf{I}.$$

The second partial derivatives of L are [19, 28]:

$$\frac{\partial^2 L}{\partial\mu^2} = -\mathbf{1}\mathbf{\Omega}^{-1}\mathbf{1}',$$

$$\frac{\partial^2 L}{\partial\mu\partial\sigma_k^2} = \frac{\partial^2 L}{\partial\sigma_k^2\partial\mu} = -\mathbf{1}\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\mathbf{\Omega}^{-1}(\mathbf{y} - \mu\mathbf{1}),$$

$$\frac{\partial^2 L}{\partial\sigma_k^2\partial\sigma_l^2} = \frac{1}{2}\mathrm{tr}\left(\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_l^2}\right) - \frac{1}{2}(\mathbf{y} - \mu\mathbf{1})'\mathbf{\Omega}^{-1} \times \left(\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_l^2} + \frac{\partial\mathbf{\Omega}}{\partial\sigma_l^2}\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\right) \times \mathbf{\Omega}^{-1}(\mathbf{y} - \mu\mathbf{1}).$$

Since $\mathrm{tr}(\mathbf{AB}) = \mathrm{tr}(\mathbf{BA})$, $\mathrm{E}[\mathbf{A}(\mathbf{Y} - \mu\mathbf{1})] = \mathbf{A}\mathrm{E}(\mathbf{Y} - \mu\mathbf{1}) = 0$, $\mathrm{E}[(\mathbf{Y} - \mu\mathbf{1})'\mathbf{A}(\mathbf{Y} - \mu\mathbf{1})] = \mathrm{tr}(\mathbf{A\Omega})$, where $\mathbf{A}$ and $\mathbf{B}$ are constant matrices and $\mathbf{Y}$ is a random vector with mean $\mu\mathbf{1}$ and variance $\mathbf{\Omega}$, the **information matrix** $\mathbf{I}(\gamma)$ can be obtained by taking expectations of the above second partial derivatives as

$$\mathbf{I}(\gamma) = \begin{pmatrix} \mathbf{1}\mathbf{\Omega}^{-1}\mathbf{1}' & 0 & 0 & 0 \\ 0 & \rho_{11} & \rho_{12} & \rho_{13} \\ 0 & \rho_{21} & \rho_{22} & \rho_{23} \\ 0 & \rho_{31} & \rho_{32} & \rho_{33} \end{pmatrix},$$

where

$$\rho_{kl} = \rho_{lk} = \frac{1}{2}\mathrm{tr}\left(\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_k^2}\mathbf{\Omega}^{-1}\frac{\partial\mathbf{\Omega}}{\partial\sigma_l^2}\right).$$

If there are m pedigrees, then the overall score vector and information matrix are the summation of score vectors and information matrices over all m pedigrees.

Now let $\gamma^{(i)}$ be the value of the parameters at the ith iteration, and let the score vector $\mathbf{S}[\gamma^{(i)}]$ be

the vector of partial derivatives of L with respect to individual parameters evaluated at $\gamma^{(i)}$. Then, the scoring algorithm takes the new value to be

$$\gamma^{(i+1)} = \gamma^{(i)} + \mathbf{I}^{-1}[\gamma^{(i)}]\mathbf{S}[\gamma^{(i)}].$$

If the iteration converges to a unique value $\hat{\gamma}$, then standard large sample theory shows that $\hat{\gamma}$ is asymptotically multivariate normal with mean γ_0 and covariance matrix $\mathbf{I}^{-1}(\hat{\gamma}_0)$, where γ_0 is the true parameter value.

The EM Algorithm

The EM equations for estimating γ are:

$$\mu^* = \frac{1}{n}\mathrm{E}_\gamma[\mathbf{1}'(\mathbf{y} - \mathbf{a} - \mathbf{d} - \mathbf{e})|\mathbf{y}],$$

$$(\sigma_a^*)^2 = \frac{1}{n}\mathrm{E}_\gamma[\mathbf{a}'(2\mathbf{\Phi})^{-1}\mathbf{a}|\mathbf{y}],$$

$$(\sigma_d^*)^2 = \frac{1}{n}\mathrm{E}_\gamma(\mathbf{d}'\mathbf{\Delta}^{-1}\mathbf{d}|\mathbf{y}),$$

and

$$(\sigma_e^*)^2 = \frac{1}{n}\mathrm{E}_\gamma(\mathbf{e}'\mathbf{e}|y),$$

where

$$\mathrm{E}_\gamma[\mathbf{a}'(2\mathbf{\Phi})^{-1}\mathbf{a}|\mathbf{y}] = \mathbf{p}'(2\mathbf{\Phi})^{-1}\mathbf{p} + \mathrm{tr}\left[(2\mathbf{\Phi})^{-1}\left(\frac{\mathbf{I}}{\boldsymbol{\sigma}_\mathbf{e}^2} + \frac{(2\mathbf{\Phi})^{-1}}{\sigma_a^2}\right)^{-1}\right],$$

$$\mathrm{E}_\gamma(\mathbf{d}'\mathbf{\Delta}^{-1}\mathbf{d}|\mathbf{y}) = \mathbf{q}'\mathbf{\Delta}^{-1}\mathbf{q} + \mathrm{tr}\left[\mathbf{\Delta}^{-1}\left(\frac{\mathbf{I}}{\boldsymbol{\sigma}_\mathbf{e}^2} + \frac{\mathbf{\Delta}^{-1}}{\sigma_d^2}\right)^{-1}\right],$$

and

$$\mathrm{E}_\gamma(\mathbf{e}'\mathbf{e}|\mathbf{y}) = \mathbf{h}'\mathbf{h} + \mathrm{tr}\left[\left(\frac{4\mathbf{I}}{\sigma_e^2} + \frac{(2\mathbf{\Phi})^{-1}}{\sigma_a^2} + \frac{\mathbf{\Delta}^{-1}}{\sigma_d^2}\right)^{-1}\right],$$

where $\mathbf{p} = \mathrm{E}_\gamma(\mathbf{a}|\mathbf{y})$, $\mathbf{q} = \mathrm{E}_\gamma(\mathbf{d}|\mathbf{y})$, and $\mathbf{h} = \mathrm{E}_\gamma(\mathbf{e}|\mathbf{y})$.

Other Methods

Both the scoring and the EM methods require repeated inversion of certain matrices of an order equivalent to the pedigree size. For small or moderate-size pedigrees, this is not a problem. However, for large pedigrees, the inversion of large matrices may not be practically feasible. Thompson & Shaw [33] proposed a method for parameter estimation using the EM algorithm that avoids repeated inversion of large matrices. Their method can be extended to multivariate traits [34]. Guo & Thompson [10, 11] proposed a Monte Carlo EM algorithm (*see* **Monte Carlo Methods**) to solve this problem.

Likelihood Computation

An EM algorithm that provides maximum likelihood estimates may be of limited use if it does not also provide a computable form of the likelihood because likelihood values are needed for statistical inferences and in monitoring the convergence process. Although direct evaluation of the likelihood for polygenic models is theoretically possible, as done by Lange et al. [19], it is practically infeasible for large pedigrees because of its demand for repeated inversion of large matrices.

Elston & Stewart [6] proposed an algorithm, later known as the **Elston–Stewart algorithm** or the "peeling algorithm", to compute the **likelihood** on pedigrees for simple genetic models. They showed that the algorithm can compute likelihoods not only for major gene models but also for simple polygenic models (i.e. with additive component only). The algorithm was later generalized to more complex pedigrees and more complex genetic models [2, 18, 24]. Thompson & Shaw [33] proposed a peeling algorithm for computing the likelihood function on large complex pedigrees for a simple polygenic model. The algorithm has been extended to complex polygenic models with multiple random effects [32] and to multiple traits [34].

Approximations to Polygenic Models

The polygenic model assumes an infinite number of loci, each contributing a small amount to the variation of the trait of interest. Another class of genetic model, called the mixed model, assumes that the expression of the trait is determined by a major gene plus polygenic background (*see* **Segregation Analysis, Mixed Models**). This model has proved to be a useful alternative to classical Mendelian models in the analysis of pedigree data. The exact calculation of the likelihood for the mixed model is virtually

impossible except for very small pedigrees [24]. To circumvent the problem, Hasstedt [12] proposed an approximation to the likelihood on large pedigrees for the mixed model. Guo & Thompson proposed a method based on a Monte Carlo EM algorithm [10].

Fernando et al. [7] and Stricker et al. [31] took a different approach, postulating a finite polygenic model that was suggested earlier by Cannings et al. [2]. The model approximates polygenic inheritance by postulating that trait values are determined by a small number of biallelic loci having equal and additive effects. This approach is computationally fast, and is attractive as an alternative to the traditional mixed model in linkage analysis.

Concluding Remarks

Polygenic inheritance is an important, and perhaps common, mode of inheritance in genetics. Sewall Wright [35, 36] was an avid advocate of the notion that each phenotype is affected by multiple genes, and that the same genes can affect more than one phenotype (pleiotropic effects). At least in plant genetics, the increasing numbers of Mendelian marker loci have helped confirm Robertson's [27] prediction that "the distribution of gene effects will probably be of an exponential kind (so that the smaller the range of the effect specified, the greater the number of loci concerned)"; see [3].

As an approximation to polygenic inheritance, polygenic models have been useful in establishing a genetic basis for many traits. Under certain assumptions, they flexibly include various random and fixed effects and are easy to parameterize. However, this flexibility in no way means that it would be easy to disentangle the joint action of a large number of loci, and their mathematical tractability is not a licence to apply the models indiscriminately to any data at hand. Many assumptions underlying the polygenic model are critical to ease the mathematical tractability, and are often difficult to verify in practice. For example, the assumption of no gene–environment interaction is difficult to verify in reality, especially so when environmental factors affecting the trait of interest have not been completely identified. Indeed, the mathematical tractability always comes with a price: restricted utility and the burden of verifying the underlying assumptions. Nonetheless, polygenic models, if used judiciously, can provide better insight into the genetic mechanism underlying traits of interest.

Polymorphism Information Content

The polymorphism information content (PIC) value is a measure of polymorphism introduced by Botstein et al. [1] to describe a genetic marker's usefulness for **linkage analysis** when attempting to localize on a chromosome the **gene** locus involved in a rare dominant disease. The **genotype** of a person with the disease is assumed to be **heterozygous**, and the PIC value is then defined as the probability that the marker genotype of such a person's offspring would allow one to deduce which marker allele was derived from the affected parent. If there are n alleles at the marker locus, the relative frequency of the ith being p_i, then, assuming **Hardy–Weinberg equilibrium**, they showed that in this situation

$$\mathrm{PIC} = 1 - \sum_{i=1}^{n} p_i^2 - 2 \sum_{i=1}^{n-1} \sum_{j=1}^{n} p_i^2 p_j^2. \qquad (1)$$

Estimating PIC and its standard error are discussed in [4].

As the number of alleles increases, each with decreasing population frequency, the PIC value approaches its maximum value of unity.

Most authors who quote PIC values base them on (1). However, Chakravarti & Buetow [3] derived analogous formulae for mapping rare traits with other modes of inheritance, and Chakravarti [2] derived expressions for the joint PIC value of two markers for a family structure consisting of four grandparents, two parents, and their offspring.

ROBERT C. ELSTON

Polymorphism

In biology, polymorphism refers to the many different forms that an organism can have. In genetics, it refers to the many different **genotypes** and phenotypes or gene products associated with a particular **gene** locus. A locus was originally defined to be polymorphic if the frequency of its least common allele is too large to be due simply to recurrent mutation, operationally taken to be at least 1% [1]. However, a locus at which there are 1000 distinct alleles each with a frequency of 0.1% would be considered extremely polymorphic, and so a more accurate definition of a polymorphic locus would put an upper bound, such as 99%, on the frequency of its most common allele. DNA polymorphisms abound. Many authors now use the terms "polymorphism" or "gene polymorphism" to denote a common allele at a locus that does not cause disease (*see* **Mutation**).

ROBERT C. ELSTON

Polynomial Approximation

A polynomial is a function that can be written in the form

$$p(x) = c_0 + c_1 x + \cdots + c_n x^n,$$

for some coefficients $c_0, \ldots, c_n$. If $c_n \neq 0$, then the polynomial is said to be of order n. A first-order (linear) polynomial is just the equation of a straight line, while a second-order (quadratic) polynomial describes a parabola.

Polynomials are just about the simplest mathematical functions that exist, requiring only multiplications and additions for their evaluation. Yet they also have the flexibility to represent very general nonlinear relationships. Approximation of more complicated functions by polynomials is a basic building block for a great many numerical techniques.

There are two distinct purposes to which polynomial approximation is put in statistics. The first is to model a nonlinear relationship between a **response variable** and an **explanatory variable** (*see* **Nonlinear Regression**; **Response Variable**). The response is usually measured with error, and the interest is on the shape of the fitted curved and perhaps also on the fitted polynomial coefficients. The demands of **parsimony** and interpretability ensure that one will seldom be interested in polynomial curves of more than third or fourth order in this context.

The second purpose is to approximate a difficult to evaluate function, such as a density or a distribution function, with the aim of fast evaluation on a computer. Here, there is no interest in the polynomial curve itself. Rather, the interest is on how closely the polynomial can follow the special function, and especially on how small the maximum error can be made. Very high order polynomials may be used here if they provide accurate approximations. Very often, a function is not approximated directly, but is first transformed or standardized so as to make it more amenable to polynomial approximation.

On either type of problem, substantial benefit can be had from orthogonal polynomials (*see* **Orthogonality**). Orthogonal polynomials can be used to make the polynomial coefficients uncorrelated, to minimize the error of approximation, and to minimize the sensitivity of calculations to roundoff error.

Suppose that the function to be approximated, $f(x)$, is observed at a series of values $x_1, \ldots, x_N$. In general, we will observe $y_i = f(x_i) + \varepsilon_i$, where the ε_i are unknown errors. The task is to estimate $f(x)$ for new values of x. If the new x is within the range of the observed abscissae, then the problem is *interpolation*. If it is outside, then the problem is **extrapolation**. Polynomials are useful for interpolation, but notoriously poor at extrapolation.

Polynomial approximation is relatively straightforward and good enough for many purposes. There are, however, many other ways to approximate functions. Many functions, for example, can be more economically approximated by rational functions, which are quotients of polynomials. A survey of approximation methods is given by Press et al. [4, Chapter 4].

Most numerical analysis texts include a treatment of polynomial approximation. Atkinson [2, Chapter 4] gives a nice treatment of minimax approximation using Chebyshev polynomials. Many specific polynomial approximation formulae to functions used by statisticians are given by Abramowitz & Stegun [1]. Many statistical texts mention polynomial regression. Kleinbaum et al. [3, Chapter 13] give a very accessible treatment, while that of Seber [5, Chapter 8] is more detailed and mathematical.

Taylor's Theorem

Use of polynomials can be motivated by Taylor's theorem. A well-behaved function f can be approximated about a point x by

$$f(x + \delta) \approx f(x) + f'(x)\delta + f''(x)\frac{\delta^2}{2!} + \cdots.$$

The right-hand side, which is a polynomial in δ, is an accurate approximation provided that δ is small.

The trouble with Taylor's theorem is that the error of approximation is not evenly distributed. The formula is very accurate for δ near zero, but becomes increasingly inaccurate as δ increases. Consider the cubic Taylor series expansion for e^x about zero on the interval $[-0, 3]$ (Figure 1). The approximation is accurate for x near zero, but becomes poor for large values of x. Meanwhile, there are other cubic polynomials which follow e^x with good accuracy over the entire interval. The Holy Grail of polynomial approximation is to find the polynomial that minimizes the maximum deviation of the polynomial from

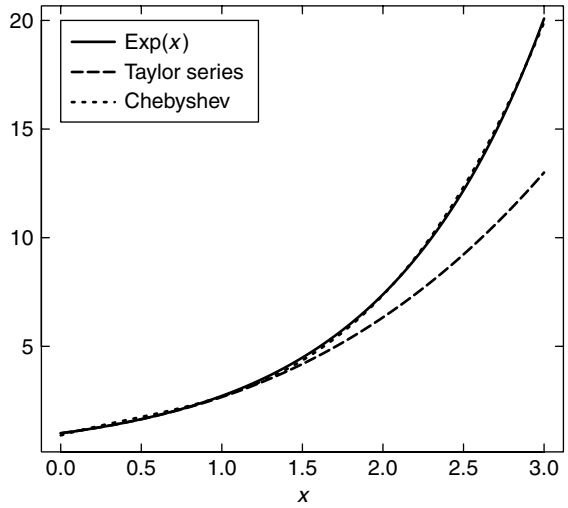

Figure 1 The cubic Taylor series approximation to $\exp(x)$ is accurate only near zero. The cubic Chebyshev polynomial approximation is indistinguishable from the function itself

the function over the entire interval, the so-called *minimax* polynomial.

Orthogonal Polynomials

The general polynomial $p(x)$ above was written in terms of the *monomials* x^j. This is known as the *natural form* of the polynomial. The trouble with the natural form is that the monomials all look very similar when plotted on [0, 1]; that is, they are very highly correlated. This means that small changes in $p(x)$ may arise from relatively large changes in the coefficients $c_0, \ldots, c_n$. The coefficients are not well determined when there is measurement or roundoff error.

The general polynomial can just as well be written in terms of any sequence of basic polynomials of increasing degree,

$$p(x) = a_0 p_0(x) + a_1 p_1(x) + \cdots + a_n p_n(x),$$

where the degree of $p_j(x)$ is j, for $j = 0, \ldots, n$. There is a linear relationship between the original coefficients c_j and the new coefficients a_j to make the resulting polynomial the same in each case.

The idea behind orthogonal polynomials is to select the basic polynomials $p_j(x)$ to be as different from each other as possible. Two polynomials p_i and p_j are said to be *orthogonal* if $p_i(X)$ and $p_j(X)$ are uncorrelated as X varies over some distribution. *Legendre polynomials* are uncorrelated when X is uniform on $(-1, 1)$. *Chebyshev polynomials* are uncorrelated when X is Beta(1/2,1/2) on $(-1, 1)$. *Laguerre polynomials* are uncorrelated when X is gamma on $(0,\infty)$. *Hermite polynomials* are uncorrelated when X is standard normal on $(-\infty, \infty)$.

Any sequence of orthogonal polynomials can be calculated recursively using a three-term recurrence formula. For example, the Chebyshev polynomials satisfy

$$\begin{aligned} p_0(x) &= 1, \\ p_1(x) &= x, \\ p_2(x) &= 2x^2 - 1, \\ &\cdots \\ p_{n+1}(x) &= 2x p_n(x) - p_{n-1}(x), \quad n \geq 1. \end{aligned}$$

Another important property of orthogonal polynomials is that $p_n(x)$ changes sign (and has a zero) n times in the interval of interest. The zeros of the nth order Chebyshev polynomial occur at

$$x_k = \cos\left(\pi \frac{k - 0.5}{n}\right), \quad k = 1, \ldots, n.$$

The Chebyshev polynomials also have the property of bounded variation. The local maxima and minima of Chebyshev polynomials on $[-1, 1]$ are exactly equal to 1 and -1, respectively, regardless of the order of the polynomial. It is this property which makes them valuable for minimax approximation. In fact, an excellent approximation to the nth order minimax polynomial on an interval can be obtained by finding the polynomial that satisfies $p_n(x) = f(x)$ at the zeros of the $(n + 1)$th order Chebyshev polynomial. Figure 1 shows the use of a third- order Chebyshev polynomial to approximate the function e^x on the interval [0, 3]. The error is less than 0.18 over the whole interval.

As another example, consider the problem of approximating the tail probability of the normal probability distribution function, $1 - \Phi(x)$, for $x > 0$. Since the tail probability decreases rapidly as x increases, we consider the ratio of the tail probability to the normal density function $[1 - \Phi(x)]/\phi(x)$. Finally, we transform x to $y = (x - 1)/(x + 1)$, which takes values on $[-1, 1]$. The resulting function $f(y) = \{1 - \Phi[x(y)]\}/\phi[x(y)]$ looks nearly linear

and can be well approximated by a polynomial. The tenth-order polynomial which interpolates $f(y)$ on the Chebyshev points on $[-1, 1]$ approximates $f(y)$ to nine or more significant figures, and hence gives an approximation to $\Phi(x)$ that remains accurate to ten significant figures for very large values of x.

Polynomial Regression

Now we turn to the case in which the nonlinear function is observed with error. Suppose that we observe $(x_i, y_i), i = 1, \ldots, N$, where

$$y_i = f(x_i) + \varepsilon_i,$$

where f is some nonlinear function and the ε_i are uncorrelated with mean zero and constant variance.

Consider height as a function of age for 318 girls who were seen in a disease study [6] in East Boston in 1980 (Figure 2). Height might be described roughly by a straight line over a short range of ages – say, ages 5–10 – but over wider age ranges a more general function is needed. We initially fit a sixth-order polynomial,

$$y_i = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \beta_3 x_i^3 + \beta_4 x_i^4 + \beta_5 x_i^5 + \beta_6 x_i^6 + \varepsilon_i,$$

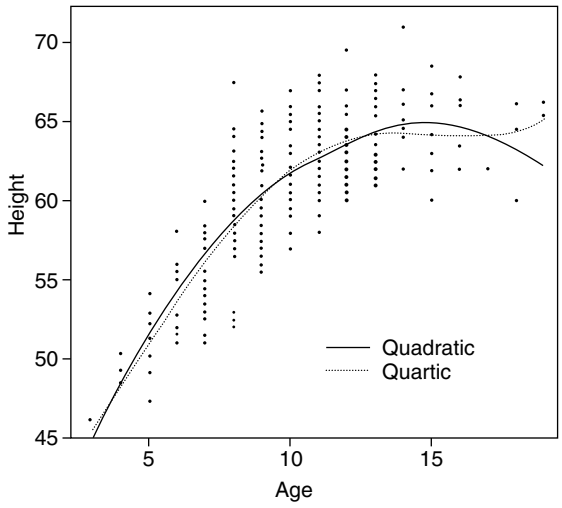

Figure 2 Height (in inches) vs. age (in years) for 318 girls who were seen in 1980 in the Childhood Respiratory Disease Study in East Boston, Massachusetts

with the intention of decreasing the order later if a simpler polynomial is found to fit just as well. This leads to a **multiple linear regression** problem for the coefficients $\beta_0, \ldots, \beta_6$, in which the design matrix is

$$\mathbf{X} = \begin{pmatrix} 1 & x_1 & x_1^2 & \ldots & x_1^6 \\ 1 & x_2 & x_2^2 & \ldots & x_2^6 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & x_{318} & x_{318}^2 & \ldots & x_{318}^6 \end{pmatrix}.$$

The columns of this matrix are very nearly **collinear**, which will make the least squares problem ill-conditioned. Nevertheless, we can obtain results from a statistical package: the regression overall is highly significant, with an F statistic of 135.7 on 6 and 311 df. However, the table of coefficients and standard errors offers little guidance as to what order of polynomial is required (Table 1). None of the regression coefficients are significantly different from zero, a reflection of the high correlations between the coefficients (Table 2). We could determine the smallest adequate order for the polynomial by fitting, in turn, a fifth-order polynomial, a fourth-order, a third-order, and so on. At each step we could test for the neglected monomial term using an adjusted F statistic. A more satisfactory solution, however, is to use orthogonal polynomials.

Table 1 Coefficients and standard errors for polynomial regression of height on age for the respiratory disease study

Coefficient	Value	se	t value	P value
β_0	80.2384	32.9342	2.4363	0.0154
β_1	−26.9075	23.0292	−1.1684	0.2435
β_2	7.8563	6.3456	1.2381	0.2166
β_3	−1.0296	0.8856	−1.1627	0.2459
β_4	0.0712	0.0663	1.0737	0.2838
β_5	−0.0025	0.0025	−1.0020	0.3171
β_6	0.0000	0.0000	0.9503	0.3427

Table 2 Correlation matrix for the polynomial regression coefficients

	β_0	β_1	β_2	β_3	β_4	β_5
β_1	−0.9935					
β_2	0.9774	−0.9950				
β_3	−0.9558	0.9824	−0.9960			
β_4	0.9313	−0.9650	0.9860	−0.9969		
β_5	−0.9058	0.9451	−0.9721	0.9888	−0.9975	
β_6	0.8805	−0.9241	0.9559	−0.9776	0.9910	−0.9980

Many statistical programs allow one to compute a sequence of polynomials which are orthogonal with respect to the observed values of x; that is, which satisfy

$$\sum_{k=1}^{N} p_i(x_k)p_j(x_k) = 0, \quad i \neq j.$$

(The function ORPOL is part of PROC MATRIX or PROC IML in SAS. In **S-PLUS** or R, the function is `poly` (*see* **Software, Biostatistical**).) It is also convenient to choose the polynomials so that

$$\sum_{k=1}^{N} p_i(x_k)^2 = 1, \quad i = 0, 1, \ldots, N-1.$$

In terms of these polynomials, the multiple regression model becomes

$$y_i = \alpha_0 p_0(x_i) + \alpha_1 p_1(x_i) + \cdots + \alpha_6 p_6(x_i) + \varepsilon_i,$$

where again there is a linear relationship between the coefficients α_j of the orthogonal polynomials and the original β_j. This model has the same fitted values, sums of squares, and F ratio as the original model. However, because of orthogonality, the least squares estimates of the α_j are uncorrelated and have identical standard errors, which greatly simplifies interpretation. In fact, each estimated coefficient $\hat{\alpha_j}$ is unchanged by the actual order of the polynomial which has been fitted.

The estimated coefficients and standard errors for the orthogonal polynomial regression are given in Table 3. In this case, the **Student's *t* statistics** and ***P* values** for the coefficients directly relate to the significance of cubic, quartic, and so on, components of the regression. We can see that the fifth- and sixth-order terms are not required, but that the third- and fourth-order terms are approaching significance. A plot of the quadratic and quartic fitted values against age (Figure 2) shows that the quartic fit might be preferred, because the quadratic is not monotonic in the observed range.

Table 3 Coefficients and standard errors for orthogonal polynomial regression of height on age for the respiratory disease study

Coefficient	Value	se	t value	P value
α_0	60.2119	0.1426	422.1543	0.0000
α_1	65.0285	2.5435	25.5669	0.0000

GORDON K. SMYTH

Polynomial Regression

It has been known for over a century [12] that a polynomial may be found which will approximate an arbitrary continuous function on a finite interval as closely as may be desired. This, one presumes, is the mathematical motivation for the introduction of polynomials into data analysis, which appears to have occurred in the early twentieth century (e.g. [3]).

At least in the initial stages of analysis, statistical models are often defined to be linear both in the parameters and in the covariates. In the simple situation of a single continuous covariate, X, the predicted value of the outcome variable in such a model is $\beta_0 + \beta_1 X$. The parameters β_0 and β_1 are estimated from the data, usually by **maximum likelihood**. If a technique such as analysis of **residuals** suggests that a straight line is a poor fit, one may wish to extend the model to accommodate nonlinearity in the relation between the outcome and X. One way is to fit a polynomial $\beta_0 + \beta_1 X + \beta_2 X^2 + \ldots$. This polynomial regression model, though no longer linear in X, is still linear in the parameters and therefore may be estimated by standard **multiple linear regression** techniques. Such models can be used for normal errors regression, but also for the **generalized linear model** (such as **logistic regression**) and Cox proportional hazards regression (*see* **Cox Regression Model**).

Polynomial regression has two main uses. The first is as a method of representing curved regression relationships in observational data and in designed experiments. The approach has been described by many writers, for example [11]. The second is essentially as a diagnostic for curvature (*see* **Diagnostics**). This is popular in the analysis of epidemiological data, where one may fit multiple regression models which involve a risk factor, X, of central interest together with several **confounding** variables. A hypothesis test for including a quadratic term (i.e. in X^2) in the model serves as a crude overall test of curvature.

Although polynomials in more than one variable (see Definitions, below) are known, they appear to be scarcely, if at all, used in biostatistical applications.

Definitions

A univariate polynomial of degree k in a scalar variable X is defined as

$$\sum_{i=0}^{k} \beta_i X^i,$$

where $X^0 \equiv 1$. A model may, of course, contain univariate polynomials in several covariates. A bivariate polynomial of degree k in a vector $\mathbf{X} = (X_1, X_2)'$ is defined as

$$\sum_{0 \le i+j \le k} \beta_{ij} X_1^i X_2^j,$$

with extension in similar fashion to higher dimensions (numbers of components in $\mathbf{X}$). The βs are parameters that need to be estimated from the data.

Advantages of Polynomials

As model functions, polynomials have several advantages. They are simple and familiar functions that are easily described and reported in nonstatistical journals. Fitting is easy using standard regression software, available in all statistical packages (*see* **Software, Biostatistical**). The resulting curves are independent of the origin and scale chosen for X, and at least for low-order polynomials ($k \le 2$) are very smooth. Derivatives of any order of the fitted curves with respect to X are easily calculated and are also smooth. Since the models are fully parametric, the standard array of tools for statistical inference – hypothesis tests of parameters, confidence intervals, and so on – is available.

Drawbacks

Unfortunately, polynomials also suffer from severe disadvantages. The low-order models are quite inflexible in the range of curve shapes they offer, whereas the higher-order ones often display artefacts such as "end effects" and "wiggliness". The Runge phenomenon [9] is an extreme manifestation of the latter (see Examples). Polynomials cannot have asymptotes as X tends to infinity, so they are unsuitable models for such relationships. Certain types of nonlinear model (*see* **Nonlinear Regression**) are almost invariably preferable. To avoid inaccuracies in parameter

estimates due to the high correlations between the powers of X in the model, special techniques such as centering or orthogonalization are needed (*see* **Orthogonality**). It is sometimes difficult to know whether a feature of the fitted polynomial (such as a peak or a nadir) is real or not. This matters in certain applications where the shape of the unknown true function is of central importance. An example is the so-called J-shaped risk relationship in epidemiology [4]. Polynomials are nonrobust in that a small number of values can considerably affect the parameter estimates and hence the entire curve shape.

Related Techniques

Royston & Altman [8] have described "fractional polynomials" which include noninteger and fractional powers of X, and have illustrated their uses with several biostatistical examples. Fractional polynomials are much more flexible than conventional polynomials and share most of their advantages. Other approaches are variants of **nonparametric regression**, and include the scatterplot smoother [1], the **spline function** ([5, 10]) and the **generalized additive model** (GAM) [7]. Although the statistical literature on nonparametric regression modeling is large and growing, alternatives to polynomials such as GAMs and fractional polynomials do not seem to be much used by authors of medical and epidemiologic papers. The situation may change as software becomes more widely available.

Examples

We shall illustrate some features of polynomial regression using two data sets. The first comprises observations on 478 patients rescued by the helicopter ambulance service of the Royal London Hospital [2]. Each patient received an injury severity score (X) between 1 and 76 at the rescue location (1 being least severe), and either died ($Y = 0$) or recovered ($Y = 1$) following subsequent hospital treatment. We attempt to predict the probability of recovery as a function of the severity score. Figure 1 shows the results of fitting several logistic regression models to the data.

The continuous line, a quadratic polynomial, shows a biologically implausible rise in the probability of recovery when $X > 60$. A cubic model (short dashes) is a significantly better fit ($P = 0.02$) but is showing some "waviness" near $X = 55$. A fractional polynomial of degree 1 (long dashes) has

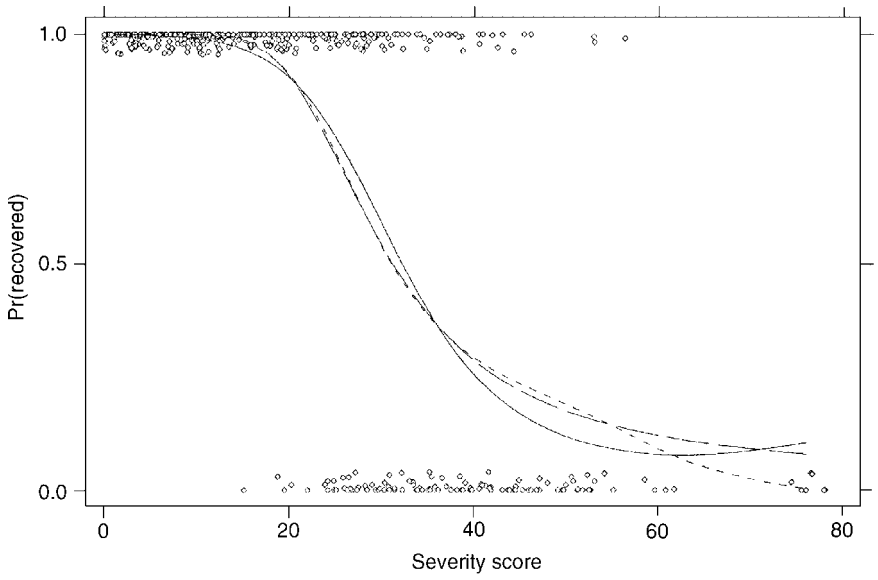

Figure 1 Fitted curves for three logistic regression models for recovery following rescue by helicopter ($n = 478$): quadratic (———); cubic ( ); fractional polynomial of degree 1 (– – –). The original binary observations (◊) are "jittered" randomly to separate the points

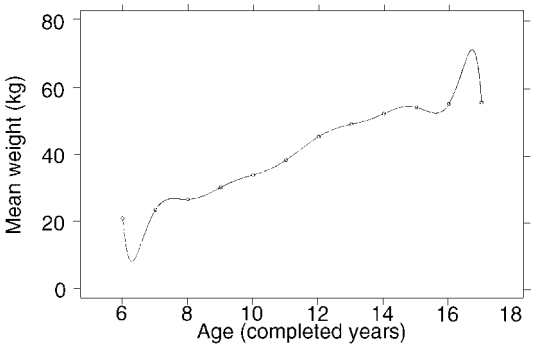

Figure 2 Mean girls' weight plotted against age group ($n = 12$), together with fitted eleventh order polynomial exhibiting the Runge phenomenon

a log **likelihood** only 0.6 lower than the cubic, but has a smoother and more convincing curve shape than either of the polynomial models. The fractional polynomial function found here is $\beta_0 + \beta_1 X^{-1/2}$, which has an asymptote of β_0 as X tends to infinity.

We use a second data set to illustrate the Runge phenomenon. Figure 2 is a plot of the mean bodyweights of several thousand US girls according to completed years of age between 6 and 17 years [6].

There are 12 pairs of observations. The continuous line shows the behavior of an eleventh order polynomial fitted to the data. The fitted line passes exactly through every observation, but between observations it oscillates wildly (the Runge phenomenon), particularly near the extreme ages. It is therefore quite useless for estimating the mean weight at intermediate ages.

The example is artificial in that an interpolating polynomial has been used, something one would be unlikely to do in practice since the "model" is clearly overfitted. However, the same thing can happen in realistic situations and its presence may escape the notice of the analyst. For example, connecting the fitted values with straight line segments between observations, as is often done automatically by statistical software, may conceal the oscillations in the true fitted curve.

PATRICK ROYSTON

Polytomous Data

In many studies the response of interest is restricted to a fixed set of possible values, the so-called response categories. Response variables of this type are called *polytomous*, or, less frequently, *polychotomous*. Examples are side effects of medical treatment with the possible categories headache, insomnia, or nausea, or several types of infection that may follow an operation. Most rating scales have fixed response categories that measure, for example, the medical condition after some treatment in categories such as good, fair, or poor, or the severity of symptoms in categories such as none, mild, moderate, or marked.

These examples show immediately that there are at least two cases to be distinguished, namely the case in which response categories are mere labels which have no inherent ordering and the case in which categories are ordered. In the first case the response Y is measured on a nominal scale (*see* **Nominal Data**). Instead of using the numbers $1, \ldots, k$ for the response categories, any set of k numbers would do. In the latter case the response is measured on an ordinal scale, on which the ordering of the categories and the corresponding numbers may be interpreted, but not the distance or spacing between categories (*see* **Ordered Categorical Data**). Examples of nominal and ordinal response categories are given in Figures 1 and 2. In the nominal case the response categories are scattered over the plane in order to show that categories have no systematic ordering. In the ordinal case the response categories are given on a straight line, thus illustrating the ordering of the categories.

Another type of response category that contains more structure than the nominal case but is not

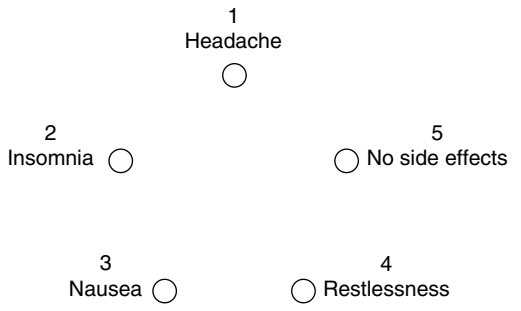

Figure 1 Side effects as example for nominal response categories where the numbers $1, \ldots, k$ are mere labels

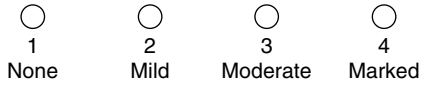

Figure 2 Severity of symptoms as ordered categories

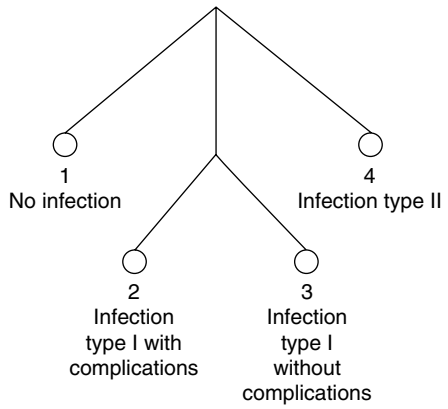

Figure 3 Type of infection as nested structure

captured by simple ordering is given by the nested or hierarchical response category. An example in which the basic response is in the categories "no infection", "infection type I," and "infection type II" is shown in Figure 3. However, for infection type I two cases have to be distinguished; namely, infection with and without additional complications. Thus, one has splits on two levels; first the split into basic categories and then the conditional split for the outcome "infection type I".

Nominal Response: The Multinomial Logit Model

Let $1, \ldots, k$ represent the response categories, i.e. $Y \in \{1, \ldots, k\}$, and let $\mathbf{x}' = (x_1, \ldots, x_p)$ be a vector of **explanatory variables** containing an intercept. The objective is to investigate the effect of the explanatory variables upon the probability of response categories $\pi_r(\mathbf{x}) = \Pr(Y = r|\mathbf{x}), r = 1, \ldots, k$. In the case of nominal response categories the most widespread model is the *multinomial logit model*, which assumes

$$\pi_r(\mathbf{x}) = \frac{\exp(\mathbf{x}'\boldsymbol{\beta}_r)}{\sum_{s=1}^{k} \exp(\mathbf{x}'\boldsymbol{\beta}_s)}, \quad r = 1, \ldots, k, \qquad (1)$$

with the parameter vectors $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_k$ being specific for the response categories. The simple structure of the model becomes obvious if one considers two response categories r and s, for which one obtains the **odds**

$$\frac{\pi_r(\mathbf{x})}{\pi_s(\mathbf{x})} = \exp[\mathbf{x}'(\boldsymbol{\beta}_r - \boldsymbol{\beta}_s)] \tag{2}$$

or, equivalently, the log odds

$$\log \frac{\pi_r(\mathbf{x})}{\pi_s(\mathbf{x})} = \mathbf{x}'(\boldsymbol{\beta}_r - \boldsymbol{\beta}_s). \tag{3}$$

Thus, by (2), the odds that the response is in category r instead of category s are specified by an exponential term depending on the difference of parameters $\boldsymbol{\beta}_r - \boldsymbol{\beta}_s$, whereas the log odds or logits depend linearly on the explanatory vector $\mathbf{x}$, with weights determined by the difference $\boldsymbol{\beta}_r - \boldsymbol{\beta}_s$.

Parameter interpretation may be illustrated by the example from Figure 1 with dichotomous covariates such as treatment ($\mathbf{x}_\mathrm{T}$; one, new; zero, conventional) and a continuous covariate such as age centered at 30 years ($\mathbf{x}_\mathrm{A}$). Then one has, for example, for the response categories 2 (insomnia) and 5 (no side effect)

$$\begin{aligned}\frac{\Pr(\text{insomnia})}{\Pr(\text{no side effects})} &= \frac{\pi_2(\mathbf{x})}{\pi_5(\mathbf{x})} \\ &= \exp(\beta_{02} - \beta_{05}) \\ &\quad \times \exp(\beta_{\mathrm{T}2} - \beta_{\mathrm{T}5})^{x_\mathrm{T}} \\ &\quad \times \exp(\beta_{\mathrm{A}2} - \beta_{\mathrm{A}5})^{x_\mathrm{A}}.\end{aligned}$$

That means that $\exp(\beta_{02} - \beta_{05})$ gives the baseline odds that insomnia occurs instead of no side effects, $\exp(\beta_{\mathrm{T}2} - \beta_{\mathrm{T}5})$ is the factor by which these odds increase or decrease for the new treatment, and $\exp(\beta_{\mathrm{A}2} - \beta_{\mathrm{A}5})$ gives the multiplicative increase or decrease per year of age.

Since in the model given in (1) it is only possible to investigate the effect of $\mathbf{x}$ upon the preference of response categories over the alternatives, not all of the parameter vectors $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_k$ are identifiable. It is common to choose a reference category, for example k, and take $\boldsymbol{\beta}_k = \mathbf{0}$. Then the model reduces to

$$\pi_r(\mathbf{x}) = \frac{\exp(\mathbf{x}'\boldsymbol{\beta}_r)}{1 + \sum_{s=1}^{k-1} \exp(\mathbf{x}'\boldsymbol{\beta}_s)}, \quad r = 1, \ldots, k-1,$$

and

$$\pi_k(\mathbf{x}) = \frac{1}{1 + \sum_{s=1}^{k-1} \exp(\mathbf{x}'\boldsymbol{\beta}_s)}.$$

Although (1) seems to imply strong assumptions about the relation between explanatory variables and the response variable, this is not generally true. In particular, for categorical explanatory variables the model may just represent a reparameterization of the conditional response categories; that is, it is a saturated model.

For simplicity, let us consider the case of two dichotomous explanatory variables, such as gender and treatment. With x_G being a dummy variable for gender (1, male; 0, female) and x_T coding treatment (1, new treatment; 0, conventional), consider the logit model

$$\begin{aligned}l_r(\mathbf{x}) &= \log \frac{\pi_r(\mathbf{x})}{\pi_k(\mathbf{x})} \\ &= \beta_{0r} + x_\mathrm{G}\beta_{\mathrm{G},r} + x_\mathrm{T}\beta_{\mathrm{T},r} + x_\mathrm{G}x_\mathrm{T}\beta_{\mathrm{G}\times\mathrm{T},r}, \\ r &= 1, \ldots, k-1.\end{aligned} \tag{4}$$

The model includes the explanatory variables x_G and x_T and their product $x_\mathrm{G}x_\mathrm{T}$, the latter representing the **interaction** between gender and treatment. For each category $r = 1, \ldots, k-1$, there are four parameters $\beta_{0r}, \beta_{\mathrm{G},r}, \beta_{\mathrm{T},r}$, and $\beta_{\mathrm{G}\times\mathrm{T},r}$ yielding a total of $4(k-1)$ parameters. However, for each of the four combinations of gender and treatment there are $k-1$ probabilities $\pi_r(x_\mathrm{G}, x_\mathrm{T}) = \Pr(Y = r|x_\mathrm{G}, x_\mathrm{T}), r = 1, \ldots, k-1$. The last one is determined by $\sum_r \Pr(Y = r|\mathbf{x}) = 1$. Consequently, the model contains as many parameters as probabilities, and any set of probabilities can be represented in the form given in (4). This may be explicitly shown by solving the system of equations resulting for different combinations of gender and treatment.

Generally, for categorical covariates any set of response probabilities $\pi_1(x), \ldots, \pi_k(x)$ may be represented by the multinomial logit model if interaction terms are included into the linear term. For three dichotomous variables for example, one has to include x_1, x_2, and x_3 and all of the interactions x_1x_2, x_1x_3, x_2x_3, and $x_1x_2x_3$. Parameter interpretation may again be based on the form given in (2), or directly on the logit form given in (3) or (4). The intercept $\beta_{0r} = \log[\pi_r(0, 0)/\pi_k(0, 0)]$ gives the odds of category r in comparison with the reference category k

if $x_G = 0$ and $x_T = 0$. The effect of x_G, given by

$$\beta_{G,r} = l_r(1,0) - l_r(0,0) = \log\left\{\frac{[\pi_r(1,0)/\pi_k(1,0)]}{[\pi_r(0,0)/\pi_k(0,0)]}\right\},$$

represents the difference between the logit for $x_G = 1$ and the logit for $x_G = 0$ (holding $x_T = 0$ constant). It may also be seen as the logarithm of the **odds ratio** between the corresponding odds. The interaction effect, given by

$$\beta_{G\times T,r} = l_r(1,1) - l_r(-,1) - l_r(1,0) + l_r(0,0) = \frac{\left[\dfrac{\pi_r(1,1)}{\pi_k(1,1)} \Big/ \dfrac{\pi_r(0,1)}{\pi_k(0,1)}\right]}{\left[\dfrac{\pi_r(1,0)}{\pi_k(1,0)} \Big/ \dfrac{\pi_r(0,0)}{\pi_k(0,0)}\right]},$$

represents the ratio between two odds ratios, reflecting the transition from $x_G = 0$ to $x_G = 1$ for $x_T = 1$ in the nominator and for $x_T = 0$ in the denominator.

If the interaction vanishes – that is, $\beta_{G\times T} = 0$ – the two explanatory variables determine the response separately. A model of this type is strongly related to **loglinear models**, or to graphical models that investigate forms of conditional independence (*see* **Antidependence Models**). Suppose that Y, x_G, and x_T are any three categorical random variables. If x_G and x_T are conditionally independent given Y (which corresponds to a special loglinear model), then the interaction terms between x_G and x_T may be omitted in the multinomial logit model, meaning that the response is determined by regressors x_G and x_T separately. For more than two explanatory variables, there is a larger variety of interaction terms that may be omitted. The resulting models correspond to loglinear models of varying complexity, and therefore various structures of conditional independence are possible. Loglinear as well as graphical models are considered extensively in [7]; for graphical models, see also [26].

In the linear term $\mathbf{x}'\boldsymbol{\beta}$, various types of variables may be included. If a covariate is dichotomous it may be used directly in (0–1)-coding, whereas if it is polytomous one has to use several **dummy variables**. Continuous scaled covariates may enter the linear term by using x, but also in polynomial form including x^2, x^3, etc. Moreover, interactions such as in the simple example above may be used. The essential restriction is the linear form $\mathbf{x}'\boldsymbol{\beta}$, which does not mean linear in the covariates but only linear in the parameters. Of course, if continuous variables are included, or only part of the interaction terms are used, model adequacy should be checked (see later section).

Ordinal Response

The multinomial logit model is based on the logits $l_r(\mathbf{x}) = \log[\pi_r(\mathbf{x})/\pi_k(\mathbf{x})]$, where k is the reference category. By assuming $l_r(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}_r$, each logit $l_r(\mathbf{x})$ has its own category specific parameter $\boldsymbol{\beta}_r$. Consequently, a permutation of the response categories does not change the validity of the model. This is also easily seen from the form given in (1), where it is obvious that no ordering of response categories is used.

Cumulative Logits

If the categories are ordered, simpler models that assume more structure will be more appropriate. By using the ordering of categories, one may consider the cumulative logits

$$l_r^c(x) = \log[\Pr(Y \le r|\mathbf{x})/\Pr(Y > r|\mathbf{x})] = \log\left\{\frac{[\pi_1(\mathbf{x}) + \cdots + \pi_r(\mathbf{x})]}{[1 - \pi_1(\mathbf{x}) - \cdots - \pi_r(\mathbf{x})]}\right\}.$$

These cumulative logits represent the logarithm of the odds that the response is below or in category r instead of being above category r. By cumulating over responses $1, \ldots, r$, the ordering is explicitly used. A simple model that is based on cumulative logits is the proportional-odds or cumulative logit model

$$l_r^c(x) = \log\left[\frac{\Pr(Y \le r|\mathbf{x})}{\Pr(Y > r|\mathbf{x})}\right] = \beta_{0r} + \mathbf{x}'\boldsymbol{\beta}, \quad r = 1, \ldots, k-1, \tag{5}$$

where the intercept is now separated; in other words, in $\mathbf{x}' = (x_1, \ldots, x_p)$, only the covariates or explanatory variables are collected. The advantage of the model given in (5) is that by using the ordering the number of parameters is strongly reduced. One has intercepts $\beta_{01}, \ldots, \beta_{0,k-1}$ and only one weight parameter $\boldsymbol{\beta}$ instead of $k-1$ weight parameters

$\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_{k-1}$ as in the multinomial logit model. Thus, the model given in (5) is simpler with respect to parameter economy. The additional structure assumed in (5) becomes obvious by consideration of the cumulative logits for two covariate values $\mathbf{x}_1$ and $\mathbf{x}_2$. One obtains

$$l_r^c(\mathbf{x}_1) - l_r^c(\mathbf{x}_2) = \log \frac{\Pr(Y \le r|\mathbf{x}_1)/\Pr(Y > r|\mathbf{x}_1)}{\Pr(Y \le r|\mathbf{x}_2)/\Pr(Y > r|\mathbf{x}_2)} = (\mathbf{x}_1 - \mathbf{x}_2)'\boldsymbol{\beta},$$

meaning that the ratios of cumulative odds with different covariate values do not depend on the category but only on the difference $\mathbf{x}_1 - \mathbf{x}_2$. This property describes a form of strict stochastic ordering [16]. One has either $l_r^c(\mathbf{x}_1) > l_r^c(\mathbf{x}_2)$ for all r or $l_r^c(\mathbf{x}_1) < l_r^c(\mathbf{x}_2)$ for all r. That means that the total response is shifted toward lower or higher response categories by the transition from subpopulation x_1 to subpopulation x_2.

This shifting is also supported if the model is motivated by an underlying continuous response. In some cases the categorical variable Y may be considered as a coarser version of a latent variable $\tilde{Y}$. For example, the severeness of a headache may subjectively have a continuous scale but a response in categories such as none, mild, or moderate, which are determined by the investigator. One assumes that the observable variable Y and the latent variable $\tilde{Y}$ are linked by

$$Y = r_3, \quad \text{if } \theta_{r-1} \le \tilde{Y} < \theta_r, \tag{6}$$

with threshold values $-\infty = \theta_0 < \theta_1 < \cdots < \theta_k = \infty$. Thus the observable response is in category r if the continuous underlying response is in interval $[\theta_{r-1}, \theta_r)$. If the continuous latent variable is given by $\tilde{Y} = -\mathbf{x}'\boldsymbol{\beta} + \varepsilon$, with an error variable that follows the logistic distribution function $F(x) = \exp(x)/[1 + \exp(x)]$, one immediately obtains the cumulative logit model given in (5), with $\beta_{0r} = \theta_r$, $r = 1, \ldots, k-1$. The response mechanism in (6), together with $\tilde{Y} = -\mathbf{x}'\boldsymbol{\beta} + \varepsilon$, shows that transition from population $\mathbf{x}_1$ to population $\mathbf{x}_2$ means a changing of the expectation from $\mathrm{E}\tilde{Y} = -\mathbf{x}_1\boldsymbol{\beta}$ to $\mathrm{E}\tilde{Y} = -\mathbf{x}_2\boldsymbol{\beta}$, and therefore a shifting on the latent scale resulting either in lower or higher response categories.

By assuming an alternative but fixed distribution function F for the noise variable x, one obtains from (6) the more general model

$$\Pr(Y \le r|\mathbf{x}) = F(\beta_{0r} + \mathbf{x}'\boldsymbol{\beta}).$$

Models of this type reduce the number of parameters by exploiting the ordinal response. This advantage is often crucial, since the response in categories contains less information than a continuous response, as is usually assumed in classic linear *regression* models. For further information and applications of cumulative models, see [5, 6, 14, 16], and [22].

Continuation-ratio or Sequential Logits

In many applications the ordering of the response categories is due to a sequential mechanism. If the response is, for example, tonsil size with categories "not enlarged", "enlarged", and "greatly enlarged" [12], then starting from the normal state "not enlarged" (category 1) one may reach "enlarged" (category 3) only if the intermediate state has previously been reached, whatever the duration in this state is. Similar responses are found in discrete duration data. If the time until recovery is measured in months, it will take at least 10 months only if the recovery process has lasted at least through 9 months previously.

Appropriate modeling of categories that are reached only successively may be based on conditional models that model explicitly the process of transition. Let us consider the continuation-ratio or sequential logits

$$l_r^s(\mathbf{x}) = \log[\Pr(Y = r|\mathbf{x})/\Pr(Y \ge r|\mathbf{x})],$$

where the underlying odds determine that the response is in category r instead of a category above or in r. These odds may be rewritten in the form

$$\frac{\Pr(Y = r|\mathbf{x})}{\Pr(Y \ge r|\mathbf{x})} = \Pr(Y = r|Y \ge r, \mathbf{x}),$$

therefore specifying the conditional probability of a response in category r given category r is reached.

The corresponding *continuation-ratio* logit model or *sequential logit* model has the form

$$l_r^s(x) = \log\left[\frac{\Pr(Y = r|\mathbf{x})}{\Pr(Y \ge r|\mathbf{x})}\right] = \mathbf{x}'\boldsymbol{\beta}_r. \tag{7}$$

The model may be seen as consecutive dichotomous steps. Starting in category 1, the first step, namely the potential transition to category 2, is determined by a dichotomous logit model with parameter $\boldsymbol{\beta}_1$. Given that category 2 is reached, the next step –

potential transition to category 3 – is determined by a dichotomous logit model with parameter $\boldsymbol{\beta}_2$. More generally, the rth step is determined by a dichotomous logit model with parameter β_r. Consequently, the parameters have to be interpreted in the same way as for dichotomous logit models, but with reference to the specific step modeled. For the tonsil size example, the model given in (7) means that one is explicitly investigating the effects of covariates upon the transition from enlarged tonsils to greatly enlarged tonsils, given one has at least enlarged tonsils. Actually, any dichotomous model may be used in the consecutive steps. The general sequential model is given by

$$\Pr(Y = r|Y \geq r, \mathbf{x}) = F(\mathbf{x}'\boldsymbol{\beta}_r),$$

with a fixed response function F and the parameter vector possibly depending on r.

An alternative way of interpreting the consecutive steps is within the context of survival analysis. If the response categories correspond to failure in discrete time (in weeks or months), the conditional odds

$$\frac{\Pr(Y = r|x)}{\Pr(Y \geq r|x)}$$

may also be interpreted as a *discrete hazard function* (*see* **Discrete Survival-time Models**), the conditional odds representing the hazard of failure at discrete time point t (corresponding to a time interval). For discrete duration models and the connection to sequential models, see [8, 10, 21], and [23]. Sequential models for ordinal data have been considered in [9, 17], and [25].

Nested or Hierarchical Responses

Let us consider the infection example given in Figure 3. The essential point is that, for response data of the nested type, some hierarchy has to be taken into account. At the first level one has the response into categories "no infection" (category 1), "infection type I" (categories 2 and 3), and "infection type II" (category 4). At the second level, infection type I is split into categories 2 and 3. Of course, one may fit the multinomial logit model for categories 1–4. Then, however, the information that categories 2 and 3 are more similar than the other categories is not used. This becomes even more important if the split into subcategories with and without complications occurs later in time than the primary first level split.

In this case an appropriate hierarchical model is a two-step model. The first level may be modeled by a trichotomous multinomial model with reference category 1, given by

$$\log \frac{\Pr(Y \in \{2, 3\}|\mathbf{x})}{\Pr(Y = 1|\mathbf{x})} = \mathbf{x}'\boldsymbol{\beta}_1^{(1)},$$
$$\log \frac{\Pr(Y = 4|\mathbf{x})}{\Pr(Y = 1|\mathbf{x})} = \mathbf{x}'\boldsymbol{\beta}_2^{(1)}.$$

The conditional split on the second level may be modeled by dichotomous logits

$$\log \frac{\Pr(Y = 3|Y \in \{2, 3\}, \mathbf{x})}{\Pr(Y = 2|Y \in \{2, 3\}, \mathbf{x})} = \mathbf{x}'\boldsymbol{\beta}^{(2)}.$$

The principle is the conditional modeling of consecutive splits. This principle allows hierarchies with more than two levels. In a straightforward way, any category – for example, "infection type I with complications" – can be split up further. The additional structure could be modeled conditionally given the response group "infection type I with complications". Not only dichotomous splits are possible. If infection type I is split into five categories of different forms of complications on the second level, one would use a multinomial model. Consequently, on each level one may use a nominal or an ordinal model, corresponding to the type of response categories on the level.

McCullagh & Nelder [17] illustrate the approach of consecutive dichotomous splits by a study of mortality and fertility of lactating cows with consecutive trials of insemination leading or not leading to pregnancy. Further examples have been given in [3, 15, 18], and [24].

Further approaches to the modeling of ordinal data include "adjacent categories logits", where the logits between adjacent categories of the ordinal scale are considered [1, Chapter 6], and the stereotype model [4], where the ordering results from the modeling.

Estimation, Testing, and Goodness of Fit

The data usually are given as pairs $(Y_i, \mathbf{x}_i)$, $i = 1, \ldots, n$, of the response variable Y_i and the covariate vectors $\mathbf{x}_i$. The estimation of the models is most often based on the **maximum likelihood** principle.

The kernel of the multinomial log likelihood has the form

$$l = \sum_{i=1}^{n} \sum_{r=1}^{k-1} y_{ir} \log[\pi_r(\mathbf{x}_i)] + (1 - y_{i1} - \cdots - y_{i,k-1}) \times \log[1 - \pi_1(\mathbf{x}_i) - \cdots - \pi_{k-1}(\mathbf{x}_i)], \quad (8)$$

where the probabilities are given by $\pi_r(\mathbf{x}_i) = \Pr(Y_i = r|\mathbf{x}_i)$ and y_{ir}, $r = 1, \ldots, k-1$, are dummy variables coding the response by $y_{ir} = 1$ if $Y_i = r$ and $y_{ir} = 0$ otherwise. When maximizing (8) the response probabilities have to be replaced by their parametric form. The models considered here are special cases of a (multivariate) **generalized linear model** for multinomial response. That means that some (known) *transformation* of the response probabilities depends linearly on the covariates, as in the models given in (3), (4), and (5). Generalized linear models provide a unified framework in which parameters can be estimated, and the influence of specific variables can be tested. For details, see [2, 11], and [17].

Of particular interest is the **goodness of fit** of models, which may be assessed by considering the difference between the data and the fitted values. If the explanatory variables are categorical, only a limited number of patterns (say g) for the vector $\mathbf{x}$ is possible. Then one may consider grouped data $(\mathbf{p}_i, \mathbf{x}_i)$, $i = 1, \ldots, g$, where $\mathbf{p}_i' = (p_{ir}, \ldots, p_{ik})$ is the vector of relative frequencies computed from the n_i observations taken at pattern $\mathbf{x}_i$. The goodness of fit of the models may be checked by the Pearson statistic

$$\chi^2 = \sum_{i=1}^{g} n_i \sum_{j=1}^{k} \frac{(p_{ir} - \hat{\pi}_{ir})}{\hat{\pi}_{ir}}$$

(*see* **Chi-square Tests**), or the deviance

$$D = 2 \sum_{i=1}^{g} n_i \sum_{r=1}^{k} p_{ir} \log\left(\frac{p_{ir}}{\hat{\pi}_{ir}}\right),$$

where $\hat{\pi}_{ir}$ denotes the maximum likelihood estimate of $\pi_{ir} = \Pr(Y_i = r|x_i)$ (*see* **Likelihood Ratio Tests**). If $n_i \to \infty$ for fixed g (n_i/n converges to $\lambda_i \in (0, 1)$), then both statistics are asymptotically χ^2 distributed with $g(k-1) - p$ degrees of freedom, where p is the length of the parameter vector $\boldsymbol{\beta}$. When applying χ^2 or D, one has to keep in mind that this fixed cell type of asymptotics assumes that the local number of observations n_i must not be too low (*see* **Likelihood Ratio Tests**). The distribution of χ^2 and D is quite different for sparse data ($n \to \infty, g \to \infty$) (see [19] and [20]). If the covariates are continuous then the number of patterns is the same as the number of groups. In this case χ^2 and D will fail as goodness-of-fit measures. Hosmer & Lemeshow [13] give a modification for this case, based on grouping within intervals.

GERHARD TUTZ

Popper, Karl R.

Born: July 28, 1902, in Vienna, Austria.
Died: September 17, 1994, in London, UK.

In his *Autobiography* (see [13] or *Unended Quest* [7]), Popper recalls being upset, as a child, by the sight of hunger and poverty in the streets of Vienna. His father was a lawyer and a "radical liberal", his mother was a musician. At the University of Vienna after World War I he studied a variety of subjects from physics, mathematics, and history of music to education, psychology, and philosophy, while earning his living mostly from schoolteaching. The encounter with Marxism, and to a lesser extent with psychoanalysis, made him conscious that he valued free critical thinking over dogmatic theories. After listening with awe to a lecture by Einstein he was reinforced in the conviction that what makes conjectures scientific is that they are open to refutation by experience.

Although not a member of the *Wiener Kreis*, he interacted with members of the Circle. He resisted their idea that philosophical questions are reducible to questions of language. His first manuscript, critical of the doctrines of the Circle, boldly attempted to solve "the two fundamental problems in the theory of knowledge" (the problems of induction and of demarcation) [1]. The manuscript was read and discussed by Feigl, Carnap, Schlick, and Frank, among others. His next work, entitled *Logik der Forschung* (1934), first published in a series edited by Frank & Schlick, would (so Popper thought) defeat the theses of logical positivism, through showing that there is no such thing as "inductive logic" ("induction is a myth"), and that the criterion of demarcation between science and pseudo-science is that scientific propositions are refutable (falsifiable), while pseudo-scientific ones are irrefutable (unfalsifiable) [2]. Valid reasoning is deductive, science is hypothetico-deductive, refutation is a case of *modus tollens*. Scientific theories are neither verifiable nor probable; they are hypothetical. The book was a great success. Popper was invited to lecture abroad. In Prague he met Tarski, whose theory of truth was to influence decisively his own philosophical realism. In England he met with Ayer and Russell, as well as with German-speaking refugees such as Schrödinger and Hayek. On account of the rise of Nazism in Austria, he then accepted a teaching position in the University of New Zealand at Canterbury. And that is how, in 1937, he became a philosophy professor.

"The *Poverty* and the *Open Society* were my war effort": they were an attack on totalitarianism, and a plea for a free society in which people "send their theories to die in their stead"; that is, expose their ideas to criticism and exchange arguments rather than blows [3, 4]. Both texts were published after World War II, thanks to Hayek, who also gave their author the opportunity to return to Europe and teach in London. Popper became a professor in logic and scientific method at the London School of Economics and stayed there for the rest of his career (1945–1969). In spite of a somewhat eccentric marginality he became a celebrity on the British philosophical scene, and was knighted in 1965.

Conjectures and Refutations (1963) expands on the thesis, already present in *Logik der Forschung*, that truth is not manifest, searching for truth takes work, cognitive delusions abound, and scientific theories are mere conjectures, the truth of which can never be conclusively established [5]. Scientific theories, however, have a degree of testability, and as a theory passes more severe tests, it gets more highly "corroborated" (which does not mean confirmed, but so far not disconfirmed). *Objective Knowledge* (1972), a collection of essays, marks a turn towards an evolutionary epistemology [6]. Essay 3 on "epistemology without a knowing subject" presents the reader with the stimulating (and realist) view that scientific problems, theories, and arguments develop within a "third world", largely autonomous with respect to the first (world of physical objects) and second (world of mental states); and that the objective traits of the growth of knowledge (world 3) are of far greater interest to epistemology than the subjective thoughts of scientists (world 2). Essay 6 "on clouds and clocks" generalizes Popper's epistemic theory (of learning through a trial and error-elimination process), via a neo-Darwinist scheme, to a metaphysical theory (of evolution through random variation and natural selection within an "open", i.e. indeterministic, universe). This is rehearsed in a clear and simple style by *A World of Propensities* [12]. *The Self and its Brain* (1977) is a fascinating dialogue between a philosopher (P) and a brain scientist (E) on the mind–body interaction [8].

While tackling a great variety of new subjects, Popper never ceased to work on his initial work,

translated into English in 1959 under the title *The Logic of Scientific Discovery* [2], revised many times, and completed by a huge *Postscript* from which three new volumes have been extracted (see [9, 10], and [11]). The reader of the *Encyclopedia of Biostatistics* will be most interested by *Realism and the Aim of Science* (1982), in which Popper re-examines in detail the problems of truth, corroboration, and **probability**. He maintains that inductive reasoning, that is [9], concluding validly from empirical observations to general regularities, is an illusion. There are neither "inductive sciences", as Mill or Whewell thought, nor a "logic" of induction, as Carnap tried to build, nor a "statistical" or "probabilistic" induction, as statisticians like **R. A. Fisher** tried to sketch. According to Popper, scientific hypotheses do not arise from experience, but are an expression of our freedom to conjecture; they do not have to be plausible, they have to be testable. He is an adept of a selective or Darwinian theory of learning (as opposed to an instructive or Lamarckian theory). We do not learn from the facts, we learn "from our mistakes" (from conjecturing and being refuted).

Popper's views on inductive **inference** gave rise to hot controversies. Inductivists objected that while Popper emphasizes the negative aspect of scientific methods (how to detect and reject errors), he does not take account of the positive aspect (how to make judicious hypotheses). The choice of a theory is guided by experience. Rationally favoring some hypothesis implies careful sampling of data, and estimation of the degree of inductive support the hypothesis gets from known data. Thus, statistical or probabilistic induction does exist and is in use. Deductivists maintained that empirical facts cannot model our ideas, and they produced more "proofs" of the impossibility of induction. Even if mutual concessions and rephrasing have now brought inductivists and deductivists somewhat closer to each other, inductivism still emerges as the winner of the contest; inductivists outnumber deductivists. But, as inductive methods remain hard to "justify", Popper's critical examination of the topic of induction remains an interesting challenge.

Population Genetics

Population genetics, as the name implies, is concerned with the analysis of factors affecting the genetic composition of a population. It is thus centrally concerned with evolutionary questions through the change in the genetic composition of a population over time as directed by natural selection, mutation, migration, and other factors, with questions associated with genetic diseases in human populations, and finally with plant and animal breeding programs, in which an attempt is made to change the genetic constitution of a population by artificial methods. To the extent that this genetic composition is in part random and can be described in quantitative terms, population genetics is a subject of prime interest to biometricians. Here we focus on biometrical aspects of evolutionary population genetics, although we will note the importance of several aspects of the evolutionary theory on human genetics and on plant and animal breeding programs.

Early Population Genetics Theory

It is a well-known curiosity that Darwin published his theory of evolution by natural selection many years before the (Mendelian) hereditary mechanism (*see* **Mendel's Laws**) was firmly established. One matter in particular troubled him: under the blending theory of heredity current during his time, which assumed that the characteristics of any offspring are a blend of the corresponding characteristics of the two parents, the variation upon which his theory of evolution by natural selection depended would soon be dissipated unless some strong variation-creating agency could be established causing offspring not to resemble their parents. Such an agency, however, would make inoperative another central component of the Darwinian theory, namely the resemblance between parents and offspring.

It was one of the early triumphs of population genetics theory, stressed repeatedly by **Fisher**, that the Mendelian hereditary system resolved this difficulty at a stroke. The main early result responsible for reaching this important breakthrough was the well-known **Hardy–Weinberg equilibrium** law. This law implies, for two alleles (or **gene** types) A_1 and A_2 at some gene locus "A", with no selection, mutation, or any other disturbing force, and if random changes in frequencies arising from **stochastic processes** in finite populations can be ignored, that if the **genotype** frequencies in any generation take the arbitrary values X (for A_1A_1), $2Y$ (for A_1A_2), and Z (for A_2A_2), then following one generation of random mating these frequencies will be of the form x^2, $2x(1-x)$ and $(1-x)^2$, where $x = X + Y$, and that under random mating these frequencies will be maintained in all future generations. This result follows essentially from the "quantal" nature of the gene.

Unfortunately this law is too often taught to students for the wrong reason: the **binomial** form of genotype frequencies which are derived under this law is certainly interesting and convenient, but what is crucial is not this but the unchanging nature of genotype frequencies, as indicated by the law, if no disturbing forces such as selection and mutation exist. The only significant area where the law does not come to grips with an important question concerns the fact that it does not handle the stochastic changes in gene frequencies implied by the finite nature of every population. This stochastic behavior is a matter we return to again later.

The quantal nature of the Mendelian scheme ensures that the natural tendency of a Mendelian population is to maintain genetic variation. Of course this variation will tend to be lost by the very process of replacing an "inferior" allele by a "superior" one, but this is an entirely different matter from a natural tendency of a hereditary system itself to destroy variation. It is thus a crucial concern to quantify the concept of variation in a Mendelian population, not only among genotypic frequencies but, more important to biometricians, among those measurable characteristics whose variation is preserved through the preservation of genetic variation.

The Correlation Between Relatives

In the early years of the century, biometricians noted various regular forms for the **correlation** of certain metrical traits such as height between various types of relatives. It was one of the early triumphs of population genetics theory, attributable to Fisher [3], to show that the form of these correlations could be accounted for by Mendelian considerations. Suppose, in the simplest case, that all individuals of genotypes A_1A_1 have measurement m_{11} for this character, all

individuals of genotype A_1A_2 have measurement m_{12}, and all individuals of genotype A_2A_2 have measurement m_{22}. Then it is easy to compute the mean $\overline{m}$ and the variance σ^2 of the measurement as

$$\overline{m} = m_{11}x^2 + 2m_{12}x(1-x) + m_{22}(1-x)^2$$

and

$$\sigma^2 = m_{11}^2x^2 + 2m_{12}^2x(1-x) + m_{22}^2(1-x)^2 - \overline{m}^2.$$

Further, since there is a one-to-one correspondence between measurement value and genotype, it is straightforward to write down all possible combinations for this measurement between any pair of relatives (mother–daughter, brother–brother, etc.), together with their probabilities, using as a key part of the argument the Mendelian rules for the transmission of genes from parent to offspring. From this it is straightforward to find the covariance, and thus also the correlation, between the two relatives for the measurement in question. When this is done, a remarkable series of formulas arises [3]. We find that all such correlations are of the form

$$\text{corr} = \frac{(\alpha\sigma_A^2 + \beta\sigma_D^2)}{\sigma^2},$$

where α and β are simple constants such as 0, 1/2, 1/4 (and more generally of the form $(1/2)^k$, for some integer k), and σ_A^2 and σ_D^2 are defined by

$$\sigma_A^2 = 2x(1-x)[xm_{11} + (1-2x)m_{12} - (1-x)m_{22}]^2$$

and

$$\sigma_D^2 = x^2(1-x)^2(m_{11} - 2m_{12} + m_{22})^2.$$

It is a matter of simple algebra to show that $\sigma^2 = \sigma_A^2 + \sigma_D^2$, so that the total variance in the measurement has been subdivided into two components which enter differently into the correlation between various forms of relatives. We see here the beginnings of the concept of the **analysis of variance**, to flower so greatly in Fisher's hands in the 1920s, and first appearing in the biometrical context of the correlation between relatives (*see* **Familial Correlations**).

The Additive and the Dominance Variances

The two components σ_A^2 and σ_D^2 have interpretations well beyond being simply components of the total variance in the measurement. Our later main focus is on σ_A^2, but we first briefly discuss σ_D^2. Clearly this component is always zero if $m_{12} = 1/2(m_{11} + m_{22})$, that is if the measurement for the heterozygote A_1A_2 is the average for that of the two homozygotes A_1A_1 and A_2A_2. When this occurs we say that there is no dominance in the measurement, and the component σ_D^2 of the total variance is nonzero only if dominance does exist. Thus σ_D^2 is called the dominance variance, and this explains the suffix in the notation.

We have just noted the occurrence of the so-called "additive genetic variance" σ_A^2 in the formulas for the correlation between various relatives. This variance is, however, of even greater value, and its significance is more clearly demonstrated, when we consider evolutionary aspects of a genetic population. To see this, suppose that the three genotypes A_1A_1, A_1A_2, and A_2A_2 have (viability) fitnesses w_{11}, w_{12}, and w_{22}, respectively, and that no other form of fitness differential (for example, fertility differentials) exists. Then the frequency x of the allele A_1 will, in general, change from generation to generation, and it is straightforward to find the formula for the change Δx in the frequency of A_1 from one generation to the next. If we define the mean fitness $\overline{w}$ as a special case of a mean measurement by the formula

$$\overline{w} = w_{11}x^2 + 2w_{12}x(1-x) + w_{22}(1-x)^2,$$

then it is also straightforward to find the change $\Delta\overline{w}$ in $\overline{w}$ from one generation to the next, and from this we find that, to a close approximation,

$$\Delta\overline{w} = \sigma_A^2.$$

The statement embodied by this formula, that the increase in mean fitness is approximately equal to the additive genetic variance, has been called Fisher's [4] "Fundamental Theorem of Natural Selection". More precisely, this statement is the "conventional wisdom" version of the Fundamental Theorem. It is, however, uncertain that this result was what Fisher claimed to have achieved, and for an alternative interpretation of Fisher's theorem, see [2].

Whatever the correct interpretation of the theorem might be, it quantifies in genetical terms the main tenet of the Darwinian theory, that for evolution by natural selection to occur, leading in some sense to an "improvement" in the population, measured here by an increase in mean fitness, there must be variation

in the population, here variation in fitnesses of the three genotypes.

However, the theorem shows that not all the variation in fitness is relevant to evolution, since only the additive part of the variance is involved in the above formula. To understand why this is so, we must first investigate more closely the interpretation of the additive genetic variance σ_A^2. The key points to note are, first, that at any given locus an individual passes on a gene to an offspring, not the two genes comprising his/her genotype at this locus, and second that evolution concerns the changes in gene frequency. It is thus necessary to define the concept of a "gene fitness" to understand the differential transmission of genes from parent to offspring as brought about by natural selection and the consequent change in mean fitness. (More correctly we should define an "allele fitness", and use "allele frequency" rather than "gene frequency" above, but we follow here the standard, albeit incorrect, usage.) We define "gene fitnesses" by noting that an A_1 gene combines with another A_1 gene, with probability x, to form an individual of fitness w_{11}, and with an A_2 gene, with probability $1-x$, to form an individual of fitness w_{12}. We thus ascribe a fitness $w_{11}x + w_{12}(1-x)$ to the gene A_1, and similarly we ascribe a fitness $w_{12}x + w_{22}(1-x)$ to the gene A_2. Since a randomly chosen gene is A_1 with probability x and A_2 with probability $1-x$, we can define a mean and a variance of gene fitness by using the probability distribution shown in Table 1.

The mean gene fitness is easily found, from this distribution, to be identical with the mean genotype fitness $\overline{w}$ given above, but the variance in gene fitness is found to be different from the variance in genotype fitness, being $x(1-x)[xw_{11} + (1-2x)w_{22}]^2$. Recalling that at any locus each individual has two genes in the genotype, we define the variance in the fitness of any individual due to the genes in his/her genotype to be twice this value, or (with the general measurement replaced by fitness), by the additive genetic variance in fitness.

If the additive genetic variance comprises all the variance in fitness, then the dominance variance is zero. This occurs, as noted above, if and only if the fitness of the heterozygote A_1A_2 is the average of the fitnesses of the two homozygotes. This in turn occurs if and only if genotype fitnesses are completely determined, in an additive way, by genes within genotypes. In this case it is not surprising that all the variance in genotype fitness, being determined solely by genes, is available for evolution.

Table 1

Gene (allele)	A_1	A_2
Gene fitness	$w_{11}x + w_{12}(1-x)$	$w_{12}x + w_{22}(1-x)$
Probability	x	$1-x$

If the additive genetic variance is zero, then either one or the other gene is absent from the population (a case we ignore from now on as trivial), or the two genes are equally "fit" (as determined by the definition of gene fitness just described). As a result there will be no change in gene frequencies through natural selection and the population is at an (internal) equilibrium point. This observation explains the occurrence of constant genetic variation in a population: if all the variance in fitness is dominance variance, then the population remains static in its genetic composition.

The above considerations also have considerable significance for artificial selection. The (narrow) **heritability** for any character is defined as the ratio of the additive genetic variance in a character to the total variance, and if this is zero, the two genes A_1 and A_2 have equal values for this character and no increase in the mean value of the character is possible through a change in gene frequencies.

All of the above shows that the concepts developed in early and elementary population genetics theory form the basis and origin of many general procedures in biostatistics. In particular, the concepts of subdividing a total variance into meaningful components, of seeking the relevance of each component, and of showing that various important quantities can be written in terms of these components, all find their origins in the simple arguments developed above.

Further Developments of Population Genetics Theory

The population genetics theory sketched above needs to be extended in many directions. For example, there may well be more than two alleles at the locus in question. The genes at different loci often interact (epistasis; *see* **Genotype**) in defining some character. Ecological considerations, such as geographical dispersal and the interactions of two or more species and their consequent mutually interactive genetic evolution, need to be examined. The stochastic effects which are inevitable in small populations are of

potential importance. While these extensions to the theory are the subject of much present-day population genetics, here we focus the discussion on only two of these extensions, namely multilocus theory and the (single locus) stochastic theory.

If (as is indeed the case) most genetic characteristics, and in particular those undergoing selection, are determined by the genes at many loci, then a proper analysis of genetic evolution must involve all such genes. The appropriate vehicle for doing this turns out to be the gamete, that is (in effect) a set of single chromosomes carrying the genes at various loci on them. Evolution then concerns changes in gametic frequencies. A description of gametic evolution is extremely complex and here we focus on the particular case where only two loci, A and B, are of interest, and where also each of these loci allows only two allelic types, namely A_1 and A_2 at the A locus and B_1 and B_2 at the B locus. We thus consider the evolution of the frequencies of the four gametes A_1B_1, A_1B_2, A_2B_1, and A_2B_2, which we denote by y_1, y_2, y_3, and y_4, respectively.

This evolution is particularly simple if knowledge of the gene at the A locus on any chromosome confers no information about the gene present at the B locus on the chromosome. It is not difficult to see that this occurs if and only if the equation $y_1y_4 = y_2y_3$ holds. However, this will not necessarily be the case and, when selection exists at the two loci, the so-called "coefficient of **linkage disequilibrium** D (more appropriately called the coefficient of association), defined by

$$D = y_1y_4 - y_2y_3,$$

will often not be zero.

This fact has several implications for biostatistics, of which we mention two here and one later when discussing human genetics. First, if all two-locus coefficients of association are zero, the overall additive genetic variance of the entire genome is simply the sum of the constituent single-locus additive genetic variance values. If these coefficients are not zero, then there is no simple relation between the overall additive genetic variance and the single-locus values. In the 1950s, when the concept of the analysis of variance was used systematically in population genetics, an attempt was made to subdivide the overall genome-wide additive genetic variance for some character into meaningful components, in particular components associated with single loci. Since the total variance does not usually divide into the sum of single locus components, this venture essentially failed. Secondly, when some character depends on the genes at many loci, the correlations between various relatives for that character are far more complex that those given by the single-locus formula above. Some simplification and indeed some explicit expressions for these correlations are possible when all possible two-locus coefficients of association are zero but in general, when these coefficients are nonzero, the correlations are hopelessly complicated, containing upwards of 100 terms even for a character determined by two loci. Thus the hope of a biostatistical investigation of realistic correlations, at least when coefficients of association are nonzero, seems to be doomed.

A classical calculation concerning D is the following. If there is no selection at either locus, no mutation or indeed any other directed force, and (most important) if the population consists of one large randomly mating group, then the value of D decreases geometrically each generation. More specifically, if D is the value of the coefficient of association in one generation and D' the value in the following generation, and if the recombination fraction between the two loci is θ, then

$$D' = (1 - \theta)D.$$

Thus, after t generations, $D^{(t)} = (1 - \theta)^t D^{(0)}$, so that, unless the two loci are closely linked, the value of D should rapidly decrease to zero. The inference that the occurrence of association between two loci implies that they are closely linked is made often in population and in **human genetics**. We discuss this inference further below.

It was very early recognized in population genetics theory that stochastic effects need to be considered for a complete picture of evolution to be attempted, since in a finite population one cannot avoid the chance events that lead to unequal transmissions of genes from parent to offspring. This inequality occurs for two reasons: first, a **heterozygous** parent A_1A_2 might, by chance alone, transmit the A_1 gene more (or less) frequently to his/her offspring than the A_2 gene, thus causing a (random, nonselected) change in the frequencies of A_1 and A_2 in the daughter generation. Secondly, by chance alone, individuals of the same genotype might transmit different numbers of genes to the following generation: as an extreme example, if one of a pair of identical twins is accidentally killed

in early life while the other survives to reproduce, their contributions to the next generation differ even though the two twins have identical genotype and hence identical fitness.

The fact that stochastic changes in gene frequency will arise was recognized very early on, and Fisher [4] and Wright [11] devised stochastic models allowing for these changes. The model at the center of their (similar but independent) work is now called the Wright–Fisher model. This is a Markov chain and represents perhaps the first major use of **Markov chains** in science (although it appears that neither Fisher nor Wright ever used the term "Markov chain"). The model is as follows. The **random variable** of interest is the number of A_1 genes in the population. The possible values of this number are $0, 1, \ldots, 2N$, where N is the population size. It is assumed in the model that if, in any generation, there are i such genes, then the number in the following generation has a binomial distribution with parameter $i/2N$ and index $2N$.

Clearly the states $i = 0$ and $i = 2N$ are absorbing, so interest focuses on the probability that a given absorbing state is entered and, from the point of view of the preservation of genetic variation, on the mean time until one or other absorbing state is entered. This then concerns a qualitatively different outcome from that in infinitely large populations, where the amount of genetic variation remains fixed. The rate at which this variation is lost can be assessed in two ways. First, one can find the leading nonunit **eigenvalue** of the matrix of transition probabilities of the Markov chain. For the Wright–Fisher model, this is easily seen to be $1 - 1/(2N)$. This suggests that, in populations of large size, genetic variation tends to be lost, on average, very slowly. This was the approach of Fisher and Wright. Secondly, a more direct assessment can be made by calculating the mean time until the population consists entirely of A_1, or entirely of A_2, genes, given some initial frequencies of A_1 and A_2. Unfortunately, this mean time cannot in practice be calculated exactly in the Wright–Fisher model. However, both Fisher and Wright were able to approximate the behavior of a population following the Wright–Fisher model by a diffusion process, for which these mean times are easily calculated. These show that the mean time until one or other gene is lost from the population is proportional to the population size. This is thus large in a large population, and this agrees with the conclusion reached as a result of the eigenvalue calculation. It is also possible to show that these mean times differ only trivially from the (unknown) values in the Wright–Fisher model. It is interesting that both Fisher and Wright used (again without knowing it) forward Kolmogorov equation methods to establish the results they needed, and never became aware of the far simpler and more appropriate methods available through use of the Kolmogorov backward equation.

Many extensions and variations to the Markov chain model have appeared in the population genetics literature over the past 40 years. The number of alleles can be arbitrary, selection can exist, and more realism has been introduced by noting that the population includes both males and females, has a geographical structure, can change in size over time, and so on. Similarly, very extensive generalizations to the diffusion process used by Fisher and Wright have been made, again incorporating more realistic features such as those described for the Markov chain model (*see* **Brownian Motion and Diffusion Processes**).

Fisher, Wright, and Haldane [5] also developed theory for, and used, **branching processes** to discuss the probability of survival of a new mutant gene. Once again, the introduction and first significant applications of what would now be viewed as standard equipment in any biometrician's toolkit was carried out in the early research in population genetics theory.

Retrospective Theory

The analyses of Markov chains, diffusion processes and branching processes by Fisher, Wright, and Haldane, and the generations of population geneticists following them (in particular Kimura [7]), are part of the *prospective* theory of population genetics: given certain selective values, mutation rates, population sizes, and so on, statements were made about the likely evolution forward in time of a population under the Mendelian hereditary mechanism. This sort of analysis was indeed needed in order to show that, contrary to the views held even in many scientific circles early in the century, the Darwinian paradigm provided a valid and workable theory for evolution. Two factors have, however, changed the broad direction of population genetics theory in recent years. First, for all practical purposes and for all reasonable

people, the Darwinian theory is indeed validated, so that there is no longer any need for further validating arguments. Secondly, the nature of the genetic material is now known. Early population genetics theory in effect conceptualized different alleles (i.e. different types of genes) as differently colored billiard balls, with the A_1 allele corresponding, say, to a red billiard ball, an A_2 allele to a blue ball, and so on. No information was available about the interior constitution of the billiard balls, and the coloring allocation (i.e. the labeling as A_1, A_2, and so on) was entirely arbitrary. All that was important was the discrete "quantal" nature of the color of the billiard ball (red, blue, etc., but never a mixture), and, apart from rare mutations, the faithful transmission by a parent of the color, unmixed with any other color, to the genetic make-up of his/her offspring.

The knowledge of the structure of genes as **DNA sequences** has completely altered population genetics, since now the description of a gene is no longer simply an arbitrary label (such as A_1 or A_2) but the actual DNA material of which the gene is made. In other words, real rather than arbitrary descriptions for genes are now available. This has led, among other things, to a blossoming of the *retrospective* theory of population genetics, in which a sample of genes is taken, their DNA examined, and the questions asked relate to the way in which, through evolution, the population arrived at its presently observed state. The broad form of population genetics theory needed to answer such questions is clearly closely allied to statistics, in that data deriving from both a stochastic process and also a sampling procedure are available and an inference deriving from those data is wanted.

Retrospective questions have entered the popular imagination: When did "Eve" live? Where did she live? What do we even mean by "Eve"? What inferences can we draw, given DNA information from a number of present-day species, about the tree of evolution leading to these species? These questions can be answered only by assuming various stochastic process population genetic models, none of which can be claimed to describe with close fidelity the actual path that evolution happens to have taken. Unfortunately, the estimates and inferences drawn are often sensitive to the assumptions made in those models, and this has led to much acrimony on the answers to the kind of question raised above.

To population geneticists, perhaps the most interesting and controversial question in retrospective population genetics concerns the so-called neutral theory [8]. This theory claims that a very large proportion of the DNA variation that we see within populations, and also much of the DNA difference that we observe between species, was not directed by natural selection but arose through purely random stochastic effects. The analysis of this theory thus requires as a starting point information concerning the properties of the Wright–Fisher and other stochastic prospective evolutionary models when no selection acts, followed by a further analysis of what properties we might expect to see in samples of genes if the theory is true. Substantial work in population genetics theory, which is in effect no more than a statistical analysis of present-day data testing certain evolutionary hypotheses, has been carried out to assess the acceptability of this theory.

An important vehicle for essentially all retrospective intrapopulation genetic inferences is the *coalescent process* of Kingman [9]. Given a sample of n genes, the coalescent traces their ancestry back in time. At some point two genes will have a common ancestor and a coalescence may be said to have occurred. Eventually all n genes will have a common ancestor and the final coalescence will have occurred. The properties of this coalescent process often provide, by moving forward in time, the simplest way of deriving the probability distributions needed for inferences from those data. An extended discussion of this process, focusing on biological questions, is given in [6], and extended mathematical and statistical aspects are discussed in [1] and [10].

Human Genetics

Several aspects of human genetics research, which focuses largely on the elucidation of the genetic basis of diseases, have parallels with, or even derive directly from, evolutionary population genetics theory.

First, there is a clear parallel with parts of the retrospective theory of population genetics and human genetics. In both cases we start with a sample of genes and attempt to make some inference from them. This is particularly true of questions concerning the population genetics concept of allelic association: if we see an association between a disease

and a marker locus (*see* **Disease-marker Association**), then one is tempted to infer that the disease and the marker loci are closely linked. This argument is supported by the fact, noted above, that in a randomly mating population the degree of allelic association decreases geometrically fast over succeeding generations. However, the assumption that the population from which the sample of genes is drawn is mating at random is crucial for this conclusion, and in practice, for human populations, this assumption is far from the truth. Simple geographical considerations imply nonrandom mating, as do the existence of racial groups. Thus if a certain disease is prevalent in some country and a certain unlinked marker gene is also prevalent there and if a sample of individuals is taken in the USA in which a significant proportion of individuals has recent ancestry from that country, then an association between the disease and the marker gene will be observed. However, this association has nothing to do with linkage between disease and marker loci. Approaches to this problem, using both population genetics theory focusing on geographical features and human genetics theory in which this form of association is separated from association due to *linkage*, have both been undertaken. This is but one example of the interwining of human genetics, one of the central areas of biometrical research, and evolutionary population genetics during the next decade will lead to an increasing linkage between evolutionary and human population genetics, and hence to an increasing use of biometrical methods in both areas.

Population Growth Models

Forecasting the growth of human populations has, for at least two centuries, been a problem that has taxed many scholars. The methods proposed have included mathematical models, sometimes including the search for an elusive "law" of human population growth; statistical forecasts; and component projections. These methods have addressed geographical areas ranging in size from local areas with very small populations to the entire world. This article summarizes the major features of each of the three types of method and highlights the purposes to which they are put.

The first person to propose a *mathematical growth model* was probably **Thomas Malthus**. In his 1798 essay he observed that "Population, when unchecked increases in a geometrical ratio" (Malthus, [16]). This can be expressed by geometric or exponential growth models:

$$P_t = P_0(1 + r)^t.$$

or

$$P_t = P_0 \mathrm{e}^{r\ t},$$

where P_0 is population at time 0, P_t is population at time t, r is the rate of growth, and t is time.

These models are still widely used and often are reasonably accurate for relatively small t. However, in the long term it is clear that populations cannot grow exponentially. This was observed first by **Quetelet** [24] who, inspired by Newton's law of viscosity, outlined a theory by which, as populations grow, they are restricted in size by increasing density. This idea was developed by Verhulst [27], who concluded that growth was a function of size and that an S-shaped curve was appropriate. He termed this the "logistic" curve (*see* **Logistic Distribution**). Much later, **Pearl** & Reed [18] made the logistic curve popular for the long-term prediction of population growth, Pearl attempting to provide empirical evidence for the mathematics through the famous fruit fly experiments. This model can be expressed as

$$P_t = \frac{a}{1 + \exp(-abt)},$$

where a and b are estimated coefficients and it can be shown that a represents the upper asymptote, t is time, and P_t is the population at time t.

The logistic model was very popular in the 1930s when slowing rates of population growth were common in most countries where reliable population data were collected. After World War II the model was not used a great deal because it was shown to be very inaccurate in a number of empirical situations. For example, Yule [28] predicted a population of England and Wales in 1971 of 58–59 million compared with the actual figure of 49 million. Brass [5] notes that the major problem was that "resource based" constraints on population growth had not continued to slow in the 1950s. However, improved techniques to estimate the model and changing demographic patterns may mean that, for short-term forecasts, the logistic model may be a possibility in the early part of the twenty-first century.

The mathematics of these simple models was developed by Sharpe & Lotka [25] who described a simple one-sex deterministic population model (one-sex because Sharpe & Lotka [25] calculate the population of men and simply assume that there are enough women to maintain population growth). Pollard [20] provides an excellent review of this model and sensibly develops it in terms of women. Using this model, Keyfitz [9] developed a formula to calculate population momentum. Although the model has not been widely used in recent years, the observations by Bongaarts & Amin [3] that population momentum will be an increasingly important factor in the growth of populations in less developed countries mean that it may gain a new prominence.

In the immediate post World War II period the development of **stochastic processes** for applications such as particle physics or telephone exchange problems led to the possibility of developing simple stochastic models for the growth of human populations. The development of these models was reviewed by Kendall [8] and more recently by Alho [1].

They typically start with a simple set of equations to determine both births and deaths and base these on a **Poisson process**. Kendall [8] was able, in addition, to include migration. These models have not been widely used despite a number of attempts to generalize them [7, 19] to take account of the dynamics between the sexes [7, 20]. The lack of success of these latter attempts stems largely from the

necessity to assume that one sex is dominant. This means that if the sex ratio diverges greatly from unity, then one sex will soon become extinct. In addition, to be mathematically tractable, the two-sex model has been dependent on the linear model. It is possible that improved numerical methods will permit a nonlinear exposition, but it seems unlikely that they will ever be particularly popular for scholars working on human populations. Pollard [20] reviews the early work, and recently Pollard & Höhn [23] revisited the problem and provided a number of extensions. A comprehensive review is provided by Pollard [22].

The development of *statistical models* for **time series** and their popularity, particularly in econometrics, led to their use to forecast population growth. To forecast total population size, Lee [11, 12] was at the forefront of adapting econometric models, particularly those of Box & Jenkins [4] (*see* **ARMA and ARIMA Models**) to predict population growth. Thorough reviews are provided by Land [10], Lee & Tuljapurkar [13] and Alho [2]. The advantage of these models is, of course, that they were developed partly for **prediction** and so interval estimates of future population size are possible. However, their use has not been widespread probably because they suffer, as do most of the mathematical models, from the problem that population growth depends on the dynamics between births, deaths, and **migration**. Therefore, most commentators would agree that it is important that population growth models take this into account.

This need to control explicitly for fertility, mortality and migration has led to *component methods* of population projection being, without doubt, the most commonly used method to estimate future population size. Component methods are based on the following simple balancing equation:

$$P_t = P_0 + {}_tB_0 - {}_tD_0 + {}_tI_0 - {}_tE_0,$$

where P_t is population at time t, and P_0 is population at time 0, ${}_tB_0$ is births between times 0 and t, ${}_tD_0$ is deaths between times 0 and t, ${}_tI_0$ is immigrants between time 0 and t, and ${}_tE_0$ is emigrants between time 0 and t.

Starting with a base population, P_0, these models account separately for trends in each of the components of population growth to make a projection of future population size. In themselves, projections are just internally consistent forecasts dependent on a set of assumptions. Methodologists always caution that a range of projections should be used but, in practice, planners and policy makers usually believe one. The mathematics of component methods were developed by Leslie [14] and the *"Leslie" matrix* is the basis for most computational models of component projections. There are many computer packages to make component projections.

The key elements in any component projections are the models used to predict future mortality, fertility, and migration. To describe these fully is outside the scope of this article but it should be noted that there are a myriad of strategies ranging from the simple (and almost always false) assumption that the three components will remain constant to very sophisticated mathematical and statistical models of future trends. Mathematical models have been proposed by a number of authors, most notably Brass [5] who developed a relational model to predict future trends in fertility and mortality. Among many authors, Murphy [17] and Pollard [21] have developed models for mortality, and there are many time series models to predict fertility, although their success has varied. Migration has not been modeled well in most countries particularly at a subnational level.

A particularly notable set of forecasts for the world was provided by Lutz [15], and Alho [2] develops an excellent strategy to estimate the uncertainty in these forecasts. In general, component models of population growth are reasonable at a national level in the short term, but difficulties, particularly in modeling future fertility, mean there are many examples of extremely inaccurate forecasts in the medium to long term.

For small areas, typically populations below 20 000, component models of population growth are used sometimes. More common, though, are simple models based on expected numbers of persons per household or on **census** data updated by ancillary information from, say, an electoral roll. In addition, **regression** models have been used a little; for example, by Erickson [6]. These models can be reasonably accurate for estimating the total population size where there is little population change. However, Simpson et al. [26] show that when age-specific estimates are required such models provide inaccurate forecasts and there is little alternative to a local census.

In summary, there have been many attempts to model population growth. If the aim is to forecast future population, then in the short term there have been a number of successful models, but in the longer term population growth models have been

less successful. However, they have been very useful in understanding the dynamics of change in human populations.

Population-based Study

A population-based study is a study of properties of a well-defined population, such as individuals residing in a defined geographic region in a given time period. The size of such a population can be estimated, and, if all cases of a disease arising from such a population are identified, **rates** of disease can be calculated. Valid **sampling frames** can be constructed for estimating the **prevalence** of risk factors and other characteristics of such a population. **Population-based case–control studies** yield not only estimates of **relative risk** for given exposures but also estimates of exposure-specific **absolute risk**. The latter are obtained by combining information on the overall **risk** of disease in the population with information on the prevalences and relative risks of various exposure levels.

Postmarketing Surveillance of New Drugs and Assessment of Risk

The assessment of the safety of newly marketed drugs (either prescription or over-the-counter products) is recognized as a fundamental public health responsibility in every developed region of the world. Efforts are under way to harmonize international standards for surveillance and reporting of adverse drug events to regulatory bodies of the US, the European Union (EU), and Japan [3]. The goal of this article is to review the role, rationale, objectives, and design of quantitative methods of surveillance strategies developed for drug safety assessment over the past 30 years. We emphasize, with several examples, the quantitative methods that have been developed in response to regulatory requirements to monitor adverse drug event data for the purpose of assessing potential risk (*see* **Drug Approval and Regulation**; **Pharmacoepidemiology, Adverse and Beneficial Effects**).

The Role of a Monitoring System

Finney [6], in a seminal paper which focused on monitoring for adverse reactions to drugs used in medical practice and on the methods for detecting drug associated reactions, stated that "the primary duty of a drug monitoring system is less to demonstrate danger or to estimate incidence than to initiate suspicions". The role of a monitoring system is to initiate a "suspicion" and not to establish cause and effect relationships or to estimate risk. When "suspicion builds", it is the task of more formal experimental and epidemiologic studies to confirm the suspicion. Generally, quantitative surveillance methods will have a hypothesis generating goal.

Types of Monitoring Systems

Finney [7] described the major components of a "monitoring system" as consisting of the reporters, the patients, the drugs, and the events, stating that there were three ways by which drug–events were reported to a system: by patient, by drug, and by event. In a related paper, Finney [6] expanded the discussion of these three methods of ascertainment by showing how these different methods impacted the statistical methodologies used either to signal or to evaluate causality of a drug–event association (*see* **Causation**) or to assess the **risk** of a drug-related event.

Finney stressed the need to identify a "reference population" as the source of the data coming into the monitoring system and to understand the underlying assumptions related to the data being reported (e.g. that events are independent and are representative of some underlying population).

The pioneering study by Inman et al. [12], in their investigation of thromboembolic disease and the steroidal content of oral contraceptives, illustrates the application of these principles to a monitoring system. An example of event ascertainment by patient (i.e. population based drug monitoring) was initiated at the Kaiser-Permanente, Department of Medical Research, in the early 1970s [8]. A unique feature of this **population-based** approach was its ability to screen over 75 000 patients for potential drug–event **associations**. Any combination of a drug and an event recorded within the system could be investigated. Once a signal occurred, the evaluation of the association for causality could be explored using traditional epidemiologic approaches (e.g. strength of association, level of statistical significance to rule out chance, consistency of the finding, specificity of the event, time relationships, biologic plausibility, and gradients, etc. [9]; *see* **Hill's Criteria for Causality**). More recent examples of population-based monitoring include the Boston Collaborative Drug Surveillance Program, Group Health Cooperative of Puget Sound, various Medicaid databases, and the Saskatchewan database [20].

Perhaps the largest and most systematic drug–event monitoring systems are those set up by governmental regulatory bodies to monitor safety of new drugs once marketed (e.g. in the US and UK [3, 23]). In the US, postmarketing surveillance systems require that manufacturers collect and send to a central point reports for which there is a suspicion that a drug and an event are associated. What is not required in the US is that the suspicion be established as a causality [13].

The particular quantitative surveillance methods for comparing drug–event reporting rates depend on a variety of issues like the method of event

ascertainment, the choice of **control** groups, the specific design of the database, and the various sources of **bias** (underreporting, patient characteristics associated with differential drug prescribing, treatment patterns, and concomitant drug treatment). Therefore, as we intend to illustrate several surveillance methods developed to signal and to alert within the reporting system available in the US, we describe the system in the US in some detail.

The Drug–Event Monitoring System at the Food and Drug Administration (FDA)

The **Food and Drug Administration (FDA)** Center for Drug Evaluation and Research has had a drug–event-based monitoring system since the late 1960s. In the US, the manufacturer and holders of new drug applications (NDA)s are required to report those adverse drug experiences (ADEs) associated with their products which come to their attention. The specific reporting requirements are described in federal regulations [25]. It is worth noting that some specific requirements for reporting may be modified pending publication of final rules and the implementations of certain recommendations of the International Conference on Harmonization (ICH).

In general, the reporting requirements for manufacturers creates a **stratification** for the timing of when some reports are sent to and received by FDA. These requirements involve distinguishing between "serious and nonserious" adverse events and between labeled and unlabeled adverse drug events (ADEs), each term being defined in regulations. Serious unlabeled ADEs must be submitted by the reporter within 15 days of learning of the event, whereas nonserious ADEs are submitted periodically in less frequent intervals of time, like quarterly for the first 3 years post approval and then every 6 months thereafter. The underlying philosophy is to obtain reports from health practitioners as soon as possible to identify new adverse events associated with exposure to new drugs. Where it is possible, an additional goal is to characterize the unique patient features which make patients susceptible to the adverse event and then to change the drug label accordingly to inform patients and prescribers about how to minimize the occurrence of these events.

The basic instrument for collecting the information on possible drug–event associations is called the Medwatch form, which includes demographic information about the patient, a description of the reaction(s) that occurred, an outcome reflecting what happened to the patient, an identification of the suspected drug and concomitant drugs and other history (see Figure 1).

Figure 2 shows the number of reports of labeled and unlabeled and serious and nonserious ADEs received for all marketed drugs in the United States entered into a computer database at FDA over the past 25 years. From Figure 2, it can be seen that there has been a continuous increase in the number of drug-associated adverse events reported to FDA. The histogram gives the number of reports entered into FDAs computer file. Starting in 1984, FDA distinguished between a manufacturer's periodic (labeled) and 15-day (serious and unlabeled) reports, and direct voluntary reports to FDA from health care providers.

Some Applications of Quantitative Methods

In this Section we describe four different situations for which specific statistical methods have been applied to postmarketing surveillance of adverse drug reaction reports. In the first three applications, we assume a centralized report registry like that of the FDA and that reporters follow similar instructions on what to report, use a standardized report form, and report either voluntarily or in accordance with some national program of reporting.

We distinguish between three situations: (i) monitoring a change in the reporting pattern of a specific drug–event; (ii) monitoring the comparative reporting of a drug–event for several drugs in the same class; and (iii) monitoring the comparative reporting of drug–events reported from multiple sources. The focus in each situation is on identifying an increased frequency of ADEs.

Monitoring a Change in a Specific Drug–Event Reporting Pattern

FDAs guideline [3] describes an "arithmetic" and a "statistical" approach to signal generation. The arithmetic approach is deterministic and is not discussed further. The statistical approach is based on the concept of a reporting rate where the numerator consists

FDA Form 3500 (6/93)

Submission of a report does not constitute an admission that medical personnel or the product caused or contributed to the event.

Figure 1 Medwatch form

ADVICE ABOUT VOLUNTARY REPORTING

Report experiences with:

- medications (drugs or biologics)
- medical devices (including in-vitro diagnostics)
- special nutritional products (dietary supplements, medical foods, infant formulas)
- other products regulated by FDA

Report SERIOUS adverse events. An event is serious when the patient outcome is:

- death
- life-threatening (real risk of dying)
- hospitalization (initial or prolonged)
- disability (significant, persistent or permanent)
- congenital anomaly
- required intervention to prevent permanent impairment or damage

Report even if:

- you're not certain the product caused the event
- you don't have all the details

Report product problems – quality, performance or safety concerns such as:

- suspected contamination
- questionable stability
- defective components
- poor packaging or labeling

How to report:

- just fill in the sections that apply to your report
- use section C for all products except medical devices
- attach additional blank pages if needed
- use a separate form for each patient
- report either to FDA or the manufacturer (or both)

Important numbers:

- 1-800-FDA-0178 to FAX report
- 1-800-FDA-7737 to report by modem
- 1-800-FDA-1088 for more information or to report quality problems
- 1-800-822-7967 for a VAERS form for vaccines

If your report involves a serious adverse event with a device and it occurred in a facility outside a doctor's office, that facility may be legally required to report to FDA and/or the manufacturer. Please notify the person in that facility who would handle such reporting.

Confidentiality: The patient's identity is held in strict confidence by FDA and protected to the fullest extent of the law. The reporter's identity may be shared with the manufacturer unless requested otherwise. However, FDA will not disclose the reporter's identity in response to a request from the public, pursuant to the Freedom of Information Act.

The public reporting burden for this collection of information has been estimated to average 30 minutes per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send your comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing this burden to:

Figure 1 (*Continued*)

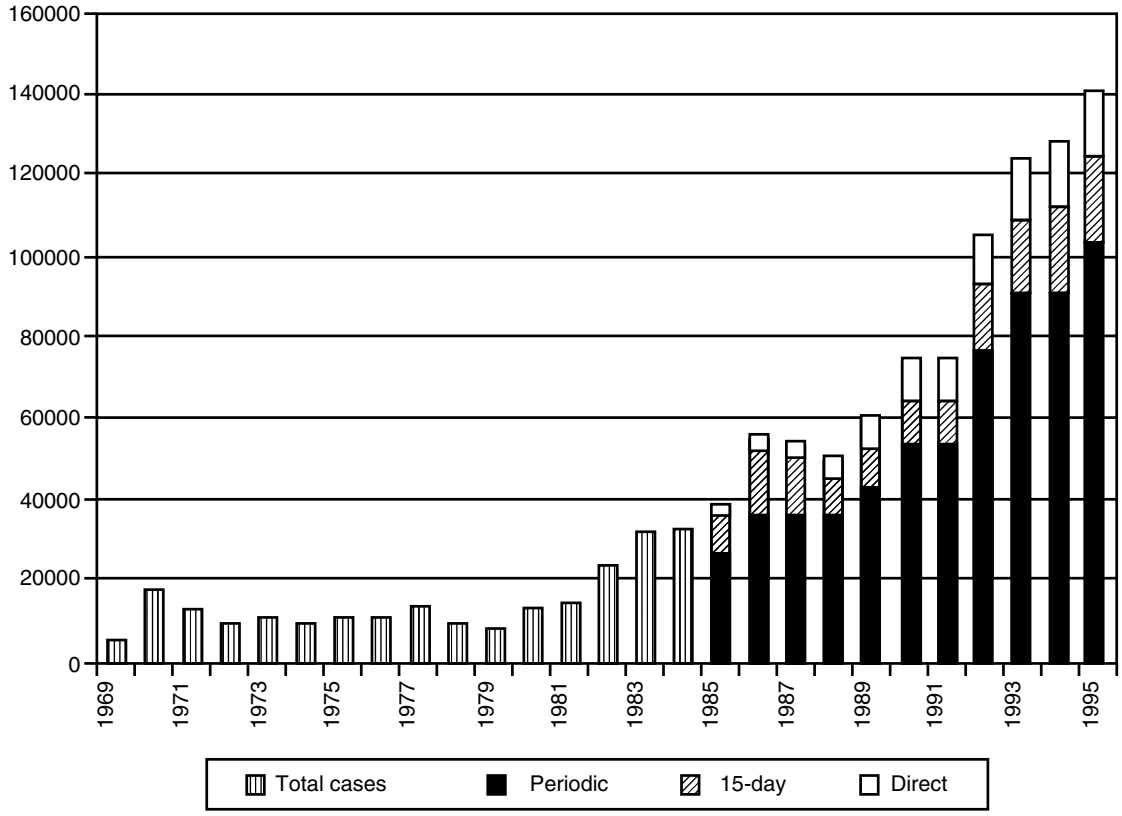

Figure 2 Count of all domestic and foreign reported adverse events by type of report by year, 1969–1995

of ADE reports and the denominator consists of some measure of exposure [22].

In proposing this approach it was recognized that the numerator, consisting of ADE reports, was subject to reporting biases, and that the denominator, consisting of estimated drug exposure based on sales data or prescription surveys, is a crude estimate of exposure. The approach attempts to detect changes from one period of reporting relative to an earlier reporting period.

Adopting the notation of Prause [17], the FDA approach assumes that ADEs are rare, and the number of reported ADEs (x_i) for a given drug–event (in the ith interval) follows a **Poisson distribution** with parameter $c_i p_i$, where i denotes period and x_i denotes the number of reported adverse reactions of a specific type of event for a given drug, c_i denotes the corresponding sales or any other estimate of drug usage for this period, and p_i denotes the rate of a reported adverse reaction per sales unit in period i. Let c_{i-1} be the sales in the historical (previous) period.

We define R_i as the proportion of the ith interval sales out of the sum of the sales for the i and $i-1$ intervals, i.e.

$$R_i = \frac{c_i}{(c_{i-1} + c_i)},$$

and denote the observed number of ADEs for the ith and $(i-1)$th intervals as x_i and x_{i-1}, respectively. X_i and X_{i-1} can be modeled as two independent Poisson random variables. Thus, the following **hypothesis testing** criteria could be used as a basis for an alert system:

$$\mathrm{H}_0 : p_i \leq p_{i-1} \text{ vs. } \mathrm{H}_1 : p_i > p_{i-1}. \qquad (1)$$

FDA proposed an asymptotic procedure to test this hypothesis based on the Poisson assumption. For the comparison of p_i and p_{i-1}, a normal approximation (*see* **Normal Distribution**) gives the test

statistic,

$$Z_{\mathrm{FDA}} = \frac{x_i - \left(\frac{R}{1-R}\right) x_{i-1}}{\left[x_i + \left(\frac{R}{1-R}\right)^2 x_{i-1}\right]^{1/2}}. \qquad (2)$$

A signal occurs when $Z_{\mathrm{FDA}} > Z_{1-\alpha}$, where Z is a standardized normal variate (*see* **Standard Normal Deviate**) and α is the tail probability. This approach signals an increased frequency of reports and assumes: (i) an **unbiased** comparison of the number of reports of a specific drug–event reaction during a recent appropriate time period with the number of reports of the same drug–event reaction during a previously observed comparative time period; and (ii) that differences in drug exposure between the intervals compared are taken into account. Norwood & Sampson [16] proposed a **binomial** approach based on the conditional distribution of x_i given $x_i + x_{i-1}$ to test the hypothesis (1).

Both the FDA Poisson-based method and the modification proposed by Norwood & Sampson test the **null hypothesis** that there is no change between the historical and the current period in the number of ADE rates adjusted for sales against the **alternative hypothesis** that there is an increase in the sales-adjusted ADE rates.

Using the same notation as above, Norwood & Sampson define

$$\Pr\left(X_i = x_i | x_i + x_{i-1}\right) = \binom{y}{x_i} R^{x_i} (1-R)^{y-x_i}, \qquad (3)$$

where $y = x_i + x_{i-1}$.

The normal approximation to the above conditional binomial distribution leads to the following asymptotic version of the exact test:

$$Z_{\mathrm{NS}} = \frac{x_i - (x_i + x_{i-1})\, R}{\left[x_i + x_{i-1} R_i\,(1-R_i)\right]^{1/2}}. \qquad (4)$$

Norwood & Sampson presented several examples of how to apply this approach to ADEs associated with a particular product line involving various dosage forms (capsules, tablets, liquid, and powder). In one of their examples, they observed four ADEs in the historical period with 18 000 sales, giving a historical reporting rate of 0.22 per thousand sales, compared to two ADEs in 5 650 sales, or a reporting rate of 0.35 per thousand in the current period. For these data the sales ratio $R = 5.65/(5.65 + 18) = 0.24$. The ***P* value** corresponding to the binomial test was 0.44 and thus the observed reporting change could be explained by chance.

CUSUM Approach

Praus et al. [17] propose the use of a cumulative sum (CUSUM) chart to address this question. They assume that a background incidence level k_0 of reported ADEs per unit of sales volume is known, together with its **standard deviation**. This information may, for example, be estimated by a run-in-series of earlier periods. Let $k_1 > k_0$ be an increase in the level that one considers important to detect and which serves as the rejection criterion.

The cusum score S_i for the period i is then defined in relation to its value in the previous period $i - 1$ by

$$S_i = \max\left(0,\, S_{i-1} + \frac{x_i}{c_i} - k_r\right), \quad i > 0, \qquad (5)$$

where $S_0 = 0$.

Here, k_r, where $k_0 < k_r \leq k_1$, is called the reference level and is usually taken as the mean of k_0 and k_1. x_i and c_i are defined as the number of ADRs and the sales volume in period i, respectively, as indicated earlier.

Whenever S_i exceeds a detection boundary h, an increased incidence level is suspected (alert case). The average run length ARL_0 under the background incidence k_0, the standard deviation of k_0, and the difference $k_1 - k_r$ will determine h, and the average run length ARL_1 under an assumed increased incidence level k_1 is determined similarly. The equations defining h and ARL_i cannot be solved explicitly, but tables and nomograms for practical use are available.

Praus et al. [17] applied the cusum procedure to the detection of serious ADEs for diphtheria vaccine. The main advantage of the cusum method in this diphtheria example is that it allows one to detect trends over time. One limitation of a cusum method is the need to have data on a drug that has been on the market for a long time to obtain a stable background rate.

Monitoring the Comparative Reporting of a Specific Drug–Event for Several Drugs in the Same Class

Tsong [21] extended the work of Rossi et al. [18] and Hsu [11] to compare the reports of ADEs associated with several nonsteroidal anti-inflammatory drugs (NSAIDs). The comparison of one marketed drug to another using data from an ADE registry introduces additional problems such as ensuring that the indication is the same for each drug compared, that the patients are comparable, that the patterns of concomitant medications are similar, and that the reporting patterns are the same if each drug is first marketed in different years. The **power** of this comparative approach has been investigated by Tsong [22].

Comparing Two Drugs First Marketed in the Same Year

Let X_{1i} and X_{2i} denote the number of reports of drug A and drug B, respectively, in year i; and C_{1i} and C_{2i} denote the number of prescriptions of drug A and drug B, respectively, in year i. Let P_{1i} and P_{2i} denote the ADE reporting rates of drug A and drug B, respectively, in year i; P_{1i} and P_{2i} are estimated by $\hat{p}_{1i} = x_{1i}/c_{1i}$ and $\hat{p}_{2i} = x_{2i}/c_{2ii}$, and $R_i = p_{1i}/p_{2i}$ denotes the ratio of reporting rates in year i.

Let $x_i = x_{1i} + x_{2i}$ be the combined number of ADE reports of both drugs, and $p_i = c_{1i}/(c_{1i} + c_{2i})$ be the proportion of prescriptions for drug A out of the total prescriptions combining drug A and drug B.

Assuming that x_{li} and p_i are given, under the hypothesis of equal reporting rates of drug A and drug B, x_{1i}, the **random variable** for the number of reports of drug A (and x_{1i} is the realization of X_{1i}) can be assumed to be distributed as BIN (x_i, P_i). For testing $H_0 : R_i = 1$ vs. $\mathrm{H_a} : R_i \neq 1$, the binomial test is the conditionally most powerful test, namely

$$Z = \frac{x_{1i} - (x_i c_i)}{x_i c_i (1 - p_i)^{1/2}} \tag{6}$$

When x_i or x_{1i} is small, the exact binomial p-values can be determined. Otherwise the normal approximation of the binomial test is the Z-test comparing against $Z_{\alpha/2}$, the $(1 - \alpha/2)$th percentile of the standard normal distribution; typically, $\alpha = 0.05$. R_i is estimated by $\hat{R}_i = (x_{1i}/c_{1i})/(x_{2i}/c_{2i})$, and its **confidence interval** can be calculated using Cornfield's method.

Monitoring Drug–Events Reported from Multiple Sources

Moussa [15] proposed a probabilistic approach to monitoring ADEs in situations where ADE reports are being collected from multiple registries (*see* **Disease Registers**) and collected at one central location (e.g. a **World Health Organization (WHO)** registry comprised of several National registries). In this situation, additional heterogeneities and irregularities associated with each reporting center or region are to be expected. In Moussa's approach each subpopulation is considered a cluster (which is defined as a homogeneous group of reports on a specific drug–event from one subpopulation in a specified time unit). The reports in a cluster are assumed to conform to a Bernoulli distribution, with the parameter varying between clusters of the same subpopulation according to a two-parameter **beta distribution**. An additional assumption is made that the cluster size follows a **negative binomial distribution**. The four parameters of the compound model are estimated by **maximum likelihood**.

Moussa uses these assumptions to construct a one-sided cumulative sum test to signal an alert. His model is applied to reports of intestinal hemorrhage associated with a specific drug submitted over 16 months to the UK Committee on Safety of Medicine, where the clusters are administrative subpopulations of the UK.

Other Computer-assisted Surveillance Methods

We now turn to several other surveillance methods that were not originally developed for drug–event monitoring but which can easily be adapted for that purpose. Recall that each report to FAD's system already has a drug–event linkage, so that aspect of the event–exposure relationship is known. Other earlier methods only assumed a reported event but assumed no exposure linked to the event. Computer-assisted surveillance was used to alert health agencies of unexpected increases in congenital malformations, not necessarily linking these events to any particular exposure. Hill et al. [10] compared the local incidence of congenital malformations to the expected national experience in various administrative areas in the UK. They used the cumulative sum

techniques of Ewan & Kemp [5] and Woodward & Goldsmith [24]. Bjerkedal & Bakketeig [1] used a system which incorporated all births in Norway on a monthly basis, and selected **International Classification of Diseases (ICD)** codes associated with a description of the event. They established control limits which would produce one false alarm every 230 months. Ericson et al. [4] compared two surveillance systems using two registries run in parallel in Sweden. One was a specific report card and the second was a computerized analysis of births, and the comparative **specificity** and timeliness of these systems was evaluated. The authors concluded that the specific report system was the only one suitable for monitoring malformations.

An alternative method to the cusum technique was introduced by Chen [2]. Chen describes a system that would be suitable for surveillance of congenital malformations in a single hospital or in several hospitals based on the number of consecutive births occurring between the birth of an infant with a specific monitored malformation and the birth of a second infant with the same malformation. The groups of such consecutive births are called sets, and the set size is a random variable with an assumed **geometric distribution**. Chen compared the relative efficiencies of the sets and the cusum techniques in monitoring the occurrence of rare events. Chen found the sets and cusum techniques to be comparable. The former was somewhat less efficient when monitoring a single hospital, although it was computationally simpler.

Levin & Kline [14] used a modification of Page's cumulative sum procedure to investigate unusual fluctuations in the proportion of spontaneous abortions. The monitoring of Nosocomial infections by the National Nosocomial Infections Study (NNIS) for the **Centers for Disease Control (CDC)** motivated Shore & Quade [19] to propose a surveillance system to detect an increase in the mean of the Poisson distribution of cases of a disease. Like Chen, they suggest an alert or signal to be based on the run-length distribution based on the tail probability of a geometric distribution.

Thus we see that several methods of assessment of risk related to newly and currently marketed drugs have been proposed. For the most part, this area of research is limited by the completeness of the numerator data and the biases associated with the reported ADEs and the difficulties in obtaining an adequate denominator as a surrogate for exposure. The most useful areas of work have focused on the search for increased frequencies of ADEs for a specific drug–event combination.

Poststratification in Survey Sampling

To stratify is to partition a set into disjoint subsets, called strata. Poststratification is partitioning a sample, i.e. after the sampling has been performed. It is an important method in statistical survey practice, e.g. in opinion polls. In textbooks it is less prominent.

Poststratification can be combined with any sampling method, but a typical situation is that the sample is viewed as obtained by **simple random sampling**. Suppose that we are investigating some gender-related property and note that there are more men than women in the sample. It is then natural to estimate within each sex group and then combine the two estimates into one with the help of the correct sex ratio in the **target population**. This is precisely the idea of poststratification.

Since poststrata have random sizes, the method results in larger estimator **variance** than stratification before sampling (*see* **Stratified Sampling**). It is still often used for practical reasons, cost or simplicity. In multipurpose studies, different poststratifications can be employed on the same sample for different estimating purposes. Sometimes stratification cannot be done in advance because it is not known to which stratum an individual belongs. In political opinion polls it is thus frequent to ask not only about voting intentions but also how you voted at the last election, and then to poststratify according to the latter variable.

Poststratification in not too many groups, within which the study variable varies less than in the whole population, can diminish **variance** substantially. Since the number of strata grows at a multiplicative rate with the introduction of new stratifiers, there is a risk of overstratification, which increases variance again. If the sampling scheme is somehow unbalanced, e.g. so that there are discrepancies between **sampling frame** and target population, or there is **nonresponse**, poststratification can also reduce **bias**.

Mathematically, the situation can be expressed as follows. Consider a study variable Y and a stratification variable X. The purpose is to estimate the population average of Y. If the sampling procedure is balanced, then this will be the same as the **expectation** of Y, $\sum yp_{xy}$, where the sum is over all possible values of the two variables, and p_{xy} denotes the probability that the ith observation (usually the ith individual) of the sample has the values x and y. The point is that the p_{xy} are unknown, whereas the marginal distribution of the stratification variable,

$$p_x := \sum_y p_{xy},$$

is known, or we have a good estimate of it from some other (large) study.

Let s denote the sample, x_i, y_i the values of the two variables for the individual i, n_x the number of sampled individuals with $x_i = x$, and

$$\overline{y}_x := \sum_{i \in s, x_i = x} \frac{y_i}{n_x}$$

if $n_x > 0$ and zero otherwise. Then the estimator of the population Y-average poststratified with respect to X is defined as

$$\hat{y} := \sum_x p_x \overline{y}_x.$$

The choice $\overline{y}_x = 0$ in empty poststrata is for mathematical convenience. It could well be argued that in such cases one should choose the full sample average or a combination of $\overline{y}_{x'}$, where the x' are stratifier values deemed to yield y-values close to those corresponding to x.

If, given strictly positive n_x, $\overline{y}_x$ is an **unbiased** estimator of the conditional expectation of Y, given $X = x$, then the poststratified estimator will have no bias, provided all $n_x > 0$. The overall bias will be $\sum_x p_x \Pr(n_x = 0)$ which is $\sim q^n$ in the usual sampling schemes, for sample size n and $q = \max_x(1 - p_x)$.

Provided the different y_i are uncorrelated, the conditional variance will be

$$\mathrm{var}(\hat{y} | n_x, \text{ all } x) = \sum_{x; n_x > 0} \frac{p_x^2 \sigma^2(Y|x)}{n_x},$$

where $\sigma^2(Y|x)$ is the conditional variance of Y, given $X = x$:

$$\sigma^2(Y|x) := \sum_y y^2 \frac{p_{xy}}{p_x} - \mu^2(X|x),$$

$$\mu(Y|x) := \sum_y y \frac{p_{xy}}{p_x}.$$

If sampling is simple and random without replacement (*see* **Sampling With and Without Replacement**) and the model is the classical one of fixed given y-values in the population, then this is still approximately true, the risk of sampling the same individual more than once being disregarded.

The overall variance is then obtained as

$$\sum_x p_x^2 \sigma^2(Y|x) \mathrm{E}\left(\frac{1}{n_x} | n_x > 0\right) \Pr(n_x > 0) + \mu^2(Y|x) \Pr(n_x = 0)(1 - \Pr(n_x = 0)).$$

Here, the latter term can often be disregarded and the expectation of $1/n_x$ approximated by

$$\frac{1}{np_x} + \frac{(1 - p_x)}{(np_x)^2}.$$

In practice, the second term is usually also neglected, leading to the impression that poststratification "always pays". As pointed out, however, this can be misleading: if within-strata variances are not considerably smaller than the overall variance of the study variable, and the number of poststrata, i.e. the number of different x-values, is of the same order as n (a situation that can be met with in practice) the second term is not negligible.

From a theoretical viewpoint, poststratification has certain desirable properties: it is **maximum likelihood** in a general model, and it has a conditional **minimal variance** property among a natural class of estimators (*see* **Estimation**). The question whether **inference** statements should be made conditionally upon poststratification or not is discussed in two articles by Jagers et al. and by Smith, the latter of which also gives an overview. The method is looked at from a **Bayesian** angle by Little.

Power Divergence Methods

Numerous asymptotic test statistics have been proposed to assess the fit of a collection of counts with a **multinomial** or product-multinomial probability model. Minimizing lack of fit, as measured by such a statistic, is a plausible approach to estimating unknown model parameters. Power divergence provides a unifying conceptual and computational framework for these statistics and their associated estimators, facilitating both analytic and simulated comparisons of their behaviors and utility in small sample and sparse large sample **categorical data analysis**.

Let the observed counts be n_{ij} for independent multinomial samples $i = 1, \ldots, s$ and response categories $j = 1, \ldots, r$, with n_{i+} the size of the i^{th} sample, $N = \sum_{i=1}^{s} n_{i+}$, and $p_{ij} = n_{ij}/n_{i+}$. Write a model for the cell probabilities $\pi_{ij} = E(p_{ij})$ as $\pi_{ij} = \pi_{ij}(\boldsymbol{\theta})$ for vector $\boldsymbol{\theta}$, with $\sum_{j=1}^{r} \pi_{ij}(\boldsymbol{\theta}) = 1$ for each i. The "**goodness-of-fit** statistics" most commonly used in this context are the log **likelihood ratio** statistic [33]

$$X_L^2 = 2\sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij} \log\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right), \qquad (1)$$

Pearson's chi-square [36]

$$\begin{aligned} X_P^2 &= \sum_{i=1}^{s} n_{i+} \sum_{j=1}^{r} \frac{(p_{ij} - \pi_{ij}(\boldsymbol{\theta}))^2}{\pi_{ij}(\boldsymbol{\theta})} \\ &= \sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij} \left(\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right) - 1\right) \\ &= \sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij} \left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right) - N, \end{aligned} \qquad (2)$$

and Neyman's modified chi-square [21, 31]

$$\begin{aligned} X_N^2 &= \sum_{i=1}^{s} n_{i+} \sum_{j=1}^{r} \frac{(p_{ij} - \pi_{ij}(\boldsymbol{\theta}))^2}{p_{ij}} \\ &= \sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij} \left(\left(\frac{\pi_{ij}(\boldsymbol{\theta})}{p_{ij}}\right)^2 - 1\right) \\ &= \sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij} \left(\frac{\pi_{ij}(\boldsymbol{\theta})}{p_{ij}}\right)^2 - N \end{aligned} \qquad (3)$$

(*see* **Chi-square Distribution**; **Chi-square Tests**). When the model specifies fixed $\boldsymbol{\theta} = \boldsymbol{\theta_0}$, each of (1)–(3) is used as an asymptotically $\chi^2_{s(r-1)}$ statistic to test the simple hypothesis (*see* **Hypothesis Testing**). Otherwise, X_L^2 and X_P^2 are evaluated at the **maximum likelihood** estimate $\widehat{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$, in which case X_P^2 is Rao's likelihood score statistic [40]. In contrast, X_N^2 is evaluated at $\arg\min_{\boldsymbol{\theta}} X_N^2(\boldsymbol{\theta})$ which, for linear $\pi_{ij}(\boldsymbol{\theta})$, yields Wald's [55] statistic. The reference distribution for testing the composite hypothesis is $\chi^2_{s(r-1)-\dim(\boldsymbol{\theta})}$.

Note that each of (1)–(3) is the size-weighted sum of departures of the ratios of observed to expected cell proportions $p_{ij}/\pi_{ij}(\boldsymbol{\theta})$ from 1. However, the departures are measured on different scales: additive in (2), logarithmic in (1), and after exponentiation by -2 in (3). Other asymptotically chi-square statistics in the literature for this problem – for example, the "externally constrained" discrimination information statistic X_I^2 [12, 24] and the Freeman–Tukey chi-square, equivalently the Hellinger distance [4, 10, 41] – take form similar to (1) and (3) but with other exponents for the ratios. Since

$$\begin{aligned} &\lim_{\delta\to 0}\left(\frac{1}{\delta}\sum_{j=1}^{r} n_{ij}\left(\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right)^{\delta} - 1\right)\right) \\ &= \sum_{j=1}^{r} n_{ij} \log\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right), \end{aligned} \qquad (4)$$

X_L^2 is naturally addressable as the "exponent 0" member of this class.

Hence, Read and Cressie [8, 43, 45] defined and studied the class of power-divergence asymptotic test statistics, which, extending (2), can be expressed as

$$\begin{aligned} &2I^{\lambda}(\{n_{ij}\}, \{\pi_{ij}(\boldsymbol{\theta})\}) \\ &= \frac{2}{\lambda(\lambda+1)}\left[\sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij}\left(\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right)^{\lambda} - 1\right)\right] \\ &= \frac{2}{\lambda(\lambda+1)}\left[\sum_{i=1}^{s}\sum_{j=1}^{r} n_{ij}\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right)^{\lambda} - N\right] \end{aligned} \qquad (5)$$

for $\lambda \neq -1, 0$, and as the limits of (5) for $\lambda = -1$ or 0. These limits are X_L^2 for $\lambda = 0$ and, for $\lambda = -1$, the discrimination information statistic

$$X_I^2 = 2I^{-1}(\{n_{ij}\}, \{\pi_{ij}(\boldsymbol{\theta})\}) = 2\sum_{i=1}^{s}\sum_{j=1}^{r} n_{i+}\pi_{ij}(\boldsymbol{\theta}) \log\left(\frac{\pi_{ij}(\boldsymbol{\theta})}{p_{ij}}\right), \quad (6)$$

which is a sample size-weighted sum across populations of **Kullback–Liebler information** numbers comparing fitted to observed distributions. By (1) and (5), for $\lambda \leq 0$, the statistic only exists when $n_{ij} > 0$ for all i and j. When $2I^{\delta}(\{n_{ij}\}, \{\pi_{ij}(\boldsymbol{\theta})\})$ exists and $\boldsymbol{\theta}$ must be estimated, $\widehat{\boldsymbol{\theta}}^{(\delta)} = \arg\min_{\boldsymbol{\theta}}(2I^{\delta}(\{n_{ij}\}, \{\pi_{ij}(\boldsymbol{\theta})\}))$ is the minimum power-divergence estimator (MPE) of order δ. In such a case, the power-divergence test statistics $2I^{\lambda}(\{n_{ij}\}, \{\pi_{ij}(\widehat{\boldsymbol{\theta}}^{(\delta)})\})$ may be used for $\delta \neq \lambda$ without affecting many asymptotic properties. Thus, as noted above, in common application X_P^2 corresponds to $\lambda = 1, \delta = 0$. For the usual Freeman–Tukey statistic, $\lambda = -1/2$ with $\delta = 0$. For unknown $\boldsymbol{\theta}$, the statistics are thus most appropriately doubly indexed. But most comparative studies of the power-divergence class have focused on relatively simple situations for which this is not necessary: either fixed $\boldsymbol{\theta}$ for a single multinomial, or $\widehat{\boldsymbol{\theta}}^{0}$ under the independence hypothesis for a two-way **contingency table**, for which the maximum likelihood estimates are typically used for tests of any order λ. We thus suppress δ here for simplicity (*see* **Independence of a Set of Variables, Tests of**).

Intuition may be gained from simple settings allowing analytic comparison of MPEs. For $\boldsymbol{\theta}$ of length t, the estimation equations are

$$\sum_{i=1}^{s}\sum_{j=1}^{r}\left(\frac{p_{ij}}{\pi_{ij}(\boldsymbol{\theta})}\right)^{\lambda+1}\frac{\partial\pi_{ij}(\boldsymbol{\theta})}{\partial\theta_k} = 0, \quad (7)$$

$k = 1, \ldots, t$. Consider a single multinomial under the constraint $\pi_j = \theta_1$ for $j = 1, \ldots, r^*$, $\pi_j = \theta_2$ for $j = r^* + 1, \ldots, r$. Then

$$(\widehat{\theta}_1^{(\lambda)}, \widehat{\theta}_2^{(\lambda)})' \sim \left(\left(\frac{1}{r^*}\sum_{j=1}^{r^*} p_j^{\lambda+1}\right)^{\frac{1}{\lambda+1}}, \left(\frac{1}{(r-r^*)}\sum_{j=r^*+1}^{r} p_j^{\lambda+1}\right)^{\frac{1}{\lambda+1}}\right)', \quad (8)$$

with proportionality constant enforcing the constraint $r^*\widehat{\theta}_1^{(\lambda)} + (r - r^*)\widehat{\theta}_2^{(\lambda)} = 1$. Similarly, for estimating $\theta' = (\pi_1, \ldots, \pi_r)'$, $\sum_{j=1}^{r}\pi_j = 1$ from s independent multinomial samples under the homogeneity hypothesis $\pi_{ij} = \pi_j, i = 1, \ldots, s, j = 1, \ldots, r$,

$$\widehat{\pi}_j^{(\lambda)} \sim \left(\sum_{i=1}^{s}\left(\frac{n_{i+}}{N}\right)p_{ij}^{\lambda+1}\right)^{\frac{1}{\lambda+1}}, \quad (9)$$

with proportionality constant such that $\sum_{j=1}^{r}\widehat{\pi}_j^{(\lambda)} = 1$ [20, 38, 45]. An extension of (9) is available for monotone **missing data**, for example, as with dropouts in **longitudinal** studies [20]. Thus, MPEs in simple cases are normalized and possibly weighted power means, with Pearson's chi-square leading to root mean squares, the Hellinger distance squared mean roots, X_I^2 the geometric mean, and X_N^2 the harmonic mean. The maximum likelihood estimator leads to arithmetic means, and consequently is the only MPE with the commonsense invariance property that estimators are unaffected by pooling, within and across populations, of categories with a common probability.

The form of (5) suggests that power-divergence statistics will be increasingly sensitive to cells with high observed to expected count ratios for increasingly large positive λ, and to cells with low ratios for increasingly large negative lambda. Read and Cressie [45] found this to be true in studies of statistical **power** against "spike" or "dip" alternatives to uniformity in a single multinomial, for which one or two cell counts substantially exceed or fall short of expectation. They recommended against the use of power-divergence statistics with $|\lambda| > 5$, on grounds that they are effectively dominated by unexpectedly low ($\lambda < 5$) or high ($\lambda > 5$) counts. Similarly, (5)–(7) suggest that MPEs will be more sensitive to the lowest among the observed proportions for increasingly negative λ. To illustrate, Figure 1 plots $\widehat{\pi}_1^{(\lambda)}$ from (9) for $\lambda = -6$ to 6, for equal size samples from two binomials with $p_1 = 0.1$, $p_2 = 0.6$. Over all λ, $\widehat{\pi}_1^{(\lambda)}$ ranges from 0.2 as $\lambda \to -\infty$ to 0.4 as $\lambda \to \infty$, as compared to $\widehat{\pi}_1^{(0)}$, the maximum likelihood estimator and pooled proportion, of 0.35.

It is somewhat surprising that the power-divergence unification was not accomplished thirty years earlier. X_N^2, X_L^2, and X_P^2 were all known before 1930 ([31, 33, 36], respectively). In a seminal unifying paper, Neyman [32] defined the

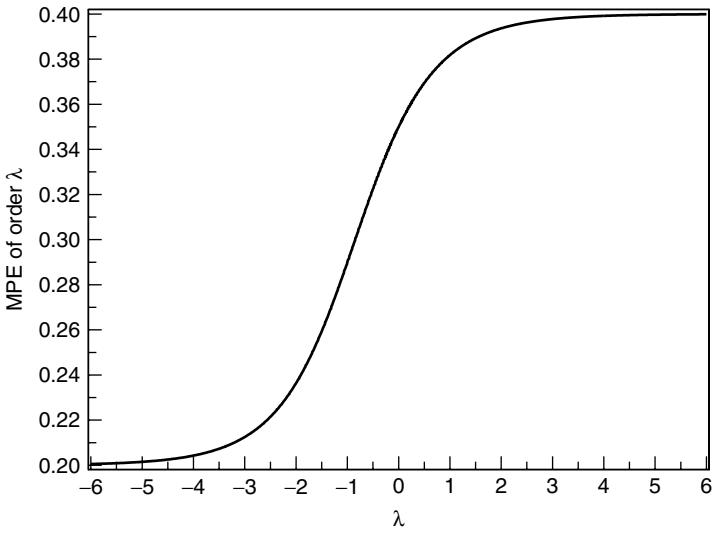

Figure 1 Minimum power-divergence estimates (MPEs) of π_1 under homogeneity of two binomials ($n_{1+} = n_{2+}$, $p_1 = .1$, $p_2 = .6$)

class of "best" asymptotically normal **(BAN) estimators** of $\boldsymbol{\theta}$: consistent, asymptotically normal continuous functions of the p_{ij}, with minimum asymptotic ($n_{i+} \to \infty, n_{i+}/n \to c_i < \infty$) variance among estimators having those properties (*see* **Efficiency and Efficient Estimators**). Neyman showed estimators minimizing any of X_L^2, X_P^2 or X_N^2 to be BAN. For testing, the minimized X_P^2 and X_N^2 were shown to share the same null chi-square distribution as X_L^2, or as X_P^2 evaluated at the MLE of $\boldsymbol{\theta}$, or as any of (1)–(3) evaluated at any BAN estimator $\widehat{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$. This result applies to all power-divergence statistics and MPEs.

Haldane [13], based on conversation with C.A.B. Smith, credits M.C.K. Tweedie with the use of the estimating equations (7) in the 1940s; they may have been used informally even earlier (*see* **Estimating Functions**). Working with a single population and parameter θ, Haldane was looking for a class of fit statistics from which improved estimates might be found, and was clearly aware of $\sum_{j=1}^{r} n_j (p_j/\pi_j(\theta))^{\lambda}$ as a candidate kernel for such a class. However, to obtain test statistics and estimators fully defined even for samples with zero cell counts, he replaced n_j with $\lambda!\binom{n_j}{\lambda}$. The remainder of [13] shows the resulting estimators to be BAN, and compares and discusses bias adjustments (*see* **Unbiasedness**). Interestingly, one estimator is a version of X_N^2 for which each cell count is augmented by 1. Haldane's "divergence" measures and "minimum discrepancy" estimator did not, however, gain widespread acceptance.

Kullback [24] obtained the logarithmic functions X_L^2 and X_I^2 as *directed divergences* between observed and fitted multinomial distributions [42]. Imrey [20] applied Tweedie's estimating equations to monotone missing data, with a general solution implicit. Much later, Read and Cressie [8, 43, 45] recognized, crucially, that other goodness-of-fit chi-square statistics are multiples of nonadditive directed divergences [42]

$$I^{\alpha}(\pi : p) = c\left(\sum_{j=1}^{r} \pi_j^{\alpha} p_j^{1-\alpha} - 1\right) \qquad (10)$$

between fitted and empirical probability mass functions. The power-divergence class, as defined in (4), follows by taking $\alpha = -\lambda$ and normalizing to the chi-square distribution.

The distributions of power-divergence statistics and performance characteristics of the corresponding goodness-of-fit tests have been compared in several ways. For simplicity we restrict to $s = 1$. With $\boldsymbol{\theta}$ defined as the probability vector $\boldsymbol{\pi}$, when increasingly large samples are drawn from a null multinomial distribution with $\boldsymbol{\theta}=\boldsymbol{\pi}_{\mathbf{0}}$, all power-divergence statistics share the limiting χ_{r-1}^2 distribution. Under the same

scenario with composite null $H_0 : \boldsymbol{\pi} = \boldsymbol{\pi}(\boldsymbol{\theta})$ for $\boldsymbol{\theta}$ of dimension t, and where the test statistic is calculated at a BAN estimate of $\boldsymbol{\theta}$, the degrees of freedom become instead $(r-1)-t$.

Under the alternative $\boldsymbol{\pi} = \boldsymbol{\pi_1}$, the power divergences with $\lambda > -1$ have limiting Gaussian distributions (*see* **Normal Distribution**) with respective means

$$\frac{2N}{\lambda(\lambda+1)}\left[\sum_{j=1}^{r}\pi_{1j}\left(\left(\frac{\pi_{1j}}{\pi_{0j}}\right)^{\lambda}-1\right)\right] \qquad (11)$$

and variances proportional to N. Consequently, all power-divergence statistics yield consistent $(\lim_{N\to\infty} Pr[2I^{\lambda}(\{n_j\},\{\pi_{1j}(\boldsymbol{\theta})\}) \geq c_{\alpha}] = 1)$ tests against fixed alternatives. The **Pitman efficiency** of test T_1 relative to test T_2 is the limiting ratio of the sample sizes required by T_2 and T_1 to maintain a specified power under a sequence of local alternatives converging to $\boldsymbol{\pi}_0$ and for which this limit exists, for example, $H_1 : \boldsymbol{\pi} = \boldsymbol{\pi}_0 + \boldsymbol{\delta}/\sqrt{N}$ with $\sum_{j=1}^{r}\delta_j = 0$, which converges at rate $N^{-1/2}$. The limiting distribution under this sequence is noncentral chi-square with noncentrality parameter $\sum_{j=1}^{r}\delta_j^2/\pi_{0j}$. In this setting, the Pitman efficiency is the ratio of noncentrality parameters of the limiting distributions of the corresponding test statistics under H_1. Since the limiting distribution does not depend on λ, all power-divergence tests have Pitman efficiency of 1 relative to X_L^2. Several power approximations for this situation have been compared for sample sizes in the range of $5r - 10r$, for which two based on **Edgeworth expansions** seem most effective [49].

For many tests, the attained significance level (i.e. ***P* value**) under a fixed **alternative hypothesis** almost surely declines exponentially to 0 with increasing sample size N, for N sufficiently large. Half the rate of exponential decline for such a test is known as its "exact slope", and the ratio of exact slopes of two tests is the limit of the ratio of sample sizes required, almost surely, for each of the tests to achieve statistical significance at level α, as $\alpha \to 0$. The Bahadur efficiency of T_1 relative to T_2 is thus defined as the ratio, where it exists, of the exact slope of T_2 to that of T_1. No power-divergence test has greater Bahadur efficiency than X_L^2, although others may have equal efficiency depending on the hypotheses being compared [37].

Efficiency results change considerably when one considers "sparse" asymptotics in which increasing sample size is associated with finer classification: as $N \to \infty$ the number of cells r_N in the multinomial expands as well, so that $r_N \to \infty$, $(N/r_N) \to c$, with $0 < c < \infty$. As suggested by the large-sample normality of chi-square distributions with many degrees of freedom, the limiting distributions of power-divergence statistics for $\lambda > -1$ are here Gaussian. The moments of these distributions are functions of λ, and hence, the behaviors of the statistics differ under both null and alternative models. For $\lambda \leq -1$ under sparse asymptotics, the probability that $2I^{\lambda}(\{n_{ij}\},\{\pi_{ij}(\boldsymbol{\theta})\})$ is undefined remains positive no matter how large the sample, so the limiting distributions can only be defined conditional on all positive cell counts. With $\lambda > -1$, for testing uniformity in a single multinomial, Pitman efficiency may be evaluated under a sequence $H_1 : \boldsymbol{\pi} = \boldsymbol{\pi}_0 + \boldsymbol{\delta}/N^{1/4}$. While dependence on λ is small for $-1 < \lambda \leq 3$, and declines with increasing cell expectations N/r_N, X_P^2 is optimally efficient. However, this optimality holds in the narrowest of circumstances, for it fails to generalize to testing a simple nonuniform null hypothesis, for which no statistic is clearly superior, or to nonlocal dip alternatives for which the relative performance of X_P^2 and X_L^2 appears dependent on the number of dips [23]. It has also been noted that limiting normal distributions under this local sequence are unchanged by the presence of **nuisance parameters**, suggesting that in this setting, power-divergence tests have low efficiency as a class [50].

Studies have compared accuracy in small sample settings of large-sample approximations to the distributions of power-divergence statistics. Read [44] notes that for testing a simple multinomial hypothesis, the standard chi-square approximation is not adequate for $\lambda < 1/3$ or $\lambda > 3/2$. Of the conventional goodness-of-fit statistics, only X_P^2 falls within the acceptable range. The poor performance of the approximation for X_L^2 relative to that for X_P^2 has been found consistently [11]. The power-divergence statistic with $\lambda = 2/3$ is sometimes known as the "Cressie–Read statistic". Read [44] and Read and Cressie [45] recommend this choice from the power-divergence class based on its generally good performance in studies of both conventional and sparse asymptotics, coupled with the convenient adequacy of the conventional null approximation for all but very small sample sizes. Recent work confirms the conventional practice of basing use of the asymptotic approximation on minimum expected count (*see*

Expectation) and shows that, for the Cressie–Read and Pearson statistics when $r > 2$, the approximations may be considerably more tolerant than has generally been appreciated [11].

While the above results on testing favor use of power-divergence tests for λ in a range no wider than perhaps 0.5–1.5, other studies indicate that MPEs for small negative $\lambda \varepsilon (-1, -0.5]$, for example, the minimum Hellinger distance MPE with $\lambda = -0.5$, may have substantial robustness advantages. Although this comes at a price in small sample efficiency, a penalized version that alters the influence of zero cell counts appears to improve the situation greatly [1, 47, 48].

Several data analytic techniques originally based upon individual power-divergence statistics have been generalized to the entire class. Thus, power-divergence tests for independence in the **2 x 2** contingency table have been compared [26]. Methods in the spirit of the "partition of chi-square" technique originally developed by Lancaster [25], who decomposed X_P^2 to localize sources of heterogeneity in contingency tables (*see* **Chi-square, Partition of**), and analysis of deviance for sequential reduction of hierarchical **loglinear models** [3], have been extended to "analysis of divergence" [7, 27–29]. **Akaike's information criterion** AIC, based upon X_L^2, has been generalized to the "power-divergence information criterion" PIC [6]. **Confidence intervals** derived by inverting Wald and score statistics have been compared to intervals obtained by inverting other power-divergence tests [2].

Recently, a class of statistics based on power divergences has been proposed for assessing fit of a categorical **time series regression** model [9]. Predictors may include external variables and the past history of the time series, which need not be stationary. The λ-order power-divergence based statistic is the sum, across observation times, of power divergences between the degenerate empirical distribution of the single observation at each time and the fitted distribution given by the predicted category probabilities at that time. The latter are based on the **partial likelihood** estimate $\widehat{\boldsymbol{\beta}}$ of the vector $\boldsymbol{\beta}$ of regression parameters. The centered power-divergence process using $\boldsymbol{\beta}$ is a zero-mean martingale, and its analogous process using $\widehat{\boldsymbol{\beta}}$ is approximated by a mean-square integrable martingale. From martingale **central limit theory**, the latter process is Gaussian for $\lambda > -1$, with variance a function of λ. It is also shown to be the partial likelihood score for expansion of the regression model in a λ-dependent direction. Notably, for $\lambda = 0$ the expanded model degenerates to the current model, so that the deviance is ineffective for detecting model inadequacy in this context. Values of λ from -1 to 1, excluding 0, are suggested as potentially useful.

MPEs have been considered for estimating parameters of continuous distributions using samples where the original observations have been grouped into categories and are no longer available. In this context, MPEs have been criticized as subject to substantial bias from low-level **misspecification** of the continuous distribution, particularly for certain distributions used commonly in econometric models [54].

Although the power-divergence class considerably generalizes classical goodness-of-fit statistics for categorical data, power divergence itself is a special case of a Csiszár's ϕ-divergences, a much broader class of directed divergences of form $\sum_{i=1}^{r} q_j \phi(p_j/q_j)$ for functions ϕ that are convex on $\Re_+$ with $\phi(1) = 0$, $\phi''(1) > 0$, and the conventions that $0\phi(0/0) \equiv 0$ and $0\phi(p/0) \equiv \lim_{u\to\infty} \phi(u)/u$. The power divergences arise from this formulation by taking

$$\phi_\lambda(u) = \frac{1}{\lambda(\lambda+1)}(x^{\lambda+1} - x + \lambda(1-x)) \qquad (12)$$

for $\lambda \neq -1$, 0, and limits at these two values. Considerable progress has been made in generalizing asymptotic results on power-divergence estimators and MPEs to ϕ-divergences and the corresponding MϕEs [30, 35]. Cressie and Pardo [7] have illustrated the increased flexibility by using a ϕ-divergence due to Renyi, evaluated at MPEs, for sequential testing of higher-order effects in hierarchical loglinear models.

Power divergences have also seen increasing use outside of the goodness-of-fit context, in their pure capacity as directed divergences representing the disparity between a set of probabilities and a reference distribution. Thus, for given λ, Tomizawa et al. [52] define a measure of asymmetry in square nominal contingency tables as a multiple of the order λ power divergence between the observed distribution among the off-diagonal cells and the reference symmetric distribution preserving the $n_{ij} + n_{ji}$ for all (i, j). For square tables with ordered categories, a similar measure is developed using power divergence applied to an artificial distribution constructed from cumulative probabilities calculated at all pairs of row and

column cut-points [51] (*see* **Square Contingency Table**). In classification trees with categorical variables, the sum of a power divergence of given order between each branch of a split and its source distribution, weighted proportionally to the observations in each branch, has been maximized over possible splits to determine the best split at each stage [46] (*see* **Tree-structured Statistical Methods**). Minimizing mean power divergence of observed from predicted observations in leave-one-out **cross-validation** has been used to determine the smoothing parameter in generalized **spline function**-based **logistic regression** [53]. Power divergence from a **uniform distribution** has been minimized subject to constraints in order to determine observation weights in unimodal kernel **density estimation** [15], monotone kernel regression [14], and monotone **hazard rate** estimation using a biased bootstrap [16] (*see* **Bootstrapping in Survival Analysis**).

Indeed, the task of minimizing divergence from uniformity is increasingly central to estimation. Empirical **likelihood** estimation [34, 39] views the empirical distribution as a multinomial. An unknown parameter θ is estimated subject to constraints by first associating with the observations a set of probabilities that maximizes the multinomial likelihood while preserving the constraints. The parameter estimate is then calculated from this weighted, or "maximum likelihood tilted," multinomial. The task of finding the tilted distribution is equivalent to minimizing the 0-order power divergence of tilted from uniform distribution, subject to the constraints. Estimation by exponential tilting [22] involves the same process, but the optimization criterion is minimization of the Kullback–Liebler information in the tilted distribution rather than maximization of the likelihood, again subject to constraints. The exponential tilting computation thus requires minimization of the order (-1) power divergence of tilted from uniform distribution. Generalized **method of moment** (GMM) estimation involves minimizing a quadratic form in a set of restrictions based on moment conditions [17]. In certain circumstances, an iterated version of GMM is equivalent to estimation from the distribution that minimizes the power divergence of order (-2) from uniformity [19]. Maximum likelihood and exponential tilting are also useful for increasing computational efficiency of **bootstrap** confidence intervals [18]. For parametric estimation, Choi et al. [5] suggest that **robustness** may be increased by a "biased bootstrap" tilted maximum likelihood estimator. The weights for tilting are obtained by maximizing the tilted loglikelihood on a constant contour of a power divergence from uniformity.

Thus, power divergence methods highlight connections between statistical inference and information theory, and provide a unifying framework for statistical procedures well beyond goodness-of-fit considerations for categorical data models.

Power Transformations

The assumptions in **regression** analysis include **normally distributed** errors of constant variance (*see* **Scedasticity**). Often these assumptions are more nearly satisfied not by the original **response variable** y, but by some **transformation** of y, $z(y)$. For nonnegative responses, one frequently used transformation is $\log y$. The original and transformed analyses can then be compared in a number of ways. **Residuals** can be plotted against fitted values, or assessed for normality by probability plots for various transformations (*see* **Normal Scores**). Another comparison is through analysis of the linear model using t or F tests – a correct transformation often yields a simple **linear regression** model, with no, or just a few, **interaction** or quadratic terms. A formal way of comparing transformations is to embed them in a parametric family and then to make inferences about the transformation parameter λ (*see* **Model, Choice of**). Transformations of three parts of the model are of differing complexity and importance. The most important is described in the following section.

Transformation of the Response: Box and Cox [5]. The logarithmic transformation is one special case of the normalized power transformation [5]

$$z(\lambda) = \begin{cases} \dfrac{y^\lambda - 1}{\lambda \dot{y}^{\lambda-1}} & \lambda \neq 0 \\ \dot{y} \log y & \lambda = 0, \end{cases} \tag{1}$$

where the geometric mean of the observations is written as $\dot{y} = \exp(\Sigma \log y_i / n)$. The regression model to be fitted is then

$$z(\lambda) = \boldsymbol{X}\boldsymbol{\beta} + \varepsilon. \tag{2}$$

For fixed λ, the value of $\boldsymbol{\beta}$ is estimated by **least squares** giving a residual sum of squares for the $z(\lambda)$ of $R(\lambda)$. The **maximum likelihood** estimate $\hat{\lambda}$ minimizing $R(\lambda)$ is found by numerical search (*see* **Optimization and Nonlinear Equations**), often over a grid of λ values. Exact minimization of $R(\lambda)$ is not required, since simple rational values of λ are customary in the analysis of data: $\lambda = 1$, no transformation: $\lambda = 1/2$, the square root; $\lambda = 0$, the logarithmic and $\lambda = -1$, the reciprocal being widely used. An approximate minimum of $R(\lambda)$ is, however, required to establish **confidence intervals** for and to test **hypotheses** about λ. It is important that these comparisons of $R(\lambda)$ do use the full form in (1) including the geometric mean. Omission of this term leads to meaningless comparisons – for most data, $\log y$ is very much smaller than y and so are the corresponding sums of squares, regardless of how well the regression models fit.

Transformation of Explanatory Variables: Box and Tidwell [6]. For a regression model with p terms, it sometimes makes sense to consider models in which one (or perhaps more) of the **explanatory variables** is transformed, when the model is

$$y = \sum_{j \neq k}^{p} \beta_j x_j + \beta_k x_k^\lambda + \varepsilon. \tag{3}$$

Again the maximizing value of λ has to be found numerically, but the calculations are more straightforward than those for the Box–Cox transformation, since the scale of the observations is unaffected by the transformation. The residual sums of squares of y can be compared directly as λ varies.

Transformation of Both Sides of the Model: Carroll and Ruppert [7]. The Box and Cox transformation often yields both approximately normal errors and a simple linear model. But sometimes the two transformations do not happen together. An example is the data on mandible length from Royston and Altman [10] plotted in **Goodness of Fit**. The analyses in **Diagnostics**, **Forward Search**, and **Residuals** showed that the log transformation yielded normal errors, but increased the evidence for the inclusion of a quadratic term in the linear model (*see* **Polynomial Regression**). If there is a simple model for y, the simplicity of the linear model can be maintained by subjecting both sides of the model to the same transformation. The purpose of the transformation is then to obtain normal errors of constant variance.

Let $\mathrm{E}(Y) = \eta = \boldsymbol{x}^T\boldsymbol{\beta}$ be the simple linear model. The transformation model is then

$$\begin{aligned} \frac{y^\lambda - 1}{\lambda \dot{y}^{\lambda-1}} &= \frac{\eta^\lambda - 1}{\lambda \dot{y}^{\lambda-1}} + \varepsilon \quad \lambda \neq 0, \\ \dot{y} \log y &= \dot{y} \log \eta + \varepsilon \quad \lambda = 0. \end{aligned} \tag{4}$$

The optimizing value of λ again minimizes the residual sum of squares of the transformed response. For given λ, estimating the parameters in general requires nonlinear estimation, although this is unaffected by

division by $\lambda\dot{y}^{\lambda-1}$. An example for the data on the volume of trees analyzed in **Residuals** is given by Atkinson [2].

The procedures using constructed variables described in **Residuals** provide tests for the value of λ, which avoid the need for calculation of $\hat{\lambda}$ whilst also giving information on the effect of individual observations on tests and parameter estimates. Numerous examples for the Box–Cox and Box–Tidwell transformations are given by Atkinson [1]. Cook and Weisberg [8, Chapter 13], describe interactive graphical methods for selecting a transformation. Diagnostic material on the transformation of both sides of the model is given by Hinkley [9], Shih [11], and by Atkinson [2]. Atkinson and Shephard [4] extend the Box–Cox transformation to time series analysis and describe the related diagnostic procedures. Diagnostic procedures for the effect of groups of observations via the **Forward Search** use the **Fan Plot**, described in greater detail in [3, Chapter 4].

A.C. ATKINSON

Power

Traditionally, the *power* of a **hypothesis test** equals the probability of rejecting the **null hypothesis**, conditional on the falseness of the null. The definition implicitly depends on a number of mathematical assumptions. Equally importantly, the definition depends on a number of philosophical assumptions concerning the logic of science and the value system of the scientist. Hence, examining the concept of power requires at least a brief discussion of decision making.

The practice of statistics involves either creating **estimates** of population properties (using sample properties), or drawing **inferences** concerning population properties (using sample properties). **Probability theory** provides models of population properties and sampling processes. **Decision theory** blends mathematics, statistics, philosophy, and behavioral science to model and guide decision making. Although the systematic study of probability began centuries ago, a completely rigorous mathematical basis was not formalized until the beginning of the twentieth century. In turn, the development of estimation trailed probability, and inference (including hypothesis testing) trailed estimation.

The most common approach to statistical hypothesis testing stems from the work of **J. Neyman** and **E.S. Pearson**, around the middle of the twentieth century. No single approach has ever achieved universal approval. More frankly, statisticians have always disagreed on how to draw inferences. Currently, the most important alternative involves a **Bayesian** approach, which avoids the language and concepts of hypothesis testing.

In evaluating a scientific decision process, one may consider (i) the scientific goal, (ii) the scientist's payoff function (values), (iii) the information gathering mechanism, (iv) the mathematical model, and (v) the mathematical objective function. Our understanding of the human perceptual system depends critically on the separate consideration of perceptual performance and payoff function. For example, two radiologists examining a chest X-ray image may differ in their ability to detect lung cancer, in their willingness to declare a perceived anomaly as lung cancer, or both. Signal detection theory, as well as the closely related **receiver operating characteristic (ROC)** curve analysis, provide tools for disentangling performance from preference. Power computations provide the same ability for statistical hypothesis testing. Power analysis informs the scientist, who then chooses alternatives based upon goals and values in the setting at hand.

This broad, and therefore necessarily shallow, discussion should allow drawing three conclusions. First, to arrive at the doorstep of a power computation requires many assumptions, with most usually left unstated. Secondly, the concepts and machinery of power presented here derive from one particular approach to the problem of drawing inference in science. Thirdly, earnest and serious disagreement among statisticians suggests that achieving consensus will require a new approach, distinct from any currently available. Until then, the popularity of the Neyman–Pearson approach encourages understanding and extensive use of power analysis.

The most common approach to hypothesis testing centers on stating a null and an **alternative hypothesis** about parameters of a population. For example, consider a physician interested in mean response under standard treatment with mean response under an innovative treatment. A traditional classification of possible decisions (see, for example, Daniel [5, p. 195]) is summarized in Table 1. In such an interpretation, power equals the probability of rejecting the null, conditional on the alternative holding (*see* **Level of a Test**).

In contrast, mathematical statisticians now prefer to define power as the probability of rejecting the null, whether or not the alternative holds. The unconditional approach, used in the remainder of this article, treats the null hypothesis situation as a special case of the alternative. Statisticians describe a test which achieves minimum power at the null hypothesis as **unbiased**.

Ideally, a technique provides the **most powerful test** among a set of candidates. Typically, restrictions must hold in order to find a "best" test. One of the most appealing approaches arises from seeking a *uniformly most powerful unbiased test*. Among the class of all unbiased tests, one seeks that test, the power of which for any alternative never falls below the power of any other unbiased test. See Kendall & Stuart [11, Sections 22.16 and 23.24], and surrounding material) for further discussion.

Table 1 The traditional approach

		Decision	
		H_0: no effect	H_a: effect
Truth	No effect	Pr{Correct negative} = $(1-\alpha)$	Pr{False positive} = Pr{Type I error} = α
	Effect	Pr{False negative} = Pr{Type II error} = β	Pr{Correct positive} = $(1-\beta)$ = Power

Sensitivity Analysis for Power

Scientists encountering the concept of power sometimes ask a statistician "Just tell me how many subjects I need" (*see* **Sample Size Determination**). The question presumes the availability of defensible choices for unknown parameters, a precise size of a scientifically important difference, a clear specification of the costs of alternative designs, and a clear specification of costs and benefits of correct and incorrect decisions. The many dimensions of uncertainty imply the need to consider a wide range of alternatives. Considering a range of values creates a **sensitivity analysis** by examining the sensitivity of the study power to the assumptions.

The power of a t test as a function of mean difference is illustrated in Figure 1. The curve summarizes results of Warshauer et al. [25] who examined the value of a contrast agent in CT images of liver cancer. A subject's score equals the difference between a baseline and IV contrast enhanced CT. The horizontal axis represents the difference between group (difference) means in Hounsfield units (HU), a measure of brightness of an object in a CT. The scientists had used a t test to assess the value of adding a particular contrast agent to a patient's IV. The most important test was not significant. Hence, they computed the power curve in order to assess whether the study had possessed enough power to detect clinically relevant effects. A difference between the groups of 10 HU was deemed clinically significant. The computations assume five subjects in the control group, four in the experimental group, and $\alpha = 0.05$. The solid power curve uses the observed value of $\hat{\sigma}^2 = 6.78$ (based on seven degrees of freedom). As a function of a **random variable** (the variance estimate), a computed power value becomes a random variable. Taylor & Muller [23] described how to create an exact confidence interval for such a power value. The dashed line provides a one-sided 95% **confidence** region for the power values. The distance between the solid and dashed lines indicates the uncertainty in the power computation due to having used $\hat{\sigma}^2$ in lieu of σ_2. The 95% quantile of χ^2 (7) implies that $6.78 \times (14.067/7) \approx 6.78 \times 2$ provides an upper bound estimate of σ^2. Using this value in the power calculations would provide approximately the exact answer embodied in the dashed line. However, the inexact approximation should never be used because the exact answer requires no additional complexity to calculate (see Taylor & Muller [23, Section 2.2] for details). A similar looking plot would occur with other types of analyses, such as the comparison of groups on a **binary** response (such as in **logistic regression**) or with time-to-event **(survival) analysis**.

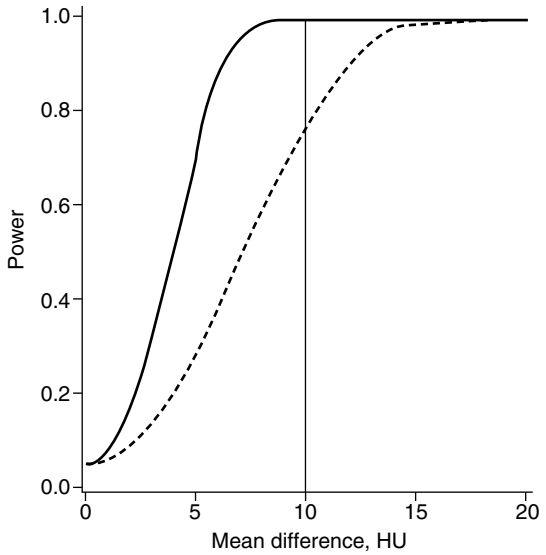

Figure 1 Power as a function of mean difference (after Warshauer et al. [25])

The example demonstrates many properties of a reasonable power analysis. For any Gaussian theory linear model analysis, such as the t test example, power varies only with (i) sample sizes, (ii) error variance, and (iii) mean differences, for a (iv) fixed α. More generally, power depends on (i) design properties, (ii) **nuisance parameters**, (iii) difference parameters, and (iv) test characteristics. Power tables and plots usually allow one or two dimensions to vary. The investigator controls and knows the values of design properties, such as total sample size and ratios of group sizes, as well as test characteristics. In contrast, the investigator does not know, with any certainty, the values of nuisance parameters and treatment differences. Hence, the latter provide the critical and interesting dimensions for plots and tables in a power analysis. A reasonable sensitivity analysis also involves varying the investigator-controlled dimensions, especially sample size.

Aligning Power

The potentially most damaging errors that commonly occur in power analysis involve misalignment. Describe a power analysis as *aligned* if the test examined in power analysis coincides with the test used in data analysis. Here, assume that the model has been correctly specified. Alignment errors may falsely inflate or deflate the power computed. Muller et al. [19] provided examples of both, in the context of using the power for **Student's *t* test** in lieu of that appropriate for **analysis of variance for longitudinal data**. Whether or not such simple power calculations apply must be defended in each particular application.

Although oversimplification of power analysis occurs most often, other sorts of misalignment also occur. Consider ignoring dropout in planning a clinical trial lasting five years. Data missing at random lead to the wrong sample size, while data missing not at random require distinct statistical methods (*see* **Nonignorable Dropout in Longitudinal Studies**). Obviously, the data analysis must align with the study, as well as the power analysis.

Ethical and monetary costs should dictate the effort expended on power analysis. Inexpensive, quick, and risk-free studies merit only limited power analysis. In contrast, expensive and lengthy studies with risky treatments merit thorough power analysis.

Increasing Power for a Fixed Sample Size

Increasing the type I error, α, automatically increases power. Scientific reviewers would frown on any blatant move of that sort. Of course, merely ignoring the issue of **multiple comparisons** (conducting many tests of the same idea with one set of data) will inflate α and hence have the same effect. The discussion here assumes that the scientist has balanced type I and II error rates by careful choice of the type and number of tests. See Muller et al. [18] for an extended discussion of the general issue in the context of toxicology.

The choice of analysis may increase power. For example, a repeated measures analysis may be more powerful than a necessarily **Bonferroni** corrected set of tests at each time, if the effect increases rapidly in time. However, a late developing effect may lead to the Bonferroni corrected set of tests being more powerful.

The choice of response variable may substantially affect power. Obviously, one variable may vary with the **explanatory variables** (or predictors) more than another. The acquisition of more knowledge and insight often rewards the scientist in this fashion. The scale of the response may play an equally important role. For example, the nature of clinical medicine pushes physicians to think in terms of binary or **categorical** responses. The practical need to assign one among many treatments naturally leads to the desire for categorical diagnosis. In studying treatments for a bacterial infection, one obvious response would be the presence or absence of disease. If the diagnosis derives from a blood level, more power would be expected from using the continuous measure of serum concentration.

Reducing error variance provides one of the simplest techniques to increase power. Merely ensuring scrupulous adherence to recruiting criteria, study protocol, and laboratory **assay** technique help. In the context of Gaussian theory linear models, cutting error variance in half has nearly the same impact as doubling the sample size.

The distribution of observations among design points affects power. Consider choosing the set of drug doses for an **analysis of variance** type design, with drug dose as the categorical predictor of interest. A design with one quarter of the subjects at each of four doses will usually have noticeably less power than a design with half of the subjects at

the two most extreme doses. With two groups, a balanced design (one with an equal number in each predictor value group) usually has more power than an unbalanced design. With a categorical outcome, such as cancer/no cancer, power tends to depend more on the distribution across predictors and number in the smaller of the two category counts, rather than on properties of the total sample.

Computing Power

Published theory may be combined with contemporary computers to facilitate computation of exact or approximate power for an extremely wide range of statistical methods. Unfortunately, currently available **software** does not fulfill the promise. Many commercial vendors provide user-friendly packages. At least until the middle of the 1990s, commercial products limited coverage only to the most common statistical techniques. Many statisticians have also written "freeware", with a similar target. Other statisticians have developed software for particular sets of complex, but narrow, applications.

Tables in books and especially journal articles may provide the most convenient current source for power values. Note that the available books tend to follow the same model as the commercial software, limiting coverage to the most popular techniques.

Using computer software and printed material for power requires a cautious approach. The issue of alignment must be addressed. More importantly, the conceptual complexity of power analysis, and the limited availability of training, leads to more mistakes than in data analysis. The user interface, whether labels for rows and columns of a table, or option names for a program, often proves to be the problem. The reader should also recognize that programs or associated documentation, whether sold for profit or free, may contain fundamental errors. For example, does the program need the variance or the standard deviation? Either provides plausible results when substituted for the other. Note also that power computation often proves more difficult numerically than data analysis. The competition in the market for data analysis software has gradually raised standards for numerical accuracy and ease of use. One rarely sees commercial data analysis programs printing negative variance estimates or probabilities greater than one. The market for power software has just started.

The limited bibliography provides sources for power analysis for many common statistical methods. Examine Muller et al. [18] and Muller & Benignus [16] for discussion of some of the philosophy of power use. Kraemer & Thiemann [12], Lipsey [15], and Cohen [3] provide general introductions to power methods. See Kupper & Hafner [13] and Gatsonis & Sampson [6] for an indication of limitations of using rough approximations. For a conceptual introduction to power for **general linear models**, see O'Brien & Muller [20]. Muller et al. [19] provide a more technical exposition, with particular attention to multivariate and repeated measures power. Odeh & Fox [21] provide extensive tables for univariate linear models. Gatsonis & Sampson [6] treat the **multiple linear regression** model with Gaussian predictors and response.

The reader should recognize that any reasonably thorough list of sources would cover many pages. Many widely used statistical methods in biostatistics and associated excellent papers have been omitted here for the sake of brevity. To find power information for a particular technique not covered in a general power book, consult texts describing the data analysis method of interest. For example, Agresti [1] describes power analysis methods for repeated measures categorical data (*see* **Longitudinal Data Analysis, Overview**). Next, consult the statistical literature. Be sure to examine primary statistical journals, not just scientific journals. The latter have many discussions of special case models, while the former may include more thorough treatments of general models.

Related Concepts

The concepts of power discussed here have generalizations in a wide range of scientific settings. In some cases, criteria other than power provide a superior measure of study quality. For example, in group sequential or purely **sequential** designs the expected sample size often proves more interesting. Power and sample size interact in nonobvious ways in problems centered on estimating **confidence intervals**. An ongoing debate in the study of **bioequivalence** surrounds the use of power for choosing sample size.

Prospective power analysis helps in planning studies to be conducted in the future. Retrospective power analysis may help evaluate studies previously completed. See Benignus et al. [2] for an example. Power

analysis also has value in **meta-analysis** [4, 7–10, 13, 21]. See Muller & Benignus [16], Taylor & Muller [23, 24], and Muller & Pasour [17] for further discussion.

Preclinical Treatment Evaluation

Every year the pharmaceutical industry develops thousands of new compounds in the hope that some of them will ultimately prove useful in the treatment of human disease. Before any prospective new drug can be tested in humans, it must undergo an extensive series of preclinical tests and assessments to ensure its safety and efficacy, to understand its **pharmacokinetics**, metabolism, and other chemical properties, and to determine safe and appropriate doses for human testing. Some of these tests are performed *in vitro* (that is, in test tubes and Petri dishes), while others involve laboratory animals (*in vivo* testing). The vast majority of compounds (some estimate more than 99%) are discarded long before reaching the steps of animal testing, and few eventually reach the marketplace.

Drug discovery sometimes begins with the observation that a compound from nature has some desirable action without knowing how the compound works. Penicillin is one such example. Large screening programs are still used to identify compounds active against bacteria and other disease-causing organisms. In the last few decades, the tools of combinatorial chemistry and molecular biology have become increasingly important. Combinatorial chemistry enables synthesis of many compounds to increase greatly the number available for screening. Molecular biology can sometimes be used to speed the search. For example, knowledge of how the **AIDS** (acquired immune deficiency syndrome) virus replicates may provide ideas for designing molecules that interfere with viral replication. These compounds are tested for activity against the virus *in vitro*, and, by a series of experiments, scientists attempt to find molecular structures with greatest potency.

Preclinical safety assessment requires a candidate drug to undergo a battery of tests to identify potential toxic effects. Statisticians are probably most involved in screening for *carcinogens* (cancer-causing agents) (*see* **Tumor Growth**; **Tumor Incidence Experiments**). However, procedures for identifying *teratogens* or *developmental toxicants* (agents that damage a developing fetus or child) (*see* **Teratology**) have become more quantitative in recent years, and many statisticians are now working in this area. While there are many other areas of toxicity testing; for example, neurotoxicity and genetic toxicology, this article focuses primarily on preclinical testing for carcinogenicity and developmental toxicity.

Historically, scientists have always been interested in devising *in vitro* tests that can assess drug safety quickly and cheaply without resorting to animal testing. One of the most well known is the Ames Salmonella assay for **mutagenicity**, wherein the test chemical is added to bacteria in a Petri dish. While the 1970s saw considerable optimism surrounding the Ames assay, most experts now agree that the test has fairly low **sensitivity** for predicting carcinogenicity in rodents. However, because its **specificity** is high, compounds found to be positive using the Ames assay are likely to be dropped from further development. *In vitro* assays are often supplemented with *in vivo* assays; for example, the mouse bone marrow cytogenetic assay. Recently, there has also been considerable interest in the use of computer-based algorithms that attempt to predict carcinogenicity on the basis of chemical structure and function, mutagenicity, 90-day toxicity, and other factors. However, the general consensus is that while these alternatives can provide useful insight into mechanisms of action, they cannot yet replace carcinogenicity bioassays (*see* **Biological Assay, Overview**) in rodents. Finding *in vitro* tests for teratogenicity and developmental toxicity is even more difficult, since less is known about their mechanisms of action than for carcinogenicity. Some tests (for example, assessing the motility and morphometry of sperm) show promise, but it is likely that *in vivo* tests will play a central role in drug testing for some time to come.

General Principles for Animal Testing

Regardless of whether the endpoint is carcinogenicity, teratogenicity, neurotoxicity, or some other kind of adverse effect, toxicologists for the most part concur on several general principles for designing a high-quality animal experiment. First, the experiment should be conducted in a familiar animal strain and under stable experimental conditions to avoid extra sources of variability that might confound study results. Secondly, the route of exposure should be the one that most closely mimics the intended clinical route(s) to humans. For example, a compound intended for intramuscular (IM) injection or intravenous (IV) administration to humans should usually

be given by the same route to laboratory animals. A drug intended for oral administration would be given to animals by gavage. A third and somewhat controversial principle is that the highest experimental dose should correspond to the maximum tolerated dose (MTD) for long-term studies (*see* **Phase I Trials**). Loosely speaking, this is the highest dose that can be administered without the experimental animals experiencing excessive systemic toxicity that could alter the test results. Precise definition of the MTD depends on the specific testing situation. The primary reason for using the MTD is to maximize the chance of detecting a carcinogenic effect, if one exists. If low doses were used instead, then experiments would need to be much larger to achieve adequate statistical **power** to detect effects. To illustrate, Table 1 shows the **sample sizes** that would be required in order to have a 95% chance of seeing at least one tumor, as a function of the true probability that an animal has a tumor:

Once pilot studies have been conducted to identify the MTD, the next choice is the number of dose groups to use, and the number of animals in each. While several different choices might be justified, most long-term experiments tend to include two or three dose groups between control and MTD, with the lowest at 1/4 (MTD) and the higher at 1/2 (MTD).

Caging is another important issue in experimental design. Specifics vary according to the type of experiment being run. For a carcinogenicity experiment, for example, some laboratories house multiple animals together in the same cage. While this practice is cost effective, it can lead to problems if the animals fight (male mice are particularly prone to this problem). Allocation of cages within the animal room is another important consideration. Because animals are sensitive to light, noise, heat, and humidity, **biases** could result if, for example, all the high-dose animals were placed on the top rack of cages. Possible approaches include completely random allocation (*see* **Randomized Treatment Assignment**) or cage rotation. However, there are practical constraints to both these strategies. Because light, heat, and humidity gradients, if they exist, are likely to be vertical, the most popular approach is a clustered block design (*see* **Blocking**) wherein each column of cages consists of just one dose group, and columns are randomly allocated to dose groups.

Table 1 Sample sizes required to observe at least one tumor with 95% probability

Pr(tumor)	Sample size needed
0.1	30
0.01	300
0.001	3000
0.0001	30000
0.00001	300000

Diet (or body weight) has received considerable attention in recent years, since food consumption is an important **confounder** in animal studies. Rodents given unlimited access to food can become obese, resulting in decreased life span, earlier onset of spontaneous tumors, and possibly altered drug metabolism and consequent incidence of treatment-induced tumors. Such considerations also add to the argument for single animal caging, because multiple animals per cage often lead to large variations in the food consumption of individual animals.

Carcinogen Bioassays

In a typical long-term rodent bioassay, control and exposed animals are followed over 18 to 24 months, and are examined at death or sacrifice for the presence of a variety of different tumors, as well as nonneoplastic lesions. Usually, the experiments are conducted in male and female animals from two different species (for example, Fischer-344 rats or $B6C3F_1$ mice), with 50 to 60 animals per dose group, sex and strain, for a total of approximately 800–960 animals (for a study with a **control** and three dosed groups). This long-term experiment is generally preceded by two shorter-term pilot studies whose main goals are to establish the doses to be used in the 24-month study and to study acute and subchronic effects.

In the early days of the carcinogen bioassay, statistical analysis was naively based on comparisons of the tumor counts observed in each dose group. For example, suppose that Table 2 represents the

Table 2 Summary data from a typical carcinogenicity study

	Dose level				
	d_0	d_1	...	d_I	Total
Number of animals with tumor	x_0	x_1	...	x_I	$x_.$
Number exposed	n_0	n_1	...	n_I	$n_.$

experimental data. Then, one could test for a dose effect using a Cochran–Armitage trend test (*see* **Trend Test for Counts and Proportions**), which can be written as

$$\chi^2_{\text{ca}} = \frac{\left[\sum_{i=0}^{I} d_i(x_i - \text{E}_i)\right]^2}{V}, \qquad (1)$$

where $\text{E}_i = n_i x_\cdot / n_\cdot$ is the expected number of tumors in the ith dose group under the **null hypothesis** of no dose effect (H_0), and

$$V = \left(\frac{x_\cdot}{n_\cdot}\right)\left(\frac{n_\cdot - x_\cdot}{n_\cdot}\right)\sum_{i=0}^{I} n_i(d_i - \overline{d})^2.$$

Under H_0, χ^2_{ca} has an asymptotic **chi-square distribution** with one **degree of freedom**. Eventually, it became apparent that such analyses based on *lifetime tumor incidence* could be biased when lifetimes were shortened due to toxicity associated with high experimental doses. Several age-adjusted tests were proposed in the early 1970s, including the *tumor prevalence test* [9], which involves stratifying time into three or four intervals (*see* **Stratification**) and then comparing exposed and controls with respect to $\pi_j = \Pr(\text{tumor-death in interval } j)$ using a **Mantel–Haenszel** test. Dinse & Lagakos [6] recognized that a prevalence analysis can be easily accomplished using **logistic regression** with tumor presence as the outcome and dose and time as **covariates**. Although the prevalence test is still widely used, many are concerned about its strong implicit assumption of nonlethality (that is, tumor onset does not change an animal's risk of death). Alternatives include a **survival analysis** treating death with tumor as the outcome [14]. However, this approach assumes that the tumor is instantly lethal. Peto et al. [15] proposed a method that relies on pathologists to assign *cause of death*. The problem with the Peto method, however, is that *cause-of-death* information is often unavailable, and can be unreliable. Much statistical research in the past 10 or 15 years has focused on the development of methods that apply to tumors of intermediate lethality. *Poly-3* is a promising method that replaces the n_i in the above table with an adjusted value, N_i, that downweights animals that died early with no tumors [1]. More precisely,

$$N_i = x_i + \sum\left(\frac{t_{ij}}{t_{\max}}\right)^3,$$

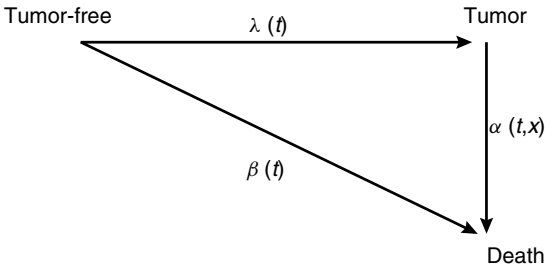

Figure 1 Three-state model for carcinogenicity

where $t_{\max}$ is the maximum death time observed in the study and the sum is over the subset of animals in the ith dose group that died with no tumor. The third power is chosen because generally it has been found that tumor **incidence rates** tend to occur as a third- or fourth-order function of time. Alternately, many have proposed methods of analysis based on fitting a *three-state model* as depicted in Figure 1, with $\lambda(t)$ representing the instantaneous rate of tumor onset at time t, $\beta(t)$ the instantaneous death rate at time t, and $\alpha(t, x)$ the instantaneous death rate at time t for an animal that developed a tumor at time x.

Many approaches to fitting the three-state model are impractical because they assume the availability of extensive interim sacrifice (wherein randomly selected animals are killed at prechosen times during the experiment and examined for tumors). Recently, Dinse [5] and Lindsey & Ryan [13] have advocated the use of **semiparametric regression** models that assume an additive $[\alpha(t, x) = \beta(t) + \Delta]$ or multiplicative relationship $[\alpha(t, x) = \beta(t)\text{e}^{\Delta}]$ between the **hazards** for death with and without tumor. These approaches are appealing from a biological perspective and can be applied to a typically sized experiment with only a single terminal sacrifice.

The carcinogen bioassay raises several other challenging statistical problems. One is the issue of **multiplicity**, wherein the chance of seeing statistically significant results is increased because many (usually over 50) different tumor sites are examined (*see* **Multiple Comparisons**). Some propose **multivariate analysis** methods that accommodate multiple tumor types [18]. Others argue that multiple testing is not a serious problem for tumor types that are rare in control animals, although this depends on sample size [8]. The role

of historical control information in the evaluation of data from a carcinogenicity study is also an important topic with interesting statistical questions that have been discussed by many authors in recent years [10].

Teratology Studies

The purpose of a teratology, or, more generally, a developmental toxicology, study is to assess adverse effects on reproduction and development. In response to the thalidomide episode and growing concern about prenatal effects of drugs, the US **Food and Drug Administration (FDA)** issued a set of guidelines in 1966 for conducting animal studies to assess the safety of drugs intended for human use. The guidelines established a three-stage testing procedure generally referred to as segments I, II and III. "Segments" refer to sequential periods during reproduction when the compound is administered. In a segment I (fertility) study, the compound is given prior to and during the mating phase and up to implantation of the embryo. In a segment II (teratology) study, the compound is administered during the major period of organogenesis. In a segment III (late gestation and lactation) study, exposure occurs from the end of the embryonic period through lactation. Subsequently, the FDA added a multigenerational protocol suitable for testing food additives and pesticides. More recently, the guidelines have been modified to allow more flexible study designs that combine segments, so long as all phases of reproduction, premating through lactation, are covered.

The remainder of this section focuses on the segment II design, since this is the one to which most of the published statistical work relates. Figure 2 summarizes the typical design, wherein pregnant animals (dams) are exposed during the critical period of major organogenesis (days 6–15, 17, or 19 for mice, rats and rabbits, respectively) and sacrificed just prior to normal delivery at which time the uterus is removed and the contents are thoroughly examined (note that "gd" denotes gestational day in Figure 2).

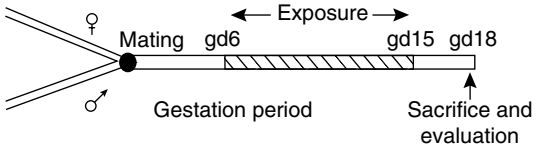

Figure 2 Chronological events in a developmental toxicity study

Ordinarily, between 20 and 30 pregnant dams are randomized to each dose group and control and typical control litter sizes (number of live-born offspring) range from eight to 10 in rabbits to 12 and 15 in mice and rats, respectively.

While the dam is the unit of randomization (*see* **Unit of Analysis**) and maternal toxicity is an important factor in these studies, interest centers primarily on fetal outcomes. Examination of the uterine contents produces several discrete and continuous fetus-level outcomes. In addition to the number of eggs that implant in the uterus, litter-specific counts of resorptions (early fetal deaths) and fetal deaths (deaths occurring later in gestation) are available. Viable fetuses (animals that would be born live if the dams were followed to term) are extensively examined for malformations. Body weight and, occasionally, other parameters, such as various body dimensions (e.g. crown to rump length) and organ weights, are also measured.

The statistical analysis of data from a teratology experiment must account for the *litter effect*, or the tendency for littermates to respond more similarly than offspring from different litters. One easy approach is to summarize data at the dam level; for example, by considering litter-specific percentages of resorptions or malformations as the endpoints for analysis. More recently, there has been considerable interest in the use of statistical methods for correlated data that allow for fetus-specific analyses. Some of these have been based on **likelihood**-based methods, such as the **beta-binomial** [3]. Others have been based on **generalized estimating equations**, which provide a relatively simple and often robust (*see* **Robustness**) approach to the analysis of **correlated binary data**. For example, Lefkopoulou & Ryan [11] propose an appealing generalization of the Cochran–Armitage trend test that applies to clustered binary data. To illustrate, suppose, for simplicity, that each fetus is classified as normal or abnormal. Let x_{ij} be the number abnormal among the n_{ij} pups in the jth litter of the ith dose group. Then, under the null hypothesis of no dose effect, the following test statistic has an asymptotic chi-square distribution with one

degree of freedom:

$$\frac{\left[\sum_i \sum_j d_i(x_{ij} - n_{ij}\tilde{\mu})\right]^2}{\sum_i \sum_j (d_i - \overline{d})^2 (x_{ij} - n_{ij}\tilde{\mu})^2},$$

where d_i is the dose level applied to the ith dose group,

$$\overline{d} = \frac{\sum_i \sum_j n_{ij} d_{ij}}{\sum_i \sum_j n_{ij}} \quad \text{and} \quad \tilde{\mu} = \frac{\sum_i \sum_j x_{ij}}{\sum_i \sum_j n_{ij}}.$$

Note that when $n_{ij} = 1$ (i.e. no litter effect), this test statistic is asymptotically equivalent to the Cochran–Armitage trend test, (1).

Handling multiple outcome data is another important issue that arises in the analysis of developmental toxicity data (*see* **Multiple Endpoints, *P* Level Procedures**). The issues here are slightly different from those encountered in carcinogenicity, since compounds that cause adverse effects are quite likely to affect a variety of organ systems in the developing fetus. Some authors [4, 16, 19] address the hierarchical nature of some outcomes (e.g. death and malformation), and suggest analyses based on **overdispersed multinomial** models. Others have suggested methods to deal with the analysis of multiple outcomes measured on the same fetus [12], as well as the challenge of analyzing the mixture of discrete and continuous outcomes that arise in developmental toxicity [2, 7].

Neurotoxicity and Other Studies

Neurotoxicity has traditionally been evaluated by histopathologic examination of slides taken at necropsy, much as other forms of toxicity. In recent years, assays that directly measure neurologic function in living animals have been increasingly used, since neurological damage may not be evident at necropsy, but may manifest later with behavioral problems [17]. For example, a swim maze may be used to measure problem-solving ability (time to find the exit), and memory (time to find the exit a few days later). An open field monitor records how a rat explores a new environment (an open box crisscrossed with electronic beams) by counting the number and location of beams broken over time. Other assays measure righting reflex, balance, or habituation to repeated loud noise. Such response data are often high-dimensional, and yet can show clear effects, suggesting a need for multivariate statistical methods (*see* **Multivariate Analysis, Overview**) to capture and summarize the information. At this time, however, little has been published on this topic.

Future Developments

Recent years have seen a number of exciting developments in toxicology. There is great interest in the development of *biologically based models* that take account of pharmacokinetics, metabolism, and physiological systems to characterize better dose response and improve the extrapolation from animals to humans. While such models are still in relatively early stages of development, it is likely that they will become more widely used in the future. The use of transgenic mouse models is also likely to become more widespread in the future.

Prediction

In statistical usage, the term *prediction* usually refers to the attempt to predict individual values of a random variable based on a statistical model, often one which relates a **response variable**, which is to be predicted, to a set of **explanatory variables**. The errors involved in prediction usually derive from uncertainty in the estimation of the mean, or some function of the mean, of the variable, and the "natural" variation of the observed value about its mean. The former is usually determined by the adequacy of an estimated statistical model, while the latter is not subject to manipulation. Prediction based on **multiple linear regression** provides an example.

Examination of the predictive ability of a statistical model is useful in a variety of situations. It is, for example, a natural aspect of **discriminant analysis** and the basis of **cross-validation**. Geisser [2, 3] has written extensively on prediction as a basis of inference procedures. A book-length treatment of prediction is [1].

In some other contexts, *prediction* takes on its more usual meaning of "predicting the future" (*see* **Forecasting**; **Predictive Modeling of Prognosis**).

VERN T. FAREWELL

Predictive Modeling of Prognosis

Changing **prognosis** over time is an essential feature of the course and treatment of chronic diseases such as cancer, HIV/**AIDS**, leukemia, and diabetes. Typically, when the patient presents initially he/she can be characterized as having a certain state of health, which the physician determines using various objective and subjective measurements. Whether the patient remains in the hospital for continuous monitoring or leaves and returns for periodic observation and treatment, many of his/her measurements will change over time. While some apparent clinical changes in the patient might be attributable to **measurement error**, others may reflect real beneficial treatment effects or a worsening of prognosis.

Having arrived at a diagnosis, the physician can assess the natural course of the disease, and, on the basis of this information, can make judgments about the patient's prognosis. Prognosis is defined in terms of the relative probability of developing one of several alternative outcomes in the natural history of the disease (*see* **Natural History Study of Prognosis**).

In recent years, **Markov models** have become important tools to describe and help understand the progression and regression of chronic diseases which are characterized by having well-defined stages. These models have been used to find possible markers for the transition from stable states to the accelerated phase and the irreversible (absorbing) state of a disease, and also to describe the natural course of these diseases. Aalen and Johansen [1] considered multistate continuous-time Markov processes assuming that transitions occurred just before the observation times (*see* **Aalen–Johansen Estimator**). Klein et al. [17] use a three-state **semi-Markov** model in a study of patients with chronic myelogenous leukemia to analyze the effect of elevated blood levels of adenosine deaminase as a marker for transition from stable disease to blast crisis, and then to death. Andersen and colleagues [2–4] introduce proportional intensity **regression** models for multistate Markov processes assuming that the transition times are known as in **proportional hazard** models [7]. Longini et al. [18] use a Markov model to describe the distribution of the **incubation period** for AIDS patients. In this model, only progression to the next higher state or a jump to the absorbing state are allowed.

Kay [16] proposed a methodology to fit a general k-disease-state Markov model in continuous time with application to the analysis of cancer markers in **survival** studies. Kay assumes that the transitions between states occur at unknown times between observations, except for transitions to the absorbing state. Andersen et al. [4] compare the approach of Aalen and Johansen [1], which assumes that the transition times are known, with the approach of Kay [16], which assumes that the transition times are unknown. Grüger et al. [13] looked at the interrelationship between the disease process and the patient's examination scheme (i.e. the study protocol).

This article discusses predictive models for prognosis using a general k-state Markov model in which the exact transition times are not observed (*see* **Transition Models for Longitudinal Data**). An important application of these models is discussed and analyzed. Data from a longitudinal study in young patients with diabetes from the Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences Center, are used to determine factors affecting the natural course of diabetic retinopathy.

Three Examples

Hepatocellular Carcinoma

Kay [16] shows the results of a multistate model (*see* **Multistage Carcinogenesis Models**) applied to 81 patients with hepatocellular carcinoma. The main goal of this statistical analysis was to determine the usefulness of serum alpha-fetoprotein (AFP) as a marker in hepatocellular carcinoma. High levels of AFP are indicative of such cancers, particularly in subjects with cirrhosis of the liver, at the diagnosis state. Kay [16] shows that when the presence of cirrhosis is taken in account, AFP levels at the diagnosis time no longer predict the survival time. However, a multistate model showed that changes in AFP levels are related to risk of death.

The patients were treated mainly by Adriamycin, but a few cases underwent resection or transplantation. AFP levels were measured on all patients at the start of the treatment and subsequently at convenient time points during the follow-up period.

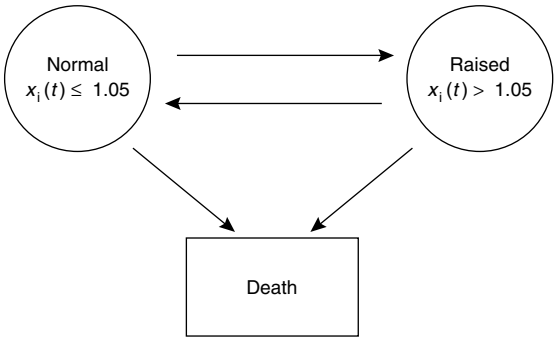

Figure 1 The three-state model for hepatocellular carcinoma

If $z_i(t)$ represents the AFP value recorded at time t for the ith patient, then the transient stages of the disease are defined based on 5% increase of $\log z_i(t)$ over the baseline value, as shown in Figure 1; this is

$$x_i(t) = \frac{\log z_i(t)}{\log z_i(0)}$$

HIV Infection

The understanding that individuals infected with human immunodeficiency virus (HIV) pass through various stages from infected but antibody-negative to acquired immune deficiency syndrome (AIDS) diagnosis implies that the mathematical modelling of the infection process is most naturally carried out using a multistate model.

To analyze the natural course of this disease, Longini et al. [18] use data on the progression of individuals to AIDS arranged in cohorts of persons recently infected whose serum specimens were found to be positive. The multistate model for HIV infection was defined using five states, as shown in Figure 2. The first stage is HIV infection but with antibody-negative status, the second is antibody-positive status but asymptomatic. The third stage occurs when an individual develops an abnormal hematologic indicator and/or prodromal illnesses (pre-AIDS symptoms), such as persistent generalized lymphadenopathy and oral candidiasis. The fourth stage is clinical AIDS. A fifth stage is included in the model to represent death due to AIDS.

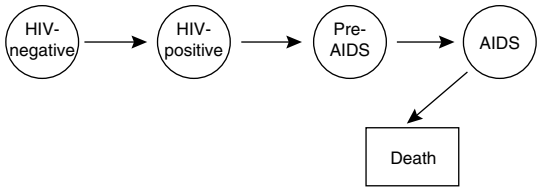

Figure 2 The multistate model for four stages of HIV infection

The Natural Course of Diabetic Retinopathy

Marshall and colleagues [19, 20] showed the results of implementing a multistate model for diabetic retinopathy in patients with type I diabetes. The study data came from the follow-up of 277 subjects who had type I diabetes for at least 5 years and ranged in age from 14 to 29 years when initially seen at the Eye-Kidney Clinic of the Barbara Davis Center for Childhood Diabetes at the University of Colorado Health Sciences Center. The Eye-Kidney Clinic was open to all patients 14 years of age or older who have had type I diabetes for at least three years. The average duration of insulin-dependent diabetes mellitus for this population was approximately 10 years, ranging from 3 to 28 years. The sex ratio was approximately one-to-one.

All subjects were seen longitudinally at least twice, with visits at an average of 1 year apart, for a mean follow-up of three years. A total of 882 patient visits occurred during the study period, an average of 3.2 visits per subject. At each visit, a retinal specialist graded retinal findings using a modified Airlie House classification [11] in which grade I indicates no retinopathy; grade II indicates microaneurysms only; grades III and IV indicate intermediate stages of background retinopathy; and grades V and VI indicate pre-proliferative and proliferative retinopathy, respectively. The worst eye grade for each visit was used to define the subject's state at the time of the visit. A four-state model was proposed to study the natural history of this disease, as shown in Figure 3.

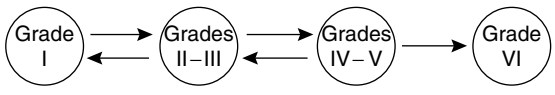

Figure 3 The multistate model for four stages of diabetic retinopathy defined on the basis of eye grades according to the Airlie House classification

Continuous-time Markov Processes

The theory of continuous-time, finite-state Markov processes is available from many sources (see, for example, [6] or [8]). Suppose we observe a continuous-time **stochastic process** $\{X(t), t \geq 0\}$ with a finite number of values in $E = \{1, 2, \ldots, k\}$ called states. We say that $\{X(t)\}$ is a continuous-time Markov process if for all times $t > s > u > 0$, and for any states i, j and $h \in E$,

$$\begin{aligned}\Pr\{X(t) = j | X(s) = i, X(u) = h\} \\ = \Pr\{X(t) = j | X(s) = i\}. \end{aligned} \quad (1)$$

This **conditional probability** represents the probability of a transition from the state i at time s to the state j at time t, and it is denoted as $p_{ij}(s, t)$. Clinically speaking, this property says that the clinical history of a patient with the disease is summarized entirely by the current stage of the disease. These transition probabilities have the basic properties, $0 \leq p_{ij}(s, t) \leq 1$, $p_{ii}(t, t) = 1$, $p_{ij}(t, t) = 0$ if $j \neq i$, and

$$\sum_{j=1}^{k} p_{ij}(s, t) = 1.$$

For any time τ in the interval (s, t) the transition probability $p_{ij}(s, t)$ can be written, using the Chapman–Kolmogorov equation, as

$$p_{ij}(s, t) = \sum_{v=1}^{k} p_{iv}(s, \tau) p_{vj}(\tau, t).$$

This equation, in matrix notation, is

$$\mathbf{P}(s, t) = \mathbf{P}(s, \tau)\mathbf{P}(\tau, t),$$

where $\mathbf{P}(s, t)$ is the transition probability matrix of dimension $k \times k$ with elements $p_{ij}(s, t)$.

The Markov process $X(t)$ is characterized by the transition intensities

$$\lambda_{ij}(t) = \lim_{\mathrm{d}t \to 0} \frac{\Pr\{X(t + \mathrm{d}t) = j | X(t) = i\}}{\mathrm{d}t}, \quad i \neq j$$

which represent instantaneous transition rates between the different states. For mathematical convenience,

$$\lambda_{ii}(t) = -\sum_{j \neq i}^{k} \lambda_{ij}(t).$$

The transition probability, $p_{ij}(s, t)$, satisfies the Kolmogorov forward differential equations

$$\frac{\mathrm{d}p_{ij}(s, t)}{\mathrm{d}t} = \sum_{v=1}^{k} p_{iv}(s, t)\lambda_{vj}(t),$$

or, in matrix notation,

$$\frac{\mathrm{d}\mathbf{P}(s, t)}{\mathrm{d}t} = \mathbf{P}(s, t)\mathbf{\Lambda}(t), \quad (2)$$

with the initial condition $\mathbf{P}(t, t) = \mathbf{I}$, where $\mathbf{I}$ is the $k \times k$ identity matrix.

Important mathematical simplifications are obtained by assuming that the process is homogeneous in time. The consequences of this assumption are that the transition intensities between the different states $\lambda_{ij}(t)$ are constant over time, and the transition probabilities $p_{ij}(s, t)$ depend only on the time differences $t - s$. Eq. (2) reduces to a system of differential equations with constant coefficients,

$$\frac{\mathrm{d}\mathbf{P}(t - s)}{\mathrm{d}t} = \mathbf{P}(t - s)\mathbf{\Lambda},$$

for which the closed-form solution is

$$\mathbf{P}(t - s) = \mathrm{e}^{\mathbf{\Lambda}(t-s)} = \sum_{n=0}^{\infty} \frac{\{\mathbf{\Lambda}(t - s)\}^n}{n!}.$$

If $\mathbf{\Lambda}$ has distinct **eigenvalues**, $\rho_1, \rho_2, \ldots, \rho_k$, and $\mathbf{A}$ is a square matrix where the jth column is the right **eigenvector** associated with ρ_j, then

$$\begin{aligned}\mathbf{P}(t - s) = \mathbf{A}\ \mathrm{diag}\{\exp[\rho_1(t - s)], \exp[\rho_2(t - s)], \\ \ldots, \exp[\rho_k(t - s)]\}\mathbf{A}^{-1}. \end{aligned} \quad (3)$$

Individual transition probabilities can be calculated, for any value of $t - s$, as

$$p_{ij}(t - s) = \sum_{v=1}^{k} a_{iv} \exp[\rho_v(t - s)]a^{vj}, \quad (4)$$

where a_{ij} and a^{ij} represent the elements (i, j) of the matrices $\mathbf{A}$ and $\mathbf{A}^{-1}$, respectively.

The Model

Suppose we have a model with $k - 1$ transient disease states $j = 1, \ldots, k - 1$ and a single absorbing state $j = k$, as in Figure 4. The transient states

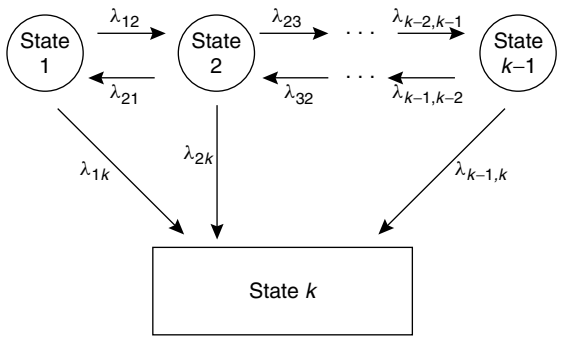

Figure 4 A multistate model with $k-1$ transient states and one absorbing state. The model has a total of $3k-5$ parameters

are assumed to be ordered according to j and instantaneous transitions can take place from state j to the adjoining states $j-1$ or $j+1$. Transitions can also take place from any of the transient states to the absorbing state k.

Submodels can be obtained by eliminating some of the parameters when some of the transitions are theoretically impossible or are unlikely to be observed during the study time. Longini et al. [18] use a submodel to describe the incubation period of AIDS with only progression transitions to the adjoining states (see Figure 2).

For the model in Figure 4 the transition intensity matrix $\mathbf{\Lambda}$ can be written as

$$\mathbf{\Lambda} = \begin{pmatrix} -(\lambda_{12}+\lambda_{1k}) & \lambda_{12} & \dots & 0 & \lambda_{1k} \\ \lambda_{21} & -(\lambda_{21}+\lambda_{23}+\lambda_{2k}) & \dots & 0 & \lambda_{2k} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & -(\lambda_{k-1,k-2}+\lambda_{k-1,k}) & \lambda_{k-1,k} \\ 0 & 0 & \dots & 0 & 0 \end{pmatrix}. \tag{5}$$

When equally spaced observations are available, and where a discrete time Markov model can be considered, a continuous-time Markov model will be more **parsimonious**. This model has $3k-5$ different parameters, in contrast to a discrete-time model with $k(k-1)$ independent parameters.

Regression Models

Suppose that each individual under study has an associated vector of **covariates** $\mathbf{z}' = (z_1, z_2, z_3, \dots, z_p)$ representing a set of characteristics and natural risk factors associated with the disease process. For a given value of this set of characteristics $\mathbf{z}$, we assume that the Markov process is homogeneous with an intensity matrix $\mathbf{\Lambda}(\mathbf{z})$ similar to the intensity matrix $\mathbf{\Lambda}$ in (5) with elements

$$\lambda_{ij}(\mathbf{z}) = \lambda_{ij} \exp(\beta_{ij}'\mathbf{z}), \tag{6}$$

where λ_{ij} represent the baseline transition rate, and β_{ij} represents the vector of regression coefficients associated with $\mathbf{z}$ for the transition from state i to state j. According to this model, for each possible transition between two states, we introduce a proportional intensity model similar to the **Cox regression model** with constant **hazard** function. Model (6) implies that each risk factor considered in the model may have a different effect in the progression and/or regression of the disease.

We must consider two types of **model** selection procedure in the context of this multistate Markov model. The first, more classical in statistical analysis, is the selection of covariates associated significantly with the progression and regression of the process. Given the large number of parameters associated with each covariate in model (6), it seems reasonable to consider a forward selection procedure. The second, more specific to this multistate model, relates to the selection of the most parsimonious representation of the association between each covariate and the disease process. Consider the case of a model with a single covariate. In the context of the four-state model for diabetic retinopathy (Figure 3), there are three natural models for representing the effect of the covariate. The first, named the saturated model, is defined as the model in which the effect of the covariate differs in each of the five disease transitions. In this model we have a total of 10 parameters, five baseline transition intensities, and five different regression coefficients.

The second model, named the progression and regression (PR) model, is defined as the model in which the effect of the covariate is the same for all progression transitions, and the same for all regression transitions. More formally, we formulate this model by assuming that the **null hypothesis** $H_0 : \beta_{j,j+1} = \beta_p$ and $\beta_{j,j-1} = \beta_r$ is true. Under this

hypothesis the number of parameters associated with each covariable reduces from five to only two. We can write the proportional intensity model (4) under this hypothesis as

$$\lambda_{ij}(z) = \begin{cases} \lambda_{ij} \exp(\beta_p' \mathbf{z}), & j = i+1, \\ \lambda_{ij} \exp(\beta_r' \mathbf{z}), & j = i-1. \end{cases} \quad (7)$$

Finally, the third model, called the progression minus regression (PMR) model, is where the effect of the covariate is the same for all progression transitions and the same, but with a sign change, for all regression transitions. Formally,

$$\lambda_{ij}(z) = \begin{cases} \lambda_{ij} \exp(\beta' \mathbf{z}), & j = i+1, \\ \lambda_{ij} \exp(-\beta' \mathbf{z}), & j = i-1. \end{cases} \quad (8)$$

Survival Analysis

A point of major interest in practical applications is the relationship between the Markov model and **survival analysis** functions, including the survival function, the hazard rate function, the median lifetime, the mean lifetime (*see* **Life Expectancy**) and the residual mean lifetime. Let T be a **random variable** which represents the lifetime of individuals in a homogeneous population. The survival function, given that the process is in state i at time $s = 0$, $S_i(t) = \Pr\{T > t | X(0) = i\}$, for a subject with covariables $\mathbf{z}$, is

$$S_i(t|\mathbf{z}) = 1 - p_{ik}(t; \mathbf{z}),$$

where $p_{ik}(t; \mathbf{z})$ is the (i, k)th element of the transition probability matrix $\mathbf{P}(t; \mathbf{z})$. The density function, expressed in terms of the survival function, $f_i(t) = -\,\mathrm{d}S_i(t)/\,\mathrm{d}t$, for a subject with covariables $\mathbf{z}$, is

$$f_i(t|\mathbf{z}) = \sum_{j=1}^{k-1} p_{ij}(t; \mathbf{z}) \lambda_{jk}(\mathbf{z}).$$

The hazard function $h_i(t|\mathbf{z}) = f_i(t|\mathbf{z})/S_i(t|\mathbf{z})$ as a function of the transition probabilities and intensities is

$$h_i(t|\mathbf{z}) = \sum_{j=1}^{k-1} \frac{p_{ij}(t; \mathbf{z})}{\sum_{v=1}^{k-1} p_{iv}(t; \mathbf{z})} \lambda_{jk}(\mathbf{z}),$$

which represents a weighted mean of the transition rates from the transient states to the absorbing state k.

The median lifetime from the transient state i to the absorbing state k is defined as the value of $t = \xi_i$ that satisfies $p_{ik}(\xi_i; \mathbf{z}) = 0.5$. The mean lifetime, $\mathrm{E}_i = \mathrm{E}\{T | X(0) = i\}$, is also a parameter of interest. Again, in terms of the transition probabilities, the mean lifetime is

$$\begin{aligned} \mathrm{E}_i(\mathbf{z}) &= \int_0^\infty S_i(t|\mathbf{z})\, \mathrm{d}t \\ &= \sum_{j=1}^{k-1} \sum_{v=1}^{k-1} a_{iv}(\mathbf{z}) \left(\frac{-1}{\rho_v(\mathbf{z})} \right) a^{vj}(\mathbf{z}), \end{aligned}$$

provided $\rho_v(\mathbf{z}) < 0$, for every state $v < k$. Finally, the residual mean lifetime, $m_i(t) = \mathrm{E}\{T - t | X(0) = i\}$, can be expressed in terms of the Markov model as

$$\begin{aligned} & m_i(t|\mathbf{z}) \\ &= \frac{\int_t^\infty S_i(u|\mathbf{z})\, \mathrm{d}u}{S_i(t|\mathbf{z})} \\ &= \frac{\sum_{j=1}^{k-1} \sum_{v=1}^{k-1} \left[\frac{-1}{\rho_v(\mathbf{z})} \right] a_{iv}(\mathbf{z}) \exp[\rho_v(\mathbf{z}) t] a^{vj}(\mathbf{z})}{1 - p_{ik}(t; \mathbf{z})}. \end{aligned}$$

The Data

The type of data collected will be different in each application and is directly dependent on the nature of the process. When the exact transition times of the process $\tau_1, \ldots, \tau_{m'}$ are available (see Figure 5), the statistical methods for estimating the parameters of the multistate model are straightforward.

Closed-form solutions for the **maximum likelihood** estimates can be derived for the basic model,

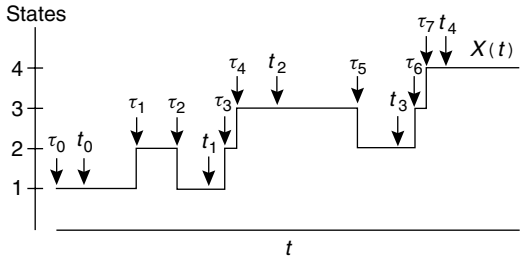

Figure 5 An example of a process with four states. The τ_i are the actual transition times and the t_i are the observation times of the process

Table 1

Patient	Data				
1	(0,2)	(41,2)	(78,1)	(95,3)	(104,4)
2	(0,1)	(17,1)	(52,4)		
3	(0,3)	(23,2)	(58,3)	(72,2)	

and an approach similar to fitting exponential regression models can be used for the model with covariables.

In clinical studies in which each realization of the process is a different patient, it is very unusual to observe the exact transition times. Data are typically only available at the times of visits to the clinic, $t_0, t_1, \ldots, t_{m+1}$, as shown also in Figure 5. We assume that the data obtained on each subject are unequally spaced in time, and that the exact transition times are not available. For a model of $k = 4$ states, the data shown in Table 1 correspond to weeks from the date of diagnosis and the state of the disease of the patient at that specific date [16]. At the date of diagnosis, patient 2 was in state 1, and 17 weeks later patient 2 was in state 1. This patient could have remained in state 1 for the whole 17 weeks, or could have transferred out of state 1 and back in again. Thirty-five weeks later, at week 52, the patient died. Survival times for these patients are 104 weeks for patient 1, 52 weeks for patient 2 and more than 72 weeks for patient 3. The data of patient 3 represent a **censored** observation.

The Likelihood Function

Suppose that the observation times for a subject are $t_0 < t_1 < \cdots < t_m < t_{m+1}$, and that $x(t_0) = i_0, x(t_1) = i_1, \ldots, x(t_{m+1}) = i_{m+1}$ represent the observed states of the process at these times. Then the joint distribution of $X(t_1), X(t_2), \ldots, X(t_{m+1})$ given $X(t_0)$ and the vector of covariables $\mathbf{z}$ can be represented, using the Markov property (1) and conditional probabilities, as

$$\prod_{j=1}^{m+1} p_{i_{j-1},i_j}(\mathbf{\Delta} t_j; \mathbf{z}), \tag{9}$$

where $\mathbf{\Delta} t_j = t_j - t_{j-1}$.

The above expression represents the contribution to the **likelihood** function for this subject if the arrival time in the absorbing state is interval-censored, i.e. if the time of transition to the absorbing state is unknown. In survival studies, t_{m+1} may represent the exact arrival time in the absorbing state k, which is the lifetime, or it may represent the end of the study for this subject, which is the censoring time.

Let $T = \tau$ be the exact arrival time in state k, and c be the censoring time for this subject. Then $t_{m+1} = \min(\tau, c)$ and

$$\delta = \begin{cases} 1, & \text{if } \tau \le c, \\ 0, & \text{if } \tau > c. \end{cases}$$

If $\delta = 1$, then the contribution of this last transition to the likelihood is

$$f_{i_m}(\mathbf{\Delta} t_{m+1}|\mathbf{z}) = \sum_{j=1}^{k-1} p_{i_m,j}(\mathbf{\Delta} t_{m+1}; \mathbf{z})\lambda_{jk}(\mathbf{z}),$$

and if $\delta = 0$ the contribution is $S_{i_m}(\mathbf{\Delta} t_{m+1}|\mathbf{z}) = 1 - p_{i_m,k}(\mathbf{\Delta} t_{m+1}; \mathbf{z})$. The above expression for $\delta = 1$ is a continuous-time version of Kay's likelihood contribution [16].

The likelihood function for this subject can then be written as

$$L_h(\theta) = \prod_{j=1}^{m} p_{i_{j-1},i_j}(\mathbf{\Delta} t_j; \mathbf{z})\{f_{i_m}(\mathbf{\Delta} t_{m+1}|\mathbf{z})\}^{\delta} \times \{S_{i_m}(\mathbf{\Delta} t_{m+1}|\mathbf{z})^{1-\delta}\}. \tag{10}$$

The full likelihood can be obtained from the product of the individual contributions. The subject subscript h has been omitted for $m, i_j, t_j, \mathbf{z}$, and δ in (10) and in the rest of this article, for simplicity.

With the expression of the first factor in (10), this likelihood function is equal to the likelihood for **parametric models in survival analysis** with censored observations. For a model with two states ($k = 2$), and with constant transition intensities, this Markov model reduces to a survival model using the **exponential distribution**. In particular, $p_{11}(t|\mathbf{z}) = \exp\{-\lambda_{12}(\mathbf{z})t\}$ and $p_{12}(t|\mathbf{z}) = 1 - \exp\{-\lambda_{12}(\mathbf{z})t\}$, and the contribution of this observation to the likelihood is $\{f(t_{m+1}|\mathbf{z})\}^{\delta}\{S(t_{m+1}|\mathbf{z})\}^{1-\delta}$.

The likelihood function (10) can be extended to the case of **time-dependent covariates** $\mathbf{z}(t)$ by replacing $\mathbf{z}$ by $\mathbf{z}_{j-1}$, where the covariates are assumed to be constant between two observations $\mathbf{z}(t) = \mathbf{z}_{j-1}$, for $t_{j-1} \le t < t_j$.

Parameter Estimation

Let $\theta_{ij} = (\log \lambda_{ij}, \beta_{ij1}, \ldots, \beta_{ijp})$ be the parameters associated with the transition between states i and j, and θ be a vector made up of the θ_{ij} vectors. A log **transformation** is used to prevent the baseline transition intensities from taking negative values during the iterative process of estimation. Let

$$\eta_{ij} = \log \lambda_{ij} + \beta_{ij1} z_1 + \cdots + \beta_{ijp} z_p$$

be the log transition intensity for a subject with covariables $\mathbf{z}$. Maximum likelihood estimates of θ can be found by maximizing the log-likelihood function $l(\theta) = \sum l_h(\theta)$ where

$$\begin{aligned} l_h(\theta) = &\sum_{j=1}^{m} \log\{p_{i_{j-1},i_j}(\boldsymbol{\Delta} t_j; \mathbf{z})\} \\ &+ \delta \log\{f_{i_m}(\boldsymbol{\Delta} t_{m+1} | \mathbf{z})\} \\ &+ (1-\delta) \log\{S_{i_m}(\boldsymbol{\Delta} t_{m+1} | \mathbf{z})\}. \end{aligned}$$

The first derivative of the log likelihood function with respect to θ_{uvl} is

$$\begin{aligned} \frac{\partial l_h(\theta)}{\partial \theta_{uvl}} = &\left\{ \sum_{j=1}^{m} \frac{1}{p_{i_{j-1},i_j}(\boldsymbol{\Delta} t_j; \theta)} \frac{\partial p_{i_{j-1},i_j}(\boldsymbol{\Delta} t_j; \theta)}{\partial \eta_{uv}} \right. \\ &+ \frac{\delta}{f_{i_m}(\boldsymbol{\Delta} t_{m+1} | \theta)} \frac{\partial f_{i_m}(\boldsymbol{\Delta} t_{m+1}; \theta)}{\partial \eta_{uv}} \\ &\left. + \frac{1-\delta}{S_{i_m}(\boldsymbol{\Delta} t_{m+1} | \theta)} \frac{\partial S_{i_m}(\boldsymbol{\Delta} t_{m+1}; \theta)}{\partial \eta_{uv}} \right\} \frac{\partial \eta_{uv}}{\partial \theta_{uvl}}, \end{aligned}$$

where the derivative of $f_i(t|\mathbf{z})$ with respect to η_{uv} is

$$\frac{\partial f_i(t|\mathbf{z})}{\partial \eta_{uv}} = \sum_{j=1}^{k-1} \left\{ \frac{\partial p_{ij}(t; \mathbf{z})}{\partial \eta_{uv}} e^{\eta_{jk}} + p_{ij}(t; \mathbf{z}) \frac{\partial e^{\eta_{jk}}}{\partial \eta_{uv}} \right\}$$

and where

$$\frac{\partial S_i(t|\mathbf{z})}{\partial \eta_{uv}} = -\frac{\partial p_{ik}(t; \mathbf{z})}{\partial \eta_{uv}}.$$

The derivative $\partial p_{ij}(t; \mathbf{z}) / \partial \eta_{uv}$ in the three expressions above is

$$\frac{\partial p_{ij}(t; \mathbf{z})}{\partial \eta_{uv}} = \sum_{r=1}^{k} \sum_{s=1}^{k} a_{ir}(\mathbf{z}) w_{rs}^{uv}(t; \mathbf{z}) a^{sj}(\mathbf{z}), \qquad (11)$$

where

$$w_{rs}^{uv}(t; \mathbf{z}) = \begin{cases} g_{rs}^{uv}(\mathbf{z}) \dfrac{\{\exp[\rho_r(\mathbf{z})t] - \exp[\rho_s(\mathbf{z})t]\}}{(\rho_r(\mathbf{z}) - \rho_s(\mathbf{z}))}, & \text{if } r \neq s, \\ g_{rr}^{uv}(\mathbf{z}) t \exp[\rho_r(\mathbf{z})t], & \text{if } r = s, \end{cases}$$

and $g_{rs}^{uv}(\mathbf{z})$ is the (r, s)th entry in

$$\mathbf{G}^{uv}(\mathbf{z}) = \mathbf{A}(\mathbf{z})^{-1} \frac{\partial \boldsymbol{\Lambda}(\mathbf{z})}{\partial \eta_{uv}} \mathbf{A}(\mathbf{z}).$$

The derivative of η_{uv} respect to θ_{uvl} is

$$\frac{\partial \eta_{uv}}{\partial \theta_{uvl}} = \begin{cases} 1, & \text{for } l = 1, \\ z_{l-1}, & \text{for } l = 2, \ldots, p+1. \end{cases}$$

The subscripts u and v refer to the transition between states u to v.

Quasi-Newton **algorithms** can be used to minimize $-2l(\theta)$ using only the likelihood function and finite differences to obtain numerical approximations of the derivatives, or the likelihood can be maximized using explicit expressions for the derivatives. A discussion of these two approaches can be found in Dennis & Schnabel [10] as well as a modular system of algorithms for unconstrained minimization. Dennis & Schnabel [10] also provide algorithms for computing numerical approximations to the second derivatives of the log likelihood using finite differences of the original function or the gradients if they are available.

Once we have the maximum likelihood estimates of the parameters of the transition intensity matrix $\boldsymbol{\Lambda}(\mathbf{z})$, we also have estimates of the transition probability matrix $\mathbf{P}(t : \mathbf{z} : \theta)$. In particular, an estimate of $p_{ij}(t; \mathbf{z}; \theta)$ can be obtained as $p_{ij}(t; \mathbf{z}; \hat{\theta})$.

An estimate of the asymptotic **covariance matrix** of $\hat{\theta}$ is obtained from the negative inverse of the empirical **information matrix**,

$$\hat{\mathbf{V}}(\hat{\theta}) = -\left\{ \frac{\partial^2 L(\theta)}{\partial \theta \partial \theta'} \right\}_{\theta=\hat{\theta}}^{-1}.$$

The estimate of the asymptotic **variance** of $p_{ij}(t; \mathbf{z}; \hat{\theta})$ can be found using the **delta method** as

$$\begin{aligned} \hat{\mathrm{V}}\{p_{ij}(t; \mathbf{z}; \hat{\theta})\} = &\left\{ \frac{\partial p_{ij}(t; \mathbf{z}; \theta)}{\partial \theta} \right\}_{\theta=\hat{\theta}}' \hat{\mathbf{V}}(\hat{\theta}) \\ &\times \left\{ \frac{\partial p_{ij}(t; \mathbf{z}; \theta)}{\partial \theta} \right\}_{\theta=\hat{\theta}}, \end{aligned}$$

where $\partial p_{ij}(t;\mathbf{z};\theta)/\partial\theta$ can be evaluated using (11). An estimate of the survival function can be obtained directly from the estimate of the transition probability matrix as $\hat{S}_i(t|\mathbf{z}) = 1 - p_{ik}(t;\mathbf{z};\hat{\theta})$. An approximate variance for $\hat{S}_i(t|\mathbf{z})$ is obtained as

$$\hat{\mathrm{V}}\{\hat{S}_i(t|\mathbf{z})\} = \hat{\mathrm{V}}\{p_{ik}(t;\mathbf{z};\hat{\theta})\}.$$

The Natural Course of Diabetic Retinopathy (Continued)

Diabetic retinopathy currently is the leading cause of new cases of blindness in people aged 20–74 years in the US, and is considered in most cases a progressive disease among people with insulin-dependent (type I) diabetes mellitus (IDDM).

Improvement of early stages of retinopathy as part of its natural history has been poorly understood. In the past, physicians believed diabetic retinopathy was a strictly progressive disease. Using a multistate Markov model, Garg, Marshall and colleagues [12, 20] have shown that the natural course of early diabetic retinopathy involves both progression and regression.

The course of early diabetic retinopathy in young subjects with type I diabetes was evaluated during 882 patient visits for 277 subjects over a mean of 2.7 years. All 277 subjects (138 males and 139 females) had direct ophthalmoscopy (with pupils dilated) by at least two examiners (one ophthalmologic and one pediatric), followed by color retinal photography, intravenous fluorescein angiography and slit-lamp examinations. The retinal specialist graded retinal findings as follows: a grade of I indicated no retinopathy; grades II–III microaneurysms or microaneurysms and one other finding; grades IV–V advanced background changes with intraretinal microvascular abnormalities; and grade VI proliferative retinopathy. The category assigned was that of the more severely involved eye.

Based on a modified Airlie House classification [11] of diabetic retinopathy, a four-state Markov model was used considering grades I, II–III and IV–V as transient states and grade VI as an absorbing state, as shown in Figure 3. In this case the exact arrival times at the absorbing state were interval-censored and the likelihood function (9) was used to estimate the parameters.

The influence of duration of diabetes, age, mean HbA_{1c}, diastolic and systolic blood pressure, HbA_{1c} at the visit, sex, smoking, cholesterol, and family history of hypertension on the transition intensities between various stages of diabetic retinopathy was evaluated. A model was fit for each of these factors for all transitions, as shown in Figure 3. All but gender, smoking and family history of hypertension are time-dependent covariates.

HbA_{1c} values were measured at each visit and blood pressure was measured at each visit after the patients rested in a sitting position for 5 minutes. Serum cholesterol levels were measured yearly. Cigarette smoking is a dichotomous indicator of ever having smoked. Family history of hypertension was considered positive if any first-degree relative had received medication for the treatment of hypertension before 50 years of age.

A single-covariate Markov model was used to assess the individual effects of factors associated with diabetic retinopathy using a custom-designed computer program [21]. The full model (6) with five regression coefficients, the PR model (7) with two regression coefficients, and the PMR model (8) with only one regression coefficient were fitted to each factor (Table 2). For each covariate, the most parsimonious model among these three was identified using the **likelihood ratio test**. If a given factor was found to be significantly associated with the disease process in the best model, the parsimonious representation of this factor was used later for **multiple regression** analysis.

Table 2 Likelihood ratio test of single-covariable Markov models for various factors associated with diabetic retinopathy using the full model (6), the PR model (7), and the PMR model (8). All tests are compared to a basic model without covariates

Factor	Full model $\chi^2(5)$	PR model $\chi^2(2)$	PMR model $\chi^2(1)$
Duration of diabetes	58.2	54.7[a]	47.5
Age	33.5[a]	26.3	20.2
Mean HbA_{1c}	27.2	22.2	22.2[a]
Diastolic blood pressure	12.0	10.9	10.5[a]
HbA_{1c} at the visit	10.7	9.0	8.9[a]
Gender	9.8[a]	3.6	1.6
Smoking	9.4	4.1	3.6[a]
Systolic blood pressure	6.7	6.4	6.1[a]
Cholesterol	5.0	4.5	4.4[a]
Family history of hypertension	4.5	4.3[a]	0.9

[a]Best model based on LR test.

The duration of diabetes, the age of the subject and the mean HbA_{1c} levels (mean of all assessments at or before visit time) were the factors most associated with transitions of diabetic retinopathy. Diastolic and systolic blood pressure and values of HbA_{1c} at visit times were also associated with the disease process. All other factors, including gender, mean cholesterol level (mean of all assessments at or before visit time), family history of hypertension, systolic blood pressure and a history of smoking, were not significantly associated with changes in diabetic retinopathy. The significance of the association between these factors and transition times was tested using the likelihood ratio test (Table 2). The only three factors in this study that are time-independent covariates are gender, family history of hypertension and a history of smoking.

Duration of diabetes shows similar effects in all progressive transitions and similar effects in all regressive transitions. Model (7) is chosen as the best representation for the association of this factor and diabetic retinopathy. The regression coefficient estimates for this model were $\hat{\beta}' = (0.0528, -0.2223)$, showing a significant departure from the assumption of model (8). Based on the **standard errors** of the estimates, (0.02774, 0.0456), and their **correlation** coefficient, $r = 0.5295$, we can construct a Wald test (*see* **Likelihood**) for the hypothesis, $H_0 : \beta_p = -\beta_r$ associated with model (8). By using, $\mathbf{L}' = (1, 1)$, the Wald statistic is

$$W = (\mathbf{L}'\hat{\beta})'(\mathbf{L}'\hat{\mathbf{V}}_{\hat{\beta}}\mathbf{L})^{-1}(\mathbf{L}'\hat{\beta}) = 6.80,$$

for which $p < 0.01$ based on the **chi-square distribution** with one **degree of freedom**. The equivalent likelihood ratio test for this hypothesis is $\chi^2_{(2)} - \chi^2_{(1)} = 54.7 - 47.5 = 7.2$ (Table 2). These two results confirm that the PMR model does not hold for duration of diabetes. **Confidence intervals** for the parameters in the model can be obtained by using a Wald-type test based on **normal** approximation.

Table 3 gives the estimates and the **standard errors** of the estimates for the parameters of the final multiple regression model. Duration of diabetes remained the most important factor for explaining changes in diabetic retinopathy. As expected, cumulative HbA_{1c} was the second most important clinical variable associated with transitions in retinopathy. The additional contribution of this factor in terms of the likelihood ratio chi-square test is slightly greater than the contribution without controlling for duration of diabetes. Diastolic blood pressure also remained in the model, showing that it is an independent factor associated with diabetic retinopathy.

Table 3 Parameter estimates and standard errors for the final multiple regression model

Factor	Parameter	Estimate	Standard error
Baseline	λ_{12}	0.0566	0.0075
Baseline	λ_{21}	0.0121	0.0024
Baseline	λ_{23}	0.0163	0.0035
Baseline	λ_{32}	0.0746	0.0243
Baseline	λ_{34}	0.0024	0.0011
Duration of diabetes	β_{p1}	0.0729	0.0283
Duration of diabetes	β_{r1}	−0.2084	0.0461
Mean HbA_{1c}	$\beta_{p2} = -\beta_{r2}$	0.2128	0.0386
Diastolic blood pressure	$\beta_{p3} = -\beta_{r3}$	0.0178	0.0056

The three covariates in the final model were centered in the mean values (in our study these are: 10.7 years of duration of diabetes, an HbA_{1c} value of 11.8 and a diastolic blood pressure of 70), therefore the baseline parameters represent the transition rates from one stage to another for a subject with average values for the risk factors for a given period of time, in this case 1 month. By multiplying the baseline transition estimate from state 3 to state 4 by 12 months and 100 subjects, we conclude that an average of $2.88 (= 0.0024 \times 12 \times 100)$ transitions will occur from stage 3 to stage 4 in a period of 1 year in a group of 100 subjects with average risk factors. Similar conclusions can be made from the remaining baseline transition estimates. The parameters associated with the covariates can be interpreted similarly to the regression coefficients in the Cox regression model. An increment of 1 year of duration of diabetes will increase the risk of progression of the disease process by 7.5% [$\exp(0.0729) = 1.075$] and reduce the chances of regression in the disease process by 19% [$\exp(-0.2084) = 0.81$].

Figure 6 shows estimated survival curves of the probability of remaining free of state 4 (grade VI) retinopathy for a subject with 8 years since onset of diabetes, 12% of HbA_{1c}, and a diastolic blood pressure of 70. The three curves represent the survival curves for starting in one of the three transient stages. Figure 6 shows that the probabilities of remaining free of state 4 (grade VI) retinopathy during a period of 5 years are 96%, 94%, and 86% starting from

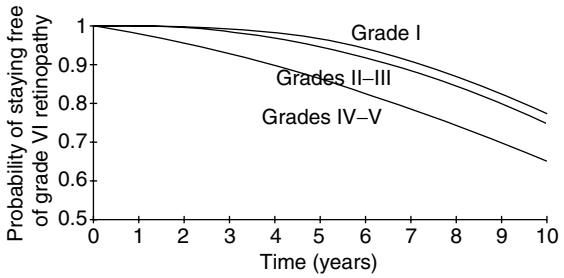

Figure 6 Survival curves for the probability of staying free of grade VI retinopathy

stages 1,2 and 3 at time 0, respectively. These probabilities dramatically decrease during a period of 10 years to 77%, 75%, and 65%, respectively.

These probabilities and Figure 6 also show that staying in stage 2 does not significantly increase the risk of progressing to diabetic retinopathy. However, stage 3 shows a significant reduction during the first 5 years of the probability of staying free of retinopathy and has similar reduction in the second 5-year period when compared to the probabilities of stages 1 and 2.

Predictive Values

The positive predictive value of a diagnostic or **screening** test refers to the proportion of individuals with positive test results who actually have the target disease or disorder, i.e. Pr(disease|positive test result). In the diagram in the article on **Sensitivity**, the positive predictive value is $a/(a+b)$. A synonym is the post-test or posterior probability of disease, given a positive test result.

Correspondingly, the negative predictive value is the proportion of individuals with negative test results who do not actually have the disease or disorder in question. This is Pr(no disease|negative test result), or $d/(c+d)$ in the diagram. A synonym is the post-test or posterior probability of no disease, given a negative test result. There is also some interest in the complement of this quantity, $c/(c+d)$, which is the post-test probability of disease, given a negative test result.

The predictive values are useful clinically, and may influence therapeutic decisions. An individual with a positive result from a test with high positive predictive value is a relatively good candidate for therapeutic intervention. Conversely, there is relatively little justification for intervention for an individual with a negative result from a test that has high negative predictive value for no disease.

Predictive values are functions both of the test characteristics, in particular sensitivity and **specificity**, and of the **prevalence** of disease in the population. For instance, if the testing is done in a high-risk population, where the prevalence (or, equivalently, the pretest probability of disease) is high, then one would expect the predictive values of disease to be relatively high. Conversely, if the disease is rare, then the predictive values for disease are relatively low; in an extreme case, even the positive predictive value may be sufficiently small that therapy cannot be justified on the basis of the test alone, particularly if the therapy is expensive or hazardous.

STEPHEN D. WALTER

Prevalence of Disease, Estimation from Screening Data

Consider a large sample survey in which the investigators have used a simple, cheap but fallible indicator of morbidity in order to assess the **prevalence** of one or more illnesses. If morbidity is estimated solely on the basis of this fallible information, then there is a possibility that the results will be **biased**. A common refinement of this sample design (particularly in psychiatric epidemiology) is to use the fallible information as a *screen* to stratify the original sample into two or more groups (usually referred to as screen positives and screen negatives), and then to subsample from these strata for a more thorough diagnostic investigation that is assumed to reveal the correct status of the subject (the **gold standard**). The results of this second phase of investigation are then used to calibrate the fallible screening instrument and to develop an **unbiased** estimator of prevalence from the whole sample. This design is an example of *two-phase sampling* (*see* **Multistage Sampling**). An alternative, related design involves supplementing the large screened sample by a completely independent *calibration* or **validation** sample of comparable subjects who are assessed using both the screen and the gold standard (*see* **Screening Benefit, Evaluation of**; **Screening, Overview**; **Screening, Models of**).

Two-phase or multiphase sampling is also often referred to as **double sampling** by survey statisticians and it is extensively used in industry as one design for lot quality assurance sampling (LQAS). In the health field it is also commonly but less satisfactorily referred to as *two-stage* or *multistage sampling*. The latter terminology is more properly and more usually applied to circumstances in which the sampling units at each stage are different (i.e. *nested* sampling designs). For example, one might take a random sample of clinics or health regions in the first stage of the survey and then randomly sample patients from within each of the selected clinics or regions. In two-phase sampling the sampling units remain the same at both phases of the survey.

The use of a **randomization** procedure while "in the field" to determine second-phase sample membership offers the possibility of concatenating initial and later phases of data collection into a single assessment of each subject. However, it is more common for first and later phases of data collection to involve both different measurement techniques and different research staff, and to take place on different occasions and in different locations. Of increasing interest is the use of registry (*see* **Disease Registers**) or other bureaucratic information systems (*see* **Administrative Databases**), such as hospital birth records, as the source of first-phase "screening" data.

The terminology of first-phase "screening" implies the purposeful application of a screening test: a cheap, robust and often noninvasive test that is, however, recognized as being fallible or less accurate than the gold standard. This is how the idea of screening was introduced in the first paragraph of the present article. From a statistical perspective, however, this is a needless limitation to this sampling design. The statistical problem remains essentially the same whether a true screening test is used to assess morbidity, or whether the screen in fact attempts to measure risk factors rather than ill health, or whether the strata in the two-phase design arise "naturalistically", say, through the operation of a patient referral process. An example of the latter would be an epidemiological study of children sampled from all hospital birth records but stratified by hospital. The critical element of the design is not the use of a screening test, but the stratification of the sampling design on a variable or variables for which inference about the outcome variable should be made marginal to the strata rather than conditional on them (*see* **Stratified Sampling**). Simple prevalence **estimation**, being marginal to all other variables, is the obvious example, but the point also applies to more general analyses. To the extent that second-phase sampling results in data missing by design, the methods to be discussed also relate to methods for data *missing at random* [19] (*see* **Missing Data**) and to the use of *surrogate* or *auxiliary* measures [22].

One final note on terminology: here we use the term "screening" to indicate the provision of a simple fallible indicator of the subjects' state in order to stratify the first-phase sample prior to subsampling and further investigation. The term "screening" is also commonly used to describe the first phase of the process of *case detection*. Suspected cases, who have been identified by the screening procedure, are then further investigated with a view to treatment (in a clinical setting) or entry into a research study, a **clinical trial** for example. In this situation interest

in the screen negatives is more limited, typically to concerns relating to **false negative** patients who ought to be receiving treatment or other forms of help, and to the costs and possible risks associated with the screening process itself. Screening for caseness is not the subject of this article, but is discussed elsewhere (*see* **Screening, Overview**).

The Analysis of Two-phase ("Screened") Samples

Prevalence Estimation Using Simple Conditional Probabilities

Figure 1 illustrates the sample selection process. From a first-phase sample of size N, $N(\mathrm{s}+)$ are screen positive and $N(\mathrm{s}-)$ are screen negative (where $N(\mathrm{s}-) = N - N(\mathrm{s}+)$). Of those subjects who are screen positive, a subsample of size $N_{v+}(\mathrm{s}+)$ are selected at random for a full diagnostic assessment (validation). These subjects will have complete data on all variables. Of these, $N_{v+}(\mathrm{s}+, \mathrm{d}+)$ are found to have a positive diagnosis and $N_{v+}(\mathrm{s}+, \mathrm{d}-)$ to have a negative diagnosis. Similarly, among the $N(\mathrm{s}-)$ screen negatives a **random sample** of size $N_{v+}(\mathrm{s}-)$ is also selected for validation. Of these second-phase subjects, $N_{v+}(\mathrm{s}-, \mathrm{d}+)$ are found to have a positive diagnosis (despite the screening information) and $N_{v+}(\mathrm{s}-, \mathrm{d}-)$ are negative. Note that the $N_{v+}(\mathrm{s}+, \mathrm{d}-)$ subjects are **false positives** (with respect to the screening information) and the $N_{v+}(\mathrm{s}-, \mathrm{d}+)$ are false negatives. Finally there are $N_{v-}(\mathrm{s}+)$ and $N_{v-}(\mathrm{s}-)$ subjects for which there are missing second-phase diagnostic data.

The proportion of cases in the screen-positive and screen-negative strata are denoted by $\pi(\mathrm{s}+)$ and $\pi(\mathrm{s}-)$, respectively. The proportion of screen positives in the first phase is ω and the proportion of screen negatives is therefore $1 - \omega$. Using simple **conditional probabilities**, the overall prevalence, π, is given by

$$\pi = \omega\pi(\mathrm{s}+) + [1 - \omega]\pi(\mathrm{s}-) \tag{1}$$

and can be estimated by inserting sample estimates of each of the components on the right-hand side of the expression. That is, ω, $\pi(\mathrm{s}+)$ and $\pi(\mathrm{s}-)$ are estimated by $n(\mathrm{s}+)/n$, $n_{v+}(\mathrm{s}+, \mathrm{d}+)/n_{v+}(\mathrm{s}+)$ and $n_{v+}(\mathrm{s}-, \mathrm{d}+)/n_{v+}(\mathrm{s}-)$, respectively.

Using the well-known **delta method**, the **variance** of π is given by

$$\begin{aligned}\mathrm{var}(\pi) = {} & \frac{\omega^2\pi(\mathrm{s}+)[1 - \pi(\mathrm{s}+)]}{N_{v+}(\mathrm{s}+)} \\ & + \frac{(1 - \omega^2)\pi(\mathrm{s}-)[1 - \pi(\mathrm{s}-)]}{N_{v+}(\mathrm{s}-)} \\ & + \frac{[\pi(\mathrm{s}+) - \pi(\mathrm{s}-)]^2\omega(1 - \omega)}{N}.\end{aligned} \tag{2}$$

This variance is estimated by insertion of the sample estimates of ω, $\pi(\mathrm{s}+)$ and $\pi(\mathrm{s}-)$, as before.

This simple approach [6] is very straightforward and that most commonly used in two-phase prevalence estimation studies. If, however, the investigator wishes to consider multiple subpopulations and/or investigate the effects of risk exposures on the prevalence of disease, then there are less cumbersome methods.

Prevalence Estimation Using Inverse Probability (Expansion) Weights

For the ith subject with complete data a *probability weight* or *expansion weight*, w_i, can be defined as the reciprocal of the sampling fraction (probability of selection) for the second-phase sample. In the simplest design the weight takes on just two distinct values, one for the screen-positive subjects and another for the screen negatives. The estimates of the sampling fractions are $n_{v+}(\mathrm{s}+)/n(\mathrm{s}+)$ and $n_{v+}(\mathrm{s}-)/n(\mathrm{s}-)$, yielding inverse probability weights of $n(\mathrm{s}+)/n_{v+}(\mathrm{s}+)$ and $n(\mathrm{s}-)/n_{v+}(\mathrm{s}-)$, respectively. The sum of the weights over the subjects in the second-phase sample will be the first-phase sample size. The sum of the products, w_iY_i, where $Y_i = 1$ for validated cases and $Y_i = 0$ for the nonvalidated

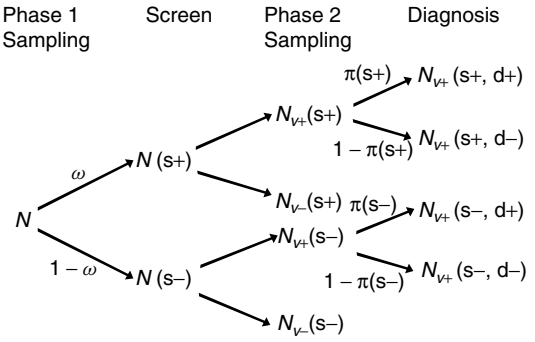

Figure 1 Two-phase data collection

cases, again over the subjects of the second phase, provides an estimate of the number of cases in the first-phase sample. An estimate of the prevalence of disorder is therefore provided by the ratio

$$\pi = \frac{\sum w_i Y_i}{\sum w_i}. \tag{3}$$

This estimator is the **Horvitz–Thompson estimator** familiar to survey methodologists (see, for example, [18]). As in the use of conditional probabilities, it is straightforward to use a *Taylor series* **linearization method** (the delta method) to estimate the variance of this ratio. Other methods of variance estimation, including the **jackknife** or **bootstrap** sampling, can also be used in the case of either of the prevalence estimation methods [18, Chapter 5].

Note that, although conditional probabilities and inverse probability weighting look superficially very different – the weighting method seeming to estimate directly the marginal model of interest while the conditional probability approach derives the marginal rate from the "uninteresting" conditional model for disease given the screen score – in this simple case the two methods of prevalence estimation are algebraically equivalent. The variance estimates, however, being based on different Taylor expansions, may differ slightly, but this is of no practical significance in large samples.

A More General Framework

Let X denote risk exposures assessed at phase 1, Z the screen score and Y the measure of true case status. If complete information were available on all subjects, the **maximum likelihood** estimator of $\boldsymbol{\beta}$, the vector of coefficients for the effects of risk exposures, would be found by maximizing the **log-likelihood** $\sum_i \log \Pr_\beta(Y_i|X_i)$. In the context of two-phase sampling, and letting i index subjects with complete data and j index subjects not selected for the second phase, then the **EM algorithm** for finding the maximum likelihood estimator would involve the iterative solution of

$$l(\boldsymbol{\beta}) = \sum_{i \in V+} \log \Pr_{\boldsymbol{\beta}}(Y_i|X_i) + \sum_{j \in V-} \mathrm{E}[\log \Pr_{\boldsymbol{\beta}}(Y|X_j)\}|\boldsymbol{\beta}^{\mathrm{c}}, X_j, Z_j], \tag{4}$$

where $\boldsymbol{\beta}^{\mathrm{c}}$ is the current estimate. Various authors have discussed the solution of such equations, primarily for categorical risk factors [4, 5, 10, 35]. Eq. (4) suggests a number of alternative estimators based on different approximations or sample-based estimates of the **expectation** term, including various forms of imputation (*see* **Multiple Imputation Methods**). In the *mean score* method of Pepe and others [22, 23, 26], the expectation is estimated by the sample average. This is equivalent to solving **score** equations of the form

$$\sum_{i \in V+} S_{\boldsymbol{\beta}}(Y_i|X_i) + \sum_{j \in V-} \times \left\{ \sum_{i \in \begin{cases} X_i = X_j \\ Z_i = Z_j \end{cases}} \frac{S_{\boldsymbol{\beta}}(Y_i|X_j)}{N_{V+}(X_i = X_j, Z_i = Z_j)} \right\} = 0, \tag{5}$$

which may be rewritten as

$$\sum_{i \in V+} \left[1 + \frac{N_{V-}(X_i, Z_i)}{N_{V+}(X_i, Z_i)} \right] S_{\boldsymbol{\beta}}(Y_i|X_i) = \sum_{i \in V+} w_i S_{\boldsymbol{\beta}}(Y_i|X_i) = 0. \tag{6}$$

The w_i here correspond to the expansion weight of the previous section. Hence, the estimating equations can be easily solved by means of weighted **regression**, with weighted **logistic regression** being the common choice.

Weighted regression estimators similar to (6) have been derived within the survey research field [2, 3]. Flanders & Greenland [11] derive the same estimator using **pseudo-likelihood** arguments, proposing the use of the variously termed "empirical", "robust", "information sandwich," "heteroscedastic consistent," and "Huberized" parameter **covariance matrix** [14]. In this case the parameter covariance matrix obtained assumes the weights W_i to be known. In practice, the weights are usually estimated and often adjusted using a variety of methods quite separate from the analysis for prevalence estimation. The weights can be **"poststratified"** [16] to conform to known population rates, or "raked" [9] to conform to some known margins, or they may

be smoothed using parametric or **nonparametric regression** methods [17], or even **trimmed** [25] or shrunken (*see* **Shrinkage**) [7]. Whatever the weights chosen, the subsequent analysis of the prevalence data can include any risk exposure measures, continuous or discrete, from either phase.

Perhaps contrary to intuition, Pepe et al. [23] illustrate how if weights are estimated by simple sample cell frequencies, then subjects in the nonvalidation set contribute information through the variation in these random weights, and worthwhile efficiency gains can be made by fully exploiting this variation rather than assuming the weights to be known. However, where some cells are empty or where one or more risk exposures or surrogate measures are continuous, the mean score method cannot be applied directly. Although under such circumstances some estimator based on smoothing might be attempted, a series of papers by Robins and others [27–29] argue that such estimators may not approach their asymptotic distribution in the moderate samples of typical studies. Instead they draw on the ideas of **semi-parametric regression** estimators to propose a modified score function of the form

$$\sum_{i \in V+} [w_i h(X_i)\varepsilon_i(\boldsymbol{\beta}) + (1 - w_i)\phi(W_i)] + \sum_{j \in V-} \phi(W_j) = 0, \quad (7)$$

where w_i is the usual expansion weight, $\varepsilon_i(\boldsymbol{\beta})$ is the simple observed minus model expected **residual**, and $h(X)$ and $\phi(W)$ are functions of the data and parameters that can be chosen to achieve optimal efficiency. Though of considerable interest, there is currently little practical experience with such estimators.

Bayesian Approaches

Many of the issues already discussed have parallels in **Bayesian methods** for multiphase sampling, including the choice as to the direction in which to model the graph [24]. Estimation is typically carried out using **Markov chain Monte Carlo** methods and *Gibbs sampling* in particular (see, for example, [12]). Although the ability to incorporate prior information may be of particular value where some screen strata may not have been subsampled, a particular focus of Bayesian work in this area has been in **model choice** and *model averaging* [36]. This typically arises where the data from the two phases are linked by happenstance rather than by formal design, for example as occurs in the overlapping samples obtained from bureaucratic systems and **capture–recapture** sampling methods, and thus where there are a number of plausible probability models that could describe the dependencies within the data. Recently, Robins & Ritov [27] have criticized the use of independent **prior distributions** for the parameters of the screen and of the diagnostic measure that have typically been used.

Comparisons of Methods

The Bayesian, conditional probability, weighting, and EM methods for a simple prevalence study are compared in Pickles et al. [24]. Schill & Drescher [30] present some comparisons for the related design where the screen is for risk exposure.

Statistical Software

In general, users of commercial statistical packages should take great care in the use of any weighting procedures provided. The use of weights within most packages (such as SPSS [20]; *see* **Software, Biostatistical**) will give the correct estimates of prevalence and **odds ratios**, but unfortunately, for the most part, will not use the appropriate variance estimator. Estimates for **confidence intervals**, for example, and associated significance tests will be invalid. This arises from the fact that the weights are typically interpreted as *frequency weights* (an indicator of the number of observations with identical data to that provided in a given record). The package accordingly treats the ith subject in the second-phase sample as if it had actually been recorded w_i times. The appropriate use of a probability weight, however, recognizes that the observation has only occurred once, but that the observed second-phase subject is representative of w_i first-phase subjects, all but one of which have not provided second-phase data. Programs such as SUDAAN [31] and STATA [34] will deal satisfactorily with weights assumed known. In general, though with substantial variation in ease of use, almost any statistical program can be persuaded to draw appropriate samples for bootstrap estimation of the variance of weighted estimates. Software for

mean score and semi-parametric regression methods is not widely available, although implementation is claimed to be straightforward. Bayesian models can now be easily fitted using Gibbs sampling programs such as BUGS [33].

Design Considerations

The relative advantages and disadvantages of screening in a two-phase survey, and also considerations of **optimal designs**, have been discussed by, among others, Deming [8] and Shrout & Newman [32]. Clearly the use of a preliminary screening instrument has potential advantages when it is both expensive, time-consuming and difficult to carry out an accurate diagnostic assessment. It is intuitively appealing (particularly for clinically trained researchers contemplating a series of long and detailed psychiatric interviews, for example) to consider some way of excluding the majority of subjects who do not have a problem in order that valuable diagnostic resources can be expended on those that do. The rarer the illness, the more appealing this idea becomes. The approach is only practically viable, however, if the potential screening procedures are cheap (relative to the full diagnostic assessment), accurate, easily administered, and accepted by the survey participants. Here accuracy implies both a high **sensitivity** and a high **specificity**, with high sensitivity being the more important of the two screening test characteristics. Clearly, we do not want a screening test which misses a relatively high proportion of our rare cases of illness. Hand [13] discusses the determination of the cut-off for a screening questionnaire that gives optimal sensitivity and specificity, and how different cut-offs may be appropriate for either prevalence estimation or case detection. Begg & Greenes [1] discuss the estimation of screen error rates from two-phase studies.

The costs involved in collecting survey data using a two-phase design come from three areas of activity: recruitment, screening, and diagnostic assessment. If it is difficult and/or expensive to recruit subjects, then the two-phase design becomes less attractive, and a better strategy might be to lower the cost of diagnostic assessment procedures. An example of the latter would be the development of fully structured interviews for use by lay interviewers. In many situations the relative gains in efficiency from two-phase sampling seem to be rather slight. In summary, in relation to single-phase designs, two-phase designs will be more efficient when the prevalence is low, and are likely to be less efficient if the screen costs more than half of the cost of the diagnostic assessment [32]. Deming [8] has argued that unless there are clear gains in terms of relative efficiency, many of the disadvantages of the design would lead us to decide not to adopt it in survey work. These include the extra administrative problems related to conducting a survey in two phases, the logistical problems in recontacting respondents selected for the second phase, scheduling their second-phase assessment and minimizing **nonresponse** and **noncompliance**. There are also the problems for the management of the more complex databases and the increased complexity in the analysis of the results. Despite all of these problems, the design seems to be growing in popularity. One suspects that investigators pay too little attention to them at the design stage of a study or, if they do, give them less weight than the obvious attractions of the design. Clinicians (and others) clearly consider that it is a waste of valuable resources to spend time assessing people without problems. The idea of only assessing a very small proportion of those likely to be well is possibly the strongest motivation for a two-phase study. Even if we accept this view we should be very wary of assessing too small a proportion of screen negatives and should definitely resist the temptation to assess none of them!

Little work has been done on the design of two-phase studies for estimating the effects of risk exposure. Design possibilities include **stratification** by potential risk factors. Palmgren [21] considers optimal design for estimating an **odds ratio** for comparing two prevalences. Reilly [26] also considers optimal two-phase designs.

Other Areas of Application

Although the purpose of this article is to discuss screening procedures for prevalence estimation, it is also useful to consider other areas of application in which either screening or two-phase sampling might be of potential value. The first is in studies specifically designed to evaluate the performance of new screening instruments or **diagnostic tests** [1]. In a prospective design all the first-phase subjects are assessed using the screen and then selected subsamples are evaluated using the gold standard. In a

retrospective study all of the first-phase subjects are given (or already have) a definitive diagnosis and in this design the selected subsamples are the ones who then get an assessment using the new test or screening procedure. Note that it is particularly important that the assessments made within the two phases (irrespective of whether the study is prospective or retrospective) are made independently, i.e. the assessors are blind to previous results (*see* **Blinding or Masking**). The value of maintaining blindness is another reason why both first-phase strata should be subsampled in a simple two-phase prevalence study (assuming, as should be the case, that first-phase results are not made available to the second-phase assessor). Similar designs might also be used in studies of diagnostic **agreement**: a trainee clinician or research student, for example, diagnosing all available patients and then their supervisor validating the diagnoses by independent assessment of subsamples of the first-phase diagnostic groups [15]. The final area of application to be mentioned here is in the use of **surrogate endpoint** measures (i.e. screens) in lengthy follow-up studies and, in particular, randomized controlled trials (*see* **Clinical Trials, Overview**). This is an area of application that is in infancy but has been discussed in the context of mean score [23] and regression methods [28].

Prevalence Rate or Ratio

The prevalence rate or ratio refers to the number of people who have a disease or condition at a given point in time in a given population divided by the number of people in that population. This quantity is also known as the *prevalence proportion*.

(*See also* **Prevalence**)

MITCHELL H. GAIL

Prevalence

Prevalence is the number of persons who have a disease or condition at a given point in time in a defined population. Sometimes prevalence refers to persons who either have currently or have previously had a disease, e.g. the prevalence of persons with a cancer diagnosis at any time up to the present. The term *prevalence* is used also to refer to the proportion of individuals with disease in the population, namely the **prevalence rate or ratio**.

MITCHELL H. GAIL

Prevalence–Incidence Bias

Bias in epidemiologic studies is a form of "systematic error in the design, conduct, or analysis of a study that results in a mistaken estimate of an exposure's effect on the risk of disease" [5]. While biases have been categorized in many ways, Rothman describes three general types: **selection bias,** *information bias*, and **confounding** [3]. Selection bias results from improper specification or selection of the study sample and leads to a distortion of the effect measured [3, 4].

Jerzy Neyman identified a form of bias in analytic epidemiologic studies which is in essence the result of the use of prevalent rather than incident cases of disease to assess etiologic relationships [2] (*see* **Causation**). *Prevalence–incidence bias* is a form of selection or sampling bias that results in part from evaluating the exposure–disease association well after the exposure first occurs. During that time interval, cases of short duration, due to death or short course of illness, cases mild in severity or asymptomatic, and cases in which the presence of disease alters or entirely removes the exposure, are missed [4].

Neyman developed a fictitious example that assessed the impact of differential survival on an etiologic association [2]. This example, which assessed the relationship between cigarette smoking and lung cancer, is shown in Table 1.

In this example, a comparison of the development of lung cancer between time 0 and time T in smokers and nonsmokers indicates a reduced risk among smokers (relative **odds ratio** = 0.44). If one assumes, however, that 95% of the lung cancer cases in nonsmokers died before time T, as opposed to only 10% of the lung cancer cases in smokers, and that lung cancer was the only source of mortality in this population, then a **case–control study** applied to those alive at time T would produce a large putative effect for smoking (relative odds = 8.0).

While clearly fictitious in terms of the known risk of smoking on lung cancer, this example serves to demonstrate the effect of using prevalent cases, at time T, to describe the risk of disease development. If an exposure, as in this example, results in selective survival and prevalent cases are used, then the estimate of the risk of disease is an overestimate. If an exposure results in selective mortality, then the estimate of the risk of disease associated with that exposure is an underestimate.

Prevalence–incidence bias is a particular problem in evaluating associations between selected risk factors and coronary heart disease [1, 4]. Many cases of coronary heart disease are rapidly fatal and some are clinically mild or asymptomatic. Each of these situations can lead a study of prevalent cases to a faulty conclusion due to an under-representation of cases. In addition, in coronary heart disease, and in perhaps other diseases, it is possible that the presence of the disease will result in a modification of the exposure being evaluated. This could make the association between an exposure and disease appear either larger or smaller than it really is. Such an example is shown in Table 2.

Here, the true risk of the development of coronary heart disease associated with high serum cholesterol, evident in the prospective study (relative odds = 2.40), is not seen in a case–control study using prevalent cases of coronary heart disease and assessment of serum cholesterol at the same time (relative odds = 1.16) [1, 4]. It is likely that persons with diagnosed coronary heart disease have altered their dietary patterns and reduced both their intake of foods high in cholesterol and their weight. It should be noted that this same change in relative odds was evident when analyses by Friedman et al. of the prospective component were restricted to persons who survived

Table 1 An example of prevalence–incidence bias using fictitious data on smoking and lung cancer [2]

	Number at time 0	Lung cancer by time T	Case–control study at time T	
			Number	Lung cancer cases
Smokers	10 000	1000[a]	9900	900
Nonsmokers	10 000	2000[b]	8100	100
Relative odds ratios	0.44		8.00	

[a]Includes 100 deaths from lung cancer.
[b]Includes 1900 deaths from lung cancer.

Table 2 Prospective versus retrospective study estimates of the relative odds of coronary heart disease among Framingham men with and without high cholesterol [1, 4]

	Prospective study[a]		Retrospective study[b]	
Cholesterol	CHD	NoCHD	CHD	NoCHD
High[c]	85	462	38	34
Low	116	1511	113	117
Relative odds ratio	2.40		1.16	

[a]Developed CHD by time T.
[b]CHD present at time T.
[c]Cholesterol measured at exam. 1 in prospective study and at exam. 6 in retrospective study.

the full time period, lending further credence to the possibility that prevalent cases of coronary heart disease may have altered their lifestyles, which resulted in lower serum cholesterol [1, 4].

In summary, prevalence–incidence bias is likely to exert its effect when a considerable amount of time elapses between exposure and selection of subjects for a study [4]. It is a bias that can result in either an overestimate or underestimate of the true risk of disease associated with a particular factor and is evident in case–control studies where prevalent, rather than incident, cases are selected as subjects.

The ability to correct, or even measure, the spurious effect caused by this bias is limited at best [4]. Avoidance of this form of bias is not simply achieved through the use of incident rather than prevalent cases in a case–control study. Ascertaining the true association between the exposure and the disease can only be achieved through the use of a prospective study of incident disease (*see* **Cohort Study**).

Prevalent Case

A prevalent case is a subject with a given disease or condition who is alive in a defined population at a given time. Sometimes the condition may refer to the previous occurrence of an illness, as for persons who now have or who previously have had cancer. Thus, prevalent cases include subjects who developed disease previously as well as **incident cases** who just developed disease.

MITCHELL H. GAIL

Preventable Fraction

When considering a protective exposure or intervention, an intuitively appealing alternative to **attributable risk** (AR) is the preventable fraction (PF). The preventable or prevented fraction measures the impact of an **association** between a protective exposure and a disease at the population level. It is defined as the proportion of disease cases averted by a protective exposure or intervention (5). It can be formally written as:

$$PF = \frac{\Pr(D|\overline{E}) - \Pr(D)}{\Pr(D|\overline{E})}, \tag{1}$$

where $\Pr(D)$ is the probability of disease in the population, which may have some exposed (E) and some unexposed ($\overline{E}$) individuals, and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same population but with all (protective) exposure eliminated. Another formulation of PF is the proportion of cases prevented by the (protective) factor or intervention among the totality of cases that would have developed in the absence of the factor or intervention [5], which is why the denominator in (1) is the hypothetical probability of disease in the population in the absence of the protective factor.

PF can be rewritten as:

$$PF = \Pr(E)(1 - RR), \tag{2}$$

where $\Pr(E)$ denotes the **prevalence** of the protective exposure in the population and RR the **relative risk**. As is apparent from (2), PF depends both on the prevalence of the protective exposure and the strength of the association between the protective exposure and disease, in a similar fashion as for AR. A strong association between exposure and disease (marked by a low RR) may therefore correspond to a high or low value of PF, depending on the prevalence of exposure, and portability from population to population is not a common property of PF.

For a protective factor ($RR < 1$), PF lies between 0 and 1 and is usually expressed as a percentage. PF increases with the prevalence of exposure and the strength of the association between exposure and disease. PF is null in the absence of association between exposure and disease ($RR = 1$) and negative when the exposure factor is a risk factor ($RR > 1$), in which case there is no rationale for using PF as a measure of impact.

Counter to what intuition might suggest, PF is not a mere negative AR; that is, PF does not equal $-AR$ (unless $RR = 1$). The relationship between AR and PF was worked out by Walter [6] and is given by

$$1 - PF = \frac{1}{1 - AR}. \tag{3}$$

For a protective factor, AR is negative but can be made positive by reversing the coding of exposure. Under reverse coding, the exposed (protective) level is relabeled as the reference level and the unexposed level as the "exposed", which leads to a positive value of AR. This value is interpreted as the proportion of cases attributable to lack of exposure to the protective factor and which could therefore potentially be prevented by generalizing exposure in the population. This valid interpretation of AR under reverse coding has been used in the literature. For example, a positive AR for protective dietary factors was estimated in a **case–control study** of gastric cancer [3]. AR under this interpretation is sometimes called the preventable fraction [2, 4], which may introduce some confusion.

It is important to note that the value of AR under reverse coding differs from the value of PF. For instance, if RR and $\Pr(E)$ are both equal to 0.5, then PF is equal to 0.25 (or 25%), and the value of AR obtained by reversing the coding is 0.33 (or 33%). This difference is not surprising in view of the differing definitions of AR and PF. AR, with reverse coding, measures the potential reduction in disease cases if all subjects in the current population became exposed (if the absence of exposure were eliminated from the population), while PF measures the reduction in disease cases obtained by moving from a totally unexposed population to the current population with exposure prevalence given by $\Pr(E)$.

Given their close relationship, AR and PF share the same properties. Regarding the interpretation of PF, the above definition implies that PF measures the actual reduction in disease load due to exposure. This interpretation is fully warranted only under the same conditions that ensure the validity of the interpretation of AR as the actual reduction of disease corresponding to the elimination of exposure. These conditions are **unbiased** estimation of PF, a causal role for the exposure (*see* **Causation**), and

invariance (*see* **Sufficient Statistic**) of the distribution of the other factors influencing disease occurrence under a change in the exposure distribution. It might therefore be wiser to define PF as the *potential* reduction in disease load *associated with* exposure.

PF can not only be defined with regard to a protective exposure factor, but also to the *de novo* introduction of a prevention program in the target population (e.g. an intervention designed to reduce smoking). In such a case, since the prevalence of the program is equal to zero before its implementation, one can assess the impact of its introduction through the estimation of PF. Clearly, the impact depends both on the effectiveness of the program and its diffusion in the population (i.e. the prevalence of "exposure" to the program), which is reflected in the estimate of PF. This has been suggested as an analytic tool for assessing the effects of interventions [1].

It follows from (3) that estimability and **estimation** issues are similar for AR and PF. Adjusted PF estimates based on the **Mantel–Haenszel** approach have been derived for **cohort**, case–control and **cross-sectional studies** [2]. Unadjusted estimates and adjusted estimates based on the weighted-sum approach have been derived for cross-sectional studies, and corresponding sample size calculations are available for using a test that PF equals 0 to assess interventions [1].

JACQUES BENICHOU

Prevention Trials

There is a considerable history of the use of randomized **clinical trials** to assess strategies for the primary prevention of disease. For example, in the US, major coronary heart disease prevention trials date from the 1960s [7, 9, 10] to the present, while a number of trials have been initiated over the past one to two decades that focus on the prevention of major cancers and other important diseases. Primary prevention trials generally focus on reducing the occurrence rate of one or more diseases, in contrast to **screening trials**, which aim to reduce mortality rates through early detection and effective treatment of disease.

However, the history of primary prevention trials is quite modest compared with that of therapeutic trials that assess strategies for the treatment of established disease. In fact, the role and place of primary prevention trials in relation to other research strategies remains controversial, and is an important topic for further methodologic research. It is useful to review some basic features of prevention trials to explain the reasons for controversy, and to highlight research needs.

First, consider the nature of the interventions or the treatments to be assessed or compared. In therapeutic research, these arise typically from basic biological research in conjunction with drug screening studies. While such sources may also generate primary disease prevention hypotheses, particularly for chemoprevention trials, observational epidemiologic sources (*see* **Observational Study**) also provide a common and important source of prevention trial hypotheses. For example, preventive interventions may involve such "lifestyle" maneuvers as physical activity increases, nutrient consumption reductions or supplementation, or modifications of sexual behavior.

A therapeutic trial among patients diagnosed with a serious disease will aim typically to identify effective treatments for the reduction of a frequent outcome, such as disease recurrence or death, and may need to be of only one or two years' duration. In contrast, a primary prevention trial of a common vascular disease or cancer will typically focus on the reduction of incidence of a disease typically occurring at a rate of 1% per year or less, and will assess interventions that may require several years to realize the most important of their hypothesized effects. Hence, therapeutic trials may require relatively small numbers of patients (*see* **Sample Size Determination for Clinical Trials**), perhaps only a few hundred, while primary prevention trials may require tens of thousands of subjects, with resulting logistical challenges and substantial costs. To cite a particular example, the Multiple Risk Factor Intervention Trial (MRFIT) [10] of combined hypertension treatment, blood cholesterol lowering and smoking cessation vs. control for the prevention of coronary heart disease, involved the **randomization** of over 12 000 middle-aged and older men thought to be at high risk of coronary heart disease, with an average follow-up duration of over seven years. Only about 2% of MRFIT men experienced the designated primary outcome (*see* **Outcome Measures in Clinical Trials**), coronary heart disease mortality, by the planned date of study completion. The cost of the trial was reported to be in the vicinity of US$100 million.

The size and cost of prevention trials may be increased further by the need to be conservative in establishing intervention goals to ensure the safety of ostensibly healthy study subjects for whom the ability to monitor adverse events carefully may be somewhat limited. In contrast, a therapeutic trial of frequently monitored patients may be able to risk toxicity to achieve efficacy. Furthermore, the long duration of prevention trial follow-up may imply a noteworthy reduction in adherence to intervention goals over time, resulting in important increases in the necessary sample size.

The interventions studied in a prevention trial, like the treatments assessed in a therapeutic trial, may have the potential to affect various disease processes, beneficially or adversely, in addition to those specifically targeted for reduction. In view of the typical dominance of the patient's disease, these other effects are often relatively unimportant in a therapeutic trial. In a prevention trial, however, overall benefit vs. risk assessments (*see* **Health Economics**) can be quite different from the assessment for the designated primary outcome alone. Even a fairly rare adverse effect can eliminate the public health utility of a preventive maneuver. The need to assess the interventions in terms of suitable measures of benefit vs. risk has implications for trial design and particularly for trial monitoring and reporting.

Role Among Possible Research Strategies

In view of the above litany of obstacles and challenges, it seems logical to take the viewpoint that a full-scale disease prevention trial is justified only if the interventions to be assessed have sufficient public health potential, and if alternate less costly research strategies appear unable to yield a sufficiently reliable assessment of intervention effects. If the intervention of interest falls outside the range of common human experience, as is often the case with chemopreventive interventions, there is little debate that randomized controlled trials constitute the research strategy of choice, and the discussion can focus on public health potential and research costs. However, if the intervention is already practiced in varying degrees by large numbers of persons, purely observational approaches may sometimes provide reliable disease prevention information at lesser cost, and perhaps in a shorter time, than can a randomized, controlled intervention trial. In fact, a single observational study; for example, a **cohort study**, may be able to assess a broader range of interventions than is practical to include in the design of a randomized prevention trial.

However, key determinants of observational study reliability include the ability to control **confounding** and the ability to measure accurately the level of intervention adopted. **Measurement error** in the "exposure" histories of interest, or in confounding factors histories, can invalidate observational study hypothesis tests and estimates of intervention effects. Furthermore, randomized trials have the major advantages that the **randomized treatment assignment** (i.e. intervention vs. control) is statistically independent of all prerandomization risk factors, whether or not these are even recognized, and that outcome comparisons among randomization groups (i.e. **intention to treat analysis**) typically will provide valid hypothesis tests, even if adherence to intervention varies among study subjects and is poorly measured (*see* **Compliance Assessment in Clinical Trials**).

Consider the specific context of the Women's Health Initiative (WHI) clinical trial [17, 21], which is enrolled 68 132 postmenopausal American women in the age range 50–79. This trial is designed to allow randomized controlled evaluation of three distinct interventions: a low-fat eating pattern, hypothesized to prevent breast cancer and colorectal cancer, and, secondarily, coronary heart disease; hormone replacement therapy, hypothesized to reduce the risk of coronary heart disease and other cardiovascular diseases, and, secondarily, to reduce the risk of hip and other fractures; and calcium and vitamin D supplementation, hypothesized to prevent hip fractures and, secondarily, other fractures and colorectal cancer. Each of these three interventions is already being practiced in some fashion by large numbers of postmenopausal American women. Important disease reductions can be hypothesized for each intervention, based on substantial observational studies, animal experiments (*see* **Preclinical Treatment Evaluation**) and randomized trials with intermediate outcomes (e.g. the Postmenopausal Estrogen/Progestin Intervention (PEPI) Trial [11]). In the case of hormone replacement therapy, a randomized trial is motivated by potential confounding in cohort and **case–control studies** as hormone users tend to be of higher socioeconomic status with fewer vascular disease risk factors, by the magnitude of the hypothesized benefits, and, importantly, by the need for reliable summary data on benefits vs. risks (*see* **Data Monitoring Committees**), particularly since breast cancer risk may be adversely affected by hormone replacement therapy. The dietary modification trial component is motivated by associations between international cancer incidence rates and per capita fat consumptions (*see* **Ecologic Study**), by **migrant study** data, and by rodent feeding experiments. A large number of case–control and cohort studies of dietary fat and various cancers have yielded mixed results. These latter studies rely exclusively on dietary self-reports, which are known from repeatability studies to involve substantial measurement error, though the absence of a **gold-standard** dietary measurement procedure precludes an assessment of measurement error characteristics as a function of actual dietary habits and of study subject characteristics, such as body mass. For example, Prentice [15] describes a plausible measurement model for dietary fat intake under which even the strong associations suggested by international disease rate comparisons would be essentially eliminated by random and systematic aspects of dietary assessment measurement error. Hence, the current observational studies of dietary fat in relation to cancer or other diseases may be uninterpretable, motivating the need for a randomized intervention trial to assess whether a change to a low-fat eating pattern during the middle decades of life can reduce the risk of selected cancers and cardiovascular diseases. This controversy over the interpretation of the

observational data on dietary fat points to the pressing need for objective measures of fat consumptions (i.e. biomarker measures) and for the development of flexible measurement models to allow self-report and objective exposure data to be combined in exposure–disease rate analyses. The issues of exposure measurement error, along with limited exposure variation within populations, and highly correlated exposure variables, also point to a possible greater role for aggregate (ecologic) study designs (e.g. [16]) among observational research strategies. The calcium and vitamin D component of the WHI is viewed as a comparatively inexpensive addition to the clinical trial. It is motivated by the public health potential of the intervention, as well as by observational data, and data from smaller clinical trials.

Prevention Trial Planning and Design

Suppose that an intervention having potential to prevent one or more diseases is to be subjected to a randomized controlled trial. The trial design should be responsive to the **target population** to which the intervention, if effective, might be applied. For example, the three interventions to be studied in the trial component of the WHI are all potentially applicable to the general population of postmenopausal women, and the trial will be open to women who are not otherwise practicing the interventions to any noteworthy degree. After identifying the potential target population for the intervention, there may still be reason to focus the trial on a subset of this population. There may be an identifiable subset at elevated risk for the primary outcome that could be chosen for trial participation, in order to reduce trial sample size. For example, it may be proposed that a colon cancer prevention strategy be assessed in subjects known to have had colonic polyps, or a breast cancer prevention strategy among women with a history of breast cancer among one or more first-degree relatives, even though it is hoped that the results will be applicable to a broader target population. There are several aspects to deciding on such an approach. First, although sample size may be reduced, trial logistics may be complicated and trial costs increased. For example, the costs of screening to identify eligible subjects will increase typically, and a larger number of participating clinical centers may be required. Depending on the intervention mechanism, high-risk study subjects may benefit less, by virtue of their stage in the targeted disease process, compared with other potential study subjects. Also, a focus on high-risk subjects may lead to a distorted view of the overall risks and benefits relative to the entire targeted population.

Within the target population, criteria may be needed to exclude study subjects with medical contraindications to either intervention or control regimens, study subjects who are already practicing the intervention to an unacceptable degree, or who may not adhere to intervention group requirements or to other protocol requirements (*see* **Eligibility and Exclusion Criteria**).

Even if study subjects are selected on the basis of elevated risk for the diseases that are targeted for prevention, primary outcome events may constitute a small minority of the disease events experienced by study subjects during the course of the trial, and perhaps even a small minority of disease events that may in some way be affected by intervention activities. Hence, there is an obligation to define sets of outcomes, to be carefully ascertained, including those that may plausibly be affected by intervention activities, in order to provide an opportunity to assess the overall risks and benefits in the target population.

The cost and logistics of a full-scale disease prevention trial may motivate a trial with some intermediate outcomes in place of the disease to be prevented. For example, a major trial was conducted in the US to prevent colonic polyps, rather than colon cancer, by means of a low-fat, high-fiber dietary pattern. This study makes the assumption that the formation of polyps is on the pathway between dietary habits and colon cancer occurrence, and that reduction in polyps occurrence will convey a corresponding reduction in colon cancer incidence. While the conditions for an intermediate outcome of this type to serve as a "surrogate" for the disease of interest are rather strict (see [4] and [13]), the benefits in terms of trial sample size, cost and duration may sometimes justify an intermediate outcome trial. In other circumstances, a trial with one or more intermediate outcomes may be conducted first to inform the decision concerning a trial with "harder" outcomes (*see* **Surrogate Endpoints**).

In some circumstances, the relationship between an intervention or behavior and a reduction in disease will be regarded as sufficiently well established that the research effort can shift logically to strategies to encourage the desired behavior change. Cigarette

smoking cessation or prevention in relation to lung cancer and heart disease, or breast screening by means of mammography and other techniques provide important examples. Randomized trials with such behaviors as outcomes can be classified as disease control research, rather than primary prevention research. In such studies, the intervention may sometimes be able to be delivered with particular economy to persons in natural groups, such as social groups, schools, or communities. In fact, the use of community organizations and media may even define the intervention strategy, as in the Community Intervention Trial for Smoking Cessation, which took place in 11 pairs of matched cities in the US. Such studies naturally involve **group randomization** and there is a range of interesting design and analysis issues [5, 6].

Returning to individually randomized prevention trials with disease outcomes, other design choices include the possible use of **factorial** designs, and intervention and control randomization fractions. Factorial designs have an obvious appeal in that they provide the potential to make two or more intervention comparisons in the same study population at a cost that will typically be considerably less than that for separate studies. For example, in the WHI trial, study subjects must be eligible and willing to participate in one or more of the hormone replacement or dietary intervention components, and, subsequently, are offered the opportunity to participate in the calcium and vitamin D component – a so-called partial factorial design. There is only a modest overlap between the hormone replacement and dietary intervention components due to component-specific exclusionary criteria, but a large overlap of either of these with the calcium and vitamin D component. As a result, the projected trial sample size is 68 132 rather than the 120 000 or more that would be required to assess the three interventions separately. The potential disadvantages to a factorial design are the possibility that the benefit associated with an intervention may be reduced by the presence of one or more other interventions, and the possibility that adherence to a given intervention may be reduced by the study demands or adverse effects that may arise from participation in the other interventions (*see* **Factorial Designs in Clinical Trials**).

The necessary sample size of a two-arm trial is approximately proportional to $[\gamma(1-\gamma)]^{-1}$, where γ is the fraction of the trial cohort assigned to the intervention group. Hence, if the average study costs associated with an intervention group subject are C times that for the corresponding control group, subject trial costs will be approximately proportional to $[C\gamma(1-\gamma)][\gamma(1-\gamma)]^{-1}$, which is minimized by setting $\gamma = (1 + C^{1/2})^{-1}$. For example, if study costs per intervention group subject are 2.25 times that per control group subject, then $\gamma = 0.4$, a randomization fraction that is used for the dietary intervention component of the WHI.

Upon selecting the interventions to be evaluated, the target population, and major trial outcomes, one needs to make a series of design assumptions that will determine the size of the trial cohort. Perhaps the most fundamental assumption concerns the anticipated primary endpoint intervention benefit, often expressed as a **relative risk** (hazard ratio) for fully adherent intervention vs. fully adherent control subjects as a function of time from randomization. Assumptions concerning primary endpoint disease rates in the absence of intervention, on intervention and control group adherence rates and accrual patterns, trial duration and **competing risks** can then be combined with the basic relative risk assumption to produce the sample size that will yield a significant result (e.g. at the 0.05 significance level) under design assumptions, with a specified probability or **power** (e.g. power of 90%). Various authors, including Self & Mauritsen [18], provide flexible sample size and power procedures that allow one to incorporate assumptions of this type. The WHI Study Group [21] details such assumptions for the WHI clinical trial. Corresponding primary endpoint power calculations played a major role in the specification of sample sizes of 48 000, 27 500, and 45 000 for the dietary modification, hormone replacement therapy, and calcium and vitamin D trial components, respectively.

Pilot and feasibility studies play a critical role in prevention trial planning. Such studies provide the opportunity to assess study subject recruitment rates, to evaluate the potential of a run-in period to identify and exclude study subjects who may not comply with study requirements, to observe biomarker changes that may help to establish the basic relative risk assumption, and to assess costs associated with all aspects of at least the early phases of trial operation. Information on these topics can be critically important to the development of an efficient trial design. See Urban et al. [19] for an example of the use of cost projections to inform the design choices for a low-fat

diet intervention trial, including eligibility criteria, average follow-up duration, randomization fraction and number of clinical centers. Careful consideration of subsampling rates for the collection and processing of baseline and follow-up data and specimens can also play an important role in controlling trial costs.

Conduct, Monitoring, and Analysis

A disease prevention trial requires a clear, concise protocol that describes trial objectives, design choices, performance goals and monitoring and analysis procedures. A detailed manual of procedures that describes how the goals will be achieved is necessary to ensure that the protocol is applied in a standardized fashion (*see* **Clinical Trials Protocols**). Carefully developed data collection and management tools and procedures, with as much automation as practical, can also enhance trial quality. Centralized training of key personnel may be required to ensure that the protocol is understood, and to enhance study subject recruitment, intervention adherence, and comparability of outcome ascertainment, possibly through **blinding** of the randomization assignment between intervention and control groups (*see* **Multicenter Trials**). A committee knowledgeable in the various aspects of the trial, and often external to the investigative group, typically will be required for the timely review of safety and clinical outcome data (*see* **Data Monitoring Committees**).

As mentioned previously, prevention trial monitoring for early stoppage (*see* **Data and Safety Monitoring**) will usually not only involve the designated primary outcome(s), but also some suitable measure of overall benefit vs. risks, as well as of important adverse effects. Some aspects of the proposed monitoring of the WHI clinical trial are described in Freedman et al. [3]. For example, early stoppage for benefit may be merited if the primary outcome incidence reduction is significant at customary levels ($p < 0.05$) and the summary benefit vs. risk measure is supportive (e.g. $p < 0.20$) without important adverse effects. Early stoppage based on harm may be indicated if an important adverse event is significant ($p < 0.05$) without suggestive evidence ($p > 0.20$) of benefit vs. risk. More sophisticated stopping criteria could also be considered and critical values that acknowledge the multiplicity of outcomes and of testing times need to be constructed (*see* **Multiplicity in Clinical Trials**). See Cook [1] for an example of such a construction for a bivariate response.

The basic test statistic to compare two randomization groups with respect to a failure time (disease) endpoint might often reasonably be defined to be of weighted **logrank** form:

$$\sum_{i=1}^{n} \delta_i g(t_i)[z_i - n_1(t_i)n(t_i)^{-1}],$$

where n is the total number of intervention and control study subjects, $n_1(t_i)$ and $n(t_i)$ are, respectively, the number of intervention subjects and total subjects at risk for failure at the failure time ($\delta_i = 1$) or **censoring** time ($\delta_i = 0$) for the ith subject, while z_i indicates whether the ith subject is assigned to intervention ($z_i = 1$) or control ($z_i = 0$). The test will have high efficiency if the "weight" $g(t)$ at time t from randomization is chosen to approximate the logarithm of the anticipated intervention vs. control group hazard ratio for the endpoint under test, taking account of anticipated adherence rates. For example, if this hazard ratio is expected to be approximately constant, then one might set $g(t) \equiv 1$, in which case one has the classical logrank test, while if the hazard ratio is expected to decline approximately exponentially over the follow-up period, then one might set $g(t) = t$. Adaptive versions in which the form of $g(t)$ is responsive to the evolving trial data may also be considered.

The above test can be generated as a **partial likelihood** [2] score test for $\beta = 0$ under a hazard ratio model $\exp[x(t)/\beta]$, where $x(t) = zg(t)$. This modeled regression vector can be extended to include other variables that may be intermediate between intervention activities and outcome events, in an attempt to explain intervention effects on disease outcomes. The trial monitoring process will have some effect on these tests and estimators, with typically larger effects if early stoppage occurs. The estimation of intervention effects may be biased (e.g. [20]) even for outcomes that do not contribute to early stoppage decisions. Analyses that attempt to explain intervention effects in terms of intermediate measures can often be based efficiently on case–control [8] or **case–cohort** [12] subsampling procedures, and should acknowledge measurement error in the intermediate variable assessment. See [22], which provides basic results from the WHI Clinical Trial component on combined hormones, following early

stoppage based on risks & feeding benefits as and example of important and unexpected trial results, and of the complexity of prevention trial reporting.

ROSS L. PRENTICE

Preventive Medicine

Statistics plays a central role in epidemiology and preventive medicine, particularly in interpretation of behavior, physiology, and pathology in groups of people. Preventive medicine follows in a political setting from findings of epidemiology and **clinical trials**, and modes of disease causation and transmission (*see* **Communicable Diseases**). Emphasized are the classical strategies of hygiene and avoidance of contact with infectious agents, as well as more recently discovered community and personal actions which can reduce the burden of chronic diseases; for example, heart disease, stroke, cancer, **AIDS and HIV**, injury, and violence.

History and Context

Excellent reviews of the history of epidemiology are available [7, 16, 21], and of statistics in epidemiology [8]. In 1662, a **life table** approach used London birth and death records to study seasonal variations in **infant mortality**, and excess male mortality compared with females [9]. A rudimentary clinical trial in 1747 [16, 17] addressed epidemic scurvy on long ocean voyages. Lind allocated 12 sailors to six dietary treatments for six days, and observed a near cure in the two who ate citrus fruit each day, with no improvement in the other 10 men. Following this finding, Captain James Cook lost no one to scurvy in his voyages of 1769–1778 [10]. Despite these dramatic findings, for political reasons it was 1795 before the British Navy (the "limeys") routinely added limes to its diet. Ignaz Semmelweis, in 1840, introduced hand-washing in a Vienna hospital, and observed a reduced rate of puerperal fever in maternity wards [7]. In the 1849 London cholera epidemic, John Snow counted cases according to residence. The epidemic was restricted to a geographic area served by two water companies which used sewage-polluted water from the Thames River; access to this water was blocked as a preventive action [20].

However, the population approach was virtually derailed by a medical advance; namely, the Henle–Koch postulates of the late 1800s, that diseases are caused by specific living organisms [7, 21]. These postulates led epidemiologists to focus on laboratory-based methodology for studying infectious diseases [21]. It was not until the mid-1900s that population approaches again emerged, led by suspicions that an environmental factor, smoking, caused lung cancer (*see* **Smoking and Health**), [21], by the study of risk factors for cardiovascular disease in the **Framingham study** [4], and by reduction of dental decay by use of fluoridated water in one of two New York communities [1, 16]. Currently, the population approach is flourishing, and should be of substantial value should the threat of antibiotic-resistant infections materialize, due to evolution of micro-organisms. The study of populations has extended into such fields as establishment of population norms, control of fertility, and **population genetics** [21]. The mapping of the human genome will allow an epidemiologic approach to defining the **gene–environment interaction** in human disease.

Modern epidemiologic design was not described in a textbook until 1960 [18, 21]. Design considerations and basic statistical methods relied heavily on the work of **R.A. Fisher** [5, 6]. The seminal paper alerting epidemiologists to multivariate analysis was published by **Jerome Cornfield** in 1962, using Framingham data [3]. The importance of the community itself was illustrated in Ancel Keys' cross-cultural studies of coronary heart disease, beginning in the 1950s [14].

The use of statistics in epidemiology is strongly influenced by need for causal inference (*see* **Causation**). If epidemiologic associations are not causal, then the corresponding preventive strategy – for example, using safer sexual practices to avoid AIDS – will not reduce disease risk. Fundamental principles to be considered when judging causality of an association were published by **A. Bradford Hill** [11, 12], including strength of association, consistency with other related observations, temporality (presumed cause precedes presumed effect) biological gradient, biological plausibility, and coherence with other relevant knowledge (*see* **Hill's Criteria for Causality**). Experimental design and statistical methods used in epidemiology are often geared toward answering questions about causality.

Specific Uses of Statistics in Epidemiology

Many texts describe epidemiologic methods [15] and related statistical methods [13]. Computer software

has made statistics accessible to nonstatisticians. Central to all statistical methods used in epidemiology is counting cases, most simply in the **two-by-two table**, from which may be computed the disease rates or **risk** in exposed (r_E) and in unexposed (r_U) persons. The term "rate" pertains to prevalent disease (existent at the time of study) while the term "risk" refers to incident disease (develops during the period of study). Large **relative risk** (r_E/r_U) is seen for exposures which are etiologically related to the disease in question, while large risk differences ($r_E - r_U$) in highly prevalent diseases suggest a large population **burden of disease** due to exposure.

The sampling method influences the estimation of **absolute risk** and differential risk. In the longitudinal **cohort study**, exposed and unexposed persons may be sampled at different sampling fractions. Because incident disease develops within exposure categories, diseased and nondiseased people have the same sampling fraction. The clinical trial is similar, but exposure status is (randomly) allocated by the investigator (*see* **Randomization**), participant inclusion characteristics are typically much narrower than in the general longitudinal study (*see* **Eligibility and Exclusion Criteria**), and explicit participant informed consent for randomization is required. In these longitudinal designs, r_E is estimated as the number diseased divided by the number exposed, and analogously for r_U. In **cross-sectional studies**, where exposure and disease status are determined at the same time, the analogous estimator is of a rate rather than a risk.

A different estimator is used in the **case–control study** [2, 19], which is useful in limiting the numbers of nondiseased subjects needed to study rare diseases. Diseased persons are sampled at one sampling fraction and nondiseased at another (typically much smaller) sampling fraction. Within disease categories, exposed and unexposed people are sampled at the same rate. In this case r_E and r_U are **biased**, but r_E/r_U is well approximated for rare diseases by the **odds ratio** (the odds of exposure to nonexposure in diseased divided by the odds of exposure to nonexposure in nondiseased). Case–control studies may be biased by changes in exposure made after disease onset. Attempts to correct this problem include retrospective recall of predisease exposure, and nesting cases and controls in previously collected data (*see* **Case–Control Study, Nested**).

The generalization of these designs to several categories or to continuous exposure is mathematically straightforward, the former being analyzed with a series of risk estimates, and the latter with a linear or other continuous **regression** model of risk change per unit change in exposure; **life table** versions of regression account for length of exposure. "Disease" variables may also be continuous.

Problems encountered throughout epidemiologic statistics include within-person variation and **confounding**. Because population studies of humans do not perfectly control the measurement condition, it is rare that a measure represents the participant exactly. The resulting within-person variation tends to bias differential risk estimates falsely toward zero (*see* **Bias Toward the Null**). Confounding, on the other hand, occurs when variables are correlated for reasons unrelated to the causality of the association in question. Proper inference demands that "like be compared with like" [8], whether through deconfounding or randomization. In deconfounding for drinking, differential risk of lung cancer, for example, is estimated for smokers vs. nonsmokers, first within drinkers and secondly within nondrinkers. The adjusted estimate is pooled across drinkers and nondrinkers, using standard weights for the drinking strata. Regression methods for deconfounding extend this process to multiple continuous variables; in most such methods the stratified analysis is implicit (*see* **Stratification**).

Much effort is expended in epidemiologic statistics on the ***P* value**, the chance that a given observation would have arisen if risk did not vary across exposure categories. This method is fraught with interpretive difficulties, because *P* values depend on valid model specification, on the number of comparisons made, and on the context of the interpreter. An emerging methodology is **meta-analysis**, in which replications of a particular study are formally examined for consistency. Drawbacks are that meta-analysis loosens definitions of what is being studied, and is subject to bias because studies with null findings may be less available than studies with provocative findings. Strengths are that it tends to reduce dependence on *P* values because of larger sample sizes in the combined studies than in individual studies; it increases inferential dependence on consistency across studies.

Primary Factors

One of the aims of **factor analysis** is to display the configuration of variables in as simple a manner as possible. The **eigenvalue** technique was used to find a set of axes to which variables could be referred. However, the eigenanalysis leads to a solution such that the variance of the variables is distributed across all factors. Thus, the factors do not separate out independent clusters of variables (*see* **Cluster Analysis, Variables**). **Rotation of axes** is an attempt to place the factors so that each contains only a few highly loaded variables. *Primary axes* are the factor axes that are rotated to a good fit to the configurations of the variables involved [2]. They are unit vectors that lie in the intersection of the primary factors. In the two-factor case, primary axes coincide with the primary factors. The *primary factors* represent the "ideal" variables, each of which measures one and only one common factor, with no unique factors. They provide the effective boundaries for the variables involved. *Reference vectors* are defined as the axes that are perpendicular to each of the primary factors. With the **oblique rotation**, the reference vectors are so located as to maximize the number of near-zero loadings on each of the reference-vector factors, with at least as many near-zero loadings on each factor as the number of factors. They produce a rotated factor matrix of a **simple structure**. These axes are important concepts for the understanding of factor rotation and the interpretation of the different **factor loading matrices**. Following the discussion in Cureton & D'Agostino [1], we illustrate and describe these axes in terms of the geometric model.

In a two-factor geometric model, we can represent the effective common-factor vector by a semicircle with axes a (vertical) and b (horizontal) as the initial axes. This is obtained by reflecting any negative first-factor loadings of any variables. Figure 1 presents this two-dimensional geometric model. In Figure 1, the axes 0I and 0II are vectors of unit length extending from the origin to the perimeter of the semicircle and provide the effective boundaries for the configuration of variable vectors. Variable vectors are vectors that extend from the origin to the plotted points of the variables. The locations of boundary vectors are determined by the type of transformation we apply to the initial factor matrix. Ideally, most of the variable vectors should lie on or close to the boundary vectors 0I and 0II. In Figure 1, we have variables 1, 5, and 6 lying close to the boundary vector 0I. Therefore, boundary 0I is overdetermined by variables 1, 5, and 6. Similarly, boundary vector 0II is overdetermined by variables 2, 3, and 7. Even though variable 4 is not close to either vector, the structure is quite clear. The reference vectors, labeled RI and RII, are in Figure 1. RI is the reference vector that is orthogonal (*see* **Orthogonality**) to the axis 0I and RII is the reference vector that is orthogonal to the axis 0II. In other words, the axis 0I is **correlated** with the reference vector RII but uncorrelated with the reference vector RI. Similarly, the axis 0II is correlated with the reference vector RI but uncorrelated with the reference vector RII. By definition, each reference vector is correlated with the corresponding primary axis and uncorrelated with the other. Therefore, in the two-dimensional case the boundary vector 0II coincides with the primary axis PI, and the boundary vector 0I coincides with the primary axis PII. The primary axes correspond to the first and second primary factors and geometrically the axes represent the primary factors.

In higher-dimensional cases ($m \geq 3$), the effective boundaries become planes ($m = 3$) or hyperplanes ($m > 3$) and the primary axes of the primary factors are the vectors lying at the intersections of these planes or hyperplanes. For the three-dimensional case, we can represent the effective common-factor vector space by a hemisphere of unit radius lying on the top of the unit circle made by the axes b and c (see Figure 2). This effective vector space is obtained by reflecting the negative first-factor loadings. Figure 2 presents the geometric model for the three-factor case. The hyperplanes are the bounding planes labeled as HI, HII, and HIII. These planes can be thought of as an inverted triangular

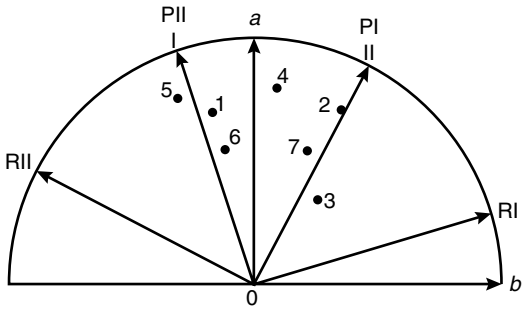

Figure 1 Geometric model for the two-factor case

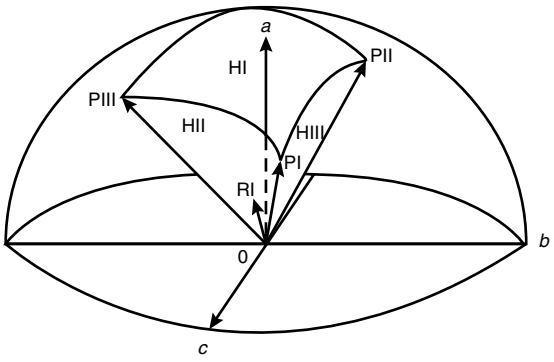

Figure 2 Geometric model for the three-factor case

pyramid with apex at the origin 0, and generate a spherical triangle at the top where they meet the surface of the hemisphere. Ideally, most of the variable vectors should lie on or close to the planes HI, HII, and HIII. The lines where these planes meet are called the primary axes. They are all unit vectors. We can see from Figure 2 that the primary axis 0PI is at the intersection of the planes HII and HIII. The primary axis 0PII is at the intersection of planes HI and HIII. The primary 0PIII is at the intersection of planes HI and HII. For reference vectors, it is not easy to locate them visually in this three-dimensional figure. Similar to the two-factor case, the reference vectors are the unit vectors that are orthogonal to the primary factors (here the planes HI, HII, and HIII). The reference vector RI is orthogonal to HI, which in turn is orthogonal to the primary axes PII and PIII since both primary axes lie in HI. Therefore, as defined, RI is correlated with the corresponding primary axis PI and uncorrelated with the other two. Similar descriptions apply to RII and RIII. The reference vector RI, greatly shortened, is contained in Figure 2.

In the m-dimensional case ($m > 3$), the sphere becomes a hypersphere. Again, by reflecting all the negative first-factor loadings, we obtain the effective vector space bounded by the part of hypersphere where all the a coordinates are positive. The three planes now become m hyperplanes of dimensionality $m - 1$. These m hyperplanes intersect at the origin. They form an inverted hyperpyramid and produce a hyperspherical triangle that meets the surface of the hyperhemisphere. Again, these hyperplanes provide effective boundaries for the variable vectors. The primary axes are the intersections of these hyperplanes, taken $m - 1$ at a time. As defined previously, the reference vector is correlated with the corresponding primary axis but uncorrelated with all other. So the reference vector RI is orthogonal to the hyperplane HI, which is therefore orthogonal to PII, . . . , PM because the primary axes PII, . . . , PM all lie in the hyperplane HI. In other words, RI is correlated with PI but uncorrelated with all other $m - 1$ primary axes. The same descriptions can be applied to the rest of the reference vectors.

As discussed in **Factor Loading Matrix**, different pattern and structure matrices can be obtained as the projections of variable vectors onto the different set of axes. They play an important role in the interpretation of the results.

Principal Components Analysis

Principal components analysis is a method for transforming a set of n **correlated** variables, $X_1, X_2, \ldots, X_n$, to m uncorrelated variables, $Y_1, Y_2, \ldots, Y_m$, where $m \leq n$, and the variances of the Ys are in descending order with the sum of these m variances equal to the "salient" or nonrandom variance of the Xs. There are a number of related aims of principal components, some of which are the following:

1. To *produce n uncorrelated variables*. Transform the original n correlated variables to n uncorrelated linear functions of the original variables.
2. To *produce the best single composite variable*. Generate a single linear composite function of the original variables which has maximum variance among all possible linear functions of the original n variables (or which maximally discriminates the subjects in the data set).
3. To *explain the salient variance*. Transform the n correlated variables to m uncorrelated variables ($m < n$) which explain the salient variance of the n original variables.
4. To *reduce dimension*. Start with the n dimensions of the original variables, and identify m dimensions ($m < n$), where the m dimensions explain the salient variance of the original n variables.
5. To *produce clusters and cluster scores*. Cluster the original n variables into m ($m < n$) subsets (possibly exclusive) and generate simple scores for these m subsets.
6. *Battery reduction*. Identify m variables from the original n variables ($m < n$) which reproduce the salient variance of the original n variables.
7. To *produce scales*. Generate from the original variables composites or "scales" that measure the dimensions underlying the original data.
8. To produce *uncorrelated regressor variables*. Produce uncorrelated variables from a set of correlated variables and use the uncorrelated variables rather than the original variables as regressor variables in a **regression** analysis.

Development of the Principal Components

The principal components are linear functions of the original variables of the form

$$Y_j = e_{1j}X_1 + e_{2j}X_2 + \cdots + e_{nj}X_n, \qquad (1)$$

with

$$e_{1j}^2 + e_{2j}^2 + \cdots + e_{nj}^2 = 1, \qquad (2)$$

for $j = 1, \ldots, n$. We can understand them best if we view them as generated in a sequential manner. The first principal component is the linear function of the form (1) subject to (2) for $j = 1$, where the variance of Y_1 has the maximum variance over all possible linear functions of the original variables subject to (2). We call this variance λ_1.

The second principal component, Y_2, is the linear function, uncorrelated with Y_1 with the next largest variance $\lambda_2 \leq \lambda_1$. In a similar fashion, each principal component is uncorrelated with all others and has the largest possible variance λ_j subject to

$$\lambda_1 \geq \cdots \geq \lambda_n. \qquad (3)$$

In practice, usually there are strict inequalities in (3).

Thus, principal components are linear transformations of the original variables, uncorrelated with each other and with decreasing variance. One can perform the principal components analysis on the Xs in their original scale, i.e. on the raw data. However, we usually perform it on standardized variables, i.e. variables derived from the original variables by subtracting the mean and dividing by the standard deviation. The principal components derived from the raw data will be different from those obtained on the standardized data. If performed on the original variables, the variables with the largest variances can dominate the results. When the analysis is performed on standardized data, all variables are on equal footing.

The method of principal components requires no assumptions about the data. Usually the sample size is large. It can be applied to a **random sample** from some population. However, in practice this is often not the case, and frequently there is interest solely in understanding the sample data themselves.

Mathematical Derivation

Components of Original Variables

Assume a sample of size N is available and on each individual n variables $X_1, \ldots, X_n$ are measured. Let

S represent the sample variance–**covariance matrix**. The sample variance of a linear function of the form (1) of the original n variables is

$$\text{var}(Y_j) = \mathbf{e'}_j \mathbf{S} \mathbf{e}_j, \tag{4}$$

where $\mathbf{e'}_j$ is the vector of weights $(e_{1j}, e_{2j}, \ldots, e_{nj})$ of (1) subject to the restriction of (2) which, in vector notation, is

$$\mathbf{e'}_j \mathbf{e}_j = 1. \tag{5}$$

Condition (2) [or (5)] is arbitrary and only guarantees a unique solution. Any multiple of $\mathbf{e}_j$ produces basically the same component.

The problem of finding the $\mathbf{e}_j$ becomes that of finding the maximum of (4) subject to (5), or finding the maximum of

$$\mathbf{e'}_j \mathbf{S} \mathbf{e}_j - \lambda_j (\mathbf{e'}_j \mathbf{e}_j - 1). \tag{6}$$

Obtaining the solution to (6) is a simple **matrix algebra** exercise where the λ_j, for $j = 1, \ldots, n$, are the solutions of

$$|\mathbf{S} - \lambda \mathbf{I}| = 0. \tag{7}$$

These λ_j are the **eigenvalues** of **S**. The $\mathbf{e}_j$ are then found for each λ_j as the solution of

$$(\mathbf{S} - \lambda_j \mathbf{I}) \mathbf{e}_j = \mathbf{0}, \tag{8}$$

for $j = 1, \ldots, n$. These are the **eigenvectors** or characteristic vectors of **S**. Because of this, $\mathbf{e'}_j \mathbf{e}_t = 0$ for $j \neq t$, which ensures that the principal components are uncorrelated.

It should be noted that the sum of the eigenvalues equals the *trace* of **S**, which is the sum of the variances of the Xs. So the sum of the variances of the n principal components is equal to the sum of the variances of the original variables.

Geometrically, $\mathbf{e}_j$ is the vector of direction cosines of the line from the vector of means of the Xs through the direction of the jth greatest variation in the n-dimensional plot of the data. When the λ_j are distinct, the successive axes are perpendicular to one another. See [7, p. 9] for more details.

Components of Standardized Variables

Because the scales of the original variables are often different, the method of principal components is usually applied to the standardized variables. In this case consider the Xs as being standardized (mean 0 and variance 1), and replace the variance–covariance matrix **S** above with the sample correlation matrix **R**. The problem of finding the appropriate $\mathbf{e}_j$ then becomes one of finding the maximum of

$$\mathbf{e'}_j \mathbf{R} \mathbf{e}_j - \lambda_j (\mathbf{e'}_j \mathbf{e}_j - 1). \tag{9}$$

The λ_j and $\mathbf{e}_j$ of (9), for $j = 1, \ldots, n$, are the solutions of

$$|\mathbf{R} - \lambda \mathbf{I}| = 0 \quad \text{and} \quad (\mathbf{R} - \lambda_j \mathbf{I}) \mathbf{e}_j = \mathbf{0}. \tag{10}$$

The λ_j are the eigenvalues of **R** and the $\mathbf{e}_j$ are the eigenvectors of **R**. So the jth principal component is $Y_j = \mathbf{e'}_j \mathbf{X}$, where **X** is the vector of the standardized original variables and the variance of Y_j is λ_j. Here the sum of the eigenvalues (variances of Y_j) equals n, which is the trace of **R**. In most of what follows we assume we are dealing with standardized data.

One can perform principal components using standard procedures in readily available **software** packages such as the SAS [16] procedure PRINCOMP. This procedure will automatically standardize the variables.

Example

In the **Framingham Heart Study**, a 10-question depression scale was administered ($n = 10$) where the responses were No or Yes to the following (note that the terms in parentheses will be used in the following in reference to the variables);

1. I felt everything I did was an effort (EFFORT)
2. My sleep was restless (RESTLESS)
3. I felt depressed (DEPRESS)
4. I was happy (HAPPY)
5. I felt lonely (LONELY)
6. People were unfriendly (UNFRIEND)
7. I enjoy life (ENJOYLIF)
8. I felt sad (FELTSAD)
9. I felt that people dislike me (DISLIKED)
10. I could not get going (GETGOING)

A Yes was scored as 1 and No as 0, except for questions 4 and 7, where the scoring was reversed

so that a score of 1 would indicated depression for all questions. Tables 1 and 2 contain the results of a principal components analysis of the *standardized* depression variables performed on $N = 1660$ observations. Table 1 contains the correlation matrix **R** (upper triangle matrix). The first section of Table 2

contains the eigenvectors $\mathbf{e}_j$ as columns of the eigenvector matrix. These are the coefficients of the principal components Y_j of (1). The eigenvalues or variances λ_j are given below this matrix.

The first principal component is

$$\begin{aligned} Y_1 = {} & 0.327 * \text{EFFORT} + 0.213 * \text{RESTLESS} \\ & + 0.419 * \text{DEPRESS} + 0.381 * \text{HAPPY} \\ & + 0.348 * \text{LONELY} + 0.191 * \text{UNFRIEND} \\ & + 0.286 * \text{ENJOYLIF} + 0.390 * \text{FELTSAD} \\ & + 0.185 * \text{DISLIKED} + 0.317 * \text{GETGOING}. \end{aligned} \tag{11}$$

Its variance is $\lambda_1 = 3.358$. We obtain the other principal components in an obvious fashion.

Initial Component Matrix

The matrix of eigenvectors contains the weights of the principal components. From these weights we can obtain a second matrix, labeled **A**, whose elements are defined as

$$a_{ij} = e_{ij}\sqrt{\lambda}_j, \tag{12}$$

for $i = 1, \ldots, n$ and $j = 1, \ldots, n$. The elements a_{ij}, are the correlations of X_i with Y_j. The matrix **A** with these elements is called the *initial component matrix*. The elements are also often called *loadings*, and so **A** is also called the *initial loading matrix*.

Example

The second section of Table 2 contains the **A** matrix for the Framingham depression data. Notice how the first component contains large loadings, and the loadings of the other components are generally of much smaller magnitude. This reflects that the earlier components are more heavily correlated with the original Xs than are the later components.

Amount of Variance Explained

As we stated earlier, the sum of the variances (or eigenvalues) λ_j of the principal components equals the sum of the variance of the original variables, called the *total variance*. With standardized variables the total variance is the trace of the correlation matrix **R**, or n, which is the number of variables. Thus the sum of the variances of the first m principal components divided by n,

$$\frac{\lambda_1 + \cdots + \lambda_m}{n}, \tag{13}$$

is the cumulative proportion of the total variance "explained" by the first m components. Table 3 contains the λ_j values for $j = 1, \ldots, 10$, the differences in these, the proportions of the total variance explained by the individual components, and the cumulative proportion of total variance explained.

Number of Components Retained

In the above we started with n variables and ended with n principal components. We still have as many new components as original variables, but the components are uncorrelated. This is the solution to Aim 1 given at the beginning of this article. Unless the matrix **R** is singular, this will always be the case. Often we desire to retain only a smaller set, say $m < n$, of the principal components, possibly for use in later analyses. The question is to decide upon m. There are a number of approaches to this. First, if we desire to retain the "best" linear function or composite variable of the original variables that explains as much variance as possible, then the first principal component is the appropriate one to retain. This is the solution to Aim 2 given at the beginning of this article. For the Framingham depression data this is given as formula (11) above. See [4, Chapter 12] for more details on this best single composite variable.

Table 3 Eigenvalues of the correlation matrix

	PRIN1	PRIN2	PRIN3	PRIN4	PRIN5	PRIN6	PRIN7	PRIN8	PRIN9	PRIN10
Eigenvalue	3.358	1.290	1.022	0.872	0.795	0.628	0.590	0.552	0.509	0.386
Difference	2.067	0.268	0.150	0.077	0.168	0.038	0.038	0.043	0.123	–
Proportion	0.336	0.129	0.102	0.087	0.080	0.063	0.059	0.055	0.051	0.039
Cumulative	0.336	0.465	0.567	0.654	0.734	0.797	0.855	0.911	0.961	1.000

Usually we desire not just one component, but rather the m components needed to explain the "salient" variance of the original n variables. Here salient means reproducing the important or nonrandom variance of the original data. Aims 3 and 4 above relate to this, where the number of components needed to explain the salient variance is also considered the meaningful dimension of the data.

There are a number of ways to determine m, most being data-analytic rather than formal procedures of statistical **inference**. Some of the popular data-analytic rules when dealing with the principal components obtained from the correlation matrix **R** are as follows (details on these are given in [4], [7–10]):

1. Retain all components with $\lambda_j \geq 1.0$ [13].
2. Retain all components with $\lambda_j \geq 0.7$ [8].
3. Cattell's **scree test** [3]. Often the differences in the eigenvalues decrease regularly up to a point, followed by a substantially larger difference, and then followed by even smaller differences (usually 0.10 or smaller). The scree test selects the number of components to retain as the number that corresponds to the component immediately preceding the substantially large difference. This test is equivalently performed by plotting the eigenvalues and retaining the number of components that come before a break in the plot (*see* **Scree Test** and [4, Chapter 5] for more details).
4. 80% rule. Retain all components needed to explain at least 80% of the total variance.
5. Broken stick rule [10]. Retain all components that correspond to eigenvalues whose proportion of the total variance explained is above what would be expected if all components were random.

The existing inferential rules for determining m are based on the assumption that the original X variables are normally distributed. Popular rules derive from Bartlett [2]. Others are due to Girshick [6] and Anderson [1].

Example

Applying the Kaiser $\lambda_j \geq 1.0$ rule to the Framingham depression data of Tables 2 and 3, we retain three components which explain 56.7% of the total variance. The other rules would have retained more components. The Jolliffe $\lambda_j \geq 0.7$ rule and the scree test would retain five components. Figure 1 displays graphically the scree test. The 80% total variance rule would retain six components.

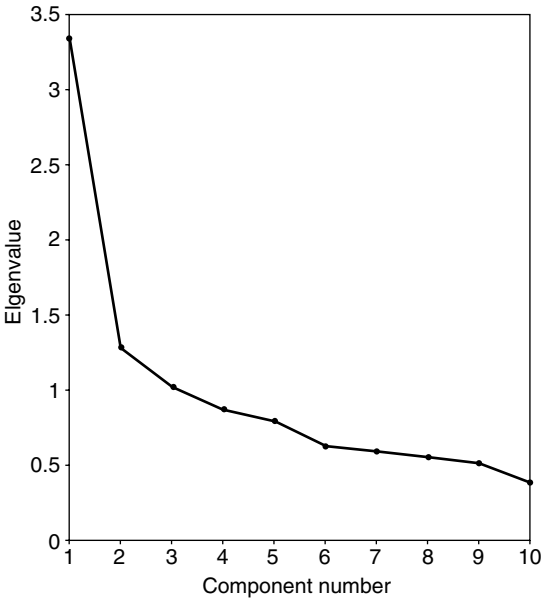

Figure 1 Scree plot of eigenvalues for Framingham depression data (principal components analysis)

For further examples we use the Kaiser rule and retain only three components. Table 4 contains the loadings for the three components. We still can designate it by **A**, but more appropriately we call it $\mathbf{A}_3$, where the subscript designates the number of components retained. Slight differences from Table 2 are due to rounding by the computer programs.

Some researchers use principal components analysis as a method to perform a **factor analysis**. In this context we can designate the reduced matrix **A** (or $\mathbf{A}_m$) with only m columns as **F** and call it the *initial factor matrix*, the initial **factor loading matrix**, or the initial *factor pattern matrix* (*see* **Factor Analysis, Overview**, and [4]). The matrix **F** is standard output from factor analysis software such as SAS Procedure FACTOR [16].

Rotations

After we decide upon the number of components to retain, the next step is to interpret them. The procedure often employed is to define the components

Table 4 Component matrices for Framingham depression data

	Initial component matrix			Varimax component matrix			Promax component matrix[a]		
	FACTOR1	FACTOR2	FACTOR3	FACTOR1	FACTOR2	FACTOR3	FACTOR1	FACTOR2	FACTOR3

[a]This is the reference structure matrix; see Cureton & D'Agostino [4] for details.

in terms of the original variables that have high loadings (high correlations) with the components. Usually this does not work well with the retained principal components. For, as is typically the case, the first principal component is an average of all the variables with high loadings on all the variables (see Table 4), while the second component has, on average, smaller loadings, some positive and some negative. The third component usually has still smaller loadings. In general none of the principal components lends itself to simple interpretation.

For interpretation purposes, usually we rotate or transform the retained principal components in such a way that the rotated components have high loadings on a small set of variables, and zero or near zero loadings on the remaining variables. Often the hope is that for the rotated components the high loadings will form nearly exclusive sets. That is to say, a variable that has a high loading on one rotated variable will have a small (near zero) loading on all other rotated components. This is also called achieving a **simple structure**. The rotated components maintain the salient variance of the original variables explained by principal components, but spread it out "usually more evenly" across the rotated components. That is, the variances of the rotated components usually have variances more equal to each other than did the principal components (*see* **Rotation of Axes** and [4, Chapters 6, 8, and 9] for more details).

There are a number of procedures for performing the rotation (outlined in the article **Rotation of Axes**). Some are **orthogonal rotations**, such as the **varimax rotation** [11, 12], where the rotated components are uncorrelated, as are the principal components. Other rotations methods are **oblique rotations** where, to obtain better interpretation or, equivalently, a simpler structure, the rotated components are allowed to be correlated. Some major oblique rotations methods are **Oblimin rotation**, **Optres rotation**, **Orthoblique**, or Harris–Kaiser rotation, and the **Promax rotation**. The latter starts with the Varimax rotation results and employs a **Procrustes rotation** to obtain a simple structure. (See the above-mentioned articles and [4] for a detailed explanation of the details.)

Example

Table 4 also contains the results of two rotations of the three retained principal components of the depression data. It contains results of the orthogonal Varimax rotation and the oblique Promax rotation. The rotated components are easy to interpret. The first is defined by DEPRESS, HAPPY, LONELY, ENJOYLIF, and FELTSAD. The second is defined

by EFFORT, RESTLESS, and GETGOING. The last component is defined by UNFRIEND and DISLIKED.

Component Scores

Eq. (11) gives the first principal component function for the Framingham depression data. If we "plug" into that formula a subject's standardized values for the original data, we refer to the output as his *first principal component score*. We obtain, in a similar fashion, the other principal component scores from (1) and (2). The coefficients e_{ij} of the principal component scores for the retained components are in the first m columns of the eigenvector matrix, **e** (Table 2 for the depression data).

These principal components, Y_j have variances equal to λ_j for $j = 1, \ldots, m$. Many researchers prefer to have principal component scores with means zero and variances equal to unity (that is, they prefer to standardize them). The basic relationship of the standardized Xs to the standardized Ys (we call them Zs) is given by

$$\mathbf{X} = \mathbf{A}_m\mathbf{Z} + \mathbf{E}, \tag{14}$$

where **X** is an n-dimensional vector of standardized scores of the original data for a subject, $\mathbf{A}_m$ is the $n \times m$ initial component matrix of the retained components, **Z** is the m-dimensional vector of retained *standardized* principal components scores of the subject, and **E** is a "deviation" vector to acknowledge that the principal components do not reproduce exactly the initial data if we retain only m components ($m < n$).

In this case we obtain the **Z** as

$$\mathbf{Z} = \mathbf{D}_m^{-1}\mathbf{A'}_m\mathbf{X}. \tag{15}$$

Here D_m^{-1} is the $m \times m$ diagonal matrix with diagonal elements equal to $1/\lambda_j$, for $j = 1, \ldots, m$, and $\mathbf{A'}_m$ is the transpose of $\mathbf{A}_m$. Note this is an exact solution and not an estimate, even though there is a deviation vector **E** in (14). The first m principal component scores are the same whether we retain all n possible principal components or just the first m. This is not the case with **factor scores**.

For an orthogonal rotation the transformed component scores are simply

$$\mathbf{Z}_t = \mathbf{\Lambda'}_m(\mathbf{D}_m^{-1}\mathbf{A'}_m\mathbf{X}), \tag{16}$$

where $\mathbf{\Lambda}_m$ is the $m \times m$ transformation matrix that rotates the original principal components to the transformed component scores $\mathbf{Z}_t$. Here $\mathbf{Z}_t$ is the m-dimensional vector of transformed component scores. We often call these *component scores* and drop the term "transformed". The formula for the component scores for oblique rotated components is more complicated [4].

Example

Table 5 gives the weights for the component scores for the Varimax and Promax oblique rotation of the Framingham depression data. We apply these to the standardized variables (see [4, Chapter 12] for a discussion of the weights for the raw, unstandardized data).

Table 5 Component scoring coefficients for retained components Framingham depression data

	Rotation method: Varimax standardized scoring coefficients			Rotation method: Promax standardized scoring coefficients

Clusters and Cluster Scores

Yet another objective of principal components analysis (Aim 5 above) is to group the original variables together into clusters and generate simple summary variables or cluster scores. This can sometimes be accomplished by an "intuitive cluster analysis" achieved by examining either the rotated component matrices (Varimax or Promax component matrices of Table 4) or the weights of the rotated component scores (Table 5) and set the "small" loadings or weights to zero and the others to unity. The variables that have the new weights equal to unity for the same component comprise a cluster. This intuitive cluster analysis works well for the Framingham depression data. From either Table 4 or Table 5 three clusters emerge:

Cluster 1: DEPRESS, HAPPY, LONELY, ENJOYLIF, FELTSAD
Cluster 2: EFFORT, RESTLESS, GETGOING
Cluster 3: UNFRIEND, DISLIKED

Note that the clusters comprise mutually exclusive and exhaustive groups. We usually consider this ideal.

After the clusters are obtained, we then desire to produce scores or summary scores for them. Extending the intuitive clustering above, a simple solution is to define the cluster scores to be the sum of the standardized variables that comprise the clusters. For the Framingham depression data the three cluster scores are:
Cluster score 1:

$$\text{DEPRESS} + \text{HAPPY} + \text{LONELY} + \text{ENJOYLIF} + \text{FELTSAD}. \quad (17)$$

Cluster score 2:

$$\text{EFFORT} + \text{RESTLESS} + \text{GETGOING}. \quad (18)$$

Cluster score 3:

$$\text{UNFRIEND} + \text{DISLIKED}. \quad (19)$$

This intuitive clustering does not always work. Also, using the principal components solution as a starting point can cause trouble, for the clusters derived from principal components solutions may not be as well determined as those from the depression data (*see* **Cluster Analysis of Subjects, Nonhierarchical Methods**; **Cluster Score** for more details and discussions of other methods).

Cluster scores usually are more stable than components scores (or factor scores from a factor analysis) across various subgroups. We recommend them as summary measures.

Battery Reduction

Both component analysis and cluster analysis retain all the original variables and combine them either into component scores or cluster scores. At times we desire to reduce the number of variables. For example, if we have a questionnaire with, say, $n = 100$ questions and are concerned about the burden a long questionnaire places on a subject, we may want to find a subset of, say $m = 20$ or 25 questions that reproduces the salient variance of the original n variables. This is battery reduction (Aim 6 above). Again the rotated component solution can be a starting point for such an analysis. (*See* **Battery Reduction** for one method that involves **Gram–Schmidt** transformations of the initial component matrix for which a SAS macro is available [5] from `ralph@math.bu.edu`. Also see Cureton & D'Agostino [4, Chapter 12] for further elaboration and other methods.)

Scale Development

Given a set of variables a scale is simply a composite function of them. The terms *scale* and *scaling* are from the social sciences. There one objective of scaling variables is to use the resulting scales to summarize the status of the subjects from which the original data came. However, more frequently the objective is to use the original sample to generate the scales and then use the variables and their scales to investigate other populations and samples. For example, from the analysis of the Framingham depression data given in this article there are four possible scales that can be used in other populations. They are the sum of all 10 items and the three subscales (from the cluster scores) given by (17), (18), and (19). The sum is a summary of overall depression status and the three subscales ideally each measure a separate component or dimension of depression. Other typical examples from biostatistical research are scales to quantify symptoms, quality of life (*see* **Quality of Life and Health Status**), and comorbid status.

Principal components analysis offers a number of means for generating scales. In the context of scale production, the first principal component is the best linear scale from the original variables. Component scores and cluster scores are scales of the variables. Also, after a battery reduction exercise the retained smaller set of variables can be combined to a scale.

In the context of scale development there are usually data analysis steps and concerns beyond those of a "typical" principal components analysis. First, principal components analysis concerns itself with explaining the variance of the data. It may be more important in scale development to be concerned with the correlation of the variables within a scale. Factor analysis may be better suited for this. Secondly, there is the concern about **reliability** (or reproducibility) of the items or variables in the scales and the final scales themselves. And finally, the **validity** of the scales is always a major issue. This relates to determining if they measure what the developers "claim" they measure. Addressing the questions of reliability and validity are major issues in **psychometrics**.

Reduced Rank Regression

It is not uncommon to have a regression analysis where the number of potential **explanatory** (independent or regressor) variables is extremely large. Principal components analysis allows one to reduce the number of regressors to a smaller set of uncorrelated composite variables, which can be the regressor variables. The composite variables will tend to be more reliable and more valid than the individual variables. If performed carefully principal components regression (also called reduced rank regression) can offer an excellent way of examining the full set of potential regressors. (*See* **Reduced Rank Regression** for more details and Jackson [7] for an extensive discussion. Further discussion is also in [4].)

Conclusion

Principal components is a major practical statistical analysis technique. We have reviewed a number of traditional uses. It continues to be a major method in the understanding and development of important multivariate techniques such as **classification** techniques, **canonical correlation analysis**, factor analysis, **principal coordinate analysis**, **correspondence analysis**, and the identification of **multivariate outliers**. There are a number of excellent treatments going far beyond our present discussion. It is easy to implement with computer software that is readily available for its many uses [5, 16]. Almost any statistical software package will have a principal components analysis procedure. The reader will be well rewarded in examining the related articles in this Encyclopedia and a number of available books [4, 7, 10, 14, 15].

Principal Coordinates Analysis

In many applications, researchers collect information on n objects which can be accumulated into an $n \times n$ symmetric matrix $\mathbf{D}$ whose (i, j)th entry, d_{ij}, gives a measure of the relationship between the ith and jth objects. These entries may be measured directly, as with *confusion matrices*, which count the number of times out of t trials that object i is deemed to be the same as object j, or they may be derived from more fundamental multivariate observations on several variables, e.g. by calculating a *(dis)similarity matrix* or a *distance matrix* (*see* **Similarity, Dissimilarity, and Distance Measure**). When observed values depend on the order in which i and j are presented, the resulting square matrix is usually asymmetric. Then we may separate out the symmetric and skew-symmetric parts of the matrix. Here, we are concerned with the symmetric part, but there may be interesting structure in the skew part which also deserves separate analysis [1, 6]. The analysis of the symmetric part is the concern of **multidimensional scaling** of which principal coordinates analysis is computationally the most simple special case. The basic idea of all multidimensional scaling methods is that the symmetric matrix may be regarded as containing distance-like information and one seeks a set of n points in ρ dimensions whose $\binom{n}{2}$ interdistances approximate the matrix; we shall say that the n points *generate* approximations to the distances. If the diagonal of $\mathbf{D}$ is not already zero, then it will be ignored. Some preliminary transformation may be required to ensure a symmetric matrix in distance-like form. Thus, similarities might be converted into dissimilarities by subtracting from unity or probabilities p_{ij} might be transformed into $-\log p_{ij}$. When ρ is small, usually $\rho = 2$, the points may be plotted to give a graphic representation, or visualization, of the distances in the matrix (*see* **Graphical Displays**). A frequently used illustration is the recovery of the geographical map of a set of towns, given the road distances between them (see, for example, [5]); practical applications include "maps" of patients with differing symptoms, species, genotypes of agricultural crops, sets of psychological stimuli, kinships or other social structures, and many others. Inspection of these maps may indicate patterns suggesting interesting relationships or the maps may just be used as a convenient way of reporting complex multivariate relationships.

The relevant algebra is in two parts. The first part concerns the possibility of finding a set of points in *any* number of dimensions that generate the given distances exactly. The second part concerns *approximating* the distances in a few dimensions.

Exact Euclidean Representations

A Euclidean representation is desirable for graphic interpretation because, overwhelmingly, that is what most people are familiar with. One way of finding whether or not a Euclidean set of generating points exists is to proceed as follows. Put the first point at the origin, the second point a distance d_{12} from the origin. Put the third point in a plane containing the first two points and a distance d_{13} from the origin and a distance d_{23} from the second point. One may proceed in this way, at each stage adding a new point and, in general, requiring a new dimension. If the rows of $\mathbf{Y}$ give a set of coordinates for n points corresponding to the first n samples, then it may be shown [5] that the coordinates $\mathbf{y}$ of the $(n+1)$th point relative to the coordinate axes of $\mathbf{Y}$ are given by

$$\mathbf{y} = -\tfrac{1}{2}(\mathbf{Y}'\mathbf{Y})^{-1}\mathbf{Y}'[\mathbf{d}_{n+1} - \mathbf{d} - (\mathbf{e}_1'\mathbf{d}_{n+1})\mathbf{1}] \qquad (1)$$

plus an extra coordinate y_{n+1}, in a new dimension orthogonal to those of $\mathbf{Y}$, given by

$$y_{n+1}^2 = \mathbf{e}_1'\mathbf{d}_{n+1} - \mathbf{y}'\mathbf{y}. \qquad (2)$$

In (1) and (2) $\mathbf{e}_1$ is a unit vector zero everywhere except for its first value of unity, $\mathbf{d}_{n+1}$ is a column vector containing all the squared distances of a new $(n+1)$th sample from the existing n samples, and $\mathbf{d}$ is the diagonal of $\mathbf{YY}'$ written as a column vector, giving the squared distances of the first n points from their origin. Thus, $\mathbf{e}_1'\mathbf{d}_{n+1}$ gives the squared distance of the $(n+1)$th point from the first point placed at the origin.

To see how (1) and (2) work, consider the set of squared distances among four points exhibited in the symmetric matrix:

$$\begin{pmatrix} 0 & 4 & 10 & 6 \\ \underline{4} & 0 & 10 & 6 \\ \underline{10} & 10 & 0 & 8 \\ \underline{6} & 6 & 8 & 0 \end{pmatrix}$$

from which we derive

$$\begin{pmatrix} 0 & 0 & 0 & 0 \\ \underline{0} & 4 & 2 & 2 \\ \underline{0} & \underline{2} & 5 & 4 \\ \underline{0} & \underline{2} & \underline{4} & 6 \end{pmatrix}$$

by replacing element a_{ij} of the first matrix by $-\frac{1}{2}(a_{ij} - a_{i1} - a_{j1})$. The underlined elements of the second matrix then turn out to be successive elements of the vector $-\frac{1}{2}[\mathbf{d}_{n+1} - \mathbf{d} - (\mathbf{e}_1'\mathbf{d}_{n+1})\mathbf{1}]$ needed in (1), while the underlined elements of the first matrix are the successive elements $\mathbf{e}_1'\mathbf{d}_{n+1}$ needed in (2). Thus, placing the first point at the origin and the second at 2 on the first axes gives our initial one-dimensional coordinates for the first two points as $\mathbf{Y}_1 = \binom{0}{2}$. The coordinates of the first dimension of the third point of $\mathbf{Y}_2$ are then obtained from (1) as $(4)^{-1}(0 \quad 2)\binom{0}{2} = 1$, where the column vector $\binom{0}{2}$ comes from the underlined elements in the third row of the derived matrix. The coordinate of the second dimension of the third point comes from the underlined element in the third row of the first matrix which, when substituted into (2), gives $y_3^2 = 10 - 1^2 = 3^2$ so that

$$\mathbf{Y}_2 = \begin{pmatrix} 0 & 0 \\ 2 & 0 \\ 1 & 3 \end{pmatrix}.$$

We may now proceed to calculate the first two dimensions of the fourth point of $\mathbf{Y}_3$ from (1) to give

$$\begin{pmatrix} 5 & 3 \\ 3 & 9 \end{pmatrix}^{-1} \begin{pmatrix} 0 & 2 & 1 \\ 0 & 0 & 3 \end{pmatrix} \begin{pmatrix} 0 \\ 2 \\ 4 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix},$$

while from (2), $y_4^2 = 6 - 1^2 - 1^2 = 2^2$ so that

$$\mathbf{Y}_3 = \begin{pmatrix} 0 & 0 & 0 \\ 2 & 0 & 0 \\ 1 & 3 & 0 \\ 1 & 1 & 2 \end{pmatrix}$$

which, as is easily verified, generates the initial squared distances. Finally, if the last row of the given squared distances were 2,2,2 rather than 6,6,8, then it may be verified that the calculation of $\mathbf{Y}$ is replaced by

$$\begin{pmatrix} 5 & 3 \\ 3 & 9 \end{pmatrix}^{-1} \begin{pmatrix} 0 & 2 & 1 \\ 0 & 0 & 3 \end{pmatrix} \begin{pmatrix} 0 \\ 2 \\ 5 \end{pmatrix} = \begin{pmatrix} 1 \\ 1\frac{1}{3} \end{pmatrix},$$

while from (2), $y_4^2 = 2 - 1^2 - \left(1\frac{1}{3}\right)^2 < 0$ and no real representation exists.

Thus, it is easy to generate the successive coordinates described above, ending up with the final version of $\mathbf{Y}$ in a lower-triangular matrix, the first value of which is zero. When the process terminates satisfactorily, the resulting configuration of n points generates the given distances, is Euclidean, and occupies, at most, $n - 1$ dimensions. If the distances do not have a Euclidean representation, then the process breaks down at some point, (2) requiring the square root of a negative number. This may be accepted but the resulting coordinates include imaginary numbers and the representation is not Euclidean. When the distances have a Euclidean representation, they are said to be *Euclidean embeddable*.

We are concerned with symmetric matrices of dissimilarities $\mathbf{D}$, with zero diagonal elements. Consider the *centered* form:

$$\mathbf{B} = (\mathbf{I} - \mathbf{1}\mathbf{s}')\mathbf{D}(\mathbf{I} - \mathbf{s}\mathbf{1}'), \tag{3}$$

where $\mathbf{s}'\mathbf{1} = 1$. When $\mathbf{B}$ is positive semidefinite, we may write

$$\mathbf{B} = \mathbf{Y}\mathbf{Y}', \tag{4}$$

nonuniquely. Regarding the ith row of $\mathbf{Y}$ as the coordinates of a point, the squared distance between the ith and jth points is given by $b_{ii} + b_{jj} - 2b_{ij}$. From (3) it follows after some elementary algebraic manipulations, that, provided we define $\mathbf{D} = \left\{-\frac{1}{2}d_{ij}^2\right\}$ then

$$b_{ii} + b_{jj} - 2b_{ij} = d_{ij}^2 \tag{5}$$

and hence $\mathbf{Y}$ generates the given distances. From now on we assume that $\mathbf{D}$ is defined in this way. Thus, that (3) be positive semidefinite guarantees the real decomposition (4), thus providing a sufficient condition for the distances d_{ij} to have a Euclidean representation. That the condition is also necessary for Euclideanarity was first proved by Schoenberg [10] for the case $\mathbf{s} = \mathbf{1}/n$ and by Householder & Young [9] for the case $\mathbf{s} = \mathbf{e}_1$, but the result is valid for all $\mathbf{s}$ where $\mathbf{s}'\mathbf{1} = 1$; an elementary proof is given by Gower [7]. Thus, $\mathbf{D} = \left\{-\frac{1}{2}d_{ij}^2\right\}$ is embeddable in a Euclidean space if and only if (3) is positive semidefinite.

From (3) we have that $\mathbf{s}'\mathbf{B}\mathbf{s} = 0$, so the vector $\mathbf{s}'\mathbf{Y} = 0$, showing that $\mathbf{s}$ determines the location of the origin of the generating points $\mathbf{Y}$; the different

solutions, $\mathbf{Y}$, that satisfy (4) represent different orientations around this origin. When $\mathbf{s} = \mathbf{e}_1$, the ith point of $\mathbf{Y}$ is at the origin, as in our example of four points where the first point is at the origin and $\mathbf{s} = \mathbf{e}_1$. Other choices of $\mathbf{s}$ are discussed by Gower [7] and by De Rooij and Gower [2]. The squares of distances of the n points from the origin are the elements in the diagonal of $\mathbf{B}$, which may be written as a column vector:

$$\mathbf{d} = (\mathbf{s}'\mathbf{D}\mathbf{s})\mathbf{1} - 2\mathbf{D}\mathbf{s} \tag{6}$$

and the sum of squares of the distances from the origin is $\mathbf{1}'\mathbf{d}$.

Of special importance is the choice $\mathbf{s} = \mathbf{1}/n$, which implies that $\mathbf{1}'\mathbf{Y} = 0$ and hence places the origin at the centroid of the generating points. The squares of the *centroid distances* are then given as

$$\mathbf{d} = \frac{1}{n^2}(\mathbf{1}'\mathbf{D}\mathbf{1})\mathbf{1} - \frac{2}{n}\mathbf{D}\mathbf{1}, \tag{7}$$

and the sum of squares about the mean (centroid) is

$$\mathbf{1}'\mathbf{d} = -\frac{1}{n}\mathbf{1}'\mathbf{D}\mathbf{1} = \frac{1}{n}\sum_{i<j}^{n} d_{ij}^2, \tag{8}$$

a classical result relating a sum of squares about the mean to the sum of squares of all $\binom{n}{2}$ intersample squared distances.

Approximate Euclidean Representations

We have seen that exact representations are multidimensional; for practical purposes low-dimensional approximations are required. Continuing with the setting $\mathbf{s} = \mathbf{1}/n$, and writing $\mathbf{N} = \mathbf{1}\mathbf{1}'/n$, (3) becomes

$$\mathbf{B} = (\mathbf{I} - \mathbf{N})\mathbf{D}(\mathbf{I} - \mathbf{N}), \tag{9}$$

and if we choose the spectral decomposition, then $\mathbf{Y}$ is given by

$$\mathbf{B} = \mathbf{Y}\mathbf{Y}', \qquad \mathbf{Y}'\mathbf{Y} = \mathbf{\Lambda}, \tag{10}$$

where $\mathbf{\Lambda}$ is the diagonal matrix of the **eigenvalues** of $\mathbf{B}$, assumed to be presented in nondecreasing order (*see* **Matrix Algebra**). Because $\mathbf{Y}'\mathbf{Y}$ is diagonal, $\mathbf{Y}$ is referred to its principal axes and it follows that $\mathbf{Y}_\rho$, the first ρ columns of $\mathbf{Y}$, gives a ρ-dimensional **principal components analysis** of $\mathbf{Y}$. Thus, with these settings, the method of approximation is that of principal components analysis so that the approximation $\mathbf{Y}_\rho$ is obtained as an orthogonal projection of the generating points with coordinates $\mathbf{Y}$ onto a ρ-dimensional subspace. It follows that the method could proceed by first computing any $\mathbf{Y}$ that satisfies (9) or, indeed, any $\mathbf{Y}$ that satisfies (4) and applying principal components analysis to it. However, the choice of (9) and (10) allows the two steps to be subsumed into one step. Because they are referred to principal axes, the rows of settings of $\mathbf{Y}$ that satisfy (9) and (10) are known as the *principal coordinates* of $\mathbf{D}$ and the method as *principal coordinates analysis* [4]. Alternatively, especially in the psychometric literature, the method is known as *classical scaling*, a terminology which stresses the links with multidimensional scaling [12]. The method could just as easily operate with other choices of $\mathbf{s}$ to give representations referred to principal axes through different origins, such as the circumcenter of the points (see [7]), but $\mathbf{s} = \mathbf{1}/n$ minimizes the sum of squares onto any ρ-dimensional subspace.

As with many statistical methods, there is interest in interpolating a new sample into an existing analysis. Of course, when interpolating a sample, we could operate on the total of $n + 1$ samples to find a ρ-dimensional principal coordinates approximation. With m separate samples we could do m separate analyses, but this would be both inefficient and, because the positions of the original n samples would change slightly in each analysis, would make it difficult to compare the different interpolations. So, sacrificing some accuracy, we seek to interpolate directly into the existing ρ-dimensional approximation; versions of (1) and (2) remain the key formulas for this operation. When the rows of $\mathbf{Y}$ are principal coordinates, $\mathbf{Y}'\mathbf{1} = 0$ and, using (7) and (10), the interpolation formula (1) simplifies to

$$\mathbf{y} = -\frac{1}{2}\mathbf{\Lambda}^{-1}\mathbf{Y}'\left(\mathbf{d}_{n+1} + \frac{2\mathbf{D}\mathbf{1}}{n}\right), \tag{11}$$

which gives coordinates in all $n - 1$ dimensions. Because $\mathbf{\Lambda}$ is diagonal the coordinates in the first ρ dimensions require only the first ρ columns, $\mathbf{Y}_\rho$ of $\mathbf{Y}$ to give

$$\mathbf{y}_\rho = -\frac{1}{2}\mathbf{\Lambda}_\rho^{-1}\mathbf{Y}_\rho'\left(\mathbf{d}_{n+1} + \frac{2\mathbf{D}\mathbf{1}}{n}\right), \tag{12}$$

which is very simple to apply. Note that the extra dimension (2) is orthogonal to the first ρ dimensions

and may be regarded as a residual, but does not enter into interpolation of further samples into the ρ-dimensional approximation.

A typical application of (11) and (12) is to add a new sample to the display, say a new town to the geographic map, without recalculating **eigenvectors**. Another application is to interpolate a point which represents a pseudo-sample that pertains to a value ξ_k of a kth variable, and then allowing ξ_k to vary while holding all other variables fixed, typically at zero. The resulting locus is a nonlinear *biplot axis* (*see* **Graphical Displays**) for the kth variable [8], unless dissimilarity is defined by the classical Pythagoras formula, when the locus is a linear axis. Such biplot axes have many of the familiar properties of Cartesian coordinate axes; in particular, the nonlinear axis may be marked at standard values of the kth variable and then the value of the variable pertaining to any point may be read off by orthogonal projection. Categorical variables may be handled similarly, replacing the kth axis by a set of category-level points, one for each permissible category level of the kth variable. Then the level of the kth variable pertaining to any point is that given by the nearest category-level point. Note that orthogonal projection is replaced by the more fundamental concept of finding the nearest point of a set, which becomes an orthogonal projection when the set forms a continuum.

When squared distances are additive, in the sense that $\mathbf{D} = \sum_1^p \mathbf{D}_k$, where $\mathbf{D}_k$ is a matrix of squared distances calculated solely from the values of the kth of p variables, the n interpolated points for the actual values of the kth variable in the sample are given by the columns of

$$\mathbf{Z} = \mathbf{\Lambda}^{-1}\mathbf{Y}'\mathbf{B}_k, \tag{13}$$

where $\mathbf{B}_k$ is calculated from $\mathbf{D}_k$ in the same way that $\mathbf{B}$ is calculated from $\mathbf{D}$ in (9). This formula is especially valuable for giving the category-level points, as all category levels will occur in a sample.

Distributional results associated with principal coordinates analysis are few. Indeed, in many applications it is difficult to see what null distribution might be reasonably assumed for the distance matrix or more fundamental variables from which it may be derived. Often, it may not even be realistic to assume that the variables are **random variables**. When stability of principal coordinates analysis, or indeed other multidimensional scaling analyses, is of interest **bootstrap methods** may be used. Sibson [11] provided a perturbation analysis for principal coordinates analysis, showing that if $\mathbf{D}$ is perturbed by a symmetric matrix $\varepsilon\mathbf{C}$, then the statistic for the Procrustean fit (*see* **Procrustes Rotation**) between the generating coordinates of $\mathbf{D}$ and its perturbed form, when expressed as a polynomial in ε, has no constant or linear terms, depending only on ε^2 and higher order terms. This suggests that principal coordinates analysis is a robust method and Sibson reports that the approximation is good, even when the perturbations are of the same order of magnitude as the given distances. Perturbation of a Euclidean distance matrix may induce non-Euclideanarity, manifesting itself as some negative eigenvalues in (9), as well as small positive eigenvalues representing noise. The principal coordinates analysis method may still be used if the negative eigenvalues are ignored, provided these are small. Sibson suggests a useful rule of thumb that small positive eigenvalues of the same, or lower, order of magnitude as the largest negative eigenvalue may be ignored. Ignoring small negative eigenvalues may also be justified by the Eckart–Young theorem [3] giving $\mathbf{Y}_\rho\mathbf{Y}_\rho'$ as a least-squares approximation to $\mathbf{B}$.

JOHN C. GOWER

Prior Distribution

Bayesian inference uses probability distributions to represent knowledge. In statistical settings, inferences are based on posterior distributions, which are computed from **Bayes' Theorem**:

$$p(\theta|y) = \frac{L(\theta)\pi(\theta)}{\int L(\theta)\pi(\theta)\,\mathrm{d}\theta}, \qquad (1)$$

where θ is the unknown parameter, y represents the data, $L(\theta)$ is the **likelihood** function, $p(\theta|y)$ is the density (pdf) of the posterior distribution, and $\pi(\theta)$ is the density of the prior distribution. The appearance of the prior distribution on the right-hand side of (1) is at once a strength and a weakness of the Bayesian approach: a strength because it allows information beyond the data at hand to be used in making inferences, and a weakness because the inferences inevitably depend, at least to some degree, on the choice of the density $\pi(\theta)$.

It is useful to distinguish three kinds of prior distributions, *informative priors*, noninformative or *reference priors*, and hierarchical priors or priors used in *hierarchical models*.

Informative Priors

When there is substantial knowledge about a phenomenon under investigation, it is natural to consider incorporating that knowledge into a statistical analysis. The most advantageous case occurs when there is much relevant data that may be summarized in the form of a prior distribution. A wonderful case study is the analysis of *The Federalist* papers (a series of early American political pamphlets) by Mosteller & Wallace [15], in which papers of known authorship were used to form prior distributions in order to determine who wrote the papers of unknown authorship. Another domain in which prior information has been incorporated with great success is in medical **imaging** (see, for example, [14]), where specific features of anticipated images are introduced to aid reconstruction.

Alternatively, available knowledge may come from opinions expressed by one or more experts. In this situation, the opinions are formulated into prior distributions through a process called *elicitation*, with the resulting priors being called *subjective*. A general review of elicitation methods, and their application to **clinical trials**, is given by Chaloner [3]; see also [2, 6, 9, 11, 12, 16], and the many additional references cited by Chaloner. The formalization of expert opinion could be especially valuable in **experimental design**; see [4] and [5]. An important attendant issue in elicitation is the manner in which various expert judgments ought to be combined [8].

Reference Priors

When there is little reliable information, or when an analyst wishes to avoid subjective elicitation of prior distributions, standard forms for priors may be invoked. An example would be the use of a **uniform** prior on the interval (0, 1) for a **binomial** proportion. Although such uniform priors are useful in many settings, allowing formal Bayesian analyses to proceed, a variety of theoretical and practical concerns have been raised about this and related techniques for selecting prior distributions. Kass & Wasserman [13] have reviewed the extensive literature on the subject, and summarized its major findings.

Ideally, one would like to have a given prior distribution selected as "standard" for each specific problem, such as the uniform prior for a binomial proportion. As reviewed by Kass & Wasserman, this was the point of view articulated by **Harold Jeffreys** in his pioneering attempts to provide formal rules for selecting priors [10]. However, despite the efforts of Jeffreys and many others, no consensus exists as to the rules to be used (except possibly in a few problems, such as the binomial). Furthermore, important complications may arise when *improper priors* are used; that is, priors that do not integrate to one. For example, the standard prior for a single normal mean is uniform on the real line. Although in this case no substantial difficulties arise, in more complicated settings a variety of problems may occur, including the possibility that the posterior also may be improper, so that Bayesian inferences are no longer well defined. An additional serious concern is that seemingly innocuous prior distributions (such as uniform) on multidimensional parameter spaces may have unintended consequences for certain functions of the parameters. The general conclusion to be drawn from the literature is that one must be careful, and cognizant of attendant potential difficulties,

when selecting prior distributions in the absence of specific information. However, the worries are greatly diminished when posteriors are computed from large samples [13].

Hierarchical Models

One of the major contributions of Bayesian methods to data analysis involves what have come to be called hierarchical models, briefly described as follows. Suppose that we have a collection of observation vectors $y_1, y_2, \ldots, y_k$ that are assumed to come from the same family of distributions $p(y|\theta)$, but for different values of the parameter $\theta_1, \theta_2, \ldots, \theta_k$. If we also assume that the θ_is are drawn from some family of distributions $p(\theta|\lambda)$, indexed by a further parameter λ, then we obtain a hierarchical model. Formally, this second family plays the role of a prior for each parameter θ_i. When the parameter λ is estimated by maximum likelihood or related techniques, the resulting analyses are usually called **empirical Bayes** methods. When, instead, a prior distribution is introduced on λ (which is often called a *hyperparameter*, to signify its role as a parameter of a distribution on parameters), then inferences are considered to be *fully Bayesian*. For many examples and further discussion, see [3] and [7].

Privacy in Genetic Studies

The concept of privacy has come through a long evolution in Western thought. Early notions of privacy focused on the ownership and use of property, with the idea that an individual could exercise dominion over property, with the right to enjoy the benefits provided by property and the right to dispose of the property, either by destroying it or by transferring full or partial ownership to another party. Concepts of privacy expanded to include the immediate space around the person, so that individuals came to enjoy a personal space that cannot be entered without the consent of the person. Early applications of the idea of privacy of the person included the development of the law of assault and battery, both in the criminal law and the law of tort, as well as the evolution of respect for the person in matters of corporal punishment. The sphere of personal privacy was expanded in the late nineteenth century to include the "right to be let alone", so the individuals could expect not to have their lives and personal activities invaded and pursued by reporters, journalists, and the public media [17]. Early in the twentieth century, in the context of the physician–patient relationship, the idea of privacy was expanded to include support for an individual's right to decide personally what course to follow in questions of medical or surgical treatment [12].

At the turn of the twentieth century the world of medical and surgical practice was profoundly altered by the introduction of anesthesia and antisepsis. These new technical benefits rapidly expanded the possibilities for treating a variety of human illnesses. Patients became aware of an expanding array of options, and they began to assert their own right to make decisions about following medical treatment regimens and about submitting to surgical procedures [9]. Patients became more informed and less tolerant when they discovered that they had been denied information about health care options, and they became quick to allege legal negligence on the part of physicians for failing to convey complete information about choices of treatment [4]. Early support for personal autonomy in treatment decisions is found in the resounding holding by Justice Benjamin Cardozo that "[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body. . ." [12]. This and other early decisions in the common law laid the foundation for building the Doctrine of Informed Consent as it governs interactions between physicians and patients in the practice of medicine and surgery. This doctrine has evolved to include the legal obligation of health care professionals to disclose all information that may influence the decision of a patient, including treatment options, the risks and benefits of the options, as well as the risk of choosing to decline treatment altogether [15]. Integral to the structure and function of the physician–patient relationship is the assurance that information shared between physician and patient will be held in confidence, so that both members of the relationship may enjoy reciprocal candor that should ultimately benefit the patient.

During the fifth and sixth decades of the twentieth century, respect for privacy of the person and the right of the individual to make autonomous decisions expanded into the world of biomedical research. The revelations of barbarous experimentation with human beings, before, during, and after the Second World War, both in the concentration camps in Nazi Germany [16] and in a variety of civilian and military arenas in the US [6], generated calls for protecting individuals who participate as subjects in biomedical research. These concerns were thoroughly studied by the federal government and became the subject of legislation and regulations that established safeguards to protect the interests of human subjects. These safeguards are now found in the structure of the nationwide system of Institutional Review Boards (IRBs) that supervise biomedical research at public and private research institutions that enjoy the benefits of federal funding. IRBs answer to the government and are responsible for the information that is conveyed to potential subjects, for their competent and voluntary consent, for their understanding of the risks and benefits of participating in research, and for their understanding of their rights as research subjects [10]. Integral to the consent process in biomedical research is consideration of how newly developed research information will be handled.

Both patients and research subjects have vital interests in the fate of information that is gathered about their own health and the health of their families. The interests of patients include candor and complete information about treatment options. The interests of research subjects include an option for access to information about research results and the implications of these results for their families. Both

patients and subjects are entitled to assurances that their personal medical and/or research information will be maintained in confidence and will not be disclosed to other parties without express consent. Indeed, the importance of confidentiality of information in these relationships is guarded by severe legal sanctions for unauthorized disclosures of personal medical or research information [7].

Over the past two decades the unprecedented expansion of knowledge of human heredity has opened significant new areas of medical practice and biomedical research. Technological innovations have driven the rapid dissection of the **human genome**, and they now permit precise determination of the **genotypes** of individuals and groups, with respect to both an array of single **gene** diseases and a growing number of complex genetic susceptibilities to future health problems. While exhaustive knowledge of the genetic endowment of the human species may remain elusive for years, the present compendium of genetic information is expanding rapidly. As more tests are developed, and as more and more questions about genetic disease and disorders are asked and answered, individuals and families are seeking information about their own genetic legacies and their genetic prospects for their own health and the health of their offspring. In response to the growing quest for genetic information, the practice of **genetic counseling** is expanding, albeit at a somewhat slower rate than the demand for counseling services [14].

The unique genetic constitution of each individual renders personal genetic information perhaps the most private information that may be generated for any human being. Genetic information is also, however, unique because it may have significant implications for members of an individual's immediate family and collateral relatives as well. Over the past two decades the power of genetic information to influence or disrupt the lives of individuals and families has been thoroughly documented [3] and has been the impetus behind numerous legislative efforts to protect the privacy and autonomy of individuals who have knowledge of their own genotypes. Most states now have enacted legislation that protects individuals from discrimination in employment and health insurance on the basis of genotype [11]. While numerous genetic discrimination bills have been introduced at the federal level, none has yet been passed [5]. However, the Health Insurance Portability and Accountability Act of 1996 [8], and the ensuing regulations, do address questions of genetic privacy in the context of protecting the health insurance status of individuals and families who move from one employer and health insurance provider to another.

During the 1960s the development of simple tests and effective treatments for a few genetic diseases resulted in the inception of newborn screening programs. These public health programs were initiated in all states after a reliable test for phenylketonuria became available, and screening quickly expanded to include testing for sickle cell anemia and congenital hypothyroidism. Some states have subsequently incorporated screening tests for several other genetic diseases as well. Newborn screening is mandated by law in most states, and screening is typically carried out just after birth, usually without the express consent of the parent(s). Screening without parental consent is an invasion of privacy, both personal and physical, that is justified because of the immense benefits that accrue from identifying and treating infants early in life: infants enjoy the prospect of a lifetime of health benefits, and public monies that would otherwise be spent on caring for severely damaged children can be directed toward other public health efforts [1].

With the exception of newborn screening, generating genetic information by genetic testing continues to be a matter of personal choice, an exercise of personal autonomy. Individuals may choose to be tested, either on their own initiative or in response to the suggestion of a professional. Parents may choose to have their children tested, although testing minors for some adult-onset genetic diseases has generated much debate and considerable caution [2]. Persons who participate in genetics research may also seek information about themselves that is recorded in research results, although disclosure of research results is far more guarded because of the tentative, or unconfirmed nature of research results and information. As the power of technology continues to expand, the possibilities of generation and disclosure of genetic information without consent have constituted a nucleus of federal concern that is now focused on the rights of individuals and their interactions with medical professionals and the research community. While the legislative and regulatory processes are slow, the depth of interest and concern for personal privacy and patient autonomy illustrates and reinforces the potential benefits from sequencing and understanding the human genome [13].

Probability Sampling

Probability sampling is a process used to select a sample from a defined population with the characteristic that every element of the population has a known, nonzero probability of being included in the sample. In probability sampling we select the sample by a random mechanism under which each element of the population receives this known selection probability [1]. Nonprobability sampling, in contrast, does not have this feature.

Probability sampling allows us to evaluate statistical properties of estimators of population characteristics and to construct estimators with desired statistical properties, since the selection probability for every sample is known (*see* **Estimation**). For instance, we can evaluate how reproducible an estimator is over repetitions of the sampling process yielding the estimate (reliability) and whether the **expectation** of an estimator over repetitions yielding the estimate is the same as the true value of the parameter being estimated (**unbiasedness**).

Nonprobability sampling is almost always less expensive and easier to carry out than probability sampling. Examples of nonprobability sampling are selection of a predetermined number of individuals having specified characteristics, or selection of individuals believed to be representative (*see* **Quota, Representative, and Other Methods of Purposive Sampling**; **Snowball Sampling**). In nonprobability sampling we cannot evaluate statistical properties of estimators such as reliability or unbiasedness since there is no known selection probability for each element in the population.

Probability Theory

Probability theory is that part of mathematics that aims to provide insight into phenomena that depend on chance or on uncertainty. The most prevalent use of the theory comes through the frequentists' interpretation of probability in terms of the outcomes of repeated experiments, but probability is also used to provide a measure of subjective beliefs, especially as judged by one's willingness to place bets.

The roots of probability theory are not as ancient as those of many parts of mathematics, and only in the sixteenth and seventeenth centuries does one find the first glimmerings of the theory in the investigations made by Gerolamo Cardano, Pierre de Fermat, and Blaise Pascal into games of chance. Despite the luminous reputations of these famous mathematicians and philosophers, the subject of probability theory remained on the periphery of respectability, and for a long time development was halting and lugubrious. Through the first third of the twentieth century, the eighteenth century works of Jakob Bernoulli (*see* **Bernoulli Family**) and **Abraham De Moivre** continued to be viewed as the nearly definitive treatises of probability theory [3, 11].

Still, even in the early days of the twentieth century when probability theory clearly suffered from the lack of a widely accepted foundation, there were profound developments, most notably Albert Einstein's use of **Brownian motion** in 1905 to provide the first determination of Avagadro's number [7]. Nevertheless, in 1933 when **Andrey Nikolayevich Kolmogorov** published his elegant succinct volume *Foundations of the Theory of Probability* [10], the mathematical world was hungry for such a treatment, and the subsequent development of probability theory was explosive.

Firm Foundation

Central to Kolmogorov's foundation for probability theory was his introduction of the triple $(\Omega, \mathcal{F}, P)$ that we now call a probability space, or sometimes the "probabilist's trinity". The triple's first element, Ω, is required only to be a set. The second element is a collection of subsets of Ω about which more will be said later. The third element is a function that assigns a real number to each of the elements of $\mathcal{F}$. This function is called a probability measure P provided that it satisfies the three following axioms:

Axiom 1. For all $A \in \mathcal{F}$ we have $P(A) \geq 0$.

Axiom 2. For any countable collection $\{A_i \in \mathcal{F} : 1 \leq i < \infty\}$ for which $A_i \cap A_j = \emptyset$ for all $i \neq j$, we have

$$P\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i).$$

Axiom 3. $P(\Omega) = 1$.

Axioms 1 and 3 are quite bland. Axiom 1 only captures our understanding that probabilities of events are nonnegative numbers, and Axiom 3 just echoes our assumption that Ω is a sensible representation for the universe of all possible outcomes of the chance experiment being modeled. Only about Axiom 2 can there be any quarrel, and at times arguments have been made for preferring a probability theory that only requires additivity of probabilities for finite collections of sets. Kolmogorov's decision to assume countable additivity is not the only possible choice, but it has been a fecund one that has proved to be appropriate in a wide variety of circumstances.

The mathematical benefit of Kolmogorov's second axiom is that it connects probability theory with the theory of measure as put forward by Borel, Lebesgue, Radon, and Fréchet in the early part of the twentieth century. It was in fact Fréchet who noted some 13 years after Lebesgue's famous 1902 thesis that the natural domain for a probability measure is a collection of sets that is closed under complementation and countable unions. Fréchet called such collections σ-algebras, and Kolmogorov required that the second term of his triple be just such a collection [4, 5].

Basic Quantities of the Theory

To the practical mind, Kolmogorov's axiomatization of probability may seem only to defer the problem of construction of probability models that serve to inform us about the physical and social world, but by putting the elusive probability function P on an axiomatic footing Kolmogorov did provide real assurance that one could study probability as sensibly as one could study measure theory, analysis, or algebra.

In particular, one could proceed with the investigation of the objects that had been of concern from probability's earliest days.

One of the most fundamental notions of probability theory is the **random variable**, and in Kolmogorov's framework a random variable is nothing more than a function from $X : \Omega \to \mathbb{R}$ with the property that for all t one has that the sets $\{\omega : X(\omega) \leq t\}$ are elements of the σ-algebra $\mathcal{F}$. With this definition we are on firm footing when we take the definition of the distribution function F of X to be

$$F(t) = P(X \leq t),$$

because the set $\{\omega : X(\omega) \leq t\}$ is in the domain of the set function P. In this framework the **expectation** $\mathrm{E}(X)$ of the random variable X can defined as the Lebesgue integral of X with regard to P, or as the Riemann–Stieltjes integral with respect to F, giving us

$$\mathrm{E}(X) = \int_{\Omega} X(\omega)\, \mathrm{d}P(\omega) = \int_{-\infty}^{\infty} x\, \mathrm{d}F(x).$$

The probability distribution function and the expectation operation provide us with the core language that is needed to express almost everything that one needs to say about individual random variables. For example, a basic measure of dispersion of a random variable is the **variance**, which one writes in terms of the expectation as

$$\mathrm{var}(X) = \mathrm{E}(X - \mu)^2,$$

where $\mu = \mathrm{E}(X)$ and the **standard deviation** of X is defined to be the square root of the variance.

Central Role of Independence

With expectations and distributions we recapture much of the most basic language of probability theory, but the real power of probability theory only emerges with the introduction of the central notion of *independence* of events, algebras, and random variables. To begin that development, one first defines elements A and B of $\mathcal{F}$ to be independent provided

$$P(A \cap B) = P(A)P(B).$$

This definition is then extended to sub-σ-algebras of $\mathcal{A}$ and $\mathcal{B}$ of $\mathcal{F}$ by calling $\mathcal{A}$ and $\mathcal{B}$ independent provided A and B are independent for all $A \in \mathcal{A}$ and all $B \in \mathcal{B}$. Finally, random variables X and Y are independent if $\mathcal{A}$ and $\mathcal{B}$ are independent when these are respectively the smallest σ-algebras containing all the sets $\{X \leq t\}$ and all the sets $\{Y \leq t\}$.

This definition of independence of random variables may look a little burdensome at first, but for many purposes it is much more convenient than the definition of independence that is sometimes given in elementary texts that call for the factorization of the joint density of X and Y. In fact, densities may not exist, but that is not the telling point. More to the heart of the matter is that with Kolmogorov's definition one clearly sees that the independence of X and Y implies the independence of $f(X)$ and $g(Y)$ for any monotone functions f and g, while this intuitive fact is cumbersome to check if one needs to verify a density factorization.

Theorems That Make the Theory

There are two theorems that live at the very heart of probability theory. The first is the **law of large numbers**, without which our most fundamental intuitions about the relationship of probability theory and the physical world would be at odds. The second is the **central limit theorem**, which is arguably the result that most clearly accounts for the practical utility of probability as a helpmate to statistics, as well as to the social and physical sciences [1, 2, 5, 6, 8, 9].

Theorem 1 (Law of Large Numbers). If $\{X_i : 1 \leq i < \infty\}$ is a sequence of independent random variables with the distribution function, F, and if $\mathrm{E}|X_i| < \infty$, then the event that the sequence

$$\frac{1}{n}\{X_1 + X_2 + \cdots + X_n\}$$

converges to $\mathrm{E}(X_1)$ has probability one.

Theorem 2 (Central Limit Theorem). If $\{X_i : 1 \leq i < \infty\}$ is a sequence of independent random variables with distribution function F, $\mathrm{E}(X_i) = \mu < \infty$, and $\mathrm{var}(X) = \sigma^2 < \infty$, then

$$\lim_{n\to\infty} P\left(\frac{1}{\sigma\sqrt{n}}\{X_1 + X_2 + \cdots + X_n - n\mu\} \leq x\right) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{x} \mathrm{e}^{-u^{2/2}}\, \mathrm{d}u.$$

Beyond Independent Random Variables

While the purest view of the aims and accomplishments of probability theory may be found in the study of sums of independent random variables, the applications of probability theory require the development of structures that also capture aspects of dependence. To give the simplest illustration of a such a system, we consider a finite set $S = \{1, 2, \ldots, n\}$ which we will call the set of "states", and a matrix $\mathbf{P} = (p_{ij})$, where all of the matrix entries satisfy $0 \leq p_{ij} \leq 1$ and where the row sums $p_{i1} + p_{i2} + \cdots + p_{in}$ all equal one. We now consider a sequence of random variables X_n that are defined by sequential transitions according to the row of the matrix $\mathbf{P}$. Specifically, if $X_n = i$, then X_{n+1} is determined by making a choice from the set S in accordance with the probability masses (p_{ij}). Such a sequence of random variables is called a **Markov chain**, and the theory of such sequences offers an important first step from the core theory of independent random variables. The index of the sequence $\{X_n : n \geq 0\}$ is usually viewed as "time" and an important extension of the notion of a Markov chain is that of a **Markov Process** where the index is taken to be the whole positive real line and the state space is permitted to be $\mathbb{R}^d$ (or even a more complex space). The most important such process is *Brownian motion* [2, 9].

Another direction for the development of probability theory that goes beyond independence is provided by the theory of *martingales* [2, 4–6]. On one level, martingales capture the notion of a fair gambling game, and although this view is interesting (and loyal to the origins of probability theory), the theory of martingales turns out to be an appropriate tool for many kinds of investigation (*see* **Counting Process Methods in Survival Analysis**). In particular, the theory of martingales provides the key to profound connections between the theory of Markov processes and the classical theory of harmonic functions.

Procrustes Rotation

Most rotation procedures associated with **principal components analysis** and **factor analysis** are designed to rotate a set of vectors associated with the retained components or vectors into a new set of vectors whose associated transformed components or factors will attain a **simple structure** (*see* **Rotation of Axes**). In *Procrustes* rotation the procedure is reversed; one is furnished with the two sets of vectors and determines the matrix that will best transform one set into the other. Although generally associated with principal components and factor analysis, Procrustes rotation may be used to relate any two matrices of the same dimension.

The problem may be stated as follows. Given two $(n \times m)$ matrices, $\mathbf{A}$ and $\mathbf{B}$, what transformation matrix $\mathbf{T}$ of dimension $(m \times m)$ will best transform $\mathbf{A}$ into $\mathbf{B}$ (i.e. what matrix $\mathbf{T}$ will make $\mathbf{AT}$ most like $\mathbf{B}$)? Let $\mathbf{E} = \mathbf{AT} - \mathbf{B}$. Then $\mathbf{E}$ is the difference between $\mathbf{B}$ and the approximation for it, $\mathbf{AT}$. The object is to obtain $\mathbf{T}$ such that $\text{tr}(\mathbf{E}'\mathbf{E})$ is a minimum.

If $\mathbf{T}$ is orthonormal ($\mathbf{TT}' = \mathbf{T}'\mathbf{T} = \mathbf{I}$) (*see* **Orthogonality**), this is called the *orthogonal Procrustes problem* and has a least squares solution [6], although the notion goes back to Mosier [4]. If $\mathbf{S} = \mathbf{A}'\mathbf{B}$, $\mathbf{U}$ are the orthonormal characteristic vectors of $\mathbf{S}'\mathbf{S}$, and $\mathbf{U}^*$ the characteristic vectors (*see* **Eigenvector**) of $\mathbf{SS}'$, then $\mathbf{T} = \mathbf{U}^*\mathbf{U}'$.

Table 1 contains the characteristic vectors for the audiometric example given in the article **Rotation of Axes**. Here, the vectors have been normalized to unit length and become the matrix $\mathbf{A}$. To facilitate the screening of large sets of medical records, these vectors were replaced by some simple approximations [2]. These are also normalized to unit length and included in Table 1 as matrix $\mathbf{B}$. The matrix $\mathbf{T}$ which best rotates $\mathbf{A}$ into $\mathbf{B}$ is:

$$\mathbf{T} = \begin{bmatrix} 0.996 & -0.062 & -0.041 & -0.057 \\ 0.058 & 0.993 & -0.099 & 0.009 \\ 0.048 & 0.096 & 0.994 & 0.021 \\ 0.056 & -0.015 & -0.022 & 0.998 \end{bmatrix}$$

$\text{tr}(\mathbf{E}'\mathbf{E}) = 0.150$.

The two-sided orthogonal Procrustes rotation [7] is used to test whether a $(p \times p)$ matrix $\mathbf{A}$ is a permutation of another $(p \times p)$ matrix $\mathbf{B}$. This is particularly useful in looking for particular patterns in matrices which may have been obscured by a permutation of the rows and/or columns. There are also solutions for *oblique Procrustes* rotation [3, 5, 8, 9]. For the audiometric example, an oblique solution reduced $\text{tr}(\mathbf{E}'\mathbf{E})$ to 0.133. There have been a number of other modifications and extensions of the Procrustes solution, including comparing three or more matrices (see [2]).

The name *Procrustes* was given to this procedure by Cattell (Hurley & Cattell [1]). In Greek mythology, Procrustes, the Stretcher, was an innkeeper who lured travelers with his "magical" bed which would fit anyone. If the guest was too short, he or she was stretched out to the length of the bed. If too long, he chopped off his or her feet. Hurley & Cattell felt this rotation procedure had about the same philosophy and urged caution in using this technique.

Product-integration

Product-integration was introduced more than 110 years ago by the Italian mathematician Vito Volterra, as a tool in the solution of a certain class of differential equations. It was studied intensively by mathematicians for half a century, but finally the subject became unfashionable and lapsed into obscurity. That is a pity, since ideas of product-integration make a very natural appearance in **survival analysis**, and the development of this subject (in particular, of the **Kaplan–Meier estimator**) could have been much smoother if product-integration had been a familiar topic from the start. The Kaplan–Meier estimator is the product-integral of the **Nelson–Aalen estimator** of the cumulative hazard function; these two estimators bear the same relation to one another as the actual survival function and the actual cumulative hazard function (*see* **Survival Distributions and Their Characteristics**). There are many other applications of product-integration in survival analysis, for instance in the study of multistate processes (connected to the theory of **Markov processes**), and in the theory of **partial likelihood**.

Ordinary integration is a generalization of summation, and properties of integrals are often easily guessed by thinking of them as sums of very, very many terms (all or most of them being very small). Similarly, product-integration generalizes the taking of products; a product-integral is a product of many, many terms (all or most of them being very close to the number 1). Thinking of product-integrals in this simplistic way is actually very helpful. Properties of product-integrals are easy to guess and to understand. The theory of product-integration can be a great help in studying the statistical properties of statistical quantities which explicitly or implicitly are defined in terms of product-integrals.

Before defining product-integrals in general and exhibiting some of their properties, we discuss the relation, in survival analysis, between the survival function and the hazard function. This leads us naturally to the notion of product-integration in the simplest of contexts.

Consider a survival time T with survival function $S(t) = \Pr(T > t), t \geq 0; S(0) = 1$. Suppose T is continuously distributed with density $f(t)$ and hazard rate $\alpha(t)$. These two functions have intuitive probabilistic meanings: for a small time interval $t, t + h$, the unconditional probability $\Pr(t \leq T \leq t + h) \approx f(t)h$, while the conditional probability $\Pr(t \leq T \leq t + h | T \geq t) \approx \alpha(t)h$. In fact, the probability density $f(t) = -(\mathrm{d}/\mathrm{d}t)S(t)$ while the hazard rate $\alpha(t) = f(t)/S(t)$. One can mathematically recover the distribution function $F(t) = 1 - S(t)$ from the density by integration; $F(t) = \int_0^t f(s)\,\mathrm{d}s$. Also, one can recover the survival function from the hazard rate. Noting that $\alpha(t) = -(\mathrm{d}/\mathrm{d}t)\log S(t)$, one finds by integration [and using $S(0) = 1$, hence $\log S(0) = 0$], that $-\log S(t) = \int_0^t \alpha(s)\,\mathrm{d}s$, and hence $S(t) = \exp[-\int_0^t \alpha(s)\,\mathrm{d}s]$. This is simple enough, but neither the result nor its derivation have a probabilistic interpretation.

If the survival time T had a discrete distribution, one would introduce the discrete density $f(t) = \Pr(T = t)$ and the discrete hazard $\alpha(t) = \Pr(T = t | T \geq t) = f(t)/S(t-)$. Still the survival function can be recovered from both density and hazard, but the formula in the latter case now seems quite different: $S(t) = \prod_0^t [1 - \alpha(s)]$. The continuous case formula $S(t) = \exp[-\int_0^t \alpha(s)\,\mathrm{d}s]$ has, therefore, two major defects: first, it does not have any intuitive interpretation; secondly, it gives the wrong generalization to the discrete case.

Here is how both formulas can be unified and made intuitively interpretable. Define the cumulative hazard $A(t)$ by, in the continuous case, $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$, and in the discrete case, $A(t) = \sum_0^t \alpha(s)$. [These two formulas are special cases of the completely general expression $A(t) = \int_0^t \mathrm{d}S(s)/S(s-)$.] Now we can write, both in the continuous and the discrete case,

$$S(t) = \prod_0^t [1 - \mathrm{d}A(s)], \tag{1}$$

which can be interpreted as the product over many small time intervals $s, s + \mathrm{d}s$ making up the interval $[0, t]$, of the probability $[1 - \mathrm{d}A(s)]$. Since the hazard $\mathrm{d}A(s)$ can be thought of as the probability of dying in the interval from s to $s + \mathrm{d}s$ given survival up to the beginning of that time interval, 1 minus the hazard is the probability of surviving through the small time interval given survival up to its start. Multiplying over the small time intervals making up $[0, t]$ yields the unconditional probability of surviving past t; in other words, (1) is just the limiting form of the

equality

$$\Pr(T > t) = \prod_{i=1}^{k} \Pr(T > t_i | T > t_{i-1})$$
$$= \prod_{i=1}^{k} [1 - \Pr(T \leq t_i | T > t_{i-1}],$$

where $0 = t_0 < t_1 < \cdots < t_k = t$ is a partition of the time interval $[0, t]$.

Consider now the statistical problem of estimating the survival curve $S(t)$ given a sample of independently censored survival times. Let $t_1 < t_2 < \cdots$ denote the distinct times when deaths are observed; let r_j denote the number of individuals at risk just before time t_j and let d_j denote the number of observed deaths at time t_j. We estimate the cumulative hazard function A corresponding to S with the Nelson–Aalen estimator

$$\hat{A}(t) = \sum_{t_j \leq t} \frac{d_j}{r_j}.$$

This is a discrete cumulative hazard function, corresponding to the discrete estimated hazard $\hat{\alpha}(t_j) = d_j / r_j$, with $\hat{\alpha}(t)$ zero for t not an observed death time. The product-integral of $\hat{A}$ is then

$$\hat{S}(t) = \prod_0^t (1 - \mathrm{d}\hat{A}) = \prod_{t_j \leq t} \left(1 - \frac{d_j}{r_j}\right),$$

which is nothing other than the Kaplan–Meier estimator.

The actual definition of the product-integral in (1) is the following:

$$\prod_0^t [1 - \mathrm{d}A(s)]$$
$$= \lim_{\max |t_i - t_{i-1}| \to 0} \prod \{1 - [A(t_i) - A(t_{i-1})]\},$$

where the limit is taken over a sequence of ever finer partitions $0 = t_0 < t_1 < \cdots < t_k = t$ of the time interval $[0, t]$.

From this point we can choose either to study properties of the product-integral or define it in greater generality. Both aspects are important in applications. Let us first give a more general definition. The important generalization is that we will define product-integrals of matrix-valued functions rather than just scalar-valued functions. The concept now really comes into its own, because when we multiply a sequence of matrices together the result will generally depend on the order in which the matrices are taken. Even in the continuous case there will not be a simple exponential formula expressing the result in terms of an ordinary integral. Multiplying products of matrices turns up in the theory of Markov processes, and this connects directly to the statistical analysis of multistate models in survival analysis.

Suppose $\mathbf{X}(t)$ is a $p \times p$ matrix-valued function of time t. Suppose also that $\mathbf{X}$ (or if you like, each component of X) is right continuous with left-hand limits. Let $\mathbf{I}$ denote the identity matrix. The product-integral of $\mathbf{X}$ over the interval $[0, t]$ is now defined as

$$\prod_0^t [I + \mathrm{d}\mathbf{X}(s)]$$
$$= \lim_{\max |t_i - t_{i-1}| \to 0} \prod \{I + [\mathbf{X}(t_i) - \mathbf{X}(t_{i-1})]\},$$

where, as always, the limit is taken over a sequence of ever finer partitions $0 = t_0 < t_1 < \cdots < t_k = t$ of the time interval $[0, t]$. For the limit to exist, $\mathbf{X}$ has to be of bounded variation; equivalently, each component of $\mathbf{X}$ is the difference of two increasing functions.

Application to Markov Processes

We briefly sketch the application of product-integration to Markov processes. Suppose an individual moves between p different states as time proceeds, staying in each state for some random length of time and then jumping to another. Suppose the individual has intensity $\alpha_{ij}(t)$ of jumping from state i to state j at time t, given the whole past history (in other words, the process is Markov: the intensity only depends on the present time and the present state). Define cumulative intensities $A_{ij}(t) = \int_0^t \alpha_{ij}(s)\,\mathrm{d}s$ and the negative total cumulative intensity of leaving a state $A_{ii} = -\sum_{j \neq i} A_{ij}$. Collect these into a square matrix valued function of time, $\mathbf{A}$. Then one can show that the matrix of transition probabilities $P(0, t)$, whose ij component is the probability of being in state j at time t given that the individual started at time 0 in state i, is given by a product-integral of $\mathbf{A}$:

$$P(0, t) = \prod_0^t [I + \mathrm{d}\mathbf{A}(s)].$$

This formula generalizes the usual formula for transition probabilities of a discrete time Markov chain, since the matrix $[\mathbf{I} + \mathrm{d}\mathbf{A}(s)]$ can be thought of as the transition probability matrix for the small time interval $s, s + \mathrm{d}s$.

Given possibly censored observations from a Markov process, one can estimate the elements of the matrix of cumulative intensities $\mathbf{A}$ by Nelson–Aalen estimators. The corresponding estimate of the transition probabilities, the **Aalen–Johansen estimator**, is found by taking the product-integral of $\hat{\mathbf{A}}$.

Mathematical Properties

A very obvious property of product-integration is its multiplicativity. Defining the product-integral over an arbitrary time interval in the natural way, we have for $0 < s < t$

$$\prod_0^t (I + \mathrm{d}X) = \prod_0^s (I + \mathrm{d}X) \prod_s^t (I + \mathrm{d}X).$$

We can guess many other useful properties of product-integrals by looking at various simple identities for finite products. For instance, it is often important to study the difference between two product-integrals. Now, if $a_1, \ldots, a_k$ and $b_1, \ldots, b_k$ are two sequences of numbers, then we have the identity:

$$\prod (1 + a_i) - \prod (1 + b_i) = \sum_j \prod_{i<j} (1 + a_i)(a_j - b_j) \times \prod_{i>j} (1 + b_i).$$

This can be easily proved by replacing the middle term on the right, $(a_j - b_j)$, by $(1 + a_i) - (1 + b_i)$. Expanding about this difference, the right-hand side becomes

$$\sum_j \left[\prod_{i \le j} (1 + a_i) \prod_{i>j} (1 + b_i) - \prod_{i \le j-1} (1 + a_i) \times \prod_{i>j-1} (1 + b_i) \right].$$

This is a telescoping sum; writing out the terms one by one, the whole expression collapses to the two outside products, giving the left-hand side of the identity. The same manipulations work for matrices. In general, it is therefore no surprise, replacing sums by integrals and products by product-integrals, that

$$\prod_0^t (I + \mathrm{d}X) - \prod_0^t (I + \mathrm{d}Y) = \int_{s=0}^t \prod_0^{s-} (I + \mathrm{d}X)[\mathrm{d}X(s) - \mathrm{d}Y(s)] \prod_{s+}^t (I + \mathrm{d}Y).$$

This valuable identity is called the Duhamel equation.

As an example, consider the scalar case; let A be a cumulative hazard function and $\hat{A}$ the Nelson–Aalen estimator based on a sample of censored survival times. Let S be the corresponding survival function and $\hat{S}$ the Kaplan–Meier estimator. The Duhamel equation then becomes the identity

$$\hat{S}(t) - S(t) = \int_{s=0}^t \hat{S}(s-)[\mathrm{d}\hat{A}(s) - \mathrm{d}A(s)] \frac{S(t)}{S(s)},$$

which can be exploited to get both small-sample and asymptotic results (*see* **Kaplan–Meier Estimator**).

We illustrate one other important identity in a similar manner. Note that

$$\prod_{i \le j} (1 + a_i) - \prod_{i \le j-1} (1 + a_i) = \prod_{i \le j-1} (1 + a_i) a_j.$$

Adding over j from 1 to k gives us

$$\prod_{i \le k} (1 + a_i) - 1 = \sum_j \prod_{i \le j-1} (1 + a_i) a_j.$$

Now we can guess the identity

$$\prod_0^t (I + \mathrm{d}X) - I = \int_{s=0}^t \prod_0^{s-} (I + \mathrm{d}X)\, \mathrm{d}X(s).$$

This is essentially Kolmogorov's forward equation from the theory of Markov processes (*see* **Brownian Motion and Diffusion Processes**), and it is the type of equation – solve $Y(t) = I + \int_0^t Y(s-)\, \mathrm{d}X(s)$ for unknown Y, given X – which originally motivated Volterra to invent product-integration. $Y(t) = \prod_0^t (I + \mathrm{d}X)$ is the unique solution of this equation. (It is also just a special case of the Duhamel equation when we take the second integrand Y identically equal to zero.)

Concluding Remarks

The product-integral seems first to have been used as a fundamental tool in modern survival analysis by

Aalen & Johansen [1], though it also appears in a more informal context in Cox [3] and in Kalbfleisch & Prentice [7]. Surveys of the theory of product-integration are given by Gill & Johansen [6] and Gill [5]. The former paper also pays attention to the earlier history of the subject. In particular, it is worth mentioning that a large variety of notations has been used for the product-integral, including large curly Ps, product-symbols, and the ordinary integral sign embellished with a half-circle over the top.

As well as playing a role in the theory of the Kaplan–Meier and the Aalen–Johansen estimators, the product-integral is also a useful way to write likelihoods and partial likelihoods in survival analysis, since these can be usefully thought of as continuous products of conditional likelihoods for the data in each new infinitesimal time interval given the past. The product-integral is also useful in **multivariate survival analysis**. In particular, Dabrowska's [4] multivariate product-limit estimator is based on a representation of a multivariate survival function in terms of product-integrals of a collection of higher-dimensional joint and conditional hazard functions. The book by Andersen et al. [2] gives a brief survey of the theory and many detailed applications, covering all the topics mentioned above.

Profile Likelihood

The profile likelihood is not a **likelihood**, but a likelihood maximized over **nuisance parameters** given the values of the parameters of interest. Let θ be the parameter(s) of interest and ϕ the nuisance parameter(s) of the statistical model $f(y|\theta, \phi)$ for data y. Once y is observed, the likelihood function is $L(\theta, \phi) = \Pr(y|\theta, \phi)$. Then the profile likelihood $P(\theta)$ is defined by $P(\theta) = L[\theta, \hat{\phi}(\theta)]$, where $\hat{\phi}(\theta)$ is the **maximum likelihood** estimate (MLE) of ϕ for given θ. The profile likelihood is thus the value of the likelihood generated as the nuisance parameter ϕ moves along the path $\phi = \hat{\phi}(\theta)$ through the parameter space. The name *profile* comes from the geometrical interpretation in three dimensions: if θ and ϕ are one-dimensional parameters, then the profile likelihood is the profile of the likelihood surface in θ as seen from a distance looking along the ϕ axis.

The profile likelihood conveniently formalizes the use of **likelihood ratio tests** to construct likelihood-based **confidence** regions for a parameter θ in the presence of nuisance parameters. For regular parametric models, the asymptotic distribution of the likelihood ratio test statistic (LRTS),

$$-2 \log \frac{L[\theta_0, \hat{\phi}(\theta_0)]}{L(\hat{\theta}, \hat{\phi})},$$

is χ^2_p, where p is the dimension of θ, under the hypothesis $\theta = \theta_0$ (*see* **Large-sample Theory**). Clearly,

$$\text{LRTS} = -2 \log \frac{P(\theta_0)}{P(\hat{\theta})},$$

and so the acceptance region for the hypothesis is the set of values of θ for which

$$\frac{P(\theta)}{P(\hat{\theta})} \geq \exp\left(-\frac{1}{2}\chi^2_{p,1-\alpha}\right),$$

where α is the size of the test. Define the profile *relative* likelihood by $PR(\theta) = P(\theta)/P(\hat{\theta})$; then the acceptance region is $[\theta : PR(\theta) \geq \exp(-\frac{1}{2}\chi^2_{p,1-\alpha})]$. Plotting the profile relative likelihood in single parameter-of-interest models provides a visual summary of the information about θ from this family of regions, and the regions themselves can be computed straightforwardly in many important models.

The main value of profile likelihoods is in constructing confidence regions for nonlinear functions of parameters, where methods based on MLEs and their asymptotic standard errors are often unsatisfactory.

A simple example is the toxicity test of a new drug on mice, described in [1]. The numbers r_i of mice dying out of n_i exposed at dose level x_i are

x_i:	422	744	948	2069
r_i:	0	1	3	5
n_i:	5	5	5	5

We fit the **logistic regression** model

$$\log \frac{p_i}{1 - p_i} = \beta_0 + \beta_1 \log x_i.$$

MLEs and standard errors for the two parameters are $\hat{\beta}_0 = -53.90(34.34)$ and $\hat{\beta}_1 = 7.93(5.08)$. For the null hypothesis $\beta_1 = 0$ of no regression on dose, the Wald test statistic $[\hat{\beta}_1/\text{se}(\hat{\beta}_1)]^2$ is 2.44, but the LRTS is 15.74, and the score test statistic is 11.29 (*see* **Likelihood**). The Wald test fails to detect the regression because the log likelihood in β_1 is far from quadratic, as is clear from the profile relative likelihood in Figure 1.

Conventional inference about the ED_{50} based on the parameter MLEs and their asymptotic covariance matrix is useless in this example because of the nonsignificance of the Wald test. However, the profile

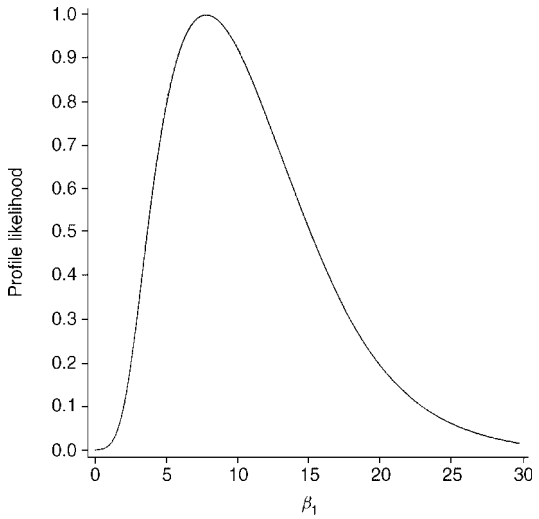

Figure 1 Profile relative likelihood for regression slope

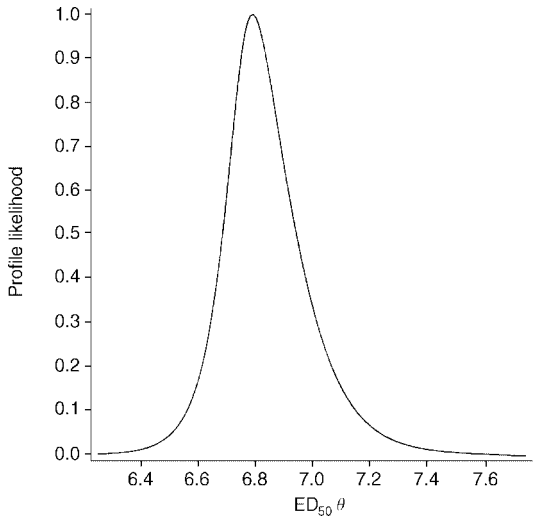

Figure 2 Profile relative likelihood for ED_{50}

likelihood is easily computed by reparameterizing the model: defining the ED_{50} by $\theta = -\beta_0/\beta_1$, the model becomes

$$\log \frac{p_i}{1-p_i} = \beta_1(\log x_i - \theta).$$

The likelihood is easily maximized over β_1 for fixed θ, generating the profile relative likelihood shown in Figure 2.

The MLE of θ is $-\beta_0/\beta_1 = 6.80$, and the 95% likelihood-based confidence interval for θ is (6.59, 7.11), corresponding to a dose interval of (728, 1224).

The advantages and disadvantages of the profile likelihood are clearly seen in the single-sample normal model $N(\mu, \sigma^2)$. Given a sample $y_1, \ldots, y_n$ with sample mean $\overline{y}$ and sum of squares $T = \sum(y_i - \overline{y})^2$, the likelihood is (omitting irrelevant constants)

$$L(\mu, \sigma) = \frac{1}{\sigma^n} \exp\left\{-\frac{1}{2\sigma^2}[T + n(\overline{y} - \mu)^2]\right\}.$$

Regarding μ as the parameter of interest and σ as the nuisance parameter gives

$$\begin{aligned}
\hat{\sigma}^2(\mu) &= \frac{1}{n}[T + n(\overline{y} - \mu)^2], \\
P(\mu) &= \frac{1}{\hat{\sigma}^n(\mu)} \exp\left(-\frac{n}{2}\right) \\
&= \frac{\exp(-n/2)n^{n/2}}{T^{n/2}} \left(1 + \frac{t^2}{n-1}\right)^{-n/2}, \\
PR(\mu) &= \left(1 + \frac{t^2}{n-1}\right)^{-n/2},
\end{aligned}$$

where $t = \sqrt{n}(\overline{y} - \mu)/s$ and $s^2 = T/(n-1)$.

Thus, $PR(\mu)$ is exactly the scaled t density (*see* **Student's *t* Distribution**), and a likelihood-ratio-test-based confidence interval for μ is exactly the usual t interval, though the exact distributional result improves on the asymptotic χ^2 distribution.

Regarding σ as the parameter of interest and μ as the nuisance parameter gives

$$\begin{aligned}
\hat{\mu}(\sigma) &= \overline{y}, \\
P(\sigma) &= \frac{1}{\sigma^n} \exp\left(-\frac{1}{2}\frac{T}{\sigma^2}\right), \\
PR(\sigma) &= \left(\frac{\hat{\sigma}}{\sigma}\right)^n \exp\left[-\frac{1}{2}\left(\frac{T}{\sigma^2} - n\right)\right] \\
&= \left(\frac{T}{n\sigma^2}\right)^{n/2} \exp\left[-\frac{n}{2}\left(\frac{T}{n\sigma^2} - 1\right)\right],
\end{aligned}$$

where $\hat{\sigma}^2 = T/n = (n-1)s^2/n$. The profile likelihood here is less satisfactory because it treats μ as known to be $\overline{y}$ and so gains an extra degree of freedom, relative to the *marginal* or *restricted* likelihood based on the χ^2_ν distribution of T/σ^2, with $\nu = n - 1$. If we observed only T and not $\overline{y}$, then we would have a marginal likelihood for σ from T of

$$M(\sigma) = \frac{1}{2^{\nu/2}\Gamma(\nu/2)\sigma^2} \left(\frac{T}{\sigma^2}\right)^{\nu/2-1} \exp\left(-\frac{1}{2}\frac{T}{\sigma^2}\right)$$

with a **restricted maximum likelihood** (REML) estimate $\tilde{\sigma}^2 = T/\nu$, giving

$$\begin{aligned}
MR(\sigma) &= \frac{M(\sigma)}{M(\tilde{\sigma})} \\
&= \left(\frac{T}{\nu\sigma^2}\right)^{\nu/2} \exp\left[-\frac{\nu}{2}\left(\frac{T}{\nu\sigma^2} - 1\right)\right].
\end{aligned}$$

Marginal likelihood-based confidence intervals based on the $\chi^2_{1,1-\alpha}$ critical value have very accurate confidence coverage and are shorter than the usual (biased) intervals based on the equal-tailed χ^2 test, while intervals based on the profile likelihood using the same critical value are even shorter because of the extra degree of freedom, but are offset to smaller values of σ and have reduced confidence coverage.

The unsatisfactory nature of the profile likelihood – its overprecision resulting from apparently

knowing the nuisance parameter as an explicit function of the data and the parameter of interest – has led to several proposals for *adjusting* or modifying it: this is a subject of continuing research interest. From a **Bayesian** viewpoint the nuisance parameter should be integrated out of the likelihood, not maximized over. Non-Bayesian adjustments have been proposed by Cox & Reid [4] and Barndorff-Nielsen [3] among others. In simple models these adjustments have an effect similar to integrating out the nuisance parameter with respect to a uniform **prior distribution**. In the normal model above when σ is the parameter of interest, integrating out μ with respect to a uniform prior gives the marginal likelihood. [A fully Bayesian analysis with the usual prior $d\sigma/\sigma$, however, gives the (normalized) *profile* likelihood as the posterior distribution of σ.] Profile likelihoods with a numerical *penalty* often appear as average (posterior mean) likelihoods in the likelihood approach of Aitkin [2].

Profiling Providers of Medical Care

The public debate on the cost and effectiveness of health care in recent years has brought much attention to the need for measuring and comparing performance of providers of medical care, such as physicians, clinics, hospitals, and health plans. Although comparative performance measures in health care were proposed as early as 1916, their use became widespread only in the late 1980s [1]. Prominent recent examples of assessing performance in the delivery of health care involved the analysis and publication of annual hospital mortality data by the Health Care Finance Administration and of heart surgery mortality rates by New York State [4, 5].

The comparison of measures of a provider's process of care, outcomes, or both, to normative or community standards is often called *profiling* [7]. The analysis may encompass several dimensions of care including **quality**, use of services (*see* **Health Care Utilization Data**), and cost (*see* **Health Economics**). After defining appropriate metrics and standards in each dimension of interest, the analyst proceeds to estimate provider-specific performance, to examine variations among providers and, ultimately, to identify possibly aberrant providers.

The results of profiling analyses are used to generate feedback for health care providers, to design educational and regulatory interventions by institutions and government agencies, to design marketing campaigns by hospitals and managed care organizations, and to select health care providers by individuals and managed care groups. Profiling information is often disseminated to the public in the form of "report cards" for health systems, hospitals, and individual health care practitioners [2]. A broad-based system for generating information for report cards is the Health Plan Employer Data and Information Set (see [2]).

Provider profiling entails a multifaceted set of analyses using data of varying quality, detail, and completeness. The process normally includes some form of **risk adjustment**, which is intended to account for possible differences in patient **case mix**. Commonly used methods for case mix adjustment are based on **regression** models for predicting a specific patient-level response, such as utilization, mortality, and cost. Many of these risk adjustment systems can be implemented using commercially available software such as APACHE and others. The adjusted responses are aggregated by provider, and comparisons are made to other providers or to normative data. Relative rankings and z-scores (*see* **Normal Scores**) for the difference between observed and expected performance are often used to compare providers [6]. More recent work approaches profiling analysis using a class of metrics of comparative and absolute performance, which are derived from the distribution of provider performance indices [8].

The methodologic challenges of **observational studies** generally apply to profiling analysis as well. In particular, a careful analysis would need to account for possible selection effects due to factors not reflected in the patient-level data (*see* **Propensity Score**; **Selection Bias**). In addition, the extent of **missing data** can be substantial and the pattern of missingness can vary across providers, even in well-designed studies. Recently developed methods for handling data not missing at random can be used to minimize bias and loss of efficiency (*see* **Multiple Imputation Methods**).

The statistical precision of provider-specific estimates and provider comparisons is seriously limited by the relatively small sample sizes of patients by provider involved in a typical profiling analysis. In addition, the analysis needs to account for **correlations** due to **clustering** in the data and to address the issue of **multiple comparisons** when **ranks** are reported and when performance indices are used to screen providers and identify "**outliers**". In response to these difficulties, recent methodologic work on profiling has made use of **hierarchical models**, with separate levels for modeling variation within and between providers [3, 7, 8]. The hierarchical model framework is suitable for accounting for sources of variation and clustering effects in the process of combining information across providers and for computing appropriate metrics of provider performance (*see* **Hierarchical Models in Health Service Research**; **Multilevel Models**).

As the process, cost, and outcomes of health care undergo close scrutiny, the need for careful profiling analysis is increasing. To meet this need successfully, further development of the statistical methods alone is not enough. Such work would have to be combined with considerable streamlining and improvement of the data collection mechanisms as well as with efforts

to formulate a consensus on standards for performing and reporting the results of profiling analysis.

Prognosis

In clinical medicine, establishing a prognosis for an individual is the estimation of the relative probability of the various possible outcomes of a disease. Essentially, this involves **prediction** of the outcome probabilities for the natural history of a disease at some point after the diagnosis has been made. The outcome might be death, for example, in which case one is trying to estimate the risk of death according to characteristics of the patient, such as age and disease severity; other examples are the prognostic assessment for remission of symptoms, future **quality of life**, or permanent disability. Conventionally, this type of prediction extends the concept of natural history to include the effects of various treatment options.

(*See also* **Clinical Epidemiology**; **Natural History Study of Prognosis**; **Predictive Modeling of Prognosis**)

STEPHEN D. WALTER

Prognostic Factors for Survival

Prognostic assessment of time to an event (death) is important in many medical studies (*see* **Prognosis**). Applications are widely varied, and include:

1. predicting the outcome to assist in making treatment selection decisions
2. development of disease classification and staging systems
3. identification of biological factors that may help elucidate disease pathophysiology
4. analysis of treatment effects in randomized **clinical trials**.

Statistical modeling is a process of discovery. One usually wishes to determine what variables are associated with outcome, the nature of this association, and how the association is modulated by other variables. There is, however, a conflict between exploratory analysis for discovery and the ability to make statistically valid statements about the resulting model. Consequently, it is useful to distinguish exploratory prognostic investigations from confirmatory studies. In the latter, the form of the model, the identity of the variables, and the nature of their representations (e.g. **binary** with specified cutpoints, **categorical** with specified categories, linear, etc.) should be specified in advance. Under such conditions, valid statistical statements can be made about the model. Simon & Altman have defined three phases of prognostic factor studies and offered guidelines for phase III (confirmatory) prognostic factor studies [17].

When a statistical model is used for the analysis of randomized clinical trials, the need for making statistically valid statements is paramount. Consequently, this type of application should be dealt with as a confirmatory investigation. In some confirmatory prognostic studies even the regression coefficients of the model are specified in advance so that the data will provide a valid estimate of predictiveness of the model. Confirmatory prognostic studies are rarely performed. Consequently, the literature of prognostic factors in medicine is often contradictory and difficult for practicing physicians to utilize.

The process of model development and **validation** can be partially simulated by splitting the data into two parts. Investigators are usually reluctant to do this because most data sets are of limited size for assessing all the variables of interest. In many cases, however, published models have been overfitted to the data. Such models may feature spurious relationships and gross overestimates of predictiveness. When one has a very large data set, it is best to split it into a portion for model development and a portion for model validation. If the data set is too small for splitting, then it is best to limit the extent of model development to the variables of greatest interest, and to develop the model in a manner that will permit valid statistical inferences. The third alternative is to conduct the study as an exploratory process of discovery and to be emphatic about the need for validation before the model should be considered for adoption. Sample reuse methods such as the **bootstrap** or **cross-validation** can also be used if the model development process is algorithmic, although this is often not the case.

We focus attention here on factors for predicting a single outcome event, such as survival. Multistate and multievent models present special problems [1, 2].

Many types of regression models for survival data have been used. These include fully parametric models based on **exponential**, **Weibull**, **normal**, **log-normal**, **gamma**, and log-gamma distributions (*see* **Parametric Models in Survival Analysis**). **Proportional hazards** (PH) models, both parametric and nonparametric types, represent the hazard function as a product of a function of time and a function of the **covariate** vector. The most commonly used prognostic survival model is **Cox's regression** (proportional hazards) **model** [3]. Cox's model avoids parametric assumptions about the function of time. **Accelerated failure** (AF) **time** models are characterized by an assumption that the log of the survival time is the sum of a linear regression function ($\boldsymbol{\beta}'\mathbf{x}$) plus a random variable which represents the log survival of a subject with all covariate values equal to zero [12]. Exponential and Weibull regression models (with only the scale parameter depending on the covariates) are both parametric PH models and AF models.

The models mentioned above are all **fixed-effects** models in which the covariates are related to outcome through a linear functional $\theta = \boldsymbol{\beta}'\mathbf{x} = \beta_1 x_1 + \cdots + \beta_p x_p$, referred to as the *"prognostic index"*. The models differ in the assumptions they make about the underlying survival distribution and the parameter of the distribution which is determined by θ.

Random-effects models such as **frailty** models have also been studied but are not widely used yet [19].

Cox's PH model is widely used, primarily because it is a reasonably flexible model that does not require an assumption concerning the underlying survival distribution. In prognostic modeling attention is often focused on inference about specific regression coefficients or on the prognostic index. Cox's PH model is almost fully efficient for such inferences. A generalization of the PH model replaces the linear functional by $\theta = \sum f_i(x_i)$, where $f_i(\cdot)$ is a function with specified form such as a cubic **spline** [9].

For normal linear models it is well known that the inclusion of spurious or marginally important variables may increase the **mean square error** of prediction, although the residual mean square error will decrease [12]. This has led to the development of various stepwise **variable selection** algorithms. Unfortunately, the use of such methods invalidates the statistical inference statements usually associated with a regression model. Variable selection procedures are also frequently the basis for claims as to which are the "most important" covariates, when in fact there may be several models that predict about equally well. Use of stepwise procedures often makes it difficult to provide direct answers to questions such as whether use of a new **assay** provides improved predictiveness compared to use of a standard covariate alone [17]. For validity of inference it is best to avoid variable selection.

Prognostic modeling is often performed on the data at hand without much thought about sample size and the number of variables that can be studied reliably (*see* **Sample Size Determination**). Harrell [6] has suggested that the number of events should be at least ten times as large as the number of **degrees of freedom** for reliable modeling of survival data. If a continuous variable is represented by a restricted cubic spline with four knots, then two degrees of freedom are devoted to the variable. Similarly, a categorical variable with three categories is represented by two indicator variables and hence counts for two degrees of freedom. The number of variables modeled can be reduced by methods such as **principal components**, variable clustering, or using clinical summary indices that do not use the outcome data [8].

Continuous variables are most often represented linearly in prognostic modeling, but there is often interest in determining the nature of the relationship between an important continuous variable and outcome. Statisticians often approach this by using **polynomials** or by making the variable categorical (*see* **Categorizing Continuous Variables**). One of the most flexible and convenient approaches, however, is to use a restricted cubic regression spline to represent the relationship [5, 7]. This only involves defining new variables, based on the variable of interest and on the number and location of knots, and then using standard software to fit the model. As long as the number and location of the knots are specified in advance, standard significance tests (*see* **Hypothesis Testing**) and **confidence intervals** can be used to interpret the resulting relationship between the values of the covariate of interest and the outcome. Restricted cubic splines require the use of few degrees of freedom if the number of knots is kept small (e.g. 3–4). An alternative way of modeling a continuous variable is to dichotomize it using an "optimally selected" cutpoint. This approach is not recommended, however, because the optimizing of the cutpoint is a nonlinear process that is often ignored in subsequent inference using the model.

Once the form of the model is selected, the variables to be included are specified, and the manner of representing continuous or categorical variables is decided upon, the parameters of the model are generally determined to maximize a **likelihood** or **partial likelihood** function. The next step is assessment of **goodness of fit** of the model. Both analytic and graphic methods can be used. To test for the additivity of effects, models containing **interactions** can be fitted and **likelihood ratio tests** performed. To test for linearity of continuous variables, residual plots, such as martingale residual plots for the Cox model, can be used [18] (*see* **Residuals for Survival Analysis**). For parametric models there is a distributional assumption to be checked. For the PH model, the proportional hazards assumption should be checked either by examining Schoenfeld residuals or in other ways [13, 16]. One should also check for overly influential observations (*see* **Diagnostics**).

Once adequacy of fit is established, the statistical significance of individual regression coefficients can be examined using the Wald test based on the asymptotic normality of the maximum likelihood estimates (*see* **Likelihood**). Confidence intervals for individual regression coefficients or for linear combinations can be similarly determined. Risk groups can also

be established based on values of the prognostic index $\boldsymbol{\beta}'\mathbf{x}$.

In many cases it will be useful to quantify the proportion of variability explained by the model. Measures of explained variability have been proposed by several authors for survival models [11, 15] (*see* **Explained Variation Measures in Survival Analysis**). There is a bias in computing these measures on the same set of data used to fit the model. This bias can be reduced using the bootstrap or cross-validation [6, 10]. Even without bias correction, however, the proportion of variability explained often will be low, and this will temper the interpretation of highly statistically significant effects. The measures of explained variation are also quite useful for comparing different models.

Usually the covariates studied represent properties measured initially on subjects. In some applications, however, there is interest in determining whether a measurement made subsequently can be used as an early indicator of disease recurrence. This can be addressed by defining the measurement as a **time-dependent covariate**. Most survival regression models can accommodate time-dependent covariates. In using a survival model to evaluate treatment effect, however, time-dependent covariates should be generally avoided because they may be influenced by treatment and hence the regression coefficient for treatment may be misinterpreted.

It is common to analyze randomized clinical trials using survival models that account for important covariates. The model is used in order to increase power for detecting treatment effects. Since the trials are randomized there should be no **confounding** between treatment effect and prognostic factors. Since these clinical trials are often intended to be definitive bases for drug approval or public health policy, the prognostic factors to be included and the form in which they are modeled should be specified in advance. Usually only main effects are included in such models in spite of the fact that treatment by covariate interactions are of considerable interest to physicians. Incorporating such interactions, however, raises multiplicity questions which may be difficult to deal with satisfactorily (*see* **Simultaneous Inference**). Dixon & Simon [4] studied a Bayesian approach based on placing an **exchangeable** prior on the regression coefficients for treatment by covariate interactions with binary prognostic factors. Their approach is applicable to the PH and other survival models.

Survival models can also be used to evaluate treatment effects in nonrandomized settings. One approach is to use the model directly to reduce confounding between treatment and prognostic factors. An alternative approach is to develop a model; for example, a **logistic regression** model, to predict treatment assigned on the basis of prognostic factors. The prognostic index of that model, called a "propensity score", is then used as a covariate in a survival model to evaluate treatment effects [14].

Program Evaluation

Most societies are confronted by many complex health problems. A *health program* may be defined as an organized response to reduce one or more of these problems. In most cases, health programs are implemented to achieve specific objectives or outcomes by performing some type of service or intervention. Common examples include prenatal care programs to improve birth outcomes, fluoridation of public water supplies to improve community oral health, smoking cessation programs to reduce smoking behavior, school immunization programs to reduce morbidity and mortality, public insurance programs to increase use of health services, or medical treatments or preventive services to improve or maintain health.

Evaluation is the application of research methods to measure and explain the effects of a program against the objectives it set out to accomplish. Program evaluations help decision makers to understand the reasons for program performance, and to make informed judgments about improving a program, extending it to other sites, or cutting back or abolishing a program so that resources may be allocated elsewhere. In essence, evaluation is a management or decision-making tool for administrators, planners, policymakers, and other health officials.

Evaluation as a Profession

Program evaluation is a well-known, international profession. In many countries, evaluators have established associations (e.g. the American and Canadian Evaluation Associations) which hold annual conferences. The American Evaluation Association has developed guiding principles to promote the ethical conduct of evaluations by its members [1]. The *Evaluation Quarterly, Evaluation Review*, and *Evaluation and the Health Professions* contain findings of health program evaluations and advances in evaluation methods.

Evaluation Methods

Most evaluations of health programs consist of three basic steps. The first step occurs in the political realm, where evaluators work with decision makers to define the questions which the evaluation will answer about a program. While evaluations may be performed for a variety of reasons, most are conducted to answer two fundamental questions: "Did the program succeed in achieving its objectives?" and "Why is this the case?".

In general, program success or failure depends on the accuracy of its underlying "theory of cause and effect" and "theory of implementation" [7]. That is, all programs have either an explicit or implicit theory of cause and effect, which states that "if the program performs X, then Y will result" (*see* **Causation**). Programs also have a theory of implementation, which is usually defined by the protocols for implementing a program in the field. Programs may fail because of faulty implementation, or because of weaknesses in the program's implementation strategy. For example, a health promotion program to increase healthy lifestyles may be delivered by nurses as part of physical examinations, or identical services may be delivered by nurses conducting healthy lifestyle classes. The strategy for delivering the intervention – through physical examinations or classes – may affect the program's success in changing people's behavior. In short, programs are successful only when their underlying theories of implementation and cause and effect are sound. Faulty assumptions in either domain often undermine program performance.

In the second step, the evaluation is conducted to answer the questions about the program. *Impact evaluations* (also known as "outcome" or "summative" evaluations) address the first question and use experimental or **quasi-experimental designs** to estimate program effects [2, 4, 8] (*see* **Outcomes Research**). Experimental designs (*see* **Clinical Trials, Overview**) use **randomization** to determine whether observed outcomes are due to the program. However, in many programs randomization is not possible because laws prohibit excluding groups from the program, logistics prevent random assignment, the evaluation is performed after the program ends, or other reasons. In these cases, quasi-experimental designs (such as interrupted **time series**, regression–discontinuity analysis, and nonequivalent control group and static comparison group designs) are often used to estimate program effects [3]. In general, the greater the political controversy about a program in the first step, the greater the importance of having a rigorous impact design that can withstand

public scrutiny when the results of the evaluation are released to the public.

Process evaluations (also known as "evaluations of program implementation" or "formative evaluations") address the second question and attempt to explain why programs have positive, negative, or no effects by examining how they were implemented [6]. Process evaluations typically are designed to answer the following questions: (i) Was the program implemented as intended? (ii) Was the intervention strong enough to make a difference (**dose–response** relationship)? (iii) Did the **control** group receive a similar intervention from another source? (iv) Did external events weaken or reinforce the program's impact? To answer these questions, process evaluations use both quantitative methods (such as **surveys** and unobtrusive indicators) and qualitative methods (such as focus groups, ethnographic methods, and case studies). When an impact evaluation is based on a quasi-experimental design, evidence from process evaluations is useful for determining whether one or more threats to validity account for program effects.

In the third step the evaluation returns to the political realm, and findings are disseminated to decision makers, interest groups, and other constituents. A central assumption is that evaluations are useful only when their results are actually used to formulate new policy or improve program management. However, history indicates that this is often not the case [5, 9]. Formal dissemination plans may be developed to ensure that each group receives the information it wants about the program in a timely manner. Results also are more likely to be used when decision makers play an active role in creating the questions in step one.

In the end, the results of an evaluation are not the final determination of a program's worth, which is ultimately a political decision. An evaluation, however, can provide public evidence about a program to reduce uncertainties and clarify the gains and losses that different decisions might incur [9].

Projection Pursuit

Projection pursuit is a multivariate data analysis technique, the idea of which originates from Kruskal [15] and Switzer [29]. Its first successful implementation was by Friedman & Tukey [10] to **exploratory data analysis**, who also suggested the felicitous name *projection pursuit*. A unified notion of projection pursuit was introduced by Huber [12], which set a basis for further statistical research in the area.

As the name suggests, projection pursuit seeks interesting structures of a high p-dimensional data set by *searching* through *projections* of the data to lower k-dimensional spaces. The interesting structures include clusters, separations, or unexpected shapes or other "nonlinear structures". The nonlinear structures are opposite to linear structures. The linear structures are found via an analysis of sample mean and covariance, as attempted in classical **multivariate analysis**. The lower dimension k is usually 1 or 2 or maybe 3. A one-dimensional (projected) data set can be viewed via a histogram; a two-dimensional data set can be viewed via a scatter plot; and a three-dimensional data set may be inspected by spinning a three-dimensional scatter plot (*see* **Graphical Displays**). There are two key elements in implementing projection pursuit. One element is the *projection pursuit index*, which measures how important a projection is. The larger the index, the more interesting the projection. Another element is the *projection pursuit algorithm*, which is an **optimization** algorithm that searches stepwise over a k-dimensional space to maximize the index.

How do we choose or specify a projection pursuit index? Since it is easier to agree on what is an *uninteresting* projection, a projection pursuit index is an estimate of some distance between an uninteresting distribution and the distribution of projected data (or a projection). A natural uninteresting distribution is the standard **normal distribution**, N(0, 1), since it is the distribution that is the simplest and the one that is studied most thoroughly in statistics. Diaconis & Freedman [3] contains another argument for regarding the normal distribution as uninteresting: if the scale is fixed, then the normal distribution maximizes *entropy*, which is a standard measure of randomness (or unstructured distribution). Thus, heuristically the projection that maximizes the index (with the normal distribution as an uninteresting distribution) is most interesting (and may be called the *least normal projection*). Huber [12], Friedman [7], Jones & Sibson [14], Hall [11], Cook et al. [2], Li & Cheng [16], and Posse [21] all considered projection pursuit indices that use the standard normal distribution as the uninteresting distribution. However, the indices can easily be adapted to other uninteresting distributions. For example, Nason [18] proposed robust projection pursuit indices that measure divergence from student t-distribution.

Example (Hermite Index)

Let $\mathbf{X}_1, \ldots, \mathbf{X}_n$ be a p-dimensional data set of size n. Consider one-dimensional projection pursuit. Then the dimension k of the lower dimensional projection space is 1 and a projection is specified by a (p-dimensional) vector $\boldsymbol{\alpha}$ such that $\boldsymbol{\alpha}^{\mathrm{T}}\boldsymbol{\alpha} = 1$. The projected data in this case are one-dimensional data points $Z_1, \ldots, Z_n$, where $Z_i = \boldsymbol{\alpha}^{\mathrm{T}}\mathbf{X}_i$ for $i = 1, \ldots, n$, the structures of which can be easily viewed via their histograms.

Assume for the moment that $\mathrm{E}(\mathbf{X}_i) = \mathbf{0}$ and $\mathrm{cov}(\mathbf{X}_i) = \mathbf{I}_p$. Then the L_2 distance between the densities of projected data $Z_i = \boldsymbol{\alpha}^{\mathrm{T}}\mathbf{X}_i$ and N(0, 1) indicates how interesting the projection by $\boldsymbol{\alpha}$ is. Here, the L_2 distance between two functions f and g is $\int [f(z) - g(z)]^2 \, \mathrm{d}z$. Since polynomials are inexpensive to compute, Hall [11] defined his index on the basis of an estimate of the m-term Hermite expansion of the L_2 distance:

$$I_m^{\mathrm{H}}(\boldsymbol{\alpha}) = \sum_{j=1}^{m} \frac{\sqrt{\pi}}{j! \times 2^{j-1}} \left[\frac{1}{N} \sum_{i=1}^{N} H_j(\boldsymbol{\alpha}^{\tau}\mathbf{X}_i)\phi(\boldsymbol{\alpha}^{\tau}\mathbf{X}_i) \right]^2 + 2\pi^{1/2} \left[\frac{1}{N} \sum_{i=1}^{N} \phi(\boldsymbol{\alpha}^{\tau}\mathbf{X}_i) - \frac{1}{2\pi^{1/2}} \right]^2, \quad (1)$$

where ϕ is the probability density function (pdf) of N(0, 1) and the H_js are Hermite polynomials. In practice, $\mathrm{E}(\mathbf{X}_i)$ and $\mathrm{cov}(\mathbf{X}_i)$ are arbitrary and the distribution of $\mathbf{X}_i$ is unknown. Thus, a practical m-term Hermite index is simply $I_m^{\mathrm{H}}(\boldsymbol{\alpha})$ above with $\mathbf{X}_i$ replaced by the sphered data $\tilde{\mathbf{X}}_i$ of $\mathbf{X}_i$. The sphered data are invariant under scale, location, and rotation changes, and they satisfy

$$\frac{1}{n} \sum_{i=1}^{n} \tilde{\mathbf{X}}_i = \mathbf{0}, \qquad \frac{1}{n} \sum_{i=1}^{n} \tilde{\mathbf{X}}_i \tilde{\mathbf{X}}_i^{\mathrm{T}} = \mathbf{I}_p. \quad (2)$$

For example, Friedman's [7] sphering scheme is $\tilde{\mathbf{X}}_i = \hat{\mathbf{D}}^{-1/2}\hat{\mathbf{U}}^\tau(\mathbf{X}_i - \overline{\mathbf{X}})$ for $i = 1, \ldots, n$, where $\hat{\mathbf{U}}\hat{\mathbf{D}}\hat{\mathbf{U}}^\tau = \hat{\mathbf{\Sigma}}$ is an **eigenvalue**–eigenvector decomposition of the sample **covariance matrix** $\hat{\mathbf{\Sigma}} = (1/n)\sum(\mathbf{X}_i - \overline{\mathbf{X}})(\mathbf{X}_i - \overline{\mathbf{X}})^\tau$ and $\overline{\mathbf{X}} = \sum \mathbf{X}_i/n$ is the sample mean.

Of course, a different m will result in a different projection pursuit index. See remarks in the next two paragraphs for a discussion on choosing m. If the resulting $\boldsymbol{\alpha}$ is close to $(1, 0, \ldots, 0)$, then it indicates that the first coordinate or the first variable in the data may be interesting. However, if $\boldsymbol{\alpha}$ is close to $(1/\sqrt{2}, -1/\sqrt{2}, \ldots, 0)$, then it indicates that the difference of the first and second coordinates of the data may have an interesting structure.

Friedman's index [6] differs from Hall's in that Friedman applied a Legendre polynomial expansion of the L_2 distance between the densities of the transformed projection and a transformed standard normal random variable. The transformation is $R = 2\Phi(Z) - 1$, where $\Phi(z)$ is the cumulative distribution function (cdf) of N(0, 1). When $k = 2$, a two-dimensional Legendre index can be obtained in a similar way (cf. [7]). Other indices include those based on the Kolmogrov distance (*see* **Kolmogorov–Smirnov Test**) (Li & Cheng [16]) **skewness, kurtosis** and lower order polynomials [14], and Hermite functions [13]. Sensitivity to a particular nonlinear structure varies from one index to another; and even the sensitivity of one type index (Hermite index, say) changes as m changes. There are some preliminary studies on comparing sensitivities of the various indices, see [2] and [25].

Using sphered data in a projection pursuit procedure is very important in practice. It usually provides a large computational gain and may unmask the "linear structures" from the "nonlinear structures". The linear structures can often be found by examining the sample mean and covariance of data, or a study of **principal components** that are obtained by an analysis of the covariance matrix. See [12] for more discussions on the importance of sphering. Note that the sphered data satisfy the constraints (2), which makes the first two terms of Legendre, Hermite, and other polynomial or polynomial-based function (such as Hermite function) indices much smaller than the higher order terms. See Sun [25], who suggested using $3 \le m \le 6$ in these indices.

How do we choose a projection pursuit algorithm? It is important that the optimization algorithm provides solutions close to the global maximum, or that its first several solutions provide the most interesting projections. Friedman [7] gave a practical projection pursuit algorithm (available in STATLIB [23]) for his one and two-dimensional Legendre indices, in which he uses a clever idea called *structure removal*. The idea of structure removal is to transform data along an "interesting" direction (a solution) into standard normal data while keeping structures along the other orthogonal directions unchanged. It has the effect that interesting directions already found will not be rediscovered, because normal structures are uninteresting and will therefore minimize the index. Structure removal should be implemented in all projection pursuit algorithms.

The next question is to judge how interesting a solution is from a projection pursuit algorithm. Even if data were **multivariate normal**, a projection pursuit algorithm would provide some solutions or projections $\boldsymbol{\alpha}$. It is useful to have a significance test (*see* **Hypothesis Testing**) to decide whether the apparent structure is real or just the effect of noise. Sun [24] derived a theoretical approximation for the significance level (or ***P* value**) associated with Friedman's one-dimensional projection pursuit index [7]. See Sun [26] for a rule of thumb in using this formula. Sun's method is applicable in principle to all polynomial or polynomial function-based indices. See Posse [21] for a nontrivial application of the idea to his modified chi-square index, a two-dimensional projection pursuit index. A by-product of the P value is that it helps a user to decide when to stop a projection pursuit algorithm. Consecutive large P values indicate that there might not be much interesting structure left.

Projection Pursuit Regression

The idea of projection pursuit goes beyond exploratory data analysis. For example, Friedman et al. [9] and Friedman & Stuetzle [8] applied projection pursuit in **density estimation, classification**, and **regression** problems. More recent applications can be found in Duan [5], Maller [17], Li & Cheng [16], Zhu et al. [31], Ngai and Zhang [19], Renaud [22] and Polzehl [20].

Consider a regression problem where $\mathbf{X}$ is a p-dimensional predictor variable and Y is the response variable. Projection pursuit regression approximates the regression function $f(\mathbf{x}) = \mathrm{E}(Y|\mathbf{X} = \mathbf{x})$, by a

finite sum of ridge functions

$$f^{(m)}(\mathbf{x}) = \sum_{i=1}^{m} g_i(\boldsymbol{\alpha}_i^{\mathrm{T}}\mathbf{x}), \tag{3}$$

where the ridge function g_i is defined on the domain of the projected data $\boldsymbol{\alpha}_i^{\mathrm{T}}\mathbf{x}$ and $\boldsymbol{\alpha}_i$ is the ith projection matrix such that $\boldsymbol{\alpha}_i^{\mathrm{T}}\boldsymbol{\alpha}_i = \mathbf{I}$, a $p \times k$ identity matrix. The projection pursuit regression model (3) is quite general. It can be used to approximate a large class of functions f well as $m \to \infty$ for suitable choices of $\boldsymbol{\alpha}_i$ and g_i (cf. Diaconis & Shahshahani [4]). For example, the simple **linear regression**, the **neural network** modeling with one hidden layer, and the **generalized additive model** can be viewed as special cases of (3), see [26]. There are many algorithms for fitting g_i and $\boldsymbol{\alpha}_i$. Friedman & Stuetzle [8] suggested a stepwise projection pursuit regression algorithm (available in **S-PLUS** software, `http://www.insightful.com/`), which allows a backfitting, where $\boldsymbol{\alpha}_i$ are found in a stepwise way by maximizing an updated index and g_i are estimated by super-smoother smoothing through the points represented by projected data $\boldsymbol{\alpha}_i^{\mathrm{T}}\mathbf{X}$ and the ith level of residuals (*see* **Nonparametric Regression**).

Projection pursuit density estimation approximates a high p-dimensional data density $f(\mathbf{x})$ of $\mathbf{X}$ by

$$f^{(m)}(\mathbf{x}) = f_0(\mathbf{x}) \prod_{j=1}^{m} f_j(z_j),$$

where $z_j = \boldsymbol{\alpha}_j^{\mathrm{T}}\mathbf{x}$ are projected data based on a suitable choice of projection operators $\boldsymbol{\alpha}_j$; f_0 is an uninteresting density or initial model; and f_i are *low* dimensional densities based on interesting projections of data. A stepwise projection pursuit density algorithm for estimating $f^{(m)}$ may be as follows. (i) Let $f^{(0)} = f_0$; (ii) given $f^{(l-1)}$, find $\hat{\boldsymbol{\alpha}}$ that maximizes the index

$$I(\boldsymbol{\alpha}) = \frac{1}{n}\sum_{i=1}^{n} \log\left[\frac{\hat{g}_{\boldsymbol{\alpha}}(Z_i)}{\hat{g}_{\boldsymbol{\alpha}}^{(l-1)}(Z_i)}\right], \tag{4}$$

where $\hat{g}_{\boldsymbol{\alpha}}$ is a marginal density estimate based on $Z_1, \ldots, Z_n$, and $\hat{g}_{\boldsymbol{\alpha}}^{(l-1)}$ is a density estimate based on the projection to $\boldsymbol{\alpha}$ of a **Monte Carlo** random sample from $f^{(l-1)}$; (iii) set

$$f_l(\hat{\boldsymbol{\alpha}}^{\mathrm{T}}\mathbf{x}) = \frac{\hat{g}_{\hat{\boldsymbol{\alpha}}}(\hat{\boldsymbol{\alpha}}^T\mathbf{x})}{\hat{g}_{\hat{\boldsymbol{\alpha}}}^{(l-1)}(\hat{\boldsymbol{\alpha}}^T\mathbf{x})},$$

$$f^{(l)}(x) = f^{(l-1)}(x) \times f_l(\hat{\boldsymbol{\alpha}}^{\mathrm{T}}\mathbf{x}).$$

Then repeat steps (ii) and (iii) until max $I(\boldsymbol{\alpha})$ is less than a preselected small value.

Conclusions

The beauty of projection pursuit is its ability to lift lower dimensional techniques to higher dimensions, and hence it helps to overcome the curse of dimensionality of a high dimensional data set. A common feature of (exploratory) projection pursuit, projection pursuit classification, projection pursuit density estimation, and projection pursuit regression is to use an *algorithm* in a stepwise way to search over low dimensional projections to maximize a projection pursuit *index*, such as (1) and (4). Projection pursuit can be applied to other multivariate analysis, too. For example, Polzehl [20] recently developed a projection pursuit **discriminant analysis**. Just like any modern data analysis technique, projection pursuit should be used in conjunction with (after) some simple preliminary data analysis, such as finding simple structures using the summary statistics, performing a predimension reduction via principal components, and sphering the data.

Searching interesting projections via a projection pursuit algorithm (which maximizes a projection pursuit index) as described above may be called *automatic* projection pursuit. This is in contrast to the *manual* projection pursuit, where a dynamic graphic system is employed and the "interesting" projections are searched by the human eye via spinning the projected data, as in *Prim-9* [30] and *Grand Tour* [1]. Manual projection pursuit can be infeasible if the data dimension is large or if a user is not experienced. Xgobi [28] is a first attempt to combine properly automatic and manual projection pursuit. Xgobi contains functions beyond projection pursuit. The interactive dynamic projection pursuit by Sun, Fleischer and Loader [27] is another new development toward the same direction. It is an S-plus function that dynamically loads some C and Fortran algorithms for conducting both one- and two-dimensional projection pursuit; it is currently the only software that provides P-values of projection pursuit indices".

JIAYANG SUN

Projections: AIDS, Cancer, Smoking

Planning for, and allocation of, health services is very much a dynamic process which is highly dependent on data and information about the current extent and distribution of diseases and injuries in a population, and, equally importantly, about how these are changing. Decisions must be made today about future health resources allocation; these decisions are ideally based on informed judgments about future epidemiologic patterns.

A prerequisite for making projections of disease and injury rates, and of their determinants, is reliable knowledge about current rates of cause-specific illness, and, in the case of determinants of health status, reliable science linking various exposures with disease and injury outcomes. Ideally, projections should be made taking into account possible changes in risks or rates of disease and injury, based usually on recent trends and on probable or possible changes in various determinants of health status. In cases where information is not considered sufficiently reliable to project future disease or injury risks, then demographic projections are still possible provided that projections of the future size and age–sex composition of the population are available. These projections assume that the age–sex patterns and levels of mortality and morbidity will remain constant, and hence the results of such projections merely indicate the implications of projected demographic changes, assuming no change in the epidemiologic parameters. This is clearly an implausible assumption and hence these projections are likely to be of limited value for health planning.

More useful projections result from making assumptions about likely or even possible changes in disease and injury rates over the projection period. The shorter the period, the more confidence there will be in the results. Projections are commonly made over a period of 10–30 years and hence the accuracy of the projections is substantially lower than for shorter projection periods, for which uncertainty in disease trends is relatively minor. To provide some bounds on this uncertainty, longer-term projections are generally prepared on the basis of various "scenarios" of the future, each of which assume different developments in the underlying determinants of disease and injury. For example, bounds may be defined by so-called "optimistic" and "pessimistic" scenarios of change over the projection period, with intermediate assumptions defining a "baseline" or "best-guess" scenario (see, for example, [10]).

Projections of disease and injury rates, and of overall survival levels, are generally made using one of two broad approaches: either past trends in rates are projected using some mathematical model relating rates in the past to time (calendar year), or projections are made on the basis of projected changes in the determinants of disease and injury levels. Mathematical **extrapolation** typically assumes that a logarithmic or higher-order polynomial expression adequately describes a previous **time series** of rates. Conversely, deterministic models usually specify future rates as a function of distal or socioeconomic variables (e.g. educational levels), or in the case of diseases where the etiology is comparatively well understood, such as major vascular diseases and several sites of cancer, as a function of qualitative and quantitative changes in exposure levels. Such methods should also consider possible changes in the underlying effect of exposure on disease outcomes, where this can be ascertained. Much more detail on these and other approaches to projecting epidemiologic parameters can be found in various studies [1, 2, 8, 10].

Whatever method is used to make projections, the results will be more or less reliable depending on the validity of the methods and the quality of the data and science used to model the past. Rather than interpreting projections as predictions of the future, it is much more appropriate to view them merely as the numerical consequences of a set of assumptions which may, or may not, turn out to be valid.

Projections have been made for a variety of health outcome indicators and for other aspects of the health sector, including health services provision. Three particular types of projections are described below in view of their importance for global health status; namely, cancer, smoking, and AIDS.

Cancer

Cancer is not a single disease, but several diseases with very different causalities (*see* **Oncology**). The etiology of some important sites in some populations is well understood (e.g. the role of tobacco in lung

cancer and cancers of the upper-aerodigestive tracts (*see* **Smoking and Health**), and alcohol as a cause of esophageal and liver cancers), whereas for others, e.g. breast cancer, the science of **causation** is still inconclusive. To the extent that the natural history of certain cancers is well known, and can be clearly described in terms of cohort-exposure to underlying determinants, projections can be made with greater reliability. This is certainly the case for lung cancer, the leading site of the disease in the world, and to a lesser extent for stomach cancer, the second most common site, for which incidence and mortality have been progressively declining for decades in most populations where trends can be reliably documented.

When making cancer projections, therefore, it may be convenient to consider three broad clusters of sites depending on major known carcinogens and overall disease trends. These sites broadly include:

1. tobacco-related cancers, which, in populations where smoking has been widespread for decades, account for up to 50% of all cancer cases [11]
2. stomach cancer, which alone has been declining during the twentieth century, thought largely to be due to less use of salt, and
3. all other sites, for which either incidence and mortality have not changed greatly, or, where large changes have occurred, are relatively insignificant causes of overall cancer burden.

Projections of lung cancer can then be made using various models that relate lung cancer risk to previous cigarette consumption, appropriately allowing for the time lag between onset of persistent smoking and disease risk, sometimes expressed as the duration of smoking (*see* **Latent Period**). Doll & Peto [4] developed a risk function of the form

$$I = 0.273 \times 10^{-12}(\text{cigarettes per day} + 6)^2 \times (\text{age} - 22.5)^{4.5},$$

whereby lung cancer incidence, I, is primarily determined by duration of smoking. Other methods have projected lung cancer as a function of various scenarios for smoking cessation, or as a direct function of cohort exposure [6, 7].

Given the steady long-term decline in stomach cancer incidence and mortality (see Figure 1), the occurrence of the disease would appear to be strongly related to dietary factors, and, in particular, to the salting of foods, which change with development. Projections of stomach cancer mortality have been made using a model with literacy (HC), GNP per capita (Y), and time (T) (as a proxy for technology and treatment advances) of the form

$$\ln M_{a,k,i} = C_{a,k,i} + \beta_1 \ln Y + \beta_2 \ln HC + \beta_3 T,$$

where $C_{a,k,i}$ is a constant term and $M_{a,k,i}$ is the predicted mortality level for age group a, sex k, and cause i [10].

It has been estimated that cancer caused about 6 million deaths in 1990, 3.4 million of whom were men, and 2.4 million (of both sexes) in the developed world. Lung cancer is already the leading site of the disease, causing 945 000 deaths worldwide in 1990, followed by cancers of the stomach (752 000 deaths), liver (500 000), colon/rectum (472 000), esophagus (358 000), and breast (322 000). By the year 2020, lung cancer is projected to cause more than 2 million deaths, mostly in men, and stomach cancer is projected to decline further to 500 000 deaths. In that year, cancer is projected to be the cause of about 10 million deaths – 70% more than today [10].

Smoking

There are two aspects of particular interest in relation to projections of smoking; namely, projections of smoking patterns and levels in different populations and, much more importantly, projections of smoking-attributable mortality. Projections of smoking **prevalence** and consumption are, by themselves, of limited public health interest. However, projections of the future health effects of current (and past) smoking patterns are of very considerable public health concern, given the extensive health effects of smoking [5, 12].

Currently, about one in two men in the developing world smoke, as do 40% of men, on average, in the developed world. Large-scale prospective evidence suggests that one in two smokers will eventually, either in middle age or old age, be killed by smoking [5, 11]. If these risks were to apply globally, and if current smoking trends were to persist, then the massive increase in cigarette consumption in developing countries over the last few decades would eventually result in an annual global toll from tobacco (primarily smoking) of about 10 million deaths each year, expected to occur in the late 2020s or early 2030s [11]. In particular, of all children and young adults alive today, these prevalence and risk measures suggest that something like 200–250 million of them will eventually be killed by tobacco.

More precise age–sex–cause and region-specific projections of smoking-attributable mortality have been prepared by Murray & Lopez [10] by projecting a measure of smoking intensity originally proposed by Peto et al. [11] to estimate smoking-attributable deaths in developed countries. This methods yields similar projections to the classical **attributable risk** approach described above but has the advantage of greater specificity and detail for the projections.

AIDS

Acquired immune deficiency syndrome (**AIDS**) results from infection with the HIV virus. Epidemiologic **surveillance** of the epidemic includes monitoring the number of individuals who have contracted the HIV virus (i.e. are seropositive) as well as the number of those who develop AIDS. Follow-up cohorts of HIV-infected people suggest that virtually all will develop AIDS, on average about 10 years after infection, and that the disease will prove fatal within about two to three years from onset.

Scientists [3, 9] have used these observations to fit a **gamma distribution** (with parameter P) of the form

$$I(t) = \frac{t^{(P-1)}\mathrm{e}^{-t}}{(P-1)!}$$

to project future AIDS cases $[I(t)]$ and deaths, given estimated HIV infection rates in different populations. By the turn of the century, about 20 million adults and 1 million children worldwide are projected to be living with the HIV virus. Murray & Lopez [10] have used estimated infection rates since 1990 to project incidence and mortality from AIDS until 2020. These projections suggest that deaths from AIDS will rise from around 400 000 in 1990 to peak at around 1.7 million somewhere between 2005 and 2010. Since incidence in some regions (primarily developed) has peaked, the global death toll from the disease is expected to slowly decline beyond about 2010.

In contrast, tobacco-induced deaths are expected to continue to rise well into the twenty-first century, making tobacco by far the leading cause of death and disease by about 2020 [10].

Promax Rotation

Promax rotation [1, 2] is a nonquartic method of performing an **oblique rotation** of a matrix $\mathbf{V}$ of dimension $(p \times k)$ associated with **principal components analysis** or **factor analysis** in order to transform these quantities into new variables by the relationship $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$ such that $\mathbf{B}$ will approximate a **simple structure**. The matrix $\mathbf{B}$ is of dimension $(p \times k)$ and the matrix $\boldsymbol{\Theta}$ is of dimension $(k \times k)$. (*see* **Rotation of Axes**). Promax rotation is a two-stage procedure which first obtains an approximation to $\mathbf{B}$ by means of an **orthogonal rotation** such as **Varimax**. The vectors obtained from this rotation are raised to some power with negative signs restored if the power is even. This has the effect of reducing the size of small coefficients faster than larger coefficients and hence approaches a simple structure. If the result of the powering is $\mathbf{H}$, then by **Procrustes rotation**, a rotation of the original vectors $\mathbf{V}$ is performed which is a least squares approximation of $\mathbf{H}$. This becomes the Promax rotation.

The choice of power will have an effect on the results. Lower powers will approach an orthogonal rotation. (Not powering the Varimax results would leave the final solution unchanged.) Higher powers would increase the obliqueness of the solution. General practice is to use powers in the range of 2 to 4.

For the Decathlon example given in **Rotation of Axes** the Promax solutions for powers of 2 and 4 are given in Table 1 along with the original principal component characteristic vectors (*see* **Eigenvector**).

Propensity Score

The propensity score is the **conditional probability** of exposure to treatment rather than control given observed **covariates** or, more generally, the conditional probability of selection given observed covariates. It is used to adjust for nonrandom treatment assignment or nonrandom selection. As a scalar summary of multidimensional covariates, the propensity score is often used for matching, **stratification**, or weighting adjustments. **Matching** and stratification are common in **observational studies**; that is, in studies of the effects of treatments not randomly assigned to subjects as they would be in a randomized **clinical trial**. Weighting adjustments are common in adjusting for **nonresponse** in surveys. Propensity scores have also been used as part of permutation inference and Bayesian inference (*see* **Bayesian Methods**), and have been incorporated as a variable in a model. Propensity scores were proposed by Rosenbaum & Rubin [25].

In thinking about what propensity scores may reasonably be expected to accomplish, it is useful to distinguish overt and hidden **biases**. An overt bias is visible in the data at hand. For instance, suppose that in comparing smokers and nonsmokers with recorded ages, one observes that smokers are somewhat older than nonsmokers. Then, a direct comparison of the mortality of smokers and nonsmokers ignoring age would be affected by an overt bias due to age. A hidden bias is similar, but it is not visible in the data at hand, though it may be suspected to exist. Adjustments for the propensity score reduce or eliminate overt biases, but the adjustments do little to address hidden biases, which must be investigated by other means; see Rosenbaum [21, Sections 4–9]).

In an observational study, N subjects are observed, of whom n receive the treatment and $N-n$ receive the control. Each subject has a vector $\mathbf{X}$ of observed covariates that describe the condition of subjects prior to treatment, so $\mathbf{X}$ is not affected by the treatment. Write $Z = 1$ if the subject receives the treatment and $Z = 0$ if the subject receives the control, so $n = \sum_{i=1}^{N} Z_i$. The propensity score $e(\mathbf{X})$ is the conditional probability of receiving the treatment given the covariates $\mathbf{X}$; that is, $e(\mathbf{X}) = \Pr(Z = 1|\mathbf{X})$. Although the propensity score will be discussed in the context of nonrandom treatment assignment in observational studies, it may be applied in other contexts, such as nonresponse in **sample surveys**; see [15].

The propensity score has several properties, the first of which is its balancing property. Pick a value of the propensity score $e(\mathbf{X})$, and sample at random treated subjects, those with $Z = 1$, and control subjects, those with $Z = 0$, having this same value of $e(\mathbf{X})$. Then these treated and control subjects with the same $e(\mathbf{X})$ have the same distribution of $\mathbf{X}$. To express this formally, follow Dawid [6] in writing $A \perp\!\!\!\perp B|C$ for A is conditionally independent of B given C. Then the balancing property of the propensity score says:

$$\mathbf{X} \perp\!\!\!\perp Z|e(\mathbf{X}) \tag{1}$$

or, equivalently,

$$\Pr[\mathbf{X}|Z = 1, e(\mathbf{X})] = \Pr[\mathbf{X}|Z = 0, e(\mathbf{X})].$$

The proof of (1) is straightforward; see [22, Theorem 1].

The balancing property is used in the following way. For each treated subject, find a **control** with approximately the same $e(\mathbf{X})$ forming a matched pair. Then the resulting matched sample will comprise a treated and control group with similar distributions for $\mathbf{X}$. If $\mathbf{X}$ is of high dimension, then matching exactly on $\mathbf{X}$ is difficult, but matching on a scalar $e(\mathbf{X})$ is straightforward. For instance, if $\mathbf{X}$ is a 20-dimensional vector of **binary** covariates, then there are 2^{20} or about a million possible values of $\mathbf{X}$, so finding controls that exactly match for all of $\mathbf{X}$ is infeasible with samples of reasonable size. In practice, one must estimate $e(\mathbf{X})$; for instance, using **logistic regression** of Z on $\mathbf{X}$. This is illustrated in [27] and [28]. There, 221 children with prenatal exposures to barbiturates were matched to 221 unexposed children drawn from a reservoir of 7027 potential controls. The vector $\mathbf{X}$ contained 20 covariates, such as gender, mother's socioeconomic status, mother's education, mother's cigarette use, etc. In this particular example, matching on the scalar estimate of the propensity score balanced all 20 covariates. Generally, after matching, the distributions of $\mathbf{X}$ in matched treated and control groups are compared to check that matching on the estimate of $e(\mathbf{X})$ has succeeded in balancing $\mathbf{X}$.

Alternatively, divide subjects into strata that are homogeneous in $e(\mathbf{X})$. Within strata, treated and control subjects tend to have similar distributions of $\mathbf{X}$.

This is illustrated in [26] where five strata formed from an estimated propensity score balance a 74-dimensional $\mathbf{X}$ of covariates in a study of coronary bypass surgery.

It is useful to compare and contrast the balancing property of propensity scores with the balancing property of **randomization** in a randomized experiment. Like randomization, strata that are homogeneous in the propensity score $e(\mathbf{X})$ may be quite heterogeneous in $\mathbf{X}$; however, within strata, the heterogeneity in $\mathbf{X}$ is not systematically related to the treatment group Z. For instance, in the coronary bypass example in [26], patients were denied bypass surgery if they were quite healthy and did not need it or if they were extremely ill and were unlikely to survive surgery. The stratum with the lowest probabilities of surgery, the lowest $e(\mathbf{X})$s, was extremely heterogeneous, containing both the healthiest and the sickest patients; however, within that stratum, the bypass patients and the controls had similar distributions of $\mathbf{X}$. Balancing does not eliminate heterogeneity; rather, it leaves the heterogeneity intact, but makes it nearly orthogonal to the treatment Z. Unlike randomization, adjustments for the propensity score balance the observed covariates $\mathbf{X}$ used in calculating $e(\mathbf{X})$, but they do not generally balance unobserved covariates. Randomization balances both observed and unobserved covariates, so randomization removes both overt and hidden biases, whereas adjustments for propensity scores reduce or eliminate only overt biases.

Each subject has two potential responses, a response r_{T} that would be observed if the subject received the treatment and a response r_{C} that would be observed if the subject received the control (see [18, 30, 31]). In fact, r_{T} is observed only if the subject receives the treatment, $Z = 1$, and r_{C} is observed only if the subject received the control, $Z = 0$. The effect caused by the treatment is a comparison of r_{T} and r_{C}, such as $r_{\mathrm{T}} - r_{\mathrm{C}}$; that is, a comparison of what the response would have been under treatment and under control. Because r_{T} and r_{C} cannot be observed jointly for one subject, causal effects cannot be calculated for individual subjects. Nonetheless, there are consistent and sometimes **unbiased** estimates of population summaries of causal effects under certain circumstances. For instance, in a randomized experiment the average response of treated subjects minus the average response of control subjects is an unbiased estimate of the average treatment effect, $\tau = \mathrm{E}(r_{\mathrm{T}} - r_{\mathrm{C}}) = \mathrm{E}(r_{\mathrm{T}}) - \mathrm{E}(r_{\mathrm{C}})$, and for binary responses, the sample **odds ratio** is a consistent estimate of the population odds ratio

$$\frac{\Psi = [\Pr(r_{\mathrm{T}} = 1)\Pr(r_{\mathrm{C}} = 0)]}{\Pr(r_{\mathrm{T}} = 0)\Pr(r_{\mathrm{C}} = 1)};$$

see Holland & Rubin [11]. Later in this discussion, it will be important to distinguish the odds ratio Ψ from the conditional odds ratio,

$$\omega_{\mathbf{X}} = \frac{\Pr(r_{\mathrm{T}} = 1|\mathbf{X} = \mathbf{x})\Pr(r_{\mathrm{C}} = 0|\mathbf{X} = \mathbf{x})}{\Pr(r_{\mathrm{T}} = 0|\mathbf{X} = \mathbf{x})\Pr(r_{\mathrm{C}} = 1|\mathbf{X} = \mathbf{x})}$$

given $\mathbf{X} = \mathbf{x}$,

which is generally a function of $\mathbf{x}$. Even when $\omega_{\mathbf{x}}$ is constant, not varying with $\mathbf{x}$, it does not typically equal the odds ratio Ψ that would be calculated in a randomized experiment without reference to covariates.

Adjustment for a covariate $\mathbf{X}$ in an observational study will yield **consistent** or unbiased estimates of population treatment effects if treatment assignment is ignorable, a term that will now be defined. Treatment assignment is said to be ignorable given $\mathbf{X}$ if

$$Z \perp\!\!\!\perp (r_{\mathrm{T}}, r_{\mathrm{C}})|\mathbf{X}$$

and (2)

$$0 < \Pr(Z = 1|\mathbf{X}) < 1, \quad \text{for all } \mathbf{X}.$$

This says that subjects may have unequal probabilities of receiving the treatment Z, but conditionally given the covariates $\mathbf{X}$, the assignment of subjects to treatment groups is equitable in the sense that it is unrelated to the responses subjects will later exhibit; that is, $\Pr(Z = 1|r_{\mathrm{T}}, r_{\mathrm{C}}, \mathbf{X}) = \Pr(Z = 1|\mathbf{X}) = e(\mathbf{X})$. It is not difficult to show that, if treatment assignment is ignorable, then exact matching or stratification or correct model-based adjustment for $\mathbf{X}$ can be used to estimate population causal effects such as τ or ψ; see [31] and [22, Theorem 4], with their $b(\mathbf{X}) = \mathbf{X}$. For instance, with ignorable assignment, an unbiased estimate of τ is obtained by sampling $\mathbf{X}$ at random, sampling a treated and a control subject at random with this same $\mathbf{X}$, and differencing their responses. The average of such differences is consistent for τ. With ignorable assignment, the odds ratio ψ is consistently estimated in an analogous way by first obtaining unbiased estimates of the four probabilities, $\Pr(r_{\mathrm{T}} = 1)$, $\Pr(r_{\mathrm{C}} = 0)$, $\Pr(r_{\mathrm{T}} =$

0), and $\Pr(r_C = 1)$, and, secondly, calculating the odds ratio of the unbiased estimates. Hamilton [10], Little [15], Sobel [36], and Stone [38] discuss related issues.

The second fact about the propensity score is that if treatment assignment is ignorable given $\mathbf{X}$, then it is also ignorable given just the propensity score $e(\mathbf{X})$, so if it suffices to adjust for $\mathbf{X}$ in estimating τ or ψ, then it suffices to adjust for the scalar $e(\mathbf{X})$. Formally, it may be shown [22, Theorem 3] that (2) implies

$$Z \perp\!\!\!\perp (r_T, r_C) | e(\mathbf{X}) \tag{3}$$

and

$$0 < \Pr[Z = 1 | e(\mathbf{X})] < 1, \quad \text{for all } e(\mathbf{X}).$$

In short, the propensity score tends to balance observed covariates $\mathbf{X}$ whether or not treatment assignment is ignorable. If treatment assignment is ignorable, then there is overt bias but no hidden bias, so it suffices to adjust for the observed covariates $\mathbf{X}$; but in this case, it suffices to adjust for the scalar $e(\mathbf{X})$. Specifically, if treatment assignment is ignorable, then parameters such as the average treatment effect τ or the odds ratio ψ can be consistently estimated by adjusting for the scalar $e(\mathbf{X})$ rather than the multivariate $\mathbf{X}$.

The performance of the propensity score in matching or stratification has been studied by **simulation**. Drake [7] compared propensity score adjustments and model-based adjustments when the propensity score or the model for the responses is incorrect. Gu & Rosenbaum [9] compared various matching techniques, in particular, concluding that matching on the propensity score was better than certain distance-based matching procedures when there are many covariates; say 20 or more covariates. Rubin & Thomas [34, 35] examine propensity score methods when covariates have **multivariate normal distributions**, ellipsoidal distributions, and empirical distributions derived from an example.

An alternative to matching or stratification for the propensity score is weighting adjustments. Although r_T is observed only if $Z = 1$ and r_C is observed only if $Z = 0$, the quantities Zr_T and $(1 - Z)r_C$ are always observed, although they are often zero. With a known propensity score, the quantity

$$\frac{Zr_T}{e(\mathbf{X})} - \frac{(1 - Z)r_C}{1 - e(\mathbf{X})} \tag{4}$$

may be computed for all N subjects. If treatment assignment is ignorable, then the average value of (4) may be shown to be unbiased for the average treatment effect τ; see [22]. In practice, estimated propensity scores are used in place of known propensity scores in (4), so the estimator becomes, in effect, the difference of two **Horvitz–Thompson estimators** [12] with estimated weights. As it turns out, the use of estimated weights is beneficial. The estimator based on (4) using estimated propensity scores is often superior to the analogous estimator based on true propensity scores for much the same reason that a **poststratified** estimator is often better than a sample **mean**; see [22] for specifics.

The propensity score is also used in various other ways. If the propensity score follows a linear logit model, then conditioning on a **sufficient statistic** for the parameters of the logit model eliminates unknown parameters in the propensity score, and yields exact permutation tests under the assumption that treatment assignment is ignorable; see [20, 24]. For instance, this may be used to adjust matched pairs for imbalances in covariates that were not fully controlled by the matching; see [23, 24]. The use of propensity scores in Bayesian inference is discussed by Rubin [33]. The propensity score may be used as a variable in a model-based adjustment; see [22, Corollary 4.3] for theory, and see [2, 37] for applications. Robins et al. [19] develop a novel semiparametric estimate of a regression coefficient using estimated propensity scores and various generalizations (*see* **Semiparametric Regression**). See also [3,4].

It is important to distinguish adjustment by balancing $\mathbf{X}$ from adjustment by control for $\mathbf{X}$. In a randomized experiment, random assignment of treatments would balance $\mathbf{X}$, while **blocking**, matching, or model-based adjustment, such as covariance adjustment, for $\mathbf{X}$ would control for $\mathbf{X}$. In experiments, balancing by randomization would permit estimation of the average treatment effect τ or the odds ratio ψ based on averaged proportions, but control for $\mathbf{X}$ would be required to estimate the conditional odds ratio $\omega_{\mathbf{x}}$ and other parameters that condition on a particular value of $\mathbf{X}$. Gail et al. [8] carefully develop some consequences of the distinction between balance and control in randomized experiments. Similarly, in an observational study with ignorable treatment assignment, matching or stratification for the propensity score $e(\mathbf{X})$ balances $\mathbf{X}$ permitting estimation of τ or ψ, but control for $\mathbf{X}$

would be required to estimate conditional parameters such as $\omega_{\mathbf{x}}$. Balancing and control may be combined. In experiments, this is done, for instance, using a **randomized complete blocks design**. In observational studies, this is done by combining matching or stratification $e(\mathbf{X})$ with further adjustments for $\mathbf{X}$. See [21, 23, 24, 26, 29, 32] for discussion of various aspects of combining matching or stratification with model-based adjustments.

When comparing several doses of treatment, rather than treated and control groups, a propensity score may sometimes be constructed using an ordinal logit model for the dose of treatment [13, 16]. When subjects begin as untreated and then sometimes switch to treatment after varied periods of time have elapsed, a time-dependent propensity score may be based on the hazard of receiving treatment given time-varying covariates [14]. The use of propensity scores in large case–cohort studies is discussed in [13].

For several applications of propensity scores, see [1, 2, 5, 17, 21, 27, 39].

PAUL R. ROSENBAUM

Proportional Hazards, Overview

In survival analysis, statistical models are frequently specified via the **hazard** function $\alpha(t)$. A simple model for the relation between the hazard functions in two groups (e.g. a treatment group 1 and a control group 0) is the *proportional hazards model*, where

$$\alpha_1(t) = \theta\alpha_0(t), \tag{1}$$

θ being the treatment effect. The relation (1) between the two hazards implies that the corresponding *survival functions* are related by the equation

$$S_1(t) = S_0(t)^\theta,$$

the so-called **Lehmann alternatives**.

To test the hypothesis $\alpha_1(t) = \alpha_0(t)$, several nonparametric tests are available. Among these, the **logrank test** is locally **most powerful** against proportional hazards alternatives.

In the **semiparametric** model (1), where "the baseline hazard" $\alpha_0(t)$ is left completely unspecified, there exist several estimators for the hazard ratio θ. Among these, the estimator based on the **Cox regression model** is the most frequently used; in fact, using this model, it is possible to adjust the treatment effect θ for effects of other **prognostic factors**. This proportional hazards model has gained widespread popularity in biostatistics.

In some epidemiologic applications, the hazard function $\alpha_1(t)$ in an exposed group is compared with a *known* hazard function; say, $\alpha_0(t)$. In this case, the **maximum likelihood** estimator $\hat{\theta}$ in the model (1) is the so-called *standardized mortality ratio*, which is the ratio between the observed number of deaths in the exposed group and the number of deaths one would expect if the hazard in the exposed group were $\alpha_0(t)$ (*see* **Standardization Methods**). Furthermore, the score test (*see* **Likelihood**) for the hypothesis $\theta = 1$ is the one-sample logrank test.

In conclusion, for survival data, proportional hazards has become the structure of choice, much like linearity in models for the mean of a quantitative outcome variable. However, other models are, indeed, available, including **additive hazard models** and **accelerated failure time models**.

PER KRAGH ANDERSEN

Proportional Mortality Ratio (PMR)

With mortality data classified by **cause of death**, the proportional mortality ratio (PMR) consists of a numerator that is the number of deaths from a particular cause and a denominator of total deaths from all causes. Thus, a PMR is simply the fraction (or percentage) of deaths from a particular cause.

In **descriptive epidemiology** involving characterization of PMRs by person, place, and time, it is customary to calculate standardized proportional mortality ratios (SPMRs) that use indirect standardization to adjust for age and often for age, gender, and race. See **standardization methods** for details of these calculations as well as for a historical description of the use of PMRs in vital statistics, the limitations of PMR analyses, and the relationships between PMRs and standardized mortality ratios (SMRs).

Particularly in **occupational epidemiology**, situations arise where the first and only available data consist of deaths classified by cause among persons who share a common occupational exposure. In these situations, a **proportional mortality study** is undertaken. Despite its major limitations and its often erroneous interpretation as an indicator of risk of mortality, PMR analysis can serve a useful role in descriptive epidemiology. A simple and low-cost proportional mortality study can suggest etiologic hypotheses and lead to a chain of increasingly complex analytic epidemiologic studies that ultimately establishes **causation**.

THEODORE COLTON

Proportional Mortality Study

Sometimes the only information available for an epidemiologic **observational study** consists of mortality records (usually death certificates) among a particular group of individuals who share some common exposure. This often occurs in occupational studies where the group consists of workers with a particular job classification, all workers in some industry, or employees at a particular installation or plant (*see* **Occupational Epidemiology**; **Occupational Mortality**). Examples of each of these are: nuclear shipyard workers, US Army veterans who served in Vietnam, and employees at a factory where inorganic arsenic compounds are handled. The intent is to see whether an exposure that the workers or group share is associated with increased risk of disease. Since the available information is only on deaths, it is mortality rather than morbidity that can be studied.

The key feature that characterizes a proportional mortality study is that there are no denominator data available that allow for the calculation of mortality risk or death rates. With information on causes of death among the group of decedents, one can calculate the proportion of *all* deaths due to a specific cause, namely the proportional mortality.

The essential strategy in a proportional mortality study is to compare the proportional mortality in the group of interest with proportional mortality in a comparison group. The comparison group can consist of an external **control** group, such as the general population for which **vital statistics** are available, or an internal control group; namely, a group of decedents from the same source population who do not share the exposure of interest. Thus, the essential comparison in a proportional mortality study is the ratio of proportional mortality in the study group to that in the comparison group, in other words, the **proportional mortality ratio (PMR)**.

The basic premise of a proportional mortality study is that if exposure is associated with increased risk of a specific disease, then with the available data on deaths by cause one should find proportionally more deaths from that cause among the exposed than among a comparison group of deaths, whether the comparison group consists of an external or an internal control group. Obviously, proportional mortality studies apply only to fatal diseases. For example, the common diseases of vision such as cataract, glaucoma, and age-related macular degeneration are each nonfatal and, hence, there is no place for proportional mortality studies of such disorders.

Of course, since mortality for virtually every disease has some relationship with age, there is the possibility that the decedents in the study and comparison groups have different age distributions. Consequently, age constitutes a potential **confounding** variable in virtually every proportional mortality study. To adjust for such potential confounding, it is customary to use **standardization methods** – in particular, indirect standardization – and to calculate a standardized proportional mortality ratio (SPMR). (Although standardization is usually by age, one can also standardize on other characteristics such as gender, race, and calendar time.)

Thus, using the three examples of occupational exposure described above, there have been proportional mortality studies conducted with calculation of SPMRs that have examined the following: (i) proportional mortality for leukemia and hematopoietic malignancies among shipyard nuclear workers vs. an internal comparison group of workers at these same shipyards but who were not involved in nuclear work [11]; (ii) proportional mortality from accidents and violent causes among US Army veterans who served in Vietnam vs. an internal comparison group of US Army veterans of the Vietnam era but who did not serve in Vietnam [2]; and (iii) proportional mortality from cancer – in particular, lung and skin – among employees at an arsenical factory in the UK vs. an external comparison group of population deaths (obtained from the death register of the area in which the factory was located) [7].

Interpretation of Proportional Mortality Studies

Proportional mortality studies need particularly cautious interpretation. A common and naive misinterpretation is to view the PMR or SPMR as equivalent to a **relative risk** as obtained in a **cohort study** or an **odds ratio** as obtained in a **case–control study**. Proportional mortality does *not* measure the *risk* of death from that cause. As defined, it measures only the relative frequency of that particular cause among all causes of death.

The basic limitation of a proportional mortality study is that one cannot determine whether an increase in proportional mortality for a particular cause of interest resulted from an increase in the risk of death from that cause (the basic premise underlying the study design), or from a deficit in mortality; namely, a lowering of risk of mortality, for various causes other than that of particular interest. For example, if a proportional mortality analysis resulted in an increased proportional mortality for some specific cancer, then one could not tell whether there was indeed an increased risk of death from that particular cancer, or whether the increased proportional mortality might have resulted from a lower risk of, say, mortality from cardiovascular diseases and accidents.

Even if there is increased risk of mortality from a particular cause, another limitation of proportional mortality is that one cannot distinguish whether such an increase resulted from an increase in the **incidence rate** of the disease or a worsening of the prognosis among existing (prevalent) cases of the disease.

The aforementioned basic limitations of the proportional mortality study severely limit its analytic potential. Proportional mortality studies are often the first, or an early, attempt to explore an association epidemiologically. Why are proportional mortality studies undertaken? In comparison with **analytic epidemiologic** studies, proportional mortality studies can be completed much more rapidly and with considerably less expenditure of resources. Often, it is the findings of a proportional mortality study that lead to a cascade of analytic epidemiologic studies of increasing complexity and cost that ultimately result in establishing a causal relationship between exposure and disease (*see* **Causation**). However, there have been proportional mortality studies with equivocal and controversial findings that have led to considerable efforts and expenditure of resources in subsequent analytic epidemiologic studies that ultimately result in the assurance to an alarmed public that there is no **association** between exposure and disease. An example of the latter is a proportional mortality study of the association of low-level occupational exposure to radiation among nuclear workers at Portsmouth Naval Shipyard, UK, with leukemia and hematopoietic cancers; a subsequent large-scale and expensive historical cohort study of mortality failed to find increased cancer mortality risks from radiation exposure [12]. In fact, a further analysis of more detailed and complete data at Portsmouth Naval Shipyard revealed **misclassification** bias in designating the causes of death in the initial proportional mortality study [5].

An important point in interpretation is that the same concerns with chance, bias (*see* **Bias in Observational Studies**), and confounding that apply to cohort and case–control studies apply also to proportional mortality studies. Of particular concern in proportional mortality studies are: the completeness of ascertainment of deaths; the accuracy of the coding of **causes of death**; the definition of exposure and its possible misclassification; and proper accounting for relevant confounding variables.

Most epidemiology textbooks, such as Henenkens & Buring [6] and Rothman & Greenland [14], describe proportional mortality studies, their characteristics, and limitations. More details about study design and analysis appear in occupational epidemiology texts such as Checkoway et al. [3] and Monson [10]. Considerable details on the statistical analysis and modeling of proportional mortality data appear in Breslow & Day [1]. One can also view a proportional mortality study as a special type of case–control study, as pointed out by Miettinen & Wang [9], and deploy the relevant design and analysis strategies for that design, in particular the calculation of a mortality odds ratio (MOR). This latter view of proportional mortality is discussed in the next section.

Design and Analysis of Proportional Mortality Studies

External Controls

The design of a proportional mortality study with external controls is indeed simple and straightforward. The basic material consists of deaths by cause among a particular group who share some exposure. One must take care that there is reasonably complete ascertainment of deaths in the series and that exposure classification is valid. As an example of an incomplete series, consider the situation of examining the employment records of an industrial plant and identifying all those instances where an employee had died. A proportional mortality analysis based on these existing records would likely find increased proportional mortality for diseases

such as acute myocardial infarction and accidents, deaths that are likely to occur during employment, and deficits in diseases such as cancer, which are likely to occur subsequent to employment and during retirement. Ideally, an appropriate proportional mortality study would include *all* deaths among those employed at the plant and would require ascertainment of deaths among former plant workers and retirees. Such ascertainment of postemployment deaths, presuming that there has not been widespread migration from the area, might entail searches of death certificates among the local health agencies, presuming that these sources can readily identify prior plant employees. Similarly, with the group of decedents assembled for analysis, one has to consider carefully the definition of exposure and have reasonable certainty that the group of deaths was indeed exposed to the agent under consideration. For example, a proportional mortality analysis of *all* employees at a plant would necessarily include office workers and others who might have minimal or no exposure to the agent under consideration. Such inclusions would tend to dilute the effects that exposure to the agent might have on proportional mortality.

The choice of the external reference standard population is also important, although one's possible choices are often extremely limited. If, for example, the group of decedents under study consists of almost exclusively white males who died during the period 1960–1975 (which was the case with the proportional mortality study of nuclear workers at Portsmouth Naval Shipyard), then one would ideally choose a reference population of white male decedents during this same calendar time. Anticipating age standardization, one needs a reference population of decedents classified by cause of death and by age, race, and calendar period. In this particular situation, although one might have preferred to use deaths from New England for the reference population, the only available proportional mortality data with this amount of detail were those for the entire US.

Once the reference population has been chosen, the calculation of SPMR is straightforward, with details of the calculations described in the article on **standardization methods**. Determination of the **standard error** of proportional mortality appears in Breslow & Day [1], although the authors warn against the conduct of statistical **inference** methods on PMRs.

Internal Controls

For a proportional mortality analysis with internal controls, one needs a group of deaths from unexposed subjects who are in other ways "comparable" with the exposed study group. For example, in a proportional mortality study of US soldiers who served in Vietnam, an obvious internal control group consists of deaths during the same time period among US soldiers who did not serve in Vietnam. In the example of shipyard nuclear workers at Portsmouth Naval Shipyard, the internal control group consisted of deaths among shipyard employees who were nonnuclear workers.

One common method for analysis of these data is to employ the methods for external controls described above to each of the exposed and unexposed groups of decedents and then to compare qualitatively the resulting SPMRs in the two groups. For example, in the initial proportional mortality study at Portsmouth Naval Shipyard [11], the SPMRs for leukemia were 5.62 for the nuclear workers (nearly a sixfold increase) and 0.71 for nonnuclear workers (close to the null value of 1.00). It is noted, however, that this initial study was particularly prone to bias in that there was (i) incomplete ascertainment of deaths; (ii) gross opportunity for misclassification of exposure (nuclear worker or not), since this was based on the recall of next of kin as to whether or not the decedent wore a radiation monitoring badge at work; and (iii) misclassification of cause of death, since the study's principal investigator determined, from his review of the data, the underlying cause of death for each decedent.

Another approach, as mentioned above, is to regard a proportional mortality study with internal controls as a variant of a case–control study. Cases consist of deaths from the cause of interest among both exposed and unexposed and controls consist of deaths from all other causes among both exposed and unexposed. Within this framework, one can analyze the data by the methods applicable to case–control studies; namely, to calculate an odds ratio. In this instance, such a calculation yields what is called a standardized mortality odds ratio (SMOR). Adjustment for confounding by age, or by other characteristics, can be accomplished with use of **Mantel–Haenszel methods**.

Viewed within the case–control framework, one might wish to be more careful in the choice of

controls in the design of such a proportional mortality study. Following the basic principle underlying the choice of controls in a case–control study; namely, that the controls should represent the source population from which the cases came, one would not necessarily choose all other deaths as controls. Instead, one would choose controls more carefully from a limited group of causes of death where there was a known lack of association of each cause with the exposure of interest. Thus, one would exclude from the control series those causes of death where there was a known or suspected association with the exposure of interest. Similar considerations apply in **hospital-based case–control studies**, in which one seeks to avoid selecting control diseases that may be associated with exposure.

Other Considerations

In some instances, one can categorize exposure according to duration and/or intensity and examine **dose–response** relationships in proportional mortality. Duration of employment often serves this purpose and, for the nuclear worker illustration, cumulative recorded radiation exposure by means of badge-monitoring constitutes an ideal dose measure. Methods for dose–response modeling with proportional mortality, based on **logistic regression**, are described by Breslow & Day [1].

There has been considerable investigation of the relationship between the PMR and the standardized mortality ratio (SMR) analyses of the same set of data. In fact, if one takes cause-specific SMRs and divides each by the all-causes SMR, then theoretically these should agree with the corresponding cause-specific PMRs. Kupper et al. [8] call this ratio of cause-specific to all-cause SMRs a relative standardized mortality ratio (RSMR). Zwerling et al. [15] give a recent example comparing the PMR and RSMR approaches with injury mortality among Iowa farmers. Decoufle et al. [4] and Roman et al. [13] also compared the PMR and SMR.

Proportional-odds Model

The proportional odds model is a class of generalized linear models used for modeling the dependence of an ordinal response (*see* **Ordered Categorical Data**) on discrete or continuous covariates. Let Y denote the response category in the range $1, \ldots, k$, with $k \geq 2$, and let $\gamma_j = \Pr(Y \leq j|\mathbf{x})$ be the cumulative response probability when the covariate is held at $\mathbf{x}$. The most general form of the linear **logistic regression** model for the jth cumulative response probability,

$$\text{logit}(\gamma_j) = \alpha_j - \boldsymbol{\beta}_j^{\mathrm{T}}\mathbf{x}, \tag{1}$$

is one in which both the intercept α and the regression coefficient $\boldsymbol{\beta}$ depend on the category j. The proportional-odds model is a linear logistic model in which the intercepts depend on j, but the slopes are all equal. Thus, we arrive at the model

$$\text{logit}(\gamma_j) = \alpha_j - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x}, \tag{2}$$

asserting that the graph of the $k-1$ cumulative logits against x is a series of parallel lines or planes with intercepts $\alpha_1, \ldots, \alpha_{k-1}$.

Ordinal response variables are common in a number of areas, notably survey research, food testing, industrial quality assurance, radiology, and clinical research. In a study of disease severity, for example, the degree of impairment might be described by one of a small collection of labels such as "none", "slight", "moderate", "severe", and "incapacitating". One of the most effective ways to construct a model for an ordinal response such as this is to invoke the concept of a latent, or unobserved, response Z. The actual recorded response Y is envisaged as a crude manifestation of the latent variable in such a way that the relationship is monotone:

$$\alpha_{j-1} < Z \leq \alpha_j \Longleftrightarrow Y = j. \tag{3}$$

The "cut-points" α_j are envisaged as unknown points on the latent scale. In the example described, the z interval $(-\infty, \alpha_1]$ is interpreted as no impairment; the interval $(\alpha_1, \alpha_2]$ as slight impairment, and so on. Unless the latent variable is close to one of the boundaries, similar values of the latent variable are not distinguished and give rise to identical responses.

This description of the model seems to require the observer to have a precisely measured latent variable Z available, if only to himself or herself, and to make the comparison (3) before reporting Y. Like all mathematical models of behavior, this is an idealization of what actually occurs, and is not to be taken literally, particularly at the edges. In fact, the model does not make these extreme demands on the observer. Although the model is capable of this mechanistic interpretation, it is not a necessary interpretation. What is important is not so much the mechanism but the prediction. If the model predictions are sufficiently close to observations and known limiting behavior, then all is well.

The dependence of the latent variable on the covariates may be specified by means of a linear or nonlinear model, as appropriate. In the case of a linear model, we have $Z = \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x} + \varepsilon$, where ε is a random variable with cumulative distribution function F. Then the probability $\Pr(Z \leq z)$ is $F(z - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x})$. Relationship (3) between the latent variable and the response gives the implied model for Y in the form

$$\gamma_j = \Pr(Y \leq j) = \Pr(Z \leq \alpha_j) = F(\alpha_j - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x}),$$

or in linearized form

$$F^{-1}(\gamma_j) = \alpha_j - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x}.$$

If $F(z) = e^z/(1+e^z)$, implying that ε has the logistic distribution, this scheme produces the proportional-odds model (2) illustrated in Figure 1. Other choices for F produce generalized linear models of the same type. The cumulative probit model arises if ε is normal, and the grouped proportional hazards model, or complementary log–log model, arises if ε has the **extreme-value** distribution; in other words, if $\exp(\varepsilon)$ has the **exponential** or **Weibull distribution**. This derivation explains the unorthodox choice of sign for the regression coefficients in (1) and (2).

Various extensions of this scheme are possible. Suppose, for example, that the covariates affect both the location and scale of the latent variable according to the model

$$Z = \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x} + \exp(\boldsymbol{\tau}^{\mathrm{T}}\mathbf{x})\varepsilon.$$

Models incorporating dispersion effects of this type are used in industrial quality assurance to detect factors whose effect is primarily on the variability of the product. The implied model for Y is then

$$F^{-1}(\gamma_j) = \frac{\alpha_j - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x}}{\exp(\boldsymbol{\tau}^{\mathrm{T}}\mathbf{x})}, \tag{4}$$

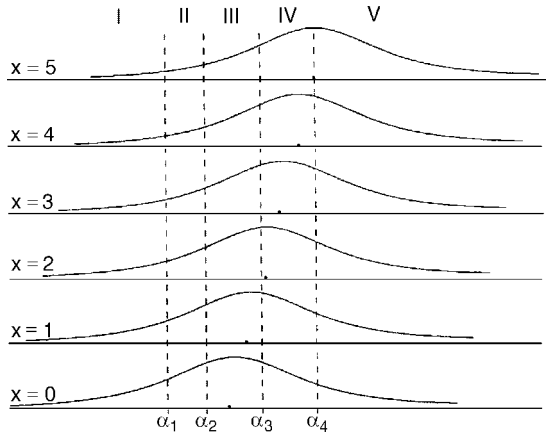

Figure 1 Diagram illustrating how the distribution of the latent variable Z changes with x in the proportional-odds model. The horizontal axis represents the latent variable, and the recorded categories are denoted by roman numerals attached to the five contiguous Z intervals. Over the range of x values shown, the probability for category IV is almost constant. By contrast, the probabilities for categories I and V vary by factors of 3–4 over the same range

which is no longer linearizable. Models (1), (2), and (4) have the limiting property for extreme covariate values, i.e. as $\boldsymbol{\beta}^{\mathrm{T}}\mathbf{x} \to \pm\infty$, all the probability accumulates in one of the extreme categories.

The class of models derivable in this way using a latent variable all have an important invariance, or closure, property connected with the amalgamation of adjacent response categories. Suppose that model (4) with $k > 2$ response categories is correct. If categories j and $j+1$ are combined into a single new response category, then model (4) still applies, but with k reduced to $k-1$ and with α_j deleted. In general, information is lost when categories are amalgamated, so the maximum likelihood estimate is affected. In extreme cases, the parameters might not be estimable from the reduced data. The model, however, is invariant, and the same regression parameters apply to the reduced data. By contrast, most of the competing models described at the end of this article are not closed under category amalgamation.

The term "proportional odds" stems from the fact that in model (3) the **odds** of the event $Y \leq j$ satisfies

$$\text{odds}(Y \leq j|\mathbf{x}) = \exp(\alpha_j - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{x}).$$

Consequently, the ratio of the odds of the event $Y \leq j$ for $\mathbf{x}_1$ and $\mathbf{x}_0$ is

$$\frac{\text{odds}(Y \leq j|\mathbf{x}_1)}{\text{odds}(Y \leq j|\mathbf{x}_0)} = \exp(-\boldsymbol{\beta}^{\mathrm{T}}(\mathbf{x}_1 - \mathbf{x}_0)),$$

which is a constant independent of j. If we arrange matters such that $x_0 = 0$ is the baseline value of the covariates, then it follows that $\exp(\alpha_j)$ is the baseline odds for the event $Y \leq j$. From this point of view, the proportional-odds model simply takes the baseline odds, which can be set arbitrarily, and multiplies by the factor $\exp(-\boldsymbol{\beta}^{\mathrm{T}}\mathbf{x})$ to obtain the response odds at a nonbaseline covariate value. Neither of the extended models (1) nor (4) is a proportional-odds model in this sense.

By definition, the cumulative response probabilities are ordered $\gamma_1 \leq \cdots \leq \gamma_{k-1} \leq 1$. The logit transformation is strictly monotone from (0,1) to the real line. The proportional-odds model (2) must therefore satisfy the constraints $\alpha_1 \leq \cdots \leq \alpha_{k-1}$. This condition is both necessary and sufficient to ensure that the fitted response-category probabilities are nonnegative for all values of the covariate and for all values of the regression coefficient β. The same condition is necessary and sufficient for the nonlinear model (4).

The analogous condition to ensure nonnegative response probabilities in model (1) is much more complicated. Nonnegativity requires that

$$\alpha_1 + \beta_1 x \leq \cdots \leq \alpha_{k-1} + \beta_{k-1}x$$

for all values of x in some set, $\mathcal{X}$. At a minimum, $\mathcal{X}$ must include the observed covariates, but the set could be much larger, particularly if the model is to be used for extrapolation or prediction. Suppose, for simplicity, that there is a single covariate x taking values in the range $[0, \infty)$. Then, considering the logits at $x = 0$ and $x \to \infty$, we require both the intercepts and slopes to be nondecreasing in j. This condition is necessary and sufficient. Likewise, if the covariate space is bounded, say $\mathcal{X} = [-1, 1]$, then a necessary and sufficient condition is that

$$|\Delta\beta| \leq \Delta\alpha,$$

componentwise, where $\Delta\alpha$ is the difference vector with components $\alpha_{j+1} - \alpha_j$ for $j = 1, \ldots, k-2$. If there are p covariates, all in the interval $[-1, 1]$, then the necessary and sufficient condition $\sum|\Delta\beta_j| \leq \Delta\alpha$ suggests that most models in class (1) are close to (2) if p is large. Finally, if χ is a vector space,

the condition $(\Delta\beta)^T x \leq \Delta\alpha$, stating that the linear functional $\Delta\beta$ is bounded on χ, implies $\Delta\beta = 0$. The only models in (1) satisfying the nonnegativity condition for x in a vector space, are those in (2).

The proportional-odds model and related family (4) is only one of several families that are designed to be used for the analysis of ordinal data. The three main competing classes are as follows:

1. **Loglinear model** with pre-assigned category scores [6, 9].
2. Canonical regression models [2, 7, 8].
3. Continuation-ratio models [4, 5].

When the categories represent temporally ordered stages of development, such as educational attainment, it is natural to consider the conditional probability of failure at stage j conditional on survival up to stage j. The conditional probability of failure at stage j, or the hazard of stage j, or the attrition rate of stage j, is $\pi_j/(1-\gamma_{j-1})$. The natural linear logistic model, in this context called a continuation-ratio model or discrete-time **proportional-hazards** model, is

$$\text{logit}\left[\frac{\pi_j}{(1-\gamma_{j-1})}\right] = \log\left[\frac{\pi_j}{1-\gamma_j}\right] = \alpha_j - \beta_j x.$$

No order constraints are required on the parameters. However, depending on the context, it may be sensible to assume that $\beta_j = \beta$, or, less commonly, that $\alpha_j = \alpha$.

The adequacy of the proportional-odds model can in principle be tested by a generalized likelihood ratio test of model (2) against either (1) or (4). Readily available commercial software, such as SAS PROC LOGISTIC, is available for fitting the proportional-odds model. Regrettably, such software is rarely sufficiently flexible to fit alternatives such as (1) or (4), so likelihood ratio testing may require specially written computer programs. In the absence of special purpose programs, a feasible alternative for model testing is to compute the residuals, and to examine them for patterns, either by plotting or by visual inspection. However, particularly for ordinal data, the visual appearance of a residual plot can be drastically affected by the definition of residuals. Cumulative residuals seem to be more appropriate than cell residuals for many plots [11, Section 5.6].

The proportional-odds model goes back to the early work of Snell [13], Williams & Grizzle [14], and Simon [12]. Similar ideas, particularly the notion of a latent variable and its use for modeling an ordinal response, can be found in **Karl Pearson's** early work. For illustrations and numerical examples of the proportional-odds model, see [1, 3, 10], and [11, Chapter 5].

PETER MCCULLAGH

Proportional-odds Regression

The well-known **proportional hazards** model can be expressed in terms of the hazard function $h(t; z)$ for a case with survival time t and **covariate** z by

$$h(t; z) = h_0(t)g(z), \tag{1}$$

where $h_0(t)$ is a baseline hazard function (*see* **Survival Distributions and Their Characteristics**). Plots of data, a priori information, and other circumstances might suggest that the proportional hazards assumption is inappropriate. An alternative model is to consider the **odds** for survival,

$$a(t; z) = \frac{[1 - S(t; z)]}{S(t; z)},$$

where $S(t; z)$ is the survival function, and assume a similar relationship to (1) above:

$$a(t; z) = a_0(t)b(z), \tag{2}$$

where $a_0(t)$ is the baseline odds of survival function. When $\log[a(t; z)]$ is plotted against t, parallel curves result, displaced by an amount $\log b(z)$ from the baseline log odds or survival function $\log a_0(t)$. Alternatively, if two cases are compared with different covariate values z_1 and z_2, then the ratio of the odds of survival functions is given by

$$\frac{a(t; z_1)}{a(t; z_2)} = \frac{b(z_1)}{b(z_2)},$$

which does not depend on t but depends only on the covariate values and the form of the "regression" function $b(\cdot)$. Eq. (2) defines the so-called *proportional-odds regression*. Particular examples are given below.

Typically, $a_0(t)$ is specified parametrically and $\log b(z)$ specified equal to a linear predictor $\boldsymbol{\beta}^{\mathrm{T}}\mathbf{z}$, with $\mathbf{z}$ a vector of known covariates and $\boldsymbol{\beta}$ an unknown regression parameter. For example, with $a_0(t) = t^{\phi}(\phi > 0)$, then $\phi \log t - \boldsymbol{\beta}^{\mathrm{T}}\mathbf{z}$ has the logistic density with $f(y) = \mathrm{e}^{y}\{1 + \mathrm{e}^{y}\}^{-2}, -\infty < y < \infty$ (*see* **Logistic Distribution**). This is also an example of **accelerated failure-time models**. If $a_0(t)$ is not specified parametrically, then estimation of $\boldsymbol{\beta}$ is still possible using a technique described by Bennett [3] based on estimating $a_0(t)$ at each failure time. Pettitt [6] develops some approximate estimates based on **ranks** of observations so that $a_0(t)$ need not be estimated explicitly. The scores used are given by Prentice [7] who developed tests for $\mathrm{H} : \beta = 0$ using linear rank statistics. Bennett [2, 3] and Pettitt [6] analyze a set of data referring to survival of lung cancer patients [5, pp. 89–90] and all authors find very similar estimates for the various parametric and nonparametric techniques. A possible explanation for this is that the signal-to-noise ratio for the data is small and therefore the ranks are almost fully efficient.

The proportional-odds model is popular in the analysis of **ordered categorical data** [1, pp. 322–324]. Hastie & Tibshirani [4, pp. 219–224] describe an additive proportional-odds regression model for ordered categorical data.

Proportions, Inferences, and Comparisons

Binomially based inferences about one proportion, or about two proportions using data from independent samples, are among the most common tasks in statistical analysis, taught in every elementary course. However, despite the ease with which these tasks can be described and the frequency with which they are encountered, they remain controversial and inconsistently handled in statistical practice.

Numerous papers in theoretical and applied publications have covered binomial point **estimation**, interval estimation (*see* **Estimation, Interval**), and **hypothesis testing** using **exact**, approximate, and **Bayesian methods**. Yet, even with the advanced computational power now widely available, no single approach to this set of tasks has emerged as clearly preferable. The methodological choices regarding testing equality of two proportions, or estimating any disparity between them, are equally perplexing.

This article surveys, nonexhaustively, a range of methods for handling each of the problems above, based on underlying binomial or two-factor product-binomial distributions. A related problem, which is a comparison of two proportions using data from a matched-pairs design (*see* **Matched Pairs With Categorical Data**), can be placed within the framework of a single proportion inference by considering the **binomial distribution** of the number of discordant pairs of the (1,0) type after conditioning on the total number of both types ((1,0) and (0,1)) of discordant pairs (*see* **McNemar Test**). Unconditional approaches to such matched dichotomous data place the problem in the context of marginal symmetry of a 2×2 multinomial **contingency table**, requiring consideration of trinomial distributions, and are beyond our scope here (*see* **Multinomial Distribution**).

One-sample Case

We observe $X \sim \text{Bin}(N, p)$ where N is fixed, and wish to estimate or test hypotheses about the unknown parameter p.

Point Estimation

The observed proportion $\hat{p} = X/N$ is simultaneously the **method of moments**, **maximum likelihood**, and **minimum variance unbiased estimator** of p [22]. The Bayesian posterior mean, under a conjugate beta **prior** $p \sim \text{Beta}(\alpha, \beta)$, is $\hat{p}_B = (X + \alpha)/(N + \alpha + \beta)$ (*see* **Beta Distribution**; **Berkson's Fallacy**). In the special case of the **uniform** prior, Beta(1,1), the posterior mean thus reduces to $\hat{p}_B = (X + 1)/(N + 2)$, which is biased toward 0.5 compared with the maximum likelihood estimator (MLE) [32]. Another popular Bayesian choice is the Jeffreys prior, Beta$(1/2, 1/2)$, which yields $\hat{p}_B = (X + (1/2))/(N + 1)$ and produces, as will be discussed, well-behaved frequentist confidence intervals.

Interval Estimation

The discreteness of the binomial distribution – there are only $N + 1$ possible outcomes when $X \sim \text{Bin}(N, p)$ – sometimes leads to erratic and unpredictable behavior by confidence intervals for p. This is particularly apparent for intervals based on the asymptotic normal approximation $N(p, p(1 - p)/N)$ to the distribution of $\hat{p}$ (*see* **Normal Distribution**). On the basis of this approximation, nearly all entry level and many advanced courses teach the Wald $100(1 - \alpha)\%$ **confidence interval**, $\hat{p} \pm z_{1-(\alpha/2)}\sqrt{(\hat{p}(1 - \hat{p})/N)}$, for p, with z_γ the 100γth percentile of the standard normal, for example, $z_\gamma = 1.96$ when $\gamma = 0.975$. This interval offers intuitive and easily understandable properties for introductory level students. For fixed $\hat{p}$, the interval narrows as N increases while, for fixed N, the interval is widest when $\hat{p} = 0.5$ and narrows as p approaches 0 or 1.

The drawback, however, is that extremely large samples are necessary for the interval to achieve nominal $100(1 - \alpha)\%$ coverage, that is, for $100(1 - \alpha)\%$ of all intervals constructed to contain p. While this is particularly true for p near its extremes of 0 or 1, the coverage probability is low over the entire range of p. Moreover, due to the binomial's discreteness, coverage does not approach $100(1 - \alpha)\%$ monotonically as N increases [20], so that a larger N can yield poorer performance.

Many classic texts, in recognition of the asymptotic origin of the Wald interval, recommend it only

when min $(Np, N(1-p)) > 5$ or > 10 or, more stringently, when $Np(1-p) > 5$ or > 10. Yet even when $N = 40$ and $p = 0.5$ and this latter condition is thus met, the exact coverage of the Wald interval is only 91.9%. Even when N is 100, the portion of the range of p for which a 95% confidence interval achieves 95% coverage is negligible (Figure 1a).

A number of methods exist to ensure at least 100(1-α)% coverage for any fixed p [1, 3, 34]. These methods vary in computational complexity and associated software requirements. While some instructors and practitioners desire closed-form formulae, others believe that "simplicity and ease of computation have no roles to play in statistical practice" [27]. Some believe the confidence coefficient is meaningful only as a guaranteed minimum coverage probability at each use of an interval, while others find a method that guarantees only average coverage over a range of conditions to be quite satisfactory. Such varied opinions leave much room for

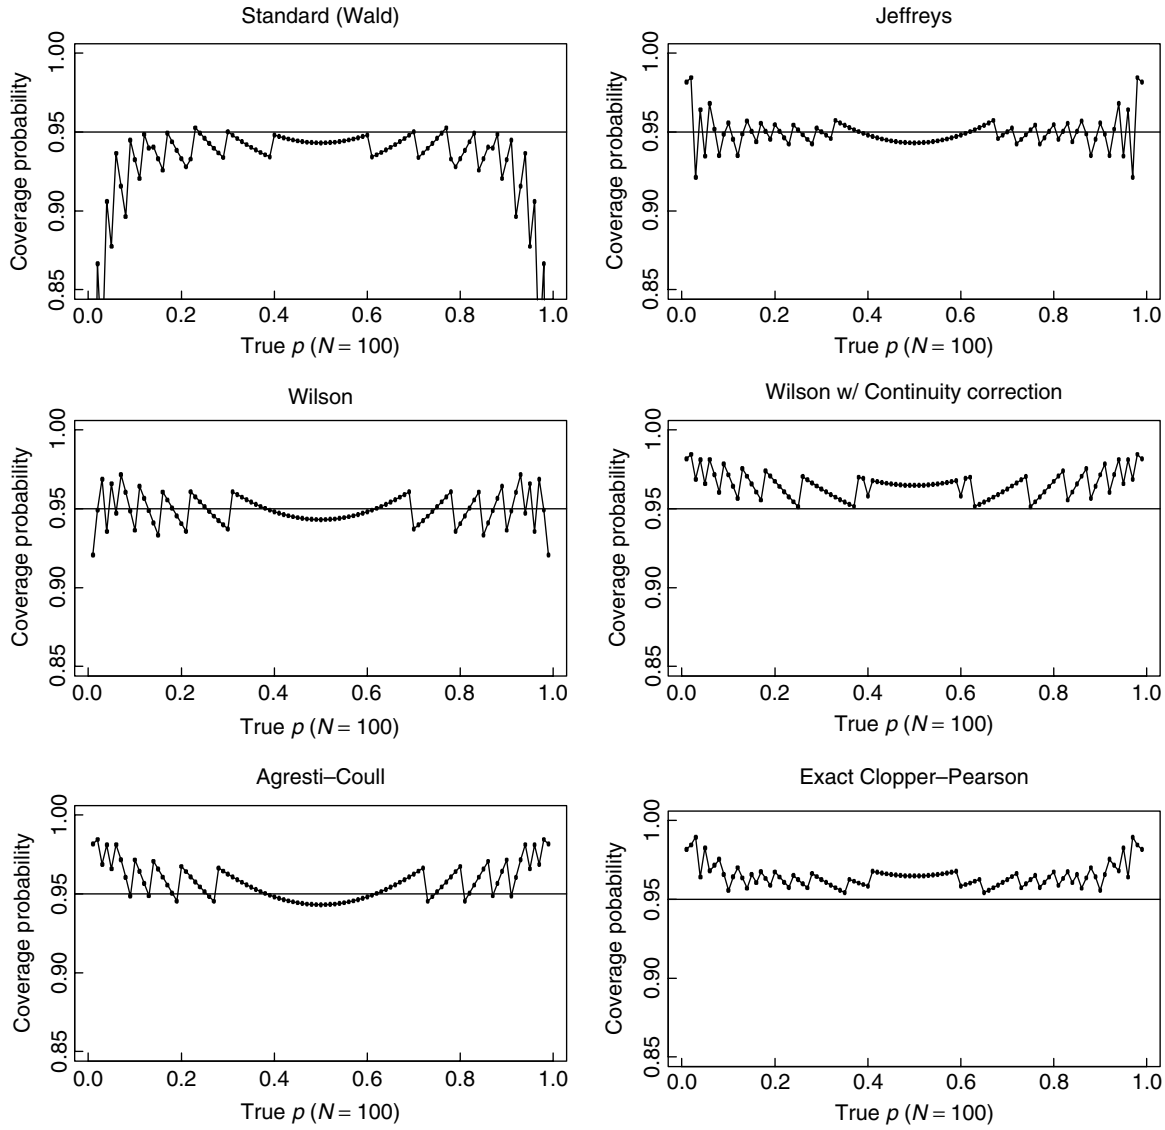

Figure 1 Coverage probabilities of six 95% confidence intervals for p, with $N = 100$

disagreement on practical recommendations. Further, to guarantee nominal coverage, one must generally form an interval by inverting the acceptance region of an exact hypothesis test. This requires computing binomial probabilities of the observed outcome and some unobserved outcomes over a range of possible values of p. Such computationally intensive calculations are now simple to perform using many statistical software packages (*see* **Software, Biostatistical**), but unsuitable for the elementary courses in which confidence intervals for proportions must be taught.

Below, we promote alternatives to the standard Wald interval that meet four criteria [18]. The confidence region must:

1. be one contiguous interval;
2. be invariant to $X \to N - X$ transformation, that is, the lower and upper endpoints of the interval for p based on X should respectively be the upper and lower endpoints of the interval for $(1 - p)$ based on $(N - X)$;
3. yield monotone endpoints in X, that is, for fixed N, $LB(X, N) < LB(X + 1, N)$ and $UB(X, N) < UB(X + 1, N)$; and
4. yield monotone endpoints in N, that is, for fixed X, $LB(X, N) > LB(X, N + 1)$, and $UB(X, N) > UB(X, N + 1)$.

We review three easily computable alternatives to the Wald interval and a more computationally demanding "exact" interval, comparing coverage properties with the Wald interval and with each other.

Jeffreys Interval

Assuming a Jeffreys prior $p \sim \text{Beta}(1/2, 1/2)$, the resulting posterior distribution is $p|X, N \sim \text{Beta}(X + (1/2), N - X + (1/2))$, and the Bayesian equal-tailed $100(1 - \alpha)\%$ credible set is formed by the $\alpha/2$ and $(1 - \alpha/2)$ quantiles. Interpreting this Bayesian credible set as a frequentist confidence interval offers desirable frequentist properties as will be demonstrated. While there are no closed-form expressions for the endpoints, all common statistical software packages (Excel, SAS, **S-PLUS**, etc.) include simple function calls for such Beta quantiles. Note that although error is allocated equally to each tail, the interval itself will be symmetric only when the posterior distribution itself is, requiring $X + (1/2) = N - X + (1/2)$ and hence $X = N/2$.

Wilson Interval

The Wald interval is formed by inverting the Wald test of $H_0 : p = p_0$. That test is based on a **Central Limit Theorem** (CLT) approximation to the distribution of $\hat{p}$ using the maximum likelihood binomial variance estimator $N\hat{p}\,\widehat{q}$, where $\widehat{q} = 1 - \hat{p}$. Wilson, in a 1927 *JASA* paper [55], introduced an interval with a similar relationship to what is now known as the score test (*see* **Likelihood**). Writing $q_0 = 1 - p_0$, the score test CLT approximation to the distribution of $\hat{p}$ uses the variance Np_0q_0 implied by the hypothesized p_0. The 100(1-α)% Wilson interval, also referred to as the score interval [2], is

$$\frac{X + \frac{z^2_{1-\alpha/2}}{2}}{N + z^2_{1-\alpha/2}} \pm \frac{z_{1-\alpha/2}\sqrt{N}}{N + z^2_{1-\alpha/2}} \sqrt{\widehat{p}\,\widehat{q} + \frac{z^2_{1-\alpha/2}}{4N}}. \quad (1)$$

As noted by Agresti and Caffo [4], this interval is centered about the pseudo-estimator $\tilde{p} = (X + z^2_{\alpha/2}/2)/(N + z^2_{\alpha/2})$, which may be viewed as a weighted average of the sample proportion and one-half or, equivalently, as obtained by adding $(z^2_{\alpha/2}/2)$ successes and $(z^2_{\alpha/2}/2)$ failures to the data. Similarly, the interval's width is a multiple of a pseudo **standard error** obtained from a weighted average of the maximum likelihood variance estimator used for the Wald interval and the true variance when $p = 1/2$.

Agresti–Coull Interval

The Agresti–Coull interval [5] takes the functional form of the standard asymptotic Wald interval but with minor adjustments in X, N, and p, to $\tilde{X} = X + (z^2_{\alpha/2}/2)$, $\tilde{N} = N + z^2_{\alpha/2}$, and $\tilde{p} = \tilde{X}/\tilde{N}$, respectively. Thus, the interval has the standard Wald-like form

$$\tilde{p} \pm z_{\frac{\alpha}{2}} \sqrt{\frac{\tilde{p}\tilde{q}}{\tilde{N}}}, \quad (2)$$

where $\tilde{q} = 1 - \tilde{p}$. The difference is that the whole experiment is treated as if there are $(z^2_{\alpha/2}/2)$ more successes and $(z^2_{\alpha/2}/2)$ more failures than were actually observed. For a 95% confidence interval, this has the affect of approximately adding two successes and two failures, or in a Bayesian sense, starting with a Beta(2, 2) prior for p. This prior has mean 1/2 and is concave with single mode 1/2, while the Jeffreys prior has mean 1/2 and is convex and bimodal at 0

and 1. Thus, in the Bayesian sense, the Agresti–Coull prior distribution on p is more informative.

The Agresti–Coull interval is never narrower than the Wilson interval, making it a more conservative choice. It offers a clear improvement over the Wald interval when $X = 0$ or $X = N$, for which the width of the Wald interval is zero, and corrects particularly well for the sometimes too narrow intervals and poor coverage of the Wilson method when p is close to 0 or 1. The Agresti–Coull and Wilson (score) intervals are very similar when p is near the center of its range. See [4] for a fine, highly accessible review of this interval.

Clopper–Pearson Interval

As always, it is easier to reach a performance goal on average than to guarantee such performance is always achieved across a range of conditions. The intervals above are superior to the Wald interval in providing approximately 100(1-α)% coverage averaged over the range of possible values of p, but coverage by each is below nominal for some combinations of p and N. In contrast, the Clopper–Pearson Interval [25], often called the Exact Interval, achieves at least nominal coverage for all combinations of p and N [1, 3, 25, 34]. For $X \neq 0$ or N, the 100(1-α)% Clopper–Pearson interval is

$$\left[\left(1+\frac{N-X+1}{XF_{2X,2(N-X+1)}(\frac{\alpha}{2})}\right)^{-1},\ \left(1+\frac{N-X}{(X+1)F_{2(X+1),2(N-X)}(1-\frac{\alpha}{2})}\right)^{-1}\right], \quad (3)$$

where $F_{df_1,df_2}(c)$ is the c **quantile** from the ***F*** **distribution** with df_1 and df_2 degrees of freedom. When $X = 0$ or N, the undefined bounds in (3) are respectively replaced by 0 and 1.

"Exact" in reference to the Clopper–Pearson interval refers to use of the exact binomial sampling distribution rather than using an asymptotic approximation to produce the interval. (The relevant exact binomial sums implicitly determine (3) through their relationship, and that of the F distributions, to the incomplete beta function.) This method, however, does not produce an exactly 100(1 − α)% interval, but rather one of at least 100(1 − α)% and sometimes much higher coverage. Thus, the price of guaranteeing at least 100 × (1 − α) coverage for each combination of N and p is loss of precision, in the sense that intervals are on average wider than necessary to achieve that coverage for most N, p combinations. Nevertheless, when preservation of nominal coverage is preferred despite this conservatism, the Clopper–Pearson interval accomplishes this objective and is widely used.

Other exact methods, for example, Blyth–Still [18], the Blaker [17] interval nested within it, and Blyth–Still–Casella intervals [21], are also available in specialized software. The **continuity correction** to the Wilson interval results in a wider, more conservative interval that better approximates the Clopper–Pearson interval. This frequently increases minimum coverage, as in Figure 1, to the nominal 100(1 − α)% [31, 38].

Coverage Comparison

For a fixed sample size of $N = 100$, and 101 possible values of the true p (0, 0.01, 0.02, . . . ,1.00), Figure 1 shows the true coverages of 95% Wald, Jeffreys, Wilson, continuity-corrected Wilson, Agresti–Coull, and Clopper–Pearson (*aka* Exact) intervals. Ideally, the coverage of each would be 95% for every value of p. While the discreteness of the binomial distribution prohibits this, one still desires coverage near 95%.

It is clear from Figure 1 that the Wald interval, even when $N = 100$, offers poor coverage. The Jeffreys interval offers better coverage properties than the interval obtained using a Uniform prior (not shown). Also, Ghosh [37] shows that the Wald interval is not only centered at the wrong place, but is also frequently wider than the Wilson interval.

Figure 2 shows interval widths for $N = 100$ and X from 1 to 50 (the plot is symmetric around 50). The Clopper–Pearson intervals are clearly wider for most values of X, and therefore for most values of p. The Exact approach produces the widest intervals except when p is near 0 or 1, when the Agresti–Coull intervals are wider. The Wilson and Agresti–Coull methods produce similar widths for p not near 0 or 1. Figure 2 also demonstrates that the Jeffreys interval is desirably narrow compared to other intervals (Figure 2) while producing coverages nearly 100(1 − α)% throughout the range of p (Figure 1).

There is philosophical debate over the relative merits of requiring *at least* 95% coverage for any value of p, as offered by exact methods or continuity

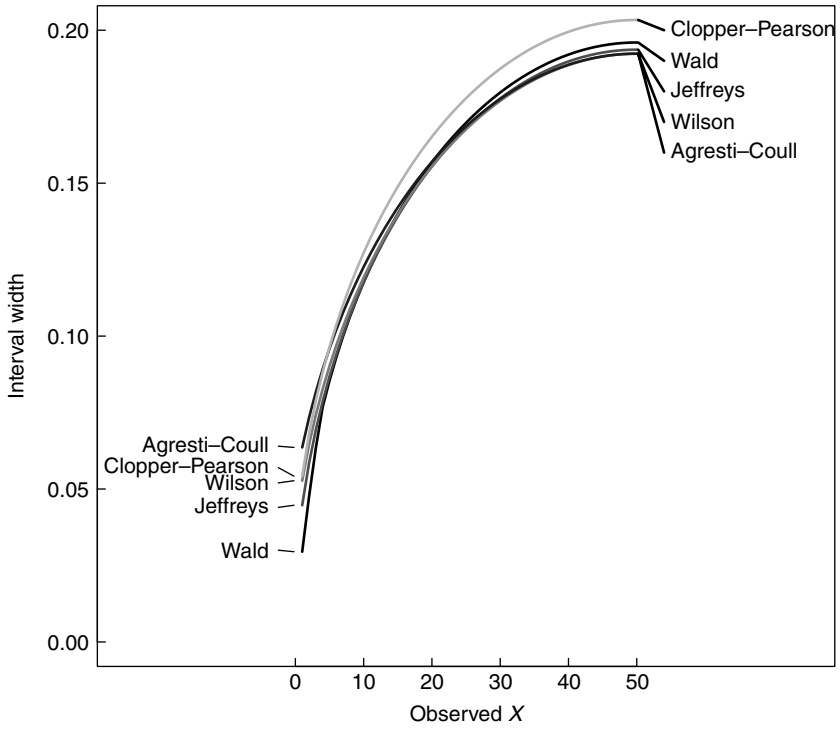

Figure 2 Widths of five 95% confidence intervals for p, $N = 100$

corrections, versus requiring average 95% coverage for all situations in which one might compute an interval. The practicing statistician must weigh the benefits and costs of each of the two competing approaches, and choose the most appropriate method for the given situation.

If guaranteed coverage is required, then the exact Clopper–Pearson interval is preferable. If average nominal coverage is satisfactory, then the Jeffreys, Wilson, and Agresti–Coull intervals offer sound frequentist properties. In the example shown, the Jeffreys interval offers tightest oscillation around 95%; this may differ, however, for other choices of $N \neq 100$. The Agresti–Coull interval may be the best compromise choice. It improves upon the Jeffreys and Wilson intervals by ensuring that coverage is not far below 100(1-α)% for values of p near 0 or 1. But it is not overly conservative, as are the continuity-corrected Wilson and the exact intervals, throughout the rest of the admissible range of p. The Agresti–Coull interval also offers the advantage of a form that is easy to remember and teach: for 95% confidence, just construct the simple Wald interval after adding two successes and two failures to the data. Various other references, for example, [1, 6, 20, 42, 53], offer similar graphical comparisons of the available choices of confidence intervals for a binomial proportion.

Hypothesis Testing

The score and Wald tests, respectively inverting the Wilson and Wald intervals, are commonly used, as is the likelihood ratio test [2]. The score statistic is equivalently Pearson's **goodness of fit** chi-square $X^2_{S1} = \sum_{i=1}^{2}(O_i - E_i)^2/E_i = (\hat{p} - p_o)^2/(p_o(1 - p_o)/N)$ (*see* **Chi-square Tests**), and the Wald statistic is Neyman's [44] modified chi-square statistic $X^2_{W1} = \sum_{i=1}^{2}(O_i - E_i)^2/O_i = (\hat{p} - p_o)^2/(\hat{p}(1 - \hat{p})/N)$, where the O_i and E_i, $i = 1, 2$ are respectively the observed counts of successes and failures and their **expectations** under H_0 : $p = p_0$. The corresponding forms of the **likelihood ratio** statistic are $X^2_{L1} = 2\sum_{i=1}^{2} O_i \log O_i/E_i = 2\,[X \log(\hat{p}/p_0) + (N - X)\,\log((1 - \hat{p})/(1 - p_0))]$.

Under H_0, all three statistics are asymptotically chi-square with one degree of freedom. As suggested by their denominator variances and the properties of their associated confidence intervals, convergence to this distribution is generally more rapid for X^2_{S1} than for X^2_{W1}, with departures for X^2_{W1} tending towards higher than nominal type I error rates (*see* **Hypothesis Testing**). The behavior of X^2_{L1} is intermediate [48].

The exact test, dual to the Clopper–Pearson interval, is easy to calculate (*see* **Exact Inference for Categorical Data**). For given p_0 and N, the binomial probability of observing $X = 0$ to $X = N$ under the null hypothesis is simply $\Pr(X = x) = \binom{N}{X} p_0^x (1 - p_0)^{N-x}$. Calculating the ***P* value**, the sum of probabilities of the observed and equally or less probable nonobserved outcomes, is straightforward.

The mid-P value, a 1961 innovation of Lancaster [40], has recently received renewed attention [2]. The mid-P value is the exact P value, as described above, less half the probability of the observed count. The mid-P value removes unattractive discrepancies between the properties of P values from discrete and continuous sampling distributions. Specifically, unlike conventional exact P values, the sum of mid-P values from two opposing one-sided exact tests equals 1.0, the mean of mid-P values is 0.5 under the null hypothesis, and the null distribution of mid-P values is closer to uniform than that of P values. However, while generally conservative, tests based on the mid-P value do not guarantee a type I error rate of less than α, nor do the corresponding confidence limits assure at least $100(1 - \alpha)\%$ coverage.

Hypothesis tests corresponding to the Jeffreys, Agresti–Coull, or another confidence interval for a binomial proportion can be performed by rejecting exactly when the interval excludes the hypothesized value. Such tests may well have type I error closer to nominal than one or more of the Wald, score, and likelihood ratio tests. To find the P value for a test formed by inverting a confidence interval, determine the confidence coefficient CC of the interval with p_0 on the boundary. Then, the P value is $1 - CC$.

For example, assuming $X = 38$ successes are observed in $N = 100$ trials with null hypothesis $p = 0.5$, the Jeffreys hypothesis test can be performed by determining which confidence coefficient provides an upper bound exactly equal to 0.5. A region of the Beta(38.5, 62.5) distribution bounded above at 0.5, and excluding equal probabilities on each tail, contains 98.40% of the distribution; hence $P = 0.0160$. Likewise, using the equation for the upper bound of the Agresti–Coull confidence interval and solving for α yields $P = 0.0165$.

Power and Sample Size Determination

Whether the endpoints of an interval or the rejection region of a test are based on exact binomial calculations or a large-sample approximation to the relevant binomial distribution(s), coverage of an interval or **power** of a test may be calculated either exactly using binomial distributions under the alternative, or approximately using a limiting normal distribution. Only direct calculation from the binomial distribution under an alternative gives true coverage or power, although Gaussian approximations to such calculations are generally used and often provide sufficient accuracy for practical purposes.

For example, the power of a two-tailed test of $H_0 : p = p_0$ under the fixed alternative of $H_A : p = p_1$ can be approximated as follows. First, find the acceptance region of the stipulated test, (T_L, T_U); for example, for X^2_{S1}, $X\varepsilon(T_L, T_U)$ with $(T_L, T_U) = Np_0 \mp z_{1-(\alpha/2)}\sqrt{(Np_0(1 - p_0))}$. Then, using normal theory under H_1, calculate the large-sample normal approximation to the probability that X falls outside that region, for example,

$$\text{Power} = \Pr\left(Z \le \frac{T_L - Np_1}{\sqrt{Np_1(1 - p_1)}}\right) + \Pr\left(Z \ge \frac{T_U - Np_1}{\sqrt{Np_1(1 - p_1)}}\right). \quad (4)$$

This approximates the true power, $\Pr(X \notin (T_L, T_U) | p = p_1)$ under $X \sim \text{Bin}(N, p_1)$, which may be calculated instead by summing the $\text{Bin}(N, p_1)$ probabilities for all values of X outside (T_L, T_U). This approach applies, with obvious modifications, to any other test procedure, specifically including exact tests and tests using the mid-P. Power, and the method for determining it, are based on the test's rejection region, not on how that rejection region is derived. Note that standard moment-based expressions in textbooks, and default power calculations in statistical software packages, are almost always asymptotic approximations to the true power of a test. The ease of inverting the moment-based expressions to yield

approximate sample size requirements has much to do with this. However, discrepancies in default sample size recommendations of software packages are common, owing to variations in defaults on the tests used and the specific power calculations inverted to obtain them (*see* **Sample Size Determination**).

While the asymptotically based counterparts to an exact test are generally more powerful, that is, type II error probabilities β for the asymptotic tests are lower than for the exact test, this gain comes at the expense of higher type I error rates, which are not guaranteed by the asymptotic tests. As shown in Figure 1 (with $\alpha = 1 -$ coverage probability), these may far exceed the nominal value used to (asymptotically) determine the rejection region. For fixed α, power as a function of sample size is also saw-toothed: counterintuitively, a small increase in sample size may slightly reduce power.

One-sample Summary

Numerous superior alternatives to the classic Wald interval exist. The Clopper–Pearson and, at least for 95% confidence, the continuity-corrected Wilson intervals, assure that coverage cannot fall below the nominal coefficient for any combination of N and p. Similarly, the tests based on inverting these intervals assure that type I error cannot exceed the nominal α. The cost is wider intervals and reduced power relative to procedures whose coverage roughly centers around, rather than below, the nominal confidence coefficient. Among such procedures are the relatively simple Jeffreys, Wilson, and Agresti–Coull intervals, the latter two with closed-form expressions, and their corresponding tests. The Agresti–Coull method produces intervals with generally sound frequentist properties, in a form easily taught and remembered.

For research design, software for sample size determination should be used cautiously. For hypothesis testing, for instance, such software typically requires specification of p_0 as well as a nominal α and a target or guess at p_1. Then, for fixed desired power, a single or a selection of sample size recommendations is provided from among the available choices. The researcher must recognize that power and sample size results for alternative tests can differ not only because one test is more efficient, but also because two tests of nominal size α may have different actual type I error rates, and/or because of approximations used in the calculations. This is particularly so since the power functions of the several tests, and even their relative performance, may be nonmonotonic with parameters and/or sample size in neighborhoods of their hypothesized or recommended values.

Two Independent Samples

Inference for two independent samples focuses on how much the relative frequency of an observed characteristic differs between two sampled populations. In general, the lessons of the one-sample case regarding (a) the liberality of the standard Wald procedure, (b) conservatism of the standard exact procedure, (c) availability of simple intermediate approaches that achieve closer to nominal type I error by sacrificing control of maximum type I error, and (d) the inherent trade-offs of coverage and power with different levels of type I error control, all continue to apply. However, the two-sample situation is more complex because (i) the **null hypothesis** of interest is typically the composite hypothesis of no difference between populations, with the common underlying proportion a **nuisance parameter**, and (ii) the disparity between populations may be parameterized in several ways, most commonly as the difference ("risk difference") [2–4, 8, 11, 43, 45, 49], ratio ("risk ratio") [2, 4, 12, 45, 49], and **odds ratio** [2, 3, 54], that are functionally dependent only for a fixed value of the nuisance parameter.

A consequence of (ii) is that there is no longer a one-to-one relationship of hypothesis tests to confidence intervals for any single parameter determined to be of primary interest, and the details of interval estimation vary depending upon the association parameter chosen. To simplify exposition, and in conformity with the historical development, the ensuing discussion will thus proceed primarily from a testing perspective, with the reader referred to the excellent reviews [1, 3] for additional detail on confidence intervals.

Comparing two binomial proportions has long occupied the field of statistics. In 1900, Karl **Pearson** introduced what became the "standard" chi-square test as a goodness-of-fit test to determine whether observed data were compatible with a proposed probability model [47]. Its proper application to contingency tables was clarified in 1922 by **Fisher** [33].

Hundreds of papers have since offered extensions, improvements, and adjustments to the test, which *Science 84*, a popular magazine of the American Association for the Advancement of Science (AAAS), called one of the 22 most important scientific breakthroughs of the twentieth century [7].

For the remainder of this section, we consider a **two-by-two** (2×2) table of observed counts under the probability model $n_{i1}|n_{i\cdot} \sim \text{Bin}(n_{i\cdot}, p_i)$,

	Response		
	Present	Absent	Total
Population 1	n_{11}	n_{12}	$n_{1\cdot}$
Population 2	n_{21}	n_{22}	$n_{2\cdot}$
Total	$n_{\cdot 1}$	$n_{\cdot 2}$	$n_{\cdot\cdot} = N$

$i = 1, 2$. Such data, with this model, may arise from several experimental or observational research designs. The row totals $n_{1\cdot}$ and $n_{2\cdot}$ may be fixed by the conditions of a designed observational study or experiment or, in an observational study, only N may have been determined by the researcher, or $n_{11}, n_{12}, n_{21}, n_{22}$ may be independent **Poisson** counts. In these latter cases, the within-row binomial distributions arise by conditioning inference on the observed row totals $n_{1\cdot}, n_{2\cdot}$ of a multinomial or product-Poisson distribution, respectively. For such situations, we will discuss a general class of asymptotic procedures, exact inference, and Bayesian inference.

Asymptotic Methods

Read and Cressie [29, 48] defined the class of **power-divergence** asymptotic test statistics $T^{\lambda}(N, \widehat{m}_{ij})$ which, for $H_0 : p_1 = p_2$ as above, take the form

$$T^{\lambda}(N, \widehat{m}_{ij}) = \frac{2}{\lambda(\lambda+1)} \sum_{i=1}^{2}\sum_{j=1}^{2} n_{ij}\left[\left(\frac{n_{ij}}{\widehat{m}_{ij}}\right)^{\lambda} - 1\right] \tag{5}$$

for $\lambda \neq -1, 0$, and the limiting forms $T^{-1}(N, \widehat{m}_{ij}) = 2\sum_{i=1}^{2}\sum_{j=1}^{2} \widehat{m}_{ij} \log(\widehat{m}_{ij}/n_{ij})$, $T^{0}(N, \widehat{m}_{ij}) = 2\sum_{i=1}^{2}\sum_{j=1}^{2} n_{ij} \log(n_{ij}/\widehat{m}_{ij})$. The $\widehat{m}_{ij}$ are estimated expected values of the n_{ij} obtained by minimizing $T^{\zeta}(N, m_{ij})$, for some ζ (not necessarily equal to λ), under the constraint $p_1 = p_2$. In our notation, we suppress ζ, which does not affect the asymptotic distribution of the test statistics. This family includes the likelihood ratio test ($\lambda = \zeta = 0$), Pearson's chi-square ($\lambda = 1, \zeta = 0$), Neyman's minimum modified chi-square ($\lambda = \zeta = -2$), and others that may be conveniently studied within this unifying framework (*see* **Chi-square Tests**).

Under all of the experimental or observational designs given above, when $p_1 = p_2$ each member of the power-divergence family converges in distribution to chi-square with one degree of freedom as $n_{1\cdot}, n_{2\cdot} \to \infty$, and hence provides an asymptotically valid test of H_0 or, equivalently when $n_{1\cdot}$ and $n_{2\cdot}$ are random, of row by column independence.

Pearson's chi-square, which is the score test as in the one-sample case, is commonly written in each of the several forms

$$X^2_{S2} = \sum_{i=1}^{2}\sum_{j=1}^{2} \frac{(O_{ij} - E_{ij})^2}{E_{ij}} = \sum_{i=1}^{2}\sum_{j=1}^{2} \frac{(n_{ij} - \widehat{m}_{ij})^2}{\widehat{m}_{ij}}$$
$$= \frac{(\hat{p}_1 - \hat{p}_2)^2}{(n_{1\cdot}^{-1} + n_{2\cdot}^{-1})\hat{p}(1-\hat{p})} = \frac{N(n_{11}n_{22} - n_{12}n_{21})^2}{n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2}} \tag{6}$$

with $\widehat{m}_{ij} = n_{i\cdot}n_{\cdot j}$, $\hat{p}_1 = n_{11}/n_{1\cdot}$, $\hat{p}_2 = n_{21}/n_{2\cdot}$, $\hat{p} = n_{\cdot 1}/N$. In the third form it is easily extended to the score test for $H_{0\Delta} : p_1 - p_2 = \Delta$,

$$X^2_{S2\Delta} = \frac{((\hat{p}_1 - \hat{p}_2) - \Delta)^2}{(n_{1\cdot}^{-1} + n_{2\cdot}^{-1})\hat{p}(1-\hat{p})}. \tag{7}$$

The set of all Δ not rejected by this test forms an asymptotic confidence interval for $p_1 - p_2$ analogous to the Wilson interval in the one-sample case.

Neyman's minimum modified chi-square [44], which as earlier is the Wald statistic, replaces the denominator $E_{ij} = \widehat{m}_{ij}$ above with n_{ij}, yielding

$$X^2_{W2} = \sum_{i=1}^{2}\sum_{j=1}^{2} \frac{(O_{ij} - E_{ij})^2}{O_{ij}} = \sum_{i=1}^{2}\sum_{j=1}^{2} \frac{(n_{ij} - \widehat{m}_{ij})^2}{n_{ij}}$$
$$= \frac{(\hat{p}_1 - \hat{p}_2)^2}{\hat{p}_1(1-\hat{p}_1)/n_{1\cdot} + \hat{p}_2(1-\hat{p}_2)/n_{2\cdot}}. \tag{8}$$

The set of all Δ not rejected by the corresponding Wald test of $H_{0\Delta}$ using

$$X^2_{W2\Delta} = \frac{((\hat{p}_1 - \hat{p}_2) - \Delta)^2}{\hat{p}_1(1-\hat{p}_1)/n_{1\cdot} + \hat{p}_2(1-\hat{p}_2)/n_{2\cdot}} \tag{9}$$

may be written directly as $(\hat{p}_1 - \hat{p}_2) \pm 1.96 \sqrt{(\hat{p}_1(1-\hat{p}_1)/n_{1\cdot} + \hat{p}_2(1-\hat{p}_2)/n_{2\cdot})}$. This is the confidence interval traditionally presented in elementary statistics courses and texts, and most commonly used in practice. Unfortunately, this shares the propensity of the one-sample Wald interval to be too narrow to achieve nominal coverage. The performance of the same interval, however, substituting $\widetilde{p}_i = (n_{i1} + 1)/(n_{i\cdot} + 2)$ for $\hat{p}_i$, is much improved [3].

As also noted by Agresti [3], the Wald interval for the log odds ratio using the empirical asymptotic variance $\left(\sum_{i=1}^{2}\sum_{j=1}^{2} n_{ij}^{-1}\right)$ derived by the **delta method**,

$$\log\left(\frac{n_{11}n_{22}}{n_{12}n_{21}}\right) \pm 1.96\sqrt{\sum_{i=1}^{2}\sum_{j=1}^{2} n_{ij}^{-1}} \qquad (10)$$

generally performs well, and its performance is improved if the n_{ij} are respectively replaced by $n_{ij} + 2n_{i\cdot}n_{\cdot j}/N^2$ and if, in addition, the intervals are extended to $\pm\infty$ respectively whenever $\min(n_{12}, n_{21}) = 0$, $\min(n_{11}, n_{22}) = 0$. Further, inverting an exact or asymptotic chi-square test of $H_0 : p_1/p_2 = \theta$ based on the score statistic

$$X_{S\theta} = \frac{n_{1\cdot}(\hat{p}_1 - \tilde{\tilde{p}}_1)^2}{\tilde{\tilde{p}}_1(1-\tilde{\tilde{p}}_1)} + \frac{n_{2\cdot}(\hat{p}_2 - \tilde{\tilde{p}}_2)^2}{\tilde{\tilde{p}}_2(1-\tilde{\tilde{p}}_2)}, \qquad (11)$$

where $\tilde{\tilde{p}}_i$ is the MLE of p_i under H_0, provides a generally well-behaved interval estimate for the risk ratio p_1/p_2.

The likelihood ratio statistic $X_{L2}^2 = 2\sum_{i=1}^{2}\sum_{j=1}^{2} n_{ij}\log[n_{ij}/(n_{i\cdot}n_{\cdot j})]$ is also a commonly used power-divergence statistic for comparing two proportions. Although the various power-divergence statistics share the same limiting null chi-square distribution as both $n_{1\cdot}$ and $n_{2\cdot}$ increase, and the tests have the same **Pitman efficiency** under local alternatives in the nonnull case, they differ in performance under nonlocal alternatives (e.g. in Bahadur efficiency), in more general problems under nonstandard "sparse" asymptotics (in which the number of cells increases with N), and in small samples (*see* **Asymptotic Relative Efficiency (ARE)**). Cox and Groeneveld [28] provide a thorough comparison of X_{S2}^2 and X_{L2}^2, predicting when each will provide a higher, that is, more powerful, test statistic, under various null hypotheses. Read and Cressie [48] recommend $\lambda = 2/3$ as the best compromise between high power under a wide range of true alternative hypotheses and the ability of the chi-square distribution to approximate the distribution of the test statistic under the null hypothesis for small samples. Of the power-divergence methods in general practical use, the Pearson chi-square, with $\lambda = 1$, is closest to this.

Continuity Corrections

Owing to the discreteness of counts, the sampling distributions of power-divergence statistics from contingency tables are discrete, that is cdfs are step functions, and cannot generally be well-approximated by the continuous χ_1^2 distribution when $n_{1\cdot}$ or $n_{2\cdot}$ is small. In such circumstances, the actual type I error rate of a test may be well above or below the desired α level. Continuity corrections are modifications to the test statistic or the approximating distribution for the purpose of reducing or minimizing the effects of such approximation errors. Such a continuity correction can be used, for instance, to control excessive type I error of an asymptotic chi-square test by shrinking the test statistic, thus making the test more conservative. The classic continuity correction does this by replacing $(O - E)^2$ by $(|O - E| - (1/2))^2$ in the numerator of X_{S1}^2.

Continuity corrections are thoroughly covered in this volume and elsewhere [1, 2, 38, 43]. They are generally constructed to better approximate the behavior of exact methods for which statistical software is increasingly available. Thus, their current utility is primarily for situations when maintaining the nominal α is crucial and statistical software for exact testing is not handy.

Exact Methods

Statistical inferences using exact methods rely on computations from one or more completely specified discrete probability laws. A disadvantage is that discreteness makes it impossible to perform tests with a precisely predetermined type I error rate without using a supplemental **randomization** to decide some test results, a process most consider unsatisfactory for scientific discourse. While the exact test and interval are straightforward in the one-sample case, with two samples the null hypothesis is composite: rather than a specified p_0, under H_0: $p_1 = p_2 = p$,

p can assume any value in [0,1]. A simplification strategy is required to select from or combine over this universe of distributions compatible with H_0.

Fisher's Exact Test

R.A. Fisher proposed conditioning on fixed row and column marginal totals (*see* **Conditional Probability**; **Fisher's Exact Test**). This restriction on the sample space allows direct numerical calculation of the distribution of any test statistic from the 2×2 table. For instance, the distribution of any single cell count is **hypergeometric**, as in

$$\Pr(n_{11} = t) = \frac{\binom{n_{1\cdot}}{t}\binom{n_{2\cdot}}{n_{\cdot 1} - t}}{\binom{N}{n_{\cdot 1}}}, \qquad (12)$$

where t ranges from $\max(0, n_{1\cdot} + n_{\cdot 1} - N)$ to $\min(n_{1\cdot}, n_{\cdot 1})$. One can calculate the probability of each possible t, and then a P value by summing the probabilities of n_{11} and all t more compatible than n_{11} with the alternative hypothesis.

The highly constrained hypergeometric setting may lead to very few possible values of n_{11}, and hence very few possible tables and P values. In the tea tasting example through which Fisher introduced the test, $N = 8$ with $n_{1\cdot} = n_{\cdot 1} = n_{2\cdot} = n_{\cdot 2} = 4$. Since $0 \le n_{11} \le 4$, there are five possible P values, respectively, 0.014, 0.24, 0.76, 0.99, and 1.0 for $n_{11} = 0, \ldots, 4$ for his one-sided test, and three possible P values (0.029, 0.48, 1.0) for the two-sided test. Thus, for instance, the common *true* type I error rate of all one-sided tests with *desired* (nominal) type I error rates between 2 and 23% is actually 1.4%. This inherent conservatism, at times extreme, can be removed by supplemental randomization to precisely achieve any nominal α; Tocher [52] has shown such randomized tests to be uniformly most powerful among unbiased tests. The mathematical optimality of randomized tests has not, however, overcome the taint of arbitrariness that restricts their use.

Consequently, a variety of alternative nonrandomized exact methods have been developed that reduce the discreteness and hence conservatism of Fisher's approach. For instance, Agresti [3] provides a thorough and readable review of confidence interval options for the difference, ratio, and odds ratio of two binomial proportions that guarantee nominal coverage. See [6, 26, 50] for details of some intervals with good properties.

Using mid-P values with Fisher's exact test has gained considerable recent support. As in the one-sample case, this method does not guarantee preservation of the nominal level α, but performance of a test using mid-P is generally closer to nominal than that of the corresponding exact test, and power is inherently higher [1].

Unconditional Exact Tests

It is more common in experiments, and always the case in **observational** research, for at least one tabular margin to be random. Conditioning on only one set of margins, say $\{n_{1\cdot}, n_{2\cdot}\}$, produces a much larger sample space than conditioning on two, allowing many more possible tables and P values under H_0, and thus tests frequently yielding closer to the nominal type I error rates. However, the indeterminate nuisance parameter $p_1 = p_2 = p$ must still be removed. This problem may be overcome, in the context of an arbitrary test statistic T such as $T = X^2_{S2}$, by maximizing the exact P value over possible values of the nuisance parameter:

$$P \text{ value} = \sup_{0 \le p \le 1} \Pr_p(T \ge t_o | n_{1\cdot}, n_{2\cdot}), \qquad (13)$$

where t_0 is the observed test statistic [9, 10, 19].

This "unconditional exact" method has been criticized precisely because it maximizes over the full range of p; Fisher [35] and others [51] have argued that possible samples with far different total successes than were observed are irrelevant. In response, Berger and Boos [15] proposed maximizing the P value over a $100(1 - \beta)\%$ confidence set C_β for p, and adjusting the result for the restriction to the confidence set. Adding β to the maximum over the confidence set yields a valid P value, namely,

$$P \text{ value} = \sup_{p \in C_\beta} \Pr_p(T \ge t_o | n_{1\cdot}, n_{2\cdot}) + \beta. \qquad (14)$$

Since the approach becomes more conservative (P values increase) as the confidence interval narrows, these authors favor a high confidence coefficient, for example, $100(1 - \beta)\% = 99.9\%$ or $\beta = 0.001$, and hence a wide interval. This modification of the approach of Boschloo [19] also maintains the guaranteed level α and is "often uniformly more powerful than other tests" including Fisher's exact test [14]. At the time of

publication, this test and its associated confidence intervals were not widely commercially available. However, both have been implemented in **StatXact** Version 6 [30], and modified Boschloo P values are obtainable using software available from Berger at `http://www4.stat.ncsu.edu/~berger/software.html`. Several alternative unconditional exact intervals that also guarantee coverage have been proposed by Chan & Zhang [24].

Bayesian Methods

The reader is referred to [39] for a thorough review of Bayesian inference for 2×2 tables based on a variety of noninformative, subjective, and correlated priors; *see also* **Bayesian Methods for Contingency Tables**.

At the price of introducing a continuous subjective prior distribution for the two unknown parameters p_1 and p_2, the choice of which is open to debate, the Bayesian statistician bypasses many frequentist difficulties due to discreteness. In a hypothesis-testing framework, the frequentist's final result is a P value – the probability of the observed data and data more compatible with the alternative, conditional on a fixed null hypothesis. Owing to discreteness of the sample space, the discrete distribution of a test statistic may yield few choices of achievable type I error rates for a nonrandomized exact test, and may be poorly approximated by the continuous chi-square or other asymptotic distribution. The Bayesian, however, conditions upon the observed data – all of it rather than selected margins – and calculates the posterior probability of a particular hypothesis of interest: $\Pr(p_1 > p_2|\{n_{ij}\})$, $\Pr(p_1 < p_2|\{n_{ij}\})$, $\Pr(|p_1 - p_2| < \varepsilon|\{n_{ij}\})$, and so on [39]. Such probabilities are determined by integrating over the appropriate space in the joint posterior distribution of (p_1, p_2), which will be continuous whenever a continuous prior is selected. Circumstances are uncommon in which a discrete bivariate prior would be reasonable for the two unknown proportions.

A more general advantage of Bayesian methods is that they satisfy the **likelihood principle**, which asserts that inference about a parameter should depend only on the relative values of the likelihood function at the parameter's admissible values and not otherwise on the data collection method. As Berger and Berry clearly illustrate [13], frequentist hypothesis testing incorporates the probability of outcomes that never occur and therefore, two different research designs that yield the exact same data may provide different P values and hence, different inferences. Bayesian methods do not exhibit this somewhat counterintuitive behavior because, no matter what the research design, they condition on all of the data rather than on a particular choice of marginal totals [41]. In a Bayesian analysis, discreteness is still manifest in the distribution of the posterior probability of a specific hypothesis, considered as a random variable. The posterior can realize only as many values as there are possible tables under the study design, but this does not produce the interpretive complications presented by the frequentist context.

As an example, when independent Jeffreys priors are placed on p_1 and p_2, $\Pr(p_1 > p_2)$ is closely approximated by $\Phi^{-1}(z)$, where

$$z = (n_{11}n_{22} - n_{12}n_{21})\sqrt{\frac{n_{11} + n_{12} + n_{21} + n_{22}}{n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2}}}. \tag{15}$$

This corresponds to the one-sided P value from X^2_{S2}. Numerical methods such as Gibbs sampling and **Markov Chain Monte Carlo** (MCMC) can be used to improve this approximation [23, 36]. Howard also considers the case of correlated priors for p_1 and p_2. Such a choice, with positive correlation, is one way to represent the subjective belief that p_1 and p_2 are unequal but not likely to differ substantially.

Study Design and Power

For **Student's *t*-test** and other tests based on continuous distributions, it is possible to choose a rejection region that guarantees precisely an arbitrary prespecified type I error rate, whatever the common value of the mean. This is not possible when comparing two proportions, regardless of the test used, without very large sample sizes or use of a supplementary randomization resisted by the scientific community. Consequently, the power of a test at a nominal α depends on the sample sizes in each group, the values of each of the two probabilities, and the true type I error rate achieved by the test in that combination of circumstances. The power is relatively increased when true type I error overshoots the nominal α, as for instance, with the Wald test based on the observed difference $\hat{p}_1 - \hat{p}_2$ in small to moderate samples, and relatively decreased when true type

I error falls below nominal α, as with Fisher's exact test in most of its uses. When designing a study, such trade offs should be kept in mind. The various widely published asymptotic formulae for approximate sample sizes or power for the chi-square, likelihood ratio, or Fisher's exact tests generally fail to capture the saw-tooth nature of this sample size/power trade off. As in the single proportion case, small increases in sample size may reduce power.

As a general rule, efficient use of data is promoted by the use of methods for which actual type I error rates are close to nominal. Methods based on power-divergence statistics and associated confidence intervals, slightly modified if needed to improve coverage, are generally useful for moderate to large samples, and for smaller samples when strict control of type I error is not essential. The power of any test against any fixed distribution in the space of alternatives is defined as the probability of the rejection region under the alternative distribution. This may generally be computed more accurately by exact calculations or **Monte Carlo methods** than by asymptotic formulae. Sample size may be chosen indirectly by this method which, although cumbersome, is reliable and avoids ambiguities associated with the use of asymptotic approximations in general purpose statistical software. Most available sample size/statistical power software packages calculate the power for Pearson, likelihood ratio, and Fisher exact tests [46], but may default to approximations.

When the true type I error rate must not be allowed to exceed the nominal α to any degree, as frequently occurs in the context of regulatory decision making, Fisher's exact test has been the conventional choice. However, unconditional exact methods generally offer more power, and under randomization, the unconditional framework for inference is no less valid than the conditional. The modified Boschloo unconditional test is usually more powerful than the original Boschloo test, which is uniformly more powerful than Fisher's exact test [14]. Similarly, inversion of the modified Boschloo test produces a narrower unconditional exact confidence interval for $p_1 - p_2$, while guaranteeing at least nominal coverage [15, 30].

We reiterate that commercially available sample-size software uses a variety of formulae and approximations that are not always well documented, and may or may not incorporate continuity corrections by default.

Two-sample Summary

The Pearson chi-square test is powerful and offers nearly α type I error rates for large samples. For smaller studies, however, test statistics are desirable that either do not require asymptotic assumptions or are adjusted to improve performance. The modified Boschloo unconditional exact test is a more powerful alternative to Fisher's exact test that strictly preserves nominal type I error when study design leaves at least one tabular margin random. If both margins are inherently fixed and preservation of nominal type I error is essential, then Fisher's exact test, with its inherent conservatism, is warranted. Bayesian tests that escape some discreteness problems and produce straightforward interpretations may also provide insight.

Confidence intervals for differences of proportions and ratios of proportions or odds are generally available by inverting hypothesis tests. These methods are discussed in a variety of texts and manuscripts [2–4, 8, 11, 12, 43, 45, 49, 54]. Bedrick provides thorough coverage of confidence intervals for ratios of two proportions within the power-divergence family of statistics. He concludes that $0.67 \leq \lambda \leq 1.25$ give intervals with the best coverage. This range includes the intervals based on the "Cressie–Read statistic" with $\lambda = 2/3$, and on the Pearson chi-square test.

For small samples, when strict preservation of coverage is not essential, confidence intervals can be constructed by inverting hypothesis tests based on mid-P values [16] to substitute for the overly-broad exact intervals. Closed forms do not exist but software such as Cytel's StatXact [30] computes these intervals.

For simple problems of inference about one and two proportions, research and expanded computing power have clarified deficiencies in methods that have formed the basis of statistical pedagogy and most scientific practice. Although improved methods have been identified, and their properties are generally well-understood, they have not yet seen widespread application. A key requirement for the acceptance of any modern statistical methodology is convenient availability in software. While many of the newer techniques discussed here are implemented in special purpose commercial software and/or can be readily programmed using SAS/IML, S-PLUS, or the freeware **R**, as of March 2004, we know of none employed as defaults, and support by the general purpose statistical packages used by most data analysts

is inconsistent. More frequent use of the improved methods, and hence better inferences for these scientifically ubiquitous situations, await more widespread and convenient implementation by the mass market software packages.

Proprietary Biostatistical Firms

A "proprietary biostatistical firm" is generally a private company offering statistical services to the pharmaceutical, biotechnology, and/or medical device industries. It might be privately owned or a publicly traded company. The more generic term, Contract Research Organization (CRO), is often used to describe such companies, but will also be used to refer to companies providing a wider range of services in pharmaceutical research and development.

Introduction

The fact that certain substances can prevent and/or relieve human conditions has played an important role in the history of mankind, spanning the centuries and cultures of the world. Today's pharmaceutical medicines; that is to say, products that have been synthesized and developed rather than naturally occurring, had their origins in the emergence of chemical companies in the nineteenth century. However, it was not until the synthesis of antibacterial substances in the 1930s that the chemotherapeutic revolution started. The outbreak of war at the end of the 1930s provoked a surge of research for other anti-infective compounds, and the therapeutic potential of penicillin, identified in 1929, was more fully realized. The modern research-based pharmaceutical industry was born.

It has been since the 1980s, and still is effectively, the exclusive right of the pharmaceutical and the biotechnology industries to research, develop, and deliver health care products to the populations of the world. As the pharmaceutical industry grew, so did the interest in, and concern for, the safety and efficacy of new medicines, and in the growth in expenditure for the health of the public. When the thalidomide misadventure happened in the early 1960s, society, through national governments, was ready to act. Regulations controlling drug development and subsequent marketing practices were born (*see* **Drug Approval and Regulation**).

With regulatory requirements established and increasing gradually since the 1960s, the drug development process has become more complex, resulting in increased costs and time pressures on the research-based pharmaceutical industry. The stimulus for reducing health care costs, the usage of generic drugs, and the emergence of the biotechnology industry in the 1980s added to the changes in the pharmaceutical environment. The industry began to consolidate and in some cases reduce the size of their staff. The concept of developmental research using sources outside the industry became a reality and the CRO industry was born.

The Beginnings in the 1970s

At first, the pharmaceutical companies were looking for services to manage peak periods in selected areas. With regulation had come the requirement for appropriate designs and statistical analyses of **clinical trials**. Although the pharmaceutical industry had rapidly expanded their in-house statistical staff in the 1970s, the specialist area of biostatistics lent itself to being contracted out. Some of this early consulting work was provided by academia (biostatistics/ statistics departments, medical schools, or other publicly funded organizations); indeed, many of today's CROs started life as consultancy services within academic departments.

As personal computing became established and continuously more powerful in the 1980s, and when commercial statistical software became more fully developed and reliable (*see* **Software, Biostatistical**), CROs began to function and offer their statistical services to the international pharmaceutical industry. Some of these companies flourished briefly and disappeared. Others expanded with the increased demand for data handling capabilities in a controlled environment and established themselves as complete data operations, providing comprehensive biostatistical and clinical data management services. Some companies expanded further by adding clinical operations to their services, such as expert medical advice in the design of studies and plans for drug development, drug packaging and distribution, monitoring of studies and adverse events (*see* **Data and Safety Monitoring**), strategies for regulatory affairs, design and development of CANDAs (Computer Assisted New Drug Applications), **post-marketing surveillance** and reporting, and economic cost–benefit evaluations of pharmacologic drugs (*see* **Pharmacoepidemiology, Adverse and Beneficial Effects**). Biostatistical services included

designs, methodology, and **sample size determination for clinical trials**, plans for statistical monitoring of the conduct of clinical trials, and analyses of studies including therapeutic **outcome measures** and **quality of life**.

Several CROs have expanded further to meet the changing needs arising from consolidations, the downsizing of pharmaceutical companies, and the growing biotechnology industry by offering other nonclinical services (e.g. analytical chemistry, toxicology, pharmacology, formulation development, laboratory services, and manufacturing). While the CROs specializing in the biostatistical aspects of clinical trials still exist, pharmaceutical companies often contract out biostatistical and other services, such as those associated with complete clinical investigations, whether they be single or multiple studies or indeed entire drug development programs.

The Biostatistical Consulting Operation

As already indicated, much biostatistical contract work is being done as part of more extensive services. In this section we outline the job and the career structures for biostatisticians, whether they are employed by a CRO specializing in biostatistics (and **data management**) or a CRO which offers biostatistics as one of their services.

The Career

The growth in biostatistical consultation and support of new drug development in the pharmaceutical industry resulted in an increased number of biostatisticians being employed during the 1970s and early 1980s. As the CROs grew in the 1980s and 1990s, they employed many biostatisticians, as may be noted by the membership in pharmaceutical statistics organizations such as The European Federation of Statisticians in the Pharmaceutical Industry (EFSPI and its national organizations) and the Biopharmaceutical Section of the **American Statistical Association**. For example, at the end of 1996, the UK national organization of EFSPI, PSI (**Statisticians in the Pharmaceutical Industry**), counted more than half of its 800 members as belonging to the contract research industry.

A career as a biostatistician in a CRO is not just a possibility but is a reality. Depending on the size of the organization and the variety of its services, as well as on the individual and his/her strengths and aspirations, careers in biostatistics span the full spectrum of both a technical and a managerial ladder. Professional and regulatory demands on the biostatistician require the highest level of technical skill, challenging any new graduate for years ahead. The academically trained biostatistician in the CRO must develop consulting skills (*see* **Statistical Consulting**) to meet the needs of varied clients, projects, therapeutic subject matter areas, and appropriate designs for clinical trials. Depending upon the responsibilities of the biostatistician, time is required to learn or enhance skills and teamwork, communicate effectively in client/customer relationships, and learn managerial skills, whether these skills are needed on a particular project or in leading and directing staff members. Biostatisticians in CROs may progress from junior/assistant to principal statistician, from leader of a team to manager of biostatistics and to a senior role as a business leader. The Chief Executive and Founder of the world's largest CRO is a biostatistician by training. A career in contract research offers a dynamic environment with opportunities for initiative and scope to develop, excel, succeed, and prosper.

The Job

The main responsibility of the biostatistician in a Biostatistics Department in a CRO is typically quite operational, i.e. writing a detailed statistical analysis plan from a prescribed study protocol, including tables, listings, and graphical analyses as well as a report outline (*see* **Clinical Trials Protocols**). The biostatistician participates in the generation and programming of analysis files, tables, listings, and graphs and prepares the statistical report or contributes to an integrated medical and statistical study report.

The work of the biostatistician often includes discussions with the client about the design, appropriate sample size, and methods of analysis of a study, interaction with the biostatistical personnel of the client concerning the statistical sections of the protocol, and consultation with appropriate clinical and/or data management departments concerning monitoring of the study and issues of data quality. Other aspects of the job include, for example, regulatory issues, drug packaging and distribution, preparation of patient **randomization** schedules (*see* **Randomized Treatment Assignment**), and

marketing/sales/business development in relation to contractual issues. In some circumstances, the biostatistician may work on-site at the client's company. Internally, work processes and standard operating procedures need constant attention. Statistical tools, especially software packages, need to be regularly reviewed and upgraded as necessary. Training is always an important concern. At a more advanced level the biostatistician may be called upon to advise the client on statistical issues and/or methodologies (*see* **Teaching Statistics to Physicians**), on regulatory statistical strategy, on drug development plans, and regulatory submission formats and documentation.

In conclusion, a successful biostatistician in a CRO will have skills in multiple areas, from the highest level of technical ability to knowledge of regulatory affairs, and be a highly effective communicator, able to function effectively with senior personnel in other disciplines.

Facts and Figures About the CRO Industry

The CRO industry, which counts biostatistical consulting as one of its components, is a burgeoning environment of industrial scientific life, which has seen sustained annual growth rates of over 50% in the last few years. The total dollars outsourced to CROs has been growing at a rapid pace for half a decade – 20% to 30% per year – and it is expected that this growth will continue at these levels for at least the next few years. In 1996, there was an estimated $15 billion spent on clinical development by pharmaceutical and biotechnology companies, of which about 18% ($2.7 billion) was contracted out to an estimated 500 CROs. Dollars for clinical development are expected to grow by 6% to 9% annually at least through 1998; with the expected increase in dollars spent on clinical development, it is estimated that approximately $3.5 billion will be outsourced in 1997 and $4.4 billion in 1998.

There are hundreds of CROs around the world competing for the drug development dollars. However, the top five to ten largest CROs currently receive over half of the outsourced business.

DIANE GEHAN & JORGEN SELDRUP

Pseudo-likelihood

The term *pseudo-likelihood* has been used by several authors (e.g. Besag [1], Suzuki [6], Prentice [3], Kalbfleisch & Lawless [2], Wild [7], and Scott & Wild [4] in a rather heuristic way, to describe a function of the data and the parameters of interest that has properties similar to those of the usual **likelihood** function. Often, the pseudo-likelihood arises as an estimate of an unobserved likelihood based on complete data; this is especially the case in the context of response-selective or response-biased sampling. In such contexts, the pseudo-likelihood function for the parameter gives rise to a pseudo-score function as its logarithmic derivative; typically, the pseudo-score function has expectation zero, though sometimes this only holds asymptotically. The primary use of the pseudo-likelihood, then, is to define an estimating equation (*see* **Estimating Functions**) through setting the pseudo-score to zero. In many instances, these heuristics lead to good inferential procedures, but there is no clear theoretical theme to develop for this article. What I shall do, however, is develop one simple example where pseudo-likelihoods have been suggested to give a general idea of the approach, and provide entry points to the literature through references to a number of papers.

Suppose that N independent individuals give rise to data (y_ℓ, x_ℓ), $\ell = 1, \ldots, N$, which have the joint probability density function (pdf)

$$f(y|\mathbf{x}, \boldsymbol{\theta})g(\mathbf{x}).$$

Here, y is a **response variable**, $\mathbf{x}$ is a vector of **explanatory variables**, and $\boldsymbol{\theta}$ is the vector of parameters of interest which describes, perhaps among other things, the regression of y on $\mathbf{x}$. It is assumed that $\mathbf{x}$ arises from some pdf $g(\mathbf{x})$ which does not depend on $\boldsymbol{\theta}$.

With complete data, inference on $\boldsymbol{\theta}$ would be based on the likelihood arising from the product of conditional densities. The log likelihood is

$$\ell(\boldsymbol{\theta}) = \sum_{\ell=1}^{N} \log f(y_\ell|\mathbf{x}_\ell; \boldsymbol{\theta}), \tag{1}$$

with the corresponding score function

$$s(\boldsymbol{\theta}) = \sum_{\ell=1}^{N} s_\ell(\boldsymbol{\theta}), \tag{2}$$

where $s_\ell(\boldsymbol{\theta}) = \partial \log f(y_\ell|\mathbf{x}_\ell, \boldsymbol{\theta})/\partial\boldsymbol{\theta}$.

We consider, however, situations in which we have incomplete data and further where the data collection is response-selective. Specifically, we suppose that the range S of the response variable Y is partitioned into k subsets: $S = S_1 \cup S_2 \ldots \cup S_k$, where $S_i S_j = \phi$ for all $i \neq j$. The data collection is response-selective in that the probability that $(y_\ell, \mathbf{x}_\ell)$ is observed depends upon the class in which y_ℓ falls. Thus, $(y_\ell, \mathbf{x}_\ell)$ is observed with known probability p_j if $y_\ell \in S_j$ for all $l = 1, \ldots, N$ and $j = 1, \ldots, k$. Such a sampling scheme could arise in several different ways, of which we mention only two:

1. *Basic* **stratified samples** (*BSS*). The N units have been generated from (1), and N_j are observed to have response y_ℓ in S_j. A simple **random sample** of $n_j = p_j N_j$ items is selected and fully observed in the jth stratum.
2. *Variable probability sampling (VPS)*. As items arise, their stratum membership is identified. If the lth item falls in S_j it is independently selected for full observation with specified probability p_j. Selection continues until we have a sample of n items.

Variations on both of these schemes are possible and arise in practice.

For simplicity, we consider VPS. An estimate of the full (unobserved) log likelihood (1) is given by the log pseudo-likelihood function

$$l_p(\boldsymbol{\theta}) = \sum_{i=1}^{k} \frac{1}{p_j} \sum_{l \in D_j} f(y_\ell|\mathbf{x}_\ell, \boldsymbol{\theta}), \tag{3}$$

where D_j is the set of items observed in the jth stratum. The corresponding pseudo-score function that estimates (2) is

$$s_p(\boldsymbol{\theta}) = \sum_{i=1}^{k} \frac{1}{p_j} \sum_{l \in D_j} s_\ell(\boldsymbol{\theta}). \tag{4}$$

It can be seen that $s_p(\boldsymbol{\theta})$ has expectation 0 and that, under fairly general conditions, the estimator $\hat{\boldsymbol{\theta}}_p$ that satisfies $s_p(\boldsymbol{\theta}) = 0$ is asymptotically normal with variance estimated by $\hat{\boldsymbol{A}}^{-1} + \hat{\boldsymbol{A}}^{-1}\hat{\boldsymbol{B}}\hat{\boldsymbol{A}}^{-1}$, where

$$\hat{\boldsymbol{A}} = \frac{\partial^2 l_p(\boldsymbol{\theta})}{\partial\boldsymbol{\theta}}\ \partial\boldsymbol{\theta}^{\mathrm{T}}|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}},$$

$$\hat{\boldsymbol{B}} = \sum (1 - p_j) p_j^{-2} \sum_{l \in D_j} s_\ell(\hat{\boldsymbol{\theta}}) s_\ell(\hat{\boldsymbol{\theta}})^{\mathrm{T}}.$$

It should be noted that there are many ways, in general, that the full log likelihood (1) could be estimated. The "weighted" pseudo-likelihood (3) and related pseudo-score (4)represent only one approach. Scott & Wild [4] compare a number of competing approaches to this problem.

One simple example of a design of this type is the **case–cohort** design of Prentice [3]. In this, N individuals are at risk of failure over an interval $(0, \tau)$, and interest centers on relating the failure rate $\lambda(t|\mathbf{z})$ to a vector of covariates $\mathbf{z}$ which can be measured on each individual under study. It is too expensive, however, to observe all individuals. Instead, the data comprise observations on all individuals who fail in $(0, \tau)$ and, in addition, a sample of those individuals who do not fail. Specifically, each individual in the cohort who does not fail is independently observed with probability p_2. Here, the response variable for the lth individual is T_ℓ and its range is divided into $S_1 = (0, \tau)$ and $S_2 = [\tau, \infty)$. The sampling rates for the two strata are $p_1 = 1$ and $p_2 < 1$, and the pseudo-likelihood described above can be applied directly for the case $\lambda(t|\mathbf{z}; \boldsymbol{\theta})$, a parametric model. Details are given in Kalbfleisch & Lawless [2], where various alternatives are also considered and compared.

Prentice [3] considers the case–cohort study in the context of a **proportional hazards model**

$$\lambda(t|\mathbf{z}) = \lambda_0(t) r(\mathbf{z}^{\mathrm{T}}\boldsymbol{\beta}), \tag{5}$$

where $\mathbf{z}$ is a vector of covariates, $\boldsymbol{\beta}$ is a vector of regression parameters, and $r(x)$ is a **relative risk** function. He derives a pseudo-likelihood based on case–cohort data, and Self & Prentice [5] evaluate its asymptotic properties.

JOHN D. KALBFLEISCH

Pseudo-random Number Generator

One of the most frequently called functions on a scientific computer is the random number generator. Random numbers are required for many purposes. A major use is in **simulations**. Large quantities of random numbers are needed to generate the **random samples** from distributions (theoretical and/or empirical) which are the basis of any stochastic simulation. Another use for random numbers is the **Monte Carlo** evaluation of multivariate integrals (*see* **Markov Chain Monte Carlo**). Ideally, what is required in a simulation is a stream of independently and uniformly distributed random variables taking values between 0 and 1 [i.e. a random sample from the **uniform distribution** on (0,1)]. At best this ideal can only be realized approximately.

Among the possible ways of generating random numbers are mechanical processes, such as those often used to select the winning numbers in lottery draws, and methods using electronic noise, as in ERNIE, the device used to select the winning numbers in the British premium bond scheme (another lottery). It is difficult to validate such machines and to ensure that they always behave correctly. Furthermore, if one needs to reproduce the stream of numbers used in a particular application, this can be done only by storing the complete stream as it is created. Such devices are also unsuitable for rapid access by the simulation program.

Nowadays, computers almost invariably use a "random number generator" program. These are, in fact, *pseudo-random number generators* (PRNGs), because it is impossible to construct a practicable program for computing truly random sequences. PRNGs are programs that produce a deterministic sequence that mimics a random sequence of numbers. Their advantages include speed, reliability, reproducibility, and portability. Because simulations may consume very large numbers of random numbers it is usually important that it takes very little time to produce a single one; PRNGs are usually highly efficient (often very short) programs and hence can be very fast. They are reliable sources of pseudo-random numbers in the sense that, *provided they are correctly implemented*, they will operate precisely as their theoretical specification predicts. There is no difficulty in producing a perfect replica of a sequence. Hence, if required, an entire simulation can be repeated exactly. PRNGs can be made extremely portable so that different users can get the identical random number stream, even on different types of computer.

Ripley [10] gives a formal definition: a sequence of pseudo-random numbers is a deterministic sequence of numbers in the interval [0, 1] having the same relevant statistical properties as a sequence of random numbers. The key word here is *relevant*. Before using a PRNG for a particular project it is essential to check whether it can be regarded as producing a sequence that is 'random enough' for the purpose in hand. For example, a sequence that is suitable for a fairly small **queueing** simulation may be unsatisfactory for a large **operations research** simulation of the ordering systems for a large health authority. It may be possible to predict suitability from a knowledge of the theoretical properties of the PRNG or it may be necessary to carry out a battery of statistical tests on trial sequences to check its suitability for various purposes. Some generators have been very well researched in both aspects. Some have been shown to have serious flaws but are, unfortunately, still in use.

The advantages and disadvantages of PRNGs can best be explained by considering a class of generators that has enjoyed wide popularity for most of the latter part of the century. These are the *multiplicative linear congruential generators* (MLCGs), often abbreviated to *multiplicative congruential generators* (MCGs). They are based on a very simple integer recurrence relationship. The **algorithm** starts with a "seed" value, say X_0. It then applies the congruency relationship,

$$X_i = aX_{i-1} (\text{mod } m), \tag{1}$$

to obtain the next member of the sequence (i.e. X_i is the remainder when the product aX_{i-1} is divided by m); X, a, and m are all integers. The pseudo-random numbers are obtained by setting

$$U_i = \frac{X_i}{m}. \tag{2}$$

At best, (1) produces each of the integers $1, 2, \ldots, m-1$ once, in some apparently random order, and then repeats that sequence exactly, i.e. the output is periodic. However, not all MCGs produce *all* the integers before starting to repeat the sequence.

The length of the period depends on a and m. A convenient choice for m, for ease of calculation on a binary computer, requires it to be a power of 2, say $m = 2^k$, but a necessary condition to achieve the maximum possible period is that m is prime. For computers with 32-bit word-length 2^{32}, 2^{31}, and especially $2^{31} - 1$ are the popular values. The MCG with $m = 2^{31} - 1$ has been particularly thoroughly researched because $2^{31} - 1$ is prime. Prime m is considered desirable for various reasons: The properties of generators with prime m are well understood. For a given m, there are many values of a which lead to a generator with the maximum possible period $(m - 1)$. Good (well-tested) implementations are available. Research has shown that, when $m = 2^{31} - 1$, one of the best choices for a is 16 807. The resultant generator has been in widespread use for many years and is still a popular choice for many applications.

In order that the actual output sequence from any generator program is precisely as theory predicts, the recurrence computations must be exact, i.e. there must be no rounding or other numerical errors. Owing to their finite word-length, computers can only represent real numbers approximately, whereas integers can be represented exactly (up to a certain size determined by word-length and the computer's arithmetic). This is the reason why the integer recurrence given in (1) is used, rather than a recurrence on the U_i directly.

The upper limit on exact integer representation causes implementation problems. For reasons of efficiency, m is often chosen to be very close to the upper limit. In this situation, aX can be very much larger than m and hence the upper limit. Thus, a naïve implementation of (1) will fail disastrously. Ways of overcoming this problem include using higher precision computer arithmetic (*see* **Floating Point Arithmetic**), or breaking up the problem and replacing the single (1) by several equations in each of which the upper limit is never exceeded.

The length of the period of the MCG with $m = 2^{31} - 1$ and $a = 16\,807$ is approximately 2×10^9. This is adequate for many problems, but the large-scale simulations that are increasingly common nowadays require PRNGs with much longer periods. One way of obtaining a generator of greater length, but which still uses only simple MCGs, is to combine the outputs of two or more different MCGs. The simplest way of doing this is by adding their outputs and taking the fractional part (as was originally proposed by Wichmann & Hill [12] for 16-bit computers). It is straightforward to compute the period of the combined generator: for suitable choices of m and a it is just the product of the individual periods. The increased period is not the only benefit. For well-chosen generators, the "randomness" of the combined generator is found to be better than that of the individual components. For example, L'Ecuyer [6] combined two particular MCGs, each of whose modulus was very close to $2^{31} - 1$. The combined generator has period 2×10^{18} and behaves very well. But period lengths of this order are still inadequate for many present-day applications. Adding more component MCGs would increase the period but it would also slow down the generator.

An alternative way of combining generators is *shuffling*: the order of the output sequence of one generator is varied "randomly" by the output from another generator. The theoretical properties of the resultant generator are difficult to determine. Such generators have not found favor generally.

Before considering other types of generator, a particular aspect of the randomness behavior of PRNGs in general needs to be mentioned. So far, we have only considered the generation of univariate uniform variables – these may be represented as random points on the unit line. However, many problems nowadays require the generation of multivariate random variables. This involves generating multivariate uniform variables – these may be regarded as random points in n-dimensional space, $n \geq 2$, depending on the specification of the random variable. The standard way of doing this is to use n consecutive numbers in the output from the PRNG as the coordinates of a pseudo-random point in n-dimensional space. Similarly, the next n numbers in the sequence form the next point, and so on. Marsaglia [8] found that for MCGs such points were located on a limited number of parallel hyperplanes instead of being distributed randomly in space. This lattice structure reflects the **serial correlation** structure (i.e. the lack of independence) in the output sequence from the MCG. For some generators the resultant regularity can easily be seen in two dimensions by plotting the output numbers against each other in pairs. Some generators are better than others, in the sense that the distance between the hyperplanes is less. Tests for lattice structure have been devised and can be applied, along with other tests, when validating a particular PRNG. Whether or not lattice structure is a serious problem in practice depends very much on the particular type

of application for which the generator is being used. It is known that combining MCGs by addition does not remove lattice structure problems.

MCGs are the special case of the *linear congruential generator* (LCG),

$$X_i = aX_{i-1} + c(\text{mod } m), \tag{3}$$

where $c = 0$. However, provided m is prime, incorporating a nonzero value of c confers no advantage over the corresponding MCG.

The LCGs are members of a much wider class of generator for which the current value X_i depends on more than one of the previous values:

$$X_i = a_1X_{i-1} + a_2X_{i-2} + \cdots + a_kX_{i-k}(\text{mod } m), \tag{4}$$

where some of the a_j may be zero.

The MCG of (1) uses large values of m. At the other extreme, we can set $m = 2$ and restrict a to either 0 or 1 in (4). The output stream is then a sequence of 0s and 1s. Viewing these as computer bits, b_j, we can construct pseudo-random numbers in the form of binary fractions, for example

$$U_i = 0 \cdot b_{i\ell}b_{i\ell+1} \ldots b_{i\ell+n}, \ell > n. \tag{5}$$

This type of generator is known as a *Tausworthe* or *feedback shift register* (FSR) generator because of the way in which it is implemented – the computer operations required to produce each pseudo-random number are very simple and fast. *Generalized feedback shift register* (GFSR) generators result if U_i is made up from nonconsecutive bits in the output stream. Instead of the simple seed that an MCG requires, FSR and particularly GFSR generators require special initialization procedures; they also use much more memory. However, given appropriate choices of constants and correct implementation, very fast generators with extremely large periods and good "randomness" properties (including their higher-dimensional behavior) can be constructed. Well-tested implementations are available. Combinations of GFSR generators by addition have also been implemented [11].

Other generators that have recently been introduced by Marsaglia & Zaman [9] are based on replacing the addition operation in special cases of (4) by other binary operators. These generators are known as *add-with-carry* (AWC) and *subtract-with-borrow* (SWB) generators. They are designed to be very fast and have extremely long periods. However recent theoretical analysis [1] suggests that their lattice structures are effectively equivalent to those of LCGs with very large moduli m.

A different approach to obtaining better lattice structure is to be found in the *inversive congruential generators* (e.g. [4]). They use the relationship

$$X_i = a\overline{X}_{i-1}(\text{mod } m), \tag{6}$$

where $\overline{X}$ (the *inverse* of X) is the solution of $X\overline{X} = 1(\text{mod } m)$. Such generators are known to have much better lattice structure than the normal MCGs, but suffer from the same constraints on period length. Also, the computation of $\overline{X}$ is time-consuming.

Properties such as period length are global (i.e. they describe overall features of the entire output sequence of a PRNG) and are derived theoretically. However, the practical question that faces any user is the behavior of samples from the sequence and, most important, the relevance of that behavior to particular applications. It is, therefore, extremely important that very thorough tests are carried out before a generator is released for general use. For the great majority of users, writing PRNG programs is not a recommended activity. However, it is not a good idea to place too much trust in the random number functions provided by computer operating systems (or indeed by various packages, particularly those that are not specifically designed for statistical use) without first checking their specifications and suitability for the application in hand. The reader is recommended to use one of the thoroughly researched and tested professional implementations (for example, in the IMSL and NAG libraries; *see* **Numerical Analysis**).

There is a very substantial research literature on the generation of pseudo-random numbers and this is increasing rapidly. General introductions to the standard methods can be found in the books by Dagpunar [2] (fairly elementary) and Ripley [10] (more mathematical). A good brief survey is given by L'Ecuyer [7]. Currently, a useful source of information on various aspects of random number generation is the World Wide Web site `http://random.mat.sbg.ac.at`, maintained by the Mathematics Department of the University of Salzberg, Austria.

The design and implementation of algorithms for converting pseudo-random numbers into pseudo-random values from various nonuniform distributions is best left to professionals. Some general methods are

available, but usually a substantial amount of work is needed to produce a workable algorithm for any particular distribution (*see* **Simulation**). For many distributions there is an *ad hoc* method based on the particular properties of that distribution. As in the case of PRNGs, the correct and efficient implementation of the algorithms is a skilled activity and the resulting programs require very thorough testing before adoption for general use. There is a very substantial research literature on nonuniform random variable generation. The books by Dagpunar [2] and Ripley [10] contain introductions to this topic as well. Devroye's encyclopedic book [3] concentrates on the theory leading to a vast range of algorithms, but contains very little practical information on implementation and efficiency. For a very recent general survey of the area and suggestions for further reading, see Kemp [5].

Psychiatry

> The mentally ill have always been with us – to be feared, marveled at, laughed at, pitied or tortured, but all too seldom cured (Alexander & Selesnick, *The History of Psychiatry*, 1967).

In his *Dictionary of Psychology*, Professor Stuart Sutherland defines psychiatry as "the medical speciality that deals with mental disorders". An almost equally brief definition appears in Campbell's *Psychiatric Dictionary*, namely "the medical speciality concerned with the study, diagnosis, treatment and prevention of behaviour disorders". In terms of either definition psychiatry has a long history since, for example, Pythagoreans employed music therapy with emotionally ill patients [11], and Aretaeus (A.D. 50–130) observed mentally ill patients and did careful follow-up studies on them. As a result, he established the fact that manic and depressive states occur in the same individual and that lucid intervals exist between manic and depressive periods. He considered mental illness in terms of outcome, emphasizing the course of the disease and its prognosis. He also understood that not all persons with mental illness are destined to suffer intellectual deterioration, a fact not again adequately emphasized until the twentieth century.

A widely quoted remark of **Galton** is that until the phenomena of any branch of knowledge have been submitted to measurement and number, it cannot assume the dignity of a science. Psychiatry, during the twentieth century, has struggled to attain such scientific respectability by making quantitative observations on mentally ill patients, and psychiatrists have become increasingly aware that a strict scientific approach is required for their discipline to progress. Statistics has, during this period, become a most important basic science in psychiatry and more and more often psychiatric researchers resort to sophisticated and powerful statistical techniques to help them unravel the complexities of their data.

But in the nineteenth century and earlier, the use of statistics in psychiatry was largely restricted to simple descriptive measures, and it is only in the second half of this century that the use of inferential (*see* **Inference**) and other more complex methods has become widespread. However, the use of even simple descriptive statistics was important and their presentation often led to changes in policy if not to changes in attitude to the problems of lunacy. Table 1, for example, taken from Schull [22], shows the number of people officially identified as insane and the rate of insanity per 10 000 people in England and Wales at various times during the nineteenth century. The increase in lunacy as suggested by these figures became one of the main weapons in reformers' arguments for new legislation to deal with the insane, since they indicated that insanity was now a serious social problem, a view endorsed by the following from the 1844 Report of the Metropolitan Commissioners on Lunacy:

> Lunatics have unfortunately become so numerous throughout the whole kingdom, that the proper construction and cost of asylums for their use has ceased to be a subject which affects a few counties only, and has become a matter of national interest and importance.

Schull points out, however, that the achievement of reform (the construction of asylums and the employment of doctors to effect the cure of the insane) failed to bring a halt or even a diminution in the rapid upward spiral of cases of lunacy. Between 1844 and 1860, when the population as a whole grew by just over 20%, the number of lunatics almost doubled; and the growth in the number of the insane continued to far outstrip the rate of increase of the general population for the rest of the century. Schull discusses the various "official" explanations for the increase, one of which was that a large number of cases previously unreported had only recently been brought under observation because the method of gathering statistics on insanity had previously been slipshod and inadequate; the apparent increase was therefore dismissed as largely a statistical artefact. Alternative explanations for the increase assumed it to be real and attributable to stresses attendant upon life in a higher "mechanical" civilization. (The arguments described here appear not to have altered dramatically over the intervening 150 years!)

Examination of early issues of the *Journal of Mental Science* (the forerunner of today's *British Journal of Psychiatry*) provides an example of "statistical proof" in Matt's [18] investigation of the inheritability of insanity, although the proof amounts only to the presentation of a set of data rather than to the use of more formal inferential methods.

An indication of the psychiatrist's attitude to mathematical and statistical topics in the early part of the

Table 1 Total population, total number officially insane, and rate of insanity per 10 000 people in England and Wales

January 1	Population	Number deemed insane[a]	Rate per 10 000	Source of data on number insane
1807	9 960 000	2248	2.26	House of Commons, 1807
1819	11 106 000	6000	5.40	Burrows, 1820
1828	13 106 000	8000	6.10	Halliday, 1828
1829	13 370 000	16 500	12.34	Halliday, 1829
1836	14 900 000	13 667	9.18	Parliamentary Return, 1836
1844	16 480 000	20 893	12.6	Metropolitan Commissioners on Lunacy
1850			Not available	
1855	18 786 914	30 993[b]	16.49	Commissioners on Lunacy
1860	19 902 713	38 058	19.12	Annual Reports
1865	21 145 151	45 950	21.73	
1870	22 501 316	54 713	24.31	
1875	23 944 459	63 793	26.64	
1880	25 480 161	71 191	27.94	
1885	27 499 041	79 704	28.98	
1890	29 407 649	86 067	29.26	

[a]Includes lunatics in asylums, but also those in workhouses, at large in the community, etc.
[b]The Commissioners found 20 493 lunatics in asylums of all types in 1855; lacking a complete enumeration of all lunatics not so confined, they estimated that these amounted to 10 500 persons.

twentieth century may perhaps be gleaned from the comments made by Edward Mapother when reviewing Spearman's book *The Abilities of Man: Their Nature and Measurement* in the *Journal of Mental Science* in 1928:

> Doubtless most readers of this Journal, like the reviewer, will be content to take for granted the mathematics involved.

Freud, too, was not convinced about statistics. Fleiss reports that in the 1920s, Joseph Zubin and a few fellow graduate students undertook a study of 4-, 5-, 6-, and 7-year-old children to put to the test Freud's Oedipus theory. Data were collected and analyzed, and the statistical results seemed to confirm the master's theory. It was Zubin's task to prepare the tables, charts, and summary statistics and to send them to Freud. "Ganz amerikanisch" was his disparaging reply, implying that only in America was the need felt to test what was obvious.

Nevertheless, statistical methodology began to appear in psychiatric journals around this time. Cameron [1], for example, in a study of perseveration used the **correlation** coefficient and a test to assess its significance. A report by the Royal Medico–Psychological Association Committee on Mental Deficiency on the evidence of neuropathic conditions in the relatives of normal persons published in the *Journal of Mental Science* in 1937 used a *t* test to examine the difference in average family size for two groups of families, those who included a weak-minded person and those who did not. (The details of the *t* test (*see* **Student's *t* Distribution**) were confined to an appendix.) The same paper also contains an application of a one-way **analysis of variance**. Masserman & Carmichael [17] used Pearson's contingency coefficient to assess the relationship between diagnosis and prognosis in psychiatry.

The first **clinical trial** in psychiatry came in response to the focal infection theory as a cause of mental disorder [3]. Kopeloff & Cheney [14] and Kopeloff & Kirby [15] undertook to test this hypothesis by removing surgically all the foci of infection from one group of patients and comparing their outcome with an untreated control group. The only difference found was a higher mortality from the experimental group but no difference in outcome. No statistical tests of differences were made, and results were reported simply in terms of numbers and percentages of improved cases. It was only 50 years later that Zubin & Zubin [25] calculated the statistical significance of the difference in percentages and found it to be nonsignificant.

The first psychiatrist to advocate the use of **Fisher's** experimental methods in the evaluation of

physical treatments in psychiatry appears to have been Sir Aubrey Lewis [16]. In this article, he criticizes the past use of small series of cases and "the common lack of a coordinated plan for the therapeutic experiment". Of a controlled trial he concludes:

> An organized experiment would demand much that has not hitherto been practicable, including voluntary acceptance by independent hospitals and clinics of an agreed procedure for the selection, management, evaluation of mental state, and follow-up investigation of treated, as well as of control cases. Such an experiment, as R.A. Fisher has demonstrated, requires much forethought and self-discipline on the part of those who carry it out.

Lewis concludes with the following statement:

> For the most important psychiatric conditions, such trials are essential, unless we are prepared to go on taking decades to decide questions which could be settled in a few years.

Although small controlled trials of electro-convulsive therapy (ECT) and psychotropic drugs began to appear in the 1950s, it was some 20 years later that the results of the first trial of the sort envisaged by Lewis were published, when, in 1965, the Medical Research Council's **multicenter trial** of drug therapy and ECT in the treatment of depression was completed.

(It is interesting to note that this trial was not universally welcomed. In a letter to the *British Journal of Psychiatry*, Sargant wrote: "There is no psychiatric illness in which bedside knowledge and long clinical experience pays better dividends; and we are never going to learn how to treat depressions properly from double-blind sampling in an MRC statistician's office.")

Early studies of the inheritance of mental disorders also had reason to be grateful to Fisher. In his **twin studies** and family studies of manic depression, the British psychiatrist Elliot Slater was concerned with the problem of the use of age-of-incidence data in the estimation of life-time risk, and acknowledges early advice on appropriate statistical methods from Fisher; the following is taken from Slater's autobiographical sketch [23]:

> I had the temerity to write to R.A. Fisher to ask for his help. He gave it at once, and in a completely satisfying way; and it was in his journal that my paper was eventually published. Fisher helped me on many occasions, in investigations I carried out in later years, and never grudged time or trouble. I came to have for him the greatest admiration and affection.

Psychiatric epidemiology was at first hampered by inconsistencies in the reporting of the characteristics of the mentally ill, but in the US, at least, became more viable after 1917 when the American Medico–Psychological Association's Committee on Statistics urged all mental hospitals to adopt a uniform reporting system. With the assistance of the National Committee for Mental Hygiene, this Association produced the first uniform nomenclature of mental diseases in 1918. After World War II there was a literal explosion of community and demographic studies of the mentally ill. The National Mental Health Act was passed in the US in 1946. A result of this Act was that responsibility for gathering data on the mentally ill was transferred to the Public Health Service and the soon-to-be-created National Institute of Mental Health.

In England, the 1949 Millbank Memorial Fund Conference on the epidemiology of mental disorders produced general agreement on the importance of epidemiology for causal research and for administrative policy. Its relevance to clinical psychiatry, however, was disputed by many of the practising psychiatrists at the Conference who questioned how far epidemiological inquiry should be based on the conventional schemata of disease, which, in their opinion, were inapplicable to mental disorders. Francis reminded the Conference that epidemiology is basically dependent upon the accuracy of diagnosis and that until a valid base for **classification** can be generally employed, data from different areas cannot be properly compared.

The realization that, as in other medical and scientific disciplines, classification is also fundamental in psychiatry led many psychiatrists and statisticians in the 1950s, 1960s, and 1970s to devote much energy to using **multivariate analysis** techniques such as **principal components analysis**, **factor analysis**, and **cluster analysis** on various sets of psychiatric data in an effort to refine or even redefine diagnostic categories. Examples of such studies are those of Fleiss & Zubin [9] and Everitt et al. [8]. In many respects, this opportunity to apply complex multivariate techniques to an important practical problem provided an impetus to research in multivariate analysis in general and cluster analysis in particular. The reciprocal impact

Table 2 *American Journal of Psychiatry (AJP), British Journal of Psychiatry (BJP)* and *Archives of General Psychiatry (AGP)* during 1980 by categories of statistical usage

	Categories of statistical usage	*AJP* (1980) 339 papers	*BJP* (1980) 148 papers	*AGP* (1980) 110 papers
1.	Expository literature review, etc.	18 (5.3%)	6 (4.1%)	4 (3.6%)
2.	No statistical data, case reports, etc.	115 (33.0%)	12 (8.1%)	2 (1.9%)
3.	Descriptive statistics only tables, graphs, means, variances	65 (19.2%)	14 (9.5%)	11 (10.0%)
4.	Chi-squared and t tests, Fisher exact test; 1 or 2 samples, contingency tables	95 (28.0%)	75 (50.7%)	66 (50.0%)
5.	Product–moment correlations, rank correlations	42 (12.4%)	22 (14.9%)	30 (27.3%)
6.	Analysis of variance F tests: 1-, 2-, and higher way	25 (7.4%)	22 (14.9%)	32 (9.1%)
7.	Nonparametric rank methods (other than rank correlations)	9 (2.7%)	11 (11.5%)	10 (9.1%)
8.	Measures of association and agreement (other than correlation)	10 (2.9%)	13 (8.8%)	9 (8.2%)
9.	Regression analysis simple, multiple, polynomial, stepwise	6 (1.8%)	9 (6.1%)	10 (9.1%)
10.	Discriminant and factor analysis	4 (1.2%)	6 (4.1%)	7 (6.4%)
11.	Estimation: maximum likelihood interval estimation, etc.	0 (0.0%)	3 (2.0%)	2 (1.8%)
12.	Cluster analysis, classification	1 (0.3%)	0 (0.0%)	1 (0.9%)
13.	Life tables, life testing, survival analysis	1 (0.3%)	0 (0.0%)	2 (1.8%)
14.	Time series analysis spectral analysis	2 (0.6%)	0 (0.0%)	1 (0.9%)
15.	Classical experimental design: Latin squares, hierarchical models	0 (0.0%)	3 (2.0%)	1 (0.9%)
16.	Bayesian methods	0 (0.0%)	0 (0.0%)	1 (0.9%)

of the latter on psychiatry has, however, been limited. Certainly, neither of the current editions of the two diagnostic classifications systems in use today, the American Psychiatric Association's *Diagnostic and Statistical Manual* and the World Health Organization's **International Classification of Diseases**, appears to have benefited from any of the many cluster analysis studies that have been reported in the psychiatric literature.

In 1985, DeGroot & Mezzich [5] produced their Table 2 showing articles in three major psychiatric journals by category of statistical usage. By a large margin, the most common appearance of statistics in psychiatric journals is in the form of a significance test (*see* **Hypothesis Testing**), usually either a simple t or **chi-squared test**. But there is considerable evidence that not even such simple methods are always used wisely. White [24], for example, considered 12 issues of the *British Journal of Psychiatry* from July 1977 to June 1978, and found statistical errors that could potentially affect at least one conclusion in over a third of the papers. One common error was failure to use a dependent samples t test for matched data (*see* **Matched**

Analysis). A similar exercise carried out nearly 20 years later by McGuigan [19] showed that the problem had, if anything, become worse, since now 40% of papers examined contained serious statistical errors.

It is likely that repeating DeGroot & Mezzich's study today would give similar percentages to those shown in their Table 2, particularly with respect to simple significance tests. Psychiatrists (or at least editors of psychiatric journals) appear to have developed a fondness for the ***P* value**, which overcomes the many criticisms of its use that have been made in the psychological and medical literature – see, for example, Rozeboom [21], Oakes [20], and Gardner & Altman [10]. But despite its likely overall similarity, the 1995 version of DeGroot & Mezzich's Table 2 would contain a number of new categories. **Logistic regression**, for example, is now applied routinely in many psychiatric investigations. **Correspondence analysis** (see Greenacre [12]) has increased in popularity and is often used to display **contingency tables** graphically. A recent example is given by Corten et al. [2] in an investigation of subjective **quality-of-life** measures in assessing rehabilitation treatment in psychiatry. **Structural equation modeling** (see Dunn et al. [7]) has also begun to appear in the psychiatric and related literature. Hines et al. [13], for example, use such models to assess the influence of the corpus callosum on verbal fluency, language lateralization and visuospatial ability. Brain structure was modeled through correlations between measures taken of the cross-sectional surface area of the posterior fifth (splenum), the posterior third minus fifth (isthmus), the anterior fourth (genu) and the midregion lying between the isthmus and the genu using magnetic resonance imaging.

Meta analysis is now used frequently in medicine in general and psychiatry in particular for combining results from different studies of the same topic. A recent example involves the possible association between schizophrenia and birth complications. Many other categories of technique could almost certainly be added, although their number of occurrences would probably be rather small.

Research in psychiatry includes components from the biological, medical, behavioral, physical and social sciences. The mixture provides many opportunities for the statistician interested in diverse application experiences, and statistics has a central role to play in the continuing development of psychiatry as a scientific discipline. Statistical thinking should pervade every stage of a research investigation in psychiatry.

Two of the most exciting features of psychiatry in the last few years of the twentieth century are the availability of techniques such as *functional magnetic resonance imaging* (fMRI) with the promise of at least the possibility of new and powerful insights into the working of the human brain and the causes of mental illness, and the appearance of powerful new drugs capable of making the last part of the quotation that began this article obsolete. Vast amounts of data are generated by fMRI and related methods and the creation of appropriate statistical methodologies for their analysis will be a further challenge for statisticians working in psychiatry in the future. Longitudinal clinical trials to test new therapies generate many statistical problems and statisticians have, over the course of the last five years or so, developed a range of new techniques for analyzing the data from such trials (see, for example, Diggle et al. [6], and Crowder & Hand [4]) (*see* **Longitudinal Data Analysis, Overview**). As yet these developments have not had a major impact on psychiatric reports of clinical trials, and a further challenge for statisticians working with psychiatrists is to persuade them that the new methods offer real advantages.

The increasing collaboration of psychiatrists and statisticians over the last 20 years has had benefits for both and the future offers further challenges and possibilities in seeking the ultimate goal of overcoming the misery that is mental illness.

BRIAN S. EVERITT

Psychometrics, Overview

Gustav Fechner (1801–1887), the founder of psychophysics, was an optimist. Not only was he convinced that the mind coexisted with the body, but he believed that he could prove it. Initially, he enthusiastically studied "after images" by staring into the sun. Because these images lasted when he turned from the sun, that was initial proof for him that conscious perception was separate from physical perception. Fechner was almost blind from these studies when he came across the work of E.H. Weber, one of his colleagues at Leipzig.

Weber was interested in muscular sensation and noticed that when subjects lifted objects of varying weights, sometimes they could perceive the difference between objects, and sometimes they could not. Weber concluded that when a person distinguishes between two stimuli, it is not the difference between them that is perceived, but rather the ratio of this difference to the magnitude of the things being compared. That is, if subjects were comparing a 20 kg weight with a 20.1 kg weight, they may not perceive the two weights as different. However, when comparing a 1 kg weight with a 1.1 kg weight, the difference was readily perceived. Weber characterized his findings with the following formula:

$$\frac{\Delta R}{R} = K,$$

where ΔR was the "just noticeable difference" between a standard and comparison stimulus, K was a constant, and R was the magnitude of the standard stimulus. This formula states that a noticeable (threshold) stimulus increment divided by the magnitude of a standard stimulus gives a constant value. Weber demonstrated that this finding held true for virtually all physical stimuli, such as light, sound, and pressure.

Fechner was very excited by Weber's work and extended it to measure psychological sensation, rather than stimulus magnitude [13]. Fechner defined sensation as the conscious experience that accompanied the brain's perception of external stimuli. By evaluating subjects' perceptions of stimulus changes, he concluded that Weber's "just noticeable differences" were equal throughout the range of sensation, and so they could be used as units for measuring internal conscious experience. Fechner noted that the magnitude of the perceived sensation was proportional to the log of the stimulus magnitude; as one's sensation of a stimulus increased linearly, the value of the physical magnitude increased exponentially. Fechner's extension of Weber's formula became known as Fechner's Law, which stated

$$S = K \log(R),$$

where S represents sensation magnitude, and K and R are from Weber's formula. He used this model to develop the concept of a "sensation scale", which described the internal psychological processes underlying perception.

Fechner is sometimes referred to as the first psychometrician. *Psychometrics* is the study of the measurement of "psychological characteristics such as abilities, aptitudes, achievement, personality traits, skills, and knowledge" [2, p. 93]. Fechner's obstinate work on measuring sensation illustrated that it was possible to measure unobservable processes within the human psyche. Today, the field of psychometrics includes educational testing, measurement of attitudes and perceptions, personality testing, opinion surveys, health inventories, and other forms of psychological measurement. Psychometric techniques created for measuring the human mind have also proven useful in biometrics and other fields that deal with measuring the intangible.

Psychological Scaling

Measurement involves **measurement scales**. The scales involved in most physical measurement are so widely known and accepted (e.g. kilograms, meters, liters) that there is little controversy surrounding the measurement process. However, in psychological measurement, the scales are more nebulous. On what type of scale can we measure the human mind? Fechner's work provided the first psychological scale measured in units of "just noticeable differences". L.L. Thurstone, another early psychometrician, extended Fechner's work to measure qualities such as attitudes in units similar to these [48]. Later, Rensis Likert introduced the method of summated ratings that measured attitudes along ordered integer scales [24]. Today, psychological measurement involves a variety of scales including those used in educational testing, such as the SAT score scale; in intelligence testing such as the IQ scale; in

personality testing such as the Minnesota Multiphasic Personality Inventory (MMPI) [7]; and in health psychology such as the Jenkins Activity Survey [18]. These tests are measured on very different scales. To understand how psychological scales are developed, the concept of measurement itself must first be understood.

Measurement and Measurement Scales

In its most general sense, *measurement* is the process of assigning numbers to objects according to a set of rules [43]. The set of rules used to make these assignments is called the *measurement model*. The numbers used to classify objects within the measurement model comprise a *measurement scale*. There is a continuum of measurement scales. Selection of an appropriate scale is motivated by both the purpose of the study and the nature of the variable(s) being measured. For example, if the purpose of an assessment is to classify people into one of two stress behavior profiles such as "type A" (high-stress) or "type B" (low-stress), the nature of the measured variable required is dichotomous. However, if the purpose of the assessment is to determine the *degree* of stress experienced by an individual, the nature of the measured variable must be continuous. The variables measured in these two situations are both related to stress. However, because these variables differ qualitatively from one another, and because there are different purposes associated with each assessment, each situation requires a different measurement model and a different measurement scale. For example, the type A/type B classification might be accomplished using the Jenkins Activity Survey, while degree of stress experienced may be measured using galvanic skin response or heart rate.

Stevens [43] provided a taxonomy of measurement scales by describing in detail four specific levels on the measurement continuum. The lowest level, called the *nominal scale*, is used for assigning numbers to objects that form mutually distinct categories (*see* **Nominal Data**). No order relations exist between the categories to suggest that one category possesses more of the attribute measured than another. Ethnicity and political party affiliation are examples of attributes measured on a nominal scale. Asians and Latinos would be assigned different numbers in the measurement process; as would Democrats, Republicans, Independents, and Conservatives. Thus, the nominal scale of measurement is essentially numerical coding. The coding rule is to assign the same number to objects in the same category and different numbers to objects in different categories.

The second level of measurement is called the *ordinal scale*. These scales include an inherent logical order among the mutually exclusive categories (*see* **Ordered Categorical Data**). Unlike the nominal scale, the magnitude of the numbers assigned to the different categories correspond to meaningful differences in magnitudes of the attribute measured. For example, on a coma inventory, patients who are assigned higher scores exhibit superior physiological responses than patients who are assigned lower scores. School grades on a letter scale (A, B, C, D, E) provide another example of an ordinal scale. Similarly, higher scores on the Apgar assessment (a test of the health of newborns) indicate better physiological functioning among newborns than lower scores. However, an important feature missing from an ordinal scale is equal interval widths between categories. That is, we cannot say that the difference in physiological functioning between Apgar scores of seven and eight is the same as the difference in physiological functioning between Apgar scores of three and four. Similarly, on rating scale inventories, we cannot say the difference between "strongly agree" and "agree" is the same as the difference between "strongly disagree" and "disagree". Such statements are reserved for variables measured on interval or ratio scales.

Interval scales have the property of equality of intervals on the scale that correspond to distinct intervals of the characteristic measured. This property allows for differences between scores to be interpreted with respect to the magnitude of the measured variable. For example, when one measures temperature in degrees Centigrade one is using an interval scale. The difference between 10°C and 20°C is the same, in some physical sense, as the difference between 80°C and 90°C. Note that the same thing cannot be said of the perceived sensation of warmth. To determine equal intervals in that scale we would need to take a logarithmic transform of these temperatures (following Fechner's Law). This illustrates how an interval scale in one realm may not be in another. Note also that it is, in general, meaningless to make statements like "80°C is twice as warm as 40°C". In no sense is this true. If we need to make such inferences we need a stronger scale.

The fourth level of measurement, the *ratio scale*, describes those scales commonly used to measure physical attributes. Ratio scales possess all the qualities of the lower scales (mutually exclusive categories, inherent logical order, and equality of intervals) as well as an absolute zero point. This absolute zero point corresponds to the absence of the characteristic measured. For example, in measuring blood alcohol level, a reading of zero indicates the absence of alcohol in the bloodstream. Similarly, before a patient steps on a triple-beam scale, the scale should read zero, which corresponds to the absence of weight on the platform. The *absolute zero* property of a ratio scale is important because it allows for relative statements to be made across measurements. Examples of such statements are "the patient's heart rate has doubled since admission", "Alice is half as tall as Eduardo", and "Melanie's range of motion in her right knee is twice her range of motion in her left knee". Note how these types of statements could not be made with respect to a variable such as intellectual functioning, which is measured on a scale without an absolute zero point.

The nature of the measurement scale must be considered when analyzing and interpreting measurement data. As illustrated above, the level of the measurement scale places restrictions on the types of inferences that can be drawn from the measurement process. For example, when a nominal scale is used, the numbers assigned to the mutually exclusive categories provide no information regarding the magnitude of the variable being measured. Consider measuring ethnicity using a nominal scale where Blacks are coded "1", Hispanics are coded "2", and Whites are coded "3". In looking at these "scores", we could not infer that Whites have more ethnicity than the other groups just because a higher number was assigned. We could easily *transform* this scale by recording Blacks as "37", Hispanics as "12", and Whites as "-1". This transformation of the original scale is admissible because the fundamental property of the scale, mutually exclusive categories, holds across the transformation. All subjects who are in the same ethnic group are assigned the same number. However, calculation of statistics such as the "mean ethnicity" is affected by the scale transformation. This issue is not restricted to the nominal scale. Consider the measurement of health care satisfaction on a five-point Likert scale. The same order relations may not hold if the scale were transformed to a three- or 12-point scale. Different measurement scales have different types of admissible transformations. Thus, the nature of the measurement scale must be considered when analyzing measurement data and reporting the results (see [31], for a more comprehensive discussion of this issue).

The issue of an absolute zero point is another important scale feature that must be considered when interpreting measurement results. In most areas of psychometrics the measurement scales are below the ratio level, and so a zero point on the scale is either absent or arbitrary. Therefore, for these scores to be understood and interpreted appropriately, they must be referenced to external information. Incorporating external information into the score scale is an important area of psychometrics. However, before discussing how this is done, we first provide information regarding the purposes and models underlying psychological measurement.

Purposes and Uses of Tests and Inventories

Tests and inventories are systematic procedures for observing the characteristics of a group of objects and describing the characteristics using a numerical scale. There are many uses of tests and inventories; however, most are used for the purposes of making diagnoses or decisions about groups or individuals. For example, psychiatric inventories are used to place patients into treatment programs, public health surveys are used to monitor the quality of health of various groups of people, and medical tests are used to provide specific information regarding a patient's condition. Such tests can provide a great breadth of information, and so it is no surprise that their use is both pervasive and growing.

Most tests are standardized in some fashion so that extraneous factors do not interfere with the interpretation of test scores. *Standardized tests* refer to tests on which the content and administrative conditions are virtually the same for all test takers. Without standardization, test scores would vary depending on the specific content and characteristics of the testing situation. Thus, comparisons of groups and individuals would be difficult to make. Standardized tests provide a level playing field for making comparisons between individuals and groups who take the same test. For this reason, standardized tests and inventories provide more objective information than unstandardized measures. However, standardized tests and

inventories do not comprise a limited type of assessment. There is a plethora of testing formats and test questions (item types) that fall into this category. Standardized tests may differ markedly from one another on the basis of the item types and test formats used.

Item Types and Test Formats

There are several different types of items that appear on tests and inventories, as well as several different testing formats. A popular item type on surveys and educational tests is the multiple-choice item. This item type features a question or item stem, followed by a series of options. Only one option contains the correct answer, and so these items can be scored dichotomously (right/wrong). An advantage of multiple-choice items is that they can be scored mechanically, such as by using an optical scanner. Many other item types that are scored dichotomously, such as true/false items, matching items, and items requiring the "bubbling-in" of numerical responses can also be scored mechanically. In fact, the recent advent of computer-administered testing (described in more detail in the section "Contemporary Testing Practices" below) has allowed for mechanical scoring of many different item types on computer. For example, the US Medical Licensing Exam is scheduled to include "simulated patient" scenarios where medical licensure candidates are required to "treat" hypothetical patients on-line.

When the scoring of test takers' responses is automatic, the assessment is said to be scored "objectively". However, some item types can currently only be scored by human judges. These item types are said to be scored "subjectively". Examples of subjective item types are open-ended questions such as those found in structured interviews, essay questions, and some tasks presented in performance-based assessments (such as simulated patient tasks that are not computerized). The distinction between objectively-scored and subjectively-scored item types is often subtle. The key feature is whether an external grader is needed to interpret test takers' responses in order to assign a score. When external graders are used, the scores are typically assigned to responses according to a well-defined set of rules. The Apgar assessment for newborns presents an inventory that uses both objectively-scored and subjectively-scored items. The heart rate "item" of the Apgar is measured objectively by reading the baby's pulse, but the color "item" is measured subjectively by looking at the baby and discriminating between blue and pink hues.

Objectively-scored items, such as the multiple-choice item, reduce subjective elements that may contaminate scores associated with other item formats. For example, if a newborn's Apgar score depends on the perceptual acuity of the observing nurse, differences in acuity among nurses may become a source of measurement error. An additional advantage of many objectively-scored item types is that a broad range of content can be tested in a relatively short amount of time. Dozens of multiple-choice items, covering a variety of content areas, can typically be answered in a smaller amount of time than it takes to complete a performance task or write an essay. However, multiple-choice items and other objectively-scored formats also have disadvantages. First, they typically take longer to develop than open-ended items. Secondly, they do not allow test takers to provide creative responses. For this reason, open-ended item formats, which usually require external judges for scoring, are used to test skills that are not conducive to testing via objectively-scored formats.

Recent advances in computer technology and measurement are providing mechanisms for scoring new, complex item formats objectively. Within the near future it is likely that behavioral measurements such as interpersonal skills and psychological well-being, which were thought to be beyond objective measurement, will be scored mechanically. Thus, physical and monetary resources, such as access to these emerging technologies, is likely to be a key determinant in the selection of different item types and testing formats. Before discussing the relative utility of different test and item formats, fundamental measurement concepts and models that are critical to all item formats are presented. We return to item and test format differences in a later section.

Fundamental Measurement Concepts

In this section we discuss three critical notions: **reliability**, generalizability, and **validity**. Psychometricians have developed increasingly sophisticated theoretical conceptions of these notions as well as the statistical machinery to allow them to serve practical purposes.

Reliability

A key issue in all measurement is the stability of the particular measure under consideration. In psychometrics we are principally interested in test scores and their stability is usually denoted by the term *reliability*. The technical meaning of this term is closest to the dictionary meaning "giving the same result on successive trials" and refers to the degree to which test scores are free from errors of measurement. There are many ways to characterize the reliability of a measuring instrument, but a common one is as a correlation between two independent measurements of the same phenomenon. For example, suppose we are trying to ascertain the reliability of a yardstick as an instrument for use by humans in measuring objects of lengths ranging from an inch to a yard. We might choose a few dozen objects of different apparent lengths to be measured then go and measure them all. After measuring them we might then go and measure them all a second time and correlate the first set of measurements with the second. This correlation would be an estimate of the reliability of the measurement process utilizing the yardstick. See Feldt & Brennan [14] for the full story.

It is easy to see that there are a number of difficulties with this sort of operational approach to reliability. For example, how does the estimate vary with different individuals carrying out the measurement process or with a different set of objects to be measured? It was in reaction to these kinds of problems that Cronbach et al. [11] proposed generalizability theory.

Generalizability

Early approaches to estimating the reliability of a measure or instrument yielded a simple number, often termed the *reliability coefficient*. Consequently, none of the different sources of variability (i.e. unreliability) was distinguished from another. It is often the case, however, that a more detailed accounting is needed of the contributions made by these different sources of variability. This leads naturally to a decomposition of the variance into its component parts.

In the ruler example described previously, we would want to know what was the variance due to measurers as well as the variance due to the characteristics of the set of objects being measured. In other circumstances we might want to measure the variation associated with the use of different rulers, or at different times or temperatures. Each aspect or facet of the measurement process adds its own contribution to the total measurement variance. By examining this decomposition we can state more precisely just what we mean by measurement accuracy than is possible with a single reliability coefficient. Moreover, we can predict the extent to which the quality of the measurement process generalizes to other circumstances, e.g. different objects being measured or different people doing the measuring. The method derives its name from this capability. Note that by using this more powerful approach, it is possible to predict the effect on reliability if one or more sources of variation is eliminated.

To calculate these **variance components** requires a more extensive data-gathering effort than that required to calculate a reliability coefficient. To estimate the variance due to different measurers we will need to have a sample of measurers make measurements. To estimate the variance due to different-sized objects being measured, for example, we will need to have ratings on several samples of objects. Often the gathering of such information is difficult or expensive. Consequently, even though a variance components conception of variability is attractive, it may not always be practicable. See Brennan [5] for more details.

Validity

The basic notion is that a measurement process is valid if "it measures what it is supposed to measure". More specifically, the term *validity* refers to the appropriateness, meaningfulness, and usefulness of the specific inferences that are made from the measurement process. Note that the term validity does not refer to the process itself, but rather to *the inferences made from it*. This is a very important distinction. As an illustration, consider a process that yields a blood pressure measurement in its typical form of systolic over diastolic. An inference one might make on the basis of a particular measurement concerns the state of the individual's cardiovascular system. Another inference might be in regard to the individual's emotional state. Under ordinary circumstances one would expect the first kind of inference to have greater validity than the second kind.

Traditionally, validity of mental measurements has been treated within three distinct subcategories – content validity, predictive validity, and construct validity. They can be described briefly as follows:

1. *Content validity*. The extent to which the content of the measuring instrument samples the class of situations or subject matter about which conclusions are to be drawn. If we are interested in making inferences about a person's health, how many of the various components of health do we measure? And how well do we measure them?
2. *Criterion/predictive validity*. The extent to which an individual's future performance on one or more external variables (the criteria) is predicted from performance on the test. The predictive validity of parental height as a predictor of a child's adult height can be empirically determined.
3. *Construct validity*. The extent to which certain explanatory theories and concepts account for performance on the test. Construct validity refers to how well the inferences derived from test scores correspond to theoretical and practical notions of the construct presumably measured by the test. As an example, consider a mental test composed of mathematics items, verbal reasoning items, verbal analogies, reading and oral comprehension, and spatial visualizing. The extent to which all individuals align themselves identically on all of these various subtests is the extent to which the underlying unitary construct of "intelligence" is supported.

Messick [30] provides a more comprehensive description of validity theory, and is considered to be the seminal work in this area.

Formal Measurement Models

In the first section we described the various sorts of measurement scales and their associated characteristics. It is a common misconception that the strength of a measurement scale is determined by the experimental procedure used in the measurement. This is not the case. The strength of the scale is determined by the measurement model, and in particular by the model for parameter estimation that is applied to the data gathered from the experiment. Over the long history of psychometrics there have been many formal models proposed. In this section we describe two of them. The first, *true score theory*, is a straightforward linear model based on observed scores. The second, *item response theory* is nonlinear (but linear in the logit – see below) and bears a surface similarity to **dose–response** curves so familiar in **bioassay**. There is an important, indeed critical, difference between item response theory and bioassay. In bioassay, one typically plots survival rates against dosage. Since both quantities are observable, at least in principle, this is straightforward. Statistical issues arise as one postulates different models to describe (as parsimoniously as possible) the dose–response curve and then tries to estimate the free parameters of the model (*see* **Quantal Response Models**).

By contrast, in a typical application of item response theory one wants to plot performance on an item (say a question about the number of visits to a doctor made in the last year) against an overall health status variable. But the latter is not directly observable. Such variables are often referred to as latent variables (*see* **Path Analysis**). Each individual in the sample is assumed to possess a value of this latent variable and this (unknown) value is represented by a parameter to be estimated. In addition, models for the curve describing the relation between performance on the item and the latent variable are of interest. Progress can only be made when data on a number of such items are available – but the statistical problems are formidable because the "dose" values must be estimated at the same time as the parameters describing the set of "dose-response" curves for the different items.

True score theory is familiar and easy, but in most circumstances does not satisfy the requirements for an interval scale. Item response theory is more complex and may seem arcane, but provides much stronger measurement characteristics. At the moment at least this is the contemporary choice for most modern testing programs and it is being adopted for measuring medical outcomes [28, 38].

True Score Theory

In what follows we employ the terms "test" and "examinee" to conform with psychometric usage. However, the ideas apply equally well to any sort of assessment or inventory.

The fundamental idea of true score theory can be stated in a single simple equation:

$$\text{observed score} = \text{true score} + \text{error}. \tag{1}$$

This equation explicitly states that the score we observe on a test is composed of two components, the true score and an error term. The term *true score* has a very specific technical meaning. It is the average score that we would expect to obtain if the examinee retook exactly similar (parallel) forms of the exam very many times. The error term characterizes the difference between what is observed on a particular occasion and the unobserved long-term average. Such errors are considered to be random and hence unrelated to true score; that is, the distribution of the errors is the same regardless of the size of the true score. This definition requires the errors to have an average size of zero.

Repeating this same discussion in mathematical terms yields an analog to (1) for examinee i on test form j:

$$x_{ij} = \tau_i + e_{ij}, \tag{2}$$

where x_{ij} is the observed score for examinee i on test form j, τ_i is the true score for examinee i, and e_{ij} is the error for examinee i on test form j. These quantities have the following properties:

$$\mathrm{E}(x_{ij}) = \tau_i, \tag{3}$$

$$\mathrm{E}(e_{ij}) = 0, \tag{4}$$

$$\mathrm{cov}(\tau_i, e_{ij}) = 0. \tag{5}$$

In much of the discussion in the rest of this article it will be important to collect the scores for many examinees and to study the variability among those scores. It is commonly assumed that the scores of any examinee are uncorrelated with any other examinee. Utilizing (2) and these properties we can decompose the variance of the observed scores into two orthogonal components, true score variance and error variance, i.e.

$$\sigma_x^2 = \sigma_\tau^2 + \sigma_e^2. \tag{6}$$

Eq. (6) follows directly from the definitions of true score and error, but provides us with many tools to study test performance. Obviously we prefer tests whose error variance, σ_e^2, is small relative to observed score variance σ_x^2. A test with small error variance would measure an examinee's true score more reliably than one with a large error variance. We can characterize how reliably a test works by the ratio of error variance to observed score variance, σ_e^2/σ_x^2. If this ratio is close to zero, then the test is working well – the observed score has very little error in it. If it is close to one, then the test is working poorly – the variation in observed score is mostly just error. When the ratio is rescaled [see (7)] so that it takes the value one when there is no error and zero when it is all error, it is the test's *reliability*:

$$\text{reliability} = 1 - \left(\frac{\sigma_e^2}{\sigma_x^2}\right). \tag{7}$$

This representation of reliability is intuitively appealing, but is not in a useful form because it cannot be directly computed from observed data; although we can observe σ_x^2, we cannot observe σ_e^2. A slightly different conception, using the idea of parallel test forms, yields an observable quantity.

Before deriving this important equation we need a formal definition of parallel test forms. Specifically two forms, say form X and form X', are parallel if

$$\mathrm{E}(x) = \mathrm{E}(x') = \tau \quad \text{and} \quad \sigma_x^2 = \sigma_{x'}^2 \tag{8}$$

for all subpopulations taking the test, where x and x' are the scores on form X and form X', respectively.

The correlation of one parallel form with another, $\rho_{xx'}$, is

$$\begin{aligned}\rho_{xx'} &= \frac{\mathrm{cov}(x, x')}{\sigma_x \sigma_{x'}} \\ &= \frac{\mathrm{cov}(\tau + e, \tau + e')}{\sigma_x \sigma_{x'}} \\ &= \frac{\left[\begin{array}{c}\mathrm{cov}(\tau, \tau) + \mathrm{cov}(\tau, e) \\ +\mathrm{cov}(\tau, e') + \mathrm{cov}(e, e')\end{array}\right]}{\sigma_x \sigma_{x'}}.\end{aligned}$$

The last three terms in the numerator are zero, yielding

$$= \frac{\mathrm{cov}(\tau, \tau)}{\sigma_x \sigma_{x'}}.$$

But $\mathrm{cov}(\tau, \tau) = \sigma_\tau^2$, and from definition (8), $\sigma_x = \sigma_{x'}$ so that $\sigma_x \sigma_{x'} = \sigma_x^2$. Combining these results we obtain:

$$\rho_{xx'} = \frac{\sigma_\tau^2}{\sigma_x^2},$$

but since $\sigma_x^2 = \sigma_\tau^2 + \sigma_e^2$ [from (6)], we can rewrite this as

$$\rho_{xx'} = 1 - \left(\frac{\sigma_e^2}{\sigma_x^2}\right). \tag{9}$$

Using a similar approach, it is possible to show that

$$\rho_{x\tau}^2 = 1 - \left(\frac{\sigma_e^2}{\sigma_x^2}\right)$$

so that

$$\rho_{xx'} = \rho_{x\tau}^2. \tag{10}$$

This result is important since $\rho_{xx'}$ is directly estimable from data, whereas $\rho_{x\tau}^2$ is not. How to estimate $\rho_{xx'}$ well is the subject of a great deal of work that we will only touch on here. One obvious way is to construct two parallel forms of a test, give them both to a reasonably large sample of appropriate people, and calculate the **correlation** between the two scores. That correlation is an estimate of the reliability of the test. But making up a second form of a test that is truly parallel to the first is a lot of work. An easier task is to take a single form, divide it randomly in half, consider each half a parallel form of the other, and correlate the scores obtained on the two halves. For obvious reasons such a measure of test reliability is called *split-half reliability*. This yields an estimate of reliability for a test similar to, but only half as long as, the test we actually gave. Some sort of adjustment is required. A second issue that must be resolved before using the split-half reliability operationally is to figure out how to split the test. Certainly all splits will not yield the same estimate, and we would not want to base our estimate on an unfortunate division. Let us consider each of these issues in turn.

The Spearman–Brown Formula for a Test of Double Length. Suppose we take a test X, containing n items and break it up into two half tests, say Y and Y', each with $n/2$ items. We can then calculate the correlation that exists between Y and Y' (call it $\rho_{yy'}$) but what we really want to know would have been the correlation between X and a hypothetical parallel form X' ($\rho_{xx'}$). A formula [(11)] for estimating this correlation was developed by Spearman [42] and Brown [6] and is named in their honor:

$$\rho_{xx'} = \frac{2\rho_{yy'}}{1 + \rho_{yy'}} \tag{11}$$

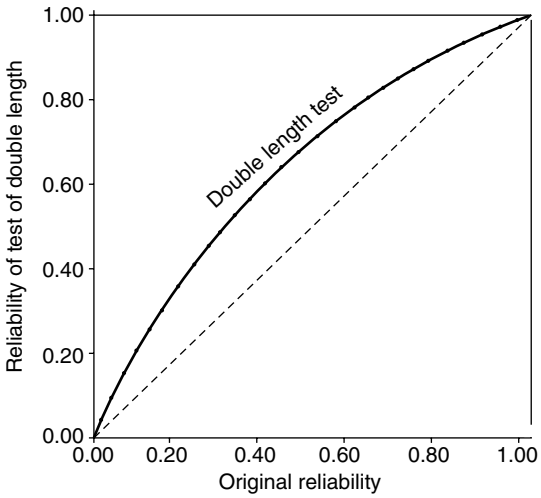

Figure 1 Reliability at double length as a function of reliability at unit length

A derivation of (11) follows directly from the characteristics of parallel tests and is given in [27, pp. 83–84].

To get an idea of how this expansion works, consider the two lines in Figure 1. The dashed diagonal line indicates equality of reliability between the original test and one of double length. The curved line shows the estimated reliability of a test of double length. Note that when reliability of the original test is extreme (0 or 1) doubling its length has no effect. The greatest effect occurs in the middle; a test whose reliability is 0.50 when made twice as long attains a reliability of 0.67.

Which Split Half? Cronbach's Coefficient α. There are many ways that we can split a test of n items in half (assuming that n is an even number). Specifically, there are

$$\frac{1}{2}\binom{n}{n/2} = \frac{n!}{2[(n/2)!]^2}$$

different ways that n items can be split in half. With all of these possible ways to divide the test in half it can be a difficult decision to determine which one we should pick to represent best the reliability of the test. One obvious way around this problem is to calculate all of them and use their mean as our best estimate. But calculating all of these for any test of nontrivial length is a very big deal. For example,

there are more than 63 trillion (63×10^{12}) split halves for 50 items! One way around this problem is due to Cronbach [10]. He derived a statistic that is a lower bound on the reliability of the test and is equivalent to taking the mean over all possible splits. Novick & Lewis [36] provided the conditions under which Cronbach's statistic is actually equal to the reliability of the test. Cronbach's statistic is usually called **Cronbach's α** in his honor, and is shown as the expression on the left-hand side of (12):

$$\frac{n}{n-1}\left[1 - \left(\frac{\sum_{i=1}^{n} \sigma_{yi}^2}{\sigma_x^2}\right)\right] = \alpha \leq \rho_{xx'}. \qquad (12)$$

A necessary and sufficient condition for Cronbach's α to be equal to the test's reliability and not just a lower bound, is that all the components making up the score have the same true score. The technical name for this condition is that all components be τ-equivalent.

To calculate α, we conceive of the test score x as being composed of the sum of n items Y_i. We calculate the variance of each item across all the examinees who took it and sum it up over all the items. Next we calculate the variance of the total score. The ratio of these two variances forms the core of Cronbach's α.

Estimating True Score. Under true score theory, the principal object of interest is the examinee's true score. A reasonable approach is to use the observed score as an estimate of the true score. Although this estimator has the virtue of being unbiased (that is, equal in expectation to its target) it can be improved upon.

The heuristic behind the improved estimator is similar to the familiar **"regression to the mean"** argument. Observed scores that fall far below the mean of the group are likely to have resulted, in part, from a relatively larger negative random error on that particular occasion. In a repeat test we would expect these observed scores still to fall below the mean, but not by nearly so great a margin. The greater the reliability of the test, the less the effect of the random errors.

The improved estimator, due to Kelley [19], requires three pieces of information: the observed score of the examinee, the mean score over the population of examinees, and a measure of the test's reliability. The estimate, $\hat{\tau}$, of the true score, τ, is given by

$$\hat{\tau} = \hat{\rho_{xx'}} x + (1 - \hat{\rho_{xx'}})\hat{\mu}, \qquad (13)$$

where $\hat{\rho_{xx'}}$ is an estimate of the reliability of the test, x is the observed score, and $\hat{\mu}$ is an estimate of the population mean. This result states that to estimate the true score from an observed score, the latter should be regressed toward the mean of the population by an amount related to the test's reliability. The amount of the "adjustment" to x increases as the reliability of the test decreases. Note too that for a fixed level of reliability, the amount of the adjustment is larger, the greater is the distance of the observed score from the population mean.

A Model for Error. The reliability coefficient that we have just discussed provides us with one measure of the stability of the measurement. It is often useful to have another measure that can be expressed on the scale of the score. For example, we would usually like to be able to present an estimate of someone's true score with error bounds: $\hat{\tau} = 1.2 \pm 0.3$. Such a statement raises two questions. The first is: What does $\pm$ 0.3 mean? The second is: How did you get 0.3?

There can be different answers to the first question depending on the situation. One common and reasonably useful answer is "it means that 95% of the time that someone whose estimated value of $\hat{\tau}$ is this value, her true score is within 0.3 of it".

The answer to the second question requires a little longer explanation. The explanation goes back to (9):

$$\rho_{xx'} = 1 - \left(\frac{\sigma_e^2}{\sigma_x^2}\right).$$

Simplifying this we can isolate error variance on one side of the equation and, by taking the square root, obtain an estimator for the *standard error of measurement*:

$$\sigma_e = \sigma_x(1 - \rho_{xx'})^{1/2} \qquad (14)$$

The uncertainty in our estimates of true score will be due to the variability of the error, e. To be able to provide a probability statement about the variability of the estimate we need to assume something about the distribution of the error. What sort of distribution we assume depends on the character of the scoring metric we use for the test. There are many choices

(see [27, Chapter 23] for an extended discussion of alternatives), but for the common situation of observed scores in the middle of the range of possible scores the assumption of a Gaussian distribution of errors is reasonable for most practical applications.

Item Response Theory

Item response theory is a family of mathematical descriptions of what happens when an examinee meets an item. It stems from early notions that test items all ought somehow to measure the same thing [26]. Item response theory formalizes this by explicitly positing a single dimension of knowledge or underlying trait on which all examinees rely, to some extent, for their correct response to all the test items. Examples of such traits are verbal proficiency, mathematical facility, jumping ability, or spatial memory. The position that each item occupies on this dimension is termed that item's *difficulty* (usually denoted b); the position of each examinee on this dimension is that examinee's *proficiency* (usually denoted θ). The item response theory model gives the probability of answering a question correctly in terms of the difference between b and θ (both of which are unobservable). The simplest model combines just these two elements within a logistic function (*see* **Logistic Distribution**). Because it characterizes each item with just a single parameter (difficulty $= b$) it is called the *one parameter logistic model*. This model was first developed and popularized by the Danish mathematician **Georg Rasch** (1901–1980) and so is often termed the **Rasch model** in his honor. We shall denote it the one parameter logistic model in this article to reinforce its position as a member of a parametric family of logistic models.

The one parameter logistic model is

$$p(\theta) = \frac{1}{1 + \exp[-(\theta - b)]}, \qquad (15)$$

where $p(\theta)$ is the probability of someone with proficiency θ responding correctly to an item of difficulty b. The interpretation of P is open for discussion. We tend to think of this P as arising from sampling. Specifically, if there is a large number of items all with the same difficulty b, a particular examinee would be able to answer some of them correctly, and some he would not. The proportion of items that a particular examinee with proficiency θ can answer correctly is given by (15). $P(\theta)$ is increasing in θ for a fixed b. For a fixed θ, $P(\theta)$ is smaller for larger values of b.

The structure of this model is most easily seen in a graph. Figure 2 shows a plot of what this function looks like for three items of different difficulty. These curves are called the *item characteristic curves* – they are also sometimes referred to as *trace lines or item response functions*. Note that the item characteristic curves for this model are parallel to one another. This is an important feature of the Rasch Model. It is informative to contrast the item characteristic curves shown in Figure 2 with those in Figure 3.

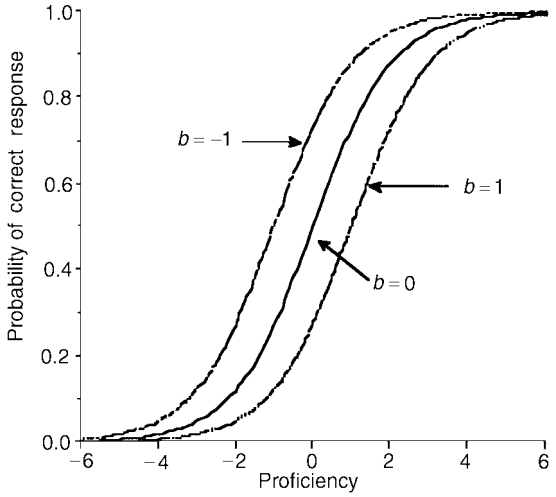

Figure 2 Item characteristic curves for the one parameterlogistic model at three levels of difficulty

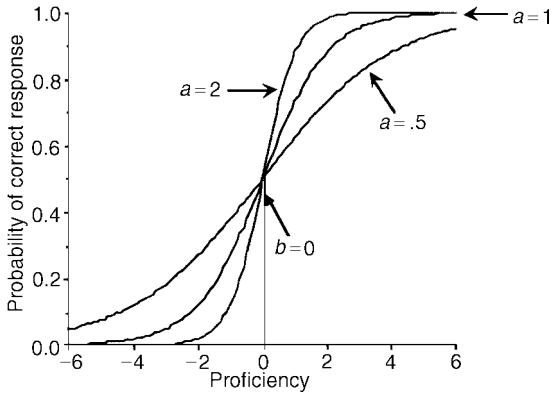

Figure 3 Typical item characteristic curves for the two parameter logistic model

The one parameter logistic model has many attractive features, and the interested reader is referred to the writings of Rasch [37] and of Wright [55] for convincing descriptions of its efficacy.

In many applications of item response theory to predetermined domains of items, it has been found that one does not get a good fit to the data with one parameter logistic model. A common cause of misfit is that the item characteristic curves of all items are not always parallel. When this occurs, there are two options. One is to delete items whose item characteristic curves show slopes that are divergent. The second is to generalize the model to allow for different slopes. This can be done through the addition of a second parameter for each item. This parameter, usually denoted a, characterizes the slope of the item characteristic curve, and is often called the *item's discrimination*. The resulting mathematical model, which now contains two parameters per item is called the two parameter logistic model and looks quite similar to the one parameter logistic model. Explicitly it is

$$P(\theta) = \frac{1}{1 + \exp[-a(\theta - b)]}. \qquad (16)$$

Once again our intuition is aided by seeing plots of the item characteristic curves achievable with this more general model. We have drawn three two parameter logistic model for items with the same b parameter ($b = 0$) in Figure 3, demonstrating the variation in slopes often seen in practice. Shown is an item that has rather high discrimination ($a = 2$), average discrimination ($a = 1$), and lower than average discrimination ($a = 0.5$).

The reason for calling the maximum value of the slope of the item characteristic curve the "discrimination" is that items with large slopes (i.e. high discrimination) are better able to distinguish between lower and higher proficiency examinees. For an item of high discrimination there is a relatively short interval along the proficiency scale where $P(\theta)$ moves from nearly zero to nearly one. Note that items of high discrimination are not very useful unless they are centered (i.e. have a b-value) in a region of the proficiency scale of interest to the examiner.

With the addition of the slope parameter, the two parameter logistic model greatly expanded the range of applicability item response theory. Many sets of items that could not fit under the strict equal slope assumption of the one parameter logistic model could be calibrated and scored with this more general model. However, this was not the end of the trail. So long as the multiple-choice item remains popular, the specter of an examinee getting an item correct through guessing remains not only a real possibility, but an event of substantial likelihood. Neither of the two models so far discussed allows for guessing – if an examinee gets an item right, it is assumed to provide evidence for greater proficiency. Yet, sometimes we see evidence in a response pattern that an examinee has not obtained the correct answer in a plausible fashion. Specifically, if someone gets a very difficult item correct, an item far beyond that examinee's estimated proficiency, then we can draw one obvious conclusion. The test is not unidimensional – the suspect item was answered using a skill or knowledge base other than the one we thought we were testing. This can be corrected by either modifying the test (removing the offending item) or generalizing the model to allow for guessing. The former fix is not likely to work, because different people may choose different items to guess on – eventually we will have to eliminate all difficult items. So, if we are to continue to use multiple-choice items, we have little choice but to use a more general model to describe examinees' performance on them. Such a model was fully explicated by Allan Birnbaum in Lord & Novick's [27] classic text. It adds a third parameter, c, which represents a binomial floor on the probability of getting an item correct. The resulting model, not surprisingly called the *three parameter model*, is shown explicitly below:

$$P(\theta) = c + \frac{1 - c}{1 + \exp[-a(\theta - b)]}. \qquad (17)$$

Once again we can get a better feel for the structure of the three parameter logistic model once we view a plot of a typical item characteristic curves. Such a plot is shown in Figure 4.

There is an indeterminacy in the estimation of the parameters of all these models that must be resolved one way or another. For example, suppose we define a new value of slope, say a^* as $a^* = a/A$, where a is the original value of the slope and A is some nonzero number. If we then define a new difficulty as $b^* = Ab + B$, where b is the original difficulty and B is some constant, a redefinition of proficiency as $\theta^* = A\theta + B$ would yield the result that $P(\theta, a, b, c) = P(\theta^*, a^*, b^*, c)$. Obviously there is no way to tell which set of parameters is better

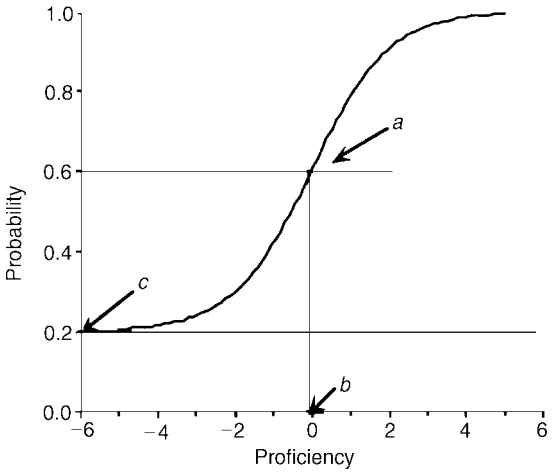

Figure 4 Typical item characteristic curve for the three parameter logistic model

because they produce identical estimates of probabilities of correct responses, and hence provide exactly the same fit to observed data. The usual way of resolving this indeterminacy is to scale proficiency so that θ has a mean of zero and a standard deviation of one in some reference population of examinees. This standardization allows us to understand at a glance the structure of our results. However, if we separately standardized with respect to two independent samples that were not randomly drawn from the same population, then we could not compare resulting item parameter estimates between them (because the first two moments of their proficiency distributions have been made to be identical artifactually). To do this we need to link these independent samples. A method for doing this is described in [50].

The three parameter logistic model is the item response theory model that is most commonly applied in large-scale testing applications, and so we confine the balance of our discussion to it. Estimating the parameters for a set of items under an item response theory model is usually called **calibration**. As indicated earlier, this is a difficult task since the examinees' proficiencies (θ values) must be estimated as well. Programs available for calibration are BILOG for **binary** (dichotomous) data [34] and MULTILOG for **polytomous data** [44].

Estimating Proficiency. In this section we assume that we have already calculated (somehow) the three parameters (a, b, and c) for each item, and have given this calibrated test to a sample of examinees. Our task is to estimate the proficiency, θ, for each of them. We do this using the method of **maximum likelihood**. In this discussion we alternate between the method of maximum likelihood and Bayes' modal estimates (*see* **Bayesian Methods**). In the way we use these terms, there is a clear connection between the two, because the *maximum likelihood estimator is just a Bayes' modal estimator with a uniform prior.*

To estimate proficiency we need to define three new symbols: $\mathbf{x}_i$ is the vector of item responses for examinee i, in which each response is coded 1 if correct, and 0 otherwise; it has elements $\{x_{ij}\}$, where the items are indexed by j. $\boldsymbol{\beta}_j$ is the item parameter vector (a_j, b_j, c_j) for item j and is a vector component of the matrix of all item parameters $\boldsymbol{\beta}$.

The conditional probability of $\mathbf{x}_i$ given θ and $\boldsymbol{\beta}$ is shown in (18):

$$P(\mathbf{x}_i|\theta_i, \boldsymbol{\beta}) = \prod_j P_j(\theta_i)^{x_{ij}} Q_j(\theta_i)^{1-x_{ij}}, \qquad (18)$$

where $Q(\theta) = 1 - P(\theta)$.

The genesis of (18) should be obvious with a little reflection. It is merely the product of the model-generated probabilities (the item characteristic curves) for each item. The first term, $P(\theta)$, in the equation reflects the item characteristic curve for correct responses (when $x = 1$); the second term, $Q(\theta)$, for incorrect responses (when $x = 0$). Sometimes this is better understood graphically. Suppose we consider a two-item test in which an examinee gets the first item correct and the second item incorrect. The probabilities for each of these occurrences are shown in the top and middle panels of Figure 5, respectively.

In order for this product to represent validly the probability of a particular response vector, the model must be true and the item responses must be conditionally independent (*see* **Statistical Dependence and Independence**). Conditional independence is a basic assumption of most item response theory models. It means that the probability of answering a particular item correctly is independent of responses to any of the other items once we have conditioned on proficiency, θ. This assumption is testable [39], and when it is violated tends to yield overestimates of the accuracy of estimation [46].

If we know $\boldsymbol{\beta}$, the item parameters, we can look upon (18), for a fixed response pattern $\mathbf{x}_i$, as the likelihood function $L(\theta|\mathbf{x}_i)$ of θ given $\mathbf{x}_i$; its value at any value of θ indicates the relative likelihood that

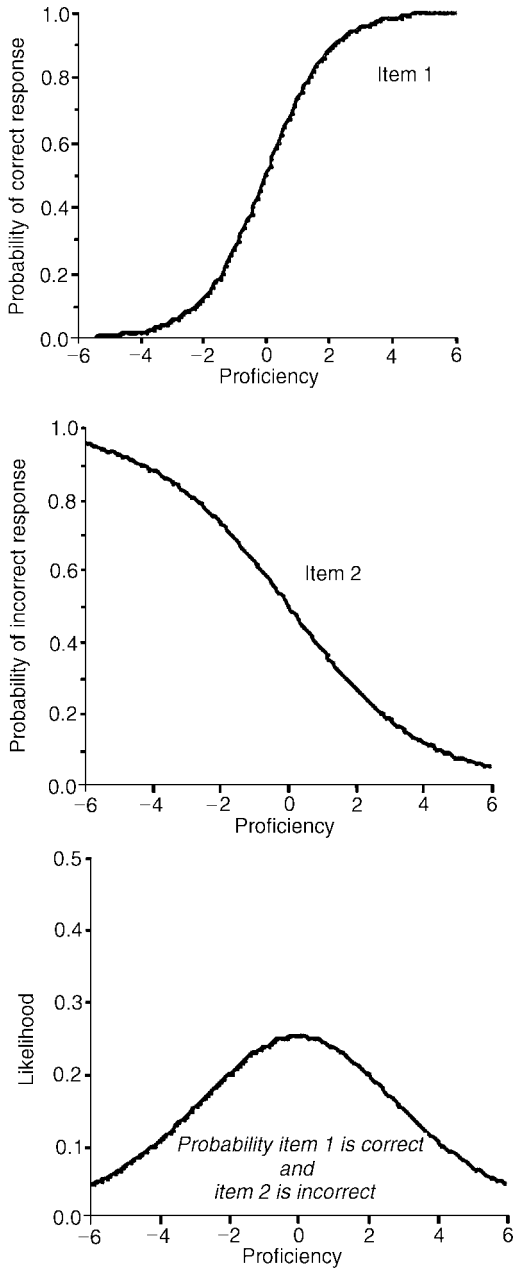

Figure 5 Example of how item characteristic curves multiply to yield posterior distribution of proficiency

$\mathbf{x}_i$ would be observed if θ were the true value. Eq. (18) thus conveys the information about θ contained in the data, and serves as a basis for estimating θ by means of maximum likelihood or Bayesian procedures. The *maximum likelihood estimate* of θ is merely the mode of the likelihood. Stated graphically, in terms of Figure 5 it is the value of θ associated with the highest point on the likelihood (the bottom panel in the figure). This likelihood was obtained by multiplying the curve in the top panel by the curve in the middle panel. The estimation methods commonly used are variations on this theme.

Another common method for estimating proficiency is the *Bayes modal estimate*. It is based upon the posterior distribution,

$$p(\theta|\mathbf{x}_i) \propto L(\theta|\mathbf{x}_i)p(\theta), \tag{19}$$

where $p(\theta)$ expresses knowledge about θ prior to the observation of $\mathbf{x}_i$. Thus, this is commonly called the **prior distribution** of θ. To accommodate the prior into the estimation scheme, we merely treat the prior as one more item and multiply it in, along with everything else. If we have no prior information whatsoever, then $p(\theta)$ has the same value for all θ – a "noninformative prior" – and the posterior distribution for θ is simply proportional to the likelihood function. Alternatively, an "informative prior" has a more profound effect; this is shown graphically in Figure 6. The prior used in this illustration is a standard normal distribution, and is shown in the top panel (labeled N). Note that in this example (taken from [47]), the examinee has taken a two-item test (labeled Items A and C), and has gotten both correct. The posterior is labeled P. If we multiply just these two item characteristic curves together to get the probability of occurrence of both events (their likelihood), then we would obtain a curve much like that shown at the bottom of Figure 5. This curve is an important component of the *posterior distribution* of proficiency because, when multiplied by the *prior distribution* of proficiency, it shows the likelihood of various values of proficiency after (posterior to) the examinee responds. The bottom panel of Figure 6 shows this posterior distribution.

Although finding the value of θ that maximizes (18) cannot be done in closed form, it is in principle straightforward using an iterative method like Newton–Raphson (*see* **Optimization and Nonlinear Equations**). In practice, many problems can arise. For example, if an examinee answers all items correctly (or all incorrectly) the estimate of proficiency will be infinite. In the three parameter logistic model there are a number of other response

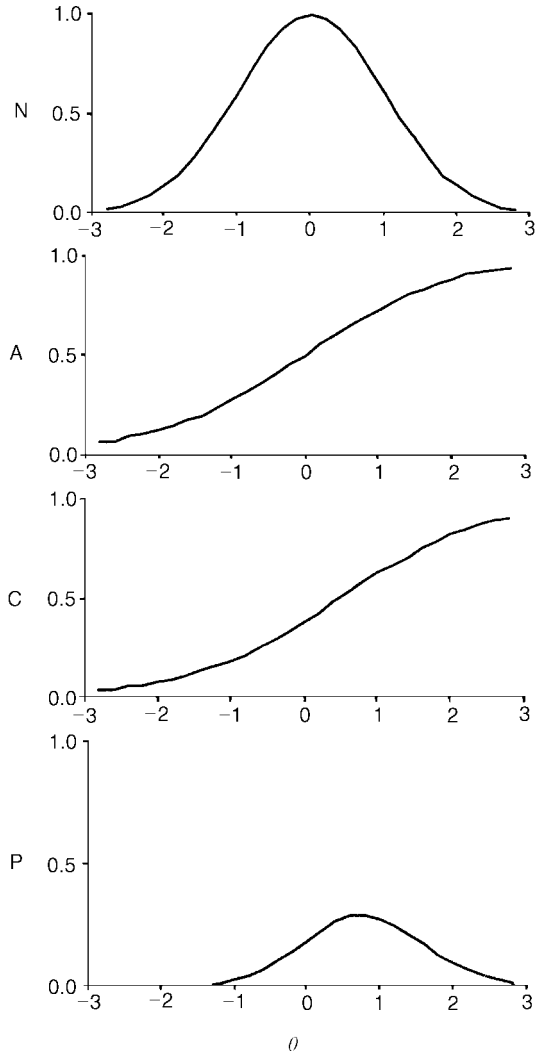

Figure 6 Schematic representation of Bayes' modal estimation, showing a normal prior (N), responses to two items (A and C), and the resulting posterior

patterns (e.g. many patterns at below chance levels) that would also yield infinite proficiency estimates. Also, the likelihood surface does not always yield a single mode; sometimes it can have a number of local extrema. In these cases, zeros may correspond to a local, but not the global, maximum of L, or even to a local minimum. The problems of infinite estimates are usually solved by utilizing a prior proficiency distribution (that is, using the kind of Bayesian estimator discussed next); those of local extrema are often resolved through the use of a "good" (i.e. close to the global maximum) starting value for the Newton–Raphson iterations (e.g. one based on a rescaled logit of percent correct).

On the Accuracy of the Proficiency Estimate

So far we have been concerned with obtaining a point estimate of an examinee's proficiency. The point we have adopted is the most likely value, the mode of the posterior distribution. But even a quick glance at the posterior in Figure 6 tells us that there is a substantial likelihood of other values. The width of the posterior distribution is commonly used to characterize the precision of the proficiency estimate. If the posterior is very narrow, then we are quite sure that the proficiency estimate we provide is a good one. If the posterior is broad, then we are less sure. In practice we can increase the accuracy of the estimate of proficiency by increasing the length of the test using *appropriately difficult* items. If we add an item that is much too easy for the examinees in question, then the item characteristic curve would essentially be a horizontal line in the neighborhood of these θs. Multiplying the posterior by a constant like this would do little to shrink the variance of the posterior. An identical thing happens if the item is much too hard. This is meant to emphasize the side condition of adding *appropriately difficult* items.

If the number of items an examinee has been administered is large, then the variance of the **likelihood** function can be approximated as the reciprocal of the **information** *function*:

$$I(\theta) = \sum_j \frac{(P_j')^2}{P_j(\theta)Q_j(\theta)}, \tag{20}$$

where P_j' is the first derivative of P_j with respect to θ. This expression has the attractive features of (i) being additive over items, and (ii) not depending on the values of the item responses. This means that for any given θ, one could calculate the contribution of information – and therefore to the precision of estimation of θ – from any item in an item pool. A typical information function is shown in Figure 7. The approximation for the estimation error variance of the maximum likelihood estimate of θ is less accurate for small numbers of items, but its advantages make it a popular and reasonable choice for practical work.

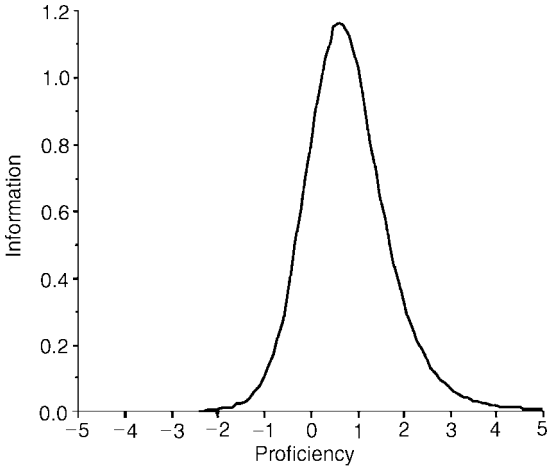

Figure 7 Typical three parameter logistic model information function

A similarly motivated expression can be used to indicate the precision of the Bayes model estimate of θ:

$$\text{var}^{-1}(\theta|\mathbf{x}_i) \approx \frac{I(\theta) - \partial^2 p(\theta)}{\partial\theta^2}.$$

The precision of the Bayes modal estimate, θ, typically exceeds that of the maximum likelihood estimate because the information from the item responses is augmented by a term that depends on the prior distribution. If $p(\theta)$ is normal with mean μ and variance σ^2, for example, then even before the first item is presented, one has at least this much knowledge about what an examinee's proficiency might be. In this case, $I(\theta) = 0$ since no items have been administered, but $\partial^2 p(\theta)/\partial\theta^2 = -\sigma^{-2}$. The impact of this prior information decreases as more items are given, however, because its contribution remains fixed while $I(\theta)$ increases with each item administered. Note also that if the prior is uniform, then the prior contributes nothing to measurement precision.

Estimating Item Parameters

Up to this point we have assumed that the item parameters were known. This is never the case in practice, when estimates must be used. Precise estimates with known properties are obviously desirable. In this section we outline a general framework for item calibration, briefly discuss the pros and cons of a variety of item calibration procedures that have been used in the past, and describe, in some detail, a Bayesian variation of the method of marginal maximum likelihood.

Notation and General Principles. The probability of observing the response matrix $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_N)$ from a sample of N independently responding examinees can be represented as

$$P(\mathbf{X}|\boldsymbol{\theta}, \beta) = \prod_i P(\mathbf{x}_i|\theta_i, \boldsymbol{\beta}) = \prod_i \prod_j P(\mathbf{x}_{ij}|\theta_i, \beta_j), \tag{21}$$

where $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_N)$ and $\boldsymbol{\beta} = (a_1, b_1, c_1, \ldots, a_n, b_n, c_n)$ are all considered unknown, fixed parameters. The continued product over items for each examinee is understood to run over only those items administered to that examinee. After responses have been observed, (18) is interpreted as a likelihood function for θ and β and serves as the foundation for item parameter estimation.

There are three commonly used approaches to item parameter estimation: *joint maximum likelihood* maximizes the likelihood depicted in (18). The other two approaches are *conditional maximum likelihood* and *marginal maximum likelihood*. The last is the method of choice. Conditional maximum likelihood is only possible for the one parameter logistic model, and even there is so computationally intensive as to be impracticable in many situations. It is never used for estimation in the three parameter logistic model and we do not dwell on it further. The interested reader is referred to [53] for details on this procedure. Before we go on to describe marginal maximum likelihood, we briefly discuss joint maximum likelihood.

Joint maximum likelihood estimates are obtained by finding the values of each β_j and each θ_i that together maximize (21). This is done by applying exactly the same ideas discussed earlier in the context of estimating $\boldsymbol{\theta}$. Direct maximization of (21) with respect to $\boldsymbol{\theta}$ and $\boldsymbol{\beta}$ jointly often proves unsatisfactory for a number of reasons. First, for a fixed number of items, these estimates of $\boldsymbol{\beta}$ are not consistent in the number of examinees; that is, the expected values do not converge to their true values. Secondly, because each of the many $\boldsymbol{\theta}$ values is poorly determined when examinees take relatively few items, numerical instabilities can result. Maximizing values of item parameters may thus yield results that are unreasonable or even infinite.

Remedies leading to finite and reasonable estimates of $\boldsymbol{\beta}$ under the three parameter logistic model require information beyond that contained in the item responses, and structure beyond that implied by the item response theory model. Let us now discuss a Bayes' modal solution, extending ideas introduced in connection with Bayes' modal estimation of $\boldsymbol{\theta}$. Prior distributions for both examinee and item parameters are required. It is perhaps best to develop the solution in two stages.

Let $p(\boldsymbol{\theta})$ represent prior knowledge about the examinee distribution, assuming we have no additional information to lead us to different beliefs for different examinees. We treat $p(\boldsymbol{\theta})$ as known a priori, but it can be estimated from previous data, or even from the same data as those from which the item parameters are to be obtained (*see* **Empirical Bayes**). Consistency and increased stability follow if maximizing values for $\boldsymbol{\beta}$ are obtained after marginalization with respect to $p(\boldsymbol{\theta})$. That is, marginal maximum likelihood estimates of $\boldsymbol{\beta}$ maximize

$$L(\boldsymbol{\beta}|\mathbf{X}) = \int P(\boldsymbol{\theta}, \boldsymbol{\beta}|\mathbf{X})\, \mathrm{d}\boldsymbol{\theta}, \tag{22}$$

or, more expansively,

$$L(\boldsymbol{\beta}|\mathbf{X}) = \prod_i \int p(\mathbf{x}_i|\boldsymbol{\theta}, \boldsymbol{\beta}) p(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}.$$

Numerical procedures for accomplishing marginal maximum likelihood estimation are described by Bock & Aitkin [3], Levine [22], and Samejima [40]. Without further precautions however, neither reasonable nor finite item parameter estimates are guaranteed.

Let $p(\boldsymbol{\beta})$ represent prior knowledge about the item parameter distribution, again assuming for the moment that we have no additional information that leads us to hold different expectations among them. We obtain a posterior distribution for item parameters by multiplying L by $p(\boldsymbol{\beta})$:

$$p(\boldsymbol{\beta}|\mathbf{X}) \propto L(\boldsymbol{\beta}|\mathbf{X}) p(\boldsymbol{\beta}). \tag{23}$$

Bayes' model estimates of $\boldsymbol{\beta}$ are the values that maximize (23) [32]. If a proper distribution $p(\boldsymbol{\theta})$ has been employed for examinees, and a proper and reasonable distribution $p(\boldsymbol{\beta})$ has been employed for items, then the resulting Bayes' modal estimates of $\boldsymbol{\beta}$ would be stable, reasonable, and consistent. Posterior means can also be employed, but modes are more often used because of their ease of calculation. When estimating item parameters, just as when estimating proficiency, one typically gets indices of the precision with which they have been estimated. Under ordinary marginal maximum likelihood, one gets standard errors of item parameter estimates; under Bayesian procedures, one gets posterior standard deviations.

The assumption of **exchangeability** among items (i.e. using the same prior distribution for all items) can be relaxed if some items have been administered previously. The prior distributions for these items can then be determined by the results of previous estimation procedures, taking the forms of distributions concentrated around previous point estimates.

Simulation studies have always been a prerequisite to using any estimation scheme. Asymptotic properties such as consistency do not necessarily characterize estimators' behavior in samples of the size and nature encountered in many specific applications. Moreover, although it is sometimes possible to obtain satisfactory parameter estimates with any of the procedures mentioned (see [35] for a comparison of two methods), the accumulation of evidence suggests that marginal maximum likelihood, with suitably chosen priors, is the best method currently available.

Interpreting Scores on Tests and Inventories

The selection of a measurement model is of critical importance for facilitating measurement precision. However, provision of an accurate score does not guarantee that the score will be interpreted appropriately. Thus, another important area of psychometrics is incorporating meaning into test scores and promoting accurate score interpretation. This section describes two common approaches for attaching meaning to test scores and describes how these different approaches affect score interpretation.

Norm-referenced and Criterion-referenced Approaches in Test Development

Consider a score of 112 obtained from an "adherence assessment" inventory, designed to predict whether a patient will stick to a critical treatment plan. Is this a "good" score? Does this score indicate that the patient is likely to adhere to her/his treatment regimen when

released from hospital? One way to make this score more informative would be to determine if it is above the average score of all patients who have taken this inventory. A related question is: Is the score at or above the average score of all patients who have stuck to their treatment plan? Interpreting scores in this fashion illustrates a *norm-referenced* interpretation. That is, norm-referenced scores are interpreted with respect to the scores attained by others.

Perhaps a more important question regarding the mysterious score of 112 is: Does this score signify that the patient should be retained in the hospital? Given this question, the performance of others on the inventory is much less relevant. The primary concern is whether the score is associated with the criterion of adherence to treatment. Interpretations attached to test scores on the basis of external criteria are called *criterion-referenced* interpretations. Meaning is attached to the scores by associating significant characteristics of the attribute measured with specific test scores. Both norm-referenced and criterion-referenced interpretations attach meaning to test scores, but they do so in different ways.

Norm-referenced interpretations describe test results in relation to the performance of one or more specific reference groups, called *norm groups*, who took the same test. Using our previous example, if we were told the average score on the adherence test was 100, we would know that a score of 112 is above average. But to what norm group does this average refer? If the average score of 100 refers to a population of patients who adhered to their treatment plan, then we may be impressed with a score of 112. Contrariwise, if the average score refers to a population of patients who did not adhere to their treatment plan, then a score of 112 may indicate that the patient is not likely to maintain treatment. Thus, in interpreting norm-referenced test scores, the appropriateness of the norm group for making inferences about a particular test taker must be considered.

Criterion-referenced interpretations describe test scores with respect to preestablished and well-defined relationships between test scores and external criteria associated with the characteristic measured. For example, the criterion variable "number of breaths taken per minute" may be used to measure respiration. Respiration is the underlying characteristic of interest, but meaningful standards of respiratory status are established on the basis of the number of breaths taken per minute. Using this criterion-referenced approach, interpretations such as "if patient takes less than seven breaths per minute, oxygen should be administered" can be made. In this situation, the breathing "scores" of other patients are irrelevant. All scores are interpreted with respect to the externally-defined standard of "less than seven breaths per minute".

Standards on criterion-referenced tests are developed using subject-matter experts to define carefully the variables to be measured, and to determine scores that reflect significant levels of the characteristic measured. These standards need not be static. For example, only a few years ago a cholesterol level of 240 was considered "normal". However, as a result of updated population analyses and reports of the incidents of coronary disease, medical experts revised their definition of normal cholesterol to correspond to a "score" of 200.

Both criterion-referenced and norm-referenced information can be used to interpret a test score. For example, if a patient's hypertension is measured by taking her/his blood pressure, it is informative to know how far the patient's blood pressure departs from the average of a comparable norm group (e.g. 120/80), as well as whether the score is above some maximum or minimum criterion of healthy blood pressure.

Criterion-referenced inventories often have several subscores indicating different factors related to the purpose of the assessment. For example, in measuring arterial blood gas, five parameters are obtained (pH level of blood, percentage of CO_2, percentage of O_2, saturation of the hemoglobin molecule, and amount of H_2CO_{3+}). Similarly, the General Health Questionnaire-28 [16], which is an inventory designed to identify nonpsychotic psychiatric disorders, provides four subscores describing somatic symptoms, anxiety and insomnia, social dysfunction, and severe depression. The provision of such subscores facilitates accurate diagnosis and the development of treatment plans.

The differences between norm-referenced and criterion-referenced scores are important for evaluating the appropriateness of a test for a particular purpose. In norm-referenced testing the character of the norm group is a primary concern when making inferences about test scores. In criterion-referenced testing it is critical that the criterion domain is appropriate and clearly defined.

Understanding and Interpreting Test Scores

The norm-referenced/criterion-referenced distinction is important when drawing inferences from test scores. However, to facilitate appropriate interpretations of test results, other distinctions and other "types" of test scores must be understood. The most straightforward test score is the raw score, which is simply the sum of the individual scores associated with each test item. For example, the score on an anxiety inventory may simply be the sum of the number of symptoms marked by a respondent. In intelligence and educational testing, items are typically scored "correct/incorrect". In these situations the raw score indicates the number of items answered correctly. An alternative way of reporting test scores is to report a *percent score*, or *percent correct score*, which is calculated by dividing the number of points earned on a test by the highest possible score on the test. For example, on a dichotomously scored intellectual functioning inventory, a percent correct score of 85 indicates that the person answered 85% of the items correctly.

Although raw and percent scores are simple to understand, they have some major limitations. First, in many assessment situations individuals take different forms of a test or take different tests altogether. For example, if an individual is given a test of academic skills as well as a performance test of various aspects of physical fitness, inferences about relative ability in the two realms are very limited if one can only use raw or percent scores. This same problem manifests itself even within a single test battery, which is comprised of many subscales. Secondly, raw and percent scores are not useful for making comparisons across subscales because the intensity, quality, and difficulty of the items comprising the subscales will be different for each scale (e.g. answering 50% of the vocabulary items correctly is unlikely to have the same interpretation as answering 50% of the arithmetic items correctly).

Norm-referenced and criterion-referenced interpretations can be used to facilitate comparisons across different tests and subscales. Percentile **rank** scores can be used to interpret an individual's relative standing on each subscale with respect to a specific norm group. A *percentile rank score* is a norm-referenced score that represents the percentage of test takers in a norm group who scored at or below the score attained by the individual. Some tests report more than one percentile rank score. Different percentile rank scores refer to different norm groups. An isometric strength measure would have separate percentile rank scores for males and females. Percentile ranks are also often calculated separately for different age groups. Percent correct scores are often enhanced using criterion-referenced interpretations such as a thorough description of the test items. For example, a percent correct score of 90 on a manual dexterity test may indicate that a physical rehabilitation patient was able individually to pick up nine of ten bolts, the thinnest of which was 2 mm; but she/he was unable to pick up the smallest bolt, which was 1 mm wide.

Although raw scores, percentile rank scores, and percent correct scores are meaningful, many test scores are reported on a standard score scale to facilitate further their interpretation. *Standard scores* are scores reported on a scale that has a predetermined mean and standard deviation. An individual's standard score represents her/his distance from the mean of a norm group in terms of the standard deviation of the score scale. Any raw score or percent correct score can be transformed to a standard score (using linear or nonlinear procedures as described earlier in the article). Standard score scales differ across tests as a result of the specific scale chosen by the test developers. For example, the SAT and ACT are both tests designed to assist colleges in making admissions decisions. However, these tests are reported on very different scales. Although two individuals taking these different tests could be compared with respect to their deviation from the mean of the score scale for each test, it must be remembered that different norm groups were used to derive these score scales, and so such comparisons are extremely limited. Standard score scales are designed to be most useful for interpreting scores associated with a single assessment instrument. However, when the same norm group is used across the different subscales comprising an assessment, relative comparisons across the subscales can be made with respect to this norm group.

Standard scores are also used to eliminate problems that may occur when comparing the performance of individuals who took different forms of a test. For example, to prevent cheating on a test that is used over a long period of time, or to prevent practice effects when tests must be administered to the same individual at different points in time, multiple test forms are needed. Unintended differences in difficulty or intensity between these forms would lead

to different raw scores or percent correct scores for the same individual. Thus, if raw or percent correct scores were used, then test takers would get different scores depending on the particular form they were administered. Through a process called *equating*, differences in test scores can be adjusted statistically so that "form effects" are eliminated when placed on the standard score scale (see [17] or [20] for descriptions of equating).

Percentile and Standard Score Bands

The standard error of measurement is another piece of information useful for interpreting test scores. As described in an earlier section, this index describes the average amount of error contained in a test score. By adding and subtracting one standard error of measurement from a particular score, a **confidence** band, or confidence interval, is formed around the test score. This band shows the probable limits of the score that would be obtained if the person were tested again. Many tests use this to report confidence bands for standard and percentile rank scores.

Setting Standards on Norm-referenced and Criterion-referenced Tests

As described previously, scores from criterion-referenced tests are usually interpreted with respect to well-defined aspects of the content domain. Many criterion-referenced tests incorporate preestablished standards of performance. Licensure tests are a conspicuous example. Test takers who score above the passing standard are awarded a license, while those who do not reach this standard are ineligible for licensure. Some tests have multiple standards. For example, in measuring brain waves, standards of electroencephalogram responses are used to classify patients into one of four states of excitement/relaxation (e.g. brain wave frequencies of 14 H_2–30 Hz signify an "excited" state [54]).

The process of determining the test scores that correspond to different categories of performance is called *standard setting*. Standard setting on norm-referenced tests is accomplished using percentile rank scores. For example, a scholarship may be awarded to the "top 10%" of examinees. The obvious disadvantage of norm-referenced passing standards is that classification decisions (e.g. pass/fail) vary primarily as a function of the characteristics of the norm group. How valuable is a bathroom scale to you if its estimate of your weight depended on who else used it that day?

Standards set on criterion-referenced tests circumvent this problem by using objectively established standards. One common criterion-referencing procedure uses subject-matter experts to scrutinize the items that comprise the test and estimate the probable performance of individuals representative of different diagnostic categories [8, 25]. These item judgments are summed over items and experts to derive a "cutscore" for each desired examinee classification.

A more empirical criterion-referenced approach is to use respondents' performance retrospectively on a criterion to establish standards on the test itself. For example, if a questionnaire is designed to predict relapse in a drug treatment program, then it could be given to all patients entering the program, and then one year later the average score of all patients who relapsed could be used as the cutscore for predicting relapse of patients entering the program in the future.

The procedures for determining criterion-referenced standards have their limitations. Standards developed using subject-matter experts are only as good as the particular group of experts employed. Standards established using external criteria are typically expensive of time and resources as well as being limited by the variation observed among the respondents used to establish the cutscores. Thus, there are tradeoffs among the different procedures for setting standards on tests. Criterion-referenced procedures have many advantages over norm-referenced procedures. Two obvious advantages are that attainment of a particular standard is not dependent on the performance of others, and also that score interpretation is especially straightforward.

Contemporary Testing Practices

Societal needs often evoke the potential inherent in science and technology. With respect to testing, there are current demands to measure attributes more thoroughly, and to measure characteristics that were previously considered untestable. Recent advances in computer technology, coupled with the newer measurement models such as item response theory, have allowed psychometricians to meet these demands. This section discusses some of these recent developments and their influence on testing in the health professions.

The two most consequential developments in psychometrics within the past decade are a renewed emphasis on "performance assessments" and delivering tests through computer-assisted technology. These two movements did not develop in complete isolation. In many cases, performance assessments became possible by capitalizing on innovations in computer technology. The new types of tests made possible by computer technology are called computer-based tests. These tests are redefining traditional testing practices along several dimensions.

Computer-based Testing

The idea of delivering tests by computer is not new. One of the earliest computer-based tests was the PLATO system designed to deliver both course material and tests to students at the University of Illinois and, eventually, around the country [1]. Like other early computer-based tests, the PLATO tests simply involved transferring existing paper-and-pencil multiple choice tests to an electronic database for later delivery via computer terminals. Two advantages of this immediately became obvious: (i) examinees could take the test whenever access to a terminal was available, and (ii) their scores were available immediately following conclusion of the test. Soon thereafter the idea of using a computer to "tailor" the test for each individual examinee emerged. This type of test, called a *computerized adaptive test*, is now widely accepted and is already implemented, or scheduled to be implemented, in many large-scale testing environments.

Computerized adaptive tests provide a test tailored to individual examinees by administering different questions to different examinees. In an administration of these an **algorithm** is programmed into the computer to select test questions that are most appropriate for the examinee currently taking the test. The NCLEX exam, which is the licensing examination for registered nurses in the US, provides a noteworthy example of how these work [56]. This computerized adaptive test involves an enormous pool of test items called an *item bank*. When a nursing candidate sits for this exam, a prespecified test item is administered. The next item administered depends on the examinee's response to the first item. If the candidate answers the item correctly, then a more difficult test item will be administered. However, if the candidate answers the test item incorrectly, then an easier item will be administered. The computer makes such item administration decisions on the basis of the candidate's responses to earlier items and other factors, such as coverage of the different content areas comprising the NCLEX. These decisions provide individualized tests, targeted to each candidate's ability level, that are essentially equivalent with respect to content coverage.

All computerized adaptive tests require a pool of content-valid items that are prearranged from simple to difficult. Typically, a middle difficulty item is administered first. If it is answered correctly, then the next item is chosen from among the items in the pool that are somewhat more difficult. If it is answered incorrectly, then the next item is chosen from among those items in the pool that are somewhat less difficult. If it too is answered incorrectly, then the third item is chosen from among those items that are even less difficult. The process continues until some suitable stopping point is reached. If the pool is sufficiently large, then each individual is likely to receive a unique sequence of items. The computer attempts to administer items that are of appropriate difficulty for each candidate (i.e. items that the candidate has about a 50–50 chance of answering correctly). Testing ceases either when a predetermined number of items have been presented or when the estimate of the uncertainty surrounding the current estimate of the candidate's ability falls below a prespecified threshold. From a psychometric perspective, items for which a candidate has about a 50–50 chance provide the most information about the candidate's skill, and so computerized adaptive tests increase testing efficiency by about 30%–40% [52]. Thus, these tend to be of much shorter duration than traditional paper-and-pencil tests of comparable accuracy.

The benefits of computerized adaptive tests include increased examinee motivation, reduced testing time, and increased precision of measurement. However, they increase the complexity of the scoring process. When examinees take such a test, they essentially take different tests. Therefore, they must include a method for placing these different test forms on a common score scale. Fortunately, item response theory methodology (described in an earlier section) provides the necessary foundation for an appropriate scoring model. The item response theory parameters are used to select items appropriate for

each candidate at a given level of proficiency, θ. Examinee's responses to early test questions are used to provide initial estimates, which govern the item selection process. The computer carries out these calculations rapidly so that the administer item $\rightarrow$ estimate $\theta \rightarrow$ administer new item cycle is transparent to the examinee. The θ scale onto which both items and examinees are mapped provides the common scale from which the test scores are derived.

In practice, computerized adaptive testing is more complicated to implement than described above. One reason is that usually there are multiple constraints operating on the process. For example, it may be required to ensure that each candidate is administered a specified number of items from different content domains during the course of the test. In that case the item selection algorithm must take into account both psychometric and substantive considerations in its choice. At present algorithms that handle nearly 200 constraints are operating on computerized adaptive tests such as the NCLEX and the Graduate Record Examination.

An additional advantage of computerized adaptive tests is that the tailored testing process lends itself naturally to diagnostic assessment. In this setting, real-time psychometric analyses identify potential examinee weaknesses and select future items to elucidate more specifically the nature of the potential weakness. In this manner a more detailed prescription for remediation is provided.

Many variants of computerized adaptive testing are currently operational. In the case of licensure tests such as the NCLEX and US Medical Licensure Examinations, interest centers on making a pass/fail decision at a particular cutscore. Some systems, such as the one implemented at Educational Testing Service (ETS) termed *computerized mastery testing*, involves building a library of mini-tests, called *testlets*, of the original full-scale paper-and-pencil examination [23, 49]. Candidates are administered two testlets, at which point a decision based on Bayesian analysis is made either to pass, fail, or continue testing. If the decision is to continue, then the candidate is administered another randomly chosen testlet and the Bayesian analysis is repeated using the additional information obtained from the testlet. Again there is a decision to pass, fail, or continue. A limit is set on the total number of testlets to be administered and a pass/fail decision is made at that point. Nearly 50% savings in testing time have been realized using this system.

Performance Assessment

With the advent of multimedia and other extensions of computer capabilities, the presentation of more complex stimuli, such as those involving video and audio, provided an impetus to move toward more complex item response formats. In most computer based test applications, multiple-choice items are typically administered. However, there is a current trend toward administering newer item formats that require the individual to construct a response rather than selecting from a number of predetermined choices [9]. These newer item formats fall under the rubric of "performance assessment". Performance assessments attempt to measure proficiency by having examinees perform a task, such as administering treatment to a simulated patient. As described earlier, multiple-choice and free-response item formats have both strengths and limitations. Thus, the features of each format are important before considering current innovations in performance assessment.

Despite recent criticisms [41], the multiple-choice item format has several attractive features. Multiple-choice items require less time to answer than free-response items, they tend to produce reliable scores, and they can be scored objectively (and inexpensively when automated scanning and sensing equipment is available). Because multiple-choice items take less time to answer than other item formats, they also provide greater ability to span the content domain tested in comparison with more time-consuming item formats. For example, in clinical settings there often is a need for instruments that can be administered quickly and do not demand much of the patient. For this reason, most psychological assessments (e.g. Beck Depression Inventory) and health inventories (e.g. MOS (Medical Outcome Study) Short-form Health Survey) rely on multiple-choice items.

However, reliance on multiple-choice items may limit the depth to which one can probe a domain. Thus, questions of test design are intimately tied to issues of validity. In addition to operational constraints, tradeoffs between broad (but perhaps superficial) coverage and in-depth analysis must be made within the context of the nature and the purpose of the assessment.

There is no universally accepted delineation of the response sets that qualify as raw material for performance assessments. One might consider a full range, extending from simple fill-in-the-blanks to short answer questions, to the kind of tasks involved in simulated patient examinations. As one moves to more extended and unconstrained response sets, accurate and reliable scoring is more difficult to achieve. It is necessary to develop scoring rubrics to guide the scorers or judges in their task. Constructing appropriate rubrics and effectively training judges to use them consistently is a demanding task that requires good judgment, experience, and considerable patience. Too often poorly executed scoring of performances has led to unreliability and reduced validity, thereby vitiating any of the hoped-for advantages of performance-based assessments [21].

Probes that are meant to elicit extended responses can present the investigator with other difficulties. One is the set of issues related to response style. To take a familiar example, a teacher may ask students to make a presentation to the class related to an assigned project. Some students may feel uncomfortable making such a presentation, either because of inexperience with the format, innate shyness, or cultural traditions. If the teacher is insensitive to these possibilities, then her assessment of student performance relative to standard learning goals may have substantially lowered validity. Similar considerations apply in clinical interviews. In other situations respondents may misinterpret the questions, may refuse to respond or respond in a perfunctory manner because of disinterest, fatigue, or frustration. While these factors may play a role when multiple-choice items are used, they are more likely to occur and to have more serious consequences when performance measures are used.

In some instances the response styles involved in performance assessments must be explicitly taken into account. For example, in scoring a Rorschach protocol, counts are taken of various kinds of responses. It is known that propensity to provide multiple responses is associated with various demographic characteristics (e.g. level of education) as well as with the psychological traits under study. Unless appropriate precautions are undertaken in the preparation and the analysis of data, misleading clinical interpretations could result. The Rorschach protocol is a good example of a response set so complex that at least five completely different scoring systems have arisen, all purporting to provide clinical indications for a comparable set of psychological states. Attempts to create a single comprehensive system have met with limited success [12].

Comparisons of the efficiency of information gathered between multiple-choice and performance assessment items typically reveal that the two formats are measuring the same construct, but that multiple-choice items are more efficient with respect to measurement precision [52]. However, when considering appropriate item formats, concerns of construct validity may be more heavily weighted than those of measurement efficiency.

It is often difficult to determine the relative worth of performance-based assessments empirically. As an example, consider a test administered to provide automobile licenses. In many states the test has two parts: a written multiple-choice section and a driving test. The latter part is a performance assessment. The two parts address different aspects of the standard set for granting a license. One aspect deals with knowledge of the rules of the road, appropriate laws, and so on; the other deals with the ability to drive the vehicle safely. It is certainly sensible to require that individuals meet both aspects of the standard. A factor analysis of the performance of a group of individuals on the two parts would very likely show a substantial positive correlation between the two. A positive correlation signifies that the ranking of individuals on the multiple-choice section is congruent with the ranking of individuals on the driving test. Nonetheless, the conclusion that one or the other of the tests is redundant is incorrect. It is important to ensure that the individual has met the standard for each aspect of the standard, which can be ascertained only by actually observing the performance on the two parts. In principle, one could use regression analysis (not correlation analysis) to estimate the level of performance on one part given performance on the other part and data from a large group on both parts. However in situations where meeting the standard carries some value, neither the test sponsor nor the majority of individuals would be likely to want to base the decision on just one component and a statistical prediction.

Despite their shortcomings, performance-based assessments are becoming increasingly popular [9]. Stringent test development procedures, appropriate scoring rubrics and procedures, and sophisticated scaling models have greatly improved the psychometric properties of many of these assessments [15]. It is

likely that the use of performance-based assessments will increase in the medical professions.

In terms of integrating performance assessment and computer based tests, two critical technologies must be in place before performance-based item formats can be delivered in practice and scored through computers. The first is the development of expert systems that can accurately score the responses. These systems, employing principles and techniques of **artificial intelligence**, exist for a number of different symbol systems including natural language, mathematics, engineering design, and graphic design [4]. In general, the cost and difficulty of building a suitable system is proportional to the complexity of the potential responses and inversely proportional to the number of constraints that are placed on the examinee. The second technology comprises the psychometric models that can be used to extract the maximum amount of information from these extended responses. Since constructed response items usually require considerable testing time, unless more useful information is obtained from each item the reliability and validity of the resulting test scores may be far below acceptable standards.

Unfortunately, measurement theory has not kept pace with the development of performance assessments. If responses to a probe can be assigned to one of a number of categories (ordered or unordered) then polytomous item response theory models [45] can be used as a measurement model. When a response set consists of a number of diverse performances (as might be the case on a certification or licensure examination), the measurement models employed typically do not take into account the multivariate character of the data. One exception is a class of multidimensional item response theory models [29] that were explicitly developed to deal with these types of data. However, these models are of increased complexity and have yet to be applied to operational test data. More recent developments employing Bayes inference networks [33] appear to hold great promise in providing a firmer foundation for the design and psychometric analysis of complex assessments.

With the problems and benefits associated with performance assessments, an appropriate conclusion is that greater thought should go into the type of application as well as the design of the probes so that more useful information can be generated. As Messick [30] argues in the context of educational assessment:

> There should be a guiding rationale akin to test specifications that ties the assessment of particular products or performances to the purposes of the testing, to the nature of the substantive domain at issue, and to construct theories of pertinent skills and knowledge (p. 27).

Thus, the decision to use performance-based assessment formats, multiple-choice items, or some combination of the two is dependent on the nature of the construct measured. The relative advantages and limitations of these item formats must be considered in the context of the reliability and validity of the scores they will provide as well as the practical constraints within which the assessment must exist.

The field of psychometrics has a short, but rich, history. Like many of the scientific fields that developed primarily during the twentieth century, psychometrics has experienced rapid growth. This article briefly presented the evolution of psychometric theory, described popular measurement models, and provided a snapshot of new directions in the field. Measuring psychological phenomena is a challenging, but rewarding endeavor. Galileo once proclaimed: "we must measure what is measurable and make measurable what cannot be measured". This goal continues to drive psychometricians to understand and measure abilities, proficiencies, attitudes, and other psychological constructs.

Pulmonary Medicine

Respiratory disease (ICD 460–519), which excludes diseases of the lung not associated with respiration, such as lung cancer, accounts for about 15% of all deaths annually in the UK. The most common respiratory cause of death is pneumonia, accounting for 60% of all respiratory deaths, and this occurs mainly in those over 70 years old. The remainder are mainly due to chronic obstructive pulmonary disease (32% of all respiratory deaths). Other lung diseases are mainly associated with occupation, such as coal workers' pneumoconiosis, asbestosis, and byssinosis, but these are relatively rare. The principal obstructive diseases are chronic bronchitis, emphysema, and asthma. A patient can be assumed to have chronic bronchitis if sputum has been coughed up on most days of at least three consecutive months for more than two successive years, provided other causes have been excluded. It develops in response to long-term action of various types of irritant on the bronchial mucosa, the most important of which is cigarette smoke, but also as part of general air pollution. Emphysema means literally "inflation" in the sense of abnormal distension with air. Persistent inflammation in the airways, mainly as a result of smoking, causes irreparable damage to the alveolar septa. Most patients with pulmonary emphysema complain of exertional breathlessness. Asthma is associated with episodic attacks of wheeze and dyspnea. During an attack of acute asthma, the chest is held near the position of full inspiration, and expiration is difficult. Pneumoconiosis is an occupational disease that causes the lung to fibrose and is diagnosed from a chest radiograph by the profusion of small rounded opacities. It is graded into three main categories in accordance with a classification provided by the International Labor Office (ILO) [13]. Clinical diagnosis of respiratory diseases requires a clinical examination, and depends on a variety of signs and symptoms. However, simple questionnaires, such as the Medical Research Council (MRC) chronic bronchitis questionnaire [18, 19], and tests of lung function, are the main methods by which epidemiologic research in respiratory medicine has developed. Much useful information is given in [11] with many statistical issues covered in an appendix by Peto. Some general points on the presentation and analysis of data from respiratory studies are given in [2].

Lung Function Measurement

Historical Development

The early history of lung function measurement has been described by Cotes [6]. The volume of air that a person can inhale during a single deep breath was first measured by Borelli in 1679. In 1831, Thackrah showed the volume of air to be less in women than in men, and to be reduced among workers and other occupations due to the inhalation of dust. Hutchinson, in 1846, was the first to quantify lung volumes and designed a spirometer to measure *vital capacity* defined as "the greatest voluntary expiration following the deepest inspiration". He showed that vital capacity increased with height, decreased with age, and is reduced by excess weight and by disease of the lung.

Main Measures in Respiratory Medicine

There are a limited number of measures that are commonly used in **clinical trials** or epidemiologic studies. These include lung function tests such as *forced expiratory volume in one second (FEV_1), forced vital capacity (FVC), and peak expiratory flow rate (PEFR)*.

The FEV_1 is the volume of gas that is expelled from the lung over one second when the subject makes a maximal expiratory effort from a position of full inspiration. Other time periods are sometimes used, and indicated by the subscript. The *FVC* is the total volume of air expired until no more gas can be expelled from the chest after a full inspiration. Both are measured in liters using a spirometer. The peak expiratory flow rate (*PEFR*) is the maximum flow rate that can be sustained for a period of 10 ms and is measured in liters per second (l/s). It is another measure of ventilatory capacity [24] and is used widely in asthma studies.

Bronchial challenge tests give measures of bronchial irritability, related to asthma susceptibility, measured by the PD_{20} and PC_{20} that are derived from the FEV_1. A bronchoconstricting agent such as histamine, AMP or methacholine is inhaled in doubling doses until the FEV_1 falls 20% from baseline. The PD_{20} is the cumulative dose of the agent inhaled, whereas the PC_{20} is the particular concentration of the agent that caused the FEV_1 to cross the critical point.

Relationship of Disease to Lung Function

In chronic bronchitis, FEV_1 is reduced in many cases and the FEV_1/FVC ratio is subnormal. *PEFR* may be reduced but shows little diurnal variation. In emphysema, FEV_1 is reduced. The hallmark of asthma is diurnal variation in *PEFR*, with lowest values being recorded in the morning ("morning dipping"). Changes in FEV_1 due to bronchodilator drugs or corticosteroids are also an important indicator. The PD_{20} or PC_{20} is used widely in clinical and epidemiologic studies of asthma. It is useful because it is independent of diagnostic patterns; that is, the willingness of a physician to name the disease as asthma, and of symptom awareness, the importance placed on the severity of symptoms by the subject or the recognition of terms used in a questionnaire.

This article concentrates on some specific points of interest for the design and analysis of studies that involve measurements of respiratory function.

Particular Techniques in Respiratory Medicine

Estimating the FEV_1

Successive measurements of the FEV_1 of an individual will vary and a number of studies have been carried out to find what is the optimum combination of these. Because the test is a measure of maximal performance, one would have expected the maximum of a number of blows to be best. The Medical Research Council [18] recommended that the best procedure would be to require five blows, the first and second to be treated as practice attempts and to report the average of the third, fourth, and fifth blows as giving the individual's FEV_1.

Ferris [10], on the basis of three sets of data, suggested that the mean of the largest three of five measurements was best. Oldham & Cole [21] examined nine indices, including the two mentioned. From two data sets they concluded that in terms of repeatability for normal subjects there was little to choose between the various indices. However, differences were found in the measured rate of decline in FEV_1 using different indices over a period of 9.5 years. The index by Ferris gave values closest to the MRC definition over the 9.5 years and also gave the largest multiple **correlation** with age and degree of pneumoconiosis. They suggested that the mean of the largest three out of five blows was logically more sensible than the MRC definition and urged that it should replace the MRC index.

Estimation of the PD_{20} (PC_{20})

Bronchial reactivity is a measure of how the lung reacts to an inhaled agent such as histamine or methacholine. In general, people with asthma react by bronchoconstriction to lower doses than people without asthma, and so reactivity can be used to provide a standardized method of estimating the prevalence of asthma. Yan et al. [25] described a quick and simple method of measuring the PD_{20} that gave reproducible results under field conditions. The test stopped when the FEV_1 had fallen by more than 20% of the baseline value, or the 4.0 μmol dose had been given, or the subject asked to stop. The PD_{20} was estimated by interpolation. Chinn et al. [4] showed that linear interpolation was unsatisfactory and fitted a curve of the form:

$$\log_e(c - y) = a + bx,$$

where y is FEV_1, x is $\log_{10}$(dose), c represents mean FEV_1 before it is affected by histamine, b is the **regression** coefficient, and a is a curve position parameter. They estimated a, b, and c using a two-step procedure and showed that this exponential curve (*see* **Parametric Models in Survival Analysis**) fitted the data well. The advantage of estimating the PD_{20} by curve fitting is that it allows extrapolation of value above 4 μmol. Another parameter that can be derived from the above method is the slope b, and O'Connor et al. [20] showed how this could be useful in population studies. Peat et al. [22] described methods for measuring repeatability of the PD_{20} and explained methods for calculating changes for doubling dose, percentage change, or fold difference. The latter concept is explained by means of an example: a mean change in responsiveness from 1.96 to 0.98 μmol would be a change of 0.5-fold differences; that is, the mean dose at which the response occurred was half that at which it occurred initially.

Standardization of FEV_1

Lung function and, in particular, FEV_1 depends on age and height and, in any comparison of groups, differing age and height distributions must be accommodated. A common method is to use **linear regression**

models that have been fitted to large normal populations to obtain the predicted FEV_1 for a given age and height. Standard regression equations are available in Cotes [6] and Enright et al. [9]. The analysis may then proceed by analyzing the ratio of the observed to expected values, but this method is not recommended because there are issues of comparability of populations and **multiple linear regression** methods are usually easier to interpret.

Kory et al. [14] recommended the simple linear regression:

$$FEV_1 = \beta_0 + \beta_1 \times \text{age} + \beta_2 \times \text{height}. \quad (1)$$

Others have argued for an **interaction** term, age × height, in the model, or to standardize for height by calculating FEV_1/height^2 or FEV_1/height^3.

From the analysis of nine **cross-sectional** surveys, Cole [5] showed that a model used

$$\frac{FEV_1}{\text{height}^2} = \alpha_0 + \alpha_1 \times \text{age} \quad (2)$$

fitted the data better than a linear model. He also argued from allometric (*see* **Allometry**) principles that although a relationship with height^3 (or even height^4) may be the true model in which both FEV_1 and height are considered as correlated variables, when log(height) is thought of as a predictor of $\log(FEV_1)$, estimates from linear regression are shallower than the true slope and on the basis of the correlations in the data, the value of the slope would be shrunk to approximately 2, so that on a linear scale one would expect FEV_1 to be related to height^2.

However, Kronmal [15] has shown that if the true relationship is described by

$$FEV_1 = \beta_0 + \beta_1 \times \text{age} + \beta_2 \times \text{height}^2, \quad (3)$$

then the estimate for α_1 in (2) is a biased estimator of β_1 in (3). He argued that the coefficient for age in (2) is measuring the joint effect of varying age and height^2, which is an interaction, whereas the coefficient obtained in (3) from linear regression is measuring the effect of age, having adjusted for height^2. Prudent statistical practice does not fit an interaction term without fitting the main effects; in this case, terms for age and height^2 as well as age × height^2. These different models can, in fact, lead to different conclusions when two groups with different heights are compared; for example, a comparison of the rate of decline in lung function for men and women. For epidemiologic studies in which a large number of subjects with age and height measurements are available, it would seem better to adjust for age and height by including them (and possibly height squared) as terms in the regression equation. It is generally accepted that lung function declines linearly with age but the possibility of quadratic relationships with height should be investigated for each data set.

Statistical Methods Stimulated by Respiratory Data

The famous paper by Bland & Altman [1] on methods for assessing **agreement** between two methods of measurement originated in a comparison of two peak-flow meters. They dealt only with measurements on the same scale. However, it may be required to compare repeatability of different indices; for example, PD_{20}, in log(mg/ml) and the slope of the FEV_1 dose response curve in liters $(\text{mg/ml})^{-1}$. Dehaut et al. [7] and Chinn [3] suggested the use of the intraclass correlation coefficient (ICC) (*see* **Correlation**), defined as the ratio of the between-subject to total variation. Chinn [3] suggested that to be useful a measurement should have an intraclass correlation coefficient of at least 0.6. Baseline FEV_1 measured on two occasions 1–14 days apart were found to have an ICC of 0.88 [4]. However, repeated measurements of FEV_1 on the same day may give an ICC as high as 0.99 [21].

The paper by McCullagh [17] on *ordinal regression* was stimulated by a study of pneumoconiosis in coalminers. A typical study in this area would be to determine factors associated with the severity of pneumoconiosis using the ordinal ILO category as the dependent variable and exposure to dust as the main predictor variable, with other potential **confounding** variables such as cigarette smoking included in the equation.

When the dependent variable is PD_{20}, it may be truncated if the FEV_1 of a subject fails to drop to below 20% of baseline or if the subject asks to stop early. This leads to *truncated regression* as the method of analysis.

In truncated regression the model is

$$y_i = \alpha + \beta x_i + \varepsilon,$$

where ε is assumed $N(0, \sigma^2)$. If y_i is not censored, then the probability of observing y_i conditional on the

parameters is $f[y_i - x_i\beta)/\sigma]$, where f is the N(0,1) density. If y_i is right-censored at u_i (i.e. the true value is known to be greater than u_i), then the probability is $1 - F[(u_i - x_i\beta)/\sigma]$, where F is the cumulative normal density. The parameters can be estimated by **maximum likelihood** and the analysis is implemented in the statistical package STATA [23] (*see* **Software, Biostatistical**). The assumption of normality of the residuals assumes a much greater importance than in unconstrained multiple regression and should be investigated carefully. An example of truncated regression in respiratory medicine has been given by Devereaux et al. [8].

The whole area of the analysis of repeated measures has been stimulated by the fact that lung function measurements are made repeatedly on individuals. The classic paper by Laird & Ware [16] on **random effect** models considered 200 school children who had their FEV_1 measured on five successive occasions to examine the effect of air pollution. This has lead to a whole plethora of papers on repeated measurement analysis.

Discussion and Conclusions

Diseases of the respiratory system form a large part of the burden of disease in Western society and are the subject of much research. Asthma, particular in children, is increasing in prevalence, and there is intensive activity to determine the reasons for this. The FEV_1, originally devised to measure the effect of certain occupations on respiratory health, has emerged as one of the most important prognostic factors for future illness, comparable in power to serum cholesterol [12].

There are some interesting statistical problems that have arisen in the field of respiratory medicine, such as the standardization of results for age or height, comparison of methods, and ordinal regression which have proven fruitful elsewhere.

Quality Control in Laboratory Medicine

The statistical aspects of quality control (QC) in the field of clinical laboratory medicine are much more intricate than might be thought. Body fluids such as human blood are a molecular "soup" of extraordinary complexity, within which even a relatively simple constituent such as calcium can exist in a number of different states, for example, intracellular, compounded, ionized, or bound to carrier proteins. Laboratory assays encompass the blood gases, electrolytes, trace elements, vitamins, clotting factors, proteins, hormones, tumor markers, drugs and poisons, and more, and the assay of any one analyte has to accommodate, potentially at least, the presence of all (*see* **Biological Assay, Overview**). This is not to mention any one or more of the legion medications that the patient might be taking.

The vast majority of clinical laboratory assay methods rely upon the elicitation of a *specific* and observable property of the test analyte that varies in proportion to the concentration of the analyte in the biological test matrix. In order to visualize that relationship (the measurement function), standard solutions, or calibrators, of *known* concentration with respect to the analyte of interest are assayed in parallel with the test specimen. The level of the property (Y) recorded for each calibrator is plotted against the **calibrators** concentration value (X), the points so defined providing an estimate of the assay calibration function. The level of the property recorded for the test specimen is translated into units of concentration by reference to the inverse of the calibration function, under the critical assumption that calibration function and the measurement function are, to all intents and purposes, identical. Regular recalibration is a characteristic feature of laboratory assay systems.

Where possible, assay methods in routine use (field methods) should be supported by a clear link to a hierarchical program of *reference technology*. Such programs embrace a series of primary and secondary reference methods and standard reference materials, discussed in detail by Uriano & Cali [34], Tietz [32] and Boutwell [1]. The problems that beset attempts at assay standardization can prove formidable: Ekins [9] provides a very clear account of the subject from the perspective of immunoassay methods (*see* **Radioimmunoassay**).

The complexity of the biological test matrix poses a number of threats to the integrity of laboratory measurement. First, it is practically impossible to reproduce in full the complexity and properties of the biological test matrix in necessarily artificial calibrators. The primary impact of a failure in this regard is the very real possibility that the calibration function will no longer mirror the measurement function, thereby introducing a systematic error (or bias) into the measurement process. Second, the complexity of the analyte itself, or of its presentation in the biological test matrix, may also pose problems in respect of constructing plausible calibrators. For example, in its native state, the analyte may be intracellular, protein-bound, or conjugated with inorganic radicals as a prelude to excretion. In the laboratory, it may be a white powder in a bottle. Transforming the latter into a credible facsimile of the former is a prerequisite of meaningful measurement and failure in that endeavor is a primary source of systematic error. The reader is referred to [30, 31] for a more detailed account of the above problems. Third, the biological test matrix may, by virtue of its physical or chemical composition, elicit a signal in the measurement system that is indistinguishable from that generated by the target analyte (cross-reaction) or, it may modify the signal generated by the target analyte (interference). These effects, which reflect a lack of specificity in the measurement chemistry, are typically specimen dependent, manifesting as a bias on repeated assay of a single test specimen and as a random variable across different test specimens. They are referred to variously as matrix effects, specimen-dependent **biases**, random biases, or subject-by-method **interactions**. Summarizing, we have, for a given test result X_i:

$$X_i = \xi_i + \phi + \psi_i + \varepsilon_i \tag{1}$$

where: X_i = observed test result for sample i.
ξ_i = true test value for sample i.
ϕ = analytical bias, primarily calibration failure.
ψ_i = specimen-dependent bias.
ε_i = random measurement error (imprecision).

The ideal for a laboratory measurement system would be a degree of measurement specificity, standardization, and control that effectively eliminated

all bias. Under such ideal circumstances, (1) would reduce to (2):

$$X_i = \xi_i + \varepsilon_i \tag{2}$$

QC would appear to have little left to concern itself with beyond regulating the magnitude of the random error term ε There is, however, another dimension of complexity to the reported test value X. That dimension is time, whose passing reveals several new sources of variation in laboratory test results and several new challenges for QC to accommodate.

First, *all* living organisms change over time as a consequence of perfectly natural biological variation. Biological variation can take a number of forms; it may be nonrandom, for example, daily, monthly, or seasonal rhythms (*see* **Chronomedicine**), along with those changes that characterize our progress from cradle to grave, or it may be random in character. For the majority of analytes of clinical interest, biological variation can be construed as a random process over time (*see* **Stochastic Processes**), changes occurring around a homeostatic setting point μ, the latter being fixed for a given individual but differing in value across a set of individuals.

Second, the random measurement error term ε is itself time dependent. Laboratory assays are typically undertaken by assaying a number of test specimens in one batch or analytical run, for example, one run a day. A single analytical run will be characterized by fewer sources of variation than a number of consecutive analytical runs, for example, one run, one calibration of the measurement system, a common set of analytical reagents, a common set of all those factors beyond strict technical control. The time element in respect of assay imprecision is captured in the terms *within-run* and *between-run* imprecision. Incorporating the above factors into model (2) we have:

$$X_{ijk} = (\mu_i + \eta_{ij}) + \varepsilon_{ij} + \varepsilon_{ijk} \tag{3}$$

(true value ξ)

where X_{ijk} = the observed result from the kth replicate assay in the jth analytical run (or day) for the ith test subject.

μ_i = the subject's individual biologic mean or homeostatic setting point.

η_{ij} = a peturbation due to biologic variation in the jth analytical run having an expected value (*see* **Expectation**) of 0 and a variance σ_η^2.

ε_{ij} = a peturbation due to random measurement error in the jth analytical run having an expected value of zero and a variance σ_B^2.

ε_{ijk} = a peturbation due to random measurement error in the kth replication within the jth analytical run having an expected value of zero and a variance σ_W^2.

We have four components of variability associated with (3) which, in the laboratory sciences, are typically expressed in terms of estimated **standard deviations** (SD) or corresponding coefficients of variation (CV = SD as a % of the relevant mean value):

SD_G = Between-subject biological variation, reflecting the differences *between* individuals in a given population in respect of their homeostatic setting-points μ_ι. SD_G^2 is an estimate of σ_μ^2. $CV_G = SD_G$ as a percent of the population mean.

SD_I = Average within-subject biological variation, reflecting the changes in a given subject's test result over time. SD_I^2 is an estimate of σ_η^2. $CV_I = SD_I$ as a % of population mean.

SD_B = Between-run imprecision component. SD_B^2 is an estimate of σ_B^2. $CV_B = SD_B$ as percent of control sample mean.

SD_W = Within-run imprecision component. SD_W^2 is an estimate of σ_W^2. $CV_W = SD_W$ as percent of control sample mean.

We also have two derived quantities:

$$SD_{\text{biol}} = \textit{Total biological variation}.$$

$$SD_{\text{biol}} = (SD_I^2 + SD_G^2)^{1/2}$$

$$\text{or } CV_{\text{biol}} = (CV_I^2 + CV_G^2)^{1/2} \tag{4}$$

$$SD_T = \textit{Total imprecision}.$$

$$SD_T = (SD_W^2 + SD_B^2)^{1/2}$$

$$\text{or } CV_T = (CV_W^2 + CV_B^2)^{1/2} \tag{5}$$

Estimates of the random measurement error components can be obtained by assaying the same control or test specimen a minimum of $k = 2$ times on each of $j = 20$ days, following the recommendations of the National Committee for Clinical Laboratory

Standards (NCCLS) [24]. The error components are obtained from a one-stage nested **analysis of variance** (ANOVA). A worked example is presented by Kringle & Bogovitch [21].

Note that for (3) we have equated runs with days (one run = one day) simply in order to minimize model complexity. *If* multiple runs within a given working day were a feature of the test service under study, an additional level of subscripting would be required for the random error term ε in order to distinguish within-run, run-to-run, and day-to-day sources of random variation. The error components can be obtained using a two-stage nested ANOVA [21].

The majority of laboratory test methods exhibit some degree of dependence between the magnitude of the error variance and analyte concentration (heteroscedasticity; *see* **Scedasticity**). This dependence may take the form of a simple proportional relationship, that is, a constant CV_T, at least as an approximation, but this is by no means the rule. Heteroscedasticity necessitates obtaining several estimates of random error variation across the working range of the test method, preferably in proximity to medical decision points for the analyte in question. Given such estimates, imprecision profiles can be constructed for both within-run and total imprecision.

Coefficients of variation need careful handling in the context of summarizing analytical imprecision (CV_W or CV_T). Users may lose sight of the connection between a CV and its parent SD, for example, an analytical error CV of 6% implies a 95% error margin of plus or minus 12% (not 6%) at the relevant test concentration or activity level.

The factors to be considered in developing estimates of biological components of variation are reviewed in detail by Fraser and Harris [13]. The authors provide a clear account of the requisite **experimental design** and subsequent data preparation, prior to the estimation of the components of variation (*see* **Variance Components**) using a two-stage nested ANOVA. Estimates of biological variance components (CV_I and CV_{biol}) have already been published for a large number of laboratory analytes [12, 27]. A comprehensive data bank of such components, along with source references, is maintained online at `www.westgard.com`. The components play a key role in subsequent discussion of analytical goals for QC.

Quality Control in Context

Quality control (QC) refers to a set of procedures by which we seek to monitor the components of error associated with laboratory test procedures in furtherance of the practice of good medicine. QC is essentially a set of techniques adapted from industrial statistical process control (SPC). QC is, or should be, embedded within the larger framework of a total quality system embracing *all* aspects of the laboratory function. Total quality management (TQM) places the *user* of the laboratory center stage in respect of defining the levels of quality (and costs) that constitute an acceptable level of service.

Waiting in the wings, Six Sigma, a total quality management *system* that aims for an error (defect) rate of no more than four in a million in the "product" of a manufacturing or service delivery process. The Six Sigma goal is achieved through the pursuit and elimination of all sources of variation impacting upon process outcome. If the process in question starts with a request for a given test, and ends with the delivery of the required test result, every conceivable aspect of the journey from request to return is the subject of ongoing scrutiny and, where required, redesign or reeducation. A statistical overview of Six Sigma is provided by Hahn et al. [16]: a collection of lab-oriented essays on the topic is available at `www.westgard.com`.

Control Charts

The day-to-day practice of QC in laboratories (internal QC) is largely focused on charts, simple graphical displays of the results obtained for control samples against time of assay. The classic laboratory "control" chart is the single value modification of the "Levey–Jennings" chart, described by Henry and Segalove [17] in 1952. It is widely referred to as a "Shewhart" control chart in clinical laboratory literature, reflecting its origins in the work of Shewhart [29] in the 1930s. An example of the chart is illustrated in Figure 1.

For the construction of the chart, SD_T should be estimated from a minimum of 20 assays of the control sample over 20 different days at a time when the assay is judged to be in statistical control.

In operation, the results obtained for a single control specimen introduced into every analytical run should be checked against the $2s$ limits, or the 3s

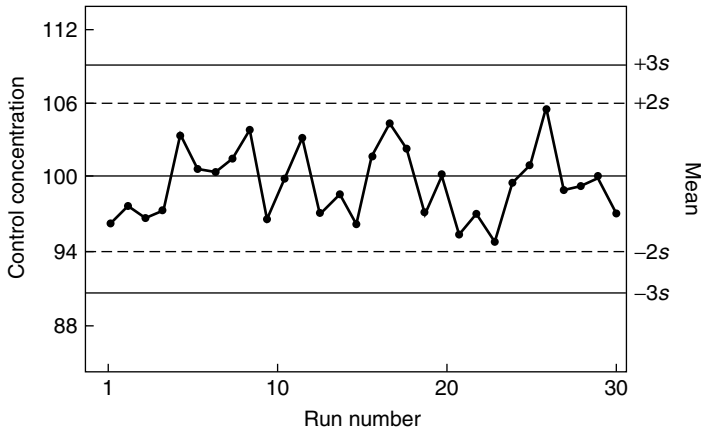

Figure 1 Levey–Jennings QC chart (s = total imprecision SD_T)

limits if there are two or more such controls. Any control value exceeding the appropriate threshold flags an out-of-control assay run, that is, no test results are to be reported from that run. In practice, many, if not most users of the above charting system rely on a simple $2s$ rule, irrespective of the number of control samples involved. Westgard & Groth [38] have published **power functions** for the above control rules, revealing the very high false-alarm rates that accompany misuse of the $2s$ rejection rule. A secondary problem with the basic Levey–Jennings chart is its relative insensitivity to systematic error (bias). To address these deficiencies, Westgard et al. [37] published their 'multi-rule' control procedure along with associated error-detection power curves. Essentially, it is an elaboration of the Levey–Jennings chart obtained by including control lines at the control mean plus or minus $1s$, $2s$, $3s$, and $4s$, preferably color-coded for clarity. Two control samples, or one control assayed twice, comprises the minimum configuration required to assess a given test run. The two control results are assessed against the following rules:

- 1_{2s} One control result exceeding the $2s$ limits. This is a warning rule that initiates reference to the remaining rules.
- 1_{3s} One control result exceeding the $3s$ limits. A REJECTION rule, primarily sensitive to random error.
- 2_{2s} Two consecutive control results both greater than $+2s$ or both less than $-2s$. A REJECTION rule, sensitive to bias.
- R_{4s} One observation exceeding $+2s$ limit and the other exceeding the $-2s$ limit. A REJECTION rule, sensitive to random error.
- 4_{1s} Four consecutive control results all exceeding the $+1s$ limit, or all exceeding the $-1s$ limit. A REJECTION rule, sensitive to bias.
- 10_m Ten consecutive control results all in excess of the mean, or all lower than the mean. A REJECTION rule, sensitive to bias.

Clinical laboratories are under increasing regulatory pressure from professional bodies and/or Government agencies in respect of meeting specified standards of performance, making it ever more important that an appropriate QC strategy is in place for every assay system in use. By appropriate, we mean a strategy that strikes a cost-effective balance between the probability of rejecting a bad run correctly, which probability we would like to be high, and the probability of rejecting a good run incorrectly, which probability we would like to be low. By "bad" we mean an assay whose *total error* (TE), a combination of both random and systematic error components, exceeds a specified threshold. What might constitute an appropriate threshold for TE is taken up in the section on analytical goals. Westgard [36, 40] provides a clear account of the steps involved in formulating an optimal QC strategy. A software package, EZ rules™, for automatic selection of statistical control rules is available through `www.westgard.com`, which also hosts a comprehensive inventory of resources in respect of laboratory QC. EZ rules™ has been reviewed by Linnet [11].

Cumulative Sum (Cusum) Control

A sensitive indicator for low-level bias in assay systems is the cumulative sum (cusum) chart, developed by Page [26] for manufacturing control. A cusum chart records the deviations of each control result in a series from a control set-point or mean μ_c, but instead of plotting the deviations individually, we plot the running, or cumulative sum of those deviations, that is, cusum value $= \Sigma(X_i - \mu_c)$. If the assay method is unbiased, we would expect an approximate balance between the positive and negative deviations, resulting in a cusum trace fluctuating around a horizontal line centered on zero. Any shift in the accuracy base (bias) will result in the accumulation of deviations of like sign, manifesting as a slope or ramp away from zero on the cusum chart.

Two control rule strategies are available to alert the user to significant bias, one visual, the V-mask template, and one numerical, the decision-interval rule. A practical account of both is presented in [30].

Westgard et al. [39] describe a combined Levey–Jennings cusum control chart, along with associated error-detection power curves. Cusum control rules are not without their problems, amongst which are the assumptions of statistical independence and constant error variance for the control results being charted. The consequences of violating these assumptions have been explored by Johnson & Bagshaw [20].

An interesting implementation of the CUSUM principle is to be found in the program "**Change-Point Analyzer**", (downloadable from `www.variation.com`). Essentially, it is a hybrid of the cusum principle and a **bootstrap** estimator for determining the probability of change (bias) in a given series. The program includes automatic checking for nonindependence and **outliers**, with a number of workarounds for both contingencies.

Alternative Control Procedures

Cembrowski et al. [6] and Neubauer [25] each describe control programs for detecting persistent systematic error, using exponentially weighted **moving averages** (EWMA), the former authors employing Trigg's tracking signal as a trend detection device [33]. Jay Smith & Myers [19] describe a procedure for detecting short-term trends in serial control results using a moving **least-squares** regression slope estimator. An original variation on the EWMA theme is described by Bull et al. [2, 3] utilizing the daily or batch mean for patient test results, for each of the erythrocyte indices, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, and mean corpuscular volume, to monitor calibration drift in automated hematology analyzers. The performance characteristics of Bull's **algorithm** have been studied by Lunetsky & Cembrowski [22].

Delta Checks

The use of patient test data to drive QC procedures has obvious attractions in terms of relevance (real test specimens rather than "artificial" controls), cost (controls cost money), and convenience. Bull's algorithm is an example. Another is the Delta check based on observing the difference between two separate test results on the same patient. The original Delta check rules were either empirical in nature, or based on studies of the observed distributions of differences in the population being served by the laboratory. The observation of unexpectedly large differences signals a possible problem, for example, mislabeling of specimens. Sheiner et al. [28] have reviewed the performance of several Delta check methods. Fraser [12] suggests an intellectually pleasing basis for Delta checking by defining the upper limit for expected change in terms of total imprecision (SD_T) and within-subject biological variation (SD_I). Fraser refers to such a limit as a reference change value (RCV):

$$RCV = 2^{0.5} * Z * (SD_T^2 + SD_I^2)^{1/2} \qquad (6)$$

where $Z =$ **standard normal deviate**, giving us:

$$RCV = 2.77 * (SD_T^2 + SD_I^2)^{1/2} \text{ for 95\% limit (2-sided).}$$
$$= 3.65 * (SD_T^2 + SD_I^2)^{1/2} \text{ for 99\% limit (2-sided).}$$

Bear in mind the possible dependence of SD_T on the level of the analyte, that is, select an appropriate value for SD_T from the assay imprecision profile. A 99% limit is recommended by Fraser for Delta checking. Large-scale Delta checking is easily incorporated into laboratory information management systems (LIMS).

As an aside, note that the RCV lends itself directly to assessing the significance of observed

changes between consecutive test results on the same patient, that is, can the observed change be ascribed to the combined effect of error plus perfectly natural biological variation, or is it so great as to signify something worthy of attention or clinical intervention?

Authoritative recommendations on the design and implementation of internal QC schemes have been published by the International Federation of Clinical Chemistry (IFCC); see [4], and by the NCCLS [23].

External Quality Control

The control procedures described above relate to internal QC, the laboratory monitoring itself on a day-to-day basis. External QC programs, run by commercial organizations or professional bodies, provide an invaluable link to the experience of hundreds of other laboratories, and they serve to alert any individual laboratory to the possibility that its performance might be inconsistent with that of the collective.

The basic operation of such schemes involves the distribution of the same "control" material to all participating laboratories, the subsequent results returned being subjected to statistical summary. Typically, the mean of results returned for a given analyte, stratified by assay methodology where this is appropriate, is viewed as a surrogate "true" value. The deviation of any one test result from the appropriate group mean is expressed in standardized form, usually based on an index of group dispersion. Schemes vary in the frequency of specimen distribution, in the definition of true or target values and in the criteria they employ for characterizing performance. All external QC schemes provide a necessarily retrospective view of performance. The topic is well covered by Buttner et al. [5], Westgard and Klee [40] and a well-informed discussion of outstanding problems from the perspective of the UK National External Quality Assessment Schemes (UK NEQASs) is provided by Hirst [18].

Analytical Goals for Laboratory Error

QC procedures are designed to monitor the performance characteristics of laboratory test methods (imprecision, bias, and blunders) and to alert us to changes in those characteristics that may impact upon the quality of the laboratory service. QC procedures do not of themselves define desirable quality standards. What standards? Defined by whom? Desirable to whom? Ask 20 different people with an interest in the laboratory (managing it, running it, paying for it, working in it, or using it) how they would define "quality" in relation to a laboratory test result. You will surely get 20 different answers, reflecting 20 different sets of priorities. And so it is with those who have busied their minds with this problem over the last two decades.

The subject is reviewed by Fraser [12, 14] who describes a hierarchy of objectivity in the definition of quality objectives. Paraphrasing from top down (from the most to the least desirable), we have quality standards defined by a specific medical need, by general medical needs in relation to case finding and case monitoring, by professional or expert recommendations, by legislation or regulation, or by what is technically possible.

The Aspen conference on Analytical Goals in Clinical Chemistry [10], organized by the College of American Pathologists in 1976, agreed guidelines for maximum tolerable imprecision in relation to two broad classes of test usage, (a) population screening, and (b), individual testing (e.g. case management). The guidelines, which drew on the work of Cotlove et al. [7], were framed in terms of a key recommendation. *Analytical variance should not exceed one-quarter of the relevant biological variance,* thereby insuring that the variability of result is increased by no more than 12% due to assay imprecision. The latter result follows from noting that the overall variability associated with an observed test result is made up of two (primary) components, one biological (within-subject biological variation) and the other analytical (total imprecision). The variability imparted to the observed test result by analytical imprecision, over and above that due to biology alone, is obtained from the following formula, adapted from [13]:

$$\left[1 + \left(\frac{CV_T^2}{CV_I^2}\right)\right]^{1/2} \tag{7}$$

If analytical variance $= 1/4$ within-subject biological variance, we have $(CV_T^2/CV_I^2) = 0.25$, so $[1 + 0.25]^{1/2} = 1.118$. That is an increase of 11.8% in observed variability due to analytical imprecision alone. The choice of 11.8% as a threshold for the inflationary effect of analytical imprecision is arbitrary. It follows from a memorably simple rule,

that is, $CV_T < 1/2\ CV_I$ (or 1/4 if using the corresponding CV^2), and from the fact that the impact of analytical imprecision on overall test variability grows appreciably larger once the Aspen threshold is exceeded.

A Working Party of the European Group for the Evaluation of Reagents and Analytical Systems in Laboratory Medicine [15] subsequently proposed quality specifications based on a pragmatic marriage of the Aspen "rule" and the current state of the art in laboratory testing as judged from external QC schemes:

The total imprecision threshold (CV_{limit}) should be:

(a) less than one-half of the average within-subject biological variation (CV_I), or
(b) less than the state of the art achieved by the best 0.20 fractile of laboratories,

whichever is the less stringent. The second approach to be used if the requisite biological data are unavailable.

The inaccuracy threshold (B_{limit}) should be:

(a) less than one-quarter of the total biological variation (CV_{biol}), or
(b) less than one-sixteenth of the clinical reference interval, when data on biological variation are unavailable, or
(c) less than twice the ideal imprecision, if the above specifications are too demanding.

Note the commonplace use of standard deviations (or corresponding CV) rather than variances (or CV^2) as descriptors of variability in clinical laboratory settings.

The user of the laboratory is unlikely to be very interested in the distinction between imprecision and inaccuracy. Of more relevance will be their combined effect in a given test result, the total error (TE), where TE% = total imprecision (%) + total bias (%). The bias prevailing in a given test system can be conveniently estimated using the cumulative performance statistics provided by external QC scheme organizers. The most commonly cited quality goal for TE is given by:

$$\text{Total error threshold} = TE_{\text{limit}} = B_{\text{limit}} + 1.65\ (CV_{\text{limit}}) \quad (8)$$

By way of illustration, we have the following basic biological reference values for serum copper, Table A1.3 of ref [12]: $CV_I = 4.9\%$ and $CV_G = 13.6\%$. It follows from (4) that the total biological variation is $CV_{\text{biol}} = 14.5\%$. The error thresholds for serum copper estimations are therefore:

for imprecision:
$CV_{\text{limit}} = 1/2\ (4.9) = 2.5\%$
for bias:
$B_{\text{limit}}\ (\%) = 1/4\ (14.5) = 3.6\%$
for total error:
$TE_{\text{limit}}\ (\%) = 3.62 + 1.65\ (2.5) = 7.7\%$

The quantity TE_{limit} plays a key role in formulating optimal internal QC strategies using Westgard's operating specifications charts [36, 40].

The logical basis of the above "European" quality goals is discussed in very accessible terms by Fraser [12]. The same publication also provides an extensive listing of the threshold values CV_{limit}, B_{limit}, and TE_{limit} for blood chemistry, immunology, urine chemistry, hematology, and hemostasis; see `www.westgard.com` for similar resources.

In the United States, quality goals have been enshrined in legislation as fixed upper limits for TE by the Clinical Laboratory Improvements Amendments of 1988 (CLIA'88), Final Rule [35]. The document is accessible online at `www.cms.hhs.gov/clia/`. In its current form, the CLIA'88 proposals call for the circulation, by approved proficiency-testing (PT) centers, of five test samples three times a year to US laboratories. In effect, a mandatory external QC program covering every pathology discipline. PT failure is getting two incorrect results out of five, in two out of three consecutive surveys.

The danger with establishing quality thresholds, however, derived or defined, is that they may be perceived to be targets to aim for, rather than lines that should not be crossed. With that in mind, Ehrmeyer et al. [8] have pointed out that any laboratory achieving a TE of one-third the CLIA thresholds will have something approaching a 100% chance of satisfying the CLIA'88 regulations. The "one-third" CLIA rule might therefore be regarded as a desirable analytical goal simply in terms of retaining a license to practice.

Complete listings of the CLIA'88 *TE* thresholds are available at `www.westgard.com`, along with a wealth of technical information and essays from

authorities in the field. European and US CLIA quality specifications are compared and contrasted by Westgard et al. [41].

Quality of Care

What is Quality of Care?

Quality of care refers to the attributes or characteristics of the delivery and subsequent outcomes of health care [4]. Health care includes the treatment of both physical and mental illnesses. High quality of care is defined by the Institute of Medicine [16] as the "degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge". This definition applies to various health providers, including physicians, nurses, and case managers; to all types of health care organizations such as preferred provider organizations, health maintenance organizations, and point-of-service plans; and to almost all settings of care such as hospitals, physician offices, nursing homes, and community sites.

Why Assess Quality of Care?

There are three general reasons for assessing quality of care delivered in the ordinary circumstances of routine practice: to improve care, to provide accountability, and to quantify information for market choices.

Improve Care

Empirical support for many treatment recommendations is surprisingly thin – most evidence arises from randomized trials (*see* **Clinical Trials, Overview**) where inclusion criteria can be stringent and in which selective practitioners participate. In contrast, routine practice consists of patients covering a wide spectrum of health status, from the very ill to the worried well. Well-collected data in these settings can provide information about the quality of treatments, of delivery strategies, and of organizational mechanisms. For example, if patients receive too much care, then this may result in the use of unnecessary interventions, unnecessary exposure to health risks, and resource waste. If patients receive too little care, either lacking in intensity or adequacy or both, then they are at risk of untoward outcomes, such as morbidity and mortality, which ultimately lead to higher costs. Identifying differences in health outcomes on the basis of quality measurement can lead to improved health outcomes.

Provide Accountability

Several constituencies have a stake in periodic disclosure of the quality of health care: consumers [1]; government [6]; professional societies [3, 13]; and purchasers [26]. Public disclosure of quality typically involves comparisons of health care providers or settings on the basis of quality measures in *report cards* [24] or **league tables** [11] (*see* **Profiling Providers of Medical Care**). Consumers of health care want to be able to identify high-quality practitioners and health plans. Professional societies want to ensure that specialists are kept informed of the latest advances to improve patient care, and may use quality measures as the basis for board certification. Government health programs wish to enforce compliance with health and safety requirements, and credentialing of medical staff. In the United States, the Joint Commission on Accreditation of Healthcare Organizations, for example, has statutory authority to certify hospitals, ambulatory surgical centers, clinical laboratories, home health agencies, and hospices. Employers who purchase health care want to avoid the effects of poor quality of care on productivity.

Market Choices

Public and private employers, business coalitions, and public programs, such as Medicaid and Medicare, have sought to redesign the health care system through negotiation with providers and insurers. These activities, denoted value-based purchasing [22], are designed to ensure and improve the quality of health programs. Purchasers contact selectively with health plans or provider organizations based on price and demonstrated quality [9]. Enhanced health benefit packages may help employers retain employees, increase employee satisfaction and productivity, decrease absenteeism, and hence reduce long-term health costs. Virtually all companies in the *Fortune 500* companies, for example, have reported collecting some information about health plan quality [18]. Some large companies, like Xerox, have used quality measures in making procurement decisions [17].

How to Measure Quality?

Prior to the mid-1980s, professional judgement was used to ensure patients received high quality of care.

This was usually accomplished by individual practitioners who would monitor care of their patients. In a 1980 article, Avedis Donabedian [7] suggested that quality of care should be measured by its structure, process, or outcome.

Structural measures include resources of the health care system that reflect the capacity of the provider to deliver good health care. The availability of diagnostic and therapeutic equipment for patient care may be assessed to determine whether quality of care is adequate. These organizational characteristics are often required by government programs through accreditation or certification requirements as a way to ensure some capacity for quality.

Process-based measures refer to what care givers do to and for patients. Typically, such measures focus on the diagnosis and management of disease, as well as preventive care such as **screening**. These measures should be under the control of the health professional. The idea is to define a population of patients who *should* get a therapy or test, and count how many actually got it. Eligible patients are identified using established guidelines or other explicit clinical criteria [20]. In Table 1, the **target population** consists of patients discharged alive or dead with a diagnosis of acute myocardial infarction (AMI). Because selected subsets of patients are used for **inference**, for example, those eligible for reperfusion therapy, achieving a sufficient sample size for valid inference and generalizing results to all patients may be difficult.

Outcomes-based measures refer to responses that characterize a patient's health status and quantifies whether the care received has improved the patient's health. Common examples include **risk-adjusted** mortality, occurrence of complications, relief of symptoms, and patient reports about their health. Thirty-day risk-adjusted mortality following an AMI is a common outcomes-based measure as the majority of treatments for care will have be given within one month of admission.

Good structural or process measures are those that, if modified, would lead to demonstrable changes in outcomes. Similarly, good outcome measures are those that, if the process measure was changed, changes in outcomes would occur.

Data Analyses

Analyses of health care quality data are challenging due to their nonexperimental nature and complex structure. Randomized studies are infrequently used

Table 1 AMI process and outcomes-based quality measures. Example measures for assessing hospital-specific quality of care for patients having a heart attack

	Process			Outcome
Measure	Reperfusion	Underuse of Angiography	Beta-blockers	30-day Mortality
What?	Therapy to open blocked vessels to restore blood to the heart	Invasive procedure to assess extent of heart disease	Medical therapy that lowers the heart's need for oxygen	All cause mortality
Definition	Angioplasty or thrombolysis within 12 hours of hospital arrival	Use within 12 hours after symptom onset & prior to discharge	Discharge R_x for beta-blockers	Died within 30-days of admission
Exclusions	No ST-elevation; onset of chest pain > 12 h prior to arrival; bleeding on arrival; hx of ulcer or chronic liver disease; CVA; warfarin on admission; age > 79; recent trauma; surgery within 2 months; aborted angiography	Not rated ACC Class I; died within 1 day of admission; underwent primary angioplasty	EF < 35%; pulmonary edema or CHF and EF < 50%; shock, systolic blood pressure < 100, or hypotension; hx of COPD, dementia; heart block; bradycardia; insulin or antidepressant trt	None but adjust for admission risk factors

hx = history; R_x = prescription; CVA = cerebrovascular accident; EF = ejection fraction; CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease; ACC = American College of Cardiology.

to assess quality of care, although some have been used to identify interventions that lead to improvements in health quality [21, 25, 27]. Because the majority of quality studies are **observational**, the lack of randomization may lead to **confounding** when identifying factors that impact quality. Health services researchers have historically adopted one of two approaches to reduce **bias** [12]. The first approach involves modeling outcomes-based measures and utilizing **regression**-adjustment techniques to balance the observed confounders across groups defined by study factors, for example, hospital type. The idea is to adjust for the patient's condition prior to the initial contact with the health system. For example, to determine if patients receive poorer quality in one type of hospital compared to another type, the analysis needs to adjust for differences in coexisting conditions (*see* **Co-morbidity**) and severity of illness between the two groups . However, process-based measures are implicitly risk-adjusted by restricting the sample to those patients who are known to benefit from treatments. In estimating use of needed beta-blocker therapy, AMI patients whose ejection fraction is less than 35%, who have bradycardia, or several other observed comorbidities (Table 1), are eliminated from the analysis.

Regardless of the risk-adjustment strategy, researchers commonly invoke ignorability assumptions. That is, given the data, quality is independent of the factor (e.g. hospital type) conditional on the observed covariates. While this assumption is more likely to hold when detailed clinical data are available, researchers need to assess the validity of the assumption and adopt appropriate modeling techniques (*see* **Model, Choice of**) for causal inference with observational data, such as **propensity scores**.

A common mistake in analyzing health care quality data has been to ignore important sources of variation due to the natural **clustering** of data, such as hospital-level variation. Ignoring clustering of individuals within health care units leads to overstated precision estimates and inflated type I error rates (*see* **Hypothesis Testing**) [23]. This problem can be substantial if the objective is to make inferences about the quality of health care units. To circumvent these problems, hierarchical regression models can be used to accommodate individual-level and cluster-level **covariates**, as well as cluster-level variation (*see* **Hierarchical Models**). While a **generalized estimating equation** approach has the advantage of making no distributional assumptions about the joint distribution of quality measures over the clusters, this approach is not applicable if the primary objective is to make inference about each cluster.

A third important analytic issue relates to the fact that health services researchers collect multiple quality measures for a particular population. The multiple quality measures could be longitudinal, such as hospital-specific 30-day mortality over a 5-year period (*see* **Longitudinal Data Analysis, Overview**). Methods have been proposed to model longitudinal health care quality data [2, 5, 19] that separate longitudinal variation from sampling variation.

Alternatively, the multiple measures could consist of mixed responses, such as 30-day mortality, reperfusion therapy, needed angiography, and health-reported quality. Health services researchers have either modeled the multiple quality measures separately or pooled the measures in some fashion. Separate analyses of quality measures have several drawbacks. The numerous measures can often confuse consumers with the information [8]. If researchers are interested in identifying factors that impact quality, separate analyses provide no formal means of evaluating how similar the effects are across the various measures. Furthermore, separate analyses may be inefficient if interest centers on estimating the association between a particular factor, such as hospital type, and quality.

Pooling quality measures, for example, score the quality measure as met if the patient received any needed therapy, also have some disadvantages. Researchers are unable to isolate effects of specific factors on each quality measure. It is also difficult to arrive at a rule when the measures are made on different scales such as **binary**, continuous, or categorical. Lastly, the optimal method for combining the measures depends on the measurement process. To accommodate multiple mixed measures, latent variable models can be used to model the **correlation** among the measures [10, 14], even if the measures are made on different scales [15] (*see* **Path Analysis**).

Quality of Life and Health Status

Introduction

Clinical studies, epidemiological investigations, population surveys, and clinical practices increasingly incorporate self-reported measures of health status and quality of life. These help to determine whether treatments are doing more good than harm, whether health and quality are improving or worsening, and to see if health status differs between groups. Self-reported outcomes are often compared to clinical or performance-based measurements that remain the primary endpoints for most **clinical trials** and are important markers of disease, injury, and their trajectories. Self-reported measures of health and quality of life, however, often have more meaning to the persons affected by disease or treatment. Because perceptions of health and illness influence what people do about their health (e.g. visit doctors, go to hospital, or ignore signs and symptoms), policy makers are also increasingly interested in self-reported outcomes.

Concepts

Self-reported outcomes, referred to as *patient-reported outcomes* (*PROs*) in the context of health care, include any report coming directly from the person or persons affected by their life, health condition(s), and treatment [1]. PROs address the source of the report rather than the content. PROs not only include health status and quality of life but also reports on satisfaction with treatment and care, adherence to prescribed regimens when directly related to end result outcomes, and any other treatment or outcome evaluation obtained directly from patients through interviews, self-completed questionnaires, diaries or other data collection.

Health status, functional status, well-being, quality of life, and *health-related quality of life* are concepts that are often used interchangeably in PROs-related discourse and measurement. There is no consensus and widely adopted definition of *quality of life* because it is used in different contexts by different people. One definition is unlikely to suit all uses or individuals. There is considerable agreement, nonetheless, that the quality of life construct is more comprehensive than health status and includes aspects of the environment that may or may not be affected by health or perceived health. The *health status* concept and its domains and constructs range from negatively valued aspects of life, including death, to the more positively valued aspects such as role function and happiness. Health status is a useful concept in the context of assessing health services and treatment effectiveness. *Functional status* measures usually refer to limitations in the performance of social roles or activity limitations. The status concept is highly dependent on the perspective of the assessor and the assessed. *Well-being* measures refer to subjective perceptions, including reports of unpleasant or pleasant sensations and global evaluations of health or subjective status. Symptoms may be included in well-being measures or considered separately. Well-being and quality of life may be distinguished by the level of evaluation; that is, quality of life contains more global evaluations of life position and perspectives, and well-being contains more domain-specific perspectives such as psychological or physical [10]. It is important to note that PROs and quality of life are sometimes equated with functional status, and this labeling can be erroneous and of particular concern to persons with disabilities. Persons with functional limitations may enjoy high quality of life through environmental supports or simply through their own life perspective and evaluation of their needs and desires. Although function may be important to many evaluations of their health, health-related quality of life or quality of life should not be used as synonyms and these concepts should be identified and labeled separately, particularly when using terminology of PROs context of health care.

The boundaries of concepts and their definition depend upon the measurement objectives, the funding sponsors' motives, the users' particular concerns, and most important of all, the evidence or data on the concept and constructs [11]. Investigators may be interested in defining the health of populations to discover or document unmet needs, to determine the effect of medical interventions, or to guide allocation of resources. Traditional measures of morbidity and mortality are limited in defining health status and leave the texture of peoples' lives unexplored. Physiological measures, along the traditional endpoints in clinical trials, often bear limited relation to how affected persons are feeling. Thus, if one wishes to determine the impact of interventions on

the outcomes of real interest to the persons most affected, it is necessary to assess persons' experience through subjective evaluation and reporting of that experience.

It is important to note that some widely valued aspects of human existence are not generally defined as health status, such as a safe environment, adequate housing, guaranteed income, and freedom. These global human concerns, however, sometimes adversely affect or are affected by health status. Thus, the term *health-related quality of life* is often used to indicate that the measure is concentrated on the health concept and the field of health outcomes. *Quality of life*, however, may include all aspects of life, including the environment or externalities outside the context of healthcare.

The World Health Organization Quality of Life (WHOQOL) group, a worldwide research group organized by the **World Health Organization** has defined quality of life as "individuals" perceptions of their position in life in the context of the culture and value systems in which they live, and in relation to their goals, expectations, standards, and concerns" [20–22]. This definition reflects the growing recognition that quality of life can be inherently subjective, although normative definitions have been proposed that include more objective standards as well as perceptions of objective conditions [3, 4]. Quality of life can be used as a descriptor (i.e. the presence or absence of a characteristic of life), an evaluative statement (i.e. some value is attached to the characteristics of an individual, population, or kind of human life), or a normative or prescriptive statement, (i.e. certain norms indicate, which characteristics must be present to have a life of quality).

The WHOQOL group places quality of life squarely in the two traditions of an internal psychological and physiological mechanism producing a sense of satisfaction or gratification with life [9] and those external conditions that trigger the internal mechanism [16]. Thus, quality of life is a broad ranging concept that incorporates in a complex way, individuals' physical health, psychological state, level of independence, social relationships, personal beliefs, and their relationships to salient features of the environment [21]. Figure 1 shows this relationship between *health concepts* and *general* quality of life, and how determinants from the internal (individual) as well as the external (social and cultural) environment influence the general quality of life.

The concepts and domains included in the measurement of quality of life help in making operational definitions. Table 1 contains core concepts and domains contained in many health and quality of life measures. Table 1 and Figure 1 also demonstrate the multidimensionality of the concepts of health status and health-related quality of life, as a result require multiple indicators to measure.

How the items are arranged, and how the domains are grouped and scored varies widely. It is generally agreed that the content validity of quality-of-life measures can be judged *only* by the persons or populations being assessed (*see* **Health Status Instruments, Measurement Properties of**).

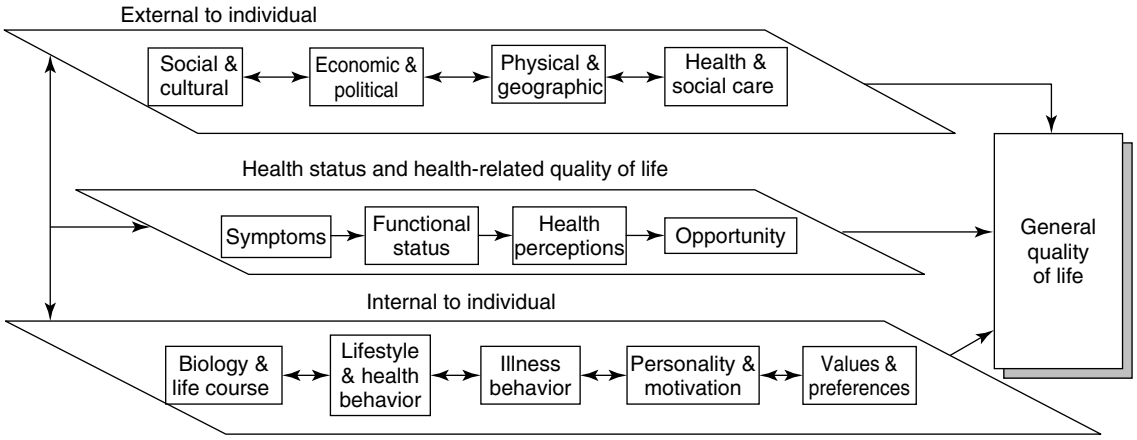

Figure 1 Relationship among quality of life and health concepts

Table 1 Concepts and domains used in defining self-reported health status, quality of life, and health-related quality of life

Concepts	Domains and *Attributes*
Symptoms	*Frequency, severity, bothersomeness* Reports of physical and psychological symptoms or sensations not directly observable, for example, energy and fatigue, nausea, irritability
Functional status	*Frequency, difficulty, severity, ability, with or without help*
Physical	Functional limitations and activity restrictions, for example, self care; walking, mobility, and sometimes sleep, and sexual function when construed narrowly
Psychological	Positive or negative affect and cognitive, for example, anger, alertness, self-esteem, sense of well-being, distress
Social	Engagement, limitations in work, school, play, household management, participation in the "community"
Health perceptions	*Frequency, severity/intensity, satisfaction*
Global	General ratings of health and quality of life, for example, satisfaction or overall well-being
Worries and concerns	About health, finances, the future
Spiritual	Meaning and purpose of life, connection to a deity, a belief system, or the universe
Disadvantage/Opportunity	*Frequency, impact* Perceptions of stigma or reports of discrimination because of health condition, reports of advantage
Resiliency	*Frequency, satisfaction, ability* Reports of ability to cope or withstand stress and illness
Environmental	*Satisfaction, importance* Evaluations of personal safety, adequacy of housing, respect, freedom, and so on
Satisfaction with treatment	*Expectations, importance, satisfaction* Reports of treatment and treatment experience
Adherence to prescribed or recommended treatment[a]	Behaviors directly linked to outcomes Reports of taking treatment, doses, attendance, or Routine behaviors like tooth-brushing intermediate to end results

[a]Included not as an end result of treatment but sometimes closely linked causally to treatment and thus a close proxy for a health status outcome. Reports of other behaviors like smoking, alcohol consumption, and so on are generally considered intermediate and not end result outcomes though this has been disputed by many.

Thus, the extent to which the domain of interest is comprehensively sampled by the items or questions in the measure can only be judged by representatives of the target population. If the target population is unable to speak for themselves, proxy judgments are considered acceptable, particularly if supported by rigorously controlled observational studies with inter-rater reliabilities. Before assuming that people cannot speak for themselves, however, they should be asked and every effort should be made to communicate with them directly. Proxy responses are not PROs.

In addition to content validity, the other **psychometric** properties of quality-of-life measures include the following: (1) specification of the measurement model including the instrument's scale and subscale structure and the conceptual and empirical basis for combining multiple items into a single score; (2) reliability, including the degree to which the instrument is free from **random error** either by testing the homogeneity of content on multi-item tests with internal consistency evaluation or testing the degree to which the instrument yields stable scores over time; (3) construct, criterion, and predictive validity wherein the logical relationships among different measures are examined; (4) responsiveness or the assessment of the ability of the measure to assess change over time when real change has occurred (longitudinal construct validation); and (5) interpretation of the effect

size, or the degree to which one can assign qualitative meaning to an instrument's quantitative scores [17].

Several concepts listed in Table 1 are considered important, but difficult to define and measure. Spirituality, often measured in end-of-life treatment evaluation and increasingly in other contexts, is rarely measured to determine generic health status even though life-threatening illness or orientation to health may be built on spiritual beliefs and practices. Resiliency can be measured as a self reported outcome of well-being, although physiologic measures may also be employed. Other concepts difficult to measure are capacity, stigma, disadvantage, and societal reaction, although self-report measures exist and major advances are being made in the analysis and interpretation of health disparities (`http://healthdisparities.nih.gov`). Both adherence to treatment and satisfaction with treatment can be measured by PROs. *Adherence* represents the patients' report of behaviors that coincide with medical or health advice, for example, to take medications, follow diets and exercise regimens, use medical devices when needed, or execute life style and behavioral change. Patient-reported measures of adherence are collected on self-reported questionnaires or interviews and often are compared to pill counts, physiological measures, or some other trace measure of adherence. Reports of adherence may be viewed both as predictors of health and treatment satisfaction or a function of health and satisfaction, and thus are not always "outcomes". Adherence is an intermediate outcome and not included as an end-result of treatment. It is discussed here to emphasize that it can be a PRO and is often considered in analyzing other outcomes.

Satisfaction with treatments and treatment experience, (i.e. care) represents salient aspects of treatment and overall evaluation of treatment experience. Ratings and reports of experience of treatment can be multidimensional or global. Global ratings of satisfaction are often positively skewed, that is patients report high levels of satisfaction, even in the face of other negative information. Rapid progress is being made to obtain patient reports of treatment satisfaction that also reflect the drivers of global satisfaction, such as expectations, outcomes, the gap between expectations and outcomes, and the importance of different attributes of treatment [14].

A large number of different examples of instruments and their development and validation process can be found in *Quality of Life Research, Journal of Clinical Epidemiology, Medical Care,* and many specialty journals. A detailed discussion of the psychometric properties and their evaluation are found in numerous places [2, 5, 6, 8, 13, 19].

Types of Measures

There are a number of ways of categorizing instruments designed to measure PROs such as health status and quality of life [7, 13]. Taxonomy of self-reported health status and quality of life measures is contained in Table 2. The measures are classified accordingly: (1) Source of the Report: information was gathered from the patient or proxy; (2) Mode of Data Collection: the data were collected through self administration, interviewer-administered, or computer administered tests; (3) Testing Content: use of adaptive or dynamic testing where the content varies for individuals and items are calibrated or standard content where everyone takes the same items; (4) Types of Scores: reflecting the level of aggregation across concepts and domains; (5) Range of Population and Concepts included or covered; and (6) Weighing System used in scoring items – whether an indicator, index, profile, or battery, instruments can be divided into two broad categories [12]. *Generic* instruments measure the full range of health and quality of life, without focusing on specific areas. They are designed for use across a wide variety of populations. *Specific* instruments are designed for application to individuals, conditions or diseases, domains, or populations. Generic and specific instruments may be *health profiles* or *utility measures* that are distinguished by having preference weights applied to the items and domains. Some utility measures, and indeed some profiles, also incorporate an index score or a single number for analyses. Utility measures, discussed more fully in **Utility in Health Studies**, are useful for economic applications, since they produce *quality-adjusted life years*, a combined measure of how long one lives as measured by survival or mortality and how well one lives, as measured by functional status and well-being.

Applications

Decision makers and analysts wanting to measure PROs should first identify the problem or application

Table 2 A taxonomy of self-reported health status and quality of life measures

Measure	Strengths	Weaknesses
Source of Report		
Person or patient	Sensations, feelings, evaluations known only to the person	When established that person cannot speak, write, or communicate to others
Proxy (Not a PRO)	Can observe and report behaviors only to patient	Cannot report feelings known
Mode of Collection		
Self-administered, with or without supervision	Privacy	Missing data, particularly by mail, and without supervision no assurance of who completed
Interviewer-administered	Control	Sensitive information like income sometimes difficult/cost
Computer-administered and/or computer-adapted	Flexibility	Cost/for persons not familiar or afraid of computer
Testing Strategy		
Dynamic or tailored content: based on health status, age, etc.	Items relevant to person More precise measurement	Requires item bank and item calibration
Standard or fixed-length content	Content same for all respondents Easy to administer	Many content items not relevant to individual Floor and ceiling effects
Types of Scores Produced		
Single *indicator* number	Global evaluation Sometimes easy to interpret	May be difficult to interpret trends
Single *index* number	Represents net impact Useful for cost effectiveness	Sometimes not possible to disaggregate contribution of domains to the overall score
Profile of interrelated scores	Single instrument Contribution of domains to overall score possible	Length may be a problem May not have overall score
Battery of independent scores	Wide range of relevant outcomes possible	Cannot relate different outcomes to common measurement scale May need to adjust for multiple comparisons May need to identify major outcome
Range of Populations and Concepts		
Generic: applied across diseases, conditions, populations, and concepts	Broadly applicable Summarizes range of concepts Detection of unanticipated effects possible	May not be responsive to change May not have focus of patient interest Length may be a problem Effects may be difficult to interpret
Specific: applied to individuals, diseases, conditions, populations, or concepts/domains	More acceptable to respondents May be more responsive to change	Cannot easily compare across conditions or populations Cannot detect unanticipated effects
Weighting System		
Utility: preference weights from patients, providers, or community	Interval scale Patient or consumer view incorporated	May have difficulty obtaining weights May not differ from statistical weights that are easier to obtain
Equal-weighting: items weighted equally or from frequency or responses	Self-weighting samples More familiar techniques Appears easier to use	May be influenced by prevalence Cannot incorporate tradeoffs

of the measure. With this information, one can then identify the desired characteristics of existing measures to be included in the assessment. For example, monitoring the health of populations and communities demands parsimonious instruments including global evaluations across a number of conditions and different population groups. For comprehensive evaluation in a clinical trial, health profiles or batteries are most appropriate according to the main effects intended and unintended or adverse consequences of treatment. For economic evaluation, utility measures are useful to produce a comparison across alternative treatments.

PROs directly from children and youth are taking greater prominence among all interested parties, following similar development as that for adults and older adults [18]. Children and youth represent a special case, however, given knowledge of variation in how and when children develop, the wide variation in willingness and ability to self-report across the age spectrum, and the "special" language of children and adolescents in different cultures of the world. Rapid progress is being made in Europe and North America, to be followed and informed by work in other parts of the world, often less accessible to Western parties.

Demand is also increasing for quality of life measures available for use in cross-cultural comparisons, which requires special attention to cultural adaptation and validation in each culture in which the measure is applied [15]. The most desirable means of development and validation is to have the goal of cross-cultural comparability in mind from the beginning. Measures developed simultaneously in different cultures have the advantage of identifying as early as possible those domains and items that are more or less valid in a particular culture or population. Translating instruments developed in one culture for use in another is more common, but the danger of this approach is the assumption that the conceptual structure, domains, and items are cross-cultural. For example, assessments of functional status that use examples such "ability to walk several blocks" run the danger that "blocks" have different if any meaning at all in different cultures. Response scale anchors, such as "quite a bit", also do not translate easily into different languages.

Testing of the psychometric properties of cross-cultural measures is similar to that for instruments used within one language or cultural group, although standards for aggregation across sites have not been rigorously applied. When it is and is not valid to use measures in different populations and to pool data across different cultures remains an area for further investigation and debate.

Conclusion

Quality of life measurements are important for measuring the impact of disease, treatment, health and social policies, and the progress of economic and social development. Developers and users should specify and label the content and type of measure for every application of a PRO and provide evidence of its appropriateness to the intended use, for validity of the measure as used in a particular case, and how to interpret results. A major challenge faces developers and user of these measures in establishing a testable theory of the expected and observed relationships among the different concepts and domains of quality of life. It is also important to establish a theory of how to link clinical variables with health-related quality of life as it is to link larger determinants of PROs such as political unrest, economic depression, inequalities, and sociocultural trends and processes [13, 23].

Researchers tend to approach the relationship inductively by collecting data and examining the correlations, but *a priori* hypotheses are important for developing systematic knowledge of how disease and treatment impacts different indicators of health outcome. The most appropriate approach to causal modeling, the use of health outcomes in **meta-analyses**, development and application of community-level indicators of health, and interpretation of observed health and quality-of-life measurements remain challenges for both the developers and uses of these measures.

Quality of Life and Survival Analysis

In clinical research, interest often centers around the survival times of patients $T(> 0)$, or, more generally speaking, the times from a suitable starting point such as, for example, time of diagnosis or randomization to the occurrence of an end point such as death or disease recurrence. For these kind of data the methodology of **survival analysis** is usually applied.

In recent years an additional end point concerned with the subjective assessment of treatment by the individual patient has been introduced which is circumscribed with the term "(health-related) *quality of life* ((H)QoL)". A large body of literature is available covering the many aspects of how to adequately and sensibly evaluate an approximation of a patient's QoL (*see*, for example, [4–7, 15], and [16]; **Quality of Life and Health Status**).

The most commonly used approach of measuring QoL is by means of standardized, self-assessed questionnaires, popular examples being the EORTC QLQ-C30 of the European Organization for Research and Treatment of Cancer, the Rotterdam Symptom Checklist (RSCL), or the Functional Assessment of Cancer Therapy (FACT). The data emerging from assessments with one of these measuring instruments consist of patients' answers to about 20 to 50 questions with mostly preformulated, ordinal answering categories. For the analysis of QoL these questions are usually condensed by suitable methods, e.g. summation over correlated questions, to yield one global, unidimensional QoL score Q or several subscores Q_j corresponding to specific QoL dimensions (*see* **Psychometrics, Overview**).

As the evaluation of changes of QoL over time is of most importance in **clinical trials**, repeated measurements on the individual patient are essential for an adequate assessment of QoL. The least necessary requirement commonly accepted is to assess QoL at baseline before treatment starts, then during and shortly after treatment to account for short-term effects, and also some time after treatment has stopped to evaluate late effects. This describes the classical measurement situation of a QoL-incorporated clinical trial, considering in parallel the length of survival via clinical follow-up and the quality of this survival by continuing QoL assessment.

Two analysis approaches are principally applicable here: analyzing length and quality of survival as two separate end points, or jointly as one combined end point. In the following we assume for simplicity that our QoL measuring instrument will provide at times $t > 0$ a unidimensional QoL variable $Q(t)$ with values standardized between a lowest possible score of 0 and a highest possible score of 1.

Separate Analysis of QoL Data Over Time

When collecting QoL data over time, the adoption of the experimental design of a classical **analysis of variance** (ANOVA) accounting for repeated measurements within patients is warranted (*see* **Analysis of Variance for Longitudinal Data**). Depending on whether normality of QoL scores, possibly after suitable **transformation**, can be assumed or not, **general linear models** or **generalized linear models** are appropriate. For standard applications in this situation the statistical methodology has been worked out and software packages like **S-PLUS**, SAS, and BMDP can be used. A review of the most important procedures with special reference to QoL data can be found in [4, 12], and [17]. However, some problems specific to QoL data have to be encountered, of which the most influential departure from straightforward applications is to deal with the situation of missing QoL data. Although **missing data** can be regarded a common problem in longitudinal sampling plans, the assumption of missing at random is generally more questionable for QoL data (*see* **Nonignorable Dropout in Longitudinal Studies**; **Bias from Nonresponse**). It has been suggested in this context that patients with either an extremely good or an extremely poor QoL will have a higher likelihood of refusing to respond to a QoL questionnaire. In the extreme, questionnaires not available due to mortality clearly are not missing at random.

Estimates can be severely biased, especially when complete case analyses are routinely applied, but also when methods are used that account for data missing at random.

Combined Analysis of Length and Quality of Survival

The separate analysis of survival times and QoL may lead to situations where a univocal decision

about treatment efficacy appears problematic especially when mortality is not negligible.

In a combined analysis of both end points, QoL data will be used in a first step to define, implicitly or explicitly, a **stochastic process** describing patients' QoL levels over time. In a direct application, the parameters of the process using either continuous or discrete time, together with a continuous or a discrete state space incorporating an absorbing death state, could be estimated depending on the availability of corresponding QoL data. In an indirect way the states of the process could be used as QoL weights for the survival times spent in these states.

Time to QoL Defined Events

The most straightforward application of a combined analysis of time and quality is by definition of an additional QoL-oriented end point such as, for example, the reaching of a deterioration in QoL of a certain amount q_0. The time T_q until this state is reached may be measured with an appropriate sampling plan and then analyzed by the classical methods of survival analysis. In this way it is possible to assess a patient's time spent alive with an acceptable QoL.

In a comparison of two radiation strategies for brain metastases in lung cancer patients, Rosenman & Choi [14] defined as such an end point the time to the first occurrence of a Karnofsky index of 60% or below. They compared product-limit estimates (*see* **Kaplan–Meier Estimator**) for the overall survival probabilities with those obtained using the times to the QoL-oriented end point. Their analysis resulted in a nonsignificant trend of favoring one treatment over the other with regard to overall survival, which drastically reverses when survival with a "good" QoL is considered. This also represents the most interesting scenario for a QoL analysis, when treatments with comparable efficacy in the primary end points can be shown to differ in an important secondary end point.

However, the choice of suitable QoL values for the definition of states usually will be arbitrary, but nevertheless might be influential for the results.

Such an approach may be extended by defining more than one QoL state in between the optimal QoL state and death. Suitable stochastic processes may be defined by modeling the times spent in the different states and the transition probabilities from one state to another. Markov-type models have been proposed for comparable situations [12] (*see* **Markov Chains**). In a full Markov model it is assumed that transitions from one QoL state to another are independent and depend only on the previously occupied state. In practice, however, the methodology of stochastic processes is applied to QoL data only rarely. The major reason is that the continuous observation of patients' QoL required for obtaining exact transition times can be regarded as infeasible in practical clinical trial settings.

Quality-Adjusted Survival Times

From the viewpoint of survival analysis it seems appealing to combine length of survival and QoL into one single end point described as *quality-adjusted survival (QAS) time*. Originally, QAS times have been introduced in the field of decision analysis where they are usually called quality-adjusted life years (QUALYs) [16].

This approach is again, but now rather implicitly, based on the stochastic process formulation of the QoL process. J different QoL states are defined only for the purpose of producing weights q_j accompanying the time T_j the patient spent in that state. QAS times are then defined by multiplying each period of the individual survival time with the weight corresponding to the QoL assessment reported by the patient, or a general **utility** assessment, and then summing these weighted times:

$$\mathrm{QAS} = \sum_{j-1}^{J} q_j T_j.$$

In this way the number of different time variables T_j representing the transition times from one state to another are condensed into one time variable representing a new quality-adjusted time scale. The conventional survival time of a patient T can be regarded as a special case of a QAS time giving constant weight equal to 1 for all time spent in the alive state and 0 after death.

A comparable QAS approach was chosen by Korn [11], who allows individual QoL measurements $Q(t)$ at arbitrary points in time $0 = t_0 < t_1 < \cdots < t_J = T$ with $Q(t) = 0$ for $t > T$, and suggests plotting $Q(t)$ vs. time t to allow a graphical representation of the development of a patient's QoL over time. The area under this quality of life curve (AUC) created by

linear interpolation of QoL between adjacent QoL measures $Q(t_j)$ and $Q(t_{j+1})$ can be interpreted either as a weighted sum of partial survival times,

$$\text{AUC} = \sum_{j=1}^{J} \frac{(t_j - t_{j-1})[Q(t_j) - Q(t_{j-1})]}{2},$$

or equivalently as a time-weighted sum of QoL scores,

$$\text{AUC} = \frac{Q(t_0)(t_1 - t_0)}{2} + \sum_{j=2}^{J-1} \frac{Q(t_j)(t_{j+1} - t_{j-1})}{2}.$$

The most important application of QAS times has been introduced by Gelber et al. [8] with their definition of TWiST (time without symptoms and toxicity) or, later, Q-TWiST (quality-adjusted TWiST). TWiST was proposed as an additional new end point in a clinical trial of adjuvant therapy in patients with advanced breast cancer. The apparent benefit of chemo- and/or endocrine therapy with respect to disease-free and overall survival is thereby balanced against the treatments' toxicity and side-effects. Formally, both the times in which a patient suffered severe side-effects during the treatment period T_{TOX} and the times after a relapse T_{REL} are subtracted from his/her total survival time T. In the terminology of QAS this is equivalent to attaching a weight of 0 to both states:

$$\begin{aligned} T_{\text{TWiST}} &= 0 \times T_{\text{TOX}} + 1 \times T_{\text{TWiST}} + 0 \times T_{\text{REL}} \\ &= T - T_{\text{TOX}} - T_{\text{REL}} \end{aligned}$$

In Q-TWiST, weights q_j greater than 0 will allow positive partial QAS times from the states toxicity and relapse:

$$\begin{aligned} T_{\text{QTWiST}} &= q_{\text{TOX}} \times T_{\text{TOX}} + 1 \times T_{\text{TWiST}} \\ &\quad + q_{\text{REL}} \times T_{\text{REL}} \\ &= T - (1 - q_{\text{TOX}})T_{\text{TOX}} - (1 - q_{\text{REL}})T_{\text{REL}}. \end{aligned}$$

A natural approach for an analysis would be to use the QAS time of each patient instead of the conventional survival time and then apply the usual methods of survival analysis. A simple treatment comparison could, for example, be based on a comparison of the distribution functions of the QAS times for each treatment $\Pr(\text{QAS} > t)$. If all QAS times were observed, this would be unproblematic.

However, Gelber et al. [8] noted that, when censored observations occur, the use of QAS times can lead to seriously biased estimates of the corresponding QAS probabilities. They show that transforming the original survival time scale to a QAS time scale introduces informative **censoring**. A reason for this bias is the fact that patients with low QoL weights can only slowly accumulate their QAS time and will therefore more likely have earlier censoring than those with higher QoL weight. The inclusion of a relatively large proportion of patients with poor QoL in the "early" risk set leads to an underestimation of the corresponding hazard function for QAS time. In a simple, hypothetical, example, Glasziou et al. [9] illustrate the severity of the bias.

Korn [11] proposes a modified Kaplan–Meier estimate for QAS that aims to reduce this bias. His conditional independence estimator (CIE) is derived under the assumption that the censoring distribution in small time intervals is independent of the QoL score just before that interval. In practice, the more frequent QoL is assessed, the more bias reduction might be achieved. However, the CIE still remains asymptotically biased, but the bias will always be smaller than that of the naive product-limit estimate.

Another drawback of the CIE is that Korn's assumption of conditional independence will in general not be fulfilled, and it will remain difficult to quantify the amount of bias for a specific trial based on the trial data alone. Recently Zhao & Tsiatis [18] for the first time proposed an asymptotically **consistent** estimator for the distribution of QAS times, applying the method of weighted estimating equations (*see* **Estimating Functions**) according to Robins & Rotnitzky [13].

One solution that avoids the bias in the estimation of the distribution of QAS times introduced by the informative censoring is by a partitioned survival analysis [7]. This is principally applicable when QoL states can be defined such that patients may pass the QoL states only in descending order. In this application QAS times are not calculated on an individual basis, but, instead, mean marginal transition times for each health state are calculated by integrating over the corresponding survival functions. If censored observations are present, these means have to be restricted to some upper limit $M < t_{\max}$ being the largest censored survival time. In a second

step, weighted sums of these means are calculated according to the definition of the individual QAS times, again using the corresponding weight of each health state q_j. For Q-TWiST this leads to

$$E(T_{\text{Q-TWiST}}) = \int_0^M S_{\text{OS}}(t)\,\mathrm{d}t - (1 - q_{\text{TOX}}) \times \int_0^M S_{\text{TOX}}(t)\,\mathrm{d}t - (1 - q_{\text{REL}}) \times \int_0^M S_{\text{REL}}(t)\,\mathrm{d}t.$$

Estimates of these restricted means are obtained by inserting the corresponding product-limit estimators $\hat{S}_j(t) = \Pr(T_j > t)$. Mean QAS times estimated for different patient groups can be used for univariate treatment comparisons [9].

In a number of papers Cole et al. [1–3] have extended the methodology of partitioned survival analysis to adapt to further models used in survival analysis. To allow for the inclusion of **covariates** additional to treatment **Cox's** (proportional hazards) **regression models** have been proposed for Q-TWiST [2]. To overcome some of the limitation of the restricted means, parametric models have been proposed to predict Kaplan–Meier estimates beyond the restriction time M [1]. One of the advantages of the Q-TWiST methodology is the ability to perform **meta-analyses** over different trials without having used the same QoL questionnaire. The methodology and an example using data from eight trials of adjuvant chemotherapy trials in breast cancer is presented in [3].

If the choice of appropriate weights for the health states is in doubt, then a threshold utility analysis, originally called "inverse inference" by Hilden [10], provides an informative way to display how changes in the QoL weights q_j influence trial results based on the definition of corresponding QAS times. In the simple Q-TWiST model of two QoL states, treatment comparisons are calculated within a particular data set in dependence of all possible combinations of the QoL weights (q_{REL}, q_{TOX}). The results of this estimation process may be displayed graphically in a plane spanned by (q_{REL}, q_{TOX}). A threshold line identifying those values (q_{REL}, q_{TOX}) that yield treatment equivalence with regard to QAS, as well as areas of significant treatment differences, could be highlighted.

It is interesting to note in this context that the edges of the unit square of (q_{REL}, q_{TOX}) correspond to the situations usually considered in survival analysis: for $q_{\text{TOX}} = 1$ and $q_{\text{REL}} = 1$, QAS time reduces to the overall survival time, for $q_{\text{TOX}} = 1$ and $q_{\text{REL}} = 0$ to disease-free survival time and for $q_{\text{TOX}} = 0$ and $q_{\text{REL}} = 0$ to TWiST. This allows the conventional end points of survival analysis to be directly linked to all theoretically possible QAS times. The major advantage of a threshold utility analysis is that it allows individual patients or their physicians to estimate a preferable treatment according to their individual choices of weights for the QoL states.

Decisions on an overall treatment superiority might also be based on an optimality of one treatment over another for all possible weights, or at least in a markedly larger area.

Discussion

The subjective assessment of the impact of treatments on the individual patient using QoL questionnaires is becoming standard practice in clinical research. The adequate sampling plan for obtaining QoL data is that of a classical repeated measurement design (*see* **Longitudinal Data Analysis, Overview**). A suitable analysis of such data could rely on well-known procedures based on linear or generalized linear models if mortality or censoring did not occur. However, in the majority of clinical trials, censored observations will be inevitable, and mortality usually the primary end point. Treating QoL measures after disease recurrence or death as missing data, or assigning it an arbitrary low value, may lead to uninterpretable results. In this situation an integration of QoL measurements into the conventional survival analysis methodology that accounts for censoring seems sensible.

With the definition and use of QAS times, however, a number of statistical and conceptual problems arise. The obvious definition of a QAS time scale for an individual introduces informative censoring which prevents a direct adaption of methods of survival analysis to QAS time. At the moment the availability of suitable unbiased statistical estimation procedures is limited.

From a conceptual point of view the use of QAS times is the subject of much criticism, too. The major criticism is that this procedure leads to an explicit equation of qualitatively differing years of survival.

Assume the four different scenarios of: (i) three years spent with perfect QoL ($q_j = 1$); (ii) four years with a moderately impaired QoL ($q_j = 0.75$); (iii) six years with medium QoL ($q_j = 0.5$); and (iv) 15 years with severely impaired QoL ($q_j = 0.2$). Each of these scenarios leads formally to the same QAS time of three years. Forcing these scenarios of different life experiences into numerical equivalence can be regarded as extremely simplifying. Applied routinely, e.g. for allocating resources in health care programmes, QAS times may lead to far-reaching consequences [16] (*see* **Health Services Research, Overview**). It is therefore necessary that any QAS time analyses should always be accompanied by the corresponding, conventional survival analyses, and should not rely on one simple set of QoL weights, but be subject to additional **sensitivity analyses** [4].

MANFRED OLSCHEWSKI

Quality of Life

Background

The term *quality of life* (QoL) has been used in a wide variety of ways. In the broadest definition, the quality of our lives is influenced by our physical and social environment as well as our emotional and existential reactions to that environment. From a societal or global perspective, measures of QoL may include social and environmental indicators, such as whether there is affordable housing and how many days of air pollution there are each year in a particular location. These are general issues that concern everyone in a society. Kaplan and Bush [22] proposed the use of the term *health-related* **quality of life** (HRQoL) to focus on the specific role of health effects on the individual's perceptions of well-being, distinguishing these from job satisfaction and environmental factors. In the medical literature, the terms QoL and Health-related quality of life (HRQoL) have become interchangeable.

Health-related Quality of Life

The **World Health Organization** (WHO) defined *health* in 1948 [38, 39] as a "state of complete physical, mental, and social well-being and not merely the absence of infirmity and disease". This definition reflects the focus on a broader picture of health. Wilson and Cleary [37] propose a conceptual model of the relationships among health outcomes. There are five levels of outcomes that progress from biomedical measures to quality of life reflecting the WHO definition of health. The biological and physiological outcomes include the results of laboratory tests, radiological scans, and physical examination as well as diagnoses. Symptom status is defined as "a patient's perception of an abnormal physical, emotional, or cognitive state". Functional status includes four dimensions: physical, physiological, social, and role activity. General health perceptions include the patients' evaluation of past and current health, their future outlook, and concerns about health. All these factors subsequently influence the overall evaluation of quality of life (see Figure 1).

Although various definitions of HRQoL have been proposed during the past decade, there is general agreement that HRQoL is a multidimensional concept that focuses on the *impact* of disease and its treatment on the well-being of an individual. Cella and Bonomi [2] state

> "Health-related quality of life refers to the extent to which one's usual or expected physical, emotional and social well-being are *affected* by a medical condition or its treatment."

We may also include other aspects like economic and existential well-being. Patrick and Erickson [29] propose a more inclusive definition that combines quality and quantity.

> "the value assigned to duration of life as modified by the impairments, functional states, perceptions and social opportunities that are influenced by disease, injury, treatment or policy."

All of these definitions emphasize the subjective nature of the evaluation of HRQoL, with a focus on its assessment by the individual. It is important to note that an individual's well-being or health status cannot be directly measured. We are only able to make inferences from measurable indicators of symptoms and reported perceptions.

Often the term *quality of life* is used when any *patient-reported outcome* is measured. This has led to both confusion and controversy. Side effects and symptoms are not equivalent to HRQoL, although clearly they influence an individual's evaluation of quality of life. While symptoms are often part of the assessment of HRQoL, solely assessing symptoms is a simple, convenient way of avoiding the more complex task of assessing HRQoL.

Measuring Health-related Quality of Life

Guyatt et al. [19] define an *instrument* to include the questionnaire, the method of administration, instructions for administration, the method of scoring and analysis, and interpretation for a **health status measure**. All these aspects are important when evaluating a measure of HRQoL.

Health Status versus Patient Preferences

There are two general types of HRQoL measures, health status assessment, and patient preference assessment [33, 40]. The development of these two forms is a result of the differences between the perspectives of two different disciplines:

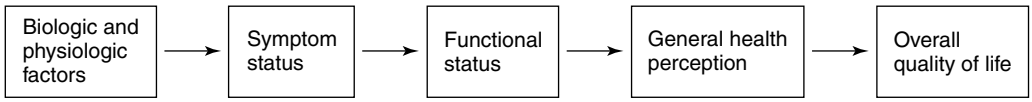

Figure 1

psychometrics and **econometrics**. In the health status assessment measures, multiple aspects of the patient's perceived well-being are self-assessed and a score is derived from the responses on a series of questions. This score reflects the patient's relative HRQoL compared with other patients and to the HRQoL of the same patient at other times. These measures are primarily designed to compare groups of patients receiving different treatments or to identify change over time within groups of patients. As a result, these measures have been used in clinical trials to facilitate the comparisons of therapeutic regimens. The assessments range from a single global question asking patients to rate their current quality of life to a series of questions about specific aspects of their daily life during a recent period of time. Among these health status measures, there is considerable range in the context of the questions with some measures focusing more on the perceived impact of the disease and therapy (How much are you bothered by hair loss?), other measures focusing on the frequency and severity of symptoms (How often do you experience pain?), and still others assessing general status (How would you rate your quality of life?).

Measures in the second group, patient preferences, are influenced strongly by the concept of *utility* (*see* **Utility in Health Studies**) borrowed from econometrics, which reflects individual decision making under uncertainty. These preference assessment measures are primarily used to evaluate the trade-off between the quality and quantity of life. Values of utilities are always between 0 and 1 with 0 generally associated with death and 1 with perfect health. Examples include **time trade offs** [24], **standard gamble** [32], and *multiattribute assessment measures* [5, 10]. Time trade-off utilities are measured by asking respondents how much of the time they expect to spend in their current state would they give up for a reduced period of time in perfect health. If, for example, a patient responded that he would trade five years in his current state for four years in perfect health (trading one year), the resulting utility is 0.8. Standard gamble utilities are measured by asking respondents to identify the point at which they become indifferent to the choices between two hypothetical situations. Suppose a patient is presented with two treatment alternatives, one option is a radical surgical procedure with no chance of relapse but significant impact on HRQoL and the other option is watchful waiting, with a chance of progressive disease and death. The chance of progressive disease and death is raised or lowered until the respondent considers the two options to be equivalent. Assessment of time trade-off and standard gamble utilities requires the presence of a trained interviewer or specialized computer program. Because of these resource needs, these approaches are generally too time- and resource-intensive to use in a large clinical trial. Multiattribute assessment measures combine the advantages of self-assessment with the conceptual advantages of utility scores. Their use is limited by the need to develop and validate the methods by which the multiattribute assessment scores are converted to utility scores for each of the possible health states defined by the multiattribute assessments. For example, the EuroQoL scale, also known as the EQ-5D, is a standardized non–disease-specific instrument for describing and evaluating HRQoL [3]. The EQ-5D covers five dimensions of health: mobility, self-care, role (or main) activity, family and leisure activities, pain and mood. Within each dimension, the respondent chooses one of three items that best describes his or her status. Weights are used in scoring the responses, reducing the 243 (3^5) possible health states to a single utility score. Utilities have traditionally been used in the calculation of quality-adjusted life years (QALYs) for economic evaluation (cost-effectiveness) and policy research as well as in analytic approaches such as Q-TwiST [14, 15]. It is important to note that the utility one gives to a hypothetical situation has been seen to vary from what the individual gives when the situation is real; results of any analysis should be interpreted carefully from that perspective.

Objective versus Subjective

Health status measures differ among themselves in the extent to which they assess observable phenomena

or require the respondent to make inferences. These measures may assess symptoms or functional benchmarks wherein individuals are asked about the frequency and severity of symptoms or whether they can perform certain tasks such as walking a mile. The measures may also, or instead, assess the impact of symptoms or conditions by asking individuals how much the symptoms *bother* them or *interfere* with their usual activities. Many instruments provide a combination. The value of each will depend on the research objectives: Is the focus to identify the intervention with the least severity of symptoms or to assess the impact of the disease and its treatment?

There has been considerable discussion of whether subjective assessments are less valid and reliable than objective measures. This misconception is generally based on the observation that patient ratings do not always agree with ratings of trained professionals. If we take the ratings of these professionals as constituting the **gold standard**, we are ignoring the valuable information of how the patient views his or her health and quality of life, especially the aspects of emotional and social functioning. There is measurement error in both subjective and objective assessments; neither is necessarily more accurate or precise in all circumstances. Most widely used measures of HRQoL are the product of careful development resulting in a measure that is highly reliable, sensitive to change with good **predictive** validity and minimal measurement error. In contrast, some of the biomedical endpoints that we consider objective can include a demonstrably high degree of measurement error (e.g. blood pressure), **misclassification** among experts, or have poor predictive and prognostic validity (e.g. pulmonary function tests) [36].

Generic versus Disease-specific Instruments

There are two basic types of health status measures – generic and disease-specific. The generic instrument is designed to assess HRQoL in individuals with and without active disease, and across disease types (e.g. heart disease, diabetes, depression, cancer). The Medical Outcomes Study Short Form (MOS SF-36) is an example of a generic instrument [35]. The broad item content of a generic instrument is an advantage when comparing vastly different groups of subjects or following subjects for extended periods after treatment has ended. Disease-specific instruments narrow the scope of assessment and address in a more detailed manner, the impact of a particular disease or treatment (e.g. joint pain and stiffness in patients with arthritis or treatment toxicities in patients with cancer) [12]. As a result, they may be more sensitive to smaller, but clinically significant changes induced by treatment [28].

Global Index versus Profile of Domain-specific Measures

HRQoL measures come in a variety of forms reflecting their intended use. The major distinction is between an index and a profile. *Profiles* consist of multiple scales that reflect the multiple dimensions of QoL such as the physical, emotional, functional, and social well-being of patients. In most instruments, each scale is constructed from the responses to multiple questions (often referred to as items). Two methods of construction are used for the creation of *indices*. In the first, a single question is used to assess the subject's assessment of quality of life. In the latter, developers provide methods to combine responses to multiple questions to provide a single index of QoL.

The advantage of the single index is that it provides a straightforward approach to decision making, which may be required in settings such as clinical trials where QoL is the primary outcome. Indices that are in the form of utilities are used in **cost-effectiveness** analyses performed in pharmacoeconomic research. On the other hand, a profile of the various domains reflects the multidimensional character of quality of life [1]. There are limitations that should be considered when using either approach. First, there is always a set of "values" being imposed when an index is constructed. These values may come from each individual's concept of what is meant by quality of life when a single question is asked, or the values that a developer assigns to the construction of the index. The values may be as arbitrary as the number of questions that are used to assess each domain, or statistically derived to maximize discrimination among different groups of patients. It is impossible to construct an index that aggregates the multiple dimensions of HRQoL that will be suitable in all contexts. The important point is that one should be aware of the weights (values) that are placed on the different domains in the interpretation of the results. A single index measuring HRQoL cannot capture changes in individual domains. For example, a particular intervention may produce benefits in one dimension and

deficits in another that cancel each other and are thus not observed in the aggregated score.

Response Format

Questionnaires may also differ in their response format. The most widely used format is the **Likert scale**, which contains a limited number of **ordered responses** that have a descriptive label associated with each level. Variations include scales in which only the extremes are anchored with a descriptive label. Individuals can discriminate at most seven to ten ordered categories [25, 31] and reliability and sensitivity to change drops off at five or fewer levels.

Dichotomous response formats and visual analog scales (VAS) (*see* **Pain**) are also used. The VAS consists of a line, generally 10 cm in length, with descriptive anchors at each end of the line. The respondent is instructed to place a mark on the line. The original motivation of the VAS was that the continuous measure could potentially discriminate more effectively than a Likert scale; this has not generally been true in most **validation studies** where both formats have been used. The VAS format has several limitations. It requires a level of eye–hand coordination that may be unrealistic for anyone with a neurological condition, those experiencing numbness and tingling side effects of chemotherapy, and for the elderly. VAS precludes telephone assessment and interview formats. Finally, it requires an additional data management step in which the position of the mark is measured. If forms are copied rather than printed, the full length of the line may vary, requiring two measurements and additional calculations. A compromise format is a numerical analog where patients provide a number between 0 and 100 (see Table 1).

Period of Recall

QoL scales often request individuals to base their evaluation over a specified period, such as the last seven days or the last four weeks. The time frame must be short enough to detect differences between treatments and long enough to minimize short-term fluctuations (noise) that do not represent real change [26]. In addition, the reliability with which individuals can rate aspects of their QoL beyond several weeks must be called into question. Scales specific to diseases or treatments where there can be rapid changes will have a shorter recall duration, whereas instruments designed for assessment of general populations will often have a longer recall duration. Longer time frames may also be appropriate when assessments are widely spaced (e.g. annually).

Scoring

The majority of HRQoL scales that are derived from a series of questions with a Likert response format are scored by summing or averaging the responses after reverse coding negatively worded questions. There are more complicated weighting schemes based on **factor analytic** weights; item response or **Rasch models** are rare but may become more common in **computer assisted testing**. To facilitate interpretation, there has been an increasing tendency to rescale this result so that the possible range of responses is 0 to 100 with 100 reflecting the best possible outcome. Most instruments also have an explicit strategy for scoring in the presence of **missing responses** to a small proportion of questions. The most common method is to impute the missing response using the average of the other responses in the specific subscale when at least half of the questions have been answered.

Table 1 Example of a Likert and visual analog scale

Likert Scale					
	Not at all	Slightly	Moderately	Quite a bit	Greatly
How bothered were you?	0	1	2	3	4
Visual analog scale					
How bothered were you?	|- -|				
	Not at all				Greatly

In contrast, utilities are always on a 0 to 1 scale. Scoring depends on the method used to elicit the preferences. Scores derived from multiattribute assessment are instrument specific.

Development and Validation of HRQoL Measures

Development

The effort and technical expertise required to develop a new instrument is generally underestimated, with most efforts taking three to five years (or more) rather than the couple of weeks initially expected. Researchers contemplating this step should research the existing instruments as well as the various methodologies for instrument development and validation including traditional psychometric theory and item response theory. To fully develop an instrument from the beginning requires multiple studies, hundreds of observations, years of testing and refinement.

Validation

There are numerous procedures for establishing the psychometric properties of an instrument. For a formal presentation, the reader is referred to one of the many available books. A partial list specific to HRQoL includes Streiner and Norman [31], McDowell and Newell [23], Juniper et al. [21] and Naughton et al. [27], Frank-Stromborg and Olsen [11], Staquet, Hays, and Fayers [30] and Fayers and Machin [9].

The validity of a measure in a particular setting is the most important and the most difficult aspect to establish. This is primarily because HRQoL is an unobservable latent variable (*see* **Path Analysis**) and there are no gold standards against which the empirical measures of validity can be compared. Nonetheless, we can learn a good deal about an instrument by examining the instrument itself and the empirical information that has been collected. For example, we can demonstrate that the measure behaves in a manner that is consistent with what we would expect and correlates with observable things that are believed to be related to HRQoL.

Face validity refers to the content of an instrument: Does the instrument measure what it proposes to measure? and Are the questions comprehensible and without ambiguity? The analogy is whether an archer has chosen the intended target. The wording of the questions should be examined to establish whether the content of the questions is relevant to the population of interest. Although experts (physicians, nurses) may make this evaluation, it is advisable to verify the face validity with patients as they may have a different perspective. *Criterion validity* is the strength of a relationship between the scale and a gold standard measure of the same construct. As there is no gold standard for the dimensions of quality of life, we rely on the demonstration of *construct validity*. This is the evidence that the instrument behaves as expected and shows similar relationships (*convergent validity)* and the lack of relationships (*divergent validity*) with other reliable measures for related and unrelated characteristics (*see* **Health Status Instruments, Measurement Properties of**). Confirmatory factor analysis **structural equation modeling** is one of the statistical methods used to support the construct validity or proposed structure (subscales) of an instrument. Application may be used to confirm that a scale is unidimensional. Results from exploratory factor analysis (*see* **Exploratory Data Analysis**) in selected populations should be interpreted cautiously especially when the sample is homogeneous with respect to stage of disease or treatment [8].

The next question is: Would a subject give the same response at another time, if they were experiencing the same HRQoL? This is referred to as *test–retest reliability* (*see* **Agreement, Measurement of**). If there is a lot of variation (noise) in responses for subjects experiencing the same level of HRQoL, then it is difficult to discriminate between subjects who are experiencing different levels of HRQoL or change in HRQoL over time. This is generally measured using Pearson or intraclass **correlations** when the data consists of two assessments. Finally, we ask: Does the instrument discriminate among subjects who are experiencing different levels of HRQoL? and Is the instrument sensitive to changes that are considered important to the patient? These characteristics are referred to as *discriminant validity* and *responsiveness*. Reliability can be characterized using the analogy of the archer's ability to hit the same target repeatedly with consistency. *Internal consistency* (*see* **Validity and Generalizability in Epidemiologic Studies**) refers to the extent to which items in the same scale (or subscale) are interrelated;

specifically the extent to which responses on a specific item increase as the responses to other items on the scale increase. **Cronbach's** coefficient α is typically reported. For the assessment of group differences, values above 0.7 are generally regarded as acceptable though values above 0.8 (good) are often recommended. For assessment of individual patients in clinical practice, it is recommended that the value should be above 0.9.

Responsiveness is the ability of a measure to detect changes that occur as the result of an intervention [16, 17]. Here the analogy is whether the archer can respond to change and hit various areas on the target consistently. One factor that can affect responsiveness is a *floor* or *ceiling effect*. If responses are clustered at either end of the scale, it may not be possible to detect change due to the intervention.

Translation/Cross-cultural Validation

When HRQoL is measured in diverse populations, attention needs to be paid to the methods of translation and cross-cultural validation. Backward and forward translations must be performed using the appropriate native language at each step. There are numerous examples where investigators have found problems with certain questions as questionnaires are validated in different languages and cultures. Techniques such as cognitive testing, with subjects describing verbally what they are thinking as they form their responses, have been very valuable when adapting a questionnaire to a new language or culture. This should be followed by formal validation studies designed to generate both standard reliability and validity statistics. Item response theory (IRT) methods (*see* **Rasch Models**) and Rasch models have facilitated the examination of differential item functioning across cultures or languages.

Item Banking and Computer-adaptive Testing

There has been considerable effort over the last decade to develop *item banks,* large databases of responses to individual questions from multiple questionnaires. One objective of this effort is to establish a method of translating results obtained on one scale to another scale. The second application, referred to as *computer-adaptive testing*, is an attempt to reduce the subject burden during testing by selectively presenting questions that will best discriminate in the range of function of that subject. Specifically, if an individual's response to the first question indicates a high level of functioning, that individual will not be presented with questions designed to discriminate among individuals with low levels of functioning. In both cases, IRT methods play a predominant role.

Use in Research Studies

> "Implicit in the use of measures of HRQoL, in clinical trials and in effectiveness research, is the concept that clinical interventions such as pharmacologic therapies, can affect parameters such as physical function, social function, or mental health." [37]

All principles of good design and analysis are applicable, but there are additional requirements specific to HRQoL. These include selection of an appropriate measure of HRQoL and the conduct of an assessment to minimize any bias. The HRQoL instruments should be selected carefully, ensuring that they are appropriate to the research question and the population under study. New instruments and questions should be considered only if all other options have been eliminated. Among the most common statistical problems are **multiple endpoints** and **missing data**.

Instrument Selection

Ware et al. [34] suggest two general principles to guide the selection of instruments to discriminate among subjects or detect change in the target population. "When studying general populations, consider using positively defined measures. Only some 15% of general population samples will have chronic physical limitations and some 10 to 20% will have substantial psychiatric impairment. Relying on negative definitions of health tells little or nothing about the health of the remaining 70 to 80% of general populations. By contrast, when studying severely ill populations, the best strategy may be to emphasize measures of the negative end of the health status continuum."

In cases where the population is experiencing periods of health and illness, very careful attention must be paid to the selection of the instrument balancing the ability to discriminate among subjects during different phases of their disease and treatment with appropriateness over the length of the study. One cannot assume that a questionnaire that works well in

one setting will work well in all settings. For example, questions about the ability to perform the tasks of daily living, which make sense to individuals who are living in their own homes, may be confusing when administered to a patient who has been in the hospital for the past week or is terminally ill and receiving hospice care. Similarly, questions about the amount of time spent in bed provide excellent discrimination among ambulatory subjects, but not among hospitalized patients.

There is a temptation to pick an HRQoL instrument, become familiar with it, and use it in all circumstances. Flexibility must be maintained in the choice of instrument to target the specific research or clinical setting, the specific population, the challenges associated with administration, and the problem of respondent burden.

Multiple Endpoints

Because QoL is a multidimensional concept that is generally measured using several scales that assess functional, physical, social, and emotional well-being, there are multiple endpoints associated with most QoL evaluations. **Longitudinal data** arise in most HRQoL investigations because we are interested in how a disease or an intervention affects an individual's well-being over time. Because of the multidimensional nature of HRQoL and repeated assessments over time, research objectives need to be explicitly specified and an analytic strategy developed for handling multiple endpoints. Although adequate for univariate outcomes such as survival, statements such as "To compare the quality-of-life of subjects on treatments A and B" are insufficient; details should include domains, population, and the time frame relevant to the research questions. Strategies addressing the **multiplicity** of endpoints include limiting confirmatory analyses, construction of summary measures/statistics [6] and **multiple comparison** procedures. Examples of summary measures that reduce multiplicity over time include area-under-the-curve (AUC) and average rates of change (slope); their interpretation is straightforward. Construction of these measures is complicated by the presence of missing data. QoL indices are used to reduce the multiplicity across domains.

Missing Data

Although analytic strategies exist for missing data, their use is much less satisfactory than initial prevention. Some missing data, such as that due to death, is not preventable; however, missing data should be minimized at both the design and implementation stages of a clinical trial [7, 26, 41].

The protocol and training materials should include specific procedures to minimize missing data. A practical schedule with HRQoL assessments linked to planned treatment or follow-up visits can decrease the number of missing HRQoL assessments. When possible, it is wise to link HRQoL assessments with other clinical assessments.

Interpretation/Clinical Significance

All new measures take time to become useful to clinicians or patients. This process requires that we define ranges of values that have clinical implications. When measures such as hemoglobin and blood pressure were first used, there was a period during which normal ranges were established; once the ranges were available, the readings became clinically useful. Nor are the rules that have been developed simple, since the benefits/risks of a change in either measure depends on where the individual started, age, gender, and current condition or lifestyle (pregnancy or about to run a marathon). Interpretation of measures of QoL is similarly complex.

Clinical significance has various meanings depending on the setting. When a treatment decision is required, there is an implied ordering of information into categories (often dichotomous) that correspond to various decisions. For example, one might consider a patient's current hemoglobin as well as gender and clinical history when making a decision to treat, monitor closely, or do nothing. In contrast, when the situation calls for evaluation of effectiveness of an intervention based on the information from a randomized clinical trial, the decision is generally based on continuous or ordered information such as grams/dL of hemoglobin. Thus, meaningful differences/changes in QoL measures will depend on whether a decision is being made for an individual or for a group of individuals. There are two general strategies used to define the *clinical significance* of QoL scores, distribution-based and anchor-based methods. There

is no single approach that is appropriate to all settings and none of the methods is without some limitations.

Distributional Methods

One general approach is based on the distribution of scores expressed as the relationship (ratio) between the magnitude of an effect and a measure of variability [3, 18]. The magnitude of the effect may be either the difference between two groups or the change within a group. Measures of variability include the **standard deviation** of a reference group, the standard deviation of change, and the **standard error** of measurement. A distributional method was used by Cohen [4] in his criteria for meaningful effect or "effect size" (*see* **Outcome Measures in Clinical Trials**) in psychosocial research. The major advantage is that values are relatively easy to generate from validation studies or clinical trials. There are a number of limitations. Many clinicians are unfamiliar with "effect size" and skeptical about defining meaningful differences solely on the basis of distributions. These values are generally applicable to groups. Measures of variability can differ across studies being affected by the selection criteria, which can influence the heterogeneity of the sample. Finally, one still needs to make a decision about the size of the effect that is relevant in any particular setting, requiring a value judgment of risks and benefits.

Anchor-based Methods

Anchor-based methods are based on the relationship between scores on the QoL measure and an independent measure or anchor. Examples of anchors are the patient's rating of health, disease status, and treatments with known efficacy. The anchor must be interpretable and there needs to be an appreciable association of the anchor with QoL. Within this group of methods, there are numerous approaches, none of which fits all needs. One concern is that the motivation for QoL measurement is to move beyond traditional clinical endpoints, but we appear to be using these same clinical endpoints to "justify" and interpret QoL measures.

One approach is to classify subjects into groups based on the anchor, and estimate differences in the QoL measures. For example, one might form three groups based on function corresponding to no, moderate, or severe limitations and observe average scores of 80, 70, and 50 respectively. The mirror image of that approach is to classify subjects using QoL measures and describe the outcomes in terms of either an external or internal anchor. In the first case, one might observe that a group of patients with a mean score of 80 experience 5% mortality, while another group of patients with a score of 60 experience 20% mortality. In the latter case, one might observe that 32% of those who score 50 on the SF-36 physical function scale can walk a block without difficulty, in contrast to 50% who score 60.

Another approach is to elicit a value, a minimum important difference (MID) from clinicians or patients; that is, the smallest difference in the scores that is perceived as important, either beneficial or harmful, and which would lead the clinician to consider a change in the patient's management [20]. Within-patient transitions are yet another approach that has been used. Individuals are asked to judge, during a specified time, whether they have improved, not changed, or gotten worse. The corresponding changes in QoL scores are then summarized within each group. The advantage of this approach is that it is easy to assess and appears simple to interpret. However, there is an accumulation of evidence that the retrospective assessment reflects the subject's current QoL rather than the change.

Conclusions

In the health sciences, QoL assessment is now an integral component of patient-focused research. Given the increasing complexity of health care, the extent of chronic illness, and the variety of therapies that generally do not improve survival but often only decrease morbidity, measurement of HRQoL outcomes provides an additional evaluation of treatment benefit. These developments have occurred in the latter half of the twentieth century, a period in which individual preferences and autonomy have been increasingly valued in many societies, especially in Europe and North America. In parallel, reliable and valid measurement strategies have evolved from social science research to make it possible to quantify subjective assessments of health status and QoL. Further, advances in statistical methodology have been integrated into research designs, making it possible to interpret these assessments in a variety of research and clinical settings. A major aspect of this

work has been to bridge the gap between psychometric/statistical theory and the language and realities of clinical practice. There are many who remain skeptical about the contributions of QoL assessments to treatment decisions and health care policies; however, the more these measurements are integrated into research, the greater the likelihood that the outcomes that matter to patients will ultimately be incorporated into medical care [13]. Many of the studies that have failed to detect changes have suffered from nonignorable missing data and the use of inappropriate analytic methods. Therefore, statisticians have an important role to play in the design and analysis of studies with QoL outcomes, if the studies are to produce interpretable results. In this article, we have provided a perspective on where we are in QoL assessment, as well as an honest evaluation of some of the limitations of this methodology. Much additional work needs to be done, and fortunately there is considerable international interest in addressing the challenges of this young measurement science.

Quantal Response Models

In 1981 a new group of anti-parasite drugs, called avermectins, was successfully introduced to treat internal parasites in cattle. However, the drugs remain in low concentrations in the cattle dung, and there was concern that this would also kill the organisms that degrade the dung. The type of experiment needed to investigate this is a quantal response experiment: a particular organism was selected – the common yellow dung fly – and exposed in groups to different concentrations of the drug for a fixed time. The result of such an experiment is then a set of proportions of the kind displayed (for a different example) in Figure 1.

Quantal response data arise in many studies. If one is interested in an effect on human beings, such as a possible carcinogenic response, then typically the substance investigated would be applied to an alternative animal, in the hope that the conclusions there could be extrapolated to different animals of interest. Care is needed in the selection of appropriate animal models. Quantal data also occur in industrial reliability testing, and from observational studies, an example of which is shown in Figure 1. The response of interest here is the onset of menarche in young girls, grouped into a range of different age-bands. It is obviously far easier to design an experimental study than an observational study. Experiments need to be tailored to the type of organism involved, and can be limited by considerations of space, time, and expense – an experiment on insects would be conducted in a very different way from one on large mammals.

The quantal response experiment has obvious similarities with a standard regression setup, but the response variable at each dose/age-group, etc. is now discrete (*see* **Binary Data**). Frequently it can be assumed that individuals respond independently, both within and between the different dose levels, etc. resulting in a likelihood function which is a product of binomial probabilities. There are many variations on the simple quantal response experiment described here, and we examine several of these later. For instance, a response may be discrete but not binary, as when fetuses are classified as dead, alive, or deformed; animals may not respond independently, which could occur if they are housed in the same cage, or come from the same litter; doses administered may differ from the nominal level, as could arise when the substance is administered through food or in the field; organisms may respond "naturally" – for example handling mortality can be high in insect experiments, but negligible in studies of large animals; we may be interested in response over time as well as with respect to dose.

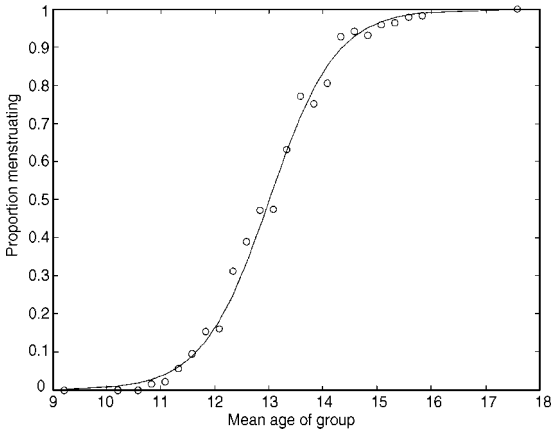

Figure 1 For each of a sample of 3918 Warsaw girls, taken in 1963, it was recorded in [29] whether or not they had reached menarche (started menstruating). The girls were divided into groups according to age, and plotted are the proportions in each group that had reached menarche v. mean age of group. The fitted curve results from a logit model, fitted by maximum likelihood

The routine testing of new substances for good behavior as potential new drugs to market regularly produces a sequence of quantal response experiments. Frequently a wide range of doses is then used, as response is usually uncertain before the experiment is conducted. However, although each experiment may be treated on its own, there is often an element of comparison involved, as when a new substance is a minor modification of an earlier one. Quantal response studies may be conducted explicitly in order to make a comparison, e.g. to investigate whether a rural environment results in an overall delay in onset of menarche, when compared with an urban environment (it does), or whether smoking advances the age of menopause (it does). To describe a set of quantal response data, or to make a comparison between two or more such sets of data, it is useful to think in terms of a simple summary of experiments.

The dung fly experiment mentioned above was thus described in the British newspaper *The Independent* (on September 23, 1996) as follows:

> ... half of the larvae of the common yellow dung fly died when exposed to just 0.05 parts of Ivermectin [the most effective avermectin] per million. Lower concentrations caused major disruption to the fly's life-cycle. Cattle dung from bolus-administered cattle contains 10 times this concentration of the drug.

The ED_{50} or **median effective dose** is the dose level that results in an expected 50% response under certain underlying model assumptions, and is the summary that has been used in the above newspaper article. In some applications, such as studies of the toxic effects of food additives, or in the evaluation of insecticides, other values such as $ED_{10^{-6}}$, or ED_{99} would, respectively, be more appropriate summaries.

Notation and the Spearman–Kärber Estimate

We assume that k doses are tested, that there are n_i individuals exposed to the ith dose, and r_i of those individuals respond.

Independence assumptions result in the **likelihood**

$$L = \prod_{i=1}^{k} \binom{n_i}{r_i} P_i^{r_i} (1 - P_i)^{n_i - r_i}, \qquad (1)$$

where P_i is the probability of response at the ith dose. In most cases, response increases as the dose level increases, and P_i is modeled by means of a cumulative distribution function, $P_i = F(d_i)$ (*see* **Random Variable**). This model is sometimes given a *threshold* or *tolerance* interpretation, as follows: any individual is assumed to have its own dose tolerance threshold, T, responding to dose d if and only if $d \geq T$. Thus if T is distributed throughout the population of individuals as a random variable with cumulative distribution function $F(t)$, then the probability that any individual responds at dose d is simply

$$\Pr(T \leq d) = F(d).$$

There are various situations where this interpretation is not appropriate, e.g. in situations where a response can result from infection by a single virus particle (*see* **Infectivity Titration**). However, the threshold model is often useful, and we see an example of this later when we discuss models for multivariate response.

The ED_{50} is now seen to be the median of $F(\cdot)$, and also its mean if $F(\cdot)$ is a symmetric function about the mean. A very simple estimate of the ED_{50} results if we make this symmetry assumption and if also the dose range has been chosen wide enough that $r_1 = 0$ and $r_k = n_k$. This is known as the Spearman–Kärber estimate of the ED_{50}, which takes its simplest form when the doses are equally spaced by an amount Δ, namely,

$$\widehat{\mathrm{ED}}_{50} = d_k + \frac{\Delta}{2} - \Delta \sum_{i=1}^{k} \left(\frac{r_i}{n_i} \right). \qquad (2)$$

For the case of $n_i \geq 2$ for all i, an unbiased estimate of $\mathrm{var}(\widehat{\mathrm{ED}}_{50})$ is then given by

$$\sum_{j=2}^{k-1} \frac{r_j (n_j - r_j) \Delta^2}{n_j^2 (n_j - 1)}. \qquad (3)$$

Extension and elaborations are described in [32].

It is convenient to possess an explicit estimate of the variance of a key quantity of interest. Experimental resources are usually limited by considerations not only of cost, space, and time, but also of limiting animal suffering and mortality. Experiments may then be designed in order to try to minimize the variance in the context of a fixed total number, $\sum_{i=1}^{k} n_i$, of animals. We discuss experimental design in more detail below. The Spearman–Kärber estimate can be made more robust by a small amount of suitable trimming, such as 5%; see [18] and [32]. The Spearman–Kärber approach is nonparametric, because it makes no assumptions about the form of the function $F(\cdot)$, other than the assumption of symmetry. Much more complex nonparametric methods now exist – see, for example, [22] for a method based on **density estimation**. We now consider parametric methods which historically came later than the Spearman–Kärber estimate of the ED_{50}. Parametric methods can make strong assumptions regarding the form of $F(\cdot)$ and this can in turn result in large increases in the precision with which, for example, the ED_{50} is estimated. This is graphically demonstrated in [16]. The advantage of a parametric approach is the flexibility with which departures from standard experimental procedures can be accommodated.

Models

Parametric models for quantal response data involve assuming a form for $F(\cdot)$. The simplest models involve the location and scale pair of parameters (α, β), usually through either $F(\alpha + \beta d)$ or $F(\alpha + \beta \log d)$. The latter form is useful if a wide dose-range has been adopted, as discussed above, in facilitating comparisons, or when natural mortality is present, as we shall discuss below. Historically the normal cumulative distribution function was assumed for $F(\cdot)$, resulting in *probit analysis*. Only the largest of data sets, and Figure 1 provides a rare example of this, permit discrimination between probit analysis and logit analysis, which is based upon

$$P(d) = \frac{1}{1 + \exp[-(\alpha + \beta d)]}, \tag{4}$$

or the same form using $\log(d)$, if appropriate. Logit analysis is the simplest example of **logistic regression**. It is usually now adopted in preference to probit analysis, but an interesting exception arises when dose levels are subject to error (as when the substance is administered through food which may only be partly eaten) – see [40]. In that case the probit model is computationally easier to handle than the logit model. The opposite is usually the case, owing to the normal cumulative distribution function lacking an explicit algebraic form. Both logit and probit models are simple examples of a **generalized linear model**.

Under probit and logit models, the likelihood is a function of α and β, and **maximum likelihood** estimates follow from routine numerical optimization, as explicit maximum likelihood estimates do not exist (*see* **Optimization and Nonlinear Equations**). This is easily accomplished using computers; computational aspects will be discussed below. When the model is parameterized in terms of α and β, the maximum likelihood estimate of the ED_{50}, when $F(\cdot)$ is symmetric, is given by $-\hat{\alpha}/\hat{\beta}$, and an estimate of its standard error is easily obtained using the **delta method** – see [6]. Alternatively, the model may be parameterized in terms of $F[\beta(\theta - d)]$, thereby providing a direct estimate of the ED_{50}, θ, and of its standard error.

The model fitted to the data illustrated in Figure 1 is the logit model, with maximum likelihood estimates of parameters. In this case the poor fit to the data in the tails is improved by switching to a probit model – the main difference between the two models is in the tail behavior. A simple graphical guide to the appropriateness of a model can be obtain from plotting $F^{-1}(r_i/n_i)$ against d_i, and checking for departures from linearity. The resulting ordinates for the logit and probit models, respectively, involve logits and probits. A wide range of more complex models have been studied to improve the fit of models to data, with particular reference to tail behavior. See, for example, [3, 43, 12], and [31].

One example of such a complex model has

$$P(d) = \begin{cases} 1 - [1 + \lambda \exp(\alpha + \beta d)]^{-1/\lambda}, \\ \qquad\qquad \text{for } \lambda \exp(\alpha + \beta d) > -1, \\ 0, \qquad \text{otherwise.} \end{cases} \tag{5}$$

The additional parameter, λ, provides a function with a more flexible shape. When $\lambda = 1$, this is simply the logit model, while if $\lambda \neq 1$, then the model has an asymmetric tolerance distribution. A likelihood ratio test, or a score test (*see* **Likelihood**) could be used to examine whether, for a particular data set, it was necessary to take $\lambda \neq 1$. In the limit as $\lambda \to 0$, the model becomes the complementary log–log model.

A simple way of modeling "natural" mortality or response also involves adding a parameter to the model, resulting in Abbott's formula:

$$P(d) = \lambda + (1 - \lambda) F(\alpha + \beta \log(d)). \tag{6}$$

Here λ is the probability of natural response. Control groups, which receive no dose, are often included as standard experimental procedure. Several papers have considered how historical controls, providing control response information from previous experiments, can be included in a current analysis; see, for example, [41] and [26].

Extensions

Making Comparisons

Assume tests of two substances result in the two fitted models

$$\Pr(\text{response to dose } d_j) = \frac{1}{[1 + \exp[-(\alpha_i + \beta_i \log d_j)]}, \quad \text{for } i = 1, 2. \tag{7}$$

Frequently we might expect parallelism (*see* **Parallel-line Assay**), which corresponds to $\beta_1 = \beta_2$, and be interested in a measure to represent the difference between the two substances. In this case the ratio d_1/d_2, of equally effective doses, may be used. It is called the *relative potency*. When both models produce the same probability of response at respective doses of d_1 and d_2 say, then

$$\alpha_1 + \beta \log d_1 = \alpha_2 + \beta \log d_2, \tag{8}$$

resulting in a constant value of the relative potency.

This approach was used in [19] to demonstrate an advancement of the age of menopause by 1.23 years due to smoking. In that case the logarithmic transformation was not used.

Mixtures of Drugs

As in certain treatments of **AIDS**, "cocktails" of drugs are sometimes found to perform especially well, in excess of expectations based on the separate performance of the components of the cocktails. The drugs are then said to exhibit synergy, the opposite effect to this being termed antagonism. A large literature exists on models for responses to drugs presented in combination – see, for example, [4] and [1] (*see* **Synergy of Exposure Effects**). An attractive application for quantal responses is described in [15].

Wadley's Problem

If the response variable has a **Poisson distribution** rather than a binomial distribution, then the resulting experiment is called Wadley's problem. It provides another example of a generalized linear model.

Polytomous Responses

When there are three responses, rather than two, at the ith dose there are probabilities (P_{i1}, P_{i2}, P_{i3}), with

$$\sum_{k=1}^{3} P_{ik} = 1.$$

If n_i individuals result in respective responses (r_{i1}, r_{i2}, r_{i3}), then the data follow a trinomial distribution:

$$\Pr(r_{i1}, r_{i2}, r_{i3}|n_i) = \frac{n_i!}{r_{i1}!r_{i2}!r_{i3}!} P_{i1}^{r_{i1}} P_{i2}^{r_{i2}} P_{i3}^{r_{i3}}. \tag{9}$$

In the case of a logit model we would then write

$$\begin{aligned} P_{i1} &= \{1 + \exp[-(\alpha_1 + \beta d_i)]\}^{-1} \\ 1 - P_{i3} &= P_{i1} + P_{i2} \\ &= \{1 + \exp[-(\alpha_2 + \beta d_i)]\}^{-1}, \\ &\quad \text{with } \alpha_1 < \alpha_2. \end{aligned} \tag{10}$$

The table of data is an example of a **contingency table** with **ordered categorical** responses. Once again, maximum likelihood estimation requires numerical iteration. This is a particular instance of the general framework established for the analysis of such data by McCullagh [27]. Simpler descriptions of data in contingency tables with ordered categories are provided by ridits [10, 48] or by rankits, if the categories can be ranked [24] (*see* **Polytomous Data**).

Multivariate Responses

In contrast, multivariate responses correspond to a single individual being classified in more than one way. An interesting example of multivariate response is provided by Ashford & Sowden [5], in which working coalminers are classified according to whether they are breathless or not and whether they wheeze or not. The model proposed for these data was a simple bivariate extension of the simple threshold model.

Bayesian Analysis

In a standard probit or logit analysis, we might have prior information relating to the pair of parameters, (α, β). This may have been obtained indirectly via prior opinions of the likely response levels to particular doses. It is shown in [39] how a classical **Bayesian** analysis can be carried out, and which would, for example, result in a posterior distribution for an ED_{50}. Toxicity classes – corresponding to ED_{50}s lying in particular intervals – can then be assigned probabilities directly. Further Bayesian work can be found in [17] and, from a design perspective, in [11].

Times to Response

Quantal response experiments are frequently run for fixed times before responses are recorded, and

popular times are one week or other multiples of days. Sometimes ED_{50} and similar dose levels are qualified by the duration of the experiment. In cases of prolonged exposure to the substance being tested, we might expect a tradeoff between dose and time, similar effects resulting from either a low dose for a long time or a high dose for a short time. In other experiments there may be a limit to the response at each dose, which would be approached as the duration of the experiment was increased. The former case is expressed in one form by Ostwald's equation [34], in which $XT^{\lambda} = \kappa_p$, for the constants λ and κ_p. Here X denotes concentration and T duration, corresponding to a level $p\%$.

Stochastic models which include a description of times to response are drawn from **survival analysis**. If $F(t;d)$ denotes the probability of response by time t to dose d, then following [36], the **Weibull** model,

$$F(t;d) = 1 - \exp[-t^{\gamma} \exp(\alpha + \beta \log d)], \quad (11)$$

can be shown to agree with Ostwald's equation. An alternative approach, which was used by Pack and Morgan [35] to describe data exhibiting limits to response at each dose, extended the standard threshold model: at each dose level there was a probability of response which was dose-related, as described by a logistic model. Responding individuals were then given a log logistic distribution, which was dose-independent.

A characteristic of time-to-response data is that it is usually interval-censored, typically with observations taken only once a day. For general discussion of such models, see [14].

Overdispersion

Data frequently exhibit more variation than that allowed for in simple binomial and Poisson models (*see* **Overdispersion**) of response. This can be due to factors such as a lack of independence of response, or heterogeneity of subjects. In a modeling context, the Poisson distribution might be replaced by the negative-binomial distribution, and the binomial by a beta-binomial distribution, though several alternatives also exist. In some cases it may be appropriate to fit mixtures of distributions, for which there may, for example, be a genetic justification – see [9] and [7]. A robust procedure results from adopting a quasi-likelihood approach, which makes use of just the means and variances of the responses – see, for example, [47] and [8].

The beta-binomial distribution has the probability function

$$\Pr(X = x|n) = \frac{\binom{n}{x} \prod_{r=0}^{x-1}(\mu + r\theta) \prod_{r=0}^{n-x-1}(1 - \mu + r\theta)}{\prod_{r=0}^{n-1}(1 + r\theta)}, \quad \text{for } 0 \le x \le n \quad (12)$$

(we interpret $\prod_{r=0}^{-1}$ as unity). We can see that $\theta = 0$ returns us to the binomial form. We have

$$\mathrm{E}[X] = n\mu,$$
$$\mathrm{var}(X) = n\mu(1-\mu)\left\{1 + \left(\frac{\theta}{1+\theta}\right)(n-1)\right\}. \quad (13)$$

Thus positive θ produces a larger variance than in the binomial case. Negative values of θ may also be used, allowing a straightforward likelihood ratio, or score, test of $\theta = 0$ [38, 44].

In the dose response context we can allow both μ and θ to be suitable functions of dose, and then use standard testing procedures to investigate whether such complexity is required – see, for example, [42, 13], and [30]. Mixed models, such as the logistic–normal and probit–normal, provide an alternative approach to dealing with overdispersion – see, for example, [20] and [37].

Design and Sequential Methods

Suppose our objective is to innoculate cattle against a disease. We might well wish to use a dose at about the PD_{90}, say, this being the dose that would protect 90% of animals. Higher doses might be thought to be too expensive to produce, or to result in undesired side effects. It may only be possible to use a small number of animals to estimate the PD_{90}, and the question then arises of how to allocate dose levels to the animals. Adopting an optimal design approach, we might, for example, focus on the PD_{90}, and try to estimate this as precisely as possible. We saw earlier an expression for the variance of the Spearman–Kärber estimate of

the ED_{50}. Prior estimates of parameters may be used to estimate numbers responding at any dose level, resulting in an expression to be optimized with regard to the allocation of a fixed number of individuals over doses. This is the basic idea of optimal design procedures. It relies on being able to produce prior estimates of parameters. The prescription can be very clear and simple – for example to distribute individuals over just two doses. However, poor performance can result from poor initial estimates of the parameters, and a more conservative approach is advisable in practice – see, for example, [2] and [21]. A two-stage design is studied in [2]; the first stage improved on prior estimates of parameters and informed the choice of doses at the second stage.

A formal Bayesian approach is adopted in [11].

Fully sequential methods involve allocating individuals to doses in a way that depends on previous responses. For example, in an up-and-down experiment, if a rat responds to a dose then the next rat is treated with a lower dose. Subsequent dose levels would then be reduced until a rat fails to respond, and the next dose level to be chosen would then increase, and so on. A form of **up-and-down** experiment results in the fixed dose procedure for evaluating toxicity – see [46]. In its simplest form, the up-and-down experiment produces dose levels according to the following sequence:

$$d_{i+1} = d_i - 2\Delta(r_i - 0.5),$$

where $r_i = 1$ if the individual exposed at dose d_i responds, and $r_i = 0$ otherwise. Here the doses are selected at intervals of Δ. For discussion of variants of this procedure, and how to analyze the resulting data, see [23] and [45]. The Robbins–Monro procedure of **stochastic approximation** for estimating an ED_{100p} value allows the step-length to decrease with increasing i, to produce the following sequence of doses:

$$d_{i+1} = d_i - \frac{c}{i}(r_i - p),$$

for a suitable constant c.

```

```

(b)

Figure 2 An example of computer code for fitting the model displayed in Figure 1, and producing the figure. The MATLAB language is used. The program of (a) reads in the data, minimizes the negative log likelihood using the *fmins* command, which uses a simplex method – see [33] – and plots the data and the results. The program of (b) establishes minus the log likelihood

Many variants have been devised – see [25] and [49]. Sequential optimization, in which optimal design ideas are used in a sequential context, has been considered in [28] and [21]. Sequential methods, even if only applied for a limited number of stages, have an obvious appeal, in limiting the use of experimental resources and individuals (*see* **Sequential Analysis**). In practice a nonsequential approach may prove to be more practicable. For example, in routine assays the experimenter will want to set up and conclude one experiment according to a laboratory schedule before starting another. In some cases responses may be slow to obtain, thereby ruling out a sequential approach. While it is simple to devise a system of new doses on paper, in practice it is usually much simpler to construct the appropriate dilutions on just one occasion, and then to select from these in future experiments.

Computing

There are several computer packages which may be used to fit models to quantal assay data (*see* **Software, Biostatistical**). A range of facilities exist in packages such as GLIM, GENSTAT, SPSS-X, SAS and S-Plus. In SAS, for example, PROC GENMOD can be used for fitting generalized linear models, and PROC LOGISTIC provides specialized software for logistic regression. The availability of powerful integrated computer languages means that for many statisticians it is a simple matter to program their own analyses. For instance, the fit and display of Figure 1 are produced by the MATLAB commands of Figure 2.

Quantile Regression

Consider the situation illustrated in Figure 1 which shows various **quantiles** of infant boys' weight plotted against age. Interest may be focused not only on the mean relationship between these two variables, but also on the relationship between the extreme quantiles and age. The quantiles may act as appropriate boundaries for indicating potential infant feeding problems, and therefore are useful when examining the progress of a child's weight gain over time. Clearly, in this and many similar situations, a standard regression model is not sufficient for predicting the relationship between all the quantiles of a dependent variable y and a vector $\mathbf{x}$ of **explanatory variables**.

With this fact in mind, Hogg [2] and Koenker & Bassett [4] generalized the method of minimum mean absolute deviation (MAD) regression (*see* **Robust Regression**) to quantile regression in which, under the assumption of linearity, they developed a technique for modeling the quantiles of the conditional distribution function $F(y|\mathbf{x})$.

To describe the method, let us examine how to specify ordinary quantiles as the solution to certain estimating equations (*see* **Generalized Estimating Equations**), which minimize a particular sample loss function. This will enable us to develop and estimate regression models for conditional quantiles. Given a sample of n univariate observations $\{y_1, y_2, \ldots, y_n\}$, the pth sample quantile $\hat{\mu}_p, 0 \leq p \leq 1$, satisfies the relationship

$$\sum_{i=1}^{n} [pI(y_i > \hat{\mu}_p) - (1-p)I(y_i < \hat{\mu}_p)] = 0, \quad (1)$$

where I is the indicator function taking the value 1 when its argument is true, and 0 otherwise. Note that $\hat{\mu}_p$ is an estimate of the corresponding population quantile μ_p, which satisfies $p[1 - F(\mu_p)] - (1-p)F(\mu_p) = 0$. Eq. (1) can be viewed as an estimating equation where positive **residuals** $r_i = y_i - \hat{\mu}_p$ are given weight p and negative residuals weight $(1-p)$, and value is measured by the sign of the residual. That is, (1) can be rewritten in the form $\sum_{i=1}^{n} \psi_p(r_i) = 0$, where

$$\psi_p(r) = \begin{cases} p\psi(r), & \text{if } r > 0, \\ (1-p)\psi(r), & \text{otherwise,} \end{cases} \quad (2)$$

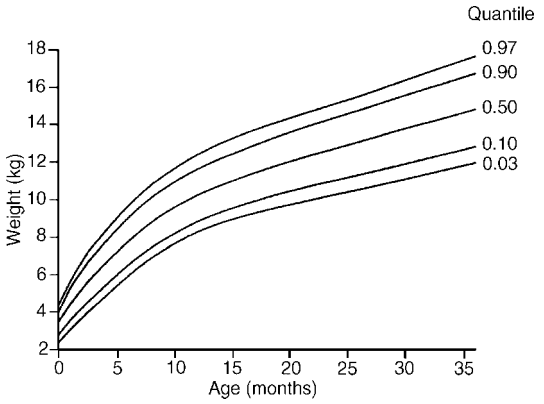

Figure 1 Quantiles of infant boys' weight against age. In this example the extreme quantile lines may be useful for indicating potential infant feeding problems

and $\psi(r) = \text{sign}(r)$. Sometimes ψ_p is referred to as the influence function (*see* **Diagnostics**) for estimating regression quantiles with corresponding asymmetrical **loss function**

$$\rho_p(r) = \begin{cases} p\rho(r), & \text{if } r > 0, \\ (1-p)\rho(r), & \text{otherwise,} \end{cases} \quad (3)$$

where $\rho(r) = |r|$. The estimating equation above, and hence $\hat{\mu}_p$, can be obtained by minimizing the corresponding mean sample loss function

$$n^{-1} \sum_{i=1}^{n} \rho_p(y_i - \mu_p). \quad (4)$$

To extend the method above to quantile regression, we proceed in a manner analogous to linear least squares regression and replace μ_p in (4) by $\mu_p(\mathbf{x}) = \mathbf{x}'\beta_p$, where β_p is a vector of regression coefficients for the pth conditional quantile. It is then fairly straightforward to see that β_p can be estimated by solving

$$\sum_{i=1}^{n} \psi_p(y_i - \mathbf{x}'_i\hat{\beta}_p)\mathbf{x}_i = \mathbf{0}. \quad (5)$$

In the special case $p = 0.5$, the fitted surface is the regression median of y on $\mathbf{x}$ that minimizes

$$n^{-1} \sum_{i=1}^{n} \left| y_i - \mathbf{x}'_i\hat{\beta}_{0.5} \right|, \quad (6)$$

the mean absolute deviation of residuals.

Expectile and M-Quantile Regression

Despite their apparent simplicity, regression quantiles suffer two distinct disadvantages in practice. First, they are usually not unique and hence are quite difficult to compute. Fairly sophisticated linear programming techniques are often used (see, for example, [8] and [6]). Secondly, and perhaps more importantly, they do not include ordinary **least squares** regression as a special case, which is generally the preferred technique for modeling average behavior.

In view of these difficulties, Newey & Powell [9] developed *expectile regression*. Expectiles are obtained by modifying the ordinary least squares criteria in the same way as (4) modifies the MAD criteria of (6). That is, they are obtained by solving (5) with $\psi(r) = r$. Clearly, expectile regression reduces to ordinary least squares regression when $p = 0.5$, and for any $0 < p < 1$, they are unique and can easily be computed using the method of iteratively reweighted least squares (*see* **Generalized Linear Model**).

Figure 2 shows the influence function ψ_p for expectiles when $p = 0.75$. One important feature worth noting is that its influence function is unbounded, which implies that estimates of expectile regression parameters may be quite sensitive to outliers. With this difficulty in mind, Breckling & Chambers [1] suggested that the influence function be modified by using the M-regression ψ-function,

$$\psi(r) = \psi(r, c) = \begin{cases} r, & \text{if } |r| < c, \\ c \ \text{sign}(r), & \text{otherwise,} \end{cases} \qquad (7)$$

in the definition of (2), where $c > 0$ (*see* **Robust Regression**). The resulting method is called M-quantile regression. As $c \to 0$ it approaches quantile regression, and as $c \to \infty$ it approaches expectile regression. In this regard it can be viewed as a compromise between the two, sharing the robustness properties of quantile regression and ease of computation of regression expectiles. In particular, when $p = 0.5$, M-quantile regression reduces to ordinary M-regression, a common choice for robust estimation of the conditional mean when the residual distribution is symmetrical around zero; see Huber [3].

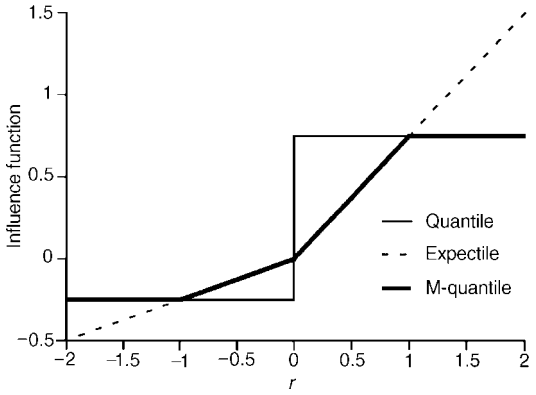

Figure 2 The influence curves ψ_p for quantiles, expectiles and M-quantiles ($c = 1$) in the case $p = 0.75$. The expectile influence curve is unbounded and hence may be sensitive to outliers in the data. The M-quantile influence curve is a compromise between the quantile and expectile influence curves

The Purpose of Modeling Quantiles

As illustrated in our introductory example, the relationship that holds between $\mathbf{x}$ and the conditional mean of y given $\mathbf{x}$ may not be appropriate or representative of those values of y not lying close to the conditional mean. One may well ask what circumstances lead to this situation.

It is often the case when modeling nonexperimental data that not all the explanatory information for the response variable y can be controlled, and only an incomplete set of covariates is available for the modeling process. There may be additional variables, $\mathbf{z}$, that also explain the variation in y, but which have not been measured. If there is an interaction between $\mathbf{z}$ and $\mathbf{x}$, then it is likely that the relationship between $\mathbf{x}$ and extreme y values differs from the mean relationship; see Figure 3. When it becomes necessary to make predictions based only on changes in the $\mathbf{x}$ values, then better forecasts could potentially be made by directly modeling the relationship between the extreme as well as mean values of y conditional upon $\mathbf{x}$. For example, it may be appropriate to use the actual quantile or M-quantile regression surface that passes through each individual observation when making forecasts. This is the basis of the prediction technique developed in [7].

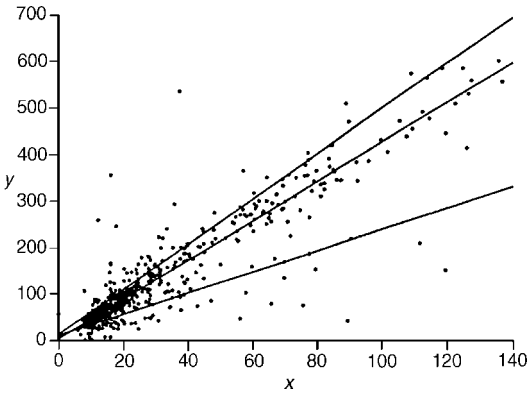

Figure 3 Regression quantiles for $p = 0.10$ (lower line), $p = 0.5$ (middle line) and $p = 0.90$ (upper line) of an indicative data set consisting of a single covariate **x** and dependent variable y. Note that the slope of the three regression lines differs significantly, indicating a varying relationship between y and **x** in the data

The varying relationship illustrated in Figure 3 of the regression quantiles with p can also be used to test for heteroscedasticity [5].

Quantiles

Quantiles divide a statistical distribution (population) or a sample of data into *equal* and *ordered* parts. *Equal* means that all parts contain the same number of sample elements, or equal population mass. *Ordered* means that the parts are arranged so that all sample elements within a part are less than those in the part following it and greater than those in the part preceding it. The term has no numerical attributes until further specification is provided for its use, usually the number of equal parts. Division into N ordered parts requires $N-1$ points or quantiles. For certain N, the set of these $N-1$ points has a well-known name related to N: **median** ($N=2$), *tertiles* ($N=3$), *quartiles* ($N=4$), *quintiles* ($N=5$), *deciles* ($N=10$), and *percentiles* ($N=100$). Because, for example, one-fifth of the population or sample data is less than the lowest quintile, a more general naming of that quintile is the 0.2 quantile. Equivalently, this is the 20th percentile. Generalizations to expressions such as the 0.2143 quantile are possible but not very useful.

There is a limited number of quantiles defined for a discrete distribution. With sample data, various conventions are useful for approximating quantiles of interest. From a sample of size M odd, the median or 50th percentile is the $(M+1)/2$th ordered value; for even M, we use the average of the $M/2$th and $(M/2+1)$th ordered values. Similar ideas may be used for other quantiles, especially for summarization and visualization of data.

Quantiles are useful in a variety of biostatistical settings. In testing of statistical hypotheses and related estimation procedures, if we choose a level of significance α (*see* **Level of a Test**) or confidence $(1-\alpha)$, we must determine the $1-\alpha$ quantile, the point in the appropriate distribution exceeded by $100\alpha\%$.

Various sets of quantiles are useful in exploration and summarization of sample data (*see* **Exploratory Data Analysis**), especially visually through box plots (*see* **Graphical Displays**), to assess symmetry, dispersion, and location. For a biological measure for which extreme values are detrimental, such as blood pressure or cholesterol, the safety and efficacy of a new treatment may be assessed and compared to others with respect to specified upper quantiles. We may decide that an improved treatment is one which yields a 98th percentile no greater than the standard and also a 75th percentile (upper quartile) markedly less than the standard.

Quantiles are also useful when modeling risk relationships between predictor (or **explanatory**) and outcome (or **response**) variables, as in **logistic regression** or **generalized linear models**. For example, in studies of the effect of improved nutrition on reducing the incidence of disease, we often find that measures of nutritional status seem unrelated to outcome until the status reaches high levels or exceeds some threshold. A common approach to model this relationship, which requires few assumptions, is based on quantiles. The distribution of nutritional status is frequently **skewed**, and we may choose to transform it by the sample quintiles into a categorical variable. The four quintiles $\{Q1, Q2, Q3, Q4\}$ divide the sample into five ordered quintile groups $\{G1, G2, G3, G4, G5\}$. An observed value X of nutritional status receives the designation (transformed value) of the quintile group of which it is a member. Thus, if $Q2 < X < Q3$, then X has transformed value or category 3, or $G3$ if you wish. The lowest quintile group is typically selected as the reference group against which higher groups are compared, and we may find that only the upper category is significantly different from the reference category in relation to risk of disease.

Strictly speaking, one should not say "in the upper quintile", because quantiles are not groups but, rather, points that demarcate groups. The second quartile is also the median, and "in the median" highlights the inconsistency. The term *quantile group* seems appropriate and not overly onerous. Nevertheless, the simpler but imprecise usage such as "in the upper quintile" is commonly found in prestigious medical, epidemiology, and even biostatistics journals as *de facto* standard.

ROY C. MILTON

Quartimax Rotation

Quartimax rotation [3, 4] is one of the earlier **orthogonal rotation** procedures for use with **principal components analysis** and **factor analysis**. Given a matrix $\mathbf{V}$ of dimension $p \times k$ consisting of a set of k vectors defining a set of principal components or factors, a new set of transformed variables is obtained by an orthogonal rotation of $\mathbf{V}$, namely $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$. Here $\boldsymbol{\Theta}$ is a matrix of dimension $k \times k$, determined such that the coefficients of the resulting matrix $\mathbf{B}$ of dimension $p \times k$, containing the new vectors defining the transformed variables, will maximize the quantity

$$Q = \sum_{j=1}^{k} \sum_{i=1}^{p} b_{ij}^4,$$

where p is the number of original variables and k is the number of retained components or factors. Quartimax rotation is a special case of *orthomax* rotation with $c = 0$ (*see* **Orthogonal Rotation**). In this procedure, the sums of squares of $\mathbf{B}$ are maximized *rowwise* as contrasted to **varimax rotation**, which maximizes them *columnwise*. There is a tendency for quartimax to produce a "general" rotated vector which has no small coefficients. Because of these properties, quartimax has generally been replaced by varimax rotation. The standard errors for quartimax loadings were given by Archer & Jennrich [1] and their asymptotic distribution also by Archer & Jennrich [2].

For the audiometric example introduced in the article on **Rotation of Axes**, $\mathbf{V}$ and $\mathbf{B}$ are given in Table 1. The results for the varimax rotation are included also, for comparison.

This is an example where the popular rotation procedures such as varimax did not produce useful results because the units of the original variables, Hz, represent points on a continuum rather than a set of qualitative variables which generally rotate much more favorably. Quartimax, on the other hand, summarizes the situation quite well. The first three rotated vectors define three groups of frequencies. The first rotated vector clusters both 500 Hz and 1000 Hz measurements, the second vector is associated with 4000 Hz, and the third vector with 2000 Hz. The fourth vector restates the left–right ear difference, as did the fourth characteristic vector.

Quasi-experimental Design

Quasi-experiments have been defined as "experiments that have treatments, outcome measures, and experimental units, but do not use random assignment to create the comparisons from which treatment-caused change is inferred" [6]. (*True experiments*, in contrast, are intervention studies that employ **randomization**.) The term *quasi-experiment* was first introduced in 1963 in Campbell & Stanley's classic *Experimental and Quasi-Experimental Designs for Research* [3]. These designs are often employed when random assignment to treatment groups (*see* **Randomized Treatment Assignment**) is not possible.

In principle, every randomized-trial design has a quasi-experimental counterpart that simply substitutes some other method of treatment allocation for random assignment. Thus, there are potentially a limitless number of quasi-experimental study designs, ranging from simple comparison of two parallel groups (*see* **Clinical Trials, Overview**) to **factorial** designs, repeated measures designs (*see* **Longitudinal Data Analysis, Overview**), **crossover designs, group-randomization designs,** and so forth. In addition, the term "quasi-experiment" has historically been considered to include certain single-group designs that have no randomized-trial counterpart, such as the interrupted **time series** design described below.

A quasi-experiment is designed around an intervention. Typically the main study goals are to estimate the size of the intervention effect on some outcome and to test whether it differs significantly from no effect. (Quasi-experiments can certainly consider multiple interventions and **multiple endpoints** simultaneously, but the theory is broadly similar, and for simplicity we shall consider only studies of a single intervention and a single main outcome.) At some point during the study, subjects are exposed to the intervention of interest, and outcomes in those subjects are observed. The crucial question in estimating the effect of the intervention is: What would have been observed on those subjects had they not been exposed to the intervention? Quasi-experimental designs differ chiefly with regard to how they seek to answer this question.

After discussing **confounding** as the central methodological issue in most quasi-experimental designs and describing a useful notation for study designs, the discussion below focuses on three quasi-experimental designs, each of which raises generic design and analysis issues that arise in a larger class of quasi-experimental studies. Cook & Campbell [6] and Campbell & Stanley [3] discuss several other specific quasi-experimental designs and comment on their strengths and weaknesses.

Confounding

Expectations about what would have happened in the experimental group in the absence of intervention are often based on outcomes observed in a non-exposed **control** group. Because quasi-experiments do not employ randomization to form comparison groups, the experimental and control groups can, and often do, differ with regard to other measured or unmeasured factors that influence the outcome. Hence observed differences in outcomes between the experimental and control groups can represent a mixture of effects of the intervention under study and the effects of these pre-existing differences between groups. Prevention or removal of **confounding** of this sort thus becomes an important methodological issue in **unbiased estimation** of intervention effects from quasi-experimental evidence [9].

Several techniques are available to overcome confounding. In the study-design stage, *restriction* or **matching** can be used. For example, confounding by gender can be prevented by restricting the study population to males alone or to females alone. Matching on one or more potential confounding factors can also be employed. However, restriction and matching are not always feasible or sufficient, particularly if the number of potential confounding factors is large. Accordingly, confounding must routinely be considered in the analysis stage of a quasi-experiment, usually by including potential confounding factors as **covariates** in an **analysis of covariance** (ANCOVA), **multiple regression** or other type of **multivariate analysis**.

Except for randomization, all of the methods for control of confounding require that the investigator know what the important confounding factors are and how to measure them. Omission of an important confounding factor from an analytic model results

in what is sometimes called a specification error or model **misspecification**, and the result can be substantial **bias** in estimation of the intervention effect.

Campbell–Stanley Notation

Campbell & Stanley [3] developed a useful notation for study designs that conveys several important features and helps distinguish one design from another at a glance. The notation applies to both randomized and nonrandomized study designs. The following symbols are used for every design:

X = exposure to an intervention;
O = observation or measurement.

Additional symbols are sometimes used to indicate the method by which subjects are allocated to treatment groups. These include:

R = random assignment;
C = assignment based on whether a subject's value on a certain score falls above or below a specified cutoff value.

These symbols are arranged in rows, each row representing a different group of study subjects. Within a row, the ordering of symbols from left to right indicates the temporal sequence in which steps are carried out. Symbols that are aligned vertically indicate performance at the same point in time. A simple example is:

$$\begin{array}{cccc} \mathrm{R} & \mathrm{O} & \mathrm{X} & \mathrm{O} \\ \mathrm{R} & \mathrm{O} & & \mathrm{O} \end{array} \qquad (1)$$

This design involves randomization (R) of subjects into two study groups, each of which is observed (O) after randomization. One group is then exposed to an intervention (X) while the other group is not. Lastly, both groups are observed (O) concurrently at follow-up.

When neither R nor C appears, then study groups are assumed to be formed on some other basis. For example, the quasi-experimental counterpart to design (1) above would be:

$$\begin{array}{ccc} \mathrm{O} & \mathrm{X} & \mathrm{O} \\ \mathrm{O} & & \mathrm{O} \end{array} \qquad (2)$$

Symbols may be subscripted as necessary to avoid ambiguity if there are multiple interventions, observation occasions, or allocation steps.

Pretest, Posttest Nonequivalent Control Group Design

In spite of its cumbersome name, design (2) above is among the most commonly used quasi-experimental designs, involving baseline ("pretest") and follow-up ("posttest") measurements on subjects in each of two groups, only one of which is exposed to the intervention. For example, Simon et al. [14] studied the effect of a $20/visit copayment for mental-health visits among government workers and their dependents who were enrolled in a large health-maintenance organization. The new copayment applied to families of state government employees, but not to families of federal government employees, who served as a no-intervention control group. Data were gathered on each enrollee's use of any mental-health services and annual visit rate during the year before the change and during the year after the change.

More generally, results from this type of quasi-experiment can be portrayed graphically as in Figure 1. Y is the outcome variable, and a value of Y is obtained for each subject in each of two treatment groups at each of two time points. (Unique identification of a particular Y-value would require three subscripts, but for simplicity we will omit the subscript that indexes individual subjects.) Baseline measures of Y are designated as Y_0 and those obtained at follow-up as Y_1. As shown in Figure 1, a

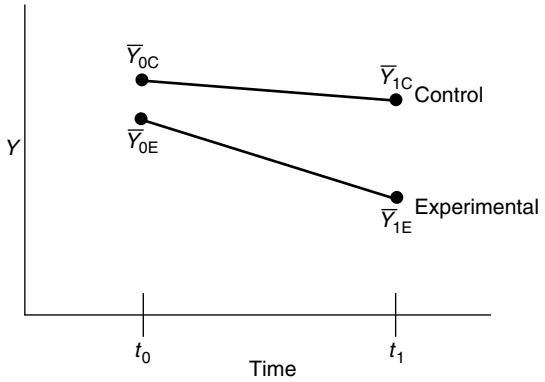

Figure 1 Diagram of results for the nonequivalent control group design

second subscript (E for experimental, C for control) is added when needed to distinguish between study groups. **Mean** values of Y are always taken across subjects within a treatment group and time point.

Despite the apparent simplicity of this design, approaches to data analysis have been varied and sometimes controversial. The parameter of main interest, τ, is the effect of the intervention. Conceptually, it can be defined as:

$$\tau = \overline{Y}_{1E} - \overline{Y}^*_{1E}, \tag{3}$$

where $\overline{Y}^*_{1E}$ is the mean value of Y that would have been observed in the experimental group at follow-up had the group not been exposed to the intervention. The alternative analytic approaches differ chiefly with regard to how they estimate $\overline{Y}^*_{1E}$. We compare three approaches here.

Separate Comparison of Baseline Means and Follow-Up Means

Under this approach, the experimental and control groups are first compared with regard to Y_0 and possibly other baseline characteristics. If no significant differences are found, the groups are treated as "essentially equivalent" (as if randomization had been performed), and τ is estimated from follow-up data alone:

$$\hat{\tau} = \overline{Y}_{1E} - \overline{Y}_{1C}. \tag{4}$$

In effect, this approach assumes that if the groups did not differ significantly at baseline, they would have been equivalent at follow-up in the absence of an intervention effect.

This approach has several shortcomings. Since the study groups were *not* formed by random assignment, they may well be found to differ significantly with regard to Y_0 or other potentially confounding variables, obligating the analyst to account for these differences in estimating τ. Even if the baseline differences are not statistically significant, the **power** to detect a true difference may be low, especially if sample sizes are small and/or if variation within groups is large. (Failing to reject the **null hypothesis** of equivalence at baseline does not necessarily mean that it is true.) Finally, ignoring baseline data when estimating τ may be a lost opportunity to increase the precision of $\hat{\tau}$, because Y_0 and Y_1 are likely to be **correlated** within the same subjects.

Difference in Change Scores

A second approach to analysis grants that the experimental and control groups may differ on Y_0 but posits that an effective intervention would produce larger (or smaller, depending on the **alternative hypothesis**) average *changes* in Y over time (i.e. $Y_1 - Y_0$) in the experimental group than in the control group. This approach leads to the following estimate of τ:

$$\hat{\tau} = (\overline{Y}_{1E} - \overline{Y}_{0E}) - (\overline{Y}_{1C} - \overline{Y}_{0C}). \tag{5}$$

Note that (5) can be rewritten as:

$$\hat{\tau} = \overline{Y}_{1E} - [\overline{Y}_{0E} + (\overline{Y}_{1C} - \overline{Y}_{0C})]. \tag{6}$$

Eq. (6) says that, in the absence of an intervention effect, one would expect the mean of Y at follow-up in the experimental group to be whatever the mean of Y was at baseline in that group, plus the average change observed in the control group from baseline to follow-up. With observations at only two time points, a test of the null hypothesis $H_0 : \tau = 0$ can be based either on an unpaired t-test of the difference in mean change scores between groups or (*see* **Student's *t* Statistics**), equivalently, on an **analysis of variance** (ANOVA) with repeated measures [1].

The main advantage of the change-score analysis is that it is a simple and easily understood method to accommodate baseline differences in Y_0 between groups. Perhaps surprisingly, however, it does not automatically improve the precision of $\hat{\tau}$ in comparison with the estimate from (4). Fleiss [7] shows that if σ_0 is the (within-group) **standard deviation** in Y_0, σ_1 is the standard deviation in Y_1, and ρ_{01} is the correlation between Y_0 and Y_1 in the same subjects, then the **standard error** of $\hat{\tau}$ from (5) is less than the standard error of $\hat{\tau}$ from (4) if and only if $\rho_{01} > (\sigma_0/\sigma_1)/2$.

A related shortcoming of change-score analysis applies when Y_0 is measured with error and/or is variable within subjects over time. Many physiologic or behavioral characteristics fit this description: systolic blood pressure, for example, is subject to both errors in measurement (*see* **Measurement Error in Epidemiologic Studies**) and short-term variability within individuals. Under these conditions, change scores tend to be negatively correlated with baseline values [7]: subjects with unusually low values of Y_0 tend to **regress toward the mean** by manifesting larger increases (or smaller decreases) in Y than do other subjects, while those with unusually high values of Y_0 show the opposite.

Finally, change-score analysis provides no way to examine possible **interaction** effects between values of Y_0 and the experimental treatment.

Analysis of Covariance

A third approach uses Y_1 as the dependent variable and treats Y_0 as one of possibly several covariates in an ANCOVA. Figure 2 illustrates the analytic model graphically. Each subject's pair of (Y_0, Y_1) values corresponds to a point on the graph. The two ovals indicate hypothetical clusterings of those points for the experimental and control groups. Within each group, Y_0 and Y_1 are positively correlated, but the data points for the experimental group form a cluster located to the left of those for the control group, implying that $\overline{Y}_{0E} < \overline{Y}_{0C}$. The unadjusted difference in $\overline{Y}_1$ between groups is the length of line segment ac, while the adjusted difference is the length of ab. The length of bc is thus the amount of bias in estimating τ if baseline differences in Y are ignored, as they are in (4).

As shown in [1], the ANCOVA formulation leads to a third estimate of τ:

$$\hat{\tau} = (\overline{Y}_{1E} - \overline{Y}_{1C}) - \beta(\overline{Y}_{0E} - \overline{Y}_{0C}) \qquad (7)$$

where β is the slope of the **regression** of Y_1 on Y_0. In Figure 2, $\overline{Y}^*_{1E}$ corresponds to the height of point b above the horizontal axis.

The relationship of this analysis to the change-score analysis is clarified by noting that (5) can be rewritten as

$$\hat{\tau} = (\overline{Y}_{1E} - \overline{Y}_{1C}) - (\overline{Y}_{0E} - \overline{Y}_{0C}). \qquad (8)$$

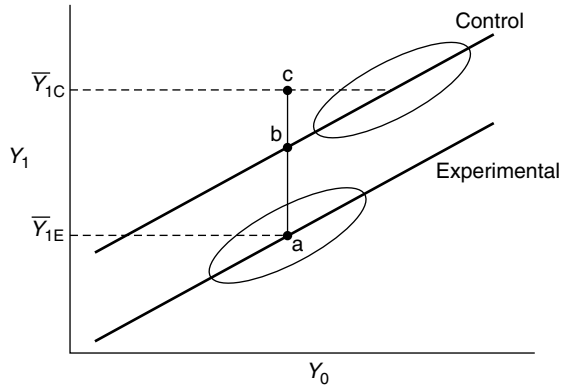

Figure 2 Analysis of covariance for the nonequivalent control group design, using Y_0 as the covariate

In other words, the change-score analysis corresponds to an ANCOVA analysis in which the slope coefficient β in (7) is constrained to be 1. In general, unless Y_1 and Y_0 are completely uncorrelated, $\hat{\tau}$ from (7) can be expected to be more precise than the corresponding estimates from (4) or (5).

Reichardt [13] notes that this basic ANCOVA model can be extended in several ways. The β parameter can be allowed to differ between experimental and control groups, thus allowing study of interaction effects between Y_0 and treatment group membership. Additional covariates besides Y_0 can also be introduced, some of which may be **transformations** of Y_0 to accommodate **nonlinear** relations between Y_1 and Y_0.

The ANCOVA model is not, however, immune to difficulties caused by extraneous **random error** in Y_0 due to measurement error or natural variation in Y over time. Cochran [4] shows that measurement variation in Y_0 leads to biased estimation of the slope parameter β toward 0, by a factor of $\sigma_{(\text{true}Y_0)}/\sigma_{(\text{measured}Y_0)}$, assuming that the measurement error is independent of true Y_0 values. This factor is sometimes termed the *reliability* of Y_0 measurements. Because of this attenuation of β, not all of the confounding by differences in $\overline{Y}_0$ between experimental and control groups is removed.

Because there is only a single baseline observation, pre-existing time trends in Y cannot be detected and taken into account in estimating $\overline{Y}^*_{1E}$. Such trends may arise, for example, from general historical changes that affect Y or from growth or maturation of study subjects over time.

Interrupted Time Series

An interrupted time series quasi-experiment can be diagrammed as follows:

$$\text{O} \quad \text{O} \quad \text{O} \quad \ldots \quad \text{O} \quad \text{X} \quad \text{O} \quad \text{O} \quad \ldots \quad \text{O} \qquad (9)$$

A single study group is examined on repeated occasions, then exposed to the intervention of interest, then examined repeatedly again thereafter. A major advantage of this design is the opportunity to recognize and characterize preintervention patterns of variation over time, which may be cyclical or monotone, and which provide a basis for predicting what would have been observed during the postintervention period in the absence of an intervention effect.

An important feature of time series data, however, is that observations closer to each other in time tend to be more correlated with each other than are observations separated more widely in time (temporal **autocorrelation**). Correlated errors violate a standard assumption of ordinary **least squares** regression and invalidate the usual tests of significance (*see* **Hypothesis Testing**) based on it.

Selection of an approach to analysis depends in part on whether individual subject or only group-level data are available for each of the time periods, and on the number of pre- and postintervention measurements. When a large number (say, 50 or more) of group-level observations are available over time, autoregressive integrated moving average (ARIMA) models, based on work by Box & Jenkins [2], offer several attractive features [10] (*see* **ARMA and ARIMA Models**). Briefly, ARIMA models seek first to model variability within the time series in terms of secular trends, cyclical variation (such as **seasonality**), autocorrelation between serial measurements, and persistence of random perturbations from one measurement to the next. The form of the ARIMA model can then be summarized as ARIMA (p, d, q), where p represents the number of autocorrelation parameters, d the number of differencing steps required to achieve **stationarity**, and q the number of **moving-average** parameters needed to accommodate persistence of random perturbations. A parameter for intervention is then added to the model in order to estimate a change in the series following the point of intervention. O'Carroll et al. [12] used ARIMA modeling to evaluate the effect of a new law in Detroit requiring a mandatory jail sentence for illegally carrying a gun in public. The evaluation was based on changes in monthly counts of firearm-related and non-firearm-related homicides occurring indoors or outdoors in public before and after the ordinance took effect.

Design (9) does not directly allow separation of intervention effects from the effects of extraneous historical factors that happen to coincide in time with the intervention. However, this shortcoming can sometimes be remedied by adding one or more no-intervention control groups followed over the same time period:

$$\begin{array}{cccccccccc} \mathrm{O} & \mathrm{O} & \mathrm{O} & \ldots & \mathrm{O} & \mathrm{X} & \mathrm{O} & \mathrm{O} & \ldots & \mathrm{O} \\ \mathrm{O} & \mathrm{O} & \mathrm{O} & \ldots & \mathrm{O} & & \mathrm{O} & \mathrm{O} & \ldots & \mathrm{O} \end{array} \tag{10}$$

Wagenaar & Holder [16], for example, used ARIMA modeling to assess the effect on alcohol consumption of privatizing wine sales in five US states, examining monthly sales of beer, wine, and spirits in those states before and after privatization and comparing the changes observed with concurrent changes in neighboring states and for the US as a whole.

When the Os in (9) and (10) represent individual-level measurements on many study subjects over time, the analyst can consider several relatively new statistical approaches for **analysis of longitudinal data**. Zeger & Liang [17] review three families of longitudinal analysis models (**marginal**, **transition**, and random effects). All of these approaches allow the use of familiar regression tools relating a response variable to several explanatory variables, while accounting properly for within-subject correlation over time.

Regression Discontinuity

The basic regression-discontinuity design can be denoted as follows:

$$\begin{array}{cccc} \mathrm{O} & \mathrm{C} & \mathrm{X} & \mathrm{O} \\ \mathrm{O} & \mathrm{C} & & \mathrm{O} \end{array} \tag{11}$$

As before, let Y represent a continuous outcome variable, measured at baseline (Y_0) and at follow-up (Y_1). The unique feature of this design is that Y_0 itself is used as the basis for allocating subjects to the experimental or control group, as indicated by the symbol C in (11). If a subject's value of Y_0 falls above (or below) a predefined cutoff value, the subject is assigned to the experimental group; if Y_0 falls on the other side of the cutoff value, the subject is assigned to the control group. Subjects in the experimental group are then exposed to the intervention, and Y_1 is measured at follow-up on everyone in both groups.

This subject-assignment scheme would at first seem to confound Y_0 and the intervention effect hopelessly. But Figure 3 illustrates the results expected if the intervention is effective. As usual, Y_1 and Y_0 are positively correlated within each group. However, the regression relation between them is discontinuous at the cutoff value: in this example, Y_1 scores on experimental-group subjects are shifted higher than Y_1 scores on control-group subjects, presumably because of the effect of the intervention. In particular, the size of the intervention effect is the

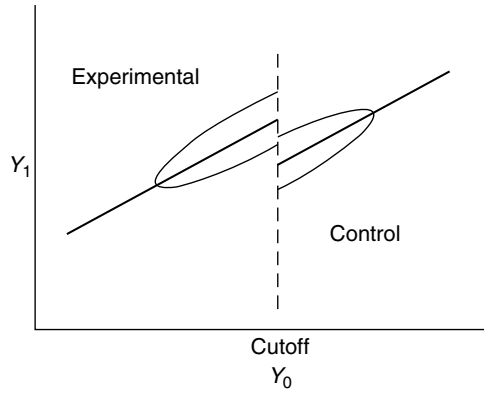

Figure 3 Illustration of the regression-discontinuity design

size of the offset between the two regression lines at the cutoff point.

The regression-discontinuity design has some very attractive features. Often resistance to randomization stems from concern that the neediest subjects would be deprived of a possibly beneficial intervention. Y_0 values may represent the severity of a disorder and may thus be good indicator of "need". The assignment scheme in the regression-discontinuity design assures that all subjects on the "needier" side of some cutoff value of Y_0 receive the intervention. Also, in contrast to many other quasi-experimental designs, in which the basis for nonequivalence of comparison groups may not always be clear, in the regression-discontinuity design the basis for assignment is known to depend completely on Y_0. Even though other potential confounding factors may be associated with Y_0 (and Y_1), they would not usually account for the sharp discontinuity illustrated in Figure 3.

An approach to data analysis from a regression-discontinuity study is described by Trochim [15] who first conceived the design. The basic regression model is:

$$Y_1 = b_0 + b_1(Y_0 - \text{cutoff}) + b_2 z + e \qquad (12)$$

where $z = 1$ for experimental-group subjects and $z = 0$ for control-group subjects, $b_0 = \overline{Y}_1$ in the control group when $Y_0 = \text{cutoff}$, and b_1 is the slope of the regression relation between Y_1 and Y_0 (assumed to be the same in both groups). The parameter of main interest is b_2, representing the intervention effect. (Subscripts indexing individual subjects have again been omitted for Y_1, Y_0, z, and e.)

Two key assumptions in (12) are a common value for b_1 in both groups and a linear relation between Y_1 and Y_0. The former assumption can be relaxed by introducing an interaction term, $b_3(Y_0 - \text{cutoff})z$. If this term improves the fit of the model significantly, it suggests that the intervention effect varies according to Y_0 and that a single summary value of effect may be insufficient. The assumption of a linear relation between Y_1 and Y_0 can be circumvented by adding pairs of terms representing quadratic, cubic, and higher-order powers of $Y_0 - \text{cutoff}$ and their corresponding interaction terms with z, as described by Trochim [15].

Correct inference about the key parameter b_2 turns out to depend heavily on correct specification of the form of the relation between Y_1, Y_0, and z. It also requires strict adherence to the assignment rule represented by C in (11). Moreover, the regression-continuity design has been shown to require about 2.75 times as many subjects as the corresponding randomized-trial design at fixed levels of power and hypothesized intervention effect [13].

Although the regression-discontinuity design has been applied for **program evaluation** in the social sciences and education, it appears to have been rarely used in health research: it is a solution awaiting a problem. However, Johnston et al. [8] describe useful potential applications in rehabilitation medicine, and the design's unique strengths seem worth exploiting in many other health-related contexts.

Conclusion

Quasi-experimental study designs are an attempt to apply some of the desirable features of controlled trials to research situations in which randomization is not possible. **Meta-analyses** that have compared the findings of randomized and nonrandomized studies have often found that the apparent benefits of new medical and surgical therapies over conventional ones tend to be larger in nonrandomized studies [5, 11]. While some of the differences may be due to features of randomized trials that confer a conservative bias (e.g. the **intention to treat** principle), it is widely believed that much is due to

confounding and **selection biases** in nonrandomized studies that cannot be completely overcome without randomization. Investigators would be prudent to continue seeking ways to use randomized designs whenever possible, be diligent in their attempts to measure and control for potential confounding factors when randomization is not possible, be appropriately modest about conclusions from quasi-experiments, and be open-minded as evidence from stronger study designs becomes available.

Quasi-independence

Many **contingency tables** contain cells whose counts are missing, unreliable, a priori structurally fixed, or ignored in certain hypotheses of interest. A contingency table with structurally fixed cell counts is said to be incomplete or truncated. A valid model for an incomplete contingency table must ignore the cell counts which are structurally fixed, and asymptotic tests of these models must have their degrees of freedom adjusted. The quasi-independence (QI) model is most commonly used to analyze incomplete contingency tables or used when our hypothesis of interest is focused on part of a complete table. For some models of a **square contingency table** only the off-diagonal cells are of interest. For complete contingency tables, QI is a form of independence *conditional* on the restriction of our interest to an incomplete portion of the table.

Incomplete contingency tables usually contain **structural zeros**, i.e. counts of zero in cells in which observations cannot occur. They are often found in genetics and medicine because of biological or logical constraints. Tables of chromosome combinations contain structural zeros for lethal genetic combinations. Cross classifications of diseases by sex contain structural zeros for sex-specific diseases, e.g. females cannot develop testicular cancer. Cross classifications of diseased patients according to birth order and sibship size yield triangular incomplete tables since birth order cannot exceed sibship size. See [5] for many examples.

A classic triangular table discussed by Bishop & Fienberg [4], among many others, is Table 1. Here, ratings of stroke patients, based on a five-point ordinal scale A to E of increasing severity, were obtained on admission to, and discharge from, hospital. As none of these patients had a second stroke and no patient was discharged if their condition worsened, then no discharged patient's final rating can be worse than their initial rating, and so for the given data there are 10 structural zeros. This cross-classification by initial and final rating yields what is termed a triangular table, since the structural zeros form a triangle.

Table 1 Initial and final ratings on disability of 121 stroke patients

		Final state				
		A	B	C	D	E
Initial state	E	11	23	12	15	8
	D	9	10	4	1	0
	C	6	4	4	0	0
	B	4	5	0	0	0
	A	5	0	0	0	0

The Quasi-Independence Model

The quasi-independence model is a useful generalization of the model of independence for a two-dimensional complete contingency table. Let Y_{ij} denote the count in cell (i, j) of a two-dimensional rectangular contingency table. Let S denote a set of cells. The QI model for S assumes that the expected value of Y_{ij}, $\mathrm{E}(Y_{ij})$, has the multiplicative form $\mathrm{E}(Y_{ij}) = \alpha_i \beta_j$ for all cells (i, j) in S, where α_i is a function only of row i and β_j only of column j. Note that the QI model for S makes no assumption about the expected counts in cells not in S, so that these expected counts are ignored by the QI model for S. If S is the set of all cells, then this is the definition of independence, but usually S will be a proper subset, namely the cells not structurally fixed. If the QI model for S holds, then the model of independence will hold conditionally for any rectangular subtable whose cells are all in S.

A loglinear form of the QI model is typically used when the QI model is fitted to complete tables, but the hypothesis of interest relates to only part of the table. The saturated **loglinear model** for the expected cell counts has the form of a constant term, a row-effects term depending only on i, a column-effects term depending only on j, and **interaction** terms for each cell in the table which depend on both i and j. The model of independence corresponds to all the interaction parameters equaling zero. The QI model for S corresponds to all the interaction parameters equaling zero for cells in S and taking nonzero values for cells not in S. In this case the fitted cell counts for cells not in S equal the observed counts, so that cells not in S are effectively ignored in the analysis. Hence, we may think of the QI model for S applied to a complete contingency table as a special model for interaction having a separate interaction parameter for each cell not in S.

The extension of the concept of QI to multidimensional contingency tables is straightforward [8]. Any

loglinear model for a complete multidimensional contingency table can be assumed to hold for a subset S of the cells in the complete table, and these models are called quasi-loglinear models.

Uses for Complete Tables

QI models can be used to analyze complete contingency tables. Sometimes when a loglinear model is fitted to a complete contingency table, a significant lack of fit can be caused by a few outlying cells, with the model fitting the remaining cells well. In two-dimensional tables, QI models have been used to detect outlying cells and to calculate deletion residuals (the **residual** from the expected count with the suspected outlying cells deleted) [16]. A related problem is that when the hypothesis of independence is rejected, the analyst may want to identify those cells that contribute most to the significant **goodness-of-fit** statistic [6].

QI models are often used in the analysis of square tables when both cross-classified variables have the same categories. A classic example is a table of interrater reliability (*see* **Observer Reliability and Agreement**; **Agreement, Measurement of**), where two observers rate a number of subjects on a nominal scale. After modeling patterns of agreement, which involves the main diagonal counts, it is natural to model patterns of disagreement, so that interest focuses on the off-diagonal cell counts. QI for the off-diagonal cells allows for differential agreement by each category and, given that the raters disagree, implies that their ratings are independent [2].

Goodman [11] used QI models to analyze the scalability of the observed response patterns for a set of three or more dichotomous items in order to estimate the proportion of intrinsically scalable (and unscalable) respondents.

Estimation

When the cell counts follow either independent Poisson, multinomial, or product-multinomial sampling, **maximum likelihood** estimation is typically used to fit QI models. Conditions for the existence of maximum likelihood estimates for incomplete tables is discussed in [13]. Explicit formulas for maximum likelihood estimates of the fitted counts usually only exist for contingency tables with very special structures, such as triangular tables [12]. Various iterative methods can be used to find maximum likelihood estimates of the parameters, including Newton–Raphson methods (*see* **Optimization and Nonlinear Equations**), some weighted least squares programs, and **iterative proportional fitting**. Iterative weighted least squares programs, which can be used for maximum likelihood estimation (*see* **Generalized Linear Model**) and which allow prior weights of zero, such as GLIM4, can be used for fitting QI models with a moderate number of parameters. In this case, the QI model for S is fitted by giving prior weights of zero to cells not in S. Alternatively, iterative proportional fitting can be used for fitting QI models with a large number of parameters when the program allows user-defined starting values for the expected counts. Starting values of zero are specified for expected counts of cells not in S, so that the fitted counts for cells not in S always equal zero at each stage of the iterative process. Both weighted least squares and iterative proportional fitting methods implicitly result in the cells not in S being ignored in the modeling.

Many computer packages can be used to fit QI models (*see* **Software, Biostatistical**). A guide to statistical software for categorical data analysis which describes fitting QI models is provided in [1, Appendix A].

Asymptotic Tests and Degrees of Freedom

Because certain cells in the contingency table are ignored when fitting QI models, the degrees of freedom (df) needed for carrying out asymptotic **chi-square tests** based on the **likelihood ratio** or Pearson chi-squared test statistics need adjustment. Procedures for calculating the correct df for asymptotic tests for many of the incomplete tables encountered in practice are given in [5, 10]. However, when the tables include sampling zeros (not structurally fixed), the calculation of the correct df are problematic even in the case of complete tables [14]. One way of diagnosing problems associated with df calculations is to use fitting methods, such as Newton–Raphson, that involve iterative matrix inversions. Typically, this problem will result in a rank problem in the iterative matrix inversions.

Exact Tests

When small cell counts in the contingency table cause concern about the validity of using asymptotic tests, such as in Table 1, exact or Monte Carlo exact tests may be used. For small contingency tables, complete enumeration may be used to calculate the exact ***P* value**. For moderate to large tables, **Monte Carlo methods** can be used to estimate the exact P value [15, 17]. One advantage of exact tests is that the concept of degrees of freedom is unnecessary, so that degrees of freedom calculations are also unnecessary.

Relationships with Other Models

Finally, we note that a number of models have been shown to be equivalent to a QI model. The **Bradley–Terry model** for **paired comparisons** is equivalent to a QI model when the data are rearranged into a specific contingency table format [9]. The model of **quasi-symmetry** or symmetric association for a square contingency table assumes that the interaction parameters in a loglinear model for symmetrically opposite cells are equal. Quasi-symmetry for a 3×3 table is equivalent to QI for the off-diagonal cells and QI for the off-diagonal cells implies quasi-symmetry for larger square tables. Certain **latent class** models are equivalent to QI models [7]. Tests of independence between two discrete or discretized random variables with random **censoring** are equivalent to testing the goodness of fit of a loglinear model applied either to complete or incomplete contingency tables [3].

JOHN W. MCDONALD

Quasi-likelihood

Quasi-likelihood (QL) is a method of estimation for **regression** analysis with discrete or continuous responses. Like weighted **least squares**, quasi-likelihood requires specification of only the first two **moments** of the response distribution. The quasi-likelihood also refers to the objective function, analogous to a **likelihood**, that is used for inference in this method. Quasi-likelihood (QL) is another successful example of a partially parametric approach to statistical modeling in which only that portion of the probability model of scientific interest is specified. Cox's **proportional hazards model** (*see* **Cox Regression Model**) and the **partial likelihood** [1] method of estimation for survival data are other leading examples.

QL is an extension of **generalized linear models** (GLMs). QL is to generalized linear models as least squares is to the **general linear model**. In the classical linear model, it is assumed that $y_i = \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i, i = 1, \ldots, n$, where the ε_i are independent Gaussian random variables with mean zero and possibly different variances v_i, here assumed to be known. The maximum likelihood estimate of $\boldsymbol{\beta}$ is then given by $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}(\mathbf{X}'\mathbf{V}^{-1}\mathbf{Y})$, where $\mathbf{X}$ is an $n \times p$ matrix with $\mathbf{x}_i$ as its ith row, $\mathbf{Y} = (y_1, y_2, \ldots, y_n)$ and $\mathbf{V} = \text{diag } (v_1, v_2, \ldots, v_n)$. But the same estimator can be arrived at by assuming only that $\text{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ and that $\text{var}(\mathbf{Y}) = \mathbf{V}$, and then finding the **minimum variance unbiased estimator** of $\boldsymbol{\beta}$. Whereas the classical linear model specifies the entire probability distribution of the responses, weighted least squares estimators rely only on assumptions about the first two moments of the distribution.

The generalized linear model [16] is a powerful extension of the classical linear model that includes models for discrete (*see* **Categorical Data Analysis**) and non-Gaussian, continuous responses. In a GLM, the response variable is assumed to follow an **exponential family** distribution which includes the **normal**, **binomial**, **Poisson**, **gamma**, and other distributions as special cases. The expected value μ_i of the outcome y_i is assumed to depend on the linear predictor $\mathbf{x}_i'\boldsymbol{\beta}$ through the *link function* g by $g(\mu_i) = \mathbf{x}_i'\boldsymbol{\beta}$. Finally, the variance v_i of the response is a known function of the mean, $v_i = v(\mu_i)$. Most common regression models, including **linear regression, logistic regression**, probit analysis (*see* **Quantal Response Models**), **Poisson** regression and some **survival analysis** models, are special cases of GLMs. The advent of GLMs has unified regression methodology for the diverse types of responses encountered in biostatistical practice.

The score equation (*see* **Likelihood**) for the regression coefficients $\boldsymbol{\beta}$ in a GLM is

$$\sum_{i=1}^{n} \frac{\partial \mu_i}{\partial \boldsymbol{\beta}} v_i^{-1}(y_i - \mu_i(\boldsymbol{\beta})) = \mathbf{0}, \tag{1}$$

which is typically solved for $\hat{\boldsymbol{\beta}}$ through an iterative weighted least squares algorithm because the weights $v_i^{-1}(\mu_i)$ depend on $\boldsymbol{\beta}$ (*see* **Generalized Linear Model**). In 1974, Wedderburn [22] pointed out that only the mean and variance of the response appear in (1). He showed that the solution of this equation had desirable statistical properties whether or not the mean and variance functions derive from a particular likelihood. Hence, Wedderburn advocated an estimation method in which we specify only: the dependence of the mean μ on explanatory variables x; and the dependence of the variance v of a response on its mean μ, and then solve (1). He further introduced the integral of (1) as the *quasi-likelihood*, to be used as an objective function for **inference**, analogous to the likelihood function when the complete probability distribution of the data is specified. The QL is given by

$$Q(y_i, \mu_i) = \int_{-\infty}^{\mu_i} \frac{y_i - t}{v_i}\, \text{d}t + f(y_i), \tag{2}$$

where $f(y_i)$ is an arbitrary function of y_i.

Properties of QL Estimators

QL estimators have desirable finite sample and asymptotic statistical properties (*see* **Large-sample Theory**). Its finite sample optimality derives from the fact that the QL estimating equation is perhaps the most important example of an *optimal* **estimating function** as defined by Godambe [5, 6]. An optimal estimating function $g(Y, \boldsymbol{\theta}) = \sum_{i=1}^{n} g(y_i, \boldsymbol{\theta})$ is a random function with expectation 0 for all $\boldsymbol{\theta}$ which minimizes

$$S_n = \text{E}\left[\left(\frac{g(Y, \boldsymbol{\theta})}{\text{E}(\partial g(Y, \boldsymbol{\theta})/\partial \boldsymbol{\theta})}\right)^2\right]. \tag{3}$$

This criterion selects for unbiased estimating functions which have small variance (numerator) and steep gradients (denominator). It is an estimating equation analog of the Gauss–Markov criterion for linear unbiased estimators (*see* **Least Squares**). Score functions minimize this criterion. Godambe & Heyde [7] show that the QL estimating function minimizes (3) among unbiased functions that are linear in the data. A related line of theory has established that the QL is the projection of the true score function into a class of unbiased estimating functions [12]. Firth [4] presented specific evidence about the **efficiency** of QL estimators in finite samples.

QL estimators also have two desirable asymptotic properties. First, under regularity conditions, the solution of the QL estimating function is a **consistent** estimator of $\boldsymbol{\beta}$ given only that $\mathrm{E}(y_i) = \mu_i(\boldsymbol{\beta})$, regardless of whether the variance assumption $v_i = v(\mu_i)$ is correct. Hence, the QL estimator will converge to the correct value as long as the regression model for the mean is correct. This important property is illustrated in the example below. Secondly, McCullagh [15] has shown that the QL estimator is asymptotically **unbiased** and efficient among the class the estimating equation of which is a linear function of the data Y.

Example

The data set below [13] is from a teratologic experiment to test the effects of a chemical agent on the survivorship of rat pups. The fraction that survived 21 days of lactation for each dam for the control and treated groups are as follows:

control	13/13	12/12	9/9	9/9	8/8
	4/5	9/10	9/10	8/9	11/13
	8/8	12/13	11/12		
	5/7	7/10	7/10		
treated	12/12	11/11	10/10	9/9	5/10
	8/9	4/5	7/9	4/7	10/11
	3/6	3/10	0/7		
	9/10	9/10	8/9		

There is nearly four times as much variation among these survivor fractions as is expected under a binomial model, indicating that the probability of pup survival is not constant across dams; in other words, that there is a substantial *litter effect* (*see* **Overdispersion**).

The scientific question – Does the chemical exposure decrease the pups' chance of survival? – can be formulated as a logistic regression model. However, there are at least two approaches to account for the litter effect. First, the survival probabilities can be assumed to vary across dams beyond that due to the treatment. The conjugate prior for the binomial sampling distribution is the **beta distribution**, giving a **beta-binomial model** for the observed fractions [11, 23]. As an alternative, the QL approach can be used where the variance of the number of surviving pups is assumed to follow $v_i = \phi n_i \mu_i (1 - \mu_i)$, where n_i is the number of pups in litter i and ϕ is the overdispersion parameter which allows for extra-binomial variation. The QL estimator of the logistic regression coefficients is consistent given that only the logistic model for the expected survival rates is correct. Unfortunately, the same is not true for the beta-binomial model. For example, if the degree of extra-binomial variation (litter effect) is assumed to be the same in the treated and control groups, then the beta-binomial, maximum likelihood estimate of the treatment log odds ratio of survival is $-0.665(\mathrm{se} = 0.460)$. When the litter effects are allowed to differ for the two treatment groups, the treatment effect MLE is $-1.13(\mathrm{se} = 0.464)$, nearly twice as large. But the QL estimate is -0.961 whether or not the overdispersion is assumed to be the same in the two groups.

Hence QL has the important advantage that it unlinks the estimation of the regression coefficients in the mean model from the specification and estimation of the variance model [20].

Extensions of Quasi-Likelihood

Extensions and applications of QL, reaching from methods for **stochastic processes** [7, 24] to **missing data** problems [10], to estimation of **semiparametric regression models** [21], have broadened its influence on biometric research. We focus on four extensions. The first is to allow inference about variance functions. As originally proposed, the QL objective function (2) is useful for inference about the mean model: choosing among **explanatory variables** or for comparing link functions, but it is not useful for choosing among variance functions. Hence, Nelder & Pregibon [19] introduced an extended quasi-likelihood function that includes a second term

$-1/2\log[2\pi\phi v_{\boldsymbol{\theta}}(y)]$ where $\text{var}(y) = \phi \mathbf{v}_{\boldsymbol{\theta}}(\mu)$ is the variance function which is now assumed to be a member of a class, indexed by the parameter $\boldsymbol{\theta}$. Mean parameters that maximize the original QL also maximize the extended QL, but variance parameters can now also be estimated by maximizing the extended version. Finite sample and asymptotic studies of the extended QL have been reported in [3, 18].

The original QL estimating equation is linear in the data. A second interesting extension, proposed by Crowder [2] and Godambe & Thompson [8], is to define an estimating function analogous to (1) for the response $W = (y_1, y_2, \ldots, y_n, y_1^2, y_1y_2, y_1y_3, \ldots, y_{n-1}y_n, y_n^2)$, giving rise to a QL-like method with quadratic estimating functions. In quadratic QL estimation, the first and second moments of the distribution must be correctly specified to make consistent inferences about their parameters, third and fourth moments must be specified to increase the efficiency of estimation.

A third extension deals with the limitation that the original QL equation does not permit **nuisance parameters**. For example, in regression analysis with correlated responses, the regression parameters are often of scientific interest, but **correlation** among responses must be modeled to make valid and efficient inferences. Liang & Zeger [14] proposed a multivariate analog of (1), called the **generalized estimating equation** or GEE, which could include nuisance parameters. They showed that the asymptotic properties of the QL carry over to the GEE as well.

A final important line of QL research addresses the question of how to define the QL objective function for cases, such as the GEE, in which there is more than one path of integration available. Such a function is needed if the QL estimating function has multiple roots, for example. McLiesh & Small [17] project the **likelihood ratio** statistic on to the space of functions linear in the responses and then propose the log of this projection as an objective function. Li & McCullagh [12] obtain a unique quasi-likelihood function by projecting the true score equation, rather than log likelihood, on to a class of estimating functions, each member of which is linear in y_i and is required to be the derivative of an objective function. Hanfelt & Liang [9] have developed an alternate approach in which they do not limit the class of estimating functions, but rather allow the integral of the QL estimating function to be path-dependent. They showed that many useful properties of the log-likelihood, including identifying consistent roots, are preserved by these extended QL functions.

Quasi-symmetry

Quasi-symmetry arises most commonly in the analysis of dependent samples in **contingency tables**. In their simplest form, such tables have a two-dimensional square structure, where the variable for rows has the same categories as the variable for columns (*see* **Square Contingency Table**). Examples are: (i) when the responses of two matched subjects (such as mothers and daughters, or patients and controls) are classified according to some categorical variable (*see* **Matched Pairs With Categorical Data**); (ii) when subjects are categorized according to two essentially similar variables (such as visual faculty of the right and the left eye); and (iii) **panel studies**, where each subject is classified according to the same criterion at two different points in time, or according to the same criterion by two judges.

Three types of symmetry can occur in such situations: complete symmetry, marginal symmetry, and quasi-symmetry. These are introduced in the next Section for two-dimensional tables.

Two-Dimensional Tables

Tables 1–3 illustrate the three types of symmetry for a two-dimensional square table (cf. [5]). In that case, observed frequencies $\{n_{ij}, i, j = 1, \ldots, I\}$ in the cells (i, j) are formed by cross-classifying two categorical responses with a random sample of size n. The joint distribution of $\{n_{ij}\}$ is **multinomial** with parameters n and $\{\pi_{ij}\}$, where π_{ij} is the probability of the cell in row i and column j of the table. *Complete symmetry* is defined by $\pi_{ij} = \pi_{ji}$ for all i and j (see Table 1). The **maximum likelihood** estimates (MLEs) are $\hat{\pi}_{ij} = (n_{ij} + n_{ji})/2n$, and the number of independent constraints is $I(I-1)/2$.

Marginal symmetry, also referred to as *marginal homogeneity*, is defined by $\pi_{i+} = \pi_{+i}$, $i = 1, \ldots, I$, where $+$ denotes the sum, e.g. $\pi_{i+} = \sum_j \pi_{ij}$. Table 2 shows an example. The number of independent constraints is $I - 1$. Although no explicit solutions exists for MLEs, numerical solutions are easily obtained by iterative methods [7, p. 289; 13, p. 493] (*see* **Iterative Proportional Fitting**). Complete symmetry implies marginal symmetry. For 2×2 tables, marginal symmetry conversely implies complete symmetry.

Table 1 Example of complete symmetry

0.10	0.15	0.05	0.30
0.15	0.25	0.10	0.50
0.05	0.10	0.05	0.20
0.30	0.50	0.20	1.00

Table 2 Example of marginal symmetry

0.08	0.17	0.05	0.30
0.12	0.25	0.13	0.50
0.10	0.08	0.02	0.20
0.30	0.50	0.20	1.00

Table 3 Example of quasi-symmetry

0.10	0.05	0.15	0.30
0.05	0.40	0.05	0.50
0.06	0.02	0.12	0.20
0.21	0.47	0.32	1.00

A third kind of symmetry occurs when there are symmetric proportions in so far as it is possible, given asymmetric marginal distributions. *Quasi-symmetry* is a weaker condition than complete symmetry, meaning that the **odds ratios** describing the association structure, rather than the probabilities themselves, are symmetric. Specifically, for all i and j, the odds ratio $(\pi_{ik}\pi_{kj})/(\pi_{ki}\pi_{jk})$ is the same for all values of k. Thus, in Table 3, for $i = 1$, $j = 2$, and $k = 1, 2, 3$: $(\pi_{11}\pi_{12})/(\pi_{11}\pi_{21}) = (0.10 \times 0.05)/(0.10 \times 0.05) = (\pi_{12}\pi_{22})/(\pi_{21}\pi_{22}) = (0.05 \times 0.40)/(0.05 \times 0.40) = (\pi_{13}\pi_{32})/(\pi_{31}\pi_{23}) = (0.15 \times 0.02)/(0.06 \times 0.05) = 1$. Quasi-symmetry applies to square tables of size 3×3 and larger. The number of independent constraints is $(I-1)(I-2)/2$. For $I = 3$, quasi-symmetry is equivalent to **quasi-independence**.

The quasi-symmetry model was introduced by Caussinus [9] in multiplicative form as

$$\pi_{ij} = \alpha_i \beta_j \gamma_{ij},$$

where the α_i describe the rows, the β_j describe the columns, and the interaction parameters γ_{ij} satisfy $\gamma_{ij} = \gamma_{ji}$, for $i \neq j$. All parameters must be suitably constrained, such as $\prod_i \alpha_i = 1$. The model implies that there is a shift in the expected off-diagonal elements, relative to the symmetry model, caused by the differing main effects $\{\alpha_i\}$ of the rows and $\{\beta_j\}$ of the columns. For a **loglinear** representation, see [3, p. 235].

The **likelihood** equations have no direct solution but can be solved iteratively. Caussinus [9] used the method of iterative proportional fitting, Haberman [13] additionally described a method for obtaining ML solutions using the Newton–Raphson procedure (*see* **Optimization and Nonlinear Equations**), and Bishop et al. [7, p. 291] used an incomplete table representation. Using standard software such as SAS, one can fit the complete symmetry model as well as the quasi-symmetry model (cf. [3, p. 276]).

Example

Table 4, given by Stuart [18] and analyzed by Bishop et al. [7, p. 284], describes data on unaided distance vision for the right and left eyes. One would expect that most people have equivalent visual faculties in both eyes. Most observations in Table 4 concentrate on the main diagonal, supporting this hypothesis. Under complete symmetry, the estimated expected cell count is $\hat{m}_{ij} = (n_{ij} + n_{ji})/2$, and the Pearson **chi-square test** statistic for checking its fit (cf. [13, p. 489]) simplifies to

$$X^2 = \sum_{i=2}^{4} \sum_{j=1}^{3} \frac{(n_{ij} - n_{ji})^2}{(n_{ij} + n_{ji})}.$$

This, or the **likelihood ratio test** statistic G^2, has asymptotic χ^2 distributions with df = 6. The values $X^2 = 19.11$ and $G^2 = 19.25$ for Table 4 suggest that the hypothesis of complete symmetry is not tenable ($p = 0.004$).

For the quasi-symmetry (QS) model fitted to Table 4, the goodness of fit statistics equal $X^2 = 7.26$ and $G^2 = 7.27$, with corresponding p values of 0.064. Thus, the QS model provides a significant improvement in fit over the complete symmetry model. Table 5 shows the estimated expected frequencies $\hat{m}_{ij}$ for the QS model.

Table 4 Observed counts for unaided distance vision

Right eye grade	Left eye grade				Total
	Best	Second	Third	Worst	
Best	1520	266	124	66	1976
Second	234	1512	432	78	2256
Third	117	362	1772	205	2456
Worst	36	82	179	492	789
Total	1907	2222	2507	841	7477

Table 5 Expected values under quasi-symmetry for the unaided distance vision data of Table 4

Right eye grade	Left eye grade				Total
	Best	Second	Third	Worst	
Best	1520.00	263.38	133.58	59.04	1976
Second	236.62	1512.00	418.99	88.39	2256
Third	107.42	375.01	1772.00	201.57	2456
Worst	42.96	71.61	182.43	492.00	789
Total	1907	2222	2507	841	7477

The interpretation of quasi-symmetry requires some care, since the model refers to symmetrical odds ratios instead of symmetrical probabilities. For instance, the ML estimate of the odds of having second-degree rather than third-degree visual faculty on the left eye, given best faculty of the right eye, equal (263.38/133.58); compared to the odds of having second-degree rather than third-degree visual faculty on the left eye, given second-degree faculty of the right eye, which is (1512.00/418.99), we obtain an odds ratio of 0.55. Symmetrically, the odds of best grade to second grade on the left eye, given second-degree faculty on the right eye, compared to the odds given third-degree faculty on the right eye, equals (236.62/1512.00)/(107.42/375.01) = 0.55. Thus, the QS model implies a certain kind of symmetric relationship between the visual faculty of the left and the right eye, even though proportions of different grades of visual faculty differ for the right and the left eyes.

Three- and Higher-Dimensional Tables

More generally, consider three responses i_1, i_2, i_3, where each response i_g has I possible categories at any occasion g, $g = 1, 2, 3$. Then an I^3 contingency table summarizes the frequencies of the possible responses at the three occasions. A cell in the contingency table is denoted by $\mathbf{i} = (i_1, i_2, i_3)$ according to the responses. The probability that a randomly selected individual enters cell $\mathbf{i}$ in the contingency table is $\pi(\mathbf{i})$, the expected frequency for that cell is $m_{\mathbf{i}} = n\pi(\mathbf{i})$, and the **marginal probability** for response in category h at the gth occasion is denoted $\pi_g(h)$. Three types of symmetry can be defined as follows:

1. Complete symmetry occurs when $\pi_{\mathbf{i}} = \pi_{\mathbf{j}}$ for any permutation $\mathbf{j} = (j_1, j_2, j_3)$ of $\mathbf{i} = (i_1, i_2, i_3)$. For

instance, if $I = 3$, the responses (0,1,2), (0,2,1), (1,0,2), (1,2,0), (2,0,1), and (2,1,0) all have the same probability.

2. Marginal symmetry of order one is defined by $\pi_1(h) = \pi_2(h) = \pi_3(h)$, for all $h = 1, \ldots, I$. Marginal symmetry of order two additionally assumes equality of the joint marginal probabilities $\pi_{g,g'}(h, h'), = \pi_{g,g'}(h', h)$, for all $g \neq g'$, and $\pi_{12}(h, h') = \pi_{13}(h, h') = \pi_{23}(h, h')$. Marginal symmetry of order two implies that of order one.
3. In an I^3 table, quasi-symmetry of order two or order one is a property of **interactions** of π. Quasi-symmetry of order two is satisfied if there are three sets of parameters $\{\alpha_g(h), h = 1, \ldots, I\}$ and parameters $\{\gamma(\mathbf{i})\}$ that are identical for all permutations of $\mathbf{i} = (i_1, i_2, i_3)$, such that

$$\pi_{\mathbf{i}} = \alpha_1(i_1)\alpha_2(i_2)\alpha_3(i_3)\gamma(\mathbf{i}),$$

with suitable identifiability constraints. Quasi-symmetry of order one holds if there are $3(3-1)/2$ additional parameters $\beta_{gg'}(h, h')$ that satisfy $\beta_{g,g'}(h, h') = \beta_{g,g'}(h', h)$ and $\beta_{12}(h, h') = \beta_{13}(h, h') = \beta_{23}(h, h')$; that is,

$$\pi_{\mathbf{i}} = \alpha_1(i_1)\,\alpha_2(i_2)\,\alpha_3(i_3) \times \beta_{12}(i_1, i_2)\beta_{13}(i_1, i_3)\beta_{23}(i_2, i_3) \times \gamma(\mathbf{i}).$$

Quasi-symmetry of order one implies that of order two.

For a detailed discussion of this case, see [5] or [7]. MLEs are not directly available for either the marginal or the quasi-symmetry models. Bishop et al. [7] gave formulas for calculating the MLEs iteratively and thus the likelihood ratio statistics to test the corresponding hypotheses. Similar considerations apply to higher-dimensional tables, which can exhibit additional orders of quasi-symmetry. A more convenient representation of these models is given by a loglinear formulation (see [1, p. 388]). Computer packages for fitting loglinear models perform the necessary computations to obtain estimates for the symmetry and quasi-symmetry models of general order.

Tests Related to Quasi-Symmetry

An important property of quasi-symmetry is that it is complementary to marginal symmetry with respect to complete symmetry. The quasi-symmetry structure for expected cell counts with the addition of marginal symmetry is equivalent to complete symmetry (cf. [9]); that is,

$$\text{quasi-symmetry} + \text{marginal symmetry} = \text{complete symmetry}.$$

Thus, to test for marginal symmetry, one can test for complete symmetry assuming that quasi-symmetry holds. In terms of likelihood-ratio goodness of fit statistics,

$$G^2(\text{CS}|\text{QS}) = G^2(\text{CS}) - G^2(\text{QS}).$$

For $I \times I$ tables, this difference has on the **null hypothesis**, an approximate **chi-square** distribution with $I - 1$ **degrees of freedom**. For the example on unaided vision, $G^2_{\text{CS}} - G^2_{\text{QS}} = 19.25 - 7.27 = 11.98$ with df $= 3$, suggesting that the hypothesis of marginal symmetry does not hold. Note that complete symmetry implies both marginal symmetry and quasi-symmetry. In the absence of complete symmetry, one could have either marginal symmetry or quasi-symmetry, but not both. For T-dimensional tables Bhapkar & Darroch [6] proved that $H_{\text{CS}} = H^{(k)}_{\text{QS}} \cap H^{(k)}_{\text{MH}}$, where $H^{(k)}_{\text{QS}}$ and $H^{(k)}_{\text{MH}}$ are the hypothesis of quasi-symmetry and marginal symmetry of order k.

Several well-known tests, such as **McNemar's test**, Cochran's Q, or the **Mantel–Haenszel** procedure are special cases of tests for marginal symmetry. See, for instance, [2, p. 229]). Alternatively, one may use the "conditional likelihood score" statistics introduced by Darroch [10].

Other Applications of Quasi-Symmetry

Many useful models are special cases of the quasi-symmetry model. A **Markov chain** is a random process in which individuals move among a limited number of states at certain points in time. The probability of moving from state i to state j at any time point is called a transition probability. For a Markov chain of order one, these conditional probabilities depend only on what happened one time point previously. The considerations of complete, marginal, and quasi-symmetry apply to this model (see [15]). If the conditional probability of transition between events is the same in each direction, then there is

reversibility. In terms of the analysis of contingency tables, this is quasi-symmetry. If the margins do not change over time, then the process described by the Markov chain is in the equilibrium state; that is, the marginal distribution is stationary. In terms of contingency tables, this is marginal symmetry.

Other applications of quasi-symmetry arise in the context of **psychometric** models. The most basic item response model used in educational testing was proposed by Rasch [17] (*see* **Rasch Models**). It applies when a sample of subjects respond to a set of items, such that the observations are Bernoulli (*see* **Binary Data**) ("correct" or "incorrect" answer). In a certain sense, this model can be regarded as a quasi-symmetry model. For theoretical and computational aspects of this connection and for examples in the context of **generalized linear models**, see [14]. The **latent class model** is closely related to the Rasch model, but the latent variable representing the subjects is categorical rather than continuous. For quasi-symmetry in latent class models, see [3] and [4]. Another model closely related to the Rasch model is a model for **paired comparisons** formulated by Bradley & Terry [8] (see **Bradley–Terry Model**). This model has been shown to be equivalent to a quasi-symmetric loglinear model (Fienberg & Larntz [12]), and Dittrich et al. [11] describe how to fit the Bradley–Terry model using GLIM.

Conclusions

In practice, the rather restrictive hypothesis of complete symmetry is often rejected in favor of the more flexible structure of quasi-symmetry. Useful introductions to the topic are [1, 3, 7, and 13]. More advanced sources are [5, 6, 16].

REINHOLD HATZINGER

Questionnaire Design

In responding to an ever-increasing demand for information gathering and analysis to assist in making policy decisions, and designing effective treatments, many health professionals find themselves in the position of developing and reviewing survey questions or relying on information based on survey data (*see* **Surveys, Health and Morbidity**). The survey research community has known for some time that poorly designed questions can result in poor data quality, particularly in household or general population surveys [15]. Since surveys are a necessary source of data, the importance of improving our understanding of the inherent flaws of survey questions remains critical.

Through the use of a survey interview, it is feasible to collect a wide array of meaningful data covering factors of possible etiologic significance for disease [1, 6, 9, 10]. Information concerning the social, psychological, and economic aspects of each individual's life situation, as well as past experiences and family medical history, can be determined with varying degrees of validity and can be related to the incidence or **prevalence** of disease [8]. Due to the usually retrospective character of such investigations and the difficulties in establishing validity for self-report measures, most researchers accept that answers to these kinds of questions rely in part on **inference**, which may be error-prone [2, 11]. Nevertheless, the broad range of factors that can be explored through surveys make them particularly suitable for sorting out a multitude of hypotheses about health issues, treatments, and outcomes.

Designing a questionnaire requires development of a set of questions used to obtain statistically useful information from an individual. While that task appears to be straightforward and clear cut, questionnaires are difficult to design for several reasons (see Schechter & Herrmann [16] for further discussion). First, each question must provide a valid and reliable measure. Secondly, the questions must clearly communicate the research intention to the survey respondent. Thirdly, the questions must be assembled into a logical, clear instrument that flows naturally and will keep the respondent sufficiently interested to continue cooperation (*see* **Interviewing Techniques**). To meet these challenges, designing a questionnaire should involve three distinct phases: initial questionnaire planning, development and testing of specific questions, and final construction of the data collection instrument as a whole.

Initial Questionnaire Planning

Low estimates of the time needed to develop early drafts of questions can have a serious effect on questionnaire quality. Typically, the person responsible for developing the survey instrument is one of many people involved in the survey process. However, since the survey cannot be fielded without a completed data collection instrument, pressure to develop a questionnaire quickly is often exerted. Experienced questionnaire designers joke that a questionnaire is finished when time runs out, not necessarily when it is the best it can be.

If the instrument needs to be constructed from scratch rather than modified from an existing one, a list of concepts or topics will first be generated. Translating general topics into series of survey questions is challenging and time-consuming. Consultations, meetings, and brainstorming sessions with subject matter experts, survey methodologists, and survey sponsors will be beneficial prior to writing any questions. Reviews of related surveys and data collection instruments that might have measured similar concepts will help facilitate the writing of new questions.

Once a draft of questions is developed, time is needed for iterative cycles of review and revision. This cyclical process is critical to the development of the instrument, because drafts of questions usually help researchers to refine and clarify their research objectives. It is through this process that the questionnaire will evolve, and the concepts included in the survey will become more focused. Reviews should insure that every item in the questionnaire is defensible as a meaningful contribution to the intended analyses. Most designers work with survey sponsors to develop table specifications that illustrate how the data from a series of questions will be analyzed. A critical examination of draft table shells is key to insuring a comprehensive, thoughtful research plan. A related approach that some find helpful is to document in written form the purpose or justification for each question.

Invariably, the length of the questionnaire becomes a topic of debate during the initial planning phase. A

lengthy instrument is cause for concern, because it increases both the cost of interviewer administration and the respondent burden. Survey sponsors and other interested researchers often view a questionnaire as a "once in a lifetime" opportunity to collect data that will contribute significantly to solving a unique problem. Reviewers of draft questions find that their topics of interest increase because they begin to see the rich potential that the data will offer. It is nevertheless necessary to limit the instrument scope for a number of reasons.

Beyond the sheer data collection expenses of long questionnaires is the impact that length has on data quality. Increased response burden may lead to cognitive problems in answering questions that can result in response error. For example, respondents may resort to guessing or less serious efforts at recalling information [13]. Respondents may begin to give wrong answers as a way to shorten their interview. They may ascertain, for example, that answering "No" to a screener question about a medical condition will eliminate a long series of follow-up questions about that condition. Interviewers also become tired and aware of the burden on respondents. In order to complete interviews successfully, they may read questions too quickly or may lead respondents to answers.

Lastly, the survey objectives and draft questions need to be reviewed together to insure that the right types of questions are being asked for a given topic. Questionnaires can contain a mix of questions that ask for reports of knowledge, behavior, practice, attitude, and opinion. In addition, many surveys ask one respondent for proxy reports of others. Consider the similarities and differences in the following questions:

1. Knowledge – How often does the National Cancer Institute recommend that women age 50 and older should get mammograms?
2. Opinion – How often do you think that women age 50 and older should get mammograms?
3. Behavior – Since turning 50, how many mammograms have you had?
4. Proxy – Since turning 50, how many mammograms has your wife had?

Sponsors sometimes suggest questions that will not measure what is needed. During the review process, categorizing questions by type (e.g. knowledge) and reviewing these categories against the list of topics can improve the instrument and subsequent analysis.

Development and Testing of Specific Questions

After draft questions have been developed, the next step is to refine these specific questions and test them with a variety of respondents. Testing questions in a cognitive laboratory offers an opportunity to identify serious question problems in a cost-effective and timely manner. Cognitive interviews are based on the theory that in answering a survey question, respondents mentally process the question in cognitive stages. Tourangeau [20], Willis et al. [21], and others (see Jobe & Herrmann [12] for further discussion) have presented cognitive models that describe four stages: comprehension of the question, retrieval of information, decision or judgment about the question and answer, and the actual response given. Applying principles of cognitive psychology when conducting laboratory interviews helps the researcher understand and resolve the problems that questions can create for respondents.

Terms and Concepts Should be Familiar and Easy to Understand

Problems arise when questions contain unfamiliar, vague, or ambiguous terms and concepts. The respondent's comprehension of the question may not coincide with the intentions of the questionnaire designer but, nevertheless, it serves as the internal frame from which the respondent develops an answer. As a general rule, questions should be written in the standard spoken version of the language being used. Wording that is specific and concrete is more apt to communicate uniform meaning. Furthermore, words that are nontechnical and shorter both in length and in syllables are preferred.

Laboratory interviews often reveal problems associated with question structure. For example, the question can be so brief that the respondent is unsure of the intent of the question. Similarly, a question can be too long and complex, so that the respondent is unsure what the question is really asking. These sorts of question problems can result in the respondent's individual interpretation of what is

being asked. If the respondent is to assume or know something specific before formulating an answer, the relevant information must be included in the question.

Cues and Ordering of Questions Should Serve to Stimulate Recall

Survey respondents are often asked to recall and access information from memory. This process may be fairly direct and a quick and accurate answer to the question may be provided. However, problems can occur when the respondent has to recall too much information, or has to recall information that is not readily accessible in memory. Recalling an event or behavior can be especially difficult if the event was relatively unimportant or trivial to the respondent, if the event happened long ago, or if the question requires recall of too much detail (*see* **Recall Bias**).

Recognizing some degree of error in reporting exact information, there are questionnaire design steps that can help the respondent's memory search. Sometimes, a short series of related questions will jog the respondent's memory and assist in more difficult recall tasks. Providing an anchor for the reference period (such as "Since last Christmas ...") can help place the memory in correct context [14]. In a face-to-face survey, recall can also be stimulated by the use of calendars, timelines, or other visual tools that may help the respondent to organize events in a time sequence. Questions should ask about information that is directly accessible to respondent memory. Recall delay should be kept to a minimum, as the recent past is generally easier to remember than more distant events. Focusing a question only on recent activity may reduce telescoping, the tendency for rare events occurring prior to the designated recall period to be erroneously included in the activity report [4, 5].

As the respondent evaluates retrieved information, he or she judges the accuracy of the response and may decide that the information is not complete or accurate. For certain questions, respondents may quickly decide that the task is too complicated to try to retrieve the information from memory and, rather, will answer with an estimate. The questionnaire designer should anticipate that respondents will rely on estimation strategies if the question requires too much detail or mental calculations.

Ordering and Format of Questions Should be Unbiased and Balanced

The ordering of questions can influence response strategies and response errors. Context effects occur when two or more questions deal with aspects of the same issue or with closely related issues. This takes on practical importance because questionnaires are ordinarily constructed by grouping together questions on the same subject matter which may, ironically, encourage context effects. General questions seem to be more sensitive to order effects than more specific questions. It may be that general questions are so broad that their frame of reference is more open to interpretation and, therefore, respondents are more likely to use the context from another question in their interpretation.

The format of the question itself can also cause cognitive problems. An open format allows the respondent to offer any answer and the interviewer records a verbatim response. However, questionnaires that are designed to collect significant amounts of data from a relatively large pool of respondents usually employ a closed format. Uniform, fixed response categories are provided and the respondent is instructed to select from them. The responses are coded, numbers are assigned to them, and they are counted and statistically analyzed. When determining the format of the responses, however, more than just an open and closed format needs to be addressed. What scales are being used (*see* **Measurement Scale**)? Are the response options consistent with the measure being sought? One typical finding in reviews of questionnaires is that the question and corresponding response categories ask for much more detail than is needed for analysis purposes [17]. This demand for detail can create an unnecessary burden on the respondent which could lead to "satisficing" (providing a quick answer, whether accurate or not, to satisfy the survey requirements [13]).

Assembling the Final Questionnaire

After the questions have been revised and tested, they must be integrated into a final data collection instrument. Sponsors and subject matter experts typically focus on the development and review of individual questions designed to measure specific items of interest. While each questionnaire item must be judged

carefully on its own merit, it is usually the responsibility of the questionnaire designer to fit the items together in a meaningful way so that the entire questionnaire is unified. The goal is for the respondent to sense that the progression between topics and questions is natural and interesting. The smooth flow of the questionnaire should not only increase the respondent's attention and cooperation, but has an important effect on the interviewer's ability to best do his/her job. Survey researchers who have observed field interviews often hear interviewers make comments such as "I know I already asked you this, but I have to ask again". This is troublesome both to the interviewer, who often worries that the respondent will break off the interview prior to completion, and to the respondent, who often becomes aggravated or irritated by questions that are repetitive, inappropriate, or abrupt (*see* **Interviewing Techniques**). It is useful to consider the following when reviewing the overall questionnaire:

1. Is there a logical progression of questions, so that the respondent is drawn into the interview by awakening interest in the topic?
2. Is the respondent first asked items that are simple to answer and then asked those which are more detailed or complex?
3. Is the respondent first asked objective, straightforward questions and then asked for more personal or sensitive information?
4. Is the respondent brought smoothly from one frame of reference to another by use of transitional statements or series of questions that fit well together?

When analyzing the questionnaire as a whole, one should experiment with moving sections of questions. The order of the question series is originally put together in a somewhat random fashion, and yet designers are hesitant to move series of questions around in order to increase logic and administration flow. One check on the flow of the questionnaire is to list, in order, the main topics of each series to determine if the ordering is appropriate and meaningful.

Questions and response formats should be reviewed for consistency. For example, it is undesirable for series of questions to shift abruptly from Yes/No to True/False to Agree/Disagree response alternatives. It is also confusing to vary the use of reference periods. For example, questions about events in the past 12 months should not be interspersed with questions about events in the past 30 days.

A thorough check of skip patterns is essential. Skip patterns insure that inappropriate questions are skipped, and also that appropriate items are not skipped. Both respondents and interviewers can quickly feel irritated by inappropriate, repetitive questions. These patterns should be tested by mock administrations of the questionnaire, following as many different branches of skip logic as possible.

Lastly, the mode of administration must be considered in the final review of the instrument. There are three common modes for data collection: (i) self-administered, where a respondent completes a form with no interviewer interaction; (ii) telephone, where an interviewer calls a respondent and asks survey questions over the phone (*see* **Telephone Sampling**); and (iii) face-to-face, where an interviewer meets with a respondent and asks the survey questions in person (*see* **Interviewer Bias**). For each mode, another level of complexity may be added by using a computer for data entry (*see* **Computer-assisted Interviewing**).

Choice of mode may seem primarily an administrative issue, but it can also affect data quality [3, 7, 18]. For self-administered questions, instructions must be clear, brief, and easy to follow without assistance. Since the respondent cannot ask for clarification, he or she will interpret questions and response alternatives from a personal frame of reference. And if the question or format is too complicated or technical, error may result as the respondent becomes frustrated in attempts to complete the questionnaire.

Personal interviews obviously offer visual communication between the interviewer and the respondent. This is important not only in motivating the respondent to answer accurately, but also in serving to troubleshoot comprehension and recall problems [19]. Interviewers can answer questions and provide detailed explanations as to what the questions really mean. In addition, face-to-face interviews provide excellent opportunities for respondents to use memory aides such as cards and calendars. When designing telephone surveys, questions should be more brief and direct than in face-to-face interviews [7]. Response alternatives should be shorter and easier to understand because the respondent must remember all the choices while selecting an answer.

Conclusions

In the 1980s, a shift in questionnaire design from a literary approach to a scientific approach was begun. Research during this period has resulted in an increased understanding of the mental processes that enable survey respondents to answer questions, and this understanding has produced a dramatic improvement in the quality of questionnaires. Clearly, a good questionnaire grows from research hypotheses that have been carefully studied and thought out. Discussion of the research problem with colleagues and subject matter experts is critical to developing good questions. Questions should be reviewed, revised, and tested on an iterative basis. Furthermore, examining the questionnaire as a whole is an essential element of good questionnaire design. Since health professionals, researchers, and policy makers rely heavily on survey data, current research on ways to reduce **nonsampling errors** in surveys will continue to have emphasis and importance.

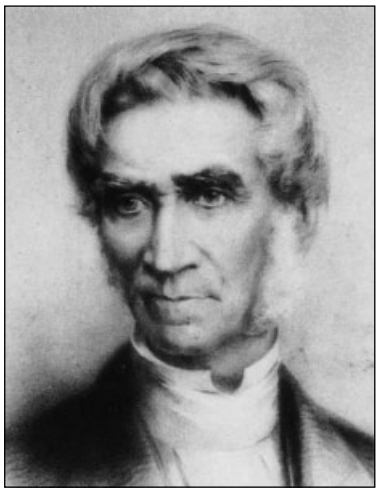
SUSAN SCHECHTER

Quetelet, Lambert–Adolphe–Jacques

Born: February 22, 1796, in Ghent, Belgium.
Died: February 17, 1874, in Brussels, Belgium.



Adolphe Quetelet received his initial scientific training from the University of Ghent. After graduating with a doctor of science degree in 1819, he taught mathematics at a collège in Brussels. When he was elected to the Académie Royale des Sciences et Belles-Lettre de Bruxelles, he campaigned for the founding of an astronomical observatory in Belgium. In 1823, the Belgian government agreed to fund the project and to finance Quetelet's visit to Paris where he learned mathematical and astronomical methods from such scientific notables as Jean Baptiste Joseph Fourier and **Siméon-Denis Poisson** and, possibly, the aging **Pierre Simon Laplace**. In addition to these theoretical concerns, Quetelet's sojourn in Paris also sparked a lifelong interest in social statistics: he began to collect data on things like birth, death, marriage, crime, and suicide, and arranged his results according to age, sex, profession, and place of residence (*see* **Vital Statistics, Overview**).

In 1835, Quetelet combined his twin interests in statistics and the natural sciences in a book entitled, *Sur l'Homme et le Dévelopment de ses Facultés*. By developing an elaborate system of metaphors and similes, Quetelet attempted to describe the statistical regularities in society in terms of the theories of physics and astronomy; he dubbed his activity "social physics" with the central organizing construct being l'homme moyen, or the statistically "average man". The average man produced stability in the social order by serving as a kind of "center of gravity". In addition to this political role, Quetelet [2] also emphasized the centrality of the concept of the average man for medical diagnosis: "The consideration of the average man is so important in medical science, that it is almost impossible to judge of the state of an individual without comparing it to that of another imagined person, regarded as being in a normal condition."

Quetelet's specific analogies from physics and astronomy proved to have little resonance among his contemporaries; nevertheless, he still had a tremendous impact on the development of biostatistical thinking. As discussed in Lécuyer [1], his general belief in the orderliness of the social world as revealed through statistical data was exceedingly influential among some of the leading statistically minded physicians and demographers of the nineteenth century, such as Louis-Adolphe **Bertillon** (1821–1883), Jacques Bertillion (1851–1922), and **William Farr** (1807–1883). Also, Quetelet had a profound impact on the nineteenth-century statistical movement more generally by playing a decisive role in the founding of numerous statistical societies, such as Section F of the British Association for the Advancement of Science (1833), the Statistical Society of London (1834), and various international statistical congresses. Even today, some of Quetelet's statistical ideas are still in use; one prominent example is his measure of body mass (now called Quetelet's Index), which is formed by computing the weight of an individual and dividing it by the height of the individual squared.

J. ROSSER MATTHEWS

Queuing Processes

A facility has s stations, or servers, for serving customers. If all the s stations are occupied, then newly arriving customers must form a queue, or a waiting line, until a station is available for service. The main features in analytic studies of queuing are the length of queue, the waiting time, and the duration of service.

Queuing phenomena can be observed in many practical situations where congestion problems exist. Queuing is apparent in everyday business transactions, in communications, in medical services, in transportation, and in industry. The objective of queuing is to resolve congestion, to optimize efficiency, to minimize waiting time or inconvenience to customers, to speed production, or even to save life.

The queuing concept was originally formulated by Erlang [3] in his study of telephone network congestion problems. In "The Life and Works of K Erlang," published in 1948, there is a good collection of articles of both practical importance and theoretical interest. However, it was the two papers by Kendall [6, 7] that brought queuing problems to the attention of theoretical people. As advances were made in **stochastic processes**, queuing theory also has flourished. Mathematicians, statisticians, engineers, and investigators in many other disciplines have made contributions to queuing theory and to the resolving of practical problems. Actual needs and the curiosity of theoretical investigators have elicited many variations of queuing problems. It has been observed, for example, that customers often arrive in groups of various sizes, rather than singly; unaccommodated incoming phone calls may be lost instead of waiting in a queue (balking); service time may vary from one station to another due to the difference in efficiency of servers (heterogeneous servers); the service provided in medical institutions, in assembly lines, and others, often consists of several phases, each requiring a separate waiting line (tandem queue). Most of the problems have been resolved with great mathematical ingenuity, some beyond the level of this article.

Generally, a queuing system is identified by: (i) the input process (arrivals may be random, planned, or patterned; (ii) the service time distribution; and (iii) the number of stations; or simply by

Input distribution/service time/number of stations.

Symbolically, G ("general") stands for an arbitrary distribution; M ("Markov") for arrivals by a **Poisson process**, **exponential** interarrival time, or exponential service time; and D ("deterministic") for constant interarrival time or service time. For example, we may denote a queuing system with Poisson arrivals, an exponential service time, and s stations by $M/M/s$, and denote a queue with arbitrary arrivals, a constant service time and one service station by $G/D/1$. In this entry, we consider $M/M/s$ queues, for $s > 1$, and discuss in some detail the number of customers in a queuing system, the length of the queue, the waiting time, the service time, and the total amount of time a customer will spend in the system, and their relationship. The corresponding formulas for an $M/M/1$ queue can be obtained from this article with the substitution of $s = 1$. The $M/M/\infty$ queue, in which there are an infinite number of stations, is also presented. The article closes with a brief account of $M/G/1$ queues. Queuing theory is a vast area with an enormous literature. This article provides just a brief introduction. Several important areas are omitted, such as networks of queues (see, for example, [5]) and queues with priorities (see, for example, [8]). The references include several sources for discovering more about this fascinating topic.

$M/M/s$ Queues

In an $M/M/s$ queue, there are s stations (servers), the arrival of customers follows a Poisson process with parameter λ; service time has an exponential distribution with parameter μ; and the service discipline is first come, first served. When all the s stations are occupied at time t, there is a probability $s\mu\Delta + o(\Delta)$ that one of the stations will be free for service within the time element $(t, t + \Delta)$. Let $X(t)$ be the number of customers in the system at time t, including those being served and those in the waiting line. If there are i customers present at time $t = 0$, so $X(0) = i$, let the transition probabilities be

$$P_{i,k}(0, t) = \Pr[X(t) = k | X(0) = i], \quad i, k = 0, 1, \ldots. \tag{1}$$

These satisfy the following system of differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,0}(0, t) = -\lambda p_{i,0}(0, t) + \mu p_{i,1}(0, t),$$

$$\frac{\mathrm{d}}{\mathrm{d}t}p_{i,k}(0,t) = -(\lambda + k\mu)p_{i,k}(0,t) + \lambda p_{i,k-1}(0,t) + (k+1)\mu p_{i,k+1}(0,t), \quad k = 1, \ldots, s-1, \tag{2}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}p_{i,k}(0,t) = -(\lambda + s\mu)p_{i,k}(0,t) + \lambda p_{i,k-1}(0,t) + s\mu p_{i,k+1}(0,t), \quad k = s, s+1, \ldots.$$

Instead of solving the above differential equations for every finite t, we consider the limiting case when $t \to \infty$, and let $X = X(\infty)$ be the corresponding limiting **random variable**. We shall call the possible values of $X(\infty)$ the *states* of the queuing system. The states in a system are said to be communicative if any state in the system can be reached by any other state in the system (*see* **Markov Chains**).

In this case, the limiting probabilities

$$\lim_{t\to\infty} \Pr[X(t) = k | X(0) = i] = \pi_k, \quad i, k = 0, 1, \ldots, \tag{3}$$

exist, independently of the initial state i. If, in addition,

$$\sum_k \pi_k = 1, \tag{4}$$

then these limiting probabilities give the stationary distribution of the Markov chain $\{X(t), t \geq 0\}$, otherwise there is no stationary distribution and $\pi_k = 0, k = 0, 1, \ldots$ (see [4, p. 261]).

Since the limiting probabilities are independent of time, their derivatives with respect to time vanish. This provides a series of difference equations, leading to the solution

$$\pi_k = \frac{(s\rho)^k}{k!}\pi_0, \quad k = 1, \ldots, s, \tag{5}$$

$$= \rho^k \frac{s^s}{s!}\pi_0, \quad k = s+1, \ldots, \tag{6}$$

or

$$\pi_k = \rho^{k-s}\pi_s, \quad k = s+1, \ldots, \tag{7}$$

where

$$\pi_0 = \left[\sum_{k=0}^{s} \frac{(s\rho)^k}{k!} + \frac{(s\rho)^s}{s!}\frac{\rho}{1-\rho}\right]^{-1} \tag{8}$$

and

$$\rho = \frac{\lambda}{s\mu} \tag{9}$$

is called the *traffic intensity*.

Note that ρ is the ratio of the arrival rate to the service rate when all s servers are busy. The above solution requires that $\rho < 1$. If $\rho \geq 1$, then $\pi_k = 0$, $k = 0, 1, \ldots$, and no stationary distribution exists. It is intuitively clear that the queue eventually grows unboundedly if $\rho > 1$.

The mean and variance of X, the number of customers, are

$$\mathrm{E}(X) = s\rho + \frac{\rho\pi_s}{(1-\rho)^2} \tag{10}$$

and

$$\mathrm{var}(X) = s\rho + \frac{\rho\pi_s}{(1-\rho)^3}[(1+\rho) + s(1-\rho)^2] - \frac{\rho^2\pi_s^2}{(1-\rho)^4}. \tag{11}$$

Length of Queue

Let $Q = Q(\infty)$ be the number of customers in a queue in the limiting case, and let (q_n) be the probability distribution of Q:

$$q_n = \Pr(Q = n), \quad n = 0, 1, \ldots. \tag{12}$$

When there are s or fewer than s customers in the system, no one will be waiting in the line, and hence

$$q_0 = \Pr(X \leq s) = 1 - \frac{\rho}{1-\rho}\pi_s. \tag{13}$$

When there are $k = s + n$ customers in the system, the length of the queue is n, and the probability is

$$q_n = \Pr(X = s + n) = \rho^n \pi_s, \quad n = 1, 2, \ldots. \tag{14}$$

It is easy to verify that

$$\sum_{n=0}^{\infty} q_n = 1. \tag{15}$$

The mean and variance of Q are:

$$\mathrm{E}(Q) = \frac{\rho\pi_s}{(1-\rho)^2} \tag{16}$$

and

$$\mathrm{var}(Q) = \frac{\rho(\rho+1)\pi_s}{(1-\rho)^3} - \frac{\rho^2\pi_s^2}{(1-\rho)^4}. \tag{17}$$

Service Time

The service time t is the length of time needed to complete service to a customer. It is assumed here that all the s stations are equally efficient and have the same exponential distribution, with density function

$$h_t(\tau) = \mu \exp(-\mu\tau), \quad \tau > 0, \tag{18}$$

and distribution function

$$H_t(\tau) = 1 - \exp(-\mu\tau), \quad \tau \geq 0. \tag{19}$$

Let $t_1, t_2, \ldots, t_s$ be the service times of the s stations. They have the same density function in (18) and the same distribution function in (19). If the s stations begin to serve customers at the same time, then it is clear that their service times will have the same distribution. In practice, at a given moment, some of the stations may already have served customers for different lengths of time, and it seems inappropriate to speak of the same distribution when services are already in progress. However, under the present assumption of the exponential density function in (18) where μ is constant, the length of time required to complete service has the same probability distribution, regardless of when the service first started. Therefore it is justified to speak of the same service time distribution for $t_1, t_2, \ldots, t_s$.

Let us arrange the s service times in order of magnitude, and introduce the **order statistics**

$$t_{(1)} < t_{(2)} < \cdots < t_{(s)}.$$

Of course, we do not know in advance which station will have the shortest service time $t_{(1)}$, or which station will have the longest service time $t_{(s)}$. According to the theory of order statistics, when the exponential function (18) is the underlying distribution, the density function of $t_{(1)}$ is

$$f_{t_{(1)}}(\tau) = s\mu \exp(-s\mu\tau), \quad \tau > 0, \tag{20}$$

which has expectation

$$\mathrm{E}(t_{(1)}) = \frac{1}{s\mu} \tag{21}$$

and variance

$$\mathrm{var}(t_{(1)}) = \frac{1}{s^2\mu^2}. \tag{22}$$

It is the distribution of $t_{(1)}$ that is needed for studying the waiting time in a queuing process.

Waiting Time

The waiting time is the length of time that a customer has to wait before receiving service. Let W_n be the waiting time of the nth customer in a queue, $n = 1, 2, \ldots$. Since the first customer in a queue will get service as soon as one of the s stations becomes available, the waiting time W_1 has the same distribution as $t_{(1)}$. The density function of W_1 is

$$f_{W_1}(\tau) = f_{t_{(1)}}(\tau) = s\mu \exp(-s\mu\tau), \quad \tau > 0, \tag{23}$$

and the distribution function of W_1 is

$$F_{W_1}(\tau) = 1 - \exp(-s\mu\tau), \quad \tau \geq 0 \tag{24}$$

which is an exponential distribution with parameter $s\mu$, as noted earlier.

As soon as the first person in a queue leaves the queue to receive service, the second person in the queue becomes the first person in the queue, and he or she in turn will have to wait for another period of W_1 before receiving the service. In other words, the waiting time of the second person in the queue is

$$W_2 = W_{11} + W_{12}, \tag{25}$$

where both W_{11} and W_{12} stand for W_1, the second subscripts are added to differentiate the two periods of waiting. The density function of W_2, $f_{w_2}(\tau)$, is obtained from the density function of W_1:

$$f_{w_2}(\tau) = \int_0^\tau f_{w_1}(\xi)\, f_{w_1}(\tau - \xi)\, \mathrm{d}\xi. \tag{26}$$

Substituting (23) in (26) and integrating the resulting expression, we obtain an explicit formula of the density function of W_2:

$$f_{w_2}(\tau) = (s\mu)^2 \tau \exp(-s\mu\tau), \quad \tau > 0. \tag{27}$$

In general, the waiting time of the nth person in a queue is

$$W_n = W_{11} + W_{12} + \cdots + W_{1n}. \tag{25a}$$

Each of $(W_{11}, W_{12}, \ldots, W_{1n})$ has the same distribution as W_1. Following formula (26), we use the density function of W_1 in formula (23) and repeated integrations to find the following formula of the density function of W_n:

$$f_{W_n}(\tau) = (s\mu)^n \frac{\tau^{n-1}}{(n-1)!} \exp(-s\mu\tau), \quad \tau > 0. \tag{27a}$$

Now, consider a newly arriving customer and their waiting time W. If there are fewer than s customers in the system, then the new customer will receive service immediately, and W will have a value zero with probability

$$\Pr\{W = 0\} = \Pr\{X < s\}$$

or

$$\Pr\{W = 0\} = \sum_{k=0}^{s-1} \pi_k = 1 - \frac{\pi_s}{1-\rho}. \tag{28}$$

If there are $s + n - 1$ customers ahead of the new customer, then his or her waiting time is W_n. Therefore the density function of W is

$$f_W(\tau) = \sum_{n=1}^{\infty} \pi_{s+n-1} f_{W_n}(\tau). \tag{29}$$

Substituting formulas (7) and (27a) in (29), and simplifying the resulting expression, we find the density function of the waiting time W:

$$f_W(\tau) = \pi_s s\mu \exp[-(1-\rho)s\mu\tau], \quad \tau > 0. \tag{30}$$

We should emphasize that the waiting time W is not an ordinary continuous variable, as it has a point of discontinuity at $W = 0$. Hence,

$$\begin{aligned} F_W(\tau) &= \left(1 - \frac{\pi_s}{1-\rho}\right) + \int_0^{\tau} \pi_s s\mu \\ &\quad \times \{\exp[-(1-\rho)s\mu\xi]\}\,\mathrm{d}\xi \\ &= 1 - \frac{\pi_s}{1-\rho}\exp[-(1-\rho)s\mu\tau], \quad \tau \geq 0. \end{aligned} \tag{31}$$

The mean and variance of W are, respectively,

$$\mathrm{E}(W) = \frac{\pi_s}{(1-\rho)^2 s\mu} \tag{32}$$

and

$$\mathrm{var}(W) = \frac{2\pi_s}{(1-\rho)^3(s\mu)^2} - \frac{\pi_s^2}{(1-\rho)^4(s\mu)^2}. \tag{33}$$

Total Length of Time in the System

The total length of time T that a customer spends in a queuing system is the sum of the waiting time W and the service time t:

$$T = W + t, \tag{34}$$

with the density function $g_T(\tau)$ and the distribution function $G_T(\tau)$. While the waiting time W and the service time t are independent continuous random variables, the point of discontinuity of the distribution of W at $W = 0$ invalidates the usual relation of convolution between their density functions. The density function $g_T(\tau)$ may be obtained by way of the distribution function $G_T(\tau)$. Using the relationship among the three distribution functions of T, W, and t,

$$G_T(\tau) = \int_0^{\tau} F_W(\xi)\,\mathrm{d}H_t(\tau - \xi), \tag{35}$$

we find that

$$\begin{aligned} G_T(\tau) &= 1 - \exp(-\mu\tau) - \frac{\pi_s}{(1-\rho)[(1-\rho)s - 1]} \\ &\quad \times \{\exp(-\mu\tau) - \exp[-(1-\rho)s\mu\tau]\} \end{aligned} \tag{36}$$

from which

$$\begin{aligned} g_T(\tau) &= \mu\exp(-\mu\tau) + \frac{\pi_s\mu}{(1-\rho)[(1-\rho)s-1]} \\ &\quad \times \{\exp(-\mu\tau) - (1-\rho)s\mu\exp[-(1-\rho)s\mu\tau]\}, \\ &\quad \tau > 0. \end{aligned} \tag{37}$$

Since $G_T(\infty) = 1$, the distribution of T is proper. From (37) we derive the expectation

$$\mathrm{E}(T) = \frac{\pi_s}{(1-\rho)^2 s\mu} + \frac{1}{\mu} \tag{38}$$

and variance

$$\mathrm{var}(T) = \frac{2\pi_s}{(1-\rho)^3(s\mu)^2} - \frac{\pi_s^2}{(1-\rho)^4(s\mu)^2} + \frac{1}{\mu^2}. \tag{39}$$

Clearly, (38) and (39) can be derived also from the relations:

$$\mathrm{E}(T) = \mathrm{E}(W) + \mathrm{E}(t) \tag{40}$$

and

$$\mathrm{var}(T) = \mathrm{var}(W) + \mathrm{var}(t). \tag{41}$$

A Busy Station

The probability that a station is busy is equal to the traffic intensity ρ. Verification of this probability is straightforward. Since, if $X > s$, the probability that

a station is busy is one, and if $X = k$ for $k < s$, the probability that a station is busy is k/s,

$$\Pr\{\text{a station will be busy at a given moment}\}$$
$$= \sum_{k=0}^{s-1} \pi_k \frac{k}{s} + \sum_{k=s}^{\infty} \pi_k = \rho \left[1 - \frac{\pi_s}{\rho(1-\rho)} \right] + \frac{\pi_s}{1-\rho}$$
$$= \rho. \tag{42}$$

$M/M/\infty$ Queues

When there are infinitely many stations in a system, the number of stations in use is the number of customers present. There are no queues and no waiting times. For $t \geq 0$, let $X(t)$ denote the number of customers present at time t. Again we consider the case where the arrival of customers follows a Poisson process with rate λ and service time has an exponential distribution with parameters μ, so the queuing system under discussion is $M/M/\infty$. In that case, it is easily seen that $\{X(t), t \geq 0\}$ follows the simple migration process (with η replaced by λ) that is analyzed in the article entitled **Migration Processes**, where the distribution of $X(t)$ is determined for any $t \geq 0$ and any given initial number of customers $X(0)$. In particular, a stationary distribution always exists for $X(t)$, and is Poisson with mean λ/μ. Note that this corresponds to letting $s \to \infty$ in the solution (5)–(9) of the $M/M/s$ queue, as one would expect on intuitive grounds.

$M/G/1$ Queues

Whilst the assumption that the arrival of customers follows a Poisson process may be reasonable in many settings (although it precludes multiple arrivals), the assumption that a typical service time follows an exponential distribution is clearly unrealistic in most applications. Thus, we now study $M/G/1$ queues, so there is a single server, customers arrive at the points of a Poisson process with rate λ and the service times are independent and identically distributed, according to some specified distribution.

Method of Stages

The *method of stages* is a device invented by Erlang for determining the properties of $M/G/1$ queues for certain service time distributions. In its simplest form, the service time of a customer is assumed to consist of k stages, labelled 1, 2, ..., k, having independent exponential service times with density given by (18), so the total service time of a given customer follows the gamma distribution with density $f_S(t) = \mu^k t^{k-1} e^{-\mu t}/(k-1)!$ $(t > 0)$. For $t \geq 0$, let $X(t)$ denote the number of customers in the system at time t and, if $X(t) > 0$, let $I(t)$ denote the stage of the customer that is being served. Then the queuing system is completely specified by the process $\{(X(t), I(t)), t \geq 0\}$. Moreover, this process is Markov, owing to the lack-of-memory property of the Poisson process and the exponential distribution. Its stationary distribution can be determined using similar methods to that described for the $M/M/s$ queue (see [2, Section 5.2]) thus facilitating analysis of the queue. Note that the k stages need not correspond to physical stages during a typical service time. Observe that, in this model, service of a typical customer is described by a continuous time Markov chain with $k+1$ states (state $k+1$ corresponds to completion of service), with the service time being given by the time to absorption in state $k+1$. This framework clearly extends so that a typical service time is given by the time to absorption of an arbitrary but specified finite state space continuous time Markov chain; such an absorption time is said to have a **phase-type** distribution. Any given service time distribution can be approximated arbitrarily closely by a phase-type distribution, so this approach provides a flexible framework for computational analysis of queues (see, for example, [1] and [9]).

Embedding

Suppose now that a typical service time, S say, follows any arbitrary but specified distribution. For $t \geq 0$, let $X(t)$ denote the number of customers in the system at t. Now $\{X(t), t \geq 0\}$ is not a Markov process, unless S follows a negative exponential distribution, however, the long-term behavior of the queue can be studied by exploiting a Markov chain that is embedded in $\{X(t), t \geq 0\}$ ([7]), as is now described. For $n = 1, 2, \ldots$, let X_n be the number of customers in the system just after completion of the nth customer's service. The lack-of-memory property of the Poisson arrival process implies that $\{X_n, n \geq 1\}$ is a Markov chain, whose asymptotic properties are analyzed in, for example, Grimmett and

Stirzaker [4, Section 11.3]. Here we just outline the main results.

Let $\rho = \lambda E[S]$ denote the traffic intensity of the queue and suppose that $\rho < 1$. Then both $\{X(t); t \geq 0\}$ and $\{X_n, n \geq 1\}$ are asymptotically stationary and

$$\lim_{t\to\infty} \Pr[X(t) = k | X(0) = i] = \lim_{n\to\infty} \Pr[X_n = k | X_1 = i] = \pi_k, \quad i, k = 0, 1, \ldots, \tag{43}$$

where $\sum_k \pi_k = 1$. Moreover, the limiting probability that the queue is empty is $\pi_0 = 1 - \rho$ and the limiting mean number of customers in the system is

$$E[X] = \rho + \frac{\rho^2 + \lambda^2 \mathrm{var}(S)}{2(1-\rho)}, \tag{44}$$

which is known as the Pollaczek–Khintchine formula. Suppose that the queue is in equilibrium, and let W and $T = W + S$ denote, respectively, the waiting time and the total time spent in the system of a typical customer. Then $E[T]$ satisfies Little's formula

$$E[T] = \lambda^{-1} E[X]. \tag{45}$$

Note that for fixed mean service time $E[S]$, the equilibrium mean queue size, mean waiting time and mean total time spent in the system are all increasing with the variance of a typical service time, so these quantities are all minimized when the service times are constant.

Busy Periods

Suppose that the queue is empty just prior to time $t = 0$ and a customer arrives at $t = 0$. Let B denote the time that elapses until the queue is empty again, that is, the length of a typical busy period of the server. The distribution of B can be studied by considering an embedded branching process, in which individuals are customers in the queue and the offspring of a given customer are those customers that arrive whilst he/she is being served (see, for example, [4, Section 11.3]). In particular,

$$\begin{aligned} &\text{if} \quad \rho < 1 \quad \text{then} \quad E[B] = \frac{E[S]}{(1-\rho)}, \\ &\text{if} \quad \rho = 1 \quad \text{then} \quad E[B] = \infty \text{ and } \Pr\{B = \infty\} = 0, \\ &\text{if} \quad \rho > 1 \quad \text{then} \quad \Pr\{B = \infty\} > 0. \end{aligned} \tag{46}$$

Note that if $\rho > 1$ then with probability one the server is ultimately busy forever.

QUORUM

Like any research enterprise, particularly one that is observational, the meta-analysis of evidence can be flawed. Accordingly, the process by which meta-analyses are conducted has recently undergone scrutiny. A 1987 survey of 86 English-language meta-analyses [5] assessed each publication on 23 items from six content areas considered important in the conduct and reporting of a meta-analysis of randomized trials: study design, combinability, control of bias, statistical analysis, sensitivity analysis, and problems of applicability. The survey results indicated that only 24 (28%) of the 86 meta-analyses reported addressed all six content areas. The updated survey, which included more recently published meta-analyses, showed little improvement in the rigor with which they were reported [6].

To help overcome inadequate reporting several authors have suggested guidelines for reporting meta-analyses [2, 7]. However, a consensus across disciplines about how meta-analyses should be reported has not been developed. Following the Consolidated Standards of Reporting Trials (CONSORT) initiative to help improve the quality of reporting of randomized trials, the Quality of Reporting of Meta-analyses (QUOROM) conference was organized to address these issues as they relate to meta-analyses of randomized trials.

The QUOROM group comprised 30 clinical epidemiologists, clinicians, statisticians, editors and researchers. In conference, the group was asked to identify items they thought should be included in a checklist of standards. Whenever possible, checklist items were guided by research evidence suggesting that failure to adhere to the item proposed could lead to biased results. For example, authors are asked (under the "Methods" heading and "Searching" subheading) to be explicit about the publication status of reports included in a meta-analysis. Only about one-third of published meta-analyses report the inclusion of unpublished data [1].

The role of the grey literature (i.e. literature that is difficult to locate and/or retrieve) was examined in 39 meta-analyses that included 467 randomized controlled trials (RCTs), 102 of which were grey literature. On average, the exclusion of grey literature, compared with its inclusion, resulted in a statistically significant exaggeration of the effectiveness of an intervention by 15% [3].

A modified Delphi technique was used in assessing candidate items.

The conference resulted in the QUOROM statement, an 18-item checklist (Table 1) and a flow diagram (Figure 1). The checklist describes an optimal way to present the Abstract, Introduction, Methods, Results and Discussion sections of a report of a meta-analysis. It is organized into six headings and 14 subheadings. Subheadings in the Methods section include searches selection, validity assessment, data abstraction, study characteristics, and quantitative data synthesis. In addition, the Results section is broken into study characteristics and quantitative data synthesis. Research documentation was identified for nine of the 18 items. The flow diagram provides information about both the number of RCTs identified, included, and excluded and the reasons for excluding trials, throughout the meta-analytic process.

The QUOROM Statement was published in *The Lancet* in 1999 [4] and is available (checklist and flow diagram) on the CONSORT Internet site (`www.consort-statement.org`).

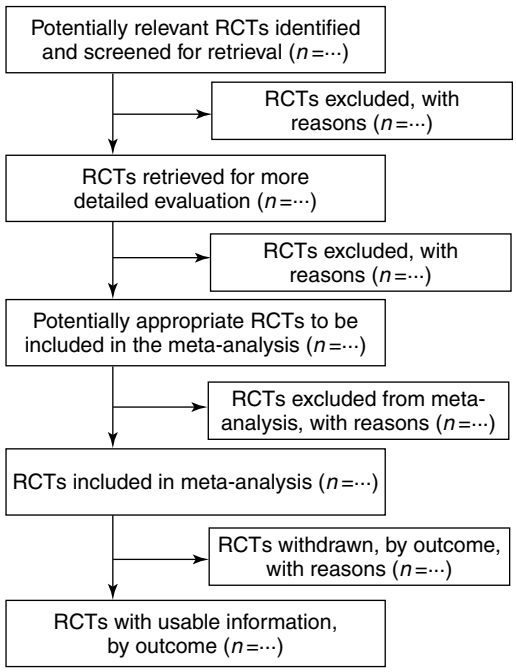

Figure 1 QUOROM flowchart

Table 1 QUOROM checklist

Heading	Subheading	Descriptor	Reported? [Y/N]
Title		Identify the report as a meta-analysis [or systematic review] of RCTs	
Abstract		Use a structured format	
		Describe	
	Objectives	The clinical question explicitly	
	Data sources	The databases, i.e. list and other information sources	
	Review methods	The selection criteria (i.e. population, intervention, outcome, and study design); methods for validity assessment, data abstraction, and study characteristics, and quantitative data synthesis in sufficient detail to permit replication	
	Results	Characteristics of the RCTs included and excluded; qualitative and quantitative findings (i.e. point estimates and confidence intervals); and subgroup analyses	
	Conclusion	The main results	
		Describe	
Introduction		The explicit clinical problem, biological rationale for the intervention, and rationale for review	
Methods	Searching	The information sources, in detail [e.g. databases, registers, personal files, expert informants, agencies, hand-searching], and any restrictions (years considered, publication status, language of publication)	
	Selection	The inclusion and exclusion criteria defining population, intervention, principal outcomes, and study design	
	Validity assessment	The criteria and process used [e.g. masked conditions, quality assessment, and their findings]	
	Data abstraction	The process or processes used [e.g. completed independently, in duplicate]	
	Study characteristics	The type of study design, participants' characteristics, details of intervention, outcome definitions, and how clinical heterogeneity was assessed	
	Quantitative data synthesis	The principal measures of effect [e.g. relative risk], method of combining results (statistical testing and confidence intervals), handling of missing data, how statistical heterogeneity was assessed, a rationale for any a priori sensitivity and subgroup analyses, and any assessment of publication bias	
Results	Trial flow	Provide a meta-analysis profile summarising trial flow (see Figure 1)	
	Study characteristics	Present descriptive data for each trial [e.g. age, sample size, intervention, dose, duration, follow-up period]	
	Quantitative data synthesis	Report agreement on the selection and validity assessment; present simple summary results (for each treatment group in each trial, for each primary outcome); present data needed to calculate effect sizes and confidence intervals in intention-to-treat analyses (e.g., 2×2 tables of counts, means and SDs, proportions)	
Discussion		Summarize key findings, discuss clinical inferences based on internal and external validity; interpret the results in light of the totality of available evidence; describe potential biases in the review process [e.g. publication bias]: and suggest a future research agenda	

At the time of this writing, 10 medical journals have participated in a randomized trial evaluating the impact of applying the QUOROM criteria on journal peer review. Accrual to this trial is now complete and the results should become available by the Spring of 2001.

Quota, Representative, and Other Methods of Purposive Sampling

The term *purposive* applies to any method of choosing a sample in which the probabilities of selection for the various sampling units cannot be calculated. For example, consider a **target population** of hospital patients. A full **probability sample** can be achieved by assigning each patient an identification label and selecting a sample wherein each subject has the same chance of selection (e.g. a **simple random sample**) using random numbers. Alternatively, the researcher can select a purposive sample based on personal judgment – literally, "this patient", "that female", "this elderly person over here", etc. The researcher might sincerely believe that by using judgment instead of letting the patients be chosen by **randomization** a more representative sample, or one that is better balanced on key variables, will result. The purposive sample, however, will always be vulnerable to charges of **selection bias** that never can be satisfactorily answered. Furthermore, without knowledge of the selection probabilities for each unit in the sample, estimation of the **mean square error** in purposive sampling is highly subjective, if not impossible.

Kruskal & Mosteller [8], and also Kish [7], have observed that a precise definition of "representative sampling" is elusive. Historically, the term was first used by Kiaer [4] to refer to sampling, in contrast to full enumeration. His concept of the "representative method", however, was broad enough to include purposive methods as well as what would be called probability sampling today. Indeed, this generality of meaning was carried down to the title of **Neyman's** seminal paper [12]. "On the two different aspects of the representative method: the method of stratified sampling and the method of purposive selection". The term *representative* has since, however, disappeared from the technical lexicon of sampling. We still encounter the informal use of "representative sample" in newspaper articles and in occasional requests for proposal (RFPs) from various agencies. Whether they fully realize it or not, when prospective sponsors of survey research ask for a "representative sample" they mean one that will lead to valid statistical **inferences**, supported by estimated sampling errors that are small, and by evidence that **biases** due to selection, noncoverage, **nonresponse**, and various sources of **measurement error** are not serious. In other words, *representative* now implies probability sampling, hopefully, under conditions sufficiently optimal that the results will stand up under close scrutiny by the scientific community or statistically sophisticated courts of law.

A Situation Where Purposive Sampling is Permissible

We have defined purposive sampling as involving selection by judgment instead of randomization. One case in which a judgment selection may be preferable to strictly random sampling is that in which the survey budget permits replication in only a small number of sites. An example is a public health experiment for which probability samples of school children in more than one metropolitan area are desired. If the costs of administering the survey in a city are so high that only a few different metropolitan locations can be selected, it is better to use expert judgment to achieve "balance" in the selection of the cities rather than let the vagaries of simple randomization determine which areas are studied. An alternative, however, to selection of the sites by judgment is the method of controlled selection [6, Section 12.8]. Controlled selection, which involves random selection of a design from a set of multistratified layouts, might be called a combination of random and purposive selection since the designs to be selected are constructed purposively.

Quota Sampling

As practiced today, quota sampling is a purposive method that enables one to obtain a desired number of completed personal interviews in a relatively short period of time without the expense of call-backs (*see* **Call-backs and Mail-backs in Sample Surveys**). In the form with the least potential bias, referred to by Sudman [16] as "probability sampling with quotas", the method involves drawing sampling locations down to the block level with exactly the same technique of **multistage sampling** selection with **sampling probabilities proportional to size** as in full

probability area sampling. Then, instead of field listing of housing units and probability sampling of households and persons contained therein, interviewers are allowed to fill quotas of respondents according to the availability of qualified subjects and whatever personal judgment may enter into the selection process. (This is why the method must be called "purposive".) In the US, the predetermined quota controls, usually few in number for administrative feasibility, are set according to the most recent **census** counts for the smallest area that immediately surrounds the sampled location. For example, an interviewer may be instructed to begin calling on households at a particular corner of a city block and proceed from door to door until five adult females and five adult males are interviewed. Not-at-homes and refusals are ignored by continuing to the next household where a cooperating individual may be found. With this procedure, it is possible that a cluster of 10 interviews, balanced with respect to sex, can be completed in a day or two. If greater control over selection is desired, the sex strata can be broken down into age groups within sex, making the filling of quotas more time-consuming, but forcing the demographic characteristics of the cluster to be more congruent with those of the immediately surrounding area. It is these considerations that led Cochran [1, p. 136] to describe quota sampling as "stratified sampling with a more or less nonrandom selection of units within strata".

Criticism and Shortcomings of Quota Sampling

Other textbooks, in addition to [1], are critical of the use of quota sampling. Deming [2, p. 31] dismisses the technique in only a few words. While Yates [17] and Kish [6] can scarcely be said to endorse the method, they do allow for occasions when the results from quota samples may be useful. Kish [6, p. 565], for example, says that he believes that "a quota sample is more likely to represent the attitudes of the nation's young people than a probability sample of a college's students", but he is, of course, not so much praising quota sampling as he is deploring an inferential leap from the population of one college to the youth of a whole country. The fundamental problem with quota sampling is that, in the absence of a full understanding of the selection mechanism that determines which individuals shall participate in the survey, one can never be sure that serious biases are not working against valid **estimation** and **inference**. For example, tests of significance (*see* **Hypothesis Testing**) and **confidence interval** estimates, if done at all, must use estimated **standard errors** about biased **means**. These may be very different from the root mean square errors about **target population** parameters that are needed for meaningful inferences. As Yates [17, p. 84] observes, "the fact that a quota system has consistently given reliable results over a period of years is no guarantee that it will also do so in the future".

Research Comparing Quota Sampling and Full Probability Sampling

Immediately after the failure of the pre-election polls to forecast the victory of the incumbent President Harry S. Truman over Thomas E. Dewey in November 1948, the US Social Science Research Council appointed a committee of statisticians and sociologists to study the technical procedures and methods of interpretation that had been used. The method of selection used by the principal polling organizations was almost uniformly quota sampling because of its time and cost advantages. Although the full blame for the forecasting débâcle is not attributed to sampling – equally important was the failure of the pollsters to interpret the undecided vote and to detect the shift in voter attitudes that occurred near the end of the campaign – the committee's report [11] observes that quota methods tended to be biased against the lower educational attainment classes and against rural dwellers.

Other comparisons of quota and probability sampling are reported by Stephan & McCarthy [14], including the carefully controlled experiments of Moser & Stuart [10] in the UK. Sudman [16] and Stephenson [15] discuss similar studies performed at the National Opinion Research Center (NORC). In a theoretical paper, King [5], applying a **Bayesian** model of biased measurement to the allocation of fixed resources to either quota sampling, full probability sampling, or a combination of both methods, finds that quota sampling is only economically feasible when the prior **correlation** between the means of the unbiased and biased processes is very high. In plain language, one has to be fairly certain that the results between quota and full probability methods will be in agreement before quota sampling should be used.

Current Practice

Although widely used by American market research firms and polling organizations during the years in which the empirical studies described above were carried out, quota sampling has largely been supplanted by **random digit dialing** and telephone interviews (*see* **Telephone Sampling**). The extent to which the latter method achieves the equivalent of full probability sampling depends on the way in which refusals are dealt with and the thoroughness of call-back procedures, but it is probable that many of the concerns about bias that were present with quota samples have been alleviated. In the UK, however, quota methods still are used extensively. In fact, the public opinion polls – almost exclusively quota samples – conducted before the British 1992 general election were by everyone's reckoning a statistical disaster. Over 50 polls conducted in the month before the election gave an average lead of 1.5 percentage points to the Labour Party, but the final result was a Conservative victory by 7.6 percentage points. This polling calamity set off a flurry of investigative activity reminiscent of the American 1948 post-election experience mentioned above. Recent papers by Jowell et al. [3], Lynn & Jowell [9], and Smith [13] all discuss whether the incorrect results can be blamed (at least in part) on quota sampling and its inability to deal with refusals. Although almost 40 years have passed since their work was published, the following quote from Stephan & McCarthy [14] in commenting on the experiments of Moser & Stuart [10] would appear to be as relevant as ever:

> the fundamental status of quota sampling, as far as evidence derived from direct comparisons is concerned, is left more or less as outlined ... Instances of serious bias can be found; close agreement with check data or with probability sample results exists for many items; the sources of serious bias are frequently related to the socio-economic control; the actual allocation of bias among possible sources is extremely difficult; and it seems impossible to place quota sampling on a sound theoretical basis.

R- and Q-analysis

This article discusses four alternative criteria for performing **principal components analysis** on a data matrix. The properties of these four criteria were given by Okamoto [6]. A numerical example illustrating all four criteria on a single data set may be found in Jackson [5].

R-Analysis

In principal component analysis, one generally begins with an $n \times p$ data matrix $\mathbf{X}$ representing n observations on p variables. From this, some type of $p \times p$ dispersion matrix is formed, usually a **covariance matrix** or its related **correlation** matrix. A set of linear transformations, utilizing the characteristic vectors of this matrix, is found which will transform the original correlated variables into a new set of variables. The variables in this new set are uncorrelated and are called *principal components*. The values of the transformed data are called *principal component scores*. Further analysis may be carried on in terms of these scores. (A subset of these transformed variables may be retained for this analysis.) This procedure is referred to as *R-analysis* and is the most common application of principal components analysis. Similar procedures are carried out in **factor analysis**.

Q-Analysis

The situation may arise where one may wish to reverse the process and study the relationships among the observations rather than the variables. This is referred to as *Q-analysis*. In this case, an $n \times n$ covariance or correlation matrix will be formed and the characteristic vectors and principal component scores obtained from these. Generally, $n > p$, so that covariance or correlation matrices will not have full rank and there will be a minimum of $n - p$ zero characteristic roots (*see* **Eigenvalue**). Q-analysis may be used in conjunction with clustering of the individuals in the data set. Some **multidimensional scaling** techniques are an extension of Q-analysis and are often used where the data are not homogeneous and require segmentation.

N-Analysis (Singular Value Decomposition)

With proper scaling or normalization, the characteristic vectors of R-analysis become the principal component scores of Q-analysis, and vice versa. These relationships can be extended to *N-analysis or singular value decomposition* [1, 4] (*See* **Correspondence Analysis**), where the characteristic roots and vectors (**eigenvectors**), as well as the principal component scores, may be determined directly from the data matrix.

Relationships Among R-, Q-, and N-Analysis

To show the relationships among R-, Q-, and N-analysis, assume that the $n \times p$ data matrix $\mathbf{X}$ has variable means equal to zero and that $\mathbf{X}$ has rank p. For R-analysis, the operations will be carried out on the $p \times p$ dispersion matrix $\mathbf{X}'\mathbf{X}$, whose unit characteristic vectors will be denoted by the $p \times p$ matrix $\mathbf{U}$ and whose characteristic roots will be the diagonal elements of the $p \times p$ matrix $\mathbf{L}$. $\mathbf{U}$ and $\mathbf{L}$ are used to obtain the principal component scores, $\mathbf{Y}$, for the observations, by the relationship $\mathbf{Y} = \mathbf{X}\mathbf{U}\mathbf{L}^{-1/2}$. For Q-analysis, the operations will be performed on the $n \times n$ dispersion matrix $\mathbf{X}\mathbf{X}'$. The nonzero characteristic roots will be the same $p \times p$ matrix $\mathbf{L}$. The corresponding p characteristic vectors will be denoted by the $n \times p$ matrix $\mathbf{U}^*$. $\mathbf{U}^*$ and $\mathbf{L}$ are used to obtain the principal component scores $\mathbf{Y}^*$ for the variables. It can be shown that the principal scores from the R-analysis are equal to the characteristic vectors from the Q-analysis, and vice versa. That is,

$$\mathbf{Y} = \mathbf{X}\mathbf{U}\mathbf{L}^{-1/2} = \mathbf{U}^* \text{ and } \mathbf{Y}^* = \mathbf{X}'\mathbf{U}^*\mathbf{L}^{-1/2} = \mathbf{U}.$$

In singular value decomposition, these quantities may be obtained for either R- or Q-analysis from the data matrix $\mathbf{X}$ directly, i.e.

$$\mathbf{X} = \mathbf{Y}\mathbf{L}^{1/2}\mathbf{U}' = \mathbf{U}^*\mathbf{L}^{1/2}\mathbf{Y}^*,$$

and, using the relationships above, it can be shown that

$$\mathbf{X} = \mathbf{U}^*\mathbf{L}^{1/2}\mathbf{U}'.$$

This relationship is employed in *dual-scaling* techniques where both variables and observations are being presented on the same chart. An example of such a technique is the biplot [2].

M-Analysis

Finally, a fourth technique, *M-analysis*, is used on a data matrix which has been corrected for both its column and row means (double-centering). This technique has been widely used for the two-way **analysis of variance** where there is no error term other than that included in the **interaction** term. The interaction sum of squares may be obtained directly from double-centered data. M-analysis is then employed on these data to detect instances of nonadditivity and/or obtain a better estimate of the true inherent variability. (See [5] for a summary of these techniques.) A version of M-analysis also used in multidimensional scaling is a method known as **principal coordinates** [3, 7, 8].

J. EDWARD JACKSON

R

The R system is an independent, open source, freely available implementation of a dialect of the S language. The S language [1, 2] is the basis for the commercial **S-PLUS** software system for data analysis and graphics. Both R and S-PLUS are described and compared in [12].

Construction of the R system has been a major statistical computing research project. Ihaka & Gentleman [7], both at that time working at the University of Auckland, developed the initial version. The ongoing development of the R system is now coordinated by an international team of expert volunteers known as "R core" but much of the work is done by very many contributors of code from many countries around the world.

The R program operates by assembling collections of functions and data sets for use at any one time. These collections are known as "packages" in R, (although the analogous concept is known as a "library" in S-PLUS). R is particularly important for developing and promulgating new statistical, data analytical, or graphical techniques; this is mostly done by releasing a new package with a suite of functions for implementing the techniques in question.

The R system has, as key features:

- an interpreted, object oriented programming language with a C-like syntax (*see* **Computer Languages and Programs**),
- a command-line input, supplemented by a system of menus that is mainly useful for file operations, for accessing the internet or for finding and reading help pages,
- code that is open source, that is, freely available for scrutiny or modification,
- support for a wide variety of static and dynamic color graphics capabilities, making it easy to produce publication quality graphical output that can include mathematical text (*see* **Graphical Displays**),
- a close integration of data analysis and graphics,
- a base package that handles commonly required types of computations, and which is a basis for adding further packages,
- a large and rapidly growing range of packages, including some standard ones for "lattice" graphics and the classes and methods of S release 4 [3],
- various mechanisms, some offered via additional packages, for interfacing to other software systems – local **database systems**, networked database systems, other interpreted languages (e.g. Python), Geographical Information Systems GIS systems, and so on.

Experimental forms of graphical user interface (GUI) are available for limited component parts of R. There are several initiatives that are aimed at developing a GUI system or systems that might be used for the base package and perhaps for other packages that are supplied as part of the base installation. More details on this and other aspects of R can be found at the URL `http://cran.r-project.org`.

In recent years, there has been a major release of R at about six-monthly intervals. Because of the somewhat experimental and rapidly changing nature of the system, it has been impossible to ensure complete backwards compatibility. Package updates happen often as well and old packages may be updated to new versions or new packages installed from within a session of R itself, which is a particularly strong feature. In principle, anyone with access to the **internet** may have the latest version of R and all of its listed packages at any time.

The Sweave package is an interesting example of the linking of the abilities of two different software systems, an idea first proposed by Donald Knuth [8]. It allows the interleaving of code and text in a LaTeX document, which can then be processed into a final document that can include tables, graphics, computer output, and associated code. Changes in the code are immediately reflected in the output document, making it straightforward to ensure that published analyses, and modifications to those analyses, are reproducible.

The R system has close points of contact with the more experimental and specifically research-directed aims of the Omegahat project [9]. These connections also result in the development of code that is of direct use to R users as well as to Omegahat. More details on Omegahat can be found at the URL `http://www.omegahat.org`

The Bioconductor project [6], which is a major cooperative effort between professional statisticians who work with microarray data, is the most substantial of a number of R-based initiatives. For many statisticians working with microarray data, R is now

a very commonly used platform. Related computing challenges, which the Bioconductor packages address, include the development of data structures that facilitate work with microarray data, linkages into associated annotation information, and local and internet-based access to databases.

Official documentation for R includes an introductory manual, an R language manual, a guide to importing and exporting data from R, a manual on extensions to R, a guide to the installation and administration of R, and a document that gives answers to frequently asked questions. For the S language on which R is based, see [1, 2, 12]. Dalgaard [4] is a careful introductory text, both for the language and for using R for elementary statistical analysis; see also [14]. Maindonald & Braun [10] (intermediate level) and Venables & Ripley [13] (advanced level) both use examples as a basis for their exposition; see also Fox [5]. The mechanisms used by R for including mathematical annotation on graphs is discussed in [11].

W.N. VENABLES & JOHN H. MAINDONALD

Radiation Epidemiology

Introduction

Radiation epidemiology is a specialized field of **epidemiology**, which seeks to characterize and quantify the health risks associated with exposure to ionizing and nonionizing **radiation**. One of the principal aims of radiation epidemiology is to provide the human data needed to recommend or set protection standards for workers and the general public. The data are also used to estimate levels of **risk** from diagnostic radiation procedures, to indicate how radiotherapy protocols can be improved to reduce acute and long-term side effects, to better understand individual susceptibility, and to learn more about disease mechanisms.

Radiation is a general term that includes both ionizing and nonionizing radiation. The many different types of radiation have a range of energy forming an electromagnetic spectrum. Ionizing radiation is located in the high frequency region of the electromagnetic spectrum. Nonionizing radiation includes optical radiation and electromagnetic fields, as well as acoustic fields. The nonionizing region of the spectrum has a wide range of frequencies and wavelengths. At the lowest frequencies there are static fields, for example, those used for magnetic resonance imaging (MRI). Further along the spectrum, nonionizing radiation includes time-varying electric and magnetic fields produced by power lines, electrical appliances, radiofrequencies, and microwaves, as well as radiation wavelengths in the infrared, visible, and ultraviolet ranges.

This article is concerned with the many types of ionizing radiation, which are emitted with different energies and penetration abilities. Ionizing radiation produces electrically charged particles (ions) that have enough energy to break chemical bonds and that can cause a range of biological damage. Exposure to ionizing radiation can come from external sources, such as X- or γ-rays, or from internal sources emanating from radioactive materials deposited through inhalation, ingestion, or rarely through dermal absorption. In radiation epidemiology, we are most concerned with X- and γ-rays, neutrons, and α-particles and other radionuclides because they are used in medicine, occur as a result of the nuclear bombings in Hiroshima and Nagasaki, are important components of fallout from nuclear testing or accidents, or occur in nature. Individuals or populations can receive one or more acute exposures to radiation or they can be exposed to protracted radiation over a long period of time, such as from occupational exposure. Unlike most other carcinogens, about 85% of radiation exposure to the general public comes from natural sources, largely radon, but also cosmic radiation and natural background radiation. The remaining public exposure comes from medical radiation (about 14%), with only about 1% coming from fallout, occupational exposure, radioactive discharges, and consumer products combined [117]. People are exposed to radiation in a variety of settings. Large numbers of the general population receives many low-dose radiologic examinations over their lifetime; whereas a relatively small percent of the population receives high-dose radiotherapy as treatment for cancer or a few benign diseases, for example, hyperthyroidism.

Radiation can cause a variety of acute and long-term biological effects at the molecular, cellular, tissue, and organ levels. Deleterious health effects occur when a sufficiently large number of cells die or are damaged so that tissue or organ function is no longer adequate, or when cells lose their proliferative capacity, transform or mutate. The important biologic consequences of radiation are thought to result primarily from direct damage to DNA [58, 117]. Recent experimental studies, however, suggest that radiation might also cause damage to the cytoplasm [121], and that radiation effects can occur in cells that are not directly exposed to radiation through bystander effects [7, 78] or genetic instability [49, 76]. Cataracts [85], neurological abnormalities [122], thyroid diseases [79, 99], cardiovascular diseases [102], benign and malignant tumors [113], and birth defects [123] are some of the more important long-term health effects associated with radiation exposure. Since radiation-related cancer has been studied in greatest detail and is of most concern to the public, it will be our major focus.

Wilhelm Röntgen discovered X-rays in 1895. They were used in medicine one year later to treat a nevus and the following year to treat cancer [34]. Owing to the very high early exposure of people working with radiation, it was recognized as a carcinogen very soon after it was discovered. Since then it has been studied intensively, and by 1920 it was already identified as the cause of

bone cancers occurring among young women who used radium to paint watch dials [25]. About two decades later, radiation was shown to increase the risk of leukemia among radiologists [69], and by the 1950s the first indication of radiation-induced malignancies was observed among the atomic bomb survivors [24]. Over the last fifty years, we have learned that most types of radiation can increase the risk of developing cancer, and that most cancers can be induced by radiation, but that there are differences in the magnitude and type of biologic effects manifested following equal doses of radiation. These differences are partly owing to the type of radiation and the duration of exposure, as well as host factors such as age, gender, and genetic susceptibility. In addition, some tissues and organs appear to be more radiosensitive than others.

The study of the long-term effects of radiation exposure began with astute observations of rare disease excesses among highly exposed individuals [20, 32]. As more was learned, larger studies of persons exposed to moderate doses of ionizing radiation were conducted and risks of disease were compared among exposed and nonexposed groups. When these studies unequivocally demonstrated that radiation was a carcinogen [81], the field moved toward more quantitative methods of describing risks. Because radiation exposure assessment (called dosimetry in radiation epidemiology) is detailed and relatively accurate compared with many other exposures, the field of radiation epidemiology has progressed to more precise quantification of risks, evaluation of the role of factors that might modify radiation risks, detecting risks at low doses, and characterizing the shape of the **dose–response** function. In parallel, the fields of radiation biology and biophysics were advancing and many relevant findings from experimental work were integrated into radiation epidemiology approaches [9]. The strong interactions between these disciplines has led to a general awareness of the importance of biological mechanisms in analyzing epidemiology results, and to a subfield of biological or mechanistic modeling of epidemiologic data [83, 84, 117]. Currently, radiation epidemiology employs sophisticated statistical methods for **risk assessment** and uncertainty analyses and has increasingly embraced a multidisciplinary approach to better understand how the physical aspects of radiation influence the biological effects observed in humans.

Major Issues in Radiation Epidemiology

Although there is a clear consensus that moderate to high radiation doses cause harmful effects in humans, a central issue in radiation today is quantifying the biological effects at low doses, that is, at doses below about 0.1 Gy (see "Radiation Measurements" section). Other important questions in radiation epidemiology include: how much cancer is caused by radiation; what is the shape of the dose–response relationship; does the increased risk associated with radiation exposure persist throughout life; how do age and gender modify effects (*see* **Effect Modification**); how does dose rate influence risk; how should known radiation risks from one population group be transferred to another population group; and to what extent do uncertainties in dose assessment influence dose–response analysis and inference on effect modifiers. As collaborations with radiobiologists, dosimetrists, and biophysicists expand, more intriguing questions are becoming the focus of attention. These include: how does radiation cause cancer; why do organs and tissues vary in sensitivity; what causes differences in individual susceptibility to radiation; and how does radiation interact with other disease-causing agents.

Types of Studies Used in Radiation Epidemiology

Epidemiology includes both observational and experimental methods, however, as in other subdisciplines of epidemiology, radiation epidemiology primarily relies on **observational studies**. Observational investigations use both **descriptive** and **analytic** study designs. In general, descriptive studies are used to generate hypotheses and analytic studies are used to test hypotheses.

Descriptive Epidemiology

Descriptive studies usually use publicly available data to describe a temporal or geographic pattern or trend in a population group. While useful observations have been made based on descriptive studies, the aggregated nature of the exposure and disease data, and the frequent lack of **confounding** information are serious drawbacks. Descriptive studies are sensitive to **biases** and can produce misleading results. Examples

of descriptive radiation studies include evaluations of cancer rates in geographic areas near nuclear power facilities compared with rates from similar areas not in proximity of a nuclear plant [47], and thyroid cancer rates in West European countries following the disastrous Chernobyl accident compared with rates before the accident [13]. Despite the rather inconsistent results from the various studies, some investigators have interpreted the positive findings as indicating an association between radiation exposure and cancer. Unfortunately, the lack of individual doses and information on potential confounding precludes concluding a cause and effect relationship between disease and exposure (*see* **Causation**).

A specific type of descriptive study, called **ecologic** (also known as correlational or geographic), has been used to a limited extent in radiation epidemiology. In this design, aggregate rates of disease are regressed on characteristics of population groups, but it is not known whether the people who are exposed are those who develop the health outcome of interest. Furthermore, because **covariate** data are limited, it is difficult to control for confounding. When the population groups are large, the statistical precision and stability is high, but when a strong confounding factor exists on the individual level, which cannot be adjusted for on the aggregate level adequately, the results can be erroneous [33, 77, 86]. (*see* **Ecologic Study** and **Ecologic Fallacy**.) A continuing controversy in radiation epidemiology concerns the role of residential radon in lung cancer etiology. Using an ecological approach, Cohen [12] aggregated lung cancer mortality rates with mean levels of radon exposure in 1600 counties in the United States. Using a surrogate smoking index to adjust for potential confounding from smoking, he reported a protective effect between lung cancer mortality and radon concentration levels indicating that radon is beneficial. Other investigators, however, have observed that a small correlation between smoking and radon concentration levels can sufficiently confound results so that a negative association is observed when the true association is positive [63]. In addition, Puskin [95] found that a variety of other smoking-related cancers were negatively correlated with radon, associations which were highly implausible, and concluded that the protective effect of radon on lung cancer was due to incomplete control of smoking. Moreover, analytic epidemiologic studies consistently show a small excess risk of lung cancer associated with residential radon.

Analytic Epidemiology

In analytic studies, such as **case–control** and **cohort** studies, the unit of observation is the individual, that is, information on outcome, exposure, and covariates is collected for individuals. In case–control studies, individuals with the disease of interest (cases) are drawn from a defined population and their exposure history is compared with appropriate nondiseased **controls** selected from a similar population with the same potential for radiation exposure. Questionnaires are most often used to collect data on exposure and covariates. Case–control studies are an efficient and cost-effective method for studying relatively rare diseases; they are, however, subject to **selection** and **recall** bias.

Studies of the carcinogenic risks associated with diagnostic radiography during early childhood have generally employed a case–control design [43, 70, 103, 104]. These studies are fraught with difficulties for a variety of reasons. Doses are generally low, and estimating individual organ doses is complicated because records of diagnostic examinations usually are not available. Dosimetry for diagnostic radiographs generally relies on patient and/or parent recall of the number, type, and date of exams and, therefore, is subject to the problem that cases and controls might remember or report their history of diagnostic examinations with different levels of accuracy. The potential for recall bias that is, cancer patients may remember their medical history better than a control who does not have a serious illness, can result in risk estimates that are artificially high. Nevertheless, despite exposure assessment weaknesses, case–control studies have been useful in highlighting the potential dangers of diagnostic X rays.

Cohort studies of selected populations exposed to radiation have been the mainstay of radiation epidemiology. In this method, exposed and nonexposed individuals are followed over time until a sufficient number of study subjects develop a particular disease outcome. A major advantage of prospective cohort studies or retrospective cohort studies (*see* **Cohort Study, Historical**) with good exposure records is that radiation exposure can be ascertained without relying on the memory of the study subjects. Fifty years after the Hiroshima and Nagasaki atomic bombings,

the Life Span Study (LSS) cohort of atomic bomb survivors continues to be the most informative study of the carcinogenic effects of radiation exposure in humans. It is the major source of epidemiologic data used for radiation risk assessment and has had the greatest impact on the development of radiation protection standards [83, 117]. Decades of dosimetry efforts, including periodic improvement in the dosimetry system, have resulted in well-characterized individual doses, for most organs and tissues, for close to 90 000 survivors in the cohort [97]. The good dosimetry and the relatively complete and unbiased cancer incidence and mortality ascertainment have helped make the LSS the "gold standard" in radiation epidemiology. Over time, it has become apparent that the LSS can provide valuable information on the nature of radiation-associated cancer risk following low doses, because about 35 000 survivors were exposed to doses between 5 and 200 mSv [89]. The latest cancer **incidence** and mortality reports demonstrate that the elevated cancer risk continues throughout life and that the shape of the dose response for solid cancers is linear with no evidence of a radiation dose threshold (*see* **Extrapolation, Low Dose**) below which there is no excess risk [89, 90, 113]. Indeed, even within the narrow low-dose range, cancer risks are well described by a simple linear dose response (*see* **Linear Regression, Simple**), and the best estimate of a threshold dose for cancer incidence, if it exists, is 0 mSv, with a 95% upper confidence bound (*see* **Confidence Intervals and Sets**) of about 60 mSv [89]. Cancer risks in the LSS are described in terms of both **excess relative risk** (ERR) and excess **absolute risk** (EAR) models. Using an ERR model, the risk per Sievert is higher for women than men and decreases with increasing age at exposure or attained age. The EAR per 10 000 person years per Sv is also higher among women, but although it tends to decrease with increasing age at exposure, the EAR has increased throughout the study period as the cohort ages. Evaluation of patterns of organ (or site) specific risks suggests that, with few exceptions, the excess risks for most solid cancers do not deviate significantly from the overall solid cancer risk estimate [88]. In the next 20 to 30 years, the number of cancer cases diagnosed in the LSS will nearly double. With the additional cases, the LSS will prove to be an important resource for evaluating **interactions** between radiation and other environmental or genetic risk factors.

Nested case–control (*see* **Case–Control Study, Nested**) and **case–cohort studies** are special types of cohort studies that are used in radiation epidemiology when detailed dosimetric data are needed, but are difficult or expensive to collect for the entire cohort. Nested case–control studies have been used very effectively to evaluate radiation treatment for a first primary cancer in the development of a second cancer. Detailed radiotherapy information is needed to estimate organ doses and chemotherapy and other data are needed to assess confounding and modifying effects, but it would be prohibitively expensive and time consuming to collect and abstract all of this information for a cohort large enough to have an adequate number of second cancers. In a population-based cohort of 19 046 patients with Hodgkin's disease, a nested case–control study was conducted to quantify the treatment-related risk of developing a second cancer of the lung [31, 115]. On the basis of the daily radiotherapy logs for each patient, dose to the subsite of the lung where cancer developed was estimated for 222 cases who developed a second lung cancer. Radiation doses to the same part of the lung as the case was estimated for the two matched controls for each case. Cumulative cytotoxic drug intake also was estimated for each study subject and information on smoking history was abstracted from patient records. This intense data collection effort allowed fairly precise radiation dose estimation and control for confounding. Lung cancer risk was found to increase significantly with radiation dose up to 40 or more Gy and also with increasing amounts of alkylating agents in an additive fashion, and tobacco appeared to multiply radiation risks.

A more recent development in radiation epidemiology is the use of meta and pooled analyses (thyroid, breast, radon, nuclear workers) to combine either published (meta analysis) or original (pooled analysis) data from several studies. Combined analyses, especially of rare diseases or exposures, can increase statistical **power** substantially [10, 14, 55, 64, 94, 99]. They are useful for detecting small risks, improving precision of risk estimates, formally comparing data from several studies with the goal of identifying consistent patterns of risk, and systematically assessing modifying factors and subgroup risks that could not be evaluated adequately in single studies. The thyroid gland of children is one of the more radiosensitive organs in humans [98], and therefore is of special interest in radiation epidemiology. But because

thyroid cancer is rare the number of cases in any individual study is likely to be small. A pooled analysis of seven studies, which included almost 120 000 people (about 58 000 exposed to radiation) and 700 thyroid cancers, demonstrated the linearity of the radiation dose response and the importance of age at exposure as a modifying effect, that is, people exposed during childhood had a very high excess relative risk, but for those exposed as adults there appeared to be little risk [99]. The ERR per Gy for people exposed before age 15 was 7.7 (95% $CI = 2.1; 28.7$), whereas for atomic bomb survivors exposed as adults it was 0.4 (95% $CI = -0.1; 1.2$). Following childhood exposure, the ERR remained elevated throughout the 40 year follow-up period, but appeared to decline somewhat after about 30 years. Linearity also described the dose response in a pooled analysis of 1502 breast cancers diagnosed among 77 527 women (almost half exposed) [94]. In this analysis, the age effects were more complicated, with age and age at exposure both being important in the excess absolute rate models, but only attained age in the excess relative risk models. This analysis also suggested that exposure at low-dose rates (protracted exposure) is less tumorigenic than acute or high-dose rate fractionated exposures. Pooled analyses of nuclear workers exposed to low levels of protracted radiation have provided more precise risk estimates than any of the individual studies [10]. While the number of excess cancers was still too small either to accept or to rule out the **null hypothesis**, the confidence bounds on the risk estimate indicated that the current occupational exposure standards are reasonable.

Radiation Measurements

Unlike many other environmental hazards, ionizing radiation can be measured with fairly good precision. The strength of a radioactive source is quantified by its activity, and the number of radioactive disintegrations per second. The unit of activity is the Becquerel (1 Bq = 1 disintegration per second). Absorbed dose deposited by ionizing radiation is quantified as the energy deposited per unit mass. The unit of absorbed dose is the Gray (1 Gy = 1 J/kg). Some types of ionizing radiation are more biologically effective (per unit dose) than others. To account for this, the quantity called equivalent dose is used, which is the absorbed dose multiplied by a radiation weighting factor. For example, the weighting factor is 20 for alpha particles. The unit of equivalent dose is the Sievert (1 Sv = 1 J/kg). To account for the effect of an inhomogeneous distribution of dose in the body, the effective dose is used. Effective dose is the sum over specified tissues of the product of the equivalent dose to the tissue, and a weighting factor for that tissue – this latter being a measure of its relative radiosensitivity. The unit of effective dose is also the Sievert (Sv). The SI units described above have replaced traditional units: 1 Bq = 2.7×10^{-11} Curie (Ci); 1 Gy = 100 rad; 1 Sv = 100 rem [44]. The concentration of radon in air is measured in Bq/m^3 (replaces the historical unit of pico Curies per liter). In studies of underground miners, exposure to alpha particles from radon (Rn-222) and its short-lived decay products, Po-218 and Po-214, is measured in working level months (WLM). One working level (WL) is any combination of the short-lived progeny of radon in 1 liter of air, under ambient temperature and pressure, that results in the ultimate emission of 1.3×10^5 MeV of alpha particle energy (1 WL = 2.08×10^{-5} Jm^{-3}). One WLM is a cumulative exposure equivalent to 1 WL for a working month of 170 hours (1 WLM = 3.5×10^{-3} Jhm^{-3}).

Retrospective Exposure Assessment

The crucial need to measure exposure from radiation carefully was clear very soon after the discovery of X rays. This need resulted in the development of the field of radiation dosimetry. The field has advanced substantially since then [51], so that today radiation dosimetry is probably the most sophisticated of epidemiologic exposure assessment methods. To quantify long-term radiation-related health risks adequately for populations exposed years ago, retrospective dose reconstruction is often performed in concert with radiation epidemiology. For epidemiologic studies, the ideal measure of exposure is the absorbed dose to the organ or tissue of interest for each study subject. Three basic methods are used in radiation dosimetry: physical measurements made in a laboratory or the environment; analytic model-based dose reconstruction, and biodosimetry. These methods have been applied to both external and internal sources of exposure. The quality of dose reconstruction will depend on the complexity of the exposure situation, the exposed population, the

quality and quantity of data relevant to the exposure, and the availability of physical and biological samples [45]. Identifying the sources of uncertainty in dose estimation is becoming more common in radiation epidemiology. With better understanding of the type and amount of these uncertainties, the influence of dose errors can be accounted for in the statistical analysis of radiation effects. This issue is discussed in detail in the section "Adjusting for errors in dosimetry".

Dosimetry for external radiotherapy largely relies on laboratory experiments, using an anthropomorphic phantom, or a water phantom in combination with a mathematical phantom, that simulate the actual exposure conditions recorded in a patient's medical record. The laboratory measurements along with computational models have been used to estimate absorbed doses and their uncertainties, to organs inside and outside the radiation field, for individual study subjects [108]. When detailed treatment parameters are known, individual organ dose estimates are fairly accurate. When treatment records are incomplete or not available, the dose estimates will have a large degree of uncertainty. Dosimetry for internal medical exposure is more complicated and, therefore, the level of uncertainty is much higher [51].

Dose estimation for past environmental exposures is difficult. The best environmental dose reconstruction is that for the Life Span Study of atomic bomb survivors in Japan. This major dosimetry program to estimate individual organ doses for most survivors is largely based on physical measurements from building materials found in the Hiroshima and Nagasaki surroundings, investigation of shielding factors made during mock-up tests in Nevada, and analytic modeling based on many variables, including what is known about the physical qualities and yields of the bombs, weather conditions at the time of the bombings, the location and shielding conditions of survivors at the time of the bombings, and the attenuation from different shielding configurations [97]. Several methods of biological dosimetry have been used to estimate doses in subgroups of the survivors [1, 6, 80, 106]. In general, there has been fair agreement with model-based dose estimates. Since the bombings, several investigators have assessed dosimetry errors in the LSS of atomic bomb survivors [27, 46, 91]. It has been estimated that there is an error of about $\pm 30\%$ in individual organ doses and that the error results in a 4 to 11% underestimate of the dose response [91]. To account for the error, an adjustment to the doses is made in the analyses.

Elaborate dose reconstruction projects have been conducted to estimate doses from fallout in the United States [8, 82, 114] and the former Soviet Union [105], from nuclear accidents [26, 57, 117], and from nuclear facility discharges [18, 19, 22]. In these situations, past environmental measurements and current measurements of soil and brick are often used in conjunction with computational modeling, especially for external exposure. Estimating radiation dose received as a consequence of intake of contaminated air, water, and food is more difficult because it not only requires knowing what radiation was released, but also past dietary intake for each individual. When possible, biodosimetric measurements are also performed. Combining several methods of exposure assessment can improve accuracy and reliability.

Studies of radiation workers provide an important source of information on the effects of low-dose protracted exposure. Occupational exposure assessment is based primarily on dosimeters worn by individual workers. The dosimeters provide a measurement of cumulative external exposure, but accurate dose estimates to an individual worker are dependent on a wide array of conditions, including the quality of the dosimeter, the precision in recording the measurements, the care in which the dosimeter is worn, and the uncertainties in the conversion from exposure to organ dose [10, 29, 118]. As in other situations, it is more complicated to estimate dose from internal occupational exposure [53].

Biodosimetry methods increasingly have been incorporated into epidemiologic studies to validate dose estimates derived from physical or model-based dosimetry methods or to provide dose estimates when other sources of dose data are missing or incomplete [116]. For many years, chromosome aberrations in lymphocytes have been evaluated as a measure of dose. For past radiation exposure, translocations can be assessed using fluorescence *in situ* hybridization (FISH) techniques. This method is one of the most accurate and sensitive of the biodosimetry methods, but is labor intensive and expensive [21, 48, 116]. More recently, the electron paramagnetic resonance (EPR) technique has been used to measure radiation dose accumulated in tooth enamel [11, 80]. New biodosimetry approaches currently are being developed.

Models for Disease Risk from Radiation Exposure

In radiation epidemiology, three general modeling approaches are used to analyze data and assess risk: the dosimetric approach; the empirical or descriptive approach; and the biologically motivated approach [84, 117]. (*see* **Model, Choice of**)

Dosimetric Risk Models

In the dosimetric approach, a model for disease risk is developed in studies with accurate disease outcome information and well-characterized dosimetry, then applied to a population with a possibly different radiation exposure experience. The dosimetric approach often requires knowledge of the relative consequences on disease outcomes of exposure to different types of radiation (specified by the relative biological effectiveness, RBE) and under different exposure regimes. For example, the application of risk models derived from the Japanese LSS of atomic bomb survivors to radon-exposed underground miners requires knowledge of differential effects of acute exposure to gamma radiation and neutrons relative to chronic exposure to alpha radiation. This process is complicated by evidence that RBE depends on dose level [71].

While the dosimetric approach has been applied historically in radiation risk assessment, it is no longer widely used because of the inherent difficulties of incorporating the wide range of exposure conditions encountered with diagnostic and therapeutic radiations and with natural radiations such as radon and cosmic rays. These diverse exposure conditions include very low and very high doses, direct and inverse dose rate effects (dose–response slope varying as a function of dose), and acute, chronic or highly fractionated doses. In addition, the need to apply risk models to populations with very different radiation exposures has diminished as more and larger populations with diverse radiation exposures are studied. Investigators, however, still conduct comparisons of risk models and risk estimates across diverse populations and types of radiation to gain insights into mechanisms of radiation effects.

Empirical or Descriptive Risk Models

The most common modeling approach with epidemiologic data uses empirical models. With the empirical approach, modeling starts with a relatively simple structure and few *a priori* assumptions. Models develop increasing complexity by including factors that statistically improve model fit, although added covariates typically require some level of biological plausibility. The approach is amenable to a broad-based exploration of diverse exposures and of factors that modify the exposure–response relationship. Although empirical models are less structured than biologically motivated models, these models still require assumptions on the basic shape of the dose–response relationship and on the functional form of factors that modify that relationship [84]. Although empirical models can be developed distinct from specific biologic assumptions, models are flexible enough to accommodate biologically hypotheses.

Data are typically analyzed under an ERR model,

$$\lambda(x_{\mathrm{bk}})[1 + \rho(d) \in (x_{\mathrm{em}})]$$

or EAR model,

$$\lambda(x_{\mathrm{bk}}) + \rho(d) \in^{*} (x_{\mathrm{em}})$$

where d is the radiation dose, x_{bk} and x_{em} are vectors of covariates used to specify the background rate of disease and effect modification, respectively, $\lambda(\bullet)$ is the background rate of disease in non-radiation-exposed individuals, $\rho(\bullet)$ is the dose–response function, and $\in(\bullet)$ and $\in^{*}(\bullet)$ are functions describing effect modification of the ERR and EAR, respectively.

In modeling radiation effects, the dose–response relationship, at least for cancer, is based on the radiobiological assumption that lesions are initiated as a result of one or two ionizing events, resulting in a molecular cascade of effects leading to malignancy, or to programmed cell death (apoptosis) [117]. With this biological interpretation as a framework, a general dose–response model is specified by the linear-quadratic-exponential form:

$$\rho(d) = (\beta_0 + \beta_1 d + \beta_2 d^2)\mathrm{e}^{-\alpha_1 d - \alpha_2 d^2} \qquad (1)$$

where the linear and quadratic terms in dose correspond to one or two ionizing events, and the exponential factor corresponds to cell death at high radiation doses. While this model is useful as a conceptual starting point for analysis, data are seldom sufficient in numbers of cases and ranges of doses to enable simultaneous estimation of all parameters (*see* **Estimation**).

In the Japanese LSS cohort, analysis is conducted under an assumption of piecewise exponential time to failure (*see* **Grouped Survival Times**), which is often referred to as **Poisson regression** due to the form of the **likelihood** function. ERR models are used to model disease rates for solid tumors, while EAR models are applied with leukemia, with dose given in Sv [83, 89, 93]. For these data, x_{bk} includes variables such as attained age, city, sex, calendar year of follow-up, and possibly other factors. For ERR models, the background disease rate, $\lambda(x_{\text{bk}})$, is often modeled **semi-parametrically** by categorizing the components of x_{bk} and jointly stratifying on all levels. Effect modifiers, x_{em}, may include variables used in the background as well as age at exposure and time since exposure. For solid tumors, the preferred risk model for ρ (d) is linear in dose, that is, only β_1 is nonzero,

$$\rho(d) = \beta_1 d$$

where β_1 is the excess relative risk per Sv (ERR/Sv). A variant of this model has been used to examine threshold relationships, where a dose below a given level is assumed to have no effect on disease rate, by setting $d' = d - d_o$ for $d > d_o$ and zero otherwise [41, 42, 62]. However, there has been no convincing evidence for the existence of such a threshold in the LSS cohort [89]. Variables to evaluated effect modification, $\in (x_{\text{em}})$, may be continuous or categorical (*see* **Random Variable**). The preferred risk model for the ERR of respiratory cancer is

$$\begin{aligned} \rho(d) &= \beta_1 d \\ \in (t, s) &= \exp\left[\alpha_1 \ln\left(\frac{t}{20}\right) + \alpha_2 I(s)\right] \end{aligned} \qquad (2)$$

where t is years after exposure and $I(\bullet)$ an indicator function (*see* **Dummy Variables**) taking value zero for females ($s = 0$) and one for males ($s = 1$) [83].

The dose–response parameter is sometimes reparameterized as

$$\rho(d) = \mathrm{e}^{\beta_1^*} d \qquad (3)$$

to remove range restrictions on β_1. However, under this formulation, the estimated parameter is constrained to be nonnegative and **standard errors** are proportional on the original dose scale.

Radiation from the Hiroshima atomic bomb includes a mixture of gamma and neutron radiation, with a neutron to gamma ratio which decreased with distance from the hypocenter [89]. For Hiroshima atomic bomb survivors, total dose is defined deterministically as $d = g + RBE \times n$, where g and n are the gamma and neutron dose, respectively, and the RBE is set to 10 (although 20 has also been used). To address the issue of neutron effects at low doses [100], Pierce and Preston apply a dose–response model of the form:

$$\rho(g, n) = \beta(g + \theta g^2 + \phi n) \qquad (4)$$

where θ defines a quadratic effect for gamma dose and ϕ specifies RBE [89]. While in theory θ and ϕ can be estimated directly along with β, data are not sufficient and results are examined for a variety of values of θ and ϕ [90].

Leukemia is one of the most radiogenic cancers. Excess cancer risks have been observed within two years of exposure. In the LSS cohort that was assembled five years following the bombings, excess risks are at their maximum 5 to 10 years after exposure then decline, although risks remain elevated 50 years after the bombings [117]. The preferred model for leukemia risk is an EAR model of the form:

$$\begin{aligned} \rho(d) &= \beta_1 d + \beta_2 d^2 \\ \in^*(t, a_0) &= \begin{cases} \exp[\alpha_1 I(t \le 15) + \alpha_2 I(15 < t \le 25)] & \text{if } a_0 \le 20 \\ \exp[\alpha_3 I(t \le 25) + \alpha_4 I(25 < t \le 30)] & \text{if } a_0 > 20 \end{cases} \end{aligned} \qquad (5)$$

where a_{o} is age at exposure. Here $I(\bullet)$ is an indicator function that takes value 1 when the argument is true and 0 otherwise.

ERR models are also applied to data from radon-exposed underground miners [66, 84]. Exposure–response has the form:

$$\rho(d) = [\beta(\theta_0 d_{5-14} + \theta_1 d_{15-29} + \theta_2 d_{30+})] \qquad (6)$$

where cumulative exposure, d, in units of Working Level Months (WLM) is redefined as "effective" cumulative exposure by weighting cumulative WLM incurred 5 to 14, 15 to 29, and 30 years or more prior to current age. The weights, θ_i, are estimated in the model fitting, with θ_0 fixed at one for **identifiability**. Exposure effects on lung cancer mortality in miners diminish over 50% after 25 years since exposure. Models for effect modification use indicator variables

and take the form

$$\in (a, z) = g_a(\alpha_1) g_z(\alpha_2) \tag{7}$$

with

$$\begin{aligned} g_a(\alpha_1) = \exp[&\alpha_{1,1} I(a < 55) + \alpha_{1,2} I(55 < a \leq 65) \\ &+ \alpha_{1,3} I(65 < a \leq 75) + \alpha_{1,4} I(75 < a)] \\ g_z(\alpha_2) = \exp[&\alpha_{2,1} I(z < 5) + \alpha_{2,2} I(5 < z \leq 15) \\ &+ \alpha_{2,3} I(15 < z \leq 25) \\ &+ \alpha_{2,4} I(25 < z \leq 35) + \alpha_{2,5} I(35 < z)] \end{aligned}$$

Here the exposure–response relationship $\rho(d)$ varies with attained age, a, and years of exposure, z. The $\alpha_{2,j}$ parameters represent variation of the exposure–response relationship with duration for fixed cumulative exposure. Parameter estimates are positive and monotonically increasing, suggesting an enhancement of radon effects with longer durations (and lower rates) of exposure. An alternative model includes categories of exposure rate, z, as an effect modifier.

Latency is the interval of time from an increment of exposure to a change in disease response. (*see* **Latent Period**) A general method based on B-splines (*see* **Spline Function**) has been used to explore the exposure-time-response patterns in Colorado Plateau uranium miners exposed to radon and its decay products [36, 35]. For each subject, suppose exposure history, $x(t)$, is given for each year $t, t = 1, \ldots, T$, where the index for subject is dropped for clarity. Cumulative exposure is $\sum x(t)$. If $w(\bullet)$ defines a weighting function for the contribution to risk of each exposure increment, then $\sum w(t)x(t)$ is the "effective" exposure. The logarithm of the relative risk is given as

$$\beta_1 \sum w(t)x(t) + \beta_2 z$$

where z is a vector of additional risk factors. Cubic B-splines, which are continuously differentiable, piecewise polynomial functions [17], are used to model the weighting function $w(t;\theta)$ by defining

$$w(t, \theta) = \sum_{j=-3}^{m} \theta_j B_j(t) \tag{8}$$

where θ_j are unknown parameters, and $B_j(t)$ are known basis functions with knots at $0 < t_1 < \ldots < t_m$, and with $\sum B_j(t) = 1$ for all t. For the Colorado miner data, Hauptmann et al. show that exposures 5 to 25 years prior to current age have the greatest impact on the relative risk of lung cancer [35]. These results are similar to a previous analysis of the same data using a bilinear latency model, which requires more restrictive assumptions [56].

Biologically Motivated Risk Models

Biologically motivated models attempt to use results from experimental animal, cellular, and molecular studies, and a detailed understanding of radiobiology to specify a structural form for the carcinogenic relationship between radiation dose (and other disease risk factors) and cancer outcome [83, 84, 117]. A number of biologically motivated models have been developed and applied to data from specific radiation studies, including experimental animal studies and epidemiologic studies. Biologically motivated models have not yet been used to develop general risk models for risk assessment and radiation protection.

It has long been recognized that age-incidence curves for many epithelial cancers vary approximately as a power of age, suggesting a multistage process for carcinogenesis (*see* **Multistage Carcinogenesis Models**). The most widely applied multistage model for carcinogenesis is the Armitage–Doll model [3] (*see* **Dose–Response Models in Risk Analysis**). The model assumes that a cell undergoes k distinct, ordered, heritable changes, and that the background rate of disease is independent of the age of the at-risk cells. An exposure acting at a single stage, say the ith stage, is postulated to modify the stage transition rate. The importance of multistage models to the analysis of epidemiological and experimental animal data lies in the assumption that age patterns of disease occurrence relative to the timing of exposure contains important information about whether exposure operates early and/or late in the carcinogenic process [16]. For many adult cancers, k generally ranges from four to six, implying five to seven stages [117]. Application of the Armitage–Doll model to the atomic bomb survivor data suggests the presence of five stages with radiation acting both at an early and at a late stage [83, 111], although others conclude incidence of solid tumors is consistent with three stages [60].

To explain age patterns of solid tumors in the LSS data and more generally, the Armitage–Doll model has been extended to allow radiation exposure to act as a general mutagen that may affect a particular

stage or all stages in the carcinogenesis pathway [87, 92]. Age–time patterns under this model are in concordance with model predictions, although some skepticism has been raised about this approach [117].

The biological and mathematical characteristics of the two-stage clonal expansion model have been discussed in the general context of carcinogenesis [72–74]. The model postulates that a pool of normal stem cells are transformed at a given rate into premalignant initiated cells, either spontaneously or in response to a specific carcinogenic agent. These initiated cells undergo a birth and death process, which may be modulated by a nongenotoxic "promoting" agent, and undergo clonal expansion. Initiated cells in the premalignant clone may undergo further genomic damages that lead to malignant transformation, growth, and malignant tumor. The two-stage clonal expansion model has been applied to radon exposure data from animal experiments [39, 67] and to radon-exposed underground miners [37, 75]. Analyses based on the two-stage clonal expansion model suggest that radon may affect both the first transformation rate of normal to initiated cells and the rate of clonal growth of the initiated cells. An alternate analysis using a generalized multistage clonal expansion model suggests that a three-stage model may offer a better fit to the Colorado data than the two-stage model [61]. Clonal expansion models have also been applied to data from the LSS cohort [40, 50, 59]. The most recent analysis suggests that a variety of models are consistent with risk patterns and that data are too limited to discriminate among the various models [40].

Adjusting for Errors in Dosimetry

Random errors in dose estimates for atomic bomb survivors and their potential impact on dose–response evaluation have long been investigated [27, 46, 91]. Errors arise principally from uncertainties in the precise location of survivors and the type of shielding, information that is used as input to a multiparameter dose prediction model. This information is based on extensive interviews with subjects, in person or by mail, several years following exposure [27]. Pierce et al. apply a regression calibration approach for error adjustment [91] (*see* **Multiplicative Model**). For true dose x and observed dose z, the regression calibration replaces z with $\mathrm{E}[x|z]$, where $\mathrm{E}[\bullet]$ denotes expected value. The density function for the true dose given the observed $f(x|z)$, is proportional to

$$f(x|z) \propto f(x)f(z|x)$$

The marginal distribution of x, $f(x)$, is assumed **Weibull**, with parameter values selected such that there is agreement between the observed z's and the theoretically values induced from $f(x)$ and $f(z|x)$ under the assumed error model. Four error models for log(z) are considered: (i) "**lognormal** with 30% error", that is, lognormal with geometric standard distribution (GSD) (*see* **Geometric Distribution**) of exp(0.30), (ii) "lognormal with 40% error", (iii) "contaminated lognormal with 40% error", that is, a mixed lognormal having GSD = exp(0.30) with probability 0.75 and GSD = exp(0.75) with probability 0.15, and (iv) z having a normal distribution with coefficient of variation 0.40. Models (iii) and (iv) are selected to evaluate a "heavy tailed" distribution and a nonsymmetric (on a log scale) distribution, respectively. The authors conclude that use of the unadjusted observed doses results in risk estimates, which are about 4 to 11% too small [91]. Most current analyses of the LSS data use adjusted doses.

Nuclear workers are studied to obtain direct estimates of the effects of radiation exposures at low doses and low dose rates. Exposure assessment is aided by annual doses estimated from dosimeters worn by workers and exchanged weekly or bi-weekly. However, exposure evaluation of nuclear workers may be influenced by both **systematic** errors and random errors [28, 29, 30]. Gilbert and Fix describe potential sources of measurement error for workers at the Hanford nuclear facility [29]. Cumulative exposures may be biased from an inability to identify workers who are truly nonexposed and have zero recorded doses, from workers who are exposed to low doses but have zero recorded doses due to the adjustment of dosimeters, which subtracts a fixed contribution from natural background radiation. Sensitivity of dosimeters over a range of photon energies and the ability to respond to radiations from a variety of directions vary over time and result in temporal changes in errors since all doses below detection limits are recorded as zero. Improvements in dosimeters result in temporal variation in the measurement error for recorded doses, with increased errors in earlier years. Risk estimates are based on dose to target tissue, while exposure assessment for workers is based on recorded doses from dosimeters. In

addition, no precise data are available for workers exposed at other nuclear facilities. Finally, computerized files include annual dose estimates and not individual dosimeter values, further potentiating underestimation of cumulative dose. Assuming errors are **multiplicative** and lognormally distributed, and that errors from different sources are independent, Gilbert presents a detailed **sensitivity analysis** on the effects of random and systematic errors for the Hanford nuclear workers [28]. Adjustment for errors in the analysis of all cancers, except leukemia are nearly unchanged, while adjustment for errors in the analysis of leukemia, excluding chronic lymphocytic leukemia, increase the upper confidence limit by a factor of 1.4. Since sampling uncertainty is large, adjustments do not fundamentally modify inference.

A cohort of children from southwestern Utah, southeastern Nevada, and southeastern Arizona who were exposed to iodine isotopes (principally ^{131}I and ^{133}I) from fallout from aboveground detonations of nuclear weapons tests conducted from 1951 through 1958 at the Nevada Test Site, were examined for incidence of thyroid disease. A positive but nonsignificant dose response was found for thyroid cancer and for thyroid nodules [52]. Dosimetry for this study is based on environmental modeling of ground deposition of radioiodine for each weapons test, interviews with subjects' parents to obtain information on dietary habits, prior medical irradiation, medical history, and lifestyle factors. A **path analysis** links the dispersion of radiation in the environment, the uptake of radioiodines into the food supply, the intake of milk and leafy vegetables, direct inhalation, and external exposure from radiation in the passing fallout cloud to create a radiation exposure estimate for each subject [114]. A dose conversion factor is then applied to convert exposure from radioiodine intake and from external sources to thyroid dose. A multiplicative error model and lognormal errors are specified and used to define a range of GSDs for uncertainty and a "subjective confidence interval" for true dose [114]. More formally, under a classical measurement error model and using a Gibbs sampling approach (*see* **Markov Chain Monte Carlo**), measurement error correction of large uncertainties in thyroid dose results in a three-fold increase in the dose–response estimate [112]. A semiparametric **Bayesian** approach that allows for a mixture of both classical and Berkson errors (*see* **Measurement Error in Epidemiologic Studies**) acting through a latent intermediate variable (*see* **Path Analysis**) has also been applied to these data [68]. The error-adjusted dose–response estimate is nearly double the unadjusted estimate, but has markedly widened confidence limits.

Diagnostic and treatment protocols for medical radiation procedures are typically well-documented in medical records, which suggests the possibility of a good characterization of errors in dosimetry. Studies using anthropomorphic phantoms, where radiation dosimeters are embedded in constructs of tissue-like material and exposed under realistic conditions, provide data for the development and testing of **prediction** equations relating radiation exposure from X ray machines to dose to target tissues. As an example, uncertainties in the estimation of dose to the thyroid are evaluated for their effects on risk estimates of thyroid cancer in a study of Israeli children aged 15 years and under, who are treated with cranial irradiation for tinea capitis (ringworm of the scalp) [101]. Data from studies of phantoms are used to develop a prediction equation on the basis of age at treatment, X ray machine output, and amount of additional machine filtration, and including estimates of within-patient error, between-patient error, and random error. This prediction equation is used with covariate information from patient records to provide individualized dose estimates. Estimation of parameters in the prediction equation results in classical error, while the need to impute unknown patient data on age at treatment and other factors results in Berkson error. Schafer et al. use **Poisson regression** methods for cohort data and compare a full likelihood approach with a regression calibration approach [101]. After adjustment for multiple sources of error, risk estimates, and their standard errors, as well as inference on effect modifiers, are not appreciably altered with either approach. The results suggest that classical error plays a relatively minor role and Berkson error is limited. Since the components of dose uncertainties in the tinea capitis study are likely present in other epidemiologic studies of patients treated with radiation, this analysis may provide a model for considering the potential role of uncertainties.

Cohort mortality studies of underground miners are an important source of information on the effects of inhalation of radon and its decay products on lung cancer occurrence. Uncertainties in miner data arise from a variety of sources [84]. While cause of death may be **misspecified** either by failure to

record deaths or miscoding of cause of death, the major source of uncertainty derives from characterization of exposures many years in the past. Errors in exposure assessment arise from limited numbers of measurements of radon in air, particularly in the early years of mine operations, the need to interpolate radon concentrations between unmeasured mines and time periods, and the need to extrapolate radon to time periods prior to measurements. Exposure measurement devices are typically not distributed throughout the mine, since measurements are often motivated by regulatory concerns. Finally, documentation on numbers of hours and precise locations of workers in mines is frequently incomplete. A precise assessment of errors is crucial for the evaluation of the shape of the exposure–response function, particularly at low exposure rates, which can influence the **extrapolation** of risks to the lower exposures in the general population. Results in miners suggest a greater exposure–response relationship for workers with increased exposure duration (or decreased exposure rate), that is, for a given total exposure, exposures for longer durations at lower rates are more deleterious than exposures of shorter durations at higher rates [66]. Uncertainties in exposures are greatest in the early mining years when mine exposures are highest and before widespread measurements are available. Thus, periods of highest exposure rates are also periods most prone to exposure measurement errors. Stram et al. address uncertainties for the complex exposure assessment in the study of Colorado plateau uranium miners [109, 110]. They fit a **multilevel** regression of the logarithms of radon concentration on mine, location, region, and year-specific data. The model defines a single imputation, which is used to estimate exposure, that is, the expected true exposure under the model given the observed measurements, for unmeasured time periods and unmeasured mines. A nested case–control study is selected from the cohort data, matching 40 controls to each case, and analyzed using conditional likelihood regression methods. They find a steeper exposure–response slope and a diminished inverse exposure-rate effect.

Studies of radon-exposed underground miners indicate that exposures up to 30 years and earlier may influence risk of lung cancer [64, 84]. For epidemiologic studies of residential radon, exposure histories must therefore be reconstructed up to 30 years prior, creating [84] substantial uncertainties in exposure assessment [65]. Uncertainties arise from contemporary measurements of radon in one or two rooms not precisely characterizing levels within a dwelling or not accurately reflecting past radon levels due to modified living patterns of the current occupant, structural alterations of the residence, or normal random variations within a room, between rooms of a house, and from year to year. The use of contemporary radon measurements to estimate concentrations in past years induce classical error, which tends to bias risk estimates towards the null [15, 96] (*see* **Bias Toward the Null**). Uncertainties also arise from gaps in the historical record, due to residences that no longer exist or are used for nonresidential purposes, are located outside the study area, are occupied only briefly and excluded by the measurement protocol, or are not measured owing to refusal of the current occupant. Investigators typically employ a single imputation approach for gaps, inserting the mean radon concentration of control houses for missing data in the calculation of time weighted average radon exposure over an exposure period of interest [120]. This single imputation induces Berkson error, which increases variance, but under a rare disease assumption, a linear model for the odds ratio and limited missing data does not appreciably bias risk estimates (*see* **Missing Data in Epidemiologic Studies**).

Precise characterization of all uncertainties in residential radon studies is problematic. Investigators have addressed uncertainties by developing models and directly adjusting risk estimates [15, 96]. Other investigators address uncertainties using simulations under realistic error models to conduct sensitivity analyses, with estimates of error based on previous measurement experience [54], or a **variance components analysis** of validation data for temporal and spatial variation [119]. These disparate approaches have consistently found that error-adjusted estimates of excess odds ratios for lung cancer incidence and radon were 50 to 100% greater than unadjusted estimates.

Investigators have also sought to limit uncertainties through study design by enrolling only long-term residents [4, 5, 23] or by analytically modeling radon levels for gaps in residential history [38]. Finally, an improved retrospective radon dosimeter has been developed that measures residual radiation embedded in glass artifacts, such as mirrors and picture frames, from radon in air. The dosimeter measures past

cumulative exposures and thereby reduce exposure uncertainty [2, 54, 107].

Radiation Hybrid Mapping

Radiation hybrid (RH) mapping is a somatic cell genetic technique for constructing maps of mammalian chromosomes. Originally developed in the 1970s, its current incarnation evolved in the early 1990s as a way to bridge the gap in map resolution between genetic linkage mapping, with a resolution of approximately 1 megabase (Mb) pairs of deoxyribonucleic acid (**DNA**), and physical mapping by pulse field gel electrophoresis, with a resolution of up to a few hundred kilobase (kb) pairs. RH maps can include nonpolymorphic markers (*see* **Genetic Markers**; **Polymorphism**) and are flexible and powerful enough to order polymorphic markers too closely linked to be easily mapped with **linkage** methods.

A set of hybrid clones ("hybrids") created in one experiment is called a RH panel. Early panels consisted of hybrids containing fragments from only a single human chromosome. This technology quickly gave way to whole-genome panels, which contain fragments from all human chromosomes, allowing one to build maps of any portion of the human genome.

Experimental Design

To develop a whole-genome RH panel for human mapping, one starts with a diploid human fibroblast cell line. The cells are irradiated with a dose of radiation strong enough to fragment the chromosomes into several pieces: the higher the radiation dose, the smaller the fragments, and the higher the mapping resolution. Cells containing the fragmented human chromosomes are recovered by fusion with a thymidine kinase (TK) deficient rodent cell line, and hybrid cells containing human chromosome fragments are selected for in hypoxanthine–aminopterin–thymine (HAT) medium. The hybrid cells retain loci near the human TK gene on chromosome 17 at high frequency, but retain loci on other human chromosomes nonselectively. The hybrids cells are propagated to create clones; each hybrid clone ("hybrid") contains cells with a unique set of fragments from the original human chromosomes, and can be tested for the presence of known human DNA markers.

Mapping begins by genotyping each hybrid for the markers to be mapped. A vector $\mathbf{X}_i$ denotes the observations for hybrid i under a given order, with a 1 indicating that a marker is present in the hybrid, and a 0 indicating absence. In reality, hybrids are often genotyped twice. If the **genotypes** at any marker are discordant, then the genotype for that hybrid at that locus is treated as missing. Whole-genome RHs may have retained 0, 1 or 2 copies of any marker. However, assays typically only determine the presence or absence of the marker, and not the number of times it is present in the hybrid. The patterns of presence and absence of the markers in the hybrid clones are used to infer marker order by exploiting the principle that the closer together two markers are on a chromosome, the fewer radiation-induced breaks are expected to occur between them, and the more likely it is that they will be retained or lost together in a hybrid. Figure 1 depicts a simple example of a single chromosome with eight markers and four hybrids.

Statistical Analysis

The goal of RH mapping is to determine the correct or most likely order of a set of markers and to estimate the distances between the markers. The analyst must choose both the criterion for evaluating and comparing individual locus orders, and a search method for traversing through the possible locus orders in order to find the optimal map.

Methods for Evaluating a Locus Order

Nonparametric. The closer together two loci lie on a chromosome, the less likely it is that a radiation-induced break will separate them, and thus the less likely it is that one will be lost and the other retained in a hybrid. A simple strategy is to find the order with the fewest total number of obligate chromosome breaks between adjacent markers (see, for example, [4]). An obligate chromosome break is observed between two markers in a hybrid if one of the markers is present and the other is absent from the hybrid. In counting the number of obligate breaks, untyped markers are ignored. For example, if hybrid 1 in Figure 1 has been typed for all eight markers, then the observation vector under the true order is $\mathbf{X}_1 = (10\,000\,111)$. This order requires two obligate

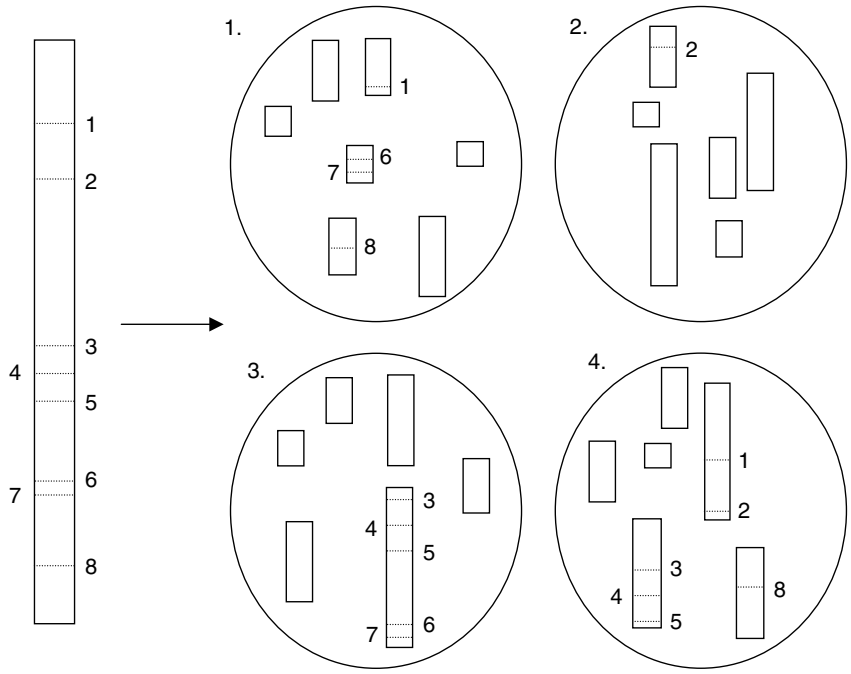

Figure 1 The figure at the left depicts the true (unknown in actual mapping experiments) locations of eight markers on a chromosome. The four circles represent four different hybrids. Within each are shown only the retained pieces of the chromosome of interest. In the first hybrid, three fragments have retained one or more markers from the chromosome. In hybrid 2, only one fragment containing a marker from this chromosome was retained. In hybrid 3, one fragment containing five markers was retained. In the last hybrid, three fragments contain six of the eight markers of interest. Using the correct chromosome order, the hybrid genotypes would be displayed as: $X_1 = (10\,000\,111)$; $X_2 = (01\,000\,000)$; $X_3 = (00\,111\,110)$; $X_4 = (11\,111\,001)$

breaks; one between the first and second markers, and one between the fifth and sixth. Other breaks may have occurred, and in fact the figure shows that there is also a break between the seventh and eight markers. However, only two breaks are required to explain the observed data for the true order. For this hybrid, any order in which the first marker is adjacent to one of the last three requires only one obligate break. Barrett [2] showed that under some common modeling assumptions the minimum breaks method is statistically consistent; as the number of hybrids increases, the probability of inferring the correct order converges to 1.0.

Maximum Likelihood. **Likelihood** methods produce an estimate of distances between markers as well as a statistic (the maximum likelihood) for evaluating a marker order. As with the obligate breaks method, we first choose a marker order. Under a given order, we estimate parameters via **maximum likelihood**. We consider the map order with the largest maximum likelihood the best order. Most researchers have parameterized their models in terms of fragment breakage and retention probabilities. Under a specific marker order $(A_1, A_2, \ldots, A_M)$, the breakage probability $\theta_i (1 \leq i < M)$ is the probability that at least one break occurs between markers A_i and A_{i+1}. The simplest assumption that can be made about fragment retention is that all fragments are equally likely to be retained. Actual data typically do not support this assumption, but it is usually adequate to order markers correctly, if not accurately estimate intermarker distances [11]. Many more realistic (and hence complex) retention models are available in RH mapping software (see, for example, [4], [10] and [15]).

Typically, we assume that breakage and retention are independent processes and that retention of one

fragment is independent of retention of any other (see, for example, [6]). Under the first assumption, breakage can be modeled as a Poisson process, and a breakage probability θ can be converted to an additive distance d using $d = -\ln(1-\theta)$, a formula analogous to Haldane's no-interference mapping function used in meiotic mapping (*see* **Genetic Map Functions**). The distance d is measured in Rays or centiRays (cR), which are analogous to Morgans and centiMorgans in meiotic mapping. A distance of 1 Ray corresponds to one expected break between the two loci per chromosome. The breakage probability between two markers, and therefore also the distance, depends on the radiation dose. Thus, it is best to state the X-ray dose with the distance, such as cR_{8000} for a dose of 8000 rads of radiation. The commercially available G3 whole-genome panel developed at Stanford [16] averages 24kb per $\mathrm{cR}_{10\,000}$. However, there is only a rough correspondence of breakage to physical length: the average ranges from 18 kb/cR for chromosome X to 33 kb/cR for chromosome Y.

For simplicity, assume a single retention rate r for all fragments. For a single hybrid and marker order $\mathrm{A}_1, \mathrm{A}_2, \ldots, \mathrm{A}_M$, we assume that the number of copies of each marker present in the hybrid $G_k, k = 1, \ldots, M$, form the states of a **Markov chain**. For whole-genome diploid (*see* **Human Genetics, Overview**) hybrids, only the presence or absence of markers is directly observable, and the states of the chain are partially hidden from view. The transition probabilities $t_{c,k}(i, j) = \Pr(G_{k+1} = j | G_k = i)$ are the probabilities that j copies of marker A_{k+1} are retained given that i copies of marker A_k are retained when the maximum number of copies (ploidy) is c.

To compute $t_{ck}(i, j)$, first consider a haploid hybrid. In this situation $c = 1$, and the transition probabilities are:

$$\begin{aligned} t_{1k}(0,0) &= 1 - \theta_k r, \\ t_{1k}(0,1) &= \theta_k r, \\ t_{1k}(1,0) &= \theta_k (1-r), \\ t_{1k}(1,1) &= 1 - \theta_k (1-r). \end{aligned} \quad (1)$$

The haploid transition probabilities (1) (*see* **Markov Chains**) can be used to construct the diploid transition matrix as follows:

$$\begin{pmatrix} t_{1k}(0,0)^2 & 2t_{1k}(0,0)t_{1k}(0,1) & t_{1k}(0,1)^2 \\ t_{1k}(1,0)t_{1k}(0,0) & \begin{matrix} t_{1k}(0,0)t_{1k}(1,1) \\ +t_{1k}(0,1)t_{1k}(1,0) \end{matrix} & t_{1k}(1,1)t_{1k}(0,1) \\ t_{1k}(1,0)^2 & 2t_{1k}(1,1)t_{1k}(1,0) & t_{1k}(1,1)^2 \end{pmatrix},$$

where the rows correspond to 0, 1, and 2 copies of marker A_k retained, and the columns to 0, 1, or 2 copies of marker A_{k+1} retained. For example, the probability of moving from a state where 0 copies of marker A_k are retained to a state where 2 copies of marker A_{k+1} are retained is found in the top right corner entry of the matrix.

For a single hybrid, let $\phi_i(x_i|g_i) = \Pr(X_i = x_i | G_i = g_i)$ be the probability that we observe marker A_i to be present ($X_i = 1$) or absent ($X_i = 0$) given that g_i copies of the marker are retained. $\phi_i(1|0)$ is the false positive error rate, and $\phi_i(0|g_i)$, $g_i = 1, 2$, are the false negative error rates for marker A_i. Here, assume that the error rates are known. Lange et al. [10] discuss aspects of error rate estimation, and Slonim et al. [15] discuss error detection. We assume that typing results for individual markers are independent given the $G_1, \ldots, G_M$; i.e.

$$\begin{aligned} &\Pr(X_1 = x_1, \ldots, X_M = x_M | G_1 = g_1, \ldots, G_M = g_M) \\ &\quad = \prod_{k=1}^{M} \phi_k(x_k|g_k). \end{aligned}$$

We further assume that the observations are independent given the underlying marker counts. Then the likelihood for the observations $(X_1, \ldots, X_M)$ from a single hybrid is

$$\begin{aligned} \Pr &= \Pr(X_1 = x_1, \ldots, X_M = x_M) \\ &= \sum_{g_1} \cdots \sum_{g_M} \binom{c}{g_1} r^g (1-r)^{c-g_1} \\ &\quad \times \prod_{k=1}^{M-1} t_{c,k}(g_k, g_{k+1}) \prod_{k=1}^{M} \phi_k(x_k|g_k). \end{aligned} \quad (2)$$

Since the hybrids are independent, their likelihoods are multiplied to get the full likelihood. For haploid hybrids with no typing error, there is no summation over the index g_k since $x_k = g_k$. The likelihood (2) can be evaluated as an iterated sum using Baum's algorithms from the theory of **hidden Markov** chains (see, for example, [10]), and the **EM algorithm** [7]

can be used to maximize the likelihood. Here, the retention patterns of the markers are the observed, "incomplete" data, and the "complete" data include the number of copies of each locus retained, the locations of the chromosome breaks, and the retention status for each fragment.

Bayesian. Bayesian methods yield posterior probabilities of locus orders that allow more easily interpretable comparisons of competing orders. However, the ease of interpretation comes at great expense in computational difficulty. Thus, the Bayesian methods that have been developed to date have not been widely used for map construction. One of the more promising methods uses a "simulated tempering" modified sampling scheme on the mixing characteristics of the Markov chain [8].

Map Building and Identifying the Best Order

For M markers, there are $M!/2$ possible marker permutations. When only a small number of markers are to be ordered, all possible orders may be evaluated and compared. For up to 10–12 markers, branch-and-bound algorithms (see, for example, [13]) also work well. Using branch and bound guarantees that the best order and all orders within a specified number of units (e.g. number of obligate breaks, or $\log_{10}$ likelihood) of the best order will be identified, while substantially decreasing the number of orders that must be evaluated. However, the number of orders to be evaluated still scales exponentially with the number of markers [4].

The locus ordering problem is a version of the classic traveling salesman problem (TSP) in combinatorial optimization. Thus, optimization algorithms that have been applied to the TSP are quite successful for building RH maps [1]. Simulated annealing [9] and genetic algorithms are explored by several authors [3, 4, 14].

For building maps across large segments or whole chromosomes, the common strategy is to first build a framework map, with markers that can be ordered with high confidence. Then, we put additional markers in "bins" along the framework using various strategies. Typically, these markers cannot be ordered among themselves with high certainty, but can be placed in a location relative to the framework (see, for example, [12], [15] and [16]). An alternative strategy for dealing with uncertainty in the order and location of markers is to calculate the posterior distribution of the position of each marker [17].

Radiation

Biostatistical applications in the area of ionizing radiation are primarily addressed at understanding the biological consequences of radiation exposure, especially the health risks. The availability of data from a wide range of epidemiological and experimental studies, many with well-characterized estimates of dose or exposure, has led to sophisticated biostatistical modeling of risks that is perhaps unique to the radiation field. This article focuses on studies that have been aimed at identifying effects, understanding biological mechanisms, and estimating **dose–response** relationships for cancer risks, although other areas such as dosimetry and environmental clean-up have also required special statistical approaches.

During the 20 or so years following the discovery of X-rays in 1895, many of the effects of exposures to high doses of radiation, including acute tissue damage, risk of progressive anemia, and risk of cancer following doses sufficient to cause macroscopic tissue damage, were identified through clinical experience. Radiation exposure was also found to produce genetic changes in insects. Subsequently, following the atomic bombings of Hiroshima and Nagasaki, surveys quickly provided evidence that irradiation at high doses increased the risk of leukemia and cataracts in survivors, and of mental retardation among those exposed *in utero*. A program of genetic research on the effects of radiation was also set up in the late 1940s. However, in the mid-1950s, there were no data for obtaining the quantitative risk estimates needed for assessing the consequences of peacetime uses of radiation or for addressing concerns regarding world radioactive fallout from testing of hydrogen bombs.

As a result, large studies of the causes of death and the incidence of cancer among those who had been irradiated were initiated, first among the survivors of the Hiroshima and Nagasaki bombings and in several populations given medical irradiation, and later in several groups occupationally exposed to radiation including nuclear industry workers (*see* **Occupational Epidemiology**). Many of the studies included extensive efforts to estimate radiation doses. In addition to these studies, which were primarily of the effects of X- and gamma-radiation, studies of underground miners exposed to inhaled alpha particles in the form of radon and its progeny were also initiated. Together these studies have shown that the most important late effect of exposure to doses of irradiation too small to cause acute effects or macroscopic tissue damage is an increased risk of cancer in many organs and tissues in the body. Recently, evidence that exposure to ionizing radiation can increase the risk of cardiovascular, respiratory, and digestive diseases has also become available [37]. By contrast, hereditary effects of radiation exposure have not been clearly demonstrated in human populations. Atomic bomb survivor studies have also demonstrated effects on the developing brain, but absence of additional appropriate human data and uncertainty about the biological mechanisms have prevented extensive study of this topic. For a detailed historical review see Doll [12] and for a more recent review, see Ron et al. [34].

All human beings are exposed to low doses of radiation environmentally, many receive medical exposures, and some are also exposed occupationally. Because some of these exposures carry benefits to the individual or to society, and because reducing exposure can be costly or may carry alternative risks, quantifying risks from such exposures is of substantial interest to society. The effects of exposure to low doses of ionizing radiation in a population may not be negligible, and one estimate concluded that around 5%–6% of the 26 000 cancer deaths that occur in the US each year are likely to be due to natural ionizing radiation [6], but such calculations are subject to many difficulties, particularly that of extrapolating from high to low doses and low dose rates (*see* **Extrapolation, Low Dose**). Other difficulties in estimating radiation risks come about because experimental studies indicate that the effects of radiation exposure vary by the type of radiation involved (gamma rays, alpha particles, etc.) and in some cases by exposure rate, while epidemiologic studies indicate that radiation effects depend on characteristics of the exposed population such as age at exposure, sex and other factors. Also, to estimate lifetime risks and to evaluate detriment in terms of life-shortening, an understanding of the patterns of risk over time following exposure is required.

The Major Studies

The many settings in which radiation exposure has occurred, together with the ability to measure radiation dose, have led to a wealth of data on the

carcinogenic effects of radiation exposure so that, with the possible exception of smoking, more is known about the carcinogenic effects of exposure to radiation than of any other potential carcinogen.

Of particular importance is the Life Span Study of the survivors of the atomic bombings of Hiroshima and Nagasaki mentioned above, in which some 100 000 persons of all ages and both sexes were identified from the 1950 population **census**, and included in a **cohort study**. Dose estimates are available for about 86 000 subjects, of whom around 18 000 received doses of about 0.1 Sv or more to major internal body organs while a further 36 000 are thought to have been essentially unexposed, with doses of less than 0.005 Sv, and these form an internal **control** group (to get this in perspective, the average annual exposure to background radiation in the US excluding radon is roughly 0.001 Sv). To date, the cohort has been followed from 1950–1990 and a total of 4863 deaths have occurred from cancer in the exposed, of which 425 are estimated to be in excess (*see* **Excess Mortality**) and likely to be due to the radiation exposure; 85 of these excess deaths were due to leukemia [29]. For leukemia, most of the excess deaths occurred in the first 15 years after exposure, while for other cancers about 25% of the excess deaths occurred in the last 5 years of follow-up and the excess **absolute risk** per unit time is still increasing. There are clear dose–response relationships both for leukemia and for solid cancers (see Figure 1). Tumor registries

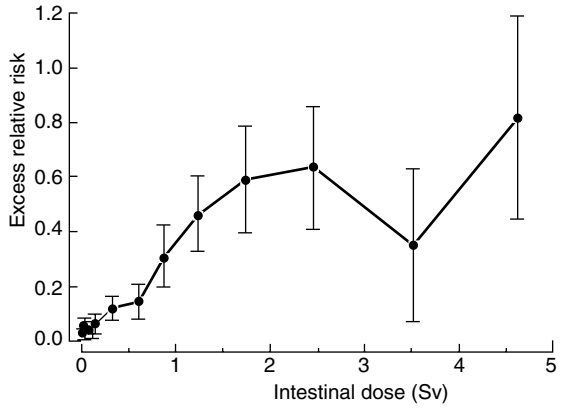

Figure 1 Shape of the dose–response curve for solid cancers among males aged 30 at exposure among survivors of the atomic bombings of Hiroshima and Nagasaki. Based on Pierce et al. [29]

in the cities of Hiroshima and Nagasaki also allow the study of cancer incidence in this cohort, with the most recent published results covering the period 1958–87 [41]. The tumor registries have also allowed detailed study of cancers of several specific sites.

As well as studies of the Japanese atomic bomb survivors, cohort studies of persons treated with generally high doses of external X-ray and gamma radiation for diseases such as ankylosing spondylitis, cervical cancer, tuberculosis, benign gynecological disease, peptic ulcer, skin hemangiomas, childhood cancers, mastitis, thymic reduction, and tinea capitis have been carried out. In addition, studies of persons exposed to internal alpha emitters have been conducted in radium dial painters and in patients with a variety of conditions injected with the contrast medium Thorotrast. In many instances these studies have reported results that are in accordance with those found in the Japanese atomic bomb survivors, but they have also provided important supplemental information. For example, they have demonstrated that, in marked contrast to other forms of leukemia, chronic lymphocytic leukemia, which occurs only very rarely among ethnic Japanese, is not readily inducible by radiation. In addition, a recent pooled analysis of several studies of breast cancer incidence have given support to the concept of a linear radiation dose response for breast cancer, have highlighted the importance of age and age at exposure on the risks, and have suggested a similarity in risks for acute and fractionated high-dose-rate exposures with much smaller effects from low-dose-rate protracted exposures. There is also a suggestion that women with some benign breast conditions may be at elevated risk of radiation-associated breast cancer Preston et al. [32].

Most of the above studies involve populations exposed to X-rays or gamma rays at doses and dose rates considerably higher than would normally be experienced and thus considerable downward extrapolation is involved in **risk assessment**. Several studies of much lower exposures have been carried out, including studies of nuclear workers [3, 26] and populations exposed to fallout [8, 38]. Where adequate dose estimates are available, such studies provide a direct evaluation of the risks at the actual levels of interest. Although these studies cover large populations, their low doses inevitably result in

reduced **power** to detect effects and substantial potential for **confounding**, and they cannot be expected to provide precise estimates of risk or much information on modifying factors (*see* **Effect Modification**). Nevertheless, they have provided reassurance that extrapolation from higher doses and dose rates has not seriously underestimated risks.

A promising source of new information comprises persons who were exposed in countries of the former Soviet Union, where exposures were generally much larger than those from similar activities in other countries. Studies include those exposed as a result of the Chornobyl accident in 1986 [43] and those exposed as a result of operations of the Mayak nuclear facility, which began operations in 1948 to produce plutonium for the Soviet Union's nuclear weapons program ([17, 18] – or cite whole issue – see references). Studies of Chornobyl clean-up workers, workers at the Mayak facility, and populations living near the Techa River downwind of the Mayak facility are unique in providing information on protracted whole body exposure at cumulative doses that are sufficiently large that risks can be estimated with some degree of precision. In addition, studies of Chornobyl exposures have clearly demonstrated that exposure to iodine-131 in childhood can increase the risk of thyroid cancer, and extensive efforts to estimate thyroid doses for individual subjects should make it possible to quantify risk as a function of dose. Studies of Mayak workers have provided the first direct demonstration in humans that exposure to plutonium increases risk of lung, liver, and bone cancers.

The studies discussed above are not directly relevant for one of the most important sources of population exposure to ionizing radiation, namely inhaled radon and its progeny. It had been known for several centuries that miners in the Erz Mountains had a high mortality from chest disease, but it was not until early in the twentieth century that it was appreciated that the disease was in fact lung cancer, and not until the 1950s that it was widely accepted that radon was likely to be the principal cause. About a dozen studies of radon-exposed miners have now been carried out including over 60 000 men. All the studies found high risks of lung cancer that were related to radon exposure [22] but the risk was very specific to this site of cancer and there was no material risk of mortality from other cancers [9].

The majority of the studies mentioned above are cohort studies. However, **case–control studies** have played an important role in documenting the association between risk of childhood cancer and obstetric X-rays [1], while **nested case–control** or **case–cohort studies** have sometimes been used to obtain information on doses [2, 44] or **covariates** [20] that would be too costly to obtain for the entire cohort. Case–control studies are also currently being used to estimate directly the risks of residential exposure to radon (e.g. [10, 28]). The need for this arises because residential radon is the largest source of exposure to ionizing radiation in many populations, often accounting for over half the population dose, whilst the available remedial measures are costly. Extrapolation of the risks from the miners' studies is particularly uncertain owing to the very different exposure conditions in mines compared with homes, and is complicated by the fact that there is evidence from the studies of radon-exposed miners that the risk per unit exposure varies with exposure rate, with a higher risk per unit exposure when the exposure is delivered at a lower compared with a higher rate [23, 42].

In addition to **observational studies** on humans, a large number of **experimental studies** have been conducted both *in vivo* and *in vitro*. These studies have increased our understanding of the carcinogenic process and have provided information in areas where human data are inadequate. Experimental studies have been especially important in developing our understanding of modifying factors such as exposure rate and type of radiation, and of the shape of the dose–response function.

The large and ever-growing number of studies has led to a sizable literature. This is reviewed periodically by a number of committees including the United Nations Scientific Committee on the Effects of Atomic Radiation UNSCEAR [43], the International Commission on Radiological Protection [16], and the Committee on Biological Effects of Ionizing Radiation of the US National Research Council [5, 27]. Their reports should be consulted for further details.

The Contribution of Biostatistics

The wealth of data and the availability of quantitative estimates of biologically relevant measures of dose

or exposure have led to the development of complex models for describing radiation risks that have drawn on information obtained from both epidemiologic and experimental studies. Statisticians have been stimulated to use a wide variety of methods to fit models that include the characterization of modifying factors and that address exposures that may be protracted over time.

As would be expected, the **Cox regression model** forms the basis of many applications. In a few cases (e.g. [14]) simple **proportional hazards** models have been fitted to data on individual subjects, but the complexity of fitting such models, especially when study sizes are large, often makes such an approach cumbersome. Furthermore, it is sometimes desirable to model absolute rather than relative risks, and this generally requires **parametric models** for the baseline risks. These difficulties can be avoided by the assumption of piecewise constant exponential hazards, enabling the data to be summarized in terms of tables of the numbers of events and **person-years at risk**. A wide variety of models can then be fitted by means of Poisson **regression**, and the flexible programme AMFIT [31] was developed to enable this type of analysis to be carried out easily (*see* **Additive Hazard Models**; **Poisson Regression in Epidemiology**).

The application of Poisson regression using AMFIT is illustrated by analyses of atomic bomb survivor mortality data in which both **excess relative risk** and excess absolute risk models were applied to data for leukemia and solid cancers with exploration of the shape of the dose–response functions and the dependence of risks on sex, city, age at exposure, and time since exposure [29]. Another application, which illustrates the feasibility of the approach for exposures that are protracted and variable over time, is an analysis of data from 11 underground miner cohorts [22], where risks were found to depend not only on cumulative exposure, but also on exposure rate, time since exposure, and age at risk. The shape of the exposure–response function and the effect of age at exposure were also explored in these analyses.

The radiobiological understanding that has come from experimental studies has sometimes affected the choice of models, and, in particular, has led to the use of models in which the relative risk is a linear or linear–quadratic function of dose. Biologically based models have also been applied to radiation data; for example, the two-stage clonal expansion model has been used to describe lung cancer risks in both Colorado miners [25] and rats [24] exposed to radon and radon progeny.

In the radiation epidemiology field there are several instances in which combined analyses of original data from several studies have been carried out. Early examples were analyses of data from three studies of radiation exposure and breast cancer [19] and analyses of data from the Life Span Study of Japanese atomic bomb survivors and patients given X-ray therapy for ankylosing spondylitis [7]. Subsequent combined analyses include those of 11 underground miner cohorts [9, 22], of several cohorts of nuclear workers in three countries [3], of several studies of radiation-induced thyroid cancer [35] and eight cohort studies of breast cancer [32]. A major reason for conducting combined analyses is to obtain more precise estimates of parameters than those based on individual studies, an advantage that is especially important for investigating modifying factors. Combined analyses also provide a more rigorous evaluation of consistency of results among studies. Some combined analyses have accounted for heterogeneity among the studies in the **confidence intervals** for the overall risk estimate [22, 35].

By contrast to the sophisticated analyses described above that have been applied to observational epidemiologic data, the statistical methods applied to experimental animal data have in many cases been fairly simple. However, in some cases the hazard has been modeled as a function of dose, age, and other factors, an approach that is similar to that applied to epidemiologic data although modifications have sometimes been required. In animals, where detailed examination of tissues is conducted after death, tumors are often not the cause of death, but are instead found incidentally to death from other causes, and appropriately modeling the hazard function requires different statistical treatment of fatal and incidental tumors. Although extensive statistical research on this statistical issue has been conducted, much of it has been addressed at appropriate tests of the **null hypotheses**, and methods need to be extended to allow the hazard modeling that is of interest in animal experiments involving exposure to radiation. Gart et al. [13] and Dewanji et al. [11] describe an approach in which two hazard functions (for fatal and incidental tumors) are modeled, and this general approach has been applied in analyses of

data on rats exposed to radon [15]. Other innovative analyses of animal data include those of Chmelevsky et al. [4] and those of Luebeck et al. [24] referred to above.

Recent Developments

Recently considerable effort has been expended on the pooled analysis of data from a number of different sources. The need for this arises in part from the desirability for further direct evaluation of risks to populations exposed at low levels, for example workers in the nuclear industry or populations exposed to environmental radon, where relative risks are small and the results from individual studies do not provide a clear answer (see Figure 2), and in part from the need to bring together data from a number of different sources, such as both high- and low-dose epidemiologic studies and experimental studies, to develop risk models. Already, some pooled analyses have revealed heterogeneity among the available studies (e.g. [22]), and in some cases there may be a need for the application of better methods to account for and describe such heterogeneity.

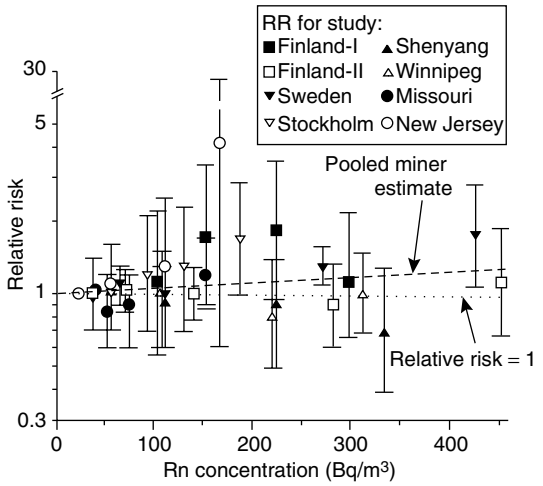

Figure 2 Relative risks for lung cancer by categories of radon (Rn) concentration for seven case–control studies of residential radon exposure. Also shown are the predicted risks from studies of underground miners exposed to radon, as estimated by the US Committee on the Biological Effects of Ionizing Radiations (BEIR IV). Based on Lubin et al. [21]

A considerable amount of effort has also been expended in the development and application of methods that account for uncertainties in the estimation of doses (or exposures) in several studies. The presence of **random errors** in individual dose estimates (*see* **Measurement Error in Epidemiologic Studies**) may cause underestimation of the effects of radiation in dose–response analyses, distort the shape of the dose–response curves, and cause confidence intervals and significance tests (*see* **Hypothesis Testing**) to give misleading answers. Some work on this topic has already been carried out in the radiation field. For example, Pierce et al. [30] estimated the distribution of true doses among Japanese atomic bomb survivors, and took an assumed coefficient of variation for the random dose errors, thereby aiming at a way to estimate E(true dose|estimated dose). Corrections based on this and related considerations are now being used in many analyses of atomic bomb survivor data. Another example is that of Thomas et al. who applied an **empirical Bayes** approach to a case–control study of leukemia in Utah residents exposed to radioactive fallout [40]. Recently, methods that model fully the effect of dose estimation uncertainties have been developed [33]. This work was carried out to provide methods for the analysis of case–control studies of indoor radon, but should also be useful for the analysis of a wide variety of case–control and cohort studies. Other recently published studies addressing measurement error include Schafer et al. [36] and by Stram et al. [39].

Finally, it seems likely that future scientific developments in radiation research and advances in understanding the biology and particularly the genetic basis of cancer will also stimulate future statistical developments.

Radioimmunoassay

Radioimmunoassays (RIAs) are commonly performed in clinical and biomedical research laboratories to estimate the concentration of an antigen in a biological specimen. The RIA is a type of radioligand assay (RLA) in which antigens are labeled with radioisotopes. An analogous approach to radioligand assays in which antibodies are radiolabeled rather than antigens is referred to as an immunoradiometric assay (IRMA).

Radioimmunoassays differ from traditional bioassays (*see* **Biological Assay, Overview**) in that they arise from specific chemical reactions in biochemical systems that follow the law of mass action and do not have the errors associated with biological test systems (*see* **Pharmacokinetics and Pharmacodynamics**). Basically, the biochemical system modeled is the immune system which produces antigens (Ag) as a response to the presence of antibodies (Ab). The binding of antigens to antibodies can be represented as a two-way chemical reaction:

$$\mathrm{Ag} + \mathrm{Ab} \rightleftharpoons \mathrm{AgAb}.$$

The concentration of AgAb follows a curvilinear function of the initial concentrations of Ag and Ab. Therefore, by measuring the AgAb complex in the system, the initial concentrations of either the antibody or antigen can be inferred. Measuring AgAb is done by labeling part of the antigen with a radioactive tracer such as iodine-131. When the labeled antigen is introduced, the unlabeled antigen of unknown concentration in the system decreases the amount of labeled antigen that is bound to the antibody; thus, measuring either the unbound labeled antigen or the radioactive AgAb complex provides a method to estimate indirectly the unknown concentration of unlabeled antigen. As with other bioassays, a standard curve is developed, to which the specimens of unknown potency are compared. The techniques for formulating a standard curve, which are based on biochemical theory and the law of mass action, are described by McHugh & Meinert [6] and Meinert & McHugh [7].

The development of modern, virtually totally automated techniques, has enabled laboratories to move from the use of unsophisticated statistical procedures based on manual curve fitting to more appropriate methods for curve fitting which incorporate routine quality control checks for systematic errors and outliers. Weighted **least squares** estimation, or **maximum likelihood** estimation, based on linear or nonlinear functions, are often utilized, augmented by **analysis of variance** techniques to test the validity of the underlying model.

Statistical Design and Models

Much of the relevant statistical methodology for RIAs is found in clinical chemistry and biochemistry journals. Chapter 16 of Finney's classical text on bioassay methods [1] provides a useful summary of the statistical considerations and standard analysis techniques. The recent text by Govindarajulu [3] gives a more detailed description of the theoretical biochemical model and a useful list of references, that encompass laboratory quality control issues and **calibration** curve fitting.

The primary response measure in an RIA is a radiation count during a specified time interval for fixed dose levels. The counts of bound labeled or free ligand labeled antigen are designated B and F respectively, with T (total) $= B + F$. The symbol B_0 will be used for the expected count bound at zero dose level and N will be used for the expected count at "infinite (nonspecific)" dose. Direct measurements can be incorporated to estimate both "zero" and "infinite" dose levels. For statistical analysis, a logarithmic transformation of dose is typically used as a dose metameter (x), and a response metameter (y) is specified that is assumed to be linearly related to x, that is, $E(y) = \alpha + \beta x$. The expected count (U) at a given dose is expressed as

$$U = \mathrm{E}(u|x) = B_0 + (N - B_0)F(x),$$

where $F(x)$ can be any of a number of sigmoidally shaped curves, such as the **logistic** or cumulative **normal**, which will vary from one to zero for an RIA as x varies between $-\infty$ and $+\infty$ [1].

Suppose that the functional form used is

$$F(x) = \frac{1}{1 + \exp(-2Y)}.$$

(Note that some references use Y rather than $2Y$ in $F(x)$. If Y is used, then the estimates of α and β will be twice the value obtained when $2Y$ is used. Parameter estimates of B_0 and N are unchanged.) Then an

often satisfactory linearizing response metameter is

$$Y = \frac{1}{2}\ln\left(\frac{U-N}{B_0-U}\right) = \alpha + \beta x,$$

where $Y = \frac{1}{2}\log\text{it}(U-N)/(B_0-N)$. Iterative methods of estimation based on weighted least squares or maximum likelihood, analogous to those used in standard quantal bioassay designs, are utilized to estimate the parameters and to calculate the potency or relative potency.

An additional factor that must be considered for an RIA is the variance function of the observed counts, which is used for weighting the observations in the regression analysis. Analyses have shown that, in general, the variance of the counts is subject to extra-Poisson dispersion (*see* **Overdispersion**). (See, for example, Rodbard & Cooper [13] and Rodbard [11].) Rodbard [12] recommended a quadratic function for the variance, whereas Finney [1] has proposed that the variance ($\phi(U)$) be specified as

$$\phi(U) = VU^J,$$

where J is the rate of increase in variance with increase in count and U is assumed to be normally distributed. While the variance function could be estimated simultaneously within a single assay in conjunction with the regression parameters, greater reliability is obtained by pooling a large body of experiments, and assuming that J remains constant across assays. The careful analyst will reassess the value of J periodically. A flexible, comprehensive computer program is desirable to permit estimation of parameters assuming various forms for the weights (reciprocals of the variance function) (see, for example, [14]).

Potency Estimation

The parameters α, β, B_0, and N are generally estimated by minimizing the weighted sum of squares

$$\sum\left[\frac{(u-U)^2}{\phi(U)}\right]$$

or, alternatively, by maximizing the log likelihood

$$-\frac{1}{2}\sum\log[\phi(U)] - \frac{1}{2}\sum\left[\frac{(u-U)^2}{\phi(U)}\right].$$

Both approaches will give asymptotically equivalent results, but weighted least squares has more frequently been employed in estimation software primarily because of practical considerations.

The log potency is obtained by inserting a specified fraction bound (P) in

$$Y = \frac{1}{2}\ln\left(\frac{P}{1-P}\right)$$

to calculate Y and then solving for log dose (x) in

$$Y = \hat{\alpha} + \hat{\beta}x.$$

If $Y = 0$, then $\log(\text{ID}_{50}) = -\hat{\alpha}/\hat{\beta}$, the estimated log midrange (ID_{50}).

A common approach in radioimmunoassay is to compare a single dose level of a test preparation to a separately estimated standard response curve, where $\hat{\alpha}$, $\hat{\beta}$, $\hat{B}_0$, and $\hat{N}$ are the estimates obtained in the logit transformation analysis for the standard curve, and $\overline{u}$ is the mean value for n independent counts at log dose x of the test preparation (T). The logit is calculated as

$$Y = \frac{1}{2}\ln\left[\frac{\overline{u}-\hat{N}}{\hat{B}_0-\overline{u}}\right].$$

The potency estimate is then $\log(\hat{\rho}) = -x + (Y - \hat{\alpha})/\hat{\beta}$. The variance of Y depends not only on the variance of $\overline{u}$ but also on the variances of $\hat{\beta}_0$ and $\hat{N}$, and the covariance terms, which are generally estimated by first-order approximations for the variance of Y. The variance of $\overline{u}$ is estimated as

$$\phi(\overline{u}) = \frac{V\overline{u}^J}{n},$$

where V is the residual mean square of the least squares estimation based on the standard curve. Usual values of J in practice range from 1.0 to 1.5. The $(1-\alpha)\%$ **confidence intervals** are estimated through application of **Fieller's theorem** for ratio estimators.

Similarly, if observations are made within a single experiment on doses of standard (S) and test preparations (T), then the fundamental assumption of assay validity is the condition of similarity, which for radioimmunoassays leads to estimation closely analogous to that for **parallel-line assays**. The estimated log relative potency ($\hat{\rho}$) is

$$\log(\hat{\rho}) = \frac{\hat{\alpha}_T - \hat{\alpha}_S}{\hat{\beta}},$$

where $\hat{\beta}$, $\hat{B}_0$, and $\hat{N}$ are common estimates across both standard and test preparations. Fieller's theorem is employed to calculate confidence limits for $\log \rho$.

Validity Testing

Typically, as noted above, the dispersion of the counts increases directly with the mean response level; that is

$$\sigma_u^2 = \sigma^2 U^J,$$

where σ^2 is the weighted mean-square within replicate sets. A precision profile calculated from the within replicate "standard error" divided by the slope of the response curve (coefficient of variation) estimates the best that the assay can achieve. Tests relevant for evaluating the validity of the assay and the adequacy of the statistical model are [10]:

1. stability of assay system;
2. excessive within-replicate dispersion among sets of tubes;
3. **goodness of fit** of the assumed response curve; and
4. parallelism of the standard and test response curves.

Stability, or lack of systematic drift, is evaluated either (i) by checking one or two quality control samples at a few points throughout the assay or (ii) by including several standard curves at different times in the assay. The latter provides a more powerful tool for identifying drift. Healy [4] proposed a **robust** estimate of dispersion, based on each mean square following a multiple of a **chi-square** or **gamma** variate. If there are n values from which the $n - k$ outlier values are omitted, then each of the k mean squares will have r degrees of freedom if the number of replicates is $r + 1$. The proposed estimate is $\hat{\sigma}^2 = \sum_{i=1}^{k} y_i / nb$. The unbiasing factor, b, depends upon the slope of the linearized response curve, the fraction of the sample omitted, the degrees of freedom, r, and the total sample size, n (see [5, Table 13.4A]).

Finney [2] recommends that a reasonable way to evaluate goodness of fit, assuming that test doses are measured in duplicate, is to plot the apparent lack of fit, measured as the difference between the mean of the replicates of each dose and the fitted curve expressed as the percentage change in dose versus log dose on the same graph as the precision profile from the within-replicate dispersion versus log dose. A variance ratio test is used to compare the weighted sum of squares of the expected mean response for each curve to the value predicted if the curve provides a good fit.

In order to check for the validity of parallelism, the test preparations must be evaluated at two or more dose levels. It is customary to evaluate parallelism when an assay is under development, but parallelism may not be verified for subsequent assays. Inclusion of some samples at multiple dilutions is advisable, particularly when any change is made in the assay system, such as using a different reagent. Not infrequently, assays of multiple test preparations will find a lack of parallelism present for only a few of the test specimens. A combined test of parallelism is often employed which incorporates the traditional bioassay test of parallelism with the goodness of fit of the test samples to the assumed response curve.

Other Calibration Methods

Although the logistic model has been most widely used for calibration curves, it has the disadvantage that it does not always provide linearity over the full range of dose concentrations. Alternate approaches have included empirically based curve fitting using **splines**, polynomials, or polygonals, which often provide excellent fits in practice and models based on chemical reactions, some of which have been generalized to allow for multiple binding sites (e.g. [8]). Criticisms of the former are that "while" splines are "well-adapted for smoothing very good data in order to secure internal consistency of interpolation. . . , they are much less suited to estimation from points subject to appreciable experimental error, especially if the precision of that estimation is important to subsequent calculations" [2]. When the binding site concentration and the equilibrium constant are both small, a four- or five-parameter logistic model provides a good fit to the observed data for a wide range of doses, comparing well with the theoretically derived model of McHugh & Meinert [6] and Meinert & McHugh [7] based on biochemical theory. While the McHugh–Meinert theoretical model may generally give somewhat narrower confidence intervals than the corresponding logistic model, a comparison by Raab [9] of the four-parameter logistic model to the four-parameter mass action curve for ten databases found the logistic model to be more robust.

CAROL K. REDMOND

Radon–Nikodym Theorem

If f is a real-valued function on a measure space $(\Omega, \mathcal{F}, \mu)$ for which the integral $\int_\Omega f \, d\mu$ exists (finite or infinite), then $\nu(B) = \int_B f \, d\mu$ defines another measure with the property that $\mu(B) = 0$ implies $\nu(B) = 0$, i.e. ν is absolutely continuous with respect to μ. When ν is a **probability** measure, the function f is called the density of ν with respect to μ; thus, the existence of a density implies absolute continuity. The Radon–Nikodým Theorem is essentially the converse of this statement, as follows. If $(\Omega, \mathscr{F}, \mu)$ is σ-finite and ν is a (possibly signed) measure on $(\Omega, \mathscr{F})$ which is absolutely continuous with respect to the measure μ, then there exists a real-valued measurable function f on Ω such that $\nu(B) = \int_B f \, d\mu$ for every $B \in \mathscr{F}$. More generally, then, for measurable functions g on Ω, $\int_\Omega g \, d\nu = \int_\Omega fg \, d\mu$ whenever either integral exists. The function f is called the *Radon–Nikodým derivative* of ν with respect to μ and is denoted $d\nu/d\mu$. It is unique up to changes on a set of μ-measure 0. For probability measures, a simplified statement of the theorem is that absolute continuity implies the existence of a density.

When μ is Lebesgue measure on the real line and ν is a probability measure with cdf F, absolute continuity of F (as a function) is equivalent to absolute continuity of ν (as a measure). By the Radon–Nikodým Theorem, this in turn implies that ν has a density.

The Lebesgue Decomposition Theorem gives a unique decomposition $\nu = \nu_{ac} + \nu_s$ of an arbitrary σ-finite measure ν on $(\Omega, \mathscr{F})$ into a measure ν_{ac} which is absolutely continuous with respect to μ and a measure ν_s which is singular with respect to μ [3]. Singularity means there is a set A with $\mu(A) = 0$ which supports all of ν_s, in the sense that $\nu_s(A^c) = 0$. Here A^c denotes the complement of A. The Radon–Nikodým Theorem then insures the existence of a Radon–Nikodým derivative for the absolutely continuous part ν_{ac}.

The theorem was proved by H. Lebesgue in the context of Euclidean space, and then generalized to abstract measure spaces by J. Radon and by O.M. Nikodým.

Applications in Probability and Statistics

Conditional Expectation

In elementary probability the conditional distribution (*see* **Conditional Probability**) of a discrete **random variable** X, given a discrete random variable Y, is given by $\Pr(X = x|Y = y) = \Pr(X = x, Y = y)/\Pr(Y = y)$. For jointly continuous X and Y with joint density $f(x, y)$, the conditional distribution is given by the conditional density $f_X(x|Y = y) = f(x, y)/f_Y(y)$, where f_Y is the marginal density of Y. These distributions determine conditional expectations $\mathrm{E}(X|Y = y)$. Taking Y random yields the random variable $\mathrm{E}(X|Y)$. Averaging the quantities $\mathrm{E}(X|Y = y)$ over y yields the overall average of X, i.e. $\mathrm{E}(X) = \mathrm{E}[\mathrm{E}(X|Y)]$. More generally, averaging over a subset of the values y yields

$$\mathrm{E}[X1_B(Y)] = \mathrm{E}[\mathrm{E}(X|Y)1_B(Y)], \quad B \in \mathscr{B}, \quad (1)$$

where $\mathscr{B}$ denotes the Borel sets of the real line and 1_B denotes the indicator function of the set B. The Radon–Nikodým Theorem makes possible the definition of the conditional expectation $\mathrm{E}(X|Y)$ for more general joint distributions, where no elementary definition is possible, and without the intermediate construction of an explicit conditional distribution of X given $Y = y$. Specifically, provided that only $\mathrm{E}(X)$ exists, the measure $\nu(B) = \mathrm{E}[X1_B(Y)]$ on $\mathscr{B}$ is absolutely continuous with respect to the distribution μ of Y, and the defining property of $d\nu/d\mu$ states that

$$\mathrm{E}[X1_B(Y)] = \int_{-\infty}^{\infty} \left(\frac{d\nu}{d\mu} \right)(y) 1_B(y) \mu(dy), \quad B \in \mathscr{B}.$$

Therefore, defining $\mathrm{E}(X|Y = y) = (d\nu/d\mu)(y)$ ensures that the fundamental property (1) of conditional expectation still holds in the more general context. The uniqueness of the Radon–Nikodým derivative means that no other definition of conditional expectation could have property (1).

Likelihood Functions and Likelihood Ratios

Given a family $\{P_\theta, \theta \in \Theta\}$ of probability measures which are all absolutely continuous with respect to some underlying measure μ, the Radon–Nikodým

derivatives $dP_\theta/d\mu$ serve as **likelihood** functions, or as **likelihood ratios** if μ is also a probability measure. This is particularly useful when one has observations which are not elements of a finite-dimensional space, such as trajectories of a continuous-time **stochastic process**, where elementary definitions of the likelihood do not apply. The **Neyman–Pearson lemma** says that **hypothesis tests** based on such likelihood ratios are optimal. In comparing two probability measures P_1 and P_2, $\mu = P_1 + P_2$ can be used as the underlying measure.

Girsanov's Formula

When μ is Wiener measure on the space of continuous functions on an interval (i.e. the distribution of **Brownian motion**), and ν is the distribution of Brownian motion with a drift, Girsanov's formula provides an explicit expression for $d\nu/d\mu$. For signal detection in the presence of additive Gaussian white noise (*see* **Noise and White Noise**), this makes possible the construction of a **likelihood ratio test** for the presence of the signal, as the value of the likelihood ratio can be calculated from an observation of the trajectory of the process [5]. Girsanov's formula covers a wide family of processes beyond Brownian motion as well.

Spectral Measures

When ν is the spectral measure of a stationary process in continuous or discrete time, for example, a **time series**, properties of the spectral density $d\nu_{ac}/d\mu$ (*see* **Spectral Analysis**) are important in analyzing mixing properties, smoothness, interpolation, and **prediction** [2, 4]. Here, μ is Lebesgue measure on the real line or on the unit circle.

Local Time

If $X(t)$ is a real-valued stochastic process indexed by time $t \geq 0$, the corresponding occupation measure on $\mathbb{R}$ at time t is given by $\nu_t(B) = \mu(\{s \in [0, t] : X(s) \in B\})$, $B \in \mathscr{B}$, where μ denotes Lebesgue measure. If ν_t is absolutely continuous with respect to μ, the local time $(d\nu_t/d\mu)(x)$ at a point x then describes the relative amount of time the process X spends at x during $[0, t]$, even though the times t for which $X(t) = x$ form a set of Lebesgue measures 0 for each fixed x [1].

KENNETH S. ALEXANDER

Random Coefficient Repeated Measures Model

This topic is concerned with the modeling of data where measurements of one or more attributes are repeated on the same set of individuals over time. Typical applications are to the modeling of the anthropometric growth of children or animals (*see* **Nonlinear Growth Curve**). The model specification will be developed for the case where a single continuous measurement is made on several occasions for a sample. This will then be extended to consider the case of multiple measurements at each time point and mention will be made of extensions to latent variable models and to discrete response data. To begin with, we look at the simple, restricted, data structure where there are a fixed number of measurement occasions and each individual has a measurement on each occasion.

Multivariate Models

Consider the data matrix of responses:

Individual	Occ. 1	Occ. 2	Occ. 3	Occ. 4
1	y_{11}	y_{21}	y_{31}	y_{41}
2	y_{12}	y_{22}	y_{32}	y_{42}
3	y_{13}	y_{23}	y_{33}	y_{43}

The first subscript refers to occasion and the second to individual. We assume multivariate normality and so for the response vector we have initially

$$Y \sim \mathrm{N}(\mu, \Sigma) \tag{1}$$

This constitutes a null model and, in general, we will wish to include further variables, notably age or time. Suppose we wish to express the response; say, a weight measurement, as a linear function of time (t) measured at each occasion. We may then write

$$y_{ij} = \beta_{0j} + \beta_{1j} t_{ij} + \varepsilon_{ij}, \tag{2}$$

where we allow the intercept and average growth rate to vary across individuals. Suppose, further more, that

$$\begin{pmatrix} \beta_{0j} \\ \beta_{1j} \end{pmatrix} \sim \mathrm{N}\left[\begin{pmatrix} \beta_0 \\ \beta_1 \end{pmatrix}, \begin{pmatrix} \sigma^2_{\beta_0} & \\ \sigma_{\beta_{01}} & \sigma^2_{\beta_1} \end{pmatrix} \right] \varepsilon_{ij} \sim \mathrm{N}(0, \sigma^2_\varepsilon). \tag{3}$$

We have replaced the general mean and covariance structure given by (1) by the specific structure given by (3). Thus, for example, the **goodness of fit** of (3) can be judged and the model elaborated with suitable **explanatory variables**. Grizzle & Allen [9] provide details of estimation and test procedures.

This multivariate model cannot deal satisfactorily with the typical situation where the spacing and number of measurement occasions are variable and has generally been superseded, except in one or two special cases such as that of latent growth models, mentioned below. We now develop an alternative approach to fitting models such as (2), based upon a *multilevel* model.

The Two-Level Repeated Measures Model

Model (2) and the associated covariance structure (3), as they are written, make no particular assumptions about the number or spacing of measurement occasions and, in fact, constitute a special case of a two-level model (*see* **Multilevel Models**). Level 1 units are the measurement occasions and level 2 units are individuals. All the usual procedures for estimation and inference in such models are therefore available, including cases of multivariate responses, nonlinear models, etc. We can additionally consider individuals as nested within further hierarchies; say, animal litters or schools for students and cross-classifications may also occur.

A consequence of (2) is that measurements made on the same individual are correlated through the sharing of common intercept and slope parameters, and it is this dependency that leads to the inadequacy of simple estimation procedures, for example, based upon ordinary **least squares**. Furthermore, interest will usually lie just as much in the covariance matrix estimates as in the average growth parameters. We may also wish to form posterior mean estimates of the individual growth parameters (β_{0j}, β_{1j}) and we shall illustrate below how these can be used for efficient prediction. As in the general multilevel model case, we may have a **Bayesian** formulation for the model with prior distributions upon the parameters (see, for example, [1]).

In the following sections we shall consider in more detail nonlinear models, multivariate response

models with more than one response on each occasion and complex structures for the level 1 residuals. For a detailed exposition of further aspects of these topics and some alternative approaches, as well as a discussion of issues related to informatively missing data and transition-type models, the reader should consult Diggle et al. [4]. In particular, these authors consider the so-called population average model, where interest centers on the estimation of the fixed or average component of (2) (*see* **Marginal Models**). This often allows simplified estimation procedures to be used with no requirement for the separate estimation of the random components. This may be appropriate in certain circumstances, but, since it ignores the specific nature of repeated measurements data, is not considered further here.

Nonlinear and Generalized Linear Models

Most attempts to fit nonlinear models to repeated measurements have fitted separate curves to each individual's set of measurements and then combined these to describe the between-individual variation (*see* **Nonlinear Growth Curve**). A major problem with this approach is that it requires many measurements on each. Also, while nonlinear curves have been used successfully to describe change, for example, in **pharmacokinetic** studies, in other areas, such as growth, they can also impose inflexible relationships among growth events that are not empirically supported [5].

Bock et al. [2] describe a maximum likelihood analysis of a human growth model using the superimposition of three logistic functions. Lindstrom & Bates [13] describe an approximate estimation procedure for nonlinear models and Goldstein [7] gives an example using the so-called Jenss–Bayley [10] curve for children aged 5 to 10 years (*see* **Growth and Development**). Davidian & Giltinan [3] give a detailed discussion of different approaches to the fitting of nonlinear models to repeated measures data.

Where the response is discrete; for example, binary or ordered as in the case of recording developmental stages over time, then a generalized linear model will be appropriate. Consider the following example where each individual, j, is measured several times, t, and their nutritional state, y, at occasion i is classified as adequate (1) or inadequate (0). A standard model would be written as

$$\begin{aligned} \text{logit}\ \{\pi_{ij}\} &= a_j + b_j t_{ij}, \\ \pi_{ij} &= \Pr(y_{ij} = 1), \\ y_{ij} &\sim \text{bin}\ (\pi_{ij}, 1). \end{aligned} \tag{4}$$

This expresses the logit of the probability of having an adequate nutritional state as a linear function of time. Such a model might be appropriate, for example, in evaluating a nutritional intervention programme and further covariates for group membership, age, etc. can readily be introduced. We can also try alternative link functions and study the possibility of further random coefficients. For responses such as counts we would typically use a log link with a Poisson or related distributional assumption.

For many longitudinal data we are effectively measuring the *cumulative* probability of a response over time. Thus, when studying the onset of menarche the probability of occurrence is an increasing function of time and successive observations will consist of a string of zeros (nonoccurrences) followed by a string of ones (occurrences). More generally, we will have an ordered sequence of stages through which all individuals pass and (4) will be modified to reflect this. One such **proportional hazards** model can be written as

$$\gamma_{ij}^{(s)} = \{1 - \exp[-\exp(\beta_0 + \beta_1 t_s)]\}, \quad \beta_1 > 0, \tag{5}$$

where s indexes the stages and the cumulative probability is

$$\gamma_{ij}^{(s)} = \sum_{h=1}^{s} \pi_{ij}^{(h)}.$$

We can add further covariates and random coefficients as before.

An extension of both (4) and (5) is to the multivariate case where multiple responses are measured on each individual at each time point, with possibly missing responses on some occasions and where some responses are discrete and some continuous. A discussion of such models and their estimation is given in [7, Chapter 7] and the multivariate model with continuous-only responses is discussed in the next section.

In these models, so far, we have made the basic assumption that the level 1 errors are independent.

We shall deal with violations of this assumption for continuous responses below, but there are also many cases for discrete responses where this assumption is untenable and this gives rise to particular difficulties. As an example, consider a repeated survey of attitudes to abortion where we wish to study the characteristics of individual and group changes over time. For a large proportion, perhaps the majority, of the population there will be no change in their attitudes; thus, the probability that they will agree with a "pro-abortion" statement will be very close to one or zero. A model such as (4) would generally require such individuals to have extremely large positive or negative random effects, since it is unlikely that we would have covariates that could discriminate precisely among such individuals. This, then, poses severe distributional problems for parametric models.

An obvious way to avoid this difficulty is to consider the vector of, say, binary responses for each individual as a multivariate vector where the distribution on each occasion is binomial and the between-occasion covariances are estimated from the data. Lipsitz et al. [14] study such models with examples. While this approach is satisfactory for a number of fixed occasions, even with missing data, and while it can also be extended to other than binary responses, it is unable directly to handle the general case of arbitrary occasions. To do this requires an extension of the serial correlation models discussed below, but that is beyond the scope of this article.

Multivariate Continuous Responses

Where several responses are recorded on individuals on each occasion we will generally wish to model the average time relationship for each response and the covariance matrix among the responses as a function of time. This is readily done by considering the multivariate response structure as a further, lowest, level in the data hierarchy with measurements nested within occasions within individuals (*see* **Multilevel Models**).

There are several advantages to considering the joint modeling of several responses. The ability to estimate their covariance matrix as a function of time allows one to study the distribution of any function of the responses with respect to time. For example, when studying issues of prior determination it may be useful to see whether the correlation between two variables a given time apart is greater when one is the prior variable rather than the other. Likewise, it provides a general prediction procedure for one measurement, conditional on any set of observed prior measurements. We illustrate this with an example concerned with the prediction of adult height given a series of height measurements taken during a period of childhood growth. In this case, one of our response measurements, adult height, is made at the level of the individual and the others are made at the occasion level.

Consider the following extension to (2):

$$
\begin{aligned}
y_{ij} &= \beta_{0j} + \beta_{1j} t_{ij} + \beta_2 t_{ij}^2 + \beta_3 t_{ij}^3 + \varepsilon_{ij}, \\
y_j &= \sum_k \gamma_{jk} x_{jk} + \alpha_j, \qquad (6) \\
\begin{pmatrix} \alpha_j \\ \beta_{0j} \\ \beta_{1j} \end{pmatrix} &\sim \mathrm{N}\left[\begin{pmatrix} \alpha \\ \beta_0 \\ \beta_1 \end{pmatrix}, \begin{pmatrix} \sigma_\alpha^2 & & \\ \sigma_{\alpha\beta_0} & \sigma_{\beta_0}^2 & \\ \sigma_{\alpha\beta_1} & \sigma_{\beta_{01}} & \sigma_{\beta_1}^2 \end{pmatrix} \right],
\end{aligned}
$$

where the adult measurement, y_j, is allowed to depend on further covariates, and we may also wish to incorporate covariates into the growth period component of the model. The key feature of this model is that we have a joint covariance matrix for the adult height component and the growth curve parameters, all of which vary at the level of the individual. Given the model parameters and any set of growth measurements for an individual, say $Y_j^* = (y_{1j}^*, y_{2j}^*, \ldots, y_{pj}^*)$, we can estimate $\mathrm{E}(y_j | Y_j^*)$ together with an estimate of its standard error, etc. Details are given in [6]. A further development of the multivariate growth model is the so-called "latent growth model". In essence, this considers each of the sets of random coefficients β_{0j}, β_{1j}, etc. as a latent variable or factor. Each observed response is thus a linear function of factor scores where the coefficients are, for example, polynomials in time, or, more generally, may be estimated from the data. One restriction of such models is that they require the same set of discrete occasions for all measurements and thus lose the flexibility of the continuous time formulation. A full discussion can be found in [15].

Serial Correlation Models

For some kinds of repeated measurements, the structure implied by (2) or (4) is inadequate. For example, daily measurements of animal weights over a long period will not usually fluctuate completely randomly about a long-term smooth trend for each animal, the departure from such a trend on any one day being more like the departures on neighboring days than on days further distant. In a study of human growth, Goldstein et al. [8] found that residuals from measurements of height made on adolescent boys had a noticeable **serial correlation** when made less than three months apart. To incorporate such possibilities, we can extend (2) by adding the following covariance condition for two level 1 residuals s time units apart, where time is continuous:

$$\mathrm{cov}(\varepsilon_t, \varepsilon_{t-s}) = \sigma_\varepsilon^2 \exp(-g(s, z)). \qquad (7)$$

Here, g is a positive function and may depend on covariates, z, which may be measured at the individual or occasion level; thus, for example, allowing the exponential decay rate implied by (7) to vary with time.

One possible simple choice, which is the continuous time analog of a first-order autoregressive series, is $g = \alpha s$ and other possibilities are discussed by Goldstein et al. [8] and Diggle et al. [4, Chapter 5]. An alternative approach is via state-space modeling, which leads to similar, although not generally identical, models [11].

In Table 1, we give an example of a model with a simple correlation structure, together with the estimation of a seasonal effect for a set of three-monthly height measurements made on a sample of 26 boys aged between 11 and 14 years. Full details are given by Goldstein et al. [8]. A fourth-degree polynomial is fitted for the average growth curve with a cosine term representing seasonal growth. The first three coefficients are random at level 2 and the serial covariance structure is given by $g = \alpha s$ fitted at level 1.

The serial correlation parameter value of 6.9 implies that the residual correlation three months apart is 0.19 and that six months apart is 0.04. The existence of a seasonal effect implies an average difference between summer and winter of about 0.5 cm with no evidence of any variation between individuals.

Table 1 Height in centimeters as a fourth-degree polynomial on age, measured about 13.0 years. Standard errors in parentheses; correlations in parentheses for covariance terms. Serial correlation structure fitted for level 1 residuals

Parameter	Estimate (se)		
Fixed			
Intercept	148.9		
age	6.19(0.35)		
age^2	2.16(0.45)		
age^3	0.39(0.17)		
age^4	−1.55(0.43)		
cos (time)	−0.24(0.07)		
Random	Intercept	age	age^2
Level 2			
Intercept	61.5(17.1)		
age	7.9 (0.61)	2.7(0.70)	
age^2	1.5 (0.25)	0.9(0.68)	0.6(0.2)
Level 1			
σ_ε^2	0.23(0.04)		
α	6.90(2.07)		

Fitting this model, with an extra parameter to describe autocorrelation among the level 1 residuals, provides a more parsimonious model than attempting to fit, say, the cubic coefficient as random at level 2. In some cases, however, the data may be equally well explained either by such a random coefficient model with independent level 1 residuals or, alternatively, by a simpler between-individual covariance structure and a complex nonindependence structure at level 1. A choice between such models will then need to be made on grounds of substantive interpretation. In the view of the present author, substantive interpretations generally are best made by adopting a level 1 serial correlation structure only after fitting a suitably complex model using random coefficients alone. The use of various diagnostic tools for judging fit in multilevel models is discussed by Lewis & Langford [12].

Software

Some of the particular models described (for example, the nonlinear model of Bock et al. [2], the latent growth model or the Bayesian models) have specialized software, details of which can be found by consulting the references given at the end of the article. Some of the major **software** packages, most notably SAS, can handle many, although not all, of the

models and the **generalized estimating equations** procedures used by Diggle et al. [4] are available in S-PLUS. The general-purpose multilevel modeling package, MLn (Rasbash & Woodhouse [16]) uses both maximum likelihood and quasi-likelihood estimation and has facilities to analyze all the models described, although it can only handle the latent growth model indirectly by providing summary input for other structural equation software packages.

Random Digit Dialing Sampling for Case–Control Studies

Random digit dialing (RDD) is a method of sampling households through the selection of telephone numbers by a random choice of the digits in the telephone numbers. RDD was initially developed as a sampling method for household surveys, but it is now considered a useful tool in epidemiologic research, particularly for selecting **controls** in a **population-based case–control study**, i.e. studies using controls selected from the general population, as distinct from hospital controls or other specialized lists. In countries with high levels of telephone coverage, RDD can provide an almost **unbiased** sample of the household population for use as controls. Furthermore, once the households are contacted by telephone, there is a relatively low cost of screening to locate persons with the demographic and health characteristics that match the cases for the disease being studied.

RDD obviously omits residents of households that do not have telephones. In the US only about 5% are without telephones, but they are mainly very low-income households, and if the causal factors for the disease are believed to be heavily influenced by income, the results could be seriously **biased**. For such studies the researcher should consider whether RDD is appropriate. However, in most case–control studies, the exclusion of nontelephone households is not believed to have any appreciable effect. It is prudent to exclude cases who do not have home telephones from the analysis so that cases and controls have similar socioeconomic characteristics.

In the US each telephone contains 10 digits, consisting of a three-digit area code, a three-digit central office code (generally referred to as an exchange), and a four-digit suffix. There are presently 35 000–40 000 active area code/central office code combinations in use in the US. Since 10 000 possible number combinations exist in the four-digit suffixes attached to each area code/central office, there are a little over 350 000 000 possible telephone numbers that can be dialed in RDD, about four times the approximately 90 000 000 households with telephones. Most of the 75% of telephone numbers that do not connect to households are unassigned numbers; others are connected to businesses, government offices, institutions, pay phones, computers, faxes, etc.

With **simple random sampling**, about three-quarters of the calls will be completely unproductive, consisting of nonworking or nonhousehold numbers. The costs of such unproductive calls are quite high, and statisticians have examined the properties of a number of sampling methods designed to reduce the number of excess calls. The general consensus among sampling and survey statisticians is that currently one of two available methods should be used – what is referred to as the *Mitofsky–Waksberg Procedure* [13], or the *List-Assisted Method* [3, 8]. Both methods increase the proportion of household numbers in the sample from about 25% to 50%–60%. Brick et al. [2] note that although the list-assisted method is slightly biased, the bias is trivial for most practical purposes. The Mitofsky–Waksberg procedure provides a completely unbiased sample of households but has several operational complications that can affect the timing and the required record-keeping. (*See* **Telephone Sampling** for a description of the two sampling methods and a list of references.)

The cheapest method of sampling is to use *directory sampling*, that is, select a simple random sample from a **sampling frame** of all telephone numbers listed in the white pages of current telephone directories for the geographic area of interest. In the US, this procedure will produce a highly biased sample since only about two-thirds of telephone households have their current numbers listed. It is not recommended by knowledgeable statisticians. If used, the biases can be reduced, although not eliminated, by restricting the cases in the study to those whose telephone numbers are listed in telephone directories. It should be noted that although restricting both cases and controls to households listed in telephone directories appears to be similar to RDD in that the cases and controls come from similar populations, the population eligible for the study with RDD is about 95% of all households as compared with about 60% for directory sampling. The potential for bias is thus generally quite small for RDD studies but can be substantial for directory sampling. For this reason, directory sampling is usually not recommended.

There are, at present, at least two commercial firms that maintain up-to-date records on existing area codes/central office codes in the US (GENESYS Sampling Systems and Survey Sampling Inc.). These companies can select samples using either of the two

recommended methods, or following other procedures specified by the client. Both companies have extensive resources for geographic coding and can help identify the area codes/central office codes in the geographic area designated for a study. Statisticians and epidemiologists who have not had extensive experiences with RDD studies would probably benefit by consulting one of these companies for assistance in sampling.

Potthoff [9] has described the steps in selecting controls. We summarize and extend his discussion. The cases are all of the eligible ones that occur in a given geographical region in a given time period. RDD controls are sampled from the same region, typically by strata (demographic categories such as sex, age, race) (*see* **Stratified Sampling**). Frequently, geographic subareas are included in the matching criteria; the subareas may be defined by census tracts, zip codes, telephone exchanges, or broader geography such as counties or central cities vs. suburbs. The areas may serve as proxies for environmental or socioeconomic matching, but they should be broad enough to produce the required number of controls. In general, everyone within a stratum (often referred to as a matching cell) is given the same chance of selection. The sample sizes are designated in advance for the strata, the size being based on the desired number of controls per case, the available budget, and possibly logistical considerations. Most population-based case–control studies use **frequency matching** of controls to cases within strata rather than individual matching. Frequency matching involves defining matching cells, for example, white females 40–44 years of age, and locating the desired number of controls in each matching cell. RDD selection can be used for both individual and frequency matching.

Telephone contacts can be used to select controls and to conduct interviews, or only for the sample selection, in which case subsequent interviews may be carried out in personal visits to the households or, more rarely, by mail. The decision on which approach to use depends on the length and content of the interview, e.g. whether physical measurements or laboratory tests are necessary, whether observation of such items as prescription drugs is required, etc. The same general principles are used for both types of studies. If personal visits will be required, then the researcher should take this into account in establishing the geographic area in which the study will be conducted in order to avoid excessive interviewer travel. Methods of sampling that tend to cluster the sampling units, e.g. the Mitofsky–Waksberg method, should be considered.

With telephone interviewing, the selection and enlistment of controls and the interviewing can be done in a single telephone contact [5, 6]. Alternatively, a two-step process can be used in which the first call is restricted to taking a household census with sample selection carried out as an office operation, and a second telephone call made for a telephone interview or to arrange for a visit [6]. If the time schedule permits, then the two-step process is usually preferable since it provides a tighter control on sample size. There is difficulty in achieving the exact sample sizes in a one-step process without incurring biases from loss of persons who are infrequently at home and require multiple attempts to reach. However, some researchers prefer the one-step method because it usually produces a somewhat higher response rate. In addition, if there is a long lapse of time between the two contacts, then a non-trivial part of the sample will have moved, introducing the potential for important biases in the study as well as some uncertainty in the number of controls that will be interviewed. If a two-step process is used, then the time period between the two steps should be kept as short as possible.

A number of issues arise in the sample selection via RDD. They are discussed briefly below. More complete discussions can be found in the references, particularly [5–7], [11], and [12].

1. RDD covers only persons living in households with telephones. It is normal practice to exclude from the analysis the cases that do not have telephones or who do not reside in ordinary households, e.g. institutions or the military. A clear definition of households and household members needs to be established to treat such ambiguous cases as college students, persons in the military, etc.
2. The geographic areas that are used to determine the boundaries of the study, or the matching cells, frequently consist of political units (counties or cities) or census tracts. These areas may not conform to telephone exchanges, leading to a considerable amount of screening to identify persons within the designated geographic area. To avoid this excessive screening, the researcher should consider the possibility of defining the

study area as the set of telephone exchanges that approximates the geography desired. Matching cells can also be defined by telephone exchanges. The same geographic rules need to be applied to cases as to controls.

3. If the boundaries of the study area are political or census-defined geography, then it is necessary to include all telephone exchanges that cover the area. If the geographic location is not obvious from the telephone exchange, then each respondent should be asked whether the residence is within the boundaries of the study area.
4. In case–control studies, it is usually desirable to select controls with equal probability. Two problems occur in RDD sampling. The first is that households with two or more telephone numbers have greater chances of selection than those with one number. The higher probability of selection of such households can be avoided by subsampling them, i.e. retaining one-half of households with two telephone numbers, one-third of those with three numbers, etc. This adds somewhat to the number of households that need to be screened to reach the required sample size (about 4% of US, households have more than one telephone number), but the resulting simplification in the analyses usually makes it worthwhile. The second problem arises when it is considered undesirable to choose more than one person in a household, either to avoid a heavy response burden in any household or because the intraclass correlations (*see* **Correlation**) within a household would appear to complicate analyses of the data. Subsampling within households will create considerable variation in probabilities of selection and is not recommended. Many case–control studies are restricted to the adult population, or to a subset, such as ages 45–69. In such cases it is possible to reduce sharply the number of households with multiple controls by designating in advance half of the sample for male controls and half for female controls. In any household, only the males, or females, are then eligible for the sample. Depending on the distribution of the desired number of controls by sex, instead of designating 50% of the sample for male controls and 50% for females, a 60–40, 70–30, or some other ratio could be used. This sex designation of the sample greatly increases the amount of screening necessary to locate the controls, and a researcher should weigh this fact against the desirability of simpler analytic methods. Potthoff [9] has described another method of choosing only one control per household with an equal probability sample, but this method also increases the required screening.
5. With frequency matching, the amount of screening that will be required can be estimated by calculating the number of households that need to be screened to locate one required control in each of the matching cells (strata), and multiplying it by the number of desired controls. The stratum with the largest value determines the screening sample size. This result should be increased to account for the percentage of refusals or those who are out of scope (e.g. persons with some types of chronic diseases may be considered ineligible for the study). It may also be necessary to increase the screening if no more than one person per household is chosen and one of the devices described earlier for doing this is used.
6. It is frequently difficult to determine the total number of households that will need to be screened to provide the desired number of controls, and the subsampling rates for the various strata. Some of the difficulty comes from the small samples desired per matching cell and the consequent large sampling errors on the household yield. Another reason may be uncertainty of the population size of the various strata when geographic matching is required. When time permits, it is useful to do the sampling in waves, (e.g. divide the workload into monthly subsamples) with each wave a **random sample** of the population. The sample sizes and subsampling rates in each wave can be based on experience in previous waves. Since the waves are all random samples, the data can be pooled without the need to take the different sample sizes and rates into account.
7. It is necessary to inquire whether the telephone number reached is for a home, business, institution, or some other nonhousehold facility. This is normally one of the first questions asked. Some small businesses operate in residential units and the telephones are used both for business and personal use. The questions asked

should be able to identify such cases and retain them in the sample. Both companies previously referred to that supply telephone samples can match the sample numbers with yellow page directory listings to reduce the number of business numbers that need to be dialed. There is a small loss of households that operate small businesses, but the bias is generally considered trivial.

8. A policy needs to be established on how to treat answering machines, that is, whether to leave messages or simply to hang up and try again. Answering machines are quite common in the US, and the method of dealing with them could have an important effect on response rates.
9. The study should include provision for a considerable number of callbacks to insure that persons who are infrequently at home have the same chance of selection as the rest of the population. Many researchers make eight to 12 calls for the hard-to-get population spread throughout daylight and evening hours and weekdays and weekends, and some researchers use larger numbers. As a result of the large number of households in which all adults are employed and the number containing only a single adult, it is necessary to mount a major follow up operation to attain a reasonable response rate. There have been a number of studies of the differences between persons who can be easily reached by telephone and those requiring more effort, and they have revealed important differences in occupational status and life styles. There are also likely to be differences in exposure and in background variables affecting many diseases. Failure to achieve reasonably consistent response rates among persons who are easily reached and those who require more callbacks could lead to serious biases that are not possible to detect and correct for. Although a main purpose of the callbacks is to make first contact with the household residents, it can also be used to try to convince potential respondents who initially refused to cooperate and to change their minds. Conversion of about one-third of those who initially refused is not uncommon (*see* **Call-backs and Mail-backs in Sample Surveys**).
10. Evening calls are necessary in a large number of households, and researchers should recognize that most of the interviewing will have to be done after normal working hours. A common practice is to start off with one round of daytime calls to the entire sample which will usually identify almost all of the nonworking, business, and institutional numbers, and a minority of the households. The remaining calls – mostly to households – are then made in the evening.

Under some circumstances, weighting the data may be necessary to avoid biases in the analysis. Weighting will be needed if all persons within a matching cell did not receive the same chance of selection, e.g. if there was subsampling of household members within the same matching cell, or if all households with more than one telephone number were retained in the sample. For example, if households with multiple telephones were not subsampled, then households with two telephone numbers should be given a weight of one-half, those with three numbers given a weight of one-third, etc. Similarly, with subsampling within households so that only one person within a cell was chosen, the weight should be the number of household members within the matching cell. If the subsampling went further so that only one person per household was selected for the control regardless of the number of matching cells represented in a household, then a more complex system of weighting will be required. Such subsampling should be avoided if at all possible since it will complicate the study operations and may have a serious effect on the precision of the results.

Standard **odds ratio** analysis is not strictly applicable in case–control studies that use **cluster sampling** such as the Mitofsky–Waksberg method or that require weighting. Modifications in the analysis that account for clustering are described by Graubard et al. [4]. Appropriate **confidence intervals** for odds ratios can also be obtained through use of either of two software packages originally developed for analyses of surveys using complex sample designs but that also contain provision for estimating the precision of odds ratios, WESVAR [1] and SUDAAN [10]. If there are only minor deviations from an unclustered, equal-probability sample selection scheme, then it is probably satisfactory to use the more common methods of establishing confidence intervals around odds ratios.

Random Effects

Consider an **explanatory variable** which takes on k possible values in a particular data set and which is to be related to a **response variable** via a **regression** model. Assume that some function of the response variable is related to the linear predictor $\mu + \alpha_i$, $i = 1, \ldots, k-1$, or equivalently α_i, $i = 1, \ldots, k$, where i indexes the possible values of the explanatory variable (*see* **Dummy Variables**). Examples of such explanatory variables are an indicator for clinics in a multiclinic study, school classrooms in a study of school children, different studies in a **meta-analysis**, and blocking factors in **experimental design**. Other explanatory variables may be included in the linear predictor. For example, a single additional variable could be added to define a linear predictor $\mu + \alpha_i + \beta X, i = 1, \ldots, k-1$.

The α_is are referred to as random effects if they are assumed to arise as a **random sample** from a distribution of effects associated with a wider range of values for the explanatory variable. For example, it might be assumed that there is a distribution of effects, $f(\alpha, \theta)$, associated with all the possible clinics which could have been recruited for a **clinical trial** or perhaps, more generally, which might be expected to use the treatments under study in the trial. The parameter α might be some measure of central tendency, sometimes taken to be zero, and θ might represent a shape parameter such as a variance. The analysis would then not focus on the particular α_is but, rather, on the characteristics of the distribution f. This analysis contrasts with that which regards the α_is as **fixed effects** (for general discussion of the distinction and of its effect on the methods of analysis *see* **Analysis of Variance**). The choice of analysis can be quite influential in, for example, meta-analysis.

With an additional variable in the linear predictor, it is possible to extend the model further to have, say, $\alpha_i + \beta_i X, i = 1, \ldots, k$, where the regression coefficient for X varies with the value of the indicator variable. The β_is can be fixed or random. When they are assumed random, then the model is sometimes called a *random coefficient* model. Such an approach is used in **multilevel models**.

Random effects are also important in a variety of **Bayesian methods**.

(*See also* **Random Coefficient Repeated Measures Model**)

VERN T. FAREWELL

Random Error

Suppose one seeks to measure the width of a table by repeatedly applying a ruler to obtain a series of measurements. One assumes that the true table width, μ, remains constant and that any given measurement, $y_i = \mu + e_i$, represents the sum of a systematic component and an error component, $e_i = y_i - \mu$. In this simple model, μ is called the systematic part, and, if the expectation of e_i is zero, e_i is called the random error. If it is assumed that the random errors are independent, then the **mean** value $\overline{y} = \mu + n^{-1} \sum e_i$ converges (almost surely) to the true value (*see* **Convergence in Distribution and in Probability**). As the sample size, n, increases, the effects of random error diminish, and, in particular, if the e_i have a common **variance**, σ^2, $\text{var}(\overline{y}) = \sigma^2/n$. The diminishing influence of random error with increasing sample size is also found in more general models with systematic and random components (*see* **Generalized Linear Model**).

Suppose, however, we subsequently learn that our ruler had been worn down so that the putative interval [0, 1] cm was only 0.9 cm long. Then, the errors $e_i = y_i - \mu$ have expectation $(\mu - 0.1) - \mu = -0.1$ cm, and $\overline{y}$ gets closer and closer to the **biased** answer, $\mu - 0.1$, as n increases. Thus, increasing the sample size offers no protection against **systematic error** and only leads to more precise biased estimates (*see* **Estimation**).

MITCHELL H. GAIL

Random Mixing

The simplest models for epidemics of infectious diseases are nonlinear owing to their mass action terms. The mass action component of these models accounts for new infections through contacts between infected and susceptible persons, usually through the assumption that "... the chance of an infection is proportional to the number of infected on the one hand, and to the number not yet infected on the other" [3, p. 703]. Random mixing is an interpretation of contact patterns which justifies that assumption (*see* **Epidemic Models, Deterministic**).

In the elementary Kermack & McKendrick [3, p. 713] epidemic model for a closed population, the rate of new infections is written $\mathrm{d}x/\mathrm{d}t = -\kappa xy$, where x and y are the numbers susceptible and infected, respectively. Decomposing κ into β, the chance of infection per contact, times μ, the rate of contact per infected/susceptible pair per unit time, reveals the basic structure of the assumed contact process: there are xy pairs capable of producing a new infection in the population, each of which has the same rate of contact, μ, per unit time; a fraction β of those contacts produces new infections. Alternatively, define c as the contact rate per person per unit time and let p_y be the proportion of contacts that are with infected persons. Then $\mathrm{d}x/\mathrm{d}t = -\beta cxp_y$. If contacts are randomly distributed, then the proportion of contacts with infected persons (in the early stages of an epidemic when the population size $n \approx x + y$) is simply the proportion infected in the population, i.e. $p_y = y/n$. Since the contact rate per person is n times the contact rate per pair, $c = \mu n$, the two formulations of the mass action term are equivalent.

Epidemic models based on simple random mixing are often inconsistent with elementary facts about human populations. This is especially true with respect to diseases associated with sexual practices, including HIV/AIDS (*see* **AIDS and HIV**), where contacts that transmit disease are strongly influenced by variations in customs, preferences, and opportunities. To build models for such cases, epidemiologists have invented generalizations of random mixing on the basis of the idea that a population can be divided into groups characterized by different rates of contact and/or different patterns of mixing with other groups. In terms of the pair-rate notation, the group-specific infection rate in these more general epidemic models can be written as

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = -\beta \sum_j \mu_{ij} X_i Y_j,$$

where x_i and y_i are the number susceptible and infected in group i and μ_{ij} is the rate of contact per i, j pair per unit of time. This class of mixing models includes decidedly nonrandom patterns as well as generalizations of random mixing. Among the latter, we include the following:

1. Wiley & Herschkorn [7] propose *quasi-random mixing* for sexual contacts among male homosexuals at risk of HIV transmission. This model is specified by setting $\mu_{ij} = \mu$ for $i, j \in S$ and $\mu_{ij} = 0$ for $i, j \notin S$, where S is a set that defines admissible pairings. This specification is motivated by the concept of inconsistent roles in sexual intercourse.
2. Hethcote & Yorke [2] build epidemic models for gonorrhea transmission that incorporate *proportional random mixing* ($\mu_{ij} = \mu_i \mu_j$), allowing groups to mix randomly but with heterogeneous contact rates.
3. Koopman et al. [4] generalize proportional random mixing to allow for a bias toward within-group mixing. They call this pattern *reserved mixing*, and it is specified in the pair-rate notation by setting $\mu_{ij} = \mu_i \mu_j$ for $i \neq j$ and $\mu_{ij} = \mu_i^* + \mu_i^2$ for $i = j$.

More complex patterns of mixing can be formed as sums of random mixing patterns in different social or physical settings (see, for example, [6]). For further reading, see [1] and [5].

Random Sample

A collection of units or observations generated by a probabilistic process is called a random sample. This apparently simple definition covers a multitude of situations.

In finite population sampling, the sample is selected from a fixed and finite population of units. Typically, the sample units are those for which data are collected. A random sample (or **"probability sample"**) is drawn by any rule that assigns a probability to every possible sample. A common additional requirement in this context is that every unit in the population has a nonzero probability of being included in the sample. One such sampling scheme is **simple random sampling** (SRS), in which the size of the sample, n, is predetermined and every sample of size n has equal probability. The term "random sampling" is loosely used for SRS, but in fact is more general, including sampling schemes in which different samples have different probabilities; furthermore, the probability of inclusion in the sample is not necessarily the same for every unit.

We may also speak of a sample from a probabilistic process capable of generating an infinite population of values. An independent and identically distributed (iid) random sample is a collection of observations on a **random variable**, each of which is independently generated from the same probability distribution; iid sampling is a natural model for repeated observations of the same process. In this context as well, however, "random sample" unmodified may also refer to samples which are not iid.

ALAN ZASLAVSKY

Random Variable

Let S be a *sample space*, the set of all possible outcomes of an experiment. A random variable is a real-valued function that assigns a real value to each outcome of the sample space S. For a more rigorous definition, see the article on **Probability Theory**.

Random variables are used to describe the uncertain outcomes of a study. Thus, in a hospital the number of patients that will be receiving treatments next year may not be known. Similarly, the survival time of a patient with a terminal disease is not known.

Let X denote a random variable and let x be a particular outcome of X. A random variable X is *discrete* if it can assume a finite or a countably infinite number of possible values. X is *continuous* if it can assume any value in some interval or intervals of real numbers and if the probability is zero that it will assume any specific value. That is, if for any real number x, $f(x) = \Pr(X = x)$ is zero.

We now consider properties of a discrete random variable X. Let $f(x) = \Pr(X = x)$. A function $f(x)$ is defined to be the *probability function* or the *probability mass function* if

$$0 \le f(x) \le 1 \tag{1}$$

and

$$\sum_x f(x) = 1, \tag{2}$$

where the summation is over all x. Here, $f(x)$ is defined for all x, and is a real-valued function. *The cumulative distribution function* (cdf) $F(x)$ is defined by $F(x) = \Pr(X \le x)$, for all real x. The *survival function* $S(x)$ is given by

$$S(x) = 1 - F(x) = \Pr(X > x). \tag{3}$$

Note $F(x)$ (and $S(x)$) are also real-valued functions, and

$$\Pr(a < x \le b) = F(b) - F(a) = S(a) - S(b). \tag{4}$$

For a continuous random variable we can use similar definitions. Let X be a continuous random variable. $f(x)$ is a *probability density function* (pdf) or density function if

$$f(x) \ge 0,$$
$$\int_{-\infty}^{\infty} f(x)\ \mathrm{d}x = 1,$$

and for any two real numbers a, b with $a < b$,

$$\Pr(a < X < b) = \Pr(a \le X \le b) = \int_a^b f(x)\ \mathrm{d}x.$$

The cdf $F(x)$ is defined by $F(x) = \Pr(X \le x)$. By definition,

$$F(x) = \int_{-\infty}^{x} f(x)\ \mathrm{d}x \tag{5}$$

and

$$f(x) = \frac{\mathrm{d}}{\mathrm{d}x} F(x). \tag{6}$$

The above definitions can be extended to two or more variables when several characters, such as height and weight, are of interest. Let us consider the bivariate case.

Let (X, Y) be a discrete bivariate random variable. Then $f(x, y) = \Pr(X = x, Y = y)$ is a *joint probability function* or *joint probability mass function*, where x and y are real numbers, if

$$f(x, y) \ge 0,$$
$$\sum_{\text{all } x} \sum_{\text{all } y} f(x, y) = 1.$$

The **bivariate distribution** function $F(x, y)$ is defined by $F(x, y) = \Pr(X \le x, Y \le y) = \sum_{X \le x} \sum_{Y \le y} f(x, y)$, where the sum is over all pairs (x, y) such that $X \le x$ and $Y \le y$. The **marginal probability** functions $f(x)$ of X and $g(y)$ of Y are given by

$$f(x) = \sum_{\text{all } y} f(x, y) \tag{7}$$

and

$$g(y) = \sum_{\text{all } x} f(x, y). \tag{8}$$

The **conditional probability** functions $f(x|y)$ of X given $Y = y$, and $g(y|x)$ of Y given $X = x$, are

defined as

$$f(x|y) = \frac{f(x, y)}{g(y)}, \quad \text{where} \quad g(y) \neq 0, \tag{9}$$

and

$$g(y|x) = \frac{f(x, y)}{f(x)}, \quad \text{where} \quad f(x) \neq 0. \tag{10}$$

X and Y are *independent* if and only if

$$f(x, y) = f(x)g(y) \tag{11}$$

for all real numbers x and y.

For continuous random variables there are similar definitions. $f(x, y)$ is the joint probability density function if

$$f(x, y) \geq 0,$$

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x, y)\ \mathrm{d}x\ \mathrm{d}y = 1,$$

$$\Pr(a \leq X \leq b \quad \text{and} \quad c \leq Y \leq d) = \int_a^b \int_c^d f(x, y)\ \mathrm{d}x\ \mathrm{d}y,$$

for all real numbers a, b, c and d. The marginal densities $f(x)$, $g(y)$ of X and Y are given by

$$f(x) = \int_{-\infty}^{\infty} f(x, y)\ \mathrm{d}y \tag{12}$$

and

$$g(y) = \int_{-\infty}^{\infty} f(x, y)\ \mathrm{d}x. \tag{13}$$

The conditional density $f(x|y)$ of X given $Y = y$ is

$$f(x|y) = \frac{f(x, y)}{g(y)}, \quad \text{where} \quad g(y) \neq 0, \tag{14}$$

and the conditional density $g(y|x)$ of Y given $X = x$ is similarly given by

$$g(y|x) = \frac{f(x, y)}{f(x)}, \quad \text{where} \quad f(x) \neq 0. \tag{15}$$

X and Y are independent if and only if

$$f(x, y) = f(x)g(y) \tag{16}$$

for all real numbers x and y.

Similar definitions in terms of distribution functions can be given. For three or more variables, similar definitions can be given in an analogous manner.

ASIT P. BASU

Randomization Tests

Using randomization to assign interventions in an experiment (such as a **clinical trial**) guarantees the validity of statistical tests of significance (*see* **Hypothesis Testing**), in that the process of randomization makes it possible to ascribe a probability distribution to the difference in outcome between groups under the **null hypothesis** [2, 7]. This can be implemented directly with randomization-based inference, wherein the outcome data are analyzed many times (once for each acceptable assignment that could have been employed) and then compared with the observed result, without dependence on additional distributional or model-based assumptions. Thus, hypothesis testing ("randomization tests" or "permutation tests") and corresponding test-based **confidence intervals** can be designed based on the randomization distribution. Often, the terms "randomization test" and "permutation test" are used interchangeably, but some authors make a distinction (for example, see [4]).

The randomization test must be selected based on the study design, to produce the appropriate randomization distribution; thus, it would differ among unrestricted, stratified (*see* **Stratification**), and pair-matched designs (*see* **Matched Analysis**). In the simplest case, with pair-matched designs, we estimate some quantity for each pair; for example, the difference in outcome between the two members of pair j, denoted $\hat{X}_{1j} - \hat{X}_{2j}$, $j = 1, 2, \ldots, J$. Then the expected value of the mean difference is 0 under the null hypothesis of no intervention (treatment) effect. For hypothesis testing, we want to know the probability that an estimate of the mean would be as large or larger than the observed estimate of the mean, by chance alone. We calculate the mean (of $\hat{X}_{1j} - \hat{X}_{2j}$) for each of the 2^J ways (permutations) that the intervention assignments could have occurred. The **rank** of the observed mean among all possible means provides the one-tailed significance level; for example, if it is in the top 1%, then it is significant at the 0.01 level. Ranking the absolute values of the means leads to a two-tailed significance level (*see* **Level of a Test**).

This randomization test, whether one-tailed or two-tailed, is conditional on the absolute differences $|\hat{X}_{1j} - \hat{X}_{2j}|$. It makes no modeling assumptions but does require that the outcome measures for the two members of a pair are **exchangeable** under the null hypothesis. As noted in [11], this requirement is equivalent to orthant symmetry on the paired differences, where, as defined by Efron [5], a random vector $\mathbf{U} = (U_1, U_2, \ldots, U_J)$ exhibits orthant symmetry if it has the same distribution as $\mathbf{U}_\partial = (\partial_1 U_1, \partial_2 U_2, \ldots, \partial_J U_J)$ for every choice of $\partial_j = \pm 1$, $j = 1, 2, \ldots, J$.

We can also use this randomization test to determine a test-based confidence interval for the between-group difference. If we shift the mean outcome of one of the groups by various amounts Δ, then the confidence interval is defined as those values of Δ for which a randomization test of $\hat{X}_{1j} - (\hat{X}_{2j} + \Delta)$ fails to reject the null hypothesis at the appropriate significance level [11–13]. Operationally, if we determine Δ_1 as the value of Δ at which the null hypothesis is just rejected at $P \leq \alpha$ in the upper tail, and Δ_2 the same for the lower tail, then Δ_1 and Δ_2 are, respectively, the lower and upper limits of a $100(1 - 2\alpha)\%$ confidence interval. Another approach, using a **bootstrap** distribution, has also been suggested for determining confidence intervals in this situation, particularly for large sample sizes, as discussed by Freedman et al. [8].

The randomization test described above applies to the pair-matched setting. For an unmatched, unstratified design in which $2n$ subjects are allocated to two equally sized groups, the approach is analogous but the number of permutations is larger; namely, $\binom{2n}{n}$. Here we assume simply that all of these reallocations of subjects to groups are equally likely. This approach can be generalized to a stratified design, the number of permutations depending on the randomization distribution.

The advantage of a randomization test in providing a robust test of significance can also be obtained in the presence of **covariates**. One situation is when baseline covariates are used to adjust the analysis of intervention effect (for an example, see [3]). Such covariates can be placed in a **regression** model to predict outcome under the null hypothesis of no intervention effect (i.e. no intervention term in the model), and then **residuals** between observed and predicted outcomes can be calculated. When differences in such residuals between groups are analyzed, a beneficial effect from intervention would lead to an expected mean difference that favored the intervention group. A randomization test using residuals is a valid test of the null hypothesis even if the model is misspecified [9, 10] (*see* **Misspecification**).

A second situation using covariates involves separate analyses in subsets defined by baseline covariates. In this situation, we use statistical tests for **interaction** to investigate whether the intervention effect differs according to the covariate value. As with the test for the main effect of intervention, tests for intervention–covariate interaction can be randomization tests; here, again, we permute the assignment to intervention group based on the randomization distribution (for an example, see [3]). Such interaction tests are of interest because of the real risk of finding spurious differences in subsets by chance alone [1] (*see* **Simultaneous Inference**).

Strictly speaking, the two-sample randomization test (described above) tests the strict null hypothesis that the two groups have the same distribution (i.e. that intervention has no effect on any of the observations), rather than the less strong hypothesis that the mean intervention effect is zero. This distinction is usually not a concern in practice, but it could affect the properties of the test in some situations; for a discussion of this issue, see [9] and [6].

Detailed discussion of randomization tests for various experimental designs can be found, for example, in [4].

Randomization

Randomization refers to the random assignment of experimental units to one of two or more treatments for the purpose of comparing the treatments on some outcome measure (*see* **Randomized Treatment Assignment**). Randomization prevents the existence of systematic differences between groups other than the treatments being compared. In statistical terms, randomization provides a sound objective basis for claiming a particular distribution for the outcome under the **null hypothesis** of no difference across treatments. In the absence of systematic differences between treatments, outcome differences across treatments are strictly a function of randomization when the null hypothesis is true.

The concept of randomization was originally made explicit and advocated in 1935 by **R.A. Fisher**, in his classic text, *The Design of Experiments* [2]. The argument for randomization is that it will prevent systematic differences of any kind, whether or not they can be identified by the researcher. This makes randomization preferable to systematic assignment of treatment groups (*see* **Systematic Sampling Methods**) to produce similar distributions on a set of recognized and measurable factors; as Fisher points out, ". . .the uncontrolled causes which may influence the result are always strictly innumerable".

Randomization may not result in exactly the same distribution of identified **confounding** factors across treatment groups in a particular sample, but does guarantee that "in the long run" distributions of any factor will be the same across treatment groups. The larger the sample size, the more similar will be the distributions of confounders across treatments. Randomization can be performed within blocks, where blocks are homogeneous with respect to identified confounders, thus guaranteeing exactly the same distribution of **blocking** factors across treatments while at the same time retaining the advantage of randomization (*see* **Randomized Complete Block Designs**). Much work has been devoted to randomization designs and to methods of implementing random assignment.

Randomization was originally used in agricultural experiments, where various plots in a field are randomly assigned to different experimental conditions. In the 1940s, the idea was adopted for use in **clinical trials**, where human subjects are randomly assigned to different experimental treatments. There has been argument against randomization in particular situations with human subjects due to practical and ethical considerations [1], for example (*see* **Ethics of Randomized Trials**), but still the statistical advantage of randomization is recognized and acknowledged as a limitation when randomization is not feasible.

SALLY FREELS

Randomized Complete Block Designs

In the completely randomized design or one-way design (*see* **Experimental Design**), we assume that experimental units (EUs) are initially homogeneous and that subsequent differences are due to differences in applied treatments. In many situations, a large enough group of "uniform" EUs may not be available. If such nonhomogeneous EUs are used, then the error term for testing treatment differences and estimating **standard errors** of treatment means will be inflated and hence the **power** of tests will be decreased.

One technique for dealing with this situation uses **covariates** (regressor variables measured on each EU) to account for such nonhomogeneity (*see* **Analysis of Covariance**).

Alternatively, **blocking** may be used so that EUs are grouped ("blocked") into uniform subgroups called "blocks" or "reps". (The term "rep" is used in a wide variety of contexts, so we will only use the term "block" here.) For example, human subjects in a **clinical trial** may be blocked on the basis of factors such as age or weight if the researcher thinks such factors could influence a subject's response to treatment. We usually assume that a blocking factor is an environmental factor which is not itself of much interest but which may influence an EU's response and hence mask the effect of the treatments if uncontrolled.

The randomized complete block design (RCBD) is the simplest block design and has only one blocking factor. More complicated block designs include the **Latin square** and **Graeco-Latin square** designs which have two and three blocking factors, respectively. In addition to the number of blocking factors, designs can be distinguished depending on whether the blocks are "complete" or "incomplete". For example, in the RCBD, the number of EUs per block is the same as the number of treatments and so each treatment occurs in each block exactly once. In the generalized randomized complete block design, the number of EUs per block is some constant multiple (say, k) of the number of treatments and so each treatment occurs in each block k times. If there are not enough homogeneous EUs to obtain complete blocks, then we have the class of designs called **incomplete block designs**, which may be either **balanced** or **partially balanced** with respect to the number of times two treatments occur in the same block together.

In the RCBD, once the EUs have been grouped together into blocks, treatments are randomly assigned to EUs within each block; that is, there is a separate treatment **randomization** for each block. With more complicated designs, such as Latin square and incomplete block designs, there are further restrictions on randomization to achieve balance or partial balance.

Note that, as both the number of blocking factors and restrictions on randomization for balance or partial balance increase, complications in the statistical analysis due to missing cells also increase. (In the RCBD, a "cell" is a block-by-treatment combination and a "missing cell" is a block-by-treatment combination that should have been observed according to the original design but was not, for whatever reason.) If it is anticipated that missing cells are likely, then complicated block designs should be avoided. As the simplest block design, the RCBD suffers less from these problems than more complicated designs. However, the researcher should consider use of the one-way design if many missing cells are likely (*see* **Missing Data Estimation, "Hot Deck" and "Cold Deck"**; **Multiple Imputation Methods**).

These topics are covered in greater depth in the wide variety of experimental design texts and the reader is urged to consult these (see, for example, [1], [4], [6], and [7]).

The Usual Statistical Model: Linearity and Normality

The usual model that describes the RCBD is a linear model, i.e. a model that is additive in the parameters (*see* **General Linear Model**), as opposed to a nonlinear model. In addition, the main distributional assumption is that the data come from a **normal distribution**.

In what follows we write the RCBD model for p treatments and r blocks, for the two basic cases of blocks either **fixed** or **random**. Treatments are assumed fixed. We also assume that there are no missing cells.

In both cases we express each model in both a full-rank or cell-means formulation [5] and a non full-rank, effects formulation [9]. In addition, we use

the notational convention that lower-case Latin letters are **random variables** while Greek letters are fixed (constant) parameters.

Fixed Treatments and Fixed Blocks

In the development of the theory of linear models, the idea of "fixed" effects came first. The ideas of fixed, random, and mixed models were codified by Eisenhart in 1947 [2]. In recent usages of the RCBD, blocks are usually considered as random, but there are cases where blocks as fixed effects make sense. For example, consider an example from Neter et al. [8, Problem 24.10, p. 940] in which treatment is "fat content of diet" and block is "age groups". Three people were randomly selected from each of five different age groups and assigned to one of three diets. The age groups were 15–24, 25–34, and so on up to 55–64. Clearly, these age groups were not randomly selected from some larger population (the usual operational definition of a "random" effect).

The cell-means model for the RCBD with p fixed treatments and r fixed blocks is written as

$$y_{ij} = \mu_{ij} + e_{ij}, i = 1, \ldots, p; j = 1, \ldots, r, \quad (1)$$

$$\text{subject to } \mu_{ij} - \mu_{ij'} - \mu_{i'j} + \mu_{i'j'} = 0, \quad (2)$$

or equivalently

$$\text{subject to } \mu_{ij} - \overline{\mu}_{i\cdot} - \overline{\mu}_{\cdot j} + \overline{\mu}_{\cdot\cdot} = 0. \quad (3)$$

Here, y_{ij} is the response on the experimental unit in treatment i and block j; $\mu_{ij} = \mathrm{E}(y_{ij})$ is the **mean** response of the (i, j)th treatment-by-block cell; and e_{ij} is the **random error** or **residual**. The e_{ij}s are assumed to be independently and identically distributed (iid) as normal random variables with mean zero and constant **variance** σ_e^2. The parameters $\overline{\mu}_{i\cdot}$, $\overline{\mu}_{\cdot j}$, and $\overline{\mu}_{\cdot\cdot}$ are marginal treatment, block, and overall means, respectively, and are obtained by averaging across block, treatment, and treatment-by-block levels, respectively.

The side condition (2) or (3) is that of "no block-by-treatment **interaction**". Because there is only one experimental unit per cell and hence no estimate of experimental error variance based on replication, this assumption is necessary to provide an estimate of σ_e^2. The side condition of no interaction means that, within a block, the difference between any pair of treatments is the same as that between the same two treatments in any other block. Thus a graph of the cell means μ_{ij} vs. the block subscript j will produce parallel lines when μ_{ij} with the same treatment subscript i are connected by lines. The condition of "no interaction" is also called **"additivity"**.

The effects model for the RCBD with blocks fixed is

$$y_{ij} = \mu + \tau_i + \beta_j + e_{ij}, i = 1, \ldots, p; j = 1, \ldots, r. \quad (4)$$

Here, μ is the overall mean, τ_i is the ith treatment effect, β_j is the jth block effect, and y_{ij} and e_{ij} are as before. The "no block-by-treatment interaction" condition is represented by the absence in the model of a term $(\tau\beta)_{ij}$; that is, setting $(\tau\beta)_{ij} = 0$ is equivalent to either of the side conditions (2) and (3).

Model (4) is "nonfull rank" or "overparameterized" and therefore additional conditions must be imposed on the τ_is and β_js to achieve full rank and thus obtain a solution to the normal equations (see below). In textbooks the most common conditions imposed are the so-called "dot" conditions: $\Sigma\tau_i = \tau_\cdot = 0$ and $\Sigma\beta_j = \beta_\cdot = 0$. Alternatively, a generalized inverse can be used to solve the normal equations. These two approaches are basically equivalent, with most computer routines opting for the latter. For the general user and for cases in which the data are balanced and there are no missing cells, these issues are somewhat unimportant. The interested reader is referred to [10] and [11] for thorough discussions of problems with nonfull rank, effects models, and unbalanced data.

Fixed Treatments and Random Blocks

The cell-means model for the RCBD with blocks random is

$$y_{ij} = \mu_i + b_j + e_{ij}, i = 1, \ldots, p; j = 1, \ldots, r. \quad (5)$$

Here, μ_i is the ith treatment mean, b_j is a random effect due to the jth block, and y_{ij} and e_{ij} are as before. The random block effects are assumed to be iid normal with mean zero and variance σ_b^2. In addition, the e_{ij}s and b_js are assumed to be mutually independent.

The effects model for the RCBD with blocks random is

$$y_{ij} = \mu + \tau_i + b_j + e_{ij}, i = 1, \ldots, p; j = 1, \ldots, r. \quad (6)$$

Table 1 Summary of the two RCBD models

	Fixed model Treatments (i) and blocks (j) both fixed	Mixed model Treatments (i) fixed, blocks (j) random
Linear models		
Cell-means (full rank)	$y_{ij} = \mu_{ij} + e_{ij}, \quad i = 1, 2, \ldots, p;$ $j = 1, 2, \ldots, r$ subject to $\mu_{ij} - \mu_{i'j} - \mu_{ij'} + \mu_{i'j'} = 0$ with e_{ij} iid $\mathrm{N}(0, \sigma_e^2)$	$y_{ij} = \mu_i + b_j + e_{ij}, \quad i = 1, 2, \ldots, p;$ $j = 1, 2, \ldots, r$ subject to $\sigma_{tb}^2 = 0$ with b_j iid $\mathrm{N}(0, \sigma_b^2)$, e_{ij} iid $\mathrm{N}(0, \sigma_e^2)$, and b_j and e_{ij} mutually independent
Effects (nonfull rank)	$y_{ij} = \mu + \tau_i + \beta_j + e_{ij}$ subject to $(\tau\beta)_{ij} = 0$ with e_{ij} iid $\mathrm{N}(0, \sigma_e^2)$ and $\sum_i \tau_i = \sum_j \beta_j = 0$ (usually)	$y_{ij} = \mu + \tau_i + b_j + e_{ij}$ subject to $\sigma_{tb}^2 = 0$ with b_j iid $\mathrm{N}(0, \sigma_b^2)$ e_{ij} iid $\mathrm{N}(0, \sigma_e^2)$ and b_j and e_{ij} mutually independent

Table 1 (*continued*)

	Fixed model Treatments (i) and blocks (j) both fixed			Mixed model Treatments (i) fixed, blocks (j) random		
	Parameter	Estimator	SE	Parameter	Estimator	SE
Fixed parameters, estimators and estimated standard errors	Cell mean μ_{ij}	$\overline{y}_{i.} + \overline{y}_{ij} - \overline{y}_{..}$	$[MS_e(p+r-1)/pr]^{1/2}$	–	–	–
	Treatment mean $\overline{\mu}_{i.}$	$\overline{y}_{i.}$	$(MS_e/r)^{1/2}$	Treatment mean μ_i	$\overline{y}_{i.}$	$\left\{\frac{1}{r}\left[MS_e + \frac{MS_b - MS_e}{p}\right]\right\}^{1/2}$
	Block mean $\overline{\mu}_{.j}$	$\overline{y}_{.j}$	$(MS_e/p)^{1/2}$	–	–	–
	Overall mean $\overline{\mu}_{..}$	$\overline{y}_{..}$	$(MS_e/pr)^{1/2}$	Overall mean $\overline{\mu}_{.}$	$\overline{y}_{..}$	$(MS_b/pr)^{1/2}$
	Treatment difference $\overline{\mu}_{i.} - \overline{\mu}_{i'.}$	$\overline{y}_{i.} - \overline{y}_{i'.}$	$(2MS_e/r)^{1/2}$	Treatment difference $\overline{\mu}_{i'} - \overline{\mu}_{i'}$	$\overline{y}_{i.} - \overline{y}_{i'.}$	$(2MS_e/r)^{1/2}$
	Variance component	REML or ANOVA estimator	SE	Variance component	Estimator	SE
Variance Component Estimators and estimated standard errors	σ_e^2	MS_e	$\left\{\frac{2(MS_e)^2}{(p-1)(r-1)}\right\}^{1/2}$	σ_e^2	MS_e	$[2(MS_e)^2/(p-1)(r-1)]^{1/2}$
				σ_b^2	$\frac{MS_b - MS_e}{p}$	$\left\{\frac{2}{p^2}\left[\frac{(MS_b)^2}{(r-1)} + \frac{(MS_e)^2}{(p-1)(r-1)}\right]\right\}^{1/2}$

The only change between (5) and (6) is that μ_i has been replaced with $\mu + \tau_i$, where again μ is the fixed overall mean and τ_i is the fixed treatment effect. Note that apart from the substitution of b_j for β_j, models (4) and (6) look identical. This resemblance is somewhat misleading, as the effect of blocking is described by quite different parameters in the two models: by means for fixed blocks and by the **variance component** σ_b^2 for random blocks. This difference is emphasized by comparing the mean, variance, and covariances of the y_{ij} for the two models (see Table 1). In addition, when blocks are random, the "no block-by-treatment interaction" assumption means that $\sigma_{tb}^2 = 0$.

The Usual Statistical Analysis

Estimation

Fixed parameters, such as treatment means or effects, are usually estimated by **least squares**, which involves minimizing the error sum of squares $SS_e = \sum_{i=1}^{p} \sum_{j=1}^{r} e_{ij}^2$. In the case of fixed blocks, this results in a set of linear equations called the normal equations. In the case of random blocks, we get a more complicated set of linear equations called the mixed model equations [3]. In the balanced case with no missing cells, formulas for the estimators are nicely intuitive, no matter whether blocks are considered fixed or random, and the estimators are, in fact, uniformly **minimum variance unbiased** (UMVU) under normality. Estimates for treatment means and pairwise treatment differences (*see* **Paired Comparisons**), along with their estimated **standard errors**, are summarized in Table 1.

There are many different techniques for estimating variance components. Three common ones are **maximum likelihood** (ML), **restricted maximum likelihood** (REML) and the **method of moments**, which is also referred to as **analysis of variance** (ANOVA) estimation. In the balanced case with no missing cells, the REML and ANOVA estimators are the same and are also UMVU under normality. These estimators are summarized in Table 1. In the balanced case, the ML estimators may be equal to the REML estimator or may differ by a simple constant, which is a function of the number of levels in the factor.

Tests of Hypothesis

Given that there are no missing cells, the data from an RCBD are usually analyzed by ANOVA, an arithmetic technique for partitioning an overall measure of variability ("sum of squares") into pieces that are associated with a particular set of effects, e.g. differences in treatment means or a variance component.

For the RCBD, the ANOVA partitions the total sum of squares into three pieces associated with treatments, blocks, and error. (Note that if the "no block-by-treatment interaction" assumption is not satisfied, the error source of variation is measuring the strength of that interaction.) These three sums of squares are then divided by their respective **degrees of freedom** to obtain mean squares, and ratios of the mean squares are then taken to obtain the F test statistics (*see* ***F* Distributions**). The ANOVA is the same whether blocks are fixed or random and is summarized in Table 2. The expected mean squares are used in mixed models to determine appropriate testing terms for the F tests. These do differ, depending on whether blocks are fixed or random, and are summarized in Table 1.

Table 2 Analysis of variance: fixed model and mixed model

Source	Degrees of freedom	Sums of squares	Mean squares	F ratio
Treatments	$p-1$	$SS_t = r\sum_{i=1}^{p}(\overline{y}_{i.} - \overline{y}_{..})^2$	$MS_t = SS_t/(p-1)$	$F_t = MS_t/MS_e$
Blocks	$r-1$	$SS_b = p\sum_{j=1}^{r}(\overline{y}_{.j} - \overline{y}_{..})^2$	$MS_b = SS_b/(r-1)$	$F_b = MS_b/MS_e$
Error	$(p-1)(r-1)$	$SS_e = \sum_{i=1}^{p}\sum_{j=1}^{r}(\overline{y}_{ij} - \overline{y}_{i.} - \overline{y}_{.j} + \overline{y}_{..})^2$	$MS_e = SS_e/(p-1)(r-1)$

L. MURRAY

Randomized Response Techniques

Randomized response (RR) sampling owes its beginning to Stanley L. Warner [29] in 1965. He developed his method to address the need which often arises in medical, psychological, or sociological investigations for facts about highly sensitive matters. For example, most survey respondents would feel uncomfortable discussing their history of abortion, participation in drug use, sexual behavior, status relative to many medical conditions, extent of use of oral contraceptives, or whether they have defrauded some governmental agency. The standard approach for such questions has been to assure the respondent of the **confidentiality** or anonymity of the information he or she provides. Nevertheless, such attempts at open inquiry into sensitive issues often result in high **nonresponse** rates, willful misstatements, and outright lies, inducing a high degree of **bias** and error that cannot be overcome.

As conceived by Warner, the method of RR sampling would (by its nature) both guarantee the respondent's anonymity *and* convince the respondent of that protection. His original procedure was to offer to the respondent a choice of questions where one was the opposite or negation of the other. For example, the respondent could be offered two questions:

1. Have you smoked marijuana in the last 30 days?
2. Have you not smoked marijuana in the last 30 days?

To determine which question is to be answered, the respondent is given a "randomizing device" (*see* **Randomization**) of some kind, e.g. a deck of cards, some of which are marked with question 1 and the rest with question 2. Thus, the drawing of a card would "randomly" determine which question the respondent would answer. The outcome of the randomizing device is seen *only* by the respondent, *not* the interviewer. Thus the interviewer may record a "yes" response but never know if that answer meant "Yes, I have smoked marijuana in the last 30 days and I am answering question 1" or "Yes, I have not smoked marijuana in the last 30 days and I am answering question 2".

The nature of the sampling is explained by the interviewer carefully to the respondent and then the respondent is allowed to investigate the randomizing device to his or her satisfaction before participating in the survey. Thus (it was hoped that) the respondent would realize his or her "perfect anonymity". That is, not even the interviewer could know for sure to which group the respondent belonged. Nevertheless, by knowing the make-up of the randomizing device as well as the aggregate results, an estimate can be obtained of the proportion of respondents, in this example, who had smoked marijuana in the last 30 days without ever knowing the precise status of any single respondent. Such knowledge would presumably not only make respondents willing to participate in the survey but also persuade them to provide truthful responses.

There are a few disadvantages to the use of RR techniques. Implicit in the nature of RR is the assumption that the respondent is sufficiently cognizant, informed, and educated to recognize and appreciate his or her anonymity. This feature could escape an audience of poor education or low sophistication. Secondly, the estimates provided by RR techniques have larger variation than a standard estimator from the same-sized sample. This naturally results because of the "noise" or "extra variation" introduced by the randomizing device. However, one can easily compensate for this shortcoming by simply increasing the size of the sample to be taken by the RR techniques. Most statisticians feel this tradeoff is a small price to pay for both the increased cooperation and the increased truthfulness by respondents that result in more accurate estimates.

In summary, the underlying rationale for all RR techniques is that a randomizing device is used to select the question to be answered by the respondent. Such a device, it is hoped, will convince the respondent that even the interviewer will be unable to determine the respondent's true status with respect to the sensitive issue(s) being addressed.

Several papers on RR provide significant reviews: see [3], [14], [16], and [17]. However, by far the most recent and most comprehensive review of RR techniques which presents 424 references and an abstract of each publication is that of Daniel [5].

Truly from humble beginnings, RR techniques have flourished both in theoretical sophistication and in practical application to actual surveys. This article attempts to cite several significant papers and direct the reader to several important dimensions developed in RR techniques.

Warner's Original Model

Continuing with our marijuana example, let π be the proportion of individuals possessing the sensitive characteristic (those who had smoked marijuana in the last 30 days) and let p be the probability of the random device giving question 1 (where $p \neq \frac{1}{2}$). Then the probability of getting a "yes" is given by

$$\lambda = \Pr(\text{yes}) = \pi p + (1-\pi)(1-p). \qquad (1)$$

The πp term is due to the "yes" answers received from those "who had smoked marijuana in the last 30 days" *and* who got question 1. The $(1-\pi)(1-p)$ term is due to the "yes" answers received from those "who have *not* smoked marijuana in the last 30 days" *and* who got question 2. If we let n_1 be the total number of "yes" responses out of a sample taken of size n, then an **unbiased** estimate of λ is given by

$$\hat{\lambda} = \frac{n_1}{n}. \qquad (2)$$

Utilizing (1) and (2), an unbiased estimate of π is given by

$$\hat{\pi} = \frac{p-1}{2p-1} + \frac{n_1}{(2p-1)n}, \qquad (3)$$

where $p \neq \frac{1}{2}$. Since n_1 follows a **binomial distribution** with parameters n and λ, it can be shown that

$$\text{var}(\hat{\pi}) = \frac{\pi(1-\pi)}{n} + \frac{p(1-p)}{n(2p-1)^2}, \qquad (4)$$

and an estimate of this **variance** can be found by using $\hat{\pi}$ for π in (4). The first term in (4) is the variance term due to binomial sampling, and the second is the variance term due to the randomizing device. Note that if $p = 0$ or if $p = 1$, RR sampling reduces to ordinary (binomial) sampling, and (3) and (4) simplify accordingly.

For sufficiently large samples this estimated variance can be used to construct a $(1-\alpha)$ 100% **confidence interval** for π:

$$\hat{\pi} \pm Z(\alpha/2)\sqrt{\widehat{\text{var}}(\hat{\pi})}.$$

In addition, Levy [18] describes how tests of hypothesis (*see* **Hypothesis Testing**) about π may naturally be done by inserting the hypothesized value of π in (4) to obtain an estimate of $\text{var}(\pi)$.

Continuing with our example, suppose $n = 400$ high school seniors were selected from a New York inner-city school and asked their marijuana use within the last 30 days by the RR method described. Let the randomizing device be a deck of 50 cards, where 15 have question 1 and 35 have question 2, so that $p = 15/50 = 0.30$. If $n_1 = 240$ answered "yes", then $\hat{\lambda} = n_1/n = 0.60$. Hence, by (3), Warner's original estimate is given by $\hat{\pi} = 0.25$ and (4) gives $\widehat{\text{var}}(\hat{\pi}) = 0.00375$.

If an earlier study seemed to indicate only 10% of these high school seniors had smoked marijuana in the last 30 days, a natural hypothesis test would be $H_0 : \pi = 0.10$ vs. $H_1 : \pi > 0.10$ at $\alpha = 0.05$. That is, does the RR method seem to indicate a proportion of marijuana use higher than 10%? Substituting the hypothesized proportion $\pi = 0.10$ into (4) gives $\text{var}(\hat{\pi}) = 0.00351$ with a resulting observed test statistic of

$$Z = \frac{\hat{\pi} - \pi_0}{[\text{var}(\hat{\pi})]^{1/2}} = \frac{0.25 - 0.10}{(0.00351)^{1/2}} = 2.53.$$

The critical value would be $+1.645$, and thus we would reject H_0 with an observed p value of $\Pr(Z > 2.53) = 0.0057$. A 95% confidence interval for π would be given by $\hat{\pi} \pm 1.96[\widehat{\text{var}}(\hat{\pi})]^{1/2} = 0.25 \pm 1.96(0.00375)^{1/2} = (0.13, 0.37)$.

Improving the Efficiency of RR Sampling Using Multiple Trials

It has already been noted that the introduction of the randomizing device induces extra variation into the estimators. This effectively decreases the sample size. So while in our example $n = 400$, the effect of randomizing might be an increase in variation so that the sample is "effectively" only 250. One obvious way to overcome this is simply to increase the sample size. Another less obvious solution is to have multiple trials performed on each respondent [19, 20]. While it does not make any sense to ask a respondent the same question repeatedly in ordinary sampling, the reader can see the potential benefit in RR sampling by considering an extreme case of our high school seniors example where $p = 0.30$. If a single respondent were asked 100 times, one could conceivably get 100 "yes" and 0 "no" answers or 0 "yes" and 100 "no" answers or anything in between. A large number of "yes" and few "no" answers (say,

70 "yes" and 30 "no") would tend to indicate that this respondent had *not* smoked marijuana in the last 30 days, since in 100 trials where $p = 0.30$, one would expect to get 30 answers to question 1 and 70 answers to question 2. Conversely, a large number of "no" and few "yes" answers (say, 70 "no" and 30 "yes") would tend to indicate that this respondent *had* smoked marijuana in the last 30 days. However, it would be expected that as a single respondent was asked the same question over and over the respondent might realize that he or she is progressively losing his or her anonymity. This could result in loss of truthfulness or random answering and a collapse of any benefit normally associated with RR sampling. Liu & Chow [20] explore the optimal number of trials per respondent and derive the model and estimators associated. Furthermore, they report on a field trial conducted in Taiwan where the randomizing device was a globe with a short neck that contained 3 red and 7 white balls. The globe was manipulated by a respondent so that a single ball fell at random into the neck. Depending on the color of the ball (which was hidden from the interviewer) the respondent answered a question related to abortion. Their study compared direct questioning to RR with one trial and to RR with three trials. Their results indicate a much higher rate obtained by both RR methods (with the three-trial estimate highest of all) and no apparent discomfort from the respondents who were asked to undergo the process three times.

Chow et al. [4] formulated a new RR model and randomizing device to obtain multiple responses without appearing to do so. Their device consisted of a glass urn with a long neck. The urn contained balls of two colors, one color associated with the sensitive category and the other to the nonsensitive. The urn is shaken by the respondent and inverted to allow balls to flow into the neck. The respondent then tells the number of balls in the neck that correspond to his or her category color. They develop estimates based on the **hypergeometric distribution**. Greenberg et al. [14] developed a **method of moments** estimators for this model and device.

Technical Concerns with Warner's Original Model

Several authors have noted some technical problems with Warner's original model. Moors [24, 25] notes that $1 - p \leq \lambda \leq p$ if $p > 1/2$ and $p \leq \lambda \leq 1 - p$ if $p < 1/2$ since $0 \leq \pi \leq 1$. Thus λ must be a truncated estimate and this prevents $\hat{\pi}$ from being a truly unbiased estimate of π. Also, although Warner originally claimed $\hat{\pi}$ was the **maximum likelihood** estimate (MLE) for π, a number of authors pointed out a flaw in his original claim [6, 8, 27, 28]. All recommend a truncated estimator that is the true MLE for π given by the following. For $p < 1/2$, the estimate is given by 1 if $\hat{\lambda} \leq p; \hat{\pi}$ if $p < \hat{\lambda} < 1 - p$; and 0 if $\hat{\lambda} \geq 1 - p$. But for $p > 1/2$, then the estimate is given by 0 if $\hat{\lambda} \leq 1 - p; \hat{\pi}$ if $1 - p < \hat{\lambda} < p$; and 1 if $\hat{\lambda} \geq p$. Without such truncations, sample estimates could give strange estimates of π that could be *negative* or *greater* than 1! For our illustrative high school example, suppose $n_1 = 300$ answered yes; then $\hat{\lambda} = n_1/n = 0.75$ and so $\hat{\pi} = -0.125$! Using the recommended truncated estimator, this value would be set to 0. Devore [6] offers a slightly modified procedure where n is an even number and stands for the number of cards in a deck, one-half of which are marked with the command to answer "yes". The other half of the cards are marked with the sensitive question of interest. The sample of n chosen persons is asked to select a card without replacement. This results in a true unbiased estimate of π that is also the MLE and is given by $\hat{\pi} = (2n_1/n) - 1$ with $\text{var}(\hat{\pi}) = (2/n)\pi(1 - \pi)$ and $\widehat{\text{var}}(\hat{\pi}) = [2/(n-2)]\hat{\pi}(1 - \hat{\pi})$.

Other Generalizations to Warner's Original Model

Abul-Ela et al. [1] extended Warner's model to consider a population of t mutually exclusive categories where at least one but not more than $t - 1$ of those categories is a sensitive category. Their study considered three categories of women who were known recently to have given birth to a child: those women who were already married when they became pregnant; those who got married during their pregnancy; and those who were still unmarried at the time of their delivery. Here, the last two categories are potentially sensitive ones. The randomizing device they used was a deck of cards with each card having one of three associated questions to which the respondent would answer "yes" or "no". The authors developed the model and estimators for this trichotomous situation and reported on some observations of a field trial

of the model. Note that (in general) a situation with t categories necessitates $t - 1$ independent samples, each of which has a different proportion of allocation of questions by the randomizing device.

Liu et al. [22] developed a new randomizing device to be used in the multiproportions environment. The device consists of a glass urn with a long neck. The urn contains beads of several colors, one color associated with each category of interest. The urn is inverted, allowing several balls of each color to flow into the neck which has locations sequentially numbered on it. The respondent is asked to reply according to the location of the first bead of his or her identifying color that appears in the neck.

Franklin [9] considered a dichotomous population (as Warner did) but used a randomizing device that used continuous distributions. Specifically, he presented a portable, programmable computerized device that presented respondents with two windows: one marked "yes" and the other marked "no". Whenever the respondent pressed a button on the device, two separate two-digit numbers appeared in these windows. The interviewer, after explaining what was to take place, then allowed the respondent as much time as he or she wished to "play with" the device and the button. Starting only after the respondent was content with the device, the interviewer then asked a sensitive question. The respondent then pushed the button on the device another time and reported the two-digit number that appeared in the appropriate "yes" or "no" window. This two digit response was recorded by the interviewer. The numbers from the "yes" window were distributed approximately normally with **mean** 40 and **standard deviation** 5, while the numbers from the "no" window were distributed approximately **normally** with mean 50 and standard deviation 5. Thus, a two-digit response such as "43" could have come from either distribution. Franklin incorporated multiple trials into his model by actually displaying six digits in each of the "yes" and "no" windows. This actually constituted three separate two-digit responses, unbeknown to the respondent who felt he or she was responding once. Franklin field-tested his device on university students, asking five sensitive questions. His article both derives the theory for his "continuous distribution randomizing device" and presents the results of his field trial which contrasts estimates of the five proportions of interest made by his RR technique with those made by direct sampling methods. His results indicate that all five RR estimates of the proportions were greater than the corresponding one from direct sampling. In addition, three of the RR proportions were significantly greater statistically than the corresponding one from direct sampling.

The Unrelated Question (RR) Model

The randomizing device that selects one of two questions to be answered is the crux of Warner's model; one question is the opposite of the other and hence they are "related". Greenberg, Horvitz and colleagues [11, 15] were the first to note that the two questions need not be related. They explored the use of two randomizing devices: one a deck of 50 cards and the other, a box with two colors of beads. Each card in the deck had one of two statements:

1. There was a baby born in this household after January 1, 1965, to an unmarried woman who was living here (sensitive).
2. I was born in North Carolina (nonsensitive).

The box of beads had a small window in which (after shaking) one bead would randomly appear. The color of the bead was associated with one of the two statements which were attached to the box. The window was not visible to the interviewer. Results of field studies undertaken in North Carolina are reported, and a "two trials per respondent" model developed for the unrelated question scenario.

The introduction of a second, unrelated and nonsensitive question appears to have both advantages and disadvantages. Presumably, the answering of two distinct questions by "yes" or "no" would not be as potentially confusing as Warner's original procedure. There, if a marijuana smoker obtained question 2, he or she must (if truthful) answer "no". This double negative answer could pose some difficulty in certain sampling situations.

However, the use of a second question introduces two proportions: the proportion of respondents who possess the sensitive characteristic (π_1) and the proportion of respondents who possess the nonsensitive characteristic (π_2). To solve for π_1, either outside or previous knowledge of the value of π_2 must be available so that the scenario reduces to solving one equation in one unknown, π_1; or, if π_2 is itself unknown, a second independent sample (with a different value of p for the randomizing device) must be obtained. This

produces a scenario of two equations obtained (one from each of the two independent samples) in two unknowns, π_1 and π_2. Whichever scenario occurs, estimators and estimates of their variances can be easily obtained.

In spite of the extra parameters introduced, Greenberg et al. [11] were able to show that under certain conditions and parameter choices, the unrelated model can be made more efficient than the original Warner model. In addition, Greenberg et al. [12] showed how the "unrelated but innocuous question" could be built into the randomizing device itself. Specifically, their randomizing device was a box with three types of colored ball: red, white, and blue.

The sensitive question they examined dealt with the occurrence of an emotional problem requiring professional help and was answered by the respondent if the ball which randomly appeared in the window of the box was red. Otherwise, the respondent answered the unrelated question of "The color of the ball in the window is blue". See [12] for derivation of estimates and their variances.

Moors [23] addressed the optimization of choices for samples and of the proportion for the randomizing devices for the unrelated question RR model.

The Use of RR Techniques in Obtaining Quantitative Data

All the RR techniques thus far considered are essentially categorical or qualitative in nature. That is, respondents fall into one of several mutually exclusive categories (at least one of which is sensitive) and the intent of the RR method is to estimate accurately the proportions associated with each category. But many scenarios may beg for a quantitative measure of the sensitive attributes. For example, instead of wishing to know "Have you smoked marijuana in the last 30 days?", one may really be interested in "How many times have you smoked marijuana in the last 30 days?".

Greenberg et al. [13] developed just such an RR technique for dealing with a quantitative response. They modified their earlier developed "unrelated question" model by having two unrelated questions (one of which was sensitive) but which both required a quantitative (numerical) response rather than a categorical (yes/no) response. The two specific questions they used were:

1. "How many abortions have you had in your lifetime?" (sensitive).
2. "If a woman has to work full-time to make a living, how many children do you think she should have?" (nonsensitive).

The randomizing device was a box with red and blue balls: The two questions were identified by "red" and "blue", respectively. The respondent shook and then tipped the box, allowing a single ball to appear randomly in a window (which was hidden from the interviewer). The respondent then answered the question which matched the color of the ball that appeared in the window.

This model allowed estimation of the means of the two distributions addressed by the questions. Since both of those means were unknown, the investigation necessitated two independent studies, each using a bead box with a different proportion of red and blue balls as the randomizing device. See [13] for derivation of estimates for the means and estimates of their respective variances.

Eriksson [7] introduced a model in which a finite set of values can be given as the response to the sensitive question. As an example, the sensitive question could be "In how many of the last 7 days have you smoked marijuana?" and thus the responses could be 0 through 7. The randomizing device he proposed was a deck of cards some of which were marked with this type of sensitive question and others were marked with statements like "Give as your answer _____!" where the blank would contain a number from 0 through 7. Knowing the proportion of the cards marked with "Give as your answer 0", "Give as your answer 1", etc., he derives estimates of the mean of the sensitive distribution.

Liu et al. [21] developed, apparently independently, a similar model and randomizing device. Their randomizing device consisted of a glass urn with a short neck that could contain precisely one ball. The urn contained balls of two colors: red and white. If after shaking, a red ball appeared in the neck of the urn, the respondent answered the sensitive, quantitative question. But the white balls all were numbered with a discrete number (such as from 0 through 7) and if a white ball was obtained, the respondent would give as his or her reply the number on the ball. Knowing the precise number of balls marked with 0s, with 1s, etc., they derived estimates

of the mean of the distribution for the quantitative, sensitive characteristic.

Poole [26] presented an RR technique capable of estimating an entire distribution function for a quantitative sensitive response. His randomizing method consisted in asking the respondent to select randomly a number from a table of random numbers, enter that number into a calculator and then multiply it by his or her salary (the sensitive issue). The resulting number is the value given by the respondent. Knowing the distribution of the random numbers, he derives an estimate of the distribution function associated with personal salaries.

Important Field Studies Using RR Techniques

Many field studies have been undertaken with a wide range of RR models and randomizing devices. While the various models and randomizing devices and field studies are not without controversy, nevertheless, it can be generally stated that RR techniques have performed at least as well as ordinary sampling methods. Four studies in particular have not only attempted to conduct a study by RR techniques but also simultaneously conducted a comparison study using ordinary sampling methods. Their results and observations are instructive.

Boruch [2] reported a study of marijuana use among college students and found no significant difference in the estimated means obtained by direct question methods, from an RR technique, and from his own contamination model. In fact, the results seem only to indicate greater variability present in the two indirect procedures than in the direct question method.

Goodstadt et al. [10] reported on a field study of drug usage involving 854 high school students and their drug usage of six separate substances over the preceding 3 months. They found that subjects were significantly more likely to respond to these questions when the RR method was used than with the direct method. Furthermore, for five of the six drugs (alcohol, marijuana, amphetamines ("speed"), tranquilizers, and heroin) the subjects claimed significantly more frequent drug use than with the traditional direct method. Only for hallucinogens was no significant difference found. One of their closing statements is insightful: "The most significant result of the reported research was the finding that the standard (direct) procedures for inquiring appear to provide a significant *underestimate* of drug use. Statistically significant differences in estimated mean drug use occurred *despite* the considerably higher variability associated with the randomized response estimates."

Liu et al. [20] presented the comparative results of rates of abortion in Taiwan by three methods: direct question; RR with one trial; and RR with three trials. The last two methods gave significantly higher estimates of the proportion of women who have had an abortion of 28.2% and 30.3% (respectively) as compared to several direct studies that never achieved over 19.5%. In addition, a matching study of 48 (successful) interviews with Taiwanese women known to have had an abortion was conducted by RR (multiple trial) and direct methods. The RR method estimated the proportion who had an abortion as 95.7% with a **standard error** of 8% so that a 95% confidence interval would contain the expected value of 100%. However, the direct method estimated a significantly lower percentage of 19.8% with a standard error of 10.5%. Thus, a 95% confidence interval estimate from the direct method would be no larger than 40%, which is considerably lower than the expected value of 100%. In their words, this "suggests that most of the abortion cases were willing to give truthful responses in this (RR) multiple trial model".

Finally, Franklin [9] reported on two studies of college students involving 473 who were interviewed by RR (using continuous randomizing distributions) and 477 who were interviewed by the direct method. The two studies were independent but conducted on one college campus within a period of a week. He deliberately chose five questions with what were judged to be varying degrees of "sensitivity". All five questions gave a higher estimated proportion by the RR method than by the direct method. However, two of the questions (of what was judged "moderate sensitivity") surprisingly showed no significant differences ("Have you smoked marijuana in the last 30 days?" and "Would you ever steal from an employer?"). There was a significantly greater estimate from the RR method than from the direct method for the other three questions, ("Have you ever participated in a homosexual act?", "Have you ever cheated on an exam here at this university?", and "Would you ever cheat on your income tax?") with all ***P* values**

less than 0.0004. It was not anticipated that the two questions on cheating would be significant as they were felt to be of "low sensitivity". However, the researcher noted that before the survey was actually conducted, the students were asked for their social security numbers, which were then used to screen "enrolled students" from "visitors on campus". The researcher reasoned that having those unique identifying numbers turned those questions about cheating into highly sensitive ones (for the "direct questioned respondents"). The article conjectures "that some of the confusion about the efficacy of the RR technique may be related to the 'true sensitivity' of the question for the interviewee as opposed to the 'perceived sensitivity' by the interviewer". The article also reported that 88.9% of the respondents who used the RR technique felt "their friends would be more likely to answer truthfully to sensitive questions by this RR technique". It should be noted also that the technique used by Franklin incorporated (unbeknown to the respondent) three trials per respondent along with sample sizes of near 500.

In summary, RR techniques seemed to establish themselves as being superior to direct question methods *if* certain reservations are understood. First, the question of interest must be "truly sensitive" to the population of interest. For example, it may well be the case that "Have you smoked marijuana in the last 30 days?" is a sensitive question for high schools students but not necessarily for college students. Secondly, RR techniques have greater variability that is inherently introduced by the randomizing device as compared to direct question methods. This additional variability needs to be factored into the circumstances and overcome *either* by multiple trial responses *or* by a careful choice of randomizing parameters *or* by a substantially increased sample size *or* by a combination of all three.

Odds and Ends

Winkler & Franklin [31] approached the original Warner dichotomous model from a **Bayesian** perspective. Taking a natural conjugate **beta** form for the **prior** density of π (the proportion of the population with the sensitive characteristic), they derived posterior density forms.

Warner [30] derived a **general linear model** for randomized response.

Chaudhuri & Mukerjee [3] present RR sampling from a finite population and develop some "unifying theory" that is very helpful and insightful.

Randomized Treatment Assignment

An important goal of clinical research is the development of therapies that improve the probability of a successful outcome in the ill or that prevent the onset of a disease in the healthy. The fundamental question asked in a **clinical trial**, "Does the therapy under investigation work," implies an interest in **causation**. Although frequently associations between therapy and outcome are observed, **association** alone does not imply causation. A rigorous answer to the question of whether a treatment actually benefits patients requires a direct concurrent comparison of those on the treatment to those not on it. Convincing evidence of effectiveness requires not only observing a difference between the two groups with respect to an outcome of interest, but also demonstrating that the therapy has most probably caused that difference. For example, patients undergoing a new surgical intervention may experience longer average survival time than patients who do not undergo the surgery. Whether that apparent benefit is due to the surgery itself or to the ability of surgeons to select patients of low surgical risk is relevant to the assessment of the effect of the intervention (*see* **Bias in Observational Studies**).

An experiment affords the best approach to inferring that an observed association reflects the actual effect of therapy, rather than a noncausal relationship. Experimentation, more rigorously than observation or a priori reasoning, isolates the effect of an intervention from systematic differences between the group of people being treated and the controls. To ensure an **unbiased** assessment of treatment, the study groups must be equivalent in all respects except for the treatment itself. In many clinical trials, the method used to render the groups equivalent is **randomization**, the allocation of people to treatment through a process governed by chance. Although lotteries, which reflect an understanding of the need for a chance mechanism to ensure unbiased selection, date back thousands of years, the application of random selection to experimentation is relatively recent. Stigler [29] credited the first application of randomization in experimentation to Pierce & Jastrow in 1885 [26]. **Fisher**, in a 1926 paper on agricultural experiments [8] and more generally in his *Statistical Methods for Research Workers* [10], stressed the centrality of randomization for statistical **inference**. He contended that statistical tests (*see* **Hypothesis Testing**) based on **normal** theory provided good approximations to the exact randomization distribution. While the literature [23] has cited Diehl's [7] clinical trial on vaccines for the common cold as the first clinical trial to randomize participants, Waller [31] has pointed out that Diehl probably used an alternating, not a random, sequence to assign treatments to participants. Armitage [1] states, "The successful implementation of randomized trials in medicine, in the 1940s, is largely due to the advocacy and example of Sir Austin Bradford Hill" (see, for example, [13]).

Randomization requires an active process of distributing experimental units by chance, not a passive, haphazard method of selection. According to Fisher,

> Apart ... from the avoidable error of the experimenter himself introducing with his test treatments, or subsequently, other differences in treatment, the effects of which the experiment is not intended to study, it may be said that the simple precaution of randomization will suffice to guarantee the validity of the test of significance, by which the result of the experiment is to be judged [9, p. 21].

Thus Fisher very early in his career stressed the importance of randomization to the valid calculation of experimental error.

Randomization has at least two purposes: it allows the deduction of causality and it removes **bias** from the selection of patients for specific treatments. The ability to deduce causality stems from the fact that randomization tends to balance the treatment groups with respect not only to known **prognostic factors**, but also with respect to unknown, unmeasured factors. By preventing investigators from consciously or unconsciously selecting patients for specific treatments, randomization removes investigators' bias from the process of the allocation of treatment groups.

Statistically, from the frequentist point of view, randomization has a third desirable feature: it allows construction of the sample space that renders statistical tests of significance valid.

While randomization is necessary for the unbiased comparison of treatments, it alone does not suffice to ensure fair comparisons. The actual assignment of participants to treatment must precisely reflect the randomization, and the formal analysis of the

data must respect the randomization; otherwise, the analysis, by violating the structural balance assured by the experimental technique, creates potential bias in the evaluation of the treatments (*see* **Intention to Treat Analysis**).

Necessity of Randomization in Clinical Trials

In many laboratory experiments, especially those in the physical sciences, the scientist has the tools to render the "subjects" equivalent. With the ability to exert exquisite control over the samples being compared, small experiments, fastidiously executed, may suffice to measure precisely the effects of stimuli. In biology, however, especially when the "subject" is the entire organism, the inherent variability among experimental units renders such tight control impossible. Even identical twins or genetic clones in the laboratory are not truly identical, because although they are genetically similar, they may differ considerably in experience and behavior. Unrelated people differ even more. Strategies to match experimental groups by controlling as much as possible the distribution of variables in the experimental groups help to achieve comparability, but the very large numbers of variables, measured and unmeasured, that characterize an individual make perfect balance impossible.

In addition to the difficulty of trying to select groups to make them comparable, in clinical trials the treating physician may have conscious or unconscious preference for a specific treatment for a given patient. Bias in construction of treatment groups can creep into a clinical trial quite subtly, because the treating physician may be reluctant to assign certain patients to certain arms. Thus an important feature of assignment of therapy to participant is unpredictability: the next treatment assignment must not be known in advance. Randomization offers the mechanism that typically achieves balance and unpredictability of assignment of treatment in experiments. Although any particular realization of a random allocation of subjects to groups may produce imbalance (otherwise, no one would ever be dealt a full house in poker!), the set of all possible random allocations does not in any way favor one group over another. Furthermore, a large sample size will yield groups in any specific experiment that will have a very high probability of being well balanced with respect both to baseline risk and intrinsic responsiveness to intervention.

Armitage [1] and Lachin et al. [21] present useful discussions of the need for randomization in clinical trials that aim to evaluate therapy (see also Friedman et al. [11]).

Randomization as the Basis of Statistical Inference

According to frequentist theory, randomization allows a direct test of cause and effect and permits construction of valid tests of statistical significance [14, 17]. A simplified description of the randomization model follows. Each patient in the study has a true value of the outcome variable. For example, in a trial that studies the effect of a new drug on the level of LDL-cholesterol (LDL) in the serum, the model conceptualizes each patient as characterized by a "true value" of LDL. The first step in the clinical trial is analogous to random shuffling of the deck of study participants into two piles. In the absence of assigned treatment, the shuffle is expected to produce two sets of cholesterol values with identical distributions.

A study with m patients in each of two treatment groups has $\binom{2m}{m}$ possible assignments of patients to the two groups. The mean levels of LDL in the two groups resulting from the random allocation are expected to be equal. Of course, in any specific allocation the means will differ from each other, but if the sample size is large, the random shuffling ensures a low probability of a large difference. To perform the clinical trial, one introduces a treatment, here a putative LDL-lowering medication, and assigns it to each member of one of the "piles". If the medication reduces LDL-cholesterol by 10 mg/dl, then the treated group is expected to have an average LDL-cholesterol level 10 mg/dl lower than the untreated group. To test the effect of treatment, one compares the observed **means** in the two populations. Under the randomization model, all possible ways the shuffle could have allocated participants to the treatment and control groups constitutes the sample space. A surprisingly large observed difference in the two groups leads to the claim that the treatment must have "caused" the difference because the only systematic characteristic that distinguishes

between the two groups is the treatment. To derive a statistical test of the **null hypothesis** of no effect of treatment, one can construct the sample space of all possible outcomes by enumerating each of the $\binom{2m}{m}$ combinations, computing the test statistic, and calculating in what position the observed sample sits in the space of all possible allocations ordered according to the **likelihood** of the occurrence under the null hypothesis. Even in relatively small samples, however, the sample space may be large enough to render this calculation intractable. In 1955, Kempthorne [17] proved Fisher's earlier contention that statistical tests based on normal theory were reasonable approximations to the randomization distributions (see also Hinkelmann & Kempthorne [14]). Lachin [18–21] presents discussions of the theory as applied specifically to randomized clinical trials. The act of randomization has provided the formal template that allows a statistical test of whether the treatment "caused" a difference in LDL. The answer in the study group leads to the inferential leap that if the treatment truly caused a difference in this specific group of people, then it should cause a difference in other people as well. The randomization procedure does not guarantee the legitimacy of this generalization of the trial's result to a larger population.

Arguments Against Randomization

While most clinical trialists view randomization as necessary to valid inference about the effects of therapy, some people object to randomization on ethical grounds (*see* **Ethics of Randomized Trials**). Some argue further that often randomization is difficult to perform, but according to Senn, "Contrary to what is sometimes claimed, randomization is not a nuisance in clinical trials: from the practical point of view it is one of the easiest allocation procedures to implement" [28]. Some hold that careful statistical modeling in the absence of randomization can in some cases discern the effect of therapy. For discussion of these arguments, see, for example, Basu [2], Levine [22], and Friedman et al. [11].

While randomization is necessary for the construction of statistical tests from the frequentist point of view, it is relevant to **Bayesian** and likelihood-based inference for another reason. Both of these methods of inference consider the data fixed after the experiment is completed; they, unlike in the frequentist approach, are not concerned with the experiments that might have occurred. Inference is based on the likelihood – the probability of the data given the parameters of interest – not the process that gave rise to the data. From the point of view of such inference, randomization enhances the validity of the likelihood. In fact, several Bayesian discussions of clinical trials urge randomization to ensure **blinding** and protection from **confounding** [16, 24]. Since the likelihood used in the Bayesian analysis is based on absence of confounding, randomization is essential.

When should Randomization Start and End?

The literature on clinical trials includes considerable discussion concerning the period during the life of development of a therapy that randomization is appropriate. Failure to randomize relatively early in the development of a new therapy or in the study of a new application of an accepted therapy may render interesting hypotheses untestable, for once the medical community regards a therapy to be safe and effective, physicians are reluctant to randomize to therapies they perceive as less effective. Chalmers [4] has therefore recommended randomizing from the first patient. On the other hand, if data from clinical trials have demonstrated the safety and effectiveness of a therapy, continuing to randomize to confirm a previous observation or to ask more refined questions about the therapy may raise ethical problems.

A reasonable practical approach is to start randomization quite early in the development of a new therapy, although not necessarily at the beginning, and to continue to randomize as long as legitimate uncertainty exists surrounding the safety and efficacy of the therapy [5] (*see* **Data and Safety Monitoring**).

Methods of Randomization

Randomization requires a mechanism governed by chance to assign treatments to people. The ideal allocation device is a perfectly unbiased coin tossed by an angel. Real clinical trials should use verifiable methods of randomization so that, after the study, the investigators can demonstrate that the allocation was free from bias. A coin flipped by a person is fallible chiefly because a less-than-honest coin flipper can fail to record tosses that land on the "wrong side".

Thus, the main problem with flipping coins is that the process permits no checks of the validity of the process.

In the past, many trials have used tables of random numbers to produce randomization lists. This method can be cumbersome for all but the simplest type of randomization. Furthermore, because published tables of random numbers are available to everyone, staff in a clinic can potentially find the sequence that is in use, thus permitting **selection bias** to affect the study.

Whenever possible, a computer should produce the randomization list. The person who generates the randomization list should be separate from the persons recruiting and treating participants. During the course of the study, the generator of the list should not divulge the details of the particular method used to construct the list to any of the clinic personnel involved with the patients.

Many studies use opaque sealed envelopes to hold the treatment assignment. This method, though quite standard, is subject to violation, especially in unmasked studies (*see* **Blinding or Masking**). An investigator intent on enrolling a patient into a specific treatment arm can hold the envelope to the light, or even open an envelope and not enter a patient if the "wrong" assignment is listed. In recent years, many clinical trials have adopted telephone, fax, or encrypted on-site computer codes for randomization. These methods allow a rigorous accounting of all persons entered into the study.

The randomization list itself should be held inviolate by the person or group controlling the assignment of treatments to participants. Because violations of randomization can invalidate the entire trial, the investigators should establish procedures for randomization and protection of the validity of the randomization before the trial begins.

For a study treatment that is viewed as a community-wide intervention, a trial might randomize one group of communities or clinics to receive the control treatment and another group to receive the study treatment. See, for example, a description of the COMMIT study [6]. Random allocation makes this approach theoretically acceptable provided that the **unit of statistical analysis** remains the community, not the individual person participating in the study. To have a **powerful** test of the effect of treatment, this method of allocation may require many communities. Moreover, the investigators must be careful to assess the impact that the intervention had on the entire community, not only on those people who participated in the program (*see* **Group-randomization Designs**).

So-called "randomized" clinical trials often use nonrandom approaches to assignment of treatment. In fact, people often use the term "random" loosely in the sense of apparent haphazardness, but strict randomization through a mechanism governed by chance prevents the treatment assignment from being predicted and protects against bias. The following paragraphs, which represent the control therapy by C and the experimental treatment by E, describe some common nonrandom ways of assigning patients. The considerations below apply with obvious modifications to the comparison of two active treatments or to the comparison of more than two study groups.

Some studies assign patients in alternating sequence. This scheme assigns the first participant to treatment C, the second to E, the third to C, and so forth. The argument adduced in favor of such alternating sequences is that because patients enroll in a "chance" order, a method that alternates patients to one treatment or other will result in groups of roughly equal risk. The flaw in this method stems from the fact that the treating physician who knows the sequence can choose which patients receive which therapy. Even if the therapy is blind, a single revelation of the treatment code unblinds the entire study. This type of assignment clearly violates the requirement of assigning treatment by chance in order to minimize physician bias. In addition, from a frequentist point of view, the sample space consists of only two possible realizations, ECECEC ... C and CECECE ... E. With only two possible outcomes, the exact two-sided ***P*-value** from the randomization test is 1.0, no matter how dramatically the two groups differ after treatment!

Another scheme allocates patients on alternating days to treatment C or E. This type of assignment has problems similar to the first one. From the frequentist view, the sample space again consists of two possible allocations, so that once more the exact P-value is always unity. From the point of view of biased selection, once the clinicians have deduced the scheme, they can control the allocation of patients to a particular therapy. Thus, this type of assignment is

subject to substantial bias in studies of nonemergency conditions. In true emergencies, practical exigencies may make such allocation necessary. If all patients are entered into the study, then the bias may be negligible since treatment cannot be delayed until the next day.

The medical literature includes many examples of studies that perform their randomization rigorously but fail to begin therapy until several hours, or even days, after randomization. Omitting from analysis the patients who drop out between the time of randomization and the time of therapy can introduce bias. Whether the dropouts in fact lead to bias depends on the reasons for failing to remain on the trial. If the treatments are unmasked, then bias should be highly suspected; if the treatments are masked, dropouts after randomization may not lead to bias. To avoid a biased comparison, the analysis should generally include all patients in the groups to which they were randomized (*see* **Intention to Treat Analysis**). When exceptions to this rule are made, the reasons for the exclusions must be strictly independent of treatment assignment.

Guidelines for Randomization

In a clinical trial that specifies the entire study sample before the experiment begins, the study statistician can construct the complete randomization schedule in advance and assign the treatments to the appropriate study participants. Phase I experiments of normal volunteers, experiments with dietary manipulations [15], or **vaccine trials** with closed populations [25] often have such prespecified study samples. The typical clinical trial, however, enters participants during a sometimes prolonged recruitment period. At the beginning of the trial, the people who will enroll are not known; perhaps some of them have not even yet manifested the disease to be studied. Thus, the assignment of treatments to participants must occur before identifying all participants. The process must be stepwise. First, the potential participant agrees to join the study, signs an informed consent (*see* **Ethics of Randomized Trials**) document, and is officially enrolled in the trial. Then the randomization process begins and the treatment is assigned. Once enrolled, a person is, except in certain special cases, part of the randomized trial, even if he or she fails to participate any further.

Some Problems with Simple Randomization

The primary purpose of randomization is to ensure comparability of the treatment and control groups. The type of randomization described above is simple randomization: each person arrives at the study, the study authority flips a theoretical coin that has probability p of assigning the participant to the control group, and, depending on the outcome, the patient receives treatment or control. On average, a proportion p, usually 1/2, of the assignments will be to treatment and $(1 - p)$ to **control**. A very large sample size guarantees that the proportions of people assigned each treatment will be arbitrarily close to the chosen values of p and $1 - p$. In practice, however, this kind of simple, unrestricted randomization will not produce exactly the prespecified proportions of patients in each study group.

Another important limitation of unrestricted randomization in clinical trials stems from the structure of the typical trial. A purely random process that generates a sequence of Cs and Es will produce, by chance, occasional long sequences of the same treatment assignment. Because participants enter trials over time, such sequences may produce unwanted homogeneity among patients entered at approximately the same time. Assignment to test and control therapies should ensure balance not only overall, but in addition, the length of sequences of the same treatment should be short and, at any particular time in the study, nearly the same number of patients should be on each therapy. Furthermore, unrestricted randomization can lead to some small clinics randomizing all, or nearly all, participants to the same treatment. Such an allocation is clearly undesirable.

Finally, some sequences of random numbers may by chance produce an unbalanced allocation with respect to a specific baseline variable. Therefore, if the primary outcome is strongly related to a specific prognostic variable, one might like to adopt a strategy that guarantees balance for that variable. Such constrained randomization is called **"blocking"** or **"stratification"**. While these words are technically synonymous, in randomized clinical trials "blocking" generally refers to randomization within small subsets without regard to specific prognostic variables, while "stratification" refers to randomization within subsets defined by categorical variables. To perform blocked randomization, one should use block sizes that are

multiples of the number of treatment groups, then assign at random the treatments within the blocks. For example, consider a study with three treatments A, B, and C to assign with equal probability. If the block size is six, then the assignment rule would allocate at random two each of A, B, and C to the six persons in each block. At the end of every six assignments, the numbers in the three treatment groups will necessarily be equal. The longest possible sequence, four of the same treatment, occurs when the last two participants in one block and the first two in the succeeding block are assigned the same treatment.

This more balanced allocation does not come without a price. Strictly, the fact that the data are blocked imposes extra complexity on any frequentist analysis, for the statistical analysis ought to reflect the randomization. Conventionally, however, the blocking is ignored in the analysis of clinical trials because the complexities incurred are generally not considered worth the very small gain in expected power. Lachin et al. [21] warn, ". . . if there is significant heterogeneity in some systematic way among the patients entering the trial, such as a change over time, then ignoring the stratification . . . may substantially distort the size of the test".

A potentially serious problem with simple blocking in unblinded studies is the fact that a clever investigator can deduce some of the allocations. For example, the first five assignments in each block of six always determine the last one. Smaller block sizes assure more balance but in unblinded trials they lead to a higher proportion of predictable allocations. In unblinded studies of treatment and control with blocks of size two, half of the allocations are known with certainty because the first allocation fully determines the configuration of the block. To prevent the clinic staff from knowing what patients are to be assigned what therapy, a study should take several precautions in selecting block sizes. First, the investigators should not know the block sizes. Secondly, the allocation should use an unpredictable mixture of block sizes, so that the sequence of assignments to therapy would confuse a person who tried to decode the system. Thirdly, block sizes can vary by clinic. In clinics that are expected to recruit many patients, the block size may be as high as 20. In clinics that are expected to recruit very small numbers of participants, the block size should be smaller to ensure reasonable balance of treatment assignments.

The type of simple or blocked randomization already described does not guarantee balance for specific baseline variables. Even in randomized clinical trials with large populations, simple unstratified randomization will lead to imbalance in some baseline variables. In fact, if tests are performed at a 5% level of significance, statistically significant imbalance is expected to occur in 1 out of 20 independent baseline variables. Although most observed imbalances will be dismissed as not germane to the question of effectiveness of therapy, sizable imbalance on important known prognostic factors can be unsettling. The statistical literature proposes several approaches to analysis of data when such imbalance occurs: ignoring the imbalance as an unlucky event but one within the range of outcomes in random assignment; "adjusting" through statistical models for the imbalance in specific variables if that imbalance is statistically significant; "adjusting" through statistical models for large imbalance in specific variables even if the degree of imbalance is not statistically significant; "adjusting" for all important prognostic variables when at least one important such variable shows considerable imbalance. The argument for the last choice is that the presence or absence of statistically significant imbalance should not be the driving force to ask whether actual allocation affects the conclusion (*see* **Covariate Imbalance, Adjustment for**).

Rather than relying on chance to avoid imbalance on important variables, one can create strata and then randomize within strata (or within blocks within strata). First, we consider precision. While heterogeneity does not generally affect the type I error (*see* **Hypothesis Testing**) – but see [21] – if there is considerable heterogeneity in the study population, then isolating sources of variation from the effect of treatment can sometimes lead to increased precision in the estimate of the treatment effect. One simple effective method to achieve such isolation is stratification of the study group into relatively homogeneous subgroups using a stratification variable strongly related to outcome. Gains in precision sometimes occur even if the sample is balanced overall.

In the absence of compelling reasons to the contrary, **multicenter trials** generally stratify randomization within clinic because of the potentially large differences among clinics. Different clinics may recruit from very different patient groups. Their approaches to treatment and concomitant therapies,

their threshold for aggressive therapy, the quality of their staff, and their available equipment may be quite heterogeneous. Furthermore, the degree to which the clinics adhere to the protocol may also vary and the quality of their data may differ markedly. Finally, even in large clinical trials the number of patients within individual clinics may be quite small. Thus allocation of treatment at random without regard to clinic leads to a high probability that some clinics will have very unequal numbers of patients assigned to the treatment groups.

Selection of the stratification variables presents a practical problem. Investigators often desire to stratify on many variables of interest. Sometimes these variables are highly **correlated**, so that stratification on one or two of them leads to near balance on the others. Thus, using a few stratifying variables can often achieve reasonable balance for all the variables of interest. A large number of strata may create so complex a routine in the clinic that the chance with which a patient receives the incorrect assignment increases. Too many strata may lead to excess costs. In drug trials, for instance, a sufficient quantity of the drug must be available for each stratum. Generally, the more strata, the more drug necessary, and often clinics will end up with unused drug. Depending on the cost of the drug and its phase of development, the need for excess drug can be very expensive. Finally, overstratification can lead in some extreme cases to *decreased* power. Too many strata can lead to incomplete strata. For example, suppose a trial to study the effect of LDL-lowering on the progression of atherosclerotic plaque uses only three important stratification variables: gender, smoking status (non-, former, or current smoker), and age (40–49, 50–64, >64). These three variables lead to $2 \times 3 \times 3 = 18$ possible strata. If all the strata were equally likely and all the clinics recruit the same number of people, a trial with 600 patients in 20 clinics would then have an expected stratum size of $600/(20 \times 18) = 1.7$, which is less than the number of treatments. Of course, some clinics will recruit more than others, and some strata are much more common than others. Nonetheless, many people will be the sole occupants of their randomization cells. A strict analysis according to the randomization would have to exclude those people. In practice, however, most data analyses would ignore the stratification [12].

Other Methods of Randomization

This discussion addresses only the usual methods of randomization in clinical trials. Other methods available include deterministic play-the-winner [33] or probabilistic urn model [32] (*see* **Ornstein–Uhlenbeck Process**) approaches to maximizing the probability of a participant's receiving the better therapy, adaptive allocation to achieve marginal balance of specific prognostic variables [3], and covariate adaptive procedures, both deterministic [30] and probabilistic [27] (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). Another option is "prerandomization" to increase the pool of people willing to enter trials (*see* **Ethics of Randomized Trials**) [34].

Other Randomization in Clinical Trials

Randomization in clinical trials is not restricted to allocation of participants to treatments. Depending on the specific trial, a given study may randomize such items as the sequence of tests, the assignment of readers for diagnostic procedures, or the order in which a panel of judges views paired "before" and "after" measurements. Investigators should consider randomization to prevent bias at various critical points in the study.

Conclusion

Randomization, the allocation of treatments to study participants by an aleatory mechanism, ensures unbiased assignment of treatments to participants, guarantees the balance of treatment groups with respect to the expected distribution of measured and unmeasured baseline variables, and, under frequentist statistical theory, allows the calculation of experimental error. Coupled with complete follow-up of the study cohort and rigorous analytic strategies, randomization leads to unbiased tests of the null hypothesis of no difference between treatments.

Randomness, Tests of

Tests of randomness are used to assess whether data are truly random or whether the data have some sort of pattern. For data that are collected over a period of time, such as blood chemistries for a patient, this pattern may be a relationship between the order in which the data were collected and the magnitude of a variable of interest. This may also be a relationship between a dichotomous characteristic of interest, such as gender, and the magnitude of another variable of interest. For data that are collected over geographic areas, such as mortality rates for a disease across counties, this may be a relationship between rate and location. Some tests of randomness are used to detect general nonrandomness, while other tests are used to detect a particular pattern of nonrandomness.

Many tests of randomness are based on the concept of runs. For example, suppose the outcome in each of a series of trials can be classified as either a success (S) or a failure (F). The results of nine trials are, in order,

F F F S S F S S S.

Each sequence of observations of the same type (success or failure) is called a "run", and in this case we have a total of four runs, two of S and two of F. The number of runs could be as few as two (F F F F S S S S S or S S S S S F F F F), if all failures occurred before all success or vice versa, or as many as nine (S F S F S F S F S), if successes alternated with failures. This illustrates the important point that "too few" or "too many" runs is evidence of a nonrandom relationship between the order of the experiments and the outcome, and we would reject the **null hypothesis** of randomness if either of these outcomes is the case. The Wald–Wolfowitz [16] runs test is the best known test that is based on the number of runs, but because this test compares the probability distribution of two populations and is not a test of randomness, the null hypothesis of identical distributions is rejected only if there are too few runs. Therefore, a test of randomness based on the number of runs can be thought of as a Wald–Wolfowitz runs test, but with a two-tailed rejection region (*see* **Alternative Hypothesis**).

Tests of randomness that focus on nonrandomness due to **clustering** can be based on the length of the runs. Mosteller [12] indicated that a test of randomness can be based on the length of the longest run, which is three in the above example. O'Brien & Dyck [13] developed a statistic using a weighted linear combination of the variances of the length of "success" runs and of "failure" runs. Larger variances suggest that the data are clustered. Agin & Godbole [1] developed a statistic based on the number of "success" runs of a given length, which can be used to detect cyclical clustering.

Tests of randomness that focus on nonrandomness due to trends can be based on the differences between values of successive observations, such as the von Neumann test [15]. This test is based on the *mean square successive difference*, the mean square of the difference of successive observations. Small squared differences between values of successive observations relative to squared difference between the values of the observations and their mean value are indicative of a trend. The rank von Neumann test of Bartels [2] is similar to the von Neumann test, except that this test uses the ranks of the observations. This test is also more powerful that the von Neumann test under certain conditions.

Daniels [5] and Mann [10] developed tests for nonrandomness due to trends that **correlate** the value of a variable with the time or order that the variable was measured, using **Spearman's** rho (Daniels) or Kendall's tau (Mann) (*see* **Rank Correlation**). A high positive or negative correlation suggests a trend. Dietz & Killeen [6] provided a multivariate extension to Mann's test which detects a trend in at least one variable.

An important application of tests of randomness involves spatial data. Some tests are used to assess whether the locations of point data are randomly distributed over a given region or whether the data are either aggregated or are distributed too regularly. These tests are primarily used in biological applications, and involve the use of techniques such as counting the number of observations in subregions, or quadrats, of the region of interest, or computing distances between each observation and its nearest neighbor [3] or its kth nearest neighbor.

Other tests involving spatial data are used to assess whether there is a relationship between a characteristic of a population and the location of that population (*see* **Geographic Epidemiology**). Cliff & Ord [4] explore the relationship between a dichotomous variable and geographic area based on the BW statistic, classifying areas as either black (B) or white (W) and

counting the number of times a black area borders, or is linked to, a white area. A small value of BW suggests that the data are aggregated, while a large value suggests that the data are too regularly distributed. This statistic is equivalent to an extension of the runs test to multidimensional data when observations are linked using orthogonal minimum spanning trees [7]. The multiresponse permutation procedure statistic discussed by Mielke et al. [11] may also be used to link data. Hubert et al. [9] discussed the relationship between unidimensional and multidimensional tests of randomness, showing that many tests, including some of those discussed above, have the same general form.

Tests of randomness can also be used to assess the randomness of a sequence of **pseudo-random numbers** generated by a given algorithm. This is important, because the validity of **simulation** techniques are dependent on whether generated random numbers are truly random. Some tests of randomness are discussed by Strube [14] and Gruenberger & Jaffray [8]. These include investigating the length of intervals between repetitions of the same number, the correlation between numbers that are close in the sequence, and the frequency of occurrence of certain numbers. In addition, goodness-of-fit tests can also be applied to a sequence of generated random numbers to test for randomness.

Range

The range of a set of observations is defined to be the difference between the largest and the smallest values of the set. For **grouped data**, it is taken to be the difference between the upper limit of the last interval and the lower limit of the first interval. In practice, the **standard deviation** of a set of measurements is roughly equal to one-sixth of the range.

In life testing, when the observations are **exponentially distributed**, the traditional **likelihood ratio test** statistic cannot answer questions of how to compare location parameters or threshold values. In **multiple comparisons** among these location parameters, the range statistic is more appropriate.

The range statistic can also be used to test the hypothesis that a set of location parameters varies "within a small but negligible difference" [3] (*see* **Equivalence Trials**; **Bioequivalence**). This is equivalent to testing the hypothesis that the location parameters fall into the zone of indifference specified in advance. When observations follow a normal distribution, the range and **studentized** range statistics can be used to test the hypothesis that all the mutual differences among means are smaller than a negligible quantity.

Exponential Distribution

Let $\pi_1, \ldots, \pi_k$ denote $k \geq 2$ populations such that the n independent observations $X_{i1}, \ldots, X_{in}$ taken from population π_i are exponentially distributed with density

$$f(x; \alpha_i, \theta) = \left(\frac{1}{\theta}\right) \exp\left[-\frac{(x-\alpha_i)}{\theta}\right],$$
$$\alpha_i < x < \infty, \theta > 0,$$

zero elsewhere, where α_i is an unknown location parameter or guaranteed life span, and θ is a common but unknown scale parameter or standard deviation.

Let Y_i denote the first **order statistic** of the sample of size n from population π_i. Let $Y_{[1]} \leq \cdots \leq Y_{[k]}$ denote the ordered values of the k first-order statistics $Y_1, \ldots, Y_k$, and take as estimator of θ

$$\hat{\theta} = \sum_{i=1}^{k} \sum_{j=1}^{n} \frac{(X_{ij} - Y_i)}{[k(n-1)]}.$$

Define the range statistic C to be $C = n(Y_{[k]} - Y_{[1]})/\hat{\theta}$. Under the null hypothesis $H_0 : \alpha_1 = \cdots = \alpha_k$, C has the density

$$g(c) = (k-1) \sum_{i=0}^{k-2} (-1)^i \binom{k-2}{i} \times \left[1 + \frac{c(i+1)}{v}\right]^{-(v+1)}, \quad c > 0,$$

where $v = k(n-1)$.

We note that, if $k = 2$, then C has an ***F* distribution** with $(2, 2v)$ **degrees of freedom**. Furthermore, the distribution of C **converges** to that of R as v goes to infinity, where R is the range of independent observations from the standard exponential distribution with the density $f(x) = e^{-x}$ for $x > 0$.

The range statistic C provides a quick test for $H_0 : \alpha_1 = \cdots = \alpha_k$ vs. $H_a : \alpha_i \neq \alpha_j$; one rejects H_0 at α level of significance if the computed value of C is larger than $c^{\alpha}_{k,v}$, where $c^{\alpha}_{k,v}$ was given by Chen [2] for $\alpha = 0.10, 0.05, 0.01$, $k = 2(1)5, 10(10)50, 100$, and $n = 2(1)6(2)10, 16, 30, 60, \infty$.

The range statistic C is not as **powerful** as the likelihood ratio test (LR). However, if multiple comparison among αs is of interest, the LR test is not applicable. Like Tukey's studentized range statistic for comparing normal means, the major role of the range statistic C rests on its extensive use in multiple comparisons of the location parameters. It is easy to find that a set of exact $1 - \alpha$ **simultaneous confidence intervals** for the difference $\alpha_i - \alpha_j$ is given by

$$\alpha_i - \alpha_j \in (Y_i - Y_j) \pm \frac{c^{\alpha}_{k,v} \hat{\theta}}{n}$$

for all $i \neq j = 1, \ldots, k$. When the sample sizes are not equal, we suggest replacing $1/n$ by $\frac{1}{2}(1/n_i + 1/n_j)$ and $k(n-1)$ by $v = \sum_i (n_i - 1)$ to obtain a conservative set of confidence intervals. Furthermore, a set of exact $1 - \alpha$ simultaneous confidence intervals for all linear contrasts of the location parameters is given by

$$\sum_{i=1}^{k} a_i \alpha_i \in \sum_{i=1}^{k} a_i Y_i \pm a^{\alpha}_{k,v} \frac{\hat{\theta}}{n} \sum_{i=1}^{k} \frac{1}{2} |a_i|,$$

where $\sum a_i = 0$.

Normal Distribution

It is well known that, given a large enough sample size, a point **null hypothesis** $\mu_1 = \mu_2 = \cdots = \mu_k$ will always be rejected. In applications, the point hypothesis is unrealistic; more appropriate is an "interval" null hypothesis: $H_0 : (\mu_{[k]} - \mu_{[1]})/\sigma \leq \delta$ vs. the **alternative hypothesis** $H_a : (\mu_{[k]} - \mu_{[1]})/\sigma > \delta$, where $\mu_{[1]} \leq \cdots \leq \mu_{[k]}$ denote the ordered population means, and $\delta(> 0)$ must be specified in advance (*see* **Ordered Alternatives**). The null hypothesis states that all standardized differences between means fall into a zone of indifference specified by a quantity δ, while the alternative describes the practically meaningful differences among means which are defined to fall in the preference zone.

Let there be k independent populations $\pi_1, \ldots, \pi_k$ such that observations obtained from π_i are independent and normally distributed with unknown mean μ_i and a common unknown variance $\sigma^2, i = 1, \ldots, k$. Our objective is to test the interval hypothesis H_0 using the range or the studentized range.

Let $X_{ij} (j = 1, \ldots, n)$ be an independent random sample of size n from population π_i. Define

$$\overline{X}_i = \sum_{j=1}^{n} \frac{X_{ij}}{n},$$

$$S = \left\{ \frac{\sum_{i=1}^{k} \sum_{j=1}^{n} (X_{ij} - \overline{X}_i)^2}{[k(n-1)]} \right\}^{1/2},$$

$$i = 1, 2, \ldots, k, \tag{1}$$

and let $\overline{X}_{[1]} \leq \cdots \leq \overline{X}_{[k]}$ be the order statistics of $\overline{X}_1, \ldots, \overline{X}_k$. The hypothesis H_0 is rejected at the α level of significance if

$$\overline{X}_{[k]} - \overline{X}_{[1]} > \frac{\gamma S}{\sqrt{n}}, \tag{2}$$

where γ is the solution to the equation

$$\begin{aligned} \alpha = 1 - l \int_0^\infty \int_{-\infty}^\infty & [\Phi(y + \gamma u) - \Phi(y)]^{l-1} \\ & \times [\Phi(y - \delta\sqrt{n} + \gamma u) - \Phi(y - \delta\sqrt{n})]^{k-l} \\ & \times \phi(y) q_v(u)\, \mathrm{d}y\, \mathrm{d}u - (k-l) \int_0^\infty \int_{-\infty}^\infty [\Phi(y \\ & + \delta\sqrt{n} + \gamma u) - \Phi(y + \delta\sqrt{n})]^l [\Phi(y + \gamma u) \\ & - \Phi(y)]^{k-l-1} \phi(y) q_v(u)\, \mathrm{d}y\, \mathrm{d}u, \end{aligned} \tag{3}$$

where $l = k/2$ for even k, and $l = (k-1)/2$ for odd k. The table of critical values γ was tabulated by Bau et al. [1] for $\alpha = 0.01, 0.05, \delta = 0.10, 0.20, 0.25, 1/3, 0.5$, $k = 2(1)10$, and $n = 2(1)20(2)30(10)60, 80, 100, 200$. If the sample sizes are not all equal, then we suggest replacing n by n_i and $k(n-1)$ by $\sum_i (n_i - 1)$ in (1) and n in (2) and (3) by the average sample size to obtain an approximate solution.

HUBERT J. CHEN

Rank Correlation

If X and Y are two observations on the same unit, both measured on an ordinal scale, then there are many circumstances in which it is important to assess the degree of **association** or **correlation** between X and Y. Such a measure of correlation may be used as a measure of **reliability** (when X and Y are two measurements of the same construct from independent observers or at two different times), or as a measure of **validity** (when X is a measurement of a construct and Y is a criterion defining the construct), or as a measure of **heritability** (when X and Y are two measurements taken from identical twins raised apart; *see* **Twin Analysis**), as well as a measure of more general types of association. The most common approach to assessing such association arises when, in a population sample, (X, Y) have a **bivariate normal distribution**, in which the correlation coefficient ρ is a natural parameter. Then the Pearson (product-moment) correlation coefficient r_{P} is the maximum likelihood estimator of ρ:

$$r_{\mathrm{P}} = \frac{\sum (X_i - M_X)(Y_i - M_Y)}{(N-1)s_X s_Y}.$$

Here the sample of size N from the population (X_i, Y_i), $i = 1, 2, \ldots, N$, has sample means M_X and M_Y, and sample standard deviations s_X and s_Y.

While r_{P} is reasonably robust to deviations from the assumptions of the bivariate normal distribution [6, 10], it can be misleading when the deviations are major. Consequently, an alternative approach, appropriate to measuring such association under less restrictive assumptions, is of value. This has given rise to proposals for rank correlation coefficients, which, like r_{P}, are measured on the interval from -1 to $+1$, are sensitive to monotonic association, take on a value of ± 1 for perfect positive or negative association, take on a value of 0 when X and Y are independent, but make no other distributional assumptions. The two most widely used such sample rank correlation coefficients were those proposed by Spearman [12] and by Kendall [3].

To compute the **Spearman rank correlation** coefficient, r_{S}, the set of observed Xs are rank-ordered from 1 to N, with tied observations assigned the average of the associated **ranks**. The same is done separately with the observed Ys. Thus, the sum of the ranks of either X or Y is always $N(N+1)/2$. Then the equation above for r_{P} is applied to the ranks rather than to the raw data. Clearly, r_{S} is invariant under strictly monotonic increasing transformations of either X or Y or both.

To compute Kendall's tau, τ, every pair of (X, Y) observations is assessed. For any pair of bivariate observations, say (X_i, Y_i) and (X_j, Y_j), a score of $+1$ is assigned to the pair if $\mathrm{sign}(X_i - Y_i) = \mathrm{sign}(X_j - Y_j)$ and -1 otherwise. The score of zero is assigned in the case of a tie. These scores are summed over the $N(N-1)/2$ possible pairs of observations to obtain S. Then,

$$\tau = \frac{S}{\left\{\left[\tfrac{1}{2}N(N-1) - U\right]\left[\tfrac{1}{2}N(N-1) - V\right]\right\}^{1/2}}.$$

If there are no ties in the X ranking, then $U = 0$; if there are no ties in the Y ranking, then $V = 0$. In that case, the denominator is simply $N(N-1)/2$. When there are ties, one counts the number of tied values in each set of tied values to obtain one value of u (for the X values) or v (for the Y values). Then,

$$U = \frac{1}{2}\sum u(u-1), \qquad V = \frac{1}{2}\sum v(v-1).$$

Once again, clearly, τ is invariant under strictly monotonic increasing transformations of either X or Y or both.

Both r_{S} and τ satisfy the general desiderata of a correlation coefficient. However, if (X, Y) were drawn from a bivariate normal population, then r_{P} would be a **consistent** estimator of ρ, r_{S} of $6/\pi[\sin^{-1}(\rho/2)]$, and τ of $2/\pi[\sin^{-1}(\rho)]$. Clearly, while the three sample correlation coefficients are measured on the same range, have the same random value, and values indicating perfect association, no two of them are measuring correlation in exactly the same way. In the case of the bivariate normal population, the differences between the parameters estimated by r_{P} and r_{S} are not major, at most a difference in the second decimal place. The parameter estimated by τ, however, may differ by as much as 0.2 from either of the other two. When the bivariate normal assumptions do not hold, the discrepancy between the r_{S} and τ may be even larger. The circumstances under which one would be preferred to the other have not been clearly enunciated. Most commonly, r_{S} is used, but largely because of its greater ease of computation and its closer correspondence to the familiar r_{P}.

In most contexts in which the correlation coefficient is used, it is clear from the outset that the population value is not exactly zero. Yet the most common statistical task is to test the **null hypothesis** that the correlation coefficient is zero. For small sample sizes, the exact distributions of both r_S and τ under the assumption of independence of X and Y are tabled [4].

For larger sample sizes, the distribution, under the null hypothesis of randomness, of each of these statistics is approximately normal. As a standard normal test statistic to test that hypothesis, one might use

$$\frac{3\tau[N(N-1)]^{1/2}}{[2(2N+5)]^{1/2}} \quad \text{or} \quad r_S(N-1)^{1/2}.$$

While it would be preferable to present **confidence intervals** rather than to perform a statistical test on a null hypothesis known a priori to be untrue, the exact non-null distributions of τ and r_S are in general unknown, since they depend on the parent distribution. If the parent distribution were bivariate normal (or the observed X and Y represented any monotonic **transformations** of X^* and Y^* drawn from a bivariate normal distribution), one might obtain approximate confidence intervals in the following way, using methods developed for r_P. Fisher's z-transformation for a correlation coefficient r is defined as $z(r) = \frac{1}{2}\ln[(1+r)/(1-r)]$. Then, two-tailed $100(1-\alpha)\%$ level confidence intervals for $z(\rho)$ are given approximately by [2]

$$z(r_S) \pm Z^{\alpha/2}\left[\frac{1.060}{(N-3)}\right]$$

$$\text{or} \quad z(\tau) \pm Z^{\alpha/2}\left[\frac{0.437}{(N-4)}\right],$$

where $Z^{\alpha/2}$ are the critical values of the standard normal distribution. **Bootstrap** methods have also proved useful for this purpose [9, 11].

The Spearman rank correlation coefficient concept can be extended to the situation where, for each unit sampled from the population, an m-dimensional vector $(X_1, X_2, \ldots, X_m)$ is observed, using Kendall's *coefficient of concordance* [5]. There are several equivalent ways to compute this coefficient, W, all based on rank ordering the units (averaging the ranks of ties) on each of $X_1, X_2, \ldots, X_m$ separately. The most revealing way is this: the Spearman rank correlation coefficient between each pair of variables is computed, and r_{S-ave} is the average Spearman rank correlation coefficient over all $m(m-1)/2$ possible pairs. The coefficient of concordance, W, equals

$$W = \frac{[1+(m-1)r_{S-ave}]}{m}.$$

It should be noted that the coefficient of concordance, W, equals $1/m$, rather than zero, when all the Xs are independent, but that it does equal $+1$ for perfect positive association. Thus, W itself does not satisfy the general qualities required of a rank correlation coefficient as stated above. Moreover, logically one cannot have perfect negative association when $m > 2$, for if X_i and X_j were perfectly negatively associated, and if X_j and X_k also were, then that would automatically mean that X_i and X_k would have to be perfectly positively associated. For this reason, the most common situation for application of this approach is that of reliability or validity assessment, where it is assumed that the pairwise correlations are all positive.

An alternative method of computation is based on applying the formula for an intraclass correlation coefficient (itself based on two-way **analysis of variance** for N units by m observations [1]; *see* **Correlation**) to the ranks. Again, for small samples, the distributions under the null hypothesis of total independence have been tabled [4]. However, once again, given the context of use, there is seldom any a priori doubt that the true correlation exceeds zero. Thus, confidence interval estimation would be preferable. It has been shown that when the distribution of the m-dimensional vector is **multivariate normal**, with equal correlation coefficients between each pair of observations, with large sample size, the distribution of r_{S-ave} is approximately that of the intraclass correlation coefficient based on the actual observed values [7, 8]. Again, since r_{S-ave} is invariant under any strictly increasing transformation of any or all of the m-variables involved, the observed values themselves does not require a multivariate normal distribution in order for the approach to yield a good approximation. Both tests and confidence interval estimation may be based on this approximation [8]. In more general circumstances, bootstrap estimation might be used.

HELENA CHMURA KRAEMER

Rank Regression

The term *rank regression* was coined by Cuzick [7] to denote a regression model in which the **ranks** of the dependent variable were regressed on a set of covariates. The approach can be viewed as a hybrid between M-estimation and R-estimation (*see* **Robustness**). It differs from M-estimation in that the dependent variable is replaced by a score based on ranks and from R-estimation in that the ranks of the dependent variable itself are used, not those of the **residuals**. Since the ranks are unaffected by strictly increasing transformations, this approach can be formally specified by the model

$$g(t) = \boldsymbol{\beta}'\mathbf{z} + \varepsilon, \tag{1}$$

where g is any strictly increasing transformation of the dependent variable t, $\mathbf{z}$ is a vector of covariates, $\boldsymbol{\beta}$ are the corresponding regression coefficients and ε is the error term, usually taken to be mean zero. These models have also been called *transformation models*. The Box–Cox [3] model in which g is restricted to be a power law, or the logarithm, forms a well-known parametric submodel (*see* **Power Transformations**).

In general, the intercept term is undefined for this model, since it can be incorporated in g, and, for the same reason, information on scale is relative to the error term. Thus, when $\mathrm{E}(\varepsilon^2) < \infty$, one usually takes $\mathrm{var}(\varepsilon) = 1$ and interprets the regression coefficients in terms of number of the standard errors.

The most well-known rank regression model is the **proportional hazards** model

$$\lambda(t|z) = \lambda_0(t)\exp(\boldsymbol{\beta}'\mathbf{z}),$$

where $\lambda_0(t)$ is the unknown and completely unspecified baseline hazard function, and $\exp(\boldsymbol{\beta}'\mathbf{z})$ is the relative risk term indicating how covariates affect the hazard. This model can be rephrased in terms of (1) by letting

$$g(t) = \log \int_0^t \lambda_0(s)\,\mathrm{d}s,$$

taking ε to have (minus) an **extreme value** distribution:

$$p(\varepsilon \geq x) = \exp(-\mathrm{e}^x),$$

and changing the sign of $\boldsymbol{\beta}$. The motivation for rank regression models has come from survival analysis, but their use is not restricted to this area. More general rank regression models allow ε to have different distributional forms (e.g. **normal** or **Pareto**). The Pareto form has an interesting interpretation in terms of a proportional hazards model with an unknown (or unmeasured) regression parameter that is assumed to have a log **gamma** distribution and to be independent of the error term and the other covariates [6]. A useful special case is when the **frailty** also has a log-exponential distribution, leading to a symmetric error distribution (**logistic**). This model has an interpretation in terms of proportional **odds** [1], i.e.

$$\frac{F(t|\mathbf{z})}{1 - F(t|\mathbf{z})} = \exp(\boldsymbol{\beta}\mathbf{z})\frac{F_0(t)}{1 - F_0(t)},$$

where $F_0(t)$ is the baseline distribution of t and $F(t|\mathbf{z})$ is the distribution when the covariates take the value $\mathbf{z}$. Fully efficient and computationally feasible methods for estimating $\boldsymbol{\beta}$ (and g) are only known for the proportional hazards model, although Wu [18] has an efficient estimator for the proportional odds model in the two-sample case. Dabrowska & Doksum [8] have constructed a class of $n^{1/2}$-consistent and asymptotically normal estimates for the general Pareto model in the two-sample case. Klaassen [12] has investigated methods based on solving Sturm–Liouville equations for the Pareto model, and Magaluri [15] has some general theoretical results. Cuzick [7] proposes a method for estimating $\boldsymbol{\beta}$ for known general error distributions that are shown to be $n^{1/2}$-consistent and asymptotically normal, provided a consistent initial estimate exists. In essence, this method consists of replacing $g(t)$ by an estimate based on the ranks of the observed values of t and the marginal distribution of $\boldsymbol{\beta}'\mathbf{z} + \varepsilon$ (which depends on $\boldsymbol{\beta}$), and then using the **maximum likelihood** (ML) estimating equation for $\boldsymbol{\beta}$ corresponding to the distribution of the error ε. Specifically, for independent identically distributed (iid) samples $\{t_i, \mathbf{z}_i, i = 1, \ldots, n\}$ and error distribution F, let

$$F_b(t) = \frac{1}{n}\sum_{i=1}^{n} F(t - b\mathbf{z}_i)$$

for general b, and define

$$\bar{t}_i^b = F_b^{-1}\left(\frac{R_i}{n+1}\right),$$

where R_i is the rank of t_i. If $\phi = (\log F')'$ is the influence function for ε, then solve

$$\sum_{i=1}^{n} \mathbf{z}_i \phi(\overline{t}_i^b - b\mathbf{z}_i) = 0$$

for $\hat{b}$. The method also provides an estimate of the covariance matrix for $\hat{b}$, and $g(t)$ can be estimated in a $n^{1/2}$-consistent manner by

$$\hat{g}(t_i) = \overline{t}_i^{\hat{b}}(t_i),$$

with interpolation between the t_i. Weak convergence of this estimator was established. The estimate can be extended to deal with censoring by replacing $(R_i/n + 1)$ with the **Kaplan–Meier estimator** and replacing ϕ with $(\log F)'$ when t_i is censored. Further details can be found in [2].

Cheng et al. [5] have proposed a similar approach that is more easily analyzed when there is censoring. They define

$$\begin{aligned}\xi(\mathbf{z}_{ij}'\boldsymbol{\beta}) &= \Pr(\varepsilon_i - \varepsilon_j > \mathbf{z}_{ij}'\boldsymbol{\beta}) \\ &= \mathrm{E}(I\{g(t_i) - g(t_j)\}|z_i, z_j),\end{aligned}$$

where $\mathbf{z}_{ij} = \mathbf{z}_i - \mathbf{z}_j$. Note that $\xi(\mathbf{z}_{ij}'\boldsymbol{\beta})$ depends only on the error distribution for ε, which is assumed known so that this can be computed. They then define the **estimating function**

$$U(\boldsymbol{\beta}) \equiv \sum_{j=1}^{n}\sum_{i=1}^{n} w(\mathbf{z}_{ij}'\boldsymbol{\beta})\mathbf{z}_{ij}\{I\{t_i > t_j\} - \xi(\mathbf{z}_{ij}', \boldsymbol{\beta})\},$$

where w is a weight function, and choose a root $\hat{\boldsymbol{\beta}}$ of $U(\boldsymbol{\beta}) = 0$ as the estimate. To mimic the quasi-likelihood approach, the weight function is taken as

$$w(0) = \frac{\xi'(0)}{\{\xi(0)[1 - \xi(0)]\}}.$$

When censoring is present, and the potential censoring times are assumed to be iid with survival function $G(t) = P(c \geq t)$, they note that

$$\mathrm{E}\left(\left.\frac{\Delta_j I\{t_i \geq t_j\}}{G^2(t_j)}\right|_{z_i, z_j}\right) = \xi(\mathbf{z}_{ij}'\boldsymbol{\beta}_0),$$

where $\Delta_j = I\{T_j \geq C_j\}$ is the censoring indicator. The estimating function is modified to become

$$\begin{aligned}U(\boldsymbol{\beta}) = \sum_{i=1}^{n}\sum_{j=1}^{n} & w(\mathbf{z}_{ij}'\boldsymbol{\beta})\mathbf{z}_{ij} \\ & \times \left\{\frac{\Delta_j I(t_i \geq t_j)}{\hat{G}^2(t_j)} - \xi(\mathbf{z}_{ij}'\boldsymbol{\beta})\right\},\end{aligned}$$

where $\hat{G}(\cdot)$ is the Kaplan–Meier estimator for the survival function G of the **censoring** distribution. Cheng et al. [5] show that if the weights $w(\cdot)$ are positive, then $U(\boldsymbol{\beta}) = 0$ asymptotically has a unique solution and that when $w \equiv 1$ and $\sum\sum \mathbf{z}_{ij}'\mathbf{z}_{ij}$ is positive definite, the above equation has a unique solution for all n. Asymptotic normality is established and an expression for the variance is given that can be approximated from the data.

Lai & Ying [13] have also used the term *rank regression* to refer to models based on ranks of residuals in censored regression models. These models have a very different character and are based on the "aligned-rank" or R-estimator methods in [10, 16], and [11] for noncensored data. The classical approach is based on solving the estimating equation

$$\sum_{i=1}^{n} \mathbf{z}_i \phi(t_i - b\mathbf{z}_i) = 0,$$

where ϕ is the influence function for the chosen error distribution (see also [9]). Note that here t_i is used directly, not after transformation into $\overline{t}_i^b$, and the main goal of this approach is to provide robustness against misspecification of the error distribution. Early results for the two-sample problem with censoring were given in [14] and [17]. Another early approach along these lines for censored data was explored by Buckley & James [4]. They chose $\phi(t) = t$ corresponding to **least squares** regression, and developed an extension for censored data in which censored observations were replaced by their expected values based on current estimates of $\boldsymbol{\beta}$ and the Kaplan–Meier estimator. For dealing with censoring (and truncation), an estimating equation based on a weighted **logrank test** and martingale theory has proved more analytically tractable but is technically very demanding [19].

Rank Transformation

If a set of univariate observations are ordered from the smallest to the largest, then the position of an observation in the ordering is termed its **rank**. The smallest observation has rank 1, the next smallest rank 2, and the largest observation has rank equal to the number of observations. If for a set of observations on a variable X, denoted $x_1, x_2, \ldots, x_n$, $r(x_i)$ denotes the rank of the ith observation, then a rank transformation of X generates the set of ranks $r(x_1), r(x_2), \ldots, r(x_n)$.

Rank transformations of response variables play a fundamental role in many **nonparametric methods**. More generally, the **response variable** measurements for a set of observations are uniquely represented by their ranks and their **order statistics**. Model-based inference based on ranks typically derives from the **marginal likelihood** generated from the marginal distribution of the ranks. For example, the **partial likelihood** used for the **Cox regression model** in **survival analysis** corresponds to a marginal distribution based on ranks for uncensored survival data with no ties.

Rank transformations of explanatory variables in regression models may also be used. Their use might be motivated by a reluctance to rely too heavily on the measured values of the explanatory variable and can be regarded as a more general procedure than grouping the variable into a small number of classes. It has been suggested that rank transformations are particularly useful for **variable selection** [2].

A discussion of the link between standard parametric analysis procedures on rank transformed data and nonparametric procedures is provided in [1]. Ranking is also an essential component of statistical procedures based on **scores**.

VERN T. FAREWELL

Ranks

We are all familiar with ranks and rankings as they occur in everyday life. Ranks arise naturally in situations where performance or some other quality possesses a natural ordering from the "best" or "first" to the "worst" or "last", as, for example, the ordering of finishers in a race. If the n objects to be ranked are represented by the symbols $(o_1, o_2, \ldots, o_n)$, we denote by $r_i = r(o_i)$ the rank assigned to object o_i. Thus,

$$\mu = [r(o_1), r(o_2), \ldots, r(o_n)] = (r_1, r_2, \ldots, r_n)$$

is a *ranking* of the n objects, and is a permutation or rearrangement of the n integers $(1, 2, 3, \ldots, n)$. For example, if a judge is asked to rank four contestants (objects), then a ranking of these may be displayed as

$$\begin{array}{cccccc} \text{Object} & 1 & 2 & 3 & 4, \\ \text{Rank} & 3 & 2 & 4 & 1, \end{array}$$

where the object subscripts appear in the first line, so that in this case

$$r_1 = r(o_1) = 3, \qquad r_2 = r(o_2) = 2,$$
$$r_3 = r(o_3) = 4, \qquad r_4 = r(o_4) = 1.$$

Sometimes we may find it more convenient to think in terms of an *ordering* of the objects, in which case the above example may be represented as

$$\begin{array}{cccccc} \text{Rank} & 1 & 2 & 3 & 4, \\ \text{Object} & 4 & 2 & 1 & 3, \end{array}$$

i.e. rank 1 goes to o_4, rank 2 goes to o_2, rank 3 goes to o_1, and rank 4 goes to o_3.

The space of all possible rankings consists of the $n!$ permutations of the integers $(1, 2, 3, \ldots, n)$, so that, for example, with $n = 4$ objects we find that the $4! = 4 \times 3 \times 2 \times 1 = 24$ possible rankings are given by

$$\begin{array}{cccccc} 1234 & 1243 & 1324 & 1342 & 1423 & 1432, \\ 2134 & 2143 & 2314 & 2341 & 2413 & 2431, \\ 3124 & 3142 & 3214 & 3241 & 3412 & 3421, \\ 4123 & 4132 & 4213 & 4231 & 4312 & 4321. \end{array}$$

In such spaces of rankings one may be interested in probability models and in various statistical questions. One model is the so-called "null" or uniform model, which assumes that every possible ranking in the space is equally likely. Under such a model each object can equally achieve any of the n ranks, so that the expected rank of a given object is simply the sum of the first n integers divided by n,

$$\mathrm{E}(r_i) = \frac{1}{n}(1 + 2 + \cdots + n) = \frac{(n+1)}{2}.$$

Using the fact that the sum of squares of the first n integers is $n(n+1)(2n+1)/6$, we can also easily compute the variances and covariances of the ranks under the uniform model,

$$\mathrm{var}(r_i) = \frac{(n^2 - 1)}{12},$$
$$\mathrm{cov}(r_i, r_j) = -\frac{(n+1)}{12}, \quad 1 \le i \ne j \le n.$$

The properties of ranks under the uniform model are fundamental to the development of many nonparametric tests (*see* **Nonparametric Methods**), in that many such tests can be represented as *linear rank statistics*, i.e. as linear combinations of functions of the ranks.

In practice, it may be difficult for judges to rank a large number of objects, as, for example, if one is asked to taste test many varieties of apples. In such a situation we may prefer to present for comparison every one of the $\frac{1}{2}n(n-1)$ pairs of objects separately. **Paired comparisons** are discussed in [5] and [12]. Note that, although every ranking uniquely determines the outcome of every paired comparison, not every set of $\frac{1}{2}n(n-1)$ paired comparisons can be resolved into a ranking. Thus, in comparing three objects, a judge may prefer o_1 to o_2, o_2 to o_3, and yet prefer o_3 over o_1, creating what Kendall refers to as a "circular triad".

Models for the mechanism by which individuals generate rankings and models for nonnull distributions on the space of rankings can incorporate paired comparisons as long as only those preferences which can produce a ranking are permitted. Such an approach was originally introduced by Babington Smith [16]. Other approaches utilize **order statistics** and distances between rankings, and these originate with Thurstone [17] and Mallows [13]. A model which decomposes the ranking process into stages is discussed in Fligner & Verducci [10].

If, in fact, we actually observe a **random sample** $x_1, x_2, \ldots, x_n$ from a continuous distribution, then the order statistics are an ordering of these variables

from the smallest to the largest, denoted by $x_{(1)} < x_{(2)} < \cdots < x_{(n)}$, so that the rank of the ith order statistic $x_{(i)}$ is $r(x_{(i)}) = i, i = 1, \ldots, n$. The rank of the observation x_i is the value $r(x_i) = r_i$ equal to the number of observations $\leq x_i$.

Distances between rankings arise naturally in any situation where we need to measure how "close" two different rankings are. Various such distances can be defined and some of the more useful ones are studied in Diaconis & Graham [7]. If we denote the distance between the rankings μ_1 and μ_2 of judges 1 and 2 by $d(\mu_1, \mu_2)$, then the **rank correlation** between the two rankings can be defined as

$$\alpha(\mu_1, \mu_2) = 1 - \frac{2d(\mu_1, \mu_2)}{M},$$

where M is the largest possible distance between two rankings. By choosing an appropriate distance we can generate both **Spearman's** and Kendall's rank correlation, among others. In the case of Spearman, the appropriate distance is the squared Euclidean distance between the two rankings, which we call Spearman's distance, defined as

$$d_s(\mu_1, \mu_2) = \frac{1}{2} \sum_{i=1}^{n} [r_1(o_i) - r_2(o_i)]^2,$$

for which the maximum is $M_S = n(n^2 - 1)/6$.

In a **randomized block design**, where m judges (blocks) rank n objects (treatments), the average distance between all $\frac{1}{2}m(m-1)$ pairs of rankings measures the level of agreement or *concordance* between the judges and generates a test statistic for treatment effects (*see* **Agreement, Measurement of**). When the distance is Spearman, this measure is essentially Kendall's coefficient of concordance W, [12], and the test reduces to Friedman's test. Other distances will generate different test statistics, so that, for example, the distance which generates Kendall's rank correlation yields a concordance statistic introduced by Ehrenberg [9] and studied in Alvo et al. [3].

Up to this point we have assumed that all objects are to be ordered so that there is a strict preference. However, either by design or by circumstance, there may not be a preference between two or more objects. In such situations the space of possible rankings is no longer the space of permutations of $(1, 2, 3, \ldots, n)$.

For example, a judge may be asked to pick from a list of eight possible qualities of a mate the three qualities that best describe an ideal partner. If the best three are to be ordered, then the ranks would be 1, 2, 3, for the top three and a 4 for each of the remaining five least preferred qualities. An example in which the best three qualities are o_4, o_2, and o_1, in that order, would give the *partial ranking*

Quality	1	2	3	4	5	6	7	8,
Rank	3	2	4	1	4	4	4	4.

If, on the other hand, the top three are not required to be ordered, then the partial ranking will contain only two distinct numbers, a 1 for each of the top three, and a 2 for each of the remaining seven. The above example then becomes

Quality	1	2	3	4	5	6	7	8,
Rank	1	1	2	1	2	2	2	2.

Distances between partial rankings may be defined in various ways and used to approach various statistical questions. An important work in this area is Critchlow [4].

A similar problem arises when a distinct ranking is expected but for some reason the ranking has *ties*. For example, the ranking may have been generated from a random sample $x_1, x_2, \ldots, x_n$ in which not all the x_i values are distinct. How we assign values to the tied ranks depends on the situation. In the context of certain nonparametric tests the usual approach is to assign each set of tied objects the *midrank*, i.e. the average of the ranks they would have received had they not been tied. This is done partly to ensure that $\mathrm{E}(r_i)$, the expected rank of observation i, remains $(n+1)/2$. The example above, in which the first three are ordered and the rest and tied, would now become

Quality	1	2	3	4	5	6	7	8,
Rank	3	2	6	1	6	6	6	6.

A very good discussion on dealing with ties may be found in Pratt & Gibbons [15]. Note that the presence of ties has various implications on the null distributions of many nonparametric tests.

Certain situations may arise as in the apple tasting example above, where it is much easier for the judges to rank a small set of objects. In such a case we may want to present to the judges only a subset of k of the possible n objects for their consideration. The ranking of this subset is known as an *incomplete ranking*. Such rankings may also arise by chance if, for example, the ranking arises from a random

sample $x_1, x_2, \ldots, x_n$ in which some of the x_i values are missing. Distances between incomplete rankings and corresponding measures of rank correlation are discussed in Alvo & Cabilio [2].

The pattern of k out of n objects (treatments) presented to each of m judges may be designed to follow a **balanced incomplete block design**. The classical test for treatment effect in such a situation is a generalization of Friedman's test due to Durbin [8]. The Durbin statistic turns out to be essentially the average of the Spearman distances between all $\frac{1}{2}m(m-1)$ pairs of incomplete rankings, and an analogous statistic can be defined using the Kendall distance (see [1]).

There has been a resurgence of interest in the area of ranking models and rank-based statistical methods in recent years. Some noteworthy books are that by Diaconis [6] and a very complete coverage of the subject by Marden [14]. Also of some interest is a collection of papers in this area edited by Fligner & Verducci [11].

PAUL CABILIO

Rao–Blackwell Theorem

This theorem gives a general way of reducing the variance of an **unbiased** estimator when a **sufficient statistic** is available. It also brings about the relevance of sufficiency to the question of seeking a **minimum variance unbiased estimator** (see [3] and [5]).

The most familiar version of the Rao–Blackwell theorem is stated in the following form.

Theorem A. Let $(P_\theta : \theta \in \Theta)$ be a family of probability distributions on a sample space X and suppose that $\tilde{\tau}$ is an unbiased estimator of a real-valued function τ of θ. Then if $T = T(X)$ is a sufficient statistic for θ, $\hat{\tau} = \mathrm{E}_\theta[\tilde{\tau}|T]$ is also an unbiased estimator of $\tau(\theta)$, and $\mathrm{var}_\theta(\hat{\tau}) \leq \mathrm{var}_\theta(\tilde{\tau})$ for all θ; that is, $\hat{\tau}$ is a uniformly better unbiased estimator.

An important use of this theorem is to establish the existence of uniformly minimum variance unbiased estimators. This is done by demanding the existence of a sufficient statistic T with an additional property such as *completeness* (*see* **Sufficient Statistic**). For example, let $X_1, X_2, \ldots, X_n$ be independently, identically distributed (iid) in a **Poisson distribution** with mean θ, and suppose that $\tau(\theta) = \mathrm{e}^{-\theta}$ is the parameter of interest. Let $\hat{\tau} = 1$ if $X_1 = 0$, and $\hat{\tau} = 0$ if $X_1 \neq 0$. This is obviously an unbiased estimator of $\tau(\theta)$. It is clear that, if we consider the statistic $\hat{\tau} = \mathrm{E}_\theta(\tilde{\tau}|T)$, where $T = \sum_{i=1}^{n} X_i$ is a complete sufficient statistic, then $\hat{\tau} = [1 - 1/n]^{\mathrm{T}}$ and is the unique minimum variance unbiased estimator of $\tau(\theta)$ (see [5, Sections 2.5 and 2.6]).

In the event that $\tau(\theta)$ is a vector or $\tilde{\tau}$ is not unbiased, Theorem A does not apply. We give below a more general version of the Rao–Blackwell theorem formulated in terms of **decision theory**.

Theorem B. Let the action space A be a convex subset of R^k, and suppose that the **loss function** $L(\theta, a)$ is a convex function of $a \in A$ for each $\theta \in \Theta$. Suppose that T is a sufficient statistic for θ. If $\tilde{\tau}(X)$ is a decision rule, then the decision rule based on T, defined by

$$\hat{\tau}(T) = \mathrm{E}[\tilde{\tau}(X)|T],$$

is a decision rule that is as good as $\tilde{\tau}$ provided that this expectation exists; that is, the **risk** of $\hat{\tau}$ is no larger than that of $\tilde{\tau}$.

The Rao–Blackwell theorem was proved by Rao [4] and Blackwell [1] for unbiased estimators with squared error loss in the form of Theorem A. The general version, Theorem B, can be found in [3] or [2].

Rasch Models

In psychological tests (*see* **Psychometrics, Overview**) or attitude studies, we are often interested in quantifying the value of an unobservable *latent trait*, such as mathematical ability or manual dexterity, on a sample of individuals (*see* **Path Analysis**). While latent traits are not directly measurable, we assume that we can assess indirectly a person's value for the latent trait from his/her responses to a set of well-chosen items on a test. In some studies, interest centers on traits associated with the items in the test (for example, difficulty of each item) rather than on individual traits.

Initial attempts at modeling latent variables included *formal measurement models*, two examples of which are the standard factor models, and what are known as Thurstone models for attitude scaling (see, for example, Molenaar [32]; **Factor Analysis, Overview**; **Latent Class Analysis**; **LISREL**). It is now widely recognized that a better alternative to classical test theory is what is known as *Item Response Theory* (IRT) – see, for example, [21] and [7]. Item response theory states that when a person is confronted with an item (for example, a question in a test), the probability of a certain response is a function of the person's position on the latent trait, plus one or more parameters associated to the particular item. For each item, the *item response function* (IRF) is the probability of a certain answer given as a function of the latent trait value.

A fundamental component of IRT is the family of Rasch models (RM), introduced by Danish statistician **Georg Rasch** [33]. Given responses from n individuals to k items in a test, the RM permits the estimation of parameters associated with individuals and with items, as well as prediction of the person's behavior when confronted with a different set of items from the same domain. The individual parameter is often referred to as *ability*, while item parameters refer to the *difficulty* (or simplicity) of each item. When the ability parameter is high and the difficulty parameter is low, the probability of a correct answer to the item increases. Here, we view "persons", "items", and "responses", in a general context, with "persons", for example, representing perhaps laboratory animals or households. In the example given later, "persons" represent individuals, "items" represent different influenza outbreaks, and "responses" are binary (individuals get sick or not in each outbreak).

Rasch models can be of at least two kinds. If the number of possible answers to each item is two, then the RM is called *dichotomous* (*see* **Binary Data**); otherwise, the model is said to be **polytomous**. In the dichotomous RM, positive answers are indicative of a high position in the latent trait scale.

The Rasch model from psychological testing is a simple but very important logistic response model (*see* **Logistic Regression**) that allows for the incorporation of individual effects. It has important technical links to a subclass of the better-known **loglinear models** involving **quasi-symmetry**. As a consequence we can think of the heterogeneity resulting from the Rasch model's individual effects as inducing a specific form of dependence in the loglinear model used to describe the cross-classification of responses to several variables when we aggregate across individuals. The Rasch model thus serves as a heuristic for interpreting this special kind of heterogeneity in more general loglinear model settings. There are, of course, alternative approaches to heterogeneity such as stratification and the use of regression-like components utilizing additional explanatory variables that "account for" heterogeneity, but we do not pursue these here. Among regression-like approaches to modeling heterogeneity, *generalized mixed linear (or nonlinear) models* (*see* **Generalized Linear Model**) have received increased attention recently, in particular in the context of **longitudinal data analysis**; see, for example, [28] and [14], and the references given therein (*see* **Generalized Linear Models for Longitudinal Data**).

This article introduces the Rasch model, describes the important link to loglinear models, and illustrates the Rasch model approach to interpreting interactions in the context of an example on infection in response to a series of influenza outbreaks.

The Rasch Model

We focus on the RM for the dichotomous case. Let $S_1, S_2, \ldots, S_n$ denote the n individuals providing binary responses to k items $I_1, \ldots, I_k$ that measure the same latent trait θ. It is assumed that each individual S_i has a value θ_i that reflects his/her position on the latent trait scale (ability). Furthermore, each item

I_j has a parameter α_j associated with it that denotes the difficulty of the item. (Generalizations of the simple RM allow for more than one parameter associated with an item. For example, an additional item parameter may reflect a change in the difficulty of the item for an individual who takes the same test at two different times. For more details, refer to Fischer [22, 23] and Embretson [17].)

If we let $\mathbf{X}$ denote the $n \times k$ matrix of responses, and $\boldsymbol{\alpha}$ and $\boldsymbol{\theta}$ denote the vectors of item and individual parameters, respectively, the simple dichotomous RM states that

$$\Pr(X_{ij} = x_{ij} | \boldsymbol{\theta}_i, \boldsymbol{\alpha}_j) = \frac{\exp[x_{ij}(\theta_i - \alpha_j)]}{1 + \exp(\theta_i - \alpha_j)}, \qquad (1)$$

where the entries x_{ij} are either 0 or 1. Thus

$$\log\left[\frac{\Pr(X_{ij} = 1 | \theta_i, \alpha_j)}{\Pr(X_{ij} = 0 | \theta_i, \alpha_j)}\right] = \theta_i - \alpha_j, \qquad (2)$$

so the RM is evocative of the *logit* model for the log **odds** for $X_{ij} = 1$ vs. $X_{ij} = 0$ (*see* **Logistic Regression**).

A standard approach to modeling the matrix of responses $\mathbf{X}$ is to assume independence of items *and* of individuals. The assumption of independence among persons is one we typically make in multivariate problems (*see* **Multivariate Analysis, Overview**), and when it fails to hold we often turn to dependence structures described by loglinear models. The assumption of independence of answers within an individual, however, deserves some explanation. Intuitively, given a sample of individuals with different values for the latent trait, we would expect a positive correlation between the value of θ and the number of positive answers. For a given individual the model assumes, however, that all systematic variation between items is explained by the value of θ. Thus, we can use a conditional independence argument and say that, given θ, the responses of an individual to different items are independent. This is referred to as *local independence*. Under these assumptions, the likelihood function for the matrix of responses $\mathbf{X} = \mathbf{x}$ is given by

$$\Pr(\mathbf{X} = \mathbf{x} | \boldsymbol{\theta}, \boldsymbol{\alpha}) = \prod_{i=1}^{n} \prod_{j=1}^{k} \frac{\exp[x_{ij}(\theta_i - \alpha_j)]}{1 + \exp(\theta_i - \alpha_j)}$$

$$= \frac{\prod_{i=1}^{n} \exp\left[\theta_i x_{i+} - \sum_{j=1}^{k} \alpha_j x_{ij}\right]}{\prod_{i=1}^{n} \prod_{j=1}^{k} (1 + \exp[\theta_i - \alpha_j])}, \qquad (3)$$

where $x_{i+} = \sum_{j=1}^{k} x_{ij}$ are the individual *scores* or total number of correct answers for each individual. Model (3) is overparameterized, since for any constant c and for $\theta_i^* = \theta_i + c$ and $\alpha_j^* = \alpha_j + c$ we have that $\theta_i^* - \alpha_j^* = \theta_i - \alpha_j$. We can estimate the parameters in the model, however, by imposing a restriction that fixes the origin of the scale. Typically, we use the restriction $\alpha_+ = \sum_j \alpha_j = 0$ but, equivalently, we could also set $\theta_+ = 0$.

One very appealing aspect of the model is the existence of very simple **sufficient statistics** for both θ_i and α_j. Note that model (3) has an **exponential family** form, and so it is simple to show that the sum of correct answers x_{i+} for an individual is sufficient for the individual parameter θ_i, and the sum of correct answers for an item across individuals, $x_{+j} = \sum_i x_{ij}$, is sufficient for the item parameter α_j (see, for example, [5], [6], [30], and [31]). Because these sufficient statistics are in fact the "margins" of the matrix $\mathbf{X}$, we should not be surprised to discover that there are interesting links between methods of estimation for RMs and certain loglinear models.

Several estimation methods for the parameters in (3) have been proposed – for example, see [21] and [24]. Essentially, unrestricted **maximum likelihood** (ML) estimation has problematic asymptotic properties. Since the model includes one parameter for each individual in the sample, as $n \to \infty$ the number of parameters also goes to infinity, and thus ML estimators of individual and of item parameters are inconsistent. We refer the reader to [5] for a detailed discussion of ML estimation in the RM and to [27] for an interesting Bayesian treatment. The method of *conditional maximum likelihood estimation* (CML), first proposed by Rasch [33] and based on maximizing the likelihood function conditional on the individual scores, is an alternative to unrestricted estimation and gives rise to consistent estimators for item parameters. Further, such a conditional approach to estimation provides some direct links to maximum likelihood estimation for *loglinear models* applied to derived contingency tables. We describe this linkage below.

RM and its Relation to Loglinear Models

The conditional approach to likelihood estimation (CML) was suggested initially by Rasch, who noted that the conditional distribution of $\mathbf{X}$ given the individual marginal totals $\{X_{i+} = x_{i+}\}$ depends only on the item parameters, $\boldsymbol{\alpha}$. Each of the row sums $\{X_{i+}\}$ can take only $k+1$ distinct values corresponding to the number of correct responses. Next, we recall the alternate representation of the data in the form of an $n \times 2^k$ array, $\{\mathbf{W}\} = \{W_{ij_1 j_2,\ldots,j_k}\}$, where $W_{ij_1 j_2,\ldots,j_k} = 1$ if individual i responds $\{j_1, j_2, \ldots, j_k\}$ to the k items, and $= 0$ otherwise. Adding across individuals we create a 2^k contingency table, $\mathbf{Y}$, with entries $Y_{j_1 j_2,\ldots,j_k} = W_{+j_1 j_2,\ldots,j_k}$.

We can work with this collapsed array since all of the information we need is the response pattern, i.e. $\{j_1, j_2, \ldots, j_k\}$, and the number of "correct" responses that correspond to that pattern. Such information allows us to completely reconstruct the original matrix of responses, $\mathbf{X}$, except for the labeling of individuals, and thus we can use the 2^k array $\mathbf{Y}$ to represent the conditional distribution of $\mathbf{X}$ given $\{X_{i+} = x_{i+}\}$.

Duncan [16] and Tjur [34] independently noted that we can estimate the item parameters for the *conditional Rasch model* that arises from expression (1) using the 2^k array $\mathbf{Y}$, and certain loglinear models. The conditional RM is obtained by conditioning on the value of the individual scores $\{x_{i+}\}$. The resulting expression is

$$\Pr(X_{ij} = x_{ij},\, j = 1, 2, \ldots, k | \{x_{i+}\}, \boldsymbol{\alpha}) = \frac{\exp\left(-\sum_{j=1}^{k} \alpha_j x_{+j}\right)}{\gamma_i(\alpha_1, \ldots, \alpha_k)}, \quad (4)$$

where $\gamma_i(\alpha_1, \ldots, \alpha_k)$ are elementary symmetric functions given by

$$\gamma_{x_{i+}}(\alpha_1, \ldots, \alpha_k) = \sum_{x_1} \cdots \sum_{x_k} \exp\left(-\sum_{j} \alpha_j x_{+j}\right), \quad (5)$$

subject to $\sum_j x_{ij} = x_{i+}$.

More specifically, Tjur [34] shows that maximum likelihood estimation of the 2^k contingency table of expected values, $\mathbf{m} = \{m_{j_1 j_2,\ldots,j_k}\}$, using a **Poisson** sampling scheme and the loglinear model

$$\log m_{j_1 j_2,\ldots,j_k} = \omega + \sum_{j=1}^{k} \delta_j - \sum_{i=1}^{n} \log \gamma_{x_{i+}}(\alpha_1, \ldots, \alpha_k), \quad (6)$$

with $\omega = \log n$ and $\delta_j = -\alpha_j x_{+j}$, leads to consistent estimators of item parameters in the conditional RM (4). The sums of elementary symmetric functions in (6) turn out to depend only on the values for the totals $\{x_{i+}\}$, and thus there are only $k+1$ distinct values. Tjur proves this equivalence by: (i) assuming that the individual parameters are independent identically distributed random variables from some completely unknown distribution, π; (ii) integrating the conditional distribution of $\mathbf{X}$ given $\{X_{i+} = x_{i+}\}$ over the mixing distribution, π; (iii) embedding this **"random-effects"** model in an "extended random model"; and (iv) noting that the likelihood for the extended model is equivalent to that for expression (6) applied to $\mathbf{Y}$. An important technical issue, not explored further here, is the set of moment inequalities that must be satisfied for π (see [10]). Kelderman [29] gives a step-by-step derivation of the loglinear models that correspond to both the unconditional RM of expression (1) and the conditional RM of expression (4), and Fienberg & Meyer [19] present a related description and also an equivalent representation in the form of a **multiplicative model**, which we reproduce here in Table 1.

The *multiplicative parameters* a, b, and c in this Table correspond to δ_1, δ_2, and δ_3, and the multiplicative parameters $\{S_i\}$ correspond to the $k+1$ distinct values of the sums of elementary symmetric functions in (6). The minimal sufficient statistics are

$$\{y_{i++}\}, \{y_{+j+}\}, \{y_{++k}\}$$

Table 1 Multiplicative form for the expected values $\mathbf{m}$ in the Rasch model for the 2^3 table

		Item C			
		Yes		No	
		Item A		Item A	
		Yes	No	Yes	No
Item B	Yes	$abcS_3$	bcS_2	abS_2	bS_1
	No	acS_2	cS_1	aS_1	S_0

and

$$\{y_{111}, y_{110} + y_{101} + y_{011}, y_{100} + y_{010} + y_{001}, y_{000}\}.$$

Note that these are the minimal sufficient statistics of the model of *quasi-symmetry* preserving one-dimensional marginal totals.

A 2^k contingency table is *symmetric* if the expected counts under all possible permutations of subscripts are equal. Symmetry implies that all of the r-way sets of marginal totals are equal to one another for $r = 1, 2, \ldots, k-1$. Quasi-symmetry generalizes this notion by allowing sets of lower-order marginal totals to differ (see [8, Chapter 8]). The quasi-symmetry model preserving one-dimensional marginal totals for a 2^k table is equivalent to that of expression (6). Additional simplifications ensue here because

$$\hat{m}_{111} = y_{111}, \qquad \hat{m}_{000} = y_{000}.$$

For more details on this relationship between quasi-symmetry and the Rasch model, see [18, 20]. In particular, they point out the relevance of the moment constraints described by Cressie and Holland [10], that are not encompassed in the quasi-symmetry structure (see also [9]). Agresti [1–4], Darroch et al. [13], and Kelderman [29] all explore further aspects of these loglinear representations for the Rasch model, as we do in a limited fashion in the example below. A parallel literature in the 1980s linked models for individual heterogeneity, similar to the Rasch model, with models of symmetry and quasi-symmetry (for example [11]). Darroch & McCloud [12] give an especially interesting application of this approach to an example involving the separation of sources of dependence in a series of four influenza outbreaks. Their model is similar to a generalized Rasch model but uses a **fixed-effects** version for heterogeneity rather than the random-effects version described above. We revisit this example in the next section.

Example: Influenza Outbreaks in Michigan

Table 2 contains infection frequencies to four influenza outbreaks for a sample of 263 individuals in Tecumseh, MI during the winters of 1977/78 to 1980/81. These data were first reported by Haber [25] and later analyzed in depth by Darroch & McCloud [12]. One interesting aspect of these data is that outbreaks 1 and 4 were caused by the same type of virus, and thus responses (conditional on individuals) to these two outbreaks are potentially dependent. Since we have already collapsed over individuals, the data form a 2^k contingency table, where $k = 4$ for the four influenza outbreaks and corresponds to the number of items for a standard Rasch model.

Table 2 Infection profiles and frequency of infection for the influenza example

j_1, j_2, j_3, j_4	Frequency	j_1, j_2, j_3, j_4	Frequency
0 0 0 0	140	1 0 0 0	20
0 0 0 1	31	1 0 0 1	2
0 0 1 0	16	1 0 1 0	9
0 0 1 1	3	1 0 1 1	0
0 1 0 0	17	1 1 0 0	12
0 1 0 1	2	1 1 0 1	1
0 1 1 0	5	1 1 1 0	4
0 1 1 1	1	1 1 1 1	0

To understand the different sources of heterogeneity in this example, consider an individual who, by virtue of her personal characteristics, is highly susceptible to influenza. She is likely to succumb to outbreaks 1, 2, and 3, as expected, but is unlikely to get sick during outbreak 4. Since outbreaks 1 and 4 are caused by the same type of organism, individuals who get sick during outbreak 1 develop some degree of immunity to the virus, thus inducing a negative dependence between outbreaks 1 and 4.

We can fit RM such as (1) to these data in a straightforward manner if we assume independence among individuals and among influenza outbreaks. This assumption might be reasonable if all influenza outbreaks were caused by different types of virus. The loglinear model arising from the conditional representation (4) of the RM (in the u-term notation of Bishop et al. [8], and used in the article on **Loglinear Models**) is

$$\log m_{j_1 j_2 j_3 j_4} = u + \sum_{j=1}^{4} u_j(x_j) + u_5(x_{i+}), \qquad (7)$$

where the $u_5(x_{i+})$ and the $u_j(x_j)$ factors correspond to individual scores and influenza parameters, respectively, and is simply the u-term representation for the loglinear model of expression (6).

The model in (7) corresponds to a standard RM, and therefore does not accommodate the negative correlation between outbreaks 1 and 4. Thus, we do not expect it to fit these data well. More appealing models for these data would include one or more interaction terms to represent the dependence between outbreaks 1 and 4. One such model, suggested by the Darroch & McCloud analysis, includes an interaction between outbreaks 1 and 4 and is given by

$$\log m_{j_1 j_2 j_3 j_4} = u + \sum_{j=1}^{4} u_j(x_j) + u_{14}(x_1 x_4) + u_5(x_{i+}), \tag{8}$$

where the $u_{14}(x_1 x_4)$ are associated with the four possible infection profiles when considering only outbreaks 1 and 4.

Model (8) may still be underparameterized, insofar as it does not include an **interaction** term for individual scores × outbreaks parameters. From an intuitive viewpoint, the interaction between scores x_{i+} and the first outbreak x_1 should be included, since the value of the score might well depend on the individual's response to x_1 and, conditional on x_1, also on the response to x_4. Another way to think about this is the following. Consider the ways an individual can obtain a score $x_{i+} = 2$. If he does not get sick during outbreak 1, then he can obtain the score of 2 in three different ways, each with the same probability of occurrence given independence among outbreaks (2, 3, 4). If he gets sick during outbreak 1, however, then he needs one more infection to round up the score, but now each of the three possible infection patterns does not have equal probability, in light of the dependence between outbreaks 1 and 4. To capture such an effect, we consider a third model closely linked to the analysis of Darroch & McCloud with an additional interaction term:

$$\log m_{j_1 j_2 j_3 j_4} = u + \sum_{j=1}^{4} u_j(x_j) + u_{14}(x_1 x_4) + u_5(x_{i+}) + u_{15}(x_1, x_{i+}). \tag{9}$$

We fitted models (7), (8), and (9) to the influenza infection data in Table 2, and compared the fit of the models using the usual likelihood-ratio chi-square statistic, G^2 (*see* **Likelihood Ratio Tests**), as reported in Table 3.

Table 3 Degrees of freedom and deviance statistics for the three models fitted to the influenza data

Model	Degrees of freedom	Deviance G^2
Rasch model (no interactions)	8	25.79
RM + outbreaks 1 and 4 interaction	7	16.11
RM + outbreak (1, 4) + score by outbreak 1 interactions	5	5.52

From Table 3 we see that, as expected, the standard RM did not fit the data well. The fit of the model improved considerably when we added the first interaction term, between the first and fourth outbreaks. While this model accounts for the fact that both outbreaks 1 and 4 are caused by the same type of virus, it ignores the effect that the response to the first outbreak has on individual scores. The last model we fitted includes this effect, and its fit is superior to that of the other two models.

Note that, while model (7) corresponds to the standard RM for this problem, neither loglinear models (8) or (9) have an RM representation. In fact, the latter two models are not RM at all, due to the presence of the interaction terms. Nonetheless it is interesting to see that reasonable loglinear models can be obtained by starting with the RM as a basis, and then adding terms as needed to model potential dependences not accommodated by the simple RM.

Finally, Table 4 gives the estimated cell counts for the 2^4 contingency table under the three fitted models. Given its better fit, model (9) produces values of cell counts that are in good agreement with observed counts. We can also compare the estimated values with observed frequencies in Table 4. Estimated infection frequencies computed from the RM (7) over- and underestimate observed cell counts in the expected direction. For example, the RM model tends to overestimate infection frequencies in cells $\{0, j_2, j_3, 0\}$ and $\{1, j_2, j_3, 1\}$, which is consistent with the assumption of independence among outbreaks.

Summary

The Rasch model comes to general statistical practice, and biostatistics in particular, from psychological

Table 4 Infection profiles, observed frequencies, and estimated frequencies under three loglinear models of infections during the four influenza outbreaks

1 1 1 1	0	0.0	0.0	0.0

testing, and it generalizes the model of independence among a set of response variables by allowing for the incorporation of individual effects. Thus we speak of local independence, conditional on the individual. In this article we have shown an important connection between the Rasch model and a special loglinear model for the usual contingency table representation of the relevant response variables, that of quasi-symmetry. As a consequence we can think of quasi-symmetry as providing a representation for dependence introduced by Rasch-model-like heterogeneity. Through an example dealing with influenza epidemics, we have illustrated here how loglinear generalizations of this Rasch model representation are useful in biostatistical contexts involving such forms of heterogeneity.

The most extensive area of application of this type of approach to heterogeneity to date has come in the area of **capture–recapture** modeling – for example, see [9, 13, 15, 20] and [26]. As we noted at the outset, there are alternative approaches to heterogeneity such as stratification and the use of regression-like components utilizing additional explanatory variables that "account for" heterogeneity. The principal example in [26], dealing with the ascertainment of diabetes in a region of Italy, contrasts the results of generalized-Rasch-like loglinear models and separate loglinear models for separate strata. Fienberg, Johnson and Junker [20] revisit this example and provide an alternative Bayesian analysis based on the Rasch model and some generalizations of it.

ALICIA L. CARRIQUIRY &
STEPHEN E. FIENBERG

Rasch, Georg

Born: September 21, 1901, in Odense, Denmark.
Died: October 19, 1980, in Byrum, Laesø, Denmark.

Georg Rasch was Professor of Statistics from 1962 to 1972 at the University of Copenhagen. He received his degree in mathematics from the University of Copenhagen in 1925 and worked as a mathematician at the university until 1930, when at age 29, he became a doctor of science on a dissertation concerned with matrix calculations and its applications in differential and difference equation theory [1]. At the time, he was considered to be one of the most talented of the new generation of Danish mathematicians. But as no satisfactory position was created for him as a mathematician, he chose to work as a consultant in applied mathematics, primarily data analysis and statistics. In the 1930s he worked with problems in medicine and biology, but he later added education, psychology and sociology as fields of interest (*see* **Social Sciences**).

Between 1935 and 1936, he visited University College in London, primarily to work with **R.A. Fisher**. He was much impressed by Fisher's ideas on the foundations of mathematical statistics and introduced them in Denmark after his return. In the following years, he worked primarily at the State Serum Institute, where he founded the Biostatistics Department and was its director from 1940 to 1956. In this capacity, he made many contributions to new developments in biology and medicine, primarily as a consultant for doctoral dissertations by the scientists at the Institute and many other medical doctors. He had, however, a much more lasting influence on the development of statistics, in both theory and applications, through the fact that most, if not all, of the next generation of Danish statisticians worked as his assistants at the Serum Institute. For example, Professor A. Hald started his career as an assistant to Rasch.

In the 1940s and 1950s he had various part-time teaching assignments at the university, but it was not until 1961, when he was almost 60 years old, that he was appointed to a chair in statistics at the University of Copenhagen. It may seem surprising, but it is nevertheless a fact, that he did not work with applications in education and psychology until the mid-1950s, when he was into his own fifties. These disciplines occupied most of his thinking in the 1960s and 1970s, and it was here that he made his most original contributions. As a consultant to the Ministry of Social Affairs, to the Office of Military Psychology, and to the Danish Educational Research Institute, he was faced with the task of extracting information on individuals from intelligence and ability tests. He rejected the traditional statistical methods, primarily based on various factor analytic techniques (*see* **Factor Analysis, Overview**), and developed new and more exact methods based on latent trait models as we know them today. The most simple and elegant of these models was fully developed by Rasch in 1960 and now bears his name: the **Rasch model**. The model was not invented as a new theoretical development, but was established through careful study of the empirical data with which he worked. He also realized that the model required a new statistical methodology based on the use of **conditional probabilities**. In 1960, in his famous book [2] and in an important paper read at the Berkeley Symposium on Probability and Statistics [3], he presented both a new revolutionary model and an associated fascinating new statistical methodology. The model was developed further in the following years and he made many important applications of it, but to a remarkable degree the theory was developed within a span of three to four years. In the 1960s and 1970s there followed a few papers in which he tried to extend his discoveries from 1960 to a more general theory of measurement primarily directed toward the social sciences. It was these ideas that occupied his thinking for the rest of his life. In his scientific works, Rasch combined mathematical skill and a skill for reading empirical evidence in a unique way. He used mathematics to make ideas precise and to formulate the theoretical framework for the analysis of data in an exact way. But data from real life were the main source for all his theoretical developments and model formulations. Rasch was thus an early and eager advocate of checking the fit of a model by statistical and/or graphical methods (*see* **Model Checking**). Georg Rasch was a knight of the Danish order of Dannebrog and an honorary member of the Danish Statistical Society.

Rate

Rate refers to a limiting ratio of the changes in two quantities as these changes tend to zero. The denominator often involves time, t, as for the **hazard rate**, $\lambda(t) = \lim_{\Delta\downarrow} \Delta^{-1} \Pr$ (disease first occurs in $[t, t+\Delta)$|disease first occurs at or after t). The notation $[t, t+\Delta)$ means that the event occurs at or after t but before $t+\Delta$.

Sometimes rate refers to a proportion, as in neonatal mortality rate and **prevalence rate**.

MITCHELL H. GAIL

Ratio and Regression Estimates

Ratio and regression estimators are used to improve the precision of estimates of a population total or **mean**, by exploiting the relationship between an outcome y, and an auxiliary measurement x. Estimates of ratios themselves are also often made – these include **rates** and proportions for the population and for targeted subgroups. Such estimates are widely used in biostatistical research; indeed most public-use data tapes are issued with **poststratified** ratio adjustments (based on sex, race, and age) to the sampling weights. Domain estimates can be viewed as ratio estimates as well, so that epidemiologic **prevalence** estimates for population subgroups are essentially ratio estimates. In the following, estimators, along with **variance** estimates for population totals, are discussed; for estimators of population means, divide by N, and adjust the variance estimate by N^{-2}.

Ratio Estimators

The ratio estimator is used when two numbers are associated with each of N units in a finite population. One of these is a positive known quantity x, and the other is an unknown y, the outcome measure of interest. Letting s be the set of n units in a sample from the population, the ratio estimate for the population total, $T = \sum_{i=1}^{N} y_i$, is

$$\hat{T}_R = \frac{\sum_{i\in s} y_i}{\sum_{i\in s} x_i} \sum_{i=1}^{N} x_i = \hat{R}X, \qquad (1)$$

where $\sum_{i\in s}$ denotes the sum over the sample units, $\hat{R} = \sum_{i\in s} y_i \big/ \sum_{i\in s} x_i$ is the sample ratio, and X is the population x-total. The sample ratio can also be written

$$\hat{R} = \frac{\overline{y}_s}{\overline{x}_s} = \frac{N\overline{y}_s}{N\overline{x}_s} = \frac{\hat{Y}}{\hat{X}},$$

where $\overline{y}_s = n^{-1}\sum_{i\in s} y_i$ and $\overline{x}_s = n^{-1}\sum_{i\in s} x_i$ are the sample means, $\hat{Y} = N\overline{y}_s$ and $\hat{X} = N\overline{x}_s$ are the simple expansion estimators of the population y-total, T, and the population x-total, X, respectively. This makes $\hat{R}$ a natural estimate of the population ratio $R = \sum_{i=1}^{N} y_i \big/ \sum_{i=1}^{N} x_i$.

A domain is defined by a sample characteristic which is generally not available until the survey has been executed. Suppose we are interested in the average number of physician visits in the past year for Latinas aged 18 to 64. Letting $z_i = 1$ if the respondent is in this category and $z_i = 0$ otherwise, and measuring the number of physician visits with y, the population characteristic we want to estimate is a population ratio $R = \sum_{i=1}^{N} y_i z_i \big/ \sum_{i=1}^{N} z_i = \sum_{i=1}^{N} y_i' \big/ \sum_{i=1}^{N} z_i$, which we estimate with $\hat{R} = \Sigma_{i\in s} y_i z_i \big/ \Sigma_{i\in s} z_i$. Thus estimates for population subgroups can be made from survey data by appropriately defining z_i and calculating a ratio estimate.

An equivalent form for the ratio estimator (1) of the y-total is $\hat{T}_R = N\overline{y}_s(\overline{X}/\overline{x}_s)$, where $\overline{X} = N^{-1}\sum_{i=1}^{N} x_i = X/N$ is the known population average of the xs. Writing $\hat{T}_R$ this way illustrates the intuitive appeal of the ratio estimator as a multiplicative adjustment to the simple expansion estimator $\hat{Y} = N\hat{y}_s$ by the factor $\overline{X}/\overline{x}_s$. This adjustment is upward if $\overline{x}_s < \overline{X}$ and downward if $\overline{x}_s > \overline{X}$; intuition supports such an adjustment for if the sample mean of the xs is smaller than the population mean, one might suspect that the sample mean of the ys would be low as an estimate of the population average, justifying an upward adjustment of the simple expansion estimate, $N\overline{y}_s$.

An example where the ratio estimator would be valuable is in estimation of the total number of hospital discharges over a given period, based on a sample of n hospitals from N. Here the auxiliary information x, known for all hospitals in the population, is bed size. If the hospitals selected for the sample are smaller (as measured by bed size) on the average than those in the population, an upwards adjustment of the simple expansion estimate of the number of discharges will be in order.

Of course intuition alone is not enough to justify use of the ratio estimator. The properties of this estimator have been extensively studied from two distinct points of view. One treats the ys as unknown constants and develops properties of the estimator with respect to the **random sampling** plan used to select the units for s. Cochran [1] gives a comprehensive treatment of this **probability sampling** theory approach to **estimation**. The other theory which treats $y_1, \ldots, y_N$ as realizations of **random**

variables $Y_1, \ldots, Y_N$, is developed using a statistical model which relates Y_i and x_i. There has been considerable contention over the role each of these theories should play in **inference** for finite populations. A number of **simulation** studies have been done where both theories apply, and situations where model-based inference has important messages are noted in the following.

Cochran [1] delineated the properties of the ratio estimator assuming a **simple random sample** (without replacement; *see* **Sampling With and Without Replacement**) of size n from the N units in the population. The properties so developed are often used as well when the sampling method is **systematic** rather than simple random, even though there is considerable evidence that appropriately chosen systematic samples can be superior to random samples for inference. Averaging over all possible samples, the ratio estimate has a **bias** of order $1/n$ and thus is negligible for large n. This bias is generally ignored even for moderate samples sizes. An empirical study by Kish et al. [4] showed that the bias relative to the root **mean square error** is small unless n is very small.

Beginning with the simple ratio, $\hat{R}$, a common formula for the estimated variance is

$$v(\hat{R}) = \hat{R}^2\{\mathrm{cv}^2(\overline{y}_s) + \mathrm{cv}^2(\overline{x}_s) - 2r\mathrm{cv}(\overline{x}_s)\mathrm{cv}(\overline{y}_s)\} \tag{2}$$

where $\mathrm{cv}^2(\overline{y}_s) = \widehat{\mathrm{var}}(\overline{y}_s)/\overline{y}_s^2 = \{(1-f)/n(n-1)\}$ $\sum_{i\in s}(y_i - \overline{y}_s)^2/\overline{y}_s^2$ so $\mathrm{cv}(\overline{y}_s)$ is the estimated coefficient of variation (*see* **Standard Deviation**) of $\overline{y}_s$, $\mathrm{cv}(\overline{x}_s)$ of $\overline{x}_s$, and r is the estimate of the **correlation** between $\overline{y}_s$ and $\overline{x}_s$, which for simple random sampling is just the ordinary sample correlation calculated from the data, $r = [\sum_{i\in s}(x_i - \overline{x}_s)y_i]/[\sum_{i\in s}(x_i - \overline{x}_s)^2 \sum_{i\in s}(y_i - \overline{y}_s)^2]^{1/2}$; f is the sampling fraction n/N. This formula follows from a simple Taylor series for $\hat{R}$, often referred to in survey research as the **linearization method**. Unfortunately, linearization has not always produced useful variance estimates in survey research. For example, this method, when applied to $\hat{T}_R$, leads to a variance estimator for $\hat{T}_R$ equal to $v_0 = N^2\{(1-f)/n(n-1)\}\sum_{i\in s}(y_i - \hat{R}x_i)^2$, which has been shown to be a poor estimator of the variability in $\hat{T}_R$.

Wu [22] and Wu & Deng [24] studied a general class of variance estimators for use with $\hat{T}_R$ of the form

$$v_g(\hat{T}_R) = \left(\frac{\overline{X}}{\overline{x}_s}\right)^g v_0.$$

The two special cases of this estimator corresponding to $g = 0$ and $g = 2$ are the variance estimators recommended in many sampling texts for use with the ratio estimate of a population total. Cochran [1] listed both, deriving v_0 via a linearization argument, and v_2 from the relation $\hat{T}_R = N\overline{X}\hat{R}$ which implies $v_2 = (N\overline{X})^2 v(\hat{R})$, where $v(\hat{R})$ is found as in (2).

When applying the ratio method of estimation, the data should show a straight-line **regression** through the origin with variance increasing with x. Its use in other situations can lead to large inefficiencies and/or large biases in estimation. Royall & Cumberland [12] studied the ratio estimator and estimators of its variance under such a model: $Y_i = \beta x_i + \varepsilon_i\sqrt{x_i}$, where $\mathrm{E}(\varepsilon_i) = 0, \mathrm{E}(\varepsilon_i^2) = \sigma^2$, and $\mathrm{E}(\varepsilon_i\varepsilon_j) = 0$ for $i \neq j$. This model assumes variance proportional to x; Royall & Cumberland [11], following Royall & Eberhardt [15], developed a class of variance estimators whose performance is **robust** against failure of this assumption and which have good properties as an estimator of the mean square error of $\hat{T}_R$ when viewed conditionally on sample characteristics. This conditional analysis allows us to see properties of the estimators which are concealed in theoretical developments which average over all possible samples. In an empirical study of the ratio estimator with different populations all of which appear to conform well to this model, Royall & Cumberland [12] concluded that v_0 should not be used to estimate the variance of the ratio estimator, that the robust variance estimators they studied did a good job of tracking the mean square error of $\hat{T}_R$, and that the ratio estimator itself can show a large conditional bias due to failure of the specification $\mathrm{E}(Y_i) = \beta x_i$ in badly balanced samples – those where $\overline{x}_s$ and $\overline{X}$ differ substantially. The use of **stratification** on x, and/or systemic sampling after ordering the population on x, can help avoid the selection of badly balanced samples, thus providing some protection against bias in $\hat{T}_R$. One of the robust variance estimators Royall & Cumberland [12] studied was very nearly v_2, hence on these grounds this estimator can be recommended. Wu and Deng [24], in an unconditional analysis of v_g, suggest using the data to choose g optimally, but in an empirical study drew the conclusion that v_2 was a good

performer in populations where variance increases with x. More recently published sampling texts [8, 18] generally recommend v_2 for use with the ratio estimator, but this is not universal among sampling texts. A simple computing formula for this variance estimator is

$$v_2(\hat{T}_R) = (N\overline{X})^2\hat{R}^2\{\mathrm{cv}^2(\overline{y}_s) + \mathrm{cv}^2(\overline{x}_s) - 2r\mathrm{cv}(\overline{x}_s)\mathrm{cv}(\overline{y}_s)\}. \quad (3)$$

The **jackknife** variance estimator for $\hat{T}_R$ has also been studied extensively [6, 7, 10–12, 22–24]. The jackknife variance estimate [3] is

$$v_J(\hat{T}_R) = (N\overline{X})^2\frac{1-f}{n}(n-1)\sum_{j\in s}(\hat{R}_{(j)} - \hat{R}_{(\cdot)})^2$$

where for every $j \in s$, $\hat{R}_{(j)} = [n\overline{y}_s - y_j]/[n\overline{x}_s - x_j]$ is the ratio estimate found after deleting unit j from the sample and $\hat{R}_{(\cdot)}$ is the average of these n estimates. Royall & Cumberland [12] showed v_J is asymptotically equivalent to v_2 and in their empirical study noted that it generally was larger than other robust variance estimators, leading to more conservative confidence intervals. Wu & Deng [24] drew similar conclusions about v_J and cautiously recommended its use with $\hat{T}_R$.

Confidence intervals for a population total $\hat{T}_R \pm 1.96\sqrt{v}$ rely on **large-sample normality** of the estimates. Conditions for asymptotic normality of the ratio and regression estimators were given in Scott & Wu [19]. Such asymptotic results should be used with caution in moderate samples; Royall & Cumberland [14] and Valliant [20] note from empirical studies poor coverage properties of confidence intervals for some populations, even though the variance estimates were appropriately tracking the mean square error.

Stratified Ratio Estimates

Sampling from strata is much more common than simple random sampling from a population. Stratification improves the efficiency of the estimators and helps to avoid conditions of extreme imbalance which can give rise to large conditional biases in the ratio estimator. Royall & Herson [16] discussed the use of stratification on x with the ratio estimator and showed the value of stratification in protecting inferences from bias due to imbalance.

Suppose the N population units are divided into H strata of sizes $N_1, \ldots, N_H$ so that $\sum_{h=1}^{H} N_h = N$. **Stratified random sampling** consists of independently choosing simple random samples of size n_h from each stratum with $\sum_{h=1}^{H} n_h = n$ the total sample size. Denote the measurements on the N population units by y_{hi} and x_{hi} for $i = 1, \ldots, N_h$ and $h = 1, \ldots, H$, and let the set of sampled units from stratum h be s_h. Two ratio estimators of the population total are commonly used with this plan, the separate ratio $\hat{T}_{RS}$, and the combined ratio $\hat{T}_{RC}$. These are

$$\hat{T}_{RS} = \sum_{h=1}^{H} N_h\overline{X}_h\left(\frac{\overline{y}_{s_h}}{\overline{x}_{s_h}}\right),$$

$$\hat{T}_{RC} = \sum_{h=1}^{H} N_h\overline{X}_h(\hat{R}_C),$$

where $\hat{R}_C = \sum_{h=1}^{H} N_h\overline{y}_{s_h} \Big/ \sum_{h=1}^{H} N_h\overline{x}_{s_h}$ is the ratio of the stratified expansion estimators for the y-total and the x-total, $\overline{y}_{s_h} = n_h^{-1}\sum_{i\in s_h} y_{hi}$ is the sample mean of the ys in stratum h, $\overline{x}_{s_h} = n_h^{-1}\sum_{i\in s_h} x_{hi}$ that of the xs, and $\overline{X}_h = N_h^{-1}\sum_{i=1}^{N_h} x_{hi}$ is the known stratum mean of the xs in stratum h.

The separate ratio estimate uses a different ratio estimate for each stratum and, if the n_h are not too small, will be a better estimator than the combined ratio estimate. The estimator $\hat{R}_C$ is used by itself with stratified designs to estimate rates and prevalences for subgroups of the population, such as disease rates among well-defined racial subgroups.

The variance estimator for $\hat{T}_{RS}$ comes directly from the single-sample case, since $\hat{T}_{RS}$ is the sum of H independent ratio estimates, $\hat{T}_{Rh} = N_h\overline{X}_h(\overline{y}_{s_h}/\overline{x}_{s_h})$. Using the robust variance estimates for $\hat{T}_{Rh}$, we have

$$v_2(\hat{T}_{RS}) = \sum_{h=1}^{H} v_2(\hat{T}_{Rh}) = \sum_{h=1}^{H}(N_h\overline{X}_h)^2\left(\frac{\overline{y}_{s_h}}{\overline{x}_{s_h}}\right)^2\{\mathrm{cv}^2(\overline{y}_{s_h}) + \mathrm{cv}^2(\overline{x}_{s_h}) - 2r_h\mathrm{cv}(\overline{x}_{s_h})\mathrm{cv}(\overline{y}_{s_h})\}$$

and each $v_2(\hat{T}_{RS})$ is calculated using only the data from stratum h, exactly as in the single-sample case[(3)]. A robust variance estimate for the combined ratio estimate can be written in a

parallel fashion. First, for the ratio $\hat{R}_{\mathrm{C}}$ itself we have

$$v(\hat{R}_{\mathrm{C}}) = \hat{R}_{\mathrm{C}}^2\{\mathrm{cv}^2(\hat{Y}) + \mathrm{cv}^2(\hat{X}) - 2r\mathrm{cv}(\hat{X})\mathrm{cv}(\hat{Y})\},$$

where $\hat{Y} = \sum_{h=1}^{H} N_h \overline{y}_{s_h}$ is the simple stratified expansion estimate of the y-total, $\mathrm{cv}^2(\hat{Y}) = \widehat{\mathrm{var}}(\hat{Y})/\hat{Y}^2$, and $\widehat{\mathrm{var}}(\hat{Y}) = \sum_{h=1}^{H} N_h^2\{(1-f_h)/n_h(n_h-1)\}\Sigma_{i\in s_h}$ $(y_{hi} - \overline{y}_{s_h})^2$ (with analogous formulas for $\mathrm{cv}^2(\hat{X})$), $f_h = n_h/N_h$, and $r = \widehat{\mathrm{cov}}(\hat{X},\hat{Y})/[\widehat{\mathrm{var}}(\hat{X})\widehat{\mathrm{var}}(\hat{Y})]^{1/2}$, where $\widehat{\mathrm{cov}}(\hat{X},\hat{Y}) = \sum_{h=1}^{H} N_h^2\{(1-f_h)/n_h(n_h-1)\}$ $\sum_{i\in s_h}(y_{hi} - \overline{y}_{s_h})(x_{hi} - \overline{x}_{s_h})$. For $\hat{T}_{RC}$ a variance estimate is

$$v_2(\hat{T}_{RC}) = X^2\hat{R}_{\mathrm{C}}^2\{\mathrm{cv}^2(\hat{Y}) + \mathrm{cv}^2(\hat{X}) - 2r\mathrm{cv}(\hat{X})\mathrm{cv}(\hat{Y})\},$$

where $X = \sum_{h=1}^{H}\sum_{i=1}^{N_h} x_{hi} = \sum_{h=1}^{H}(N_h\overline{X}_h)$ is the population total of the xs. The variance estimators $v_2(\hat{T}_{RS})$ and $v_2(\hat{T}_{RC})$ (or close variants of them) have been studied empirically by Valliant [20], Wu [23], and Deng & Wu [2], and they generally perform quite well. Both Valliant [20] & Wu [23] also considered the stratified jackknife variance estimator defined generally [3] as

$$v_{\mathrm{J}} = \sum_{h=1}^{H} \frac{1-f_h}{n_h}(n_h-1)\sum_{j\in s_h}(\hat{T}_{(hj)} - \hat{T}_{(h)})^2,$$

where $\hat{T}_{(hj)}$ is the estimate calculated without the hjth unit and $\hat{T}_{(h)} = \sum_{j\in s_h}\hat{T}_{(hj)}/n_h$. Rao & Wu [9], Krewski & Rao [6], and Lemeshow & Levy [7] considered other versions of the jackknife variance estimator. Wu [23] argued that $v_2(\hat{T}_{RC})$ and v_{J} applied to $\hat{T}_{RC}$ should have similar performance. In a simulation study Valliant [20] compared the performances of several variance estimators for $\hat{T}_{RC}$ and $\hat{T}_{RS}$; among these were stratified versions of robust variance estimators, one with similar properties to $v_2(\hat{T}_{RC})$, and another the jackknife variance estimator. With respect to conditional coverage properties, their performance was better than the other estimators considered. Valliant further pointed out in his study that stratification on x alone was not sufficient to protect oneself from a conditional bias due to imbalance on x, although it does guard against gross imbalances that can occur with simple random sampling. He suggested a combination of stratification on x with systematic sampling within strata ordered on x, and the use of a robust variance estimator (like v_{J} or v_2) for reliable inference.

Regression Estimators

From a simple random sample s from a population, the **simple linear regression** estimator for a population total can be calculated as

$$\hat{T}_{\mathrm{L}} = N\overline{y}_s + b(N\overline{X} - N\overline{x}_s)$$

where $b = \sum_{i\in s}(x_i - \overline{x}_s)(y_i - \overline{y}_s)\big/\sum_{i\in s}(x_i - \overline{x}_s)^2$, which is the usual estimate of a slope in a simple linear regression. Like the ratio estimator, the regression estimator has considerable intuitive appeal as an adjustment to the simple expansion estimator, $N\overline{y}_s$. If a plot of the data indicates a straight-line regression of y on x with constant variance, then a linear regression estimator is appropriate and will be superior to a ratio estimator when the intercept is not the origin. Under simple random sampling, the regression estimator is biased, but, as in the case of ratio estimation, this is usually ignored when n is not small. A variance estimator found in most sampling textbooks [1] is $v_{\mathrm{C}} = N^2\{(1-f)/n(n-2)\}\sum_{i\in s} d_i^2$, where $d_i = y_i - \overline{y}_s - b(x_i - \overline{x}_s)$ are the **residuals**. In an empirical study of the regression estimator, Royall & Cumberland [13] showed that v_{C} was seriously flawed as an estimator of the variance of $\hat{T}_{\mathrm{L}}$, and suggested several superior variance estimates. One choice was

$$v_{\mathrm{D}}(\hat{T}_{\mathrm{L}}) = N^2\sum_{i\in s}\frac{a_i d_i^2}{(1-p_i)}, \tag{4}$$

where

$$a_i = \left(\frac{1-f}{n} + \frac{(x_i - \overline{x}_s)(\overline{X} - \overline{x}_s)}{\sum_{j\in s}(x_j - \overline{x}_s)^2}\right)^2 + \frac{1-f}{nN}$$

and $p_i = 1/n + (x_i - \overline{x}_s)^2/\sum_{j\in s}(x_j - \overline{x}_s)^2$ is the ith diagonal element of the "hat" matrix in a standard linear regression. Another choice was the jackknife variance estimator

$$v_{\mathrm{J}}(\hat{T}_{\mathrm{L}}) = \frac{1-f}{n}(n-1)\sum_{j\in s}(\hat{T}_{\mathrm{L}(j)} - \hat{T}_{\mathrm{L}(\cdot)})^2,$$

where $\hat{T}_{\mathrm{L}(j)}$ is the regression estimator based on the sample obtained by deleting unit j from the sample, and $\hat{T}_{\mathrm{L}(\cdot)}$ is the average of the $n\hat{T}_{\mathrm{L}(j)}$s. Royall & Cumberland [13] indicated that the jackknife variance estimate and v_{D} should perform similarly

as they were asymptotically equivalent. Deng & Wu [2] studied v_J, v_D, and a class of adjusted estimators $v_g(\hat{T}_L) = (\overline{X}/\overline{x}_s)^g v_C$, where g is to be chosen optimally from the sample. They also caution against the use of v_C, and note, with respect to both conditional and unconditional coverage of confidence intervals, that v_J, v_D, and v_2 are much better than v_C. Särndal et al. [17] proposed a variance estimator for $\hat{T}_L$ which, like (4), is calculated from weighted squared residuals.

Stratified Regression Estimators

Regression estimators of a population mean or total can also be defined when stratified random sampling is used, and an auxiliary variable x is available. Analogous to the case of ratio estimation, there is the separate regression estimator $\hat{T}_{LS}$, and the combined regression estimator $\hat{T}_{LC}$. The separate regression estimate of a population total is

$$\hat{T}_{LS} = \sum_{h=1}^{H} \hat{T}_{Lh},$$

where $\hat{T}_{Lh} = N_h \overline{y}_{s_h} + b_h(N_h \overline{X}_h - N_h \overline{x}_{s_h})$ is the linear regression estimator of the stratum total, $\sum_{i=1}^{N_h} y_{hi}$, using data only from that stratum. Here

$$b_h = \frac{\sum_{i \in s_h} (x_{hi} - \overline{x}_{s_h})(y_{hi} - \overline{y}_{s_h})}{\sum_{i \in s_h} (x_{hi} - \overline{x}_{s_h})^2}$$

is the estimated slope in stratum h. The combined regression estimator uses a single slope estimate, combining information across strata,

$$b_c = \frac{\widehat{\mathrm{cov}}(\hat{X}, \hat{Y})}{\widehat{\mathrm{var}}(\hat{X})} = \frac{\sum_{h=1}^{H} N_h^2 \frac{1 - f_h}{n_h(n_h - 1)} \sum_{i \in s_h} (x_{hi} - \overline{x}_{s_h})(y_{hi} - \overline{y}_{s_h})}{\sum_{h=1}^{H} N_h^2 \frac{1 - f_h}{n_h(n_h - 1)} \sum_{i \in s_h} (x_{hi} - \overline{x}_{s_h})^2},$$

where $\hat{X}$ and $\hat{Y}$ are the simple stratified expansion estimators of the x-total and the y-total, respectively.

Variance estimation for the separate linear regression estimator is straightforward, since it is a sum of H independent regression estimates. Hence a robust estimator is $v_D(\hat{T}_{LS}) = \sum_{h=1}^{H} v_D(\hat{T}_{Lh})$, where each $v_D(\hat{T}_{Lh})$ is calculated as described earlier in (4) for the unstratified case. A similar calculation can be done summing the jackknife variance estimates. For the combined regression estimator $\hat{T}_{LC}$, variance estimation is more problematical. Valliant [20] studied several variance estimators for $\hat{T}_{LC}$, and recommended a robust version analogous to v_D (4). He also found the performance of the traditional linearization estimators unacceptable. Valliant showed empirically that the robust estimator and a jackknife variance estimate were generally superior to the other choices of variance estimator. Because the formula for v_D is unwieldy, the jackknife variance estimate for $\hat{T}_{LC}$ is a good choice for variance estimation for the combined regression estimator. Its calculation is

$$v_J(\hat{T}_{RC}) = \sum_{h=1}^{H} \frac{1 - f_h}{n_h} (n_h - 1) \sum_{j \in s_h} (\hat{T}_{(hj)} - \hat{T}_{(h)})^2,$$

where $\hat{T}_{(hj)}$ is the estimate calculated without the hjth unit and $\hat{T}_{(h)} = \sum_{j \in s_h} \hat{T}_{(hj)}/n_h$. Valliant [20] indicated some simplifications to v_J that considerably lessen the computational burden of the jackknife in stratified sampling.

Stratified Systematic Sampling

We have already indicated some of the benefits of using stratification on x or systematic sampling from strata ordered on x, with the ratio or regression estimators. Kott [5] noted that systematic sampling is one way of protecting against certain kinds of model failure. Valliant [21] studied stratification on x and, using systematic sampling within strata, compared this plan with simple random sampling within strata. He considered the ratio and regression estimators (both separate and combined) and a number of variance estimators. From theoretical considerations and an empirical study, he recommended for moderate n_h the separate regression estimator, $\hat{T}_{LS}$, combined with stratified systematic sampling, and suggested using either a jackknife variance estimator or the robust variance estimate $v_D(\hat{T}_{LS})$ (4). This combination provided the most reliable inferences for the population total.

Real Time Approach in Survival Analysis

The *real time approach* in survival analysis (or, more generally, event history analysis) means that the statistical modeling respects the original order in calendar time in which the events recorded in the data took place.

This principle is realized naturally in parametric **likelihood** inference and in **Bayesian** inference, where, if the modeling is based on conditional intensities **(hazards)** conditioned at each point in calendar time on the events in the past, the likelihood expression will always assume the same simple canonical form.

In more explicit terms, we can express the data from an observation interval $(0, t]$ in the form of $N(t)$ *marked points* (T_i, X_i), where $0 < T_1 < T_2 < \cdots < T_{N(t)} \leq t$ and where X_i is a description of the event (such as the index or label of a failed individual) which occurred at time T_i. If $\lambda_t(x)$ denotes the conditional intensity of an event indexed by x occurring at time t, and $\overline{\lambda}_t = \sum_x \lambda_t(x)$ is the corresponding "crude" intensity of an event regardless of its index, then the likelihood expression will be of the well-known canonical form

$$L_t = \prod_{(i:T_i \leq t)} \lambda_{T_i}(X_i) \times \exp\left(-\int_0^t \overline{\lambda}_s \, \mathrm{d}s\right).$$

Depending on the studied context, the intensity $\lambda_t(x)$ can correspond, for example, to the failure of individual x, and then depend on the recorded pre-t history through (possibly time-dependent) internal and/or external **covariates**, such as the age of individual x at time t, time elapsed from a treatment, if any, type of the treatment received, and, possibly, calendar time itself. Such dependencies, when modeled explicitly, will then lead to the model parameters appearing in some particular functional form in the likelihood expression. The real time approach can accommodate, without any additional difficulty, study designs involving **staggered entry** of individuals or general noninformative **censoring** schemes. Noninformative censoring will simply result in multiplicative contributions to the likelihood expression which do not depend on the model parameters of interest, and which therefore can be ignored in likelihood-based inference. For a concrete example, see [3]. From the point of view of asymptotic theory, the real time approach has the additional advantage that the *score* $\partial \log L_t / \partial \theta$, evaluated at the "correct" parameter value $\theta = \theta_0$, and viewed as a **stochastic process** in time parameter t, will always be a martingale with respect to the recorded pre-t histories and the probability P_{θ_0} [1, 2] (*see* **Counting Process Methods in Survival Analysis**). This can be used as a convenient technical device in proving **consistency** and asymptotic normality of the parameter estimators under weak mathematical conditions (see, for example, [4]).

The real time approach can be compared and, to some extent, contrasted with more commonly used **nonparametric** and **semiparametric** estimation techniques in survival analysis, such as the **Nelson–Aalen**, **Kaplan–Meier**, and the **Cox regression** estimators. In these methods, the individuals are first aligned according to some time reading which is used as a baseline, and statistical estimators are formed by comparing, for each individual failure, the intensity of the failing individual to the crude intensity of all individuals who were then at risk simultaneously (according to the baseline). If the baseline time reading does not match with calendar time (e.g. if the study design involves staggered entry and age or time from treatment is used as a baseline), then the original sequencing of the events recorded in the data will be changed in the realignment of the individuals. As a result, the natural notion of pre-t "past" may be lost, and this in turn may violate the assumptions underlying the statistical survival model, under consideration.

Recall Bias

Recall bias occurs in **case–control studies** and refers to the **bias** that results when cases with the disease of interest tend to over- or underestimate their previous exposures, compared with controls without disease. For example, a woman who has just given birth to a malformed infant may more assiduously recall her antenatal drug exposures than a **control** woman who had a normal infant. Recall bias induces **differential error** and can seriously distort the results of a case–control study.

Receiver Operating Characteristic (ROC) Curves

Receiver operating characteristic (ROC) analysis was developed to summarize data from signal detection experiments in psychophysics [21]. Today, the term refers to

> a method of quantifying how accurately experimental subjects, professional diagnosticians and prognosticators (and their various tools: tests or instruments yielding numerical results, combinations of data-collection and data-display devices, different amounts and types of information ...) perform when they are required to make a series of fine discriminations or to say which of two conditions or states of nature, confusable at the moment of decision, exists or will exist [50].

In biomedical applications, the two states are often referred to as diseased and nondiseased, or D+ and D− for short. Central to this analysis is the ROC curve, which displays diagnostic accuracy as *a series of pairs* of performance measures. Each pair consists of a true positive fraction (TPF) and the corresponding **false positive** fraction (FPF) for a given definition of "test" (t) positivity, t+. These fractions are calculated from the D+ and D− groups respectively, TPF as the proportion of (t+, D+) among those D+, and FPF as the proportion of (t+, D−) among those D−. In the medical literature, the term TPF is called **sensitivity** and the complement of the FPF is called **specificity**. For the performance of statistical tests, the term **power**, rather than sensitivity, tends to be used. Equivalently, one can use its complement, the **false negative** fraction (FNF, the complement of TPF) or the frequency (β) of a so-called type II error. There is no direct statistical term for specificity. Instead, statisticians again focus on the complement, using the false positive fraction (FPF, the complement of the true negative fraction, TNF) to denote the frequency (α) of what they call type I error.

Diagnostic performance is sometimes naively characterized using a *single* overall index of "accuracy", calculated as the sum of two proportions, i.e. the proportion of (t+, D+) instances plus the proportion of (t−, D−) instances, where the proportions are based on all patients undergoing the test. This index is a weighted average of sensitivity and specificity, using as weights the (particularistic) relative frequencies of the D+ and D− states. Using two measures, namely a (TPF, FPF) *pair*, avoids this arbitrariness.

Although a (TPF, FPF) pair is a big improvement over an overall accuracy index, it is often not sufficient. A single (TPF, FPF) pair still does not allow meaningful comparison of the performance of one diagnostic test with another, or even with the same test performed in another setting or by another observer, when different criteria for test positivity are used in the two instances compared. The ROC curve, in the form of a *series* of (TPF, FPF) pairs (see Figure 1), isolates a test's capacity to discriminate between a given disease and its absence, from the **confounding** influence of the decision criterion (confidence level or cutting score) that is adopted for test positivity [37, 52, 58]. A more accurate test will be located on an ROC curve closer to the top left corner than a less accurate one. A noninformative test will have an ROC curve that lies along the diagonal.

Statistical techniques to handle the full range of ROC study designs continue to be developed [3, 5, 9, 26]. Analyses can vary in complexity from deriving an ROC curve for a single diagnostic test involving numerical values derived from patients at a single institution, to complex multi-institution studies to compare two or more imaging modalities. The complexity also depends on the purpose of the discrimination test, the setting and context to which it refers, whether in the study interpretations are performed individually in real time [18] or later in "batch" mode [52], and whether the tests under study and the procedures for independent definitive determination of the true state of nature (the **gold standard**) are costly, invasive, uncomfortable or dangerous.

This latter issue can create special problems since ROC curves are strongly influenced by the source of the test material used [6]. Distortions occur when the result of the test being studied affects the subsequent work-up needed to establish a definitive diagnosis. Information available on the distribution of test results and clinical indicants in the source population can be used to remove quantitatively this "verification bias" from ROC curves [20, 30]. Other **biases** in the assessment of diagnostic tests and guidelines for circumventing the problems in prospective studies have been described [4, 7].

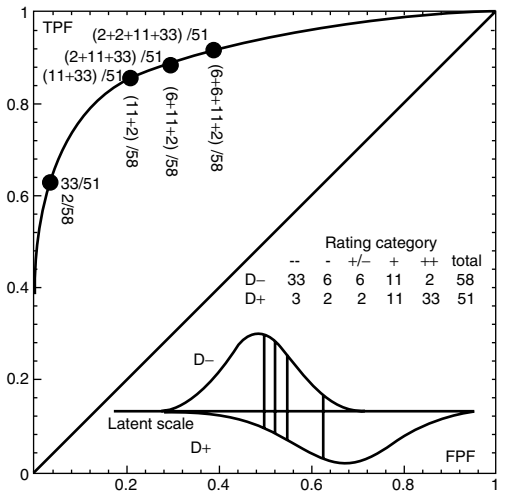

Figure 1 Example of empirical ROC points and smooth curve fitted to them. The empirical points are calculated from successively more liberal definitions of test positivity applied to the 2×5 table (inset) of disease status (D+ or D−) and rating category (−− to ++). The smooth ROC curve is derived from the fitted binormal model (inset, lower right, with parameters $a = 1.657$ and $b = 0.713$ on a continuous latent scale) by using all possible scale values for test positivity. The fitted parameters a and b, together with the four estimated cutpoints, produce fitted frequencies of $\{32.9, 6.4, 5.9, 10.7, 2.1\}$ and $\{3.2, 1.5, 2.1, 11.2, 32.9\}$ for the D− and D+ rows of the 2×5 table. Note that a monotonic transformation of the latent axis may produce overlapping distributions with nonbinormal shapes, but will yield the same multinomial distributions and the same fitted ROC curve

The complexity of the test material can have an important bearing on the ability of a study to compare tests. Cases resulting in an ROC curve that is midway between the diagonal (subtle or completely obscure ones) and the upper left corner (all 'obvious') allow for sizable differences in performance; however, the closer the curve is to the upper left corner, the narrower is the **sampling distribution** of the various indices derived from the curve [39].

For clinical imaging studies involving interpretations, the most economical method of collecting a reader's impression of each case is through the use of a rating scale, i.e. graded levels of confidence that the case is D+. A discrete five-point scale – 1 = "definitely not diseased", 2 = "probably not diseased", 3 = "possibly diseased", 4 = "probably diseased", 5 = "definitely diseased" – is commonly used. Getting a reader to use all of the rating categories provided yields a more stable ROC curve estimate, but is not always easy to accomplish without causing other problems [23]. Use of ratings from the continuous 0–100% confidence scale [31, 49] has several advantages: it more closely resembles reader's clinical thinking and reporting; its use of a finer scale leads to somewhat smaller **standard errors** of estimated indices of accuracy; and it increases the possibility that the data will allow parametric curve fitting.

Obtaining an ROC Curve and Summary Indices Derived from it

For *rating scale data*, the 2 (D states) $\times$ k (rating categories) frequency table of the ratings yields $k - 1$ empirical (TPF, FPF) ROC points. As shown in Figure 1, these are obtained from the $k - 1$ possible **two-by-two tables** formed by different re-expressions of the $2 \times k$ data table. After TPF = 0 at FPF = 0, the lowest leftmost ROC point is derived using the strictest cutpoint, where only the most positive category would be regarded as positive; each subsequent point towards the top right ROC corner (TPF = 1, FPF = 1) is obtained by employing successively laxer criteria for test positivity. For objective tests that yield *numerical data*, the same procedure – with each distinct observed numerical test value as a category boundary and with k no longer fixed a priori but rather determined by the numbers of 'runs' of D+ and D− in the aggregated data – is used to calculate the series of empirical ROC data points. The sequence of points can then be joined to form the empirical ROC curve or a smooth curve can be fitted.

As a summary measure of accuracy, one can use: (i) TPF[FPF], the TPF corresponding to a single selected FPF; (ii) the area under the ROC curve; or (iii) the area under a selected portion of the curve, often called the partial area. Summary (i) is readily understood and most clinically pertinent. However, reported TPFs are often in reference to different FPF values, and it may be unclear whether a reference FPF was chosen in advance or after inspection of the curve. Moreover, the statistical reliability tends to be lower than that of other summary indices.

Summary (ii) has been recommended as an alternative [52]. It has an interpretation in signal detection theory as the proportion of correct choices in a two-alternative forced choice experiment [21], i.e. an

experiment where in each trial the subject is presented with a pair of stimuli, one from a randomly chosen D+ and one from a randomly chosen D−, and is asked to decide which derives from which. This method of reporting judgments is common in psychophysics and has statistical advantages when using synthetic images, where observer time is the limiting factor [8].

To some, the area index has a serious limitation. Since a large part of the area comes from the rightmost part of the curve, it includes FPFs of no clinical relevance, and so can be insensitive when used to compare the performance of two tests. One curve may have higher TPFs than another in the region of relevant FPFs, but they could conceivably cross. Since the area under the entire curve averages the sensitivity over the full (0, 1) range of FPFs, any superiority in the relevant FPF region may be lost, or even reversed, when the curves are ranked on the basis of the entire area. The average sensitivity (TPF) over a range of relevant FPFs, summary index (iii) [34, 53, 60], is a compromise between (i) and (ii).

All three indices can be calculated either from the empirical or a (parametrically fitted) smooth curve. The statistical precision of nonparametric estimates can be calculated using a general method applicable to all three indices [60]; in the case of (ii) other essentially equivalent but less cumbersome methods, based on ***U*-statistics**, are also available [11, 28]. The case of (i) is more subtle than most realize: the standard error of an estimated TPF must include, in addition to its own obvious **binomial** variation, the uncertainty associated with determining the position of the FPF point [32].

A smooth ROC curve can be fitted to rating scale data by fitting two overlapping distributions on a continuous but "latent" scale underlying the results for D− and D+ cases [12, 36] In the most commonly used, "binormal", model, the two distributions are taken to be, without loss of generality, N(0, 1) for D−, and N(μ, σ) for D+. The distributions of the ratings are thus **multinomial**, with **expectations** that are functions of the $k-1$ cutpoints and the two parameters μ and σ, allowing the $k+1$ (two relevant and $k-1$ **nuisance**) parameters to be fitted to the observed data table ($2k-2$ **degrees of freedom** in total, leaving $k-3$ degrees of freedom to test the fit) using the criterion of **maximum likelihood**. Small additions to empty cells can be used to avoid "degenerate" situations [13]. The extent to which the normal deviate (*see* **Normal Scores**) **transformations** (z[TPF], z[FPF]) of the empirical (TPF, FPF) pairs are linear provides a visual test of the fit, since under the binormal model their expectations satisfy

$$z(\text{TPF}) = (1/\sigma)z(\text{FPF}) - \mu/\sigma = bz(\text{FPF}) - a.$$

When $b = 1$, the curve in (TPF, FPF) space is symmetric about the negative diagonal, while $b < 1$ produces a curve which rises more steeply at first and "flattens out" at the end.

Since the various summary indices derived from the fitted curve are functions of the estimates of a and b, their statistical precision – used in tests (*see* **Hypothesis Testing**) and **confidence intervals** – can be calculated from the corresponding variance/covariances provided by the maximum likelihood procedure. Confidence intervals can also be calculated for the entire curve [33].

For rating scale data, the popularity of the binormal model over bilogistic [22, 47] or other competitors [16] is more historical than theoretical. Use of a binormal model for rating data does not imply that if one could observe the latent distributions, they would have this exact form [38]. Rather, the working assumption is that the two overlapping multinomial distributions can be mathematically predicted from the discretization of two **normal distributions** on some unspecified latent scale. Whereas any two overlapping distributions will uniquely determine a specific ROC curve, the reverse is not true: the "binormal" assumption concerns only the functional form of the ROC curve, which can always be examined empirically, and not the form of the underlying distributions themselves, which cannot be determined in many applications of ROC analysis [38]. Use of a small number of rating categories, with few degrees of freedom, to distinguish the fit of one specific form over another, leaves considerable freedom to fit different distributional forms. This freedom is not a function of sample sizes (numbers of cases) but of the number of rating categories [25].

More important than the choice of distributional family seems to be the need to allow for unequal **variances** ($b \neq 1$). Empirically, b tends to be less than 1 [51], possibly because of the presence of unidentified subtypes in the D+ sample. Thus, whereas one-parameter models, with $b = 1$, would have practical advantages, particularly for **meta-analyses** and for fitting an entire (but symmetric)

ROC curve to a single empirical (TPF, FPF) data point, they are not supported by empirical findings.

Care must be taken in the fitting of parametric curves to results recorded on a numerical scale: directly fitting $N(\mu_1, \sigma_1)$ for D− and $N(\mu_2, \sigma_2)$ for D+ can yield severe distortions when the data do not arise from normal distributions [19]. The method in which the raw data are first categorized and the categorized data analyzed as if they were rating data [41] – with the assumptions of overlapping normal distributions on an unspecified transform of the actual measurement scale – is a much more **robust** approach.

Comparison of ROC Curves

Because of the need to account for large differences in case difficulty, compared curves are usually based on the same set of cases, and one must therefore take the **correlation** of the estimated curves – and summaries derived from them – into account when calculating the standard error of differences.

Parametric methods for comparing two curves are based on the estimates of the binormal (or bilogistic, or other model) parameters (a, b) associated with each curve, and their variances and covariances [34, 42]. The equality of two curves can be assessed by testing the equality of the two vectors (a_1, b_1) and (a_2, b_2). Comparisons involving a summary index are made by computing, for each curve, the appropriate function of the parameter estimates, then using the **delta method** to calculate the standard error of the difference in indices.

A **nonparametric method** is now available to compare two curves based on continuous data from the same set of cases [59]. A criterion for positivity that is common for the two tests is induced using the **ranks** in the combined D+ and D− data for each test. Using this calibration, one first computes the difference in the numbers of errors made by the two tests at each possible level of test positivity and then calculates the average of the absolute differences over the different levels. The test statistic is referred to the permutation distribution obtained by randomly interchanging pairs of ranks. Nonparametric comparisons of the areas under two curves are based on correlated U-statistics [11] or equivalently on the **jackknife method** [27], while partial areas, and – ultimately – sensitivity at a single specificity value can be compared with a more general method [60].

Guidelines for **sample size determination** and **power** calculations are available for both parametric [software program ROCPWR from Charles Metz at the University of Chicago, or the article by Obuchowski & McClish [43]] and nonparametric approaches [29].

Comparison of Accuracy of Imaging Procedures

The methods just described deal only with simple comparisons of two tests that yield objective numerical results, and are not sufficient for imaging studies (*see* **Image Analysis and Tomography**) which produce interpretations of each case by multiple readers. For example, the performance with conventional versus laser printed films might be studied by having several readers interpret each image; a comparison of computed tomography, magnetic resonance and ultrasound images might involve different readers for each modality [46]. Several refinements and some alternatives to the method initially proposed for dealing with these more complex comparisons have been suggested. The challenge is to include and estimate properly each of the several relevant **components of variance** and covariance since the comparison is necessarily an average over cases, readers and (possibly) rereadings [40, 52]. Two methods [15, 44] deal with the problem by modeling the variation in the summary index in question, while another [54] models the raw rating data responses. From the investigations thus far [14, 55], both modeling approaches appear to give comparable answers, but commentators [48, 35] have called for some further work to investigate the performance of analysis strategies that use statistical tests to decide what is the appropriate error term and denominator **degrees of freedom** when reader x modality **interactions** are involved.

When studies of imaging procedures involve multiple centers, complex procedures, ethical concerns, "real-time" readings, and different experts in the different imaging modalities [18], the data can quickly become imbalanced and/or incomplete. Analysis problems are thus aggravated by the subjective (and thus possibly nonpoolable) nature of the ratings, the often large numbers of case–reader sets, each containing too few observations to allow parametric fitting of separate ROC curves, and the fact that,

unlike the usual response measures in **clinical trials**, the elemental ROC data are not absolute numbers that can be easily averaged or displayed individually in a descriptive way. If all available data are to be used, the only logical approach is to use **regression** methods. Since the first regression work in this area [57], there has been considerable activity in developing **parsimonious** approaches to the problem, including **random effects** models [2], Gibbs sampling (*see* **Markov Chain Monte Carlo**) [17], and **generalized estimating equations** [56, 61].

In some situations, the study material may involve more than one region of interest on an image. Sample reuse methods can help to calculate the precision with which statistical contrasts are made [1, 10, 24, 45] (*see* **Bootstrap Method**).

Software

Programs for parametric estimation are available from the WWW location `www-radiology.uchicago.edu/cgi-bin/software.cgi` maintained by the developer, Charles Metz. Special-purpose programs for nonparametric inference are more numerous, but most of the tasks can be accomplished using a spreadsheet [27]. Software for the multireader, multicase approach to imaging data is available from the authors of ref. [15]; software for the other approaches is still evolving and interested users should contact the various authors cited above.

Future Developments

Whereas methods for comparing ROC curves associated with tests that yield objective test results have now become routine, solutions to the complex analytic problems involved in the comprehensive comparison of accuracy of imaging procedures have not been completely achieved. The methods proposed in the last 5 years need further testing; the links between them need to be better understood; and user-friendly software to implement these newest approaches remains to be developed.

Record Linkage

At the core of all **descriptive epidemiology** studies lies a data set, with many variables, which has been gathered to answer a specific hypothesis. Often it is only as the project develops that the researcher realizes the potential of exploring alternate study endpoints by adding in other data about the same respondents. The tried and tested technique is for a clerk to look at the individual records, sorted in some logical order, and put the records together, applying intuitive decision rules based on human judgment. As record systems have been computerized over the past 20 years, one of the greatest impacts of increased processing power has been to facilitate linkages between related data sets, even when they do not share a unique identifier.

Three main techniques are used for record linkage, Newcombe [13] and Jamieson et al. [9] describe in detail the technical issues relating to exact matching and probability linkage (*see* **Matching, Probabilistic**). They can be summarized as follows:

1. *Unique*. Records are linked together where unique identifiers such as insurance number or health service number match exactly. The files of records are computer sorted into the same order, and matched together within blocks. It is a fairly simple process, but may only identify 80%–85% of true matches due to errors in recording of identifiers.
2. *Fuzzy*. For data sets which do not have unique identifiers, key identifiers such as surname, date of birth, sex, date of interview/treatment, and postal district are used for linkage. To cope with coding errors, fuzzy matching identifies records which are "almost" the same, such as surname spelling incorrect, or year and month of birth correct, but day wrong. Computer programs either present a choice of matches for the user to choose the best match, or have incorporated a simple scoring system and determine the best match from the score. Computer **algorithms** are well developed for matching on individual variables, and this technique provides 85%–90% of true matches. It requires human intervention and there may be operator **bias**.
3. *Probability*. This is the most sophisticated form of linkage, in which decision rules on records matching are programmed based on the probability of two records being from different people having the same identifier. These probabilities are aggregated to a score and checked against a threshold to determine whether a match is made. The computer system needs to be tailored for the data sets to be matched and is processor intensive, but provides linkages of 95%–99% true matches with false positive rates of 1%–2%.

The following are examples of the uses made of record linkage within healthcare systems and demonstrate the value of this powerful technique. Many of the examples come from uses made of the Scottish Medical Record Linkage Database [7], which contains morbidity records from Scottish hospitals, and mortality records from the General Register Office (Scotland) from 1968 onwards – almost 4 million people with 12 million episodes.
