Aalen's Additive Regression Model

Introduction

The dominating regression model in **survival analysis** is the **proportional hazards** model (or **Cox model**). Although very useful, it is clear that the Cox model cannot cover all relevant situations and that alternatives are needed. There are a number of other possible models, parametric and nonparametric ones. A member of the latter group is the additive regression model suggested by Aalen [2, 3]. One reason for seeking alternatives to the Cox model is that practitioners applying this model may not fully understand its complexities nor be able to check assumptions like proportionality. There is undoubtedly a somewhat uncritical use of the Cox model in the medical field. Clearly, other models may be no more easy to use, but by trying different approaches, one may get more insight into the data and develop a more critical attitude to the whole analysis. After all, there is no reason to assume that hazards will always be proportional.

In fact, experience tells one that effects are sometimes proportional, sometimes additive (*see* **Additive Hazard Models**; **Additive Model**), and often in between. Even when proportionality is a reasonable assumption, one often sees that the proportionality coefficient decreases over time. In fact, this is to be expected from **frailty** considerations; one basic consequence of frailty theory is that **relative risk** will often be expected to decrease over time. One advantage of the additive regression model presented here is that effects of **covariates** are allowed to vary freely over time. In contrast, when applying Cox analysis with standard packages, the normal approach will be to let the coefficients be constant over time and deviations from this may be difficult to incorporate. Thus, a standard Cox analysis gives no information about how the effects change over time and valuable information may be lost. It may also occur that significant effects may be masked. For instance, analyzing a set of survival data, it was found that a covariate indicating the extent of spread of the cancer ("N-stage") was not significant in the Cox analysis, while an additive model showed a clearly significant effect for the first year, but with the effect disappearing later [3, Table I and Figure 7(d)].

From a practical statistical point of view, it has been asserted that additive effects may be more informative than proportional effects. A hazard ratio of 2, say, may not be of much interest if the underlying basic hazard is very small. Then, the suggestion of a substantial effect may be misleading, and the real effect is better brought out by looking at the difference between hazards, which is by an additive approach.

The additive regression model generalizes the **Nelson–Aalen estimator**. For simplicity, assume that one wants to compare two groups. One way of doing this would be to make a Nelson–Aalen curve within each group and then plot the difference between the two curves. Now, this would be a fine procedure if the groups were defined by **randomization**, say. Otherwise, one will have to introduce the **covariates**, or **confounders**, which may explain the difference and adjust for them. The question then arises how to adjust the difference between two Nelson–Aalen curves, and the additive regression model is an answer to this.

A weakness of the additive approach is that the hazard rate is not naturally constrained to be positive. This may have odd effects occasionally, especially when predicting survival for individuals with extreme covariates where negative hazard may arise; see [9]. However, this does not prevent the additive model from being useful in most cases. As pointed out in [18], there is one important case for which the possibility of negative hazard rate is no problem, namely, when modeling excess hazard (*see* **Excess Risk**), for example, in cancer epidemiology. This subject is discussed further below.

The Additive Model

As indicated by the word "additive", the model has a linear structure. To be specific, assume that one observes the possibly censored life times of a number of individuals, the **censoring** times being assumed to be stopping times in the martingale sense [1] (*see* **Counting Process Methods in Survival Analysis**). Let $\lambda_i(t)$ denote the hazard rate of individual i, n the number of individuals, and r the number of covariates in the analysis. Consider the column vector $\boldsymbol{\lambda}(t)$ of hazard rates $\lambda_i(t), i = 1, \ldots, n$. The linear model is given as follows:

$$\boldsymbol{\lambda}(t) = \mathbf{Y}(t)\boldsymbol{\alpha}(t) \tag{1}$$

where the $n \times (r+1)$ matrix $\mathbf{Y}(t)$ is constructed as follows: If the ith individual is a member of the **risk set** at time t, then the i th row of $\mathbf{Y}(t)$ is the vector $\mathbf{Z}^i(t) = (1, Z_1^i(t), Z_2^i(t), \ldots, Z_r^i(t))'$, where $Z_j^i(t)$, $j = 1, \ldots, r$ are, possibly **time-dependent, covariate** values. If the ith individual is not in the risk set at time t, then the corresponding row of $\mathbf{Y}(t)$ contains only zeros. All sample paths of $\mathbf{Y}(t)$ are assumed to be left-continuous functions of t.

The vector $\boldsymbol{\alpha}(t) = (\alpha_0(t), \alpha_1(t), \ldots, \alpha_r(t))'$ contains the important regression information: The first element is a baseline function; while the remaining elements, called *regression functions*, measure the influence of the respective covariates. These functions are allowed to vary freely over time.

When turning to estimation, we concentrate on the cumulative regression functions defined by $A_j(t) = \int_0^t \alpha_j(s)\, ds$. Let $\mathbf{A}(t)$ be the column vector with elements $A_j(t)$, $j = 0, \ldots, r$. This is estimated by an approach that is similar to that for ordinary linear models [2, 3], resulting in the following estimator:

$$\mathbf{A}^*(t) = \sum_{T_k \le t} \mathbf{X}(T_k)\mathbf{I}_k \tag{2}$$

Here $T_1 < T_2 < \cdots$ are the ordered event times, while $\mathbf{I}_k$ is a column vector consisting of zeros except for a one in the place corresponding to the subject who experiences an event at time T_k. The estimator is only defined over the time interval, where $\mathbf{Y}(t)$ has full rank. The matrix $\mathbf{X}(t)$ is a generalized inverse of $\mathbf{Y}(t)$ (*see* **Matrix Algebra**) and will ordinarily be defined by the ordinary **least squares** inverse:

$$\mathbf{X}(t) = [\mathbf{Y}(t)'\mathbf{Y}(t)]^{-1}\mathbf{Y}(t)' \tag{3}$$

The components of $\mathbf{A}^*(t)$ are intended to be plotted against time and to give information about effects of covariates. Notice that the regression functions are the derivatives of the cumulative functions, and so it is the slopes of the plots that are informative. A decreasing slope means a decreasing additive effect (but this may not imply that the *relative* effect decreases).

The components of $\mathbf{A}^*(t)$ converge asymptotically, under appropriate conditions, to normal processes with independent increments. An estimator for the **covariance matrix** of $\mathbf{A}^*(t)$ is given by:

$$\boldsymbol{\Omega}^*(t) = \sum_{T_k \le t} \mathbf{X}(T_k)\, \mathbf{I}_k^D\, \mathbf{X}(T_k)', \tag{4}$$

where $\mathbf{I}_k^D$ is a diagonal matrix with the vector $\mathbf{I}_k$ as diagonal.

The model may also be formulated in terms of **counting processes** where the justification of the estimator and its properties is more easily seen [6]. The linear nature of the additive model fits very nicely with the counting process apparatus of stochastic integrals and so on. An extensive theory for the model has been derived, including asymptotic theory, test statistics, and martingale **residuals**. The latter ones and other checking procedures developed for the Cox model apply equally well to the additive approach [4]. Various issues concerning the model and its generalizations have been dealt with in [9, 10, 12, 14, 15, 17].

A practical advice concerning the analysis may be given: It is usually advantageous to center the covariates (subtracting the mean) before analysis. Then, the estimate of the cumulative baseline function, $A_0^*(t)$, will have a clear interpretation, namely, as the estimated cumulative hazard of an "average" individual.

The Semiparametric Additive Risk Model

One practical problem with the additive model in the above form is that all effects are nonparametric, thus making the description of some covariate effects unnecessarily complicated even when it is not needed. McKeague and Sasieni [15] suggested a very useful submodel of the additive model

$$\boldsymbol{\lambda}(t) = \mathbf{Y}(t)\boldsymbol{\alpha}(t) + \mathbf{W}(t)\boldsymbol{\gamma}, \tag{5}$$

where the first component of the model, $\mathbf{Y}(t)\boldsymbol{\alpha}(t)$, is defined as above and the second component, $\mathbf{W}(t)\boldsymbol{\gamma}$, is defined similarly ($\mathbf{W}(t)$ is an $n \times q$ dimensional matrix), and $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_q)$ is a regression parameter. The covariates of the model are thus partitioned in those whose effects depend on time and those whose effects are constant. Lin and Ying [13] considered a special case of this model in which the nonparametric part of the model only contains a baseline. Scheike [17] suggested a procedure for testing if effects in the **semiparametric** model depends significantly on time, thus making a stepwise model reduction strategy possible. The semiparametric model allows the data analyst to reduce effects that are not time varying to a parametric form thus giving a much simpler description to those effects.

McKeague and Sasieni [15] derived explicit estimators for $\mathbf{A}(t)$ and $\boldsymbol{\gamma}$ and their standard errors that are simple to compute.

Example

As an example of the additive analysis, we will use the (PBC) data on survival of 418 patients with primary biliary cirrhosis presented in [8]. The source of our data set is the survival package of **S-Plus/R**. The following covariates are included: age (in years), log(albumin), bilirubin (dichotomized as 0 when bilirubin is less than 3.25 mg/dl and 1 otherwise), edema (dichotomized as 0 for no edema and 1 for edema present now or before), and log(prothrombin time). Figures 1 and 2 present cumulative regression functions for the covariates bilirubin and edema. Pointwise 95% **confidence intervals** are also indicated. The null hypothesis: $\alpha_j(s) = 0$ over a suitable interval, may be tested by the supremum test of Scheike [17]. Here, it gives the values of 5.72

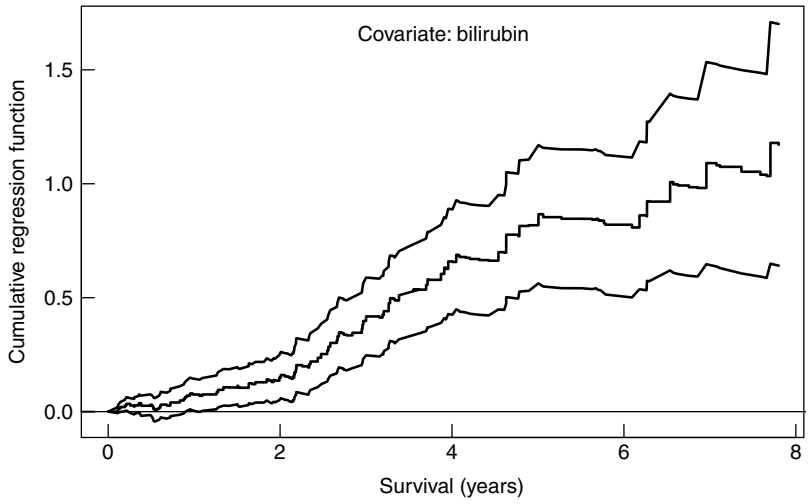

Figure 1 Estimated cumulative regression function for covariate bilirubin

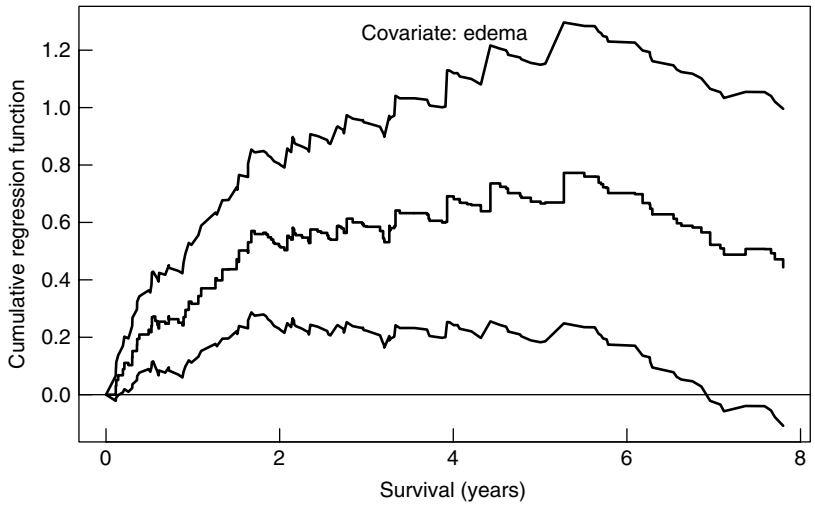

Figure 2 Estimated cumulative regression function for covariate edema

($p < 0.001$) and 4.00 ($p = 0.001$) for bilirubin and edema respectively. The plots may be interpreted as follows: For bilirubin, one sees a strongly positive slope, especially after 800 days, indicating a long-term effect on survival. For edema, the slope of the plot is largest to begin with. In fact, the plot soon levels off, and so it is clear that the effect of this covariate on survival is an initial effect that does not last. This is also found by Fleming and Harrington ([8], p. 191) by studying $\log(-\log(\text{survival}))$ plots, but the present procedure is a simpler way of discovering it, and it simultaneously adjusts for other covariates.

We now illustrate, the use of the semiparametric model and show that the data can be further summarized. In Aalen's additive model with all covariates (age, log(albumin), bilirubin, edema, and log(protime)), a test for constant covariate effects [17] gave the p value 0.88 for log(albumin). We, therefore, reduced the model to the semiparametric model in which log(albumin) had a constant effect, and other effects were time varying. In this model, it was found that age had a constant effect over time ($p = 0.89$). Further, stepwise model reduction lead to a model in which edema and log(protime) had time-varying effects (with **P-values** for constant effects at 0.01 and 0.04, respectively), and the remaining covariates were found to be well described by constant effects. Bilirubin had a constant effect of 0.143 (0.026), age 0.002 (0.001), and log(albumin) −0.263 (0.098). Note, that the cumulative regression effect of bilirubin shown in Figure 1 is well approximated by a line with slope 0.143.

Relative Survival Rate

There is an alternative useful representation of the results of the above analysis [19]. Consider a binary covariate with values 0 and 1, and let $A_j^*(t)$ be its cumulative regression function. Instead of plotting this, one could rather plot $R^*(t) = \exp(-A_j^*(t))$ versus t. This will be an estimate of the ratio between the survival curves, namely, the one with covariate value 1 divided by the one with covariate value 0, while the other covariates are kept constant. The quantity $R^*(t)$ is similar to what in epidemiology is termed a relative survival rate (*see* **Excess Mortality**).

The relative survival rates have been computed for the covariates bilirubin and edema in the example and presented in Figures 3 and 4. One sees that the relative survival declines to about 35% for bilirubin and a little above 60% for edema.

Excess Hazard Models

When studying the survival of cancer patients, one is interested in modeling the excess mortality, which is the mortality that remains when one subtracts the expected mortality (which is derived from ordinary

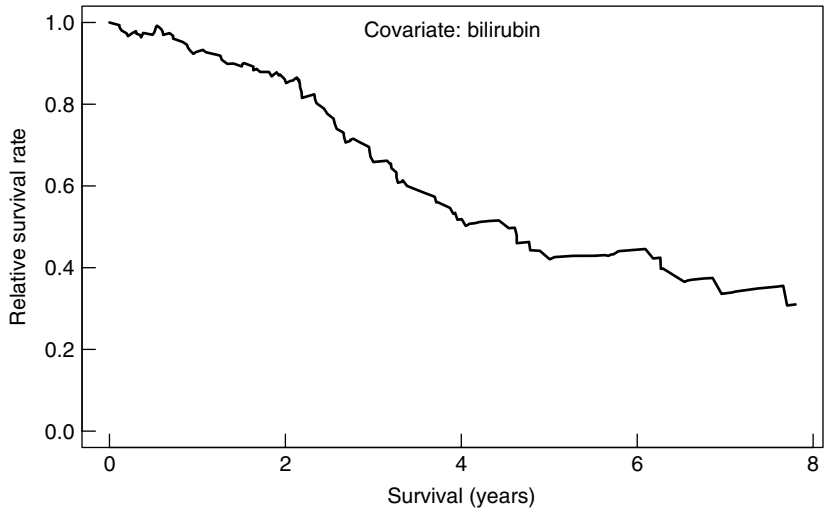

Figure 3 Estimated relative survival rate for covariate bilirubin

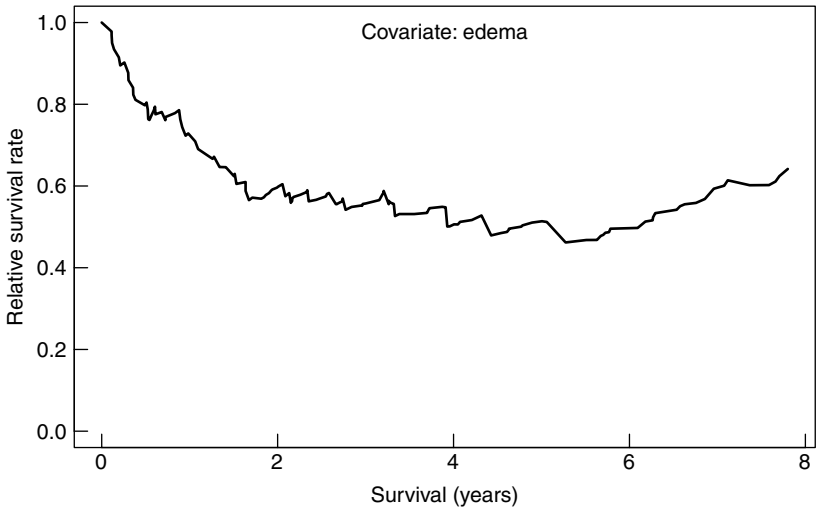

Figure 4 Estimated relative survival rate for covariate edema

life tables). It is this excess hazard that is supposed to be the cause-specific hazard related to the disease in question. Following up work of Andersen and Væth [7], Zahl [18] has extended the additive model to the excess hazards framework; see also [20]. Such excess hazards may well be negative and Zahl has shown that the additive model may give a better fit than the proportional hazards model.

Further Developments

The additive risk model, including the semiparametric version, has certain **robustness** properties that have been described along with robust **standard errors** in [17].

Estimating transition probabilities in **Markov chains** are of great interest in many practical applications. The additive model is suitable when one wants to adjust the transition probabilities for covariates [5]. An application of the additive model to adjusting for censoring in a more general multistage framework is given by Satten and Datta [16].

Software

An S-plus program, called Addreg, for making the cumulative regression plots is available on the web page `www.med.uio.no/imb/stat/addreg/`. Programs developed by T. Scheike are available on the web page: `www.biostat.ku.dk/~ts/`. Also, a program is available in Stata; see [11]. Finally, the survival package in S-plus contains a routine called aareg, which can make the plots described here.

ODD O. AALEN & THOMAS H. SCHEIKE

Aalen–Johansen Estimator

The survival data situation may be described by the **Markov process** with the two states "alive" and "dead". Splitting the state "dead" into two or more states, corresponding to different causes of death, a Markov model for **competing risks** is obtained. Another Markov model of importance for biostatistical research is the illness–death model with states "healthy", "diseased" and "dead". For survival data, the probability of a transition from state "alive" to state "dead" may be estimated as one minus the **Kaplan–Meier** estimator. The Kaplan–Meier estimator may be generalized to nonhomogeneous Markov processes with a finite number of states. Such a generalization was considered by Aalen [1] for the competing risks model and independently by Aalen & Johansen [2] and Fleming [5, 6] for the general case. In particular, the **product–integral** formulation of Aalen & Johansen [2] shows how the estimator, usually denoted the Aalen–Johansen estimator, can be seen as a matrix version of the Kaplan–Meier estimator.

Below, we first consider the competing risks model and the Markov illness–death model for a chronic disease. This gives illustrations of the Aalen–Johansen estimator in two simple situations where its elements take an explicit form. Then we present the Aalen–Johansen estimator in general, and show how it is obtained as the product–integral of the **Nelson–Aalen estimators** for the cumulative transition intensities. We also indicate briefly how this may be used to study its statistical properties. A detailed account is given in the monograph by Andersen et al. [3, Section IV.4].

Competing Risks

Assume that we want to study the time to death and cause of death in a homogeneous population. This situation with competing causes of death may be modeled by a Markov process with one transient state 0, corresponding to "alive", and k absorbing states corresponding to "dead by cause h", $h = 1, 2, \ldots, k$. The transition intensity from state 0 to state h is denoted $\alpha_{0h}(t)$ and describes the instantaneous risk of dying from cause h, i.e. $\alpha_{0h}(t)\,\mathrm{d}t$ is the probability that an individual will die of cause h in the small time interval $[t, t + \mathrm{d}t)$, given that it is still alive just prior to t. The $\alpha_{0h}(t)$ are also termed cause-specific **hazard rate** functions. For $h = 1, 2, \ldots, k$, we write $P_{0h}(s, t)$ for the probability that an individual in state 0 (i.e. alive) at time s will be in state h (i.e. dead from cause h) at a later time t. These transition probabilities are often termed cumulative incidence functions. Finally, let $P_{00}(s, t)$ denote the probability that an individual who is alive (i.e. in state 0) at time s will still be alive at a later time t. Then

$$P_{00}(s,t) = \exp\left[-\int_s^t \sum_{h=1}^{k} \alpha_{0h}(u)\,\mathrm{d}u\right], \qquad (1)$$

and

$$P_{0h}(s,t) = \int_s^t P_{00}(s,u)\alpha_{0h}(u)\,\mathrm{d}u, \qquad (2)$$

for $h = 1, 2, \ldots, k$.

Assume that we have a sample of n individuals from the population under study. Each individual is followed from an entry time to death or **censoring**, i.e. our observations may be subject to right censoring and/or left **truncation**. We denote by $t_1 < t_2 < \cdots$ the times when deaths (of any cause) are observed, and let d_{0hj} be the number of individuals who die from cause h (i.e. make a transition from state 0 to state h) at t_j. We also introduce $d_{0j} = \sum_{h=1}^{k} d_{0hj}$ for the number of deaths at t_j due to any cause, and let r_{0j} be the number of individuals at risk (i.e. in state 0) just prior to time t_j. Then the survival probability (1) may be estimated by the Kaplan–Meier estimator:

$$\hat{P}_{00}(s,t) = \prod_{s<t_j\le t}\left(1 - \frac{d_{0j}}{r_{0j}}\right), \qquad (3)$$

while the **cumulative incidence** function (2) may be estimated by

$$\hat{P}_{0h}(s,t) = \sum_{s<t_j\le t} \hat{P}_{00}(s,t_{j-1})\left(\frac{d_{0hj}}{r_{0j}}\right), \qquad (4)$$

for $h = 1, 2, \ldots, k$. Note that (4) is obtained from (2) by replacing $P_{00}(s,u) = P_{00}(s,u-)$ by $\hat{P}_{00}(s,u-)$ and $\alpha_{0h}(u)\,\mathrm{d}u$ by $\mathrm{d}\hat{A}_{0h}(u)$, the increment of the Nelson–Aalen estimator $\hat{A}_{0h}(t) = \sum_{t_j\le t} d_{0hj}/r_{0j}$ for the cumulative cause-specific **hazard rate** function $A_{0h}(t) = \int_0^t \alpha_{0h}(u)\,\mathrm{d}u$.

The variance of the Kaplan–Meier estimator (3) may in the usual way be estimated by Greenwood's formula (*see* **Kaplan–Meier Estimator**), while when there are no ties in the data,

$$\widehat{\mathrm{var}}\,\hat{P}_{0h}(s,t) = \sum_{s<t_j\le t} [\hat{P}_{00}(s,t_{j-1})\hat{P}_{0h}(t_j,t)]^2 \times (r_{0j}-1)r_{0j}^{-3}d_{0j} + \sum_{s<t_j\le t} \hat{P}_{00}(s,t_{j-1})^2[1-2\hat{P}_{0h}(t_j,t)] \times (r_{0j}-1)r_{0j}^{-3}d_{0hj}. \quad (5)$$

By breaking the ties at random, this variance estimator may also be used when there are a small number of tied observations (*see* **Tied Survival Times**). A more systematic treatment of variance estimation in the presence of ties is discussed below.

To illustrate the above results, we consider data on a cohort of uranium miners from the Colorado Plateau (see, for example, [7]). The cohort consisted of 3347 Caucasian male miners recruited between 1950 and 1960 and was traced for mortality outcomes to December 31, 1982, by which time there were 258 lung cancer deaths and 1000 deaths from other causes. Of these deaths, 145 and 442 occurred between 40 and 60 years of age. The data were collected to study the effects of radon exposure and smoking on mortality, but for our illustrative purposes we will study the (marginal) risk of death from lung cancer disregarding the information on these exposures.

We use the competing risks model with two competing causes of death, corresponding to "dead from lung cancer" (state 1) and "dead from other causes" (state 2), and with age as the time-scale. Figure 1 shows $\hat{P}_{01}(40,t)$ for $40 < t \le 60$, i.e. the estimated risk that a 40 years old miner will die from lung cancer between 40 and t years of age taking into account the risk of death from other causes. Pointwise 95% (log-transformed) confidence intervals based on the approximate normality of the Aalen–Johansen estimator (cf. below) are also shown. For comparison, Figure 1 also shows the estimated risk of lung cancer death disregarding the competing causes of death (computed as one minus the Kaplan–Meier estimator treating deaths from other causes as censorings). This estimate is sometimes interpreted as estimating the probability of death due to lung cancer, assuming this to be the only possible cause of death. Such an interpretation may be quite speculative, however; see the discussion in [9, Chapter 7]. The estimate disregarding competing risks is, of course, larger than the estimate that takes the competing causes of death into account; the difference between them increases with age as the risk of dying from other causes increases.

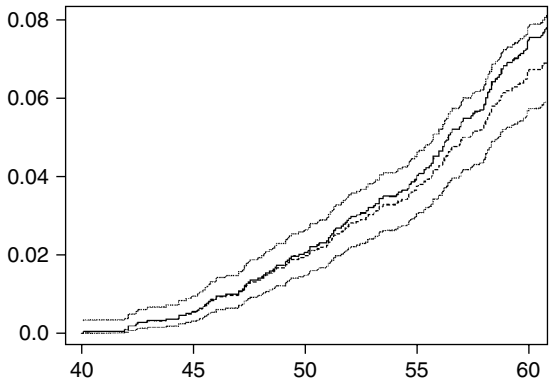

Figure 1 Aalen–Johansen estimate for the risk of dying from lung cancer taking into account the risk of death from other causes (- - - - - -) with 95% log-transformed confidence intervals (· · · · · · ·). Risk estimate disregarding other causes of death is also given (————)

An Illness–Death Model

To study the occurrence of a chronic disease as well as death in a homogeneous population, we may adopt the Markov illness–death model with states 0, 1 and 2 corresponding to "healthy", "diseased" and "dead", respectively, and where no recovery (i.e. transition from state 1 to state 0) is possible. The transition intensities of the model are denoted $\alpha_{01}(t), \alpha_{02}(t)$ and $\alpha_{12}(t)$ and describe the instantaneous risks of transitions between the states, i.e. $\alpha_{01}(t)\,\mathrm{d}t$ is the probability that an individual who is healthy just prior to time t will get diseased in the small time interval $[t, t+\mathrm{d}t)$, while $\alpha_{02}(t)\,\mathrm{d}t$ and $\alpha_{12}(t)\,\mathrm{d}t$ are the probabilities that an individual who is disease-free, respectively diseased, just before time t, will die in the small time interval $[t, t+\mathrm{d}t)$. For an individual who is healthy (i.e. in state 0) at time s, we write $P_{01}(s,t)$ for the probability that he is diseased (i.e. in state 1) at a later time t, while $P_{00}(s,t)$ is the probability that he is still healthy (i.e. in state 0) at

that time. Similarly, for an individual who is diseased (i.e. in state 1) at time s, we let $P_{11}(s,t)$ denote the probability that he is still alive (i.e. in state 1) at time t. Then we have

$$P_{00}(s,t) = \exp\left\{-\int_s^t [\alpha_{01}(u) + \alpha_{02}(u)]\,\mathrm{d}u\right\}, \quad (6)$$

$$P_{11}(s,t) = \exp\left[-\int_s^t \alpha_{12}(u)\,\mathrm{d}u\right], \quad (7)$$

$$P_{01}(s,t) = \int_s^t P_{00}(s,u)\alpha_{01}(u)P_{11}(u,t)\,\mathrm{d}u. \quad (8)$$

It is seen that (6) and (7) are of the same form as the survival probability in the survival data situation.

Assume, then, that we have a sample of n individuals from the population under study, and that each individual is followed from an entry time to death or censoring. Exact times of disease occurrences and deaths are recorded, and we denote by $t_1 < t_2 < \cdots$ the times of any observed event (disease occurrence or death). Furthermore, we let d_{01j} be the number of individuals who get diseased (i.e. make a transition from state 0 to state 1) at t_j, while d_{02j} and d_{12j} denote the numbers of disease-free, respectively diseased, individuals who die at that time. Finally, we introduce $d_{0j} = d_{01j} + d_{02j}$ for the total number of transitions out of state 0, and let r_{0j} and r_{1j} be the number of healthy (i.e. in state 0) and diseased (i.e. in state 1) individuals, respectively, just prior to time t_j. Then (6) and (7) may be estimated by the Kaplan–Meier estimators:

$$\hat{P}_{00}(s,t) = \prod_{s<t_j\le t}\left(\frac{1-d_{0j}}{r_{0j}}\right), \quad (9)$$

$$\hat{P}_{11}(s,t) = \prod_{s<t_j\le t}\left(\frac{1-d_{12j}}{r_{1j}}\right), \quad (10)$$

while an estimator for (8) is

$$\hat{P}_{01}(s,t) = \sum_{s<t_j\le t}\hat{P}_{00}(s,t_{j-1})\left(\frac{d_{01j}}{r_{0j}}\right)\hat{P}_{11}(t_j,t). \quad (11)$$

Note that (11) is obtained from (8) by replacing $P_{00}(s,u) = P_{00}(s,u-)$ by $\hat{P}_{00}(s,u-)$, $P_{11}(u,t)$ by $\hat{P}_{11}(u,t)$ and $\alpha_{01}(u)\,\mathrm{d}u$ by $\mathrm{d}\hat{A}_{01}(u)$, the increment of the Nelson–Aalen estimator $\hat{A}_{01}(t) = \sum_{t_j\le t} d_{01j}/r_{0j}$ for the cumulative disease intensity $A_{01}(t) = \int_0^t \alpha_{01}(u)\,\mathrm{d}u$. The variance of the Kaplan–Meier estimators (9) and (10) may be estimated by Greenwood's formula, while

$$\begin{aligned}\widehat{\mathrm{var}}\,\hat{P}_{01}(s,t) &= \sum_{s<t_j\le t}\hat{P}_{00}(s,t_{j-1})^2[\hat{P}_{11}(t_j,t) - \hat{P}_{01}(t_j,t)]^2 \\ &\quad\times (r_{0j}-1)r_{0j}^{-3}d_{01j} \\ &\quad+ \sum_{s<t_j\le t}[\hat{P}_{00}(s,t_{j-1})\hat{P}_{01}(t_j,t)]^2(r_{0j}-1)r_{0j}^{-3}d_{02j} \\ &\quad+ \sum_{s<t_j\le t}[\hat{P}_{01}(s,t_{j-1})\hat{P}_{11}(t_j,t)]^2(r_{1j}-1)r_{1j}^{-3}d_{12j},\end{aligned} \quad (12)$$

when there are no ties in the data, or when a few ties have been broken at random.

Before we illustrate these results, let us mention that other interpretations of the states are possible. In particular, in a study involving the treatment of cancer, state 0 could correspond to "no response to treatment", state 1 to "response to treatment" and state 2 to "relapse". The probability $P_{01}(s,t)$ is then the probability of being in response function suggested by Temkin [10] and sometimes used as an outcome measure when studying the efficacy of cancer chemotherapy. Another interpretation arises in the study of complications to a disease. Here, state 0 could correspond to "diseased with no complications", state 1 to "diseased with complications" and state 2 to "dead". This interpretation of the states is the one relevant for the following illustration.

The Steno Memorial Hospital in Greater Copenhagen has, since 1933, served as a diabetes specialist hospital for patients from the whole of Denmark. From the medical records at Steno we use for illustration data on the 374 female patients referred between 1933 and 1981 in whom the diagnosis insulin-dependent diabetes mellitus was established (usually by a general practitioner or another hospital) before the age of 10 years and between 1933 and 1972. The patients were followed from first contact with Steno to death, emigration, or December 31, 1984. One of the major complications of insulin-dependent diabetes is diabetic nephropathy, which is a sign of kidney failure. Seventeen patients had diabetic nephropathy at first admission to Steno, while 76 developed this complication during the observation period. The seriousness of diabetic nephropathy is reflected by the fact that among these 93 patients

54 were observed to die, whereas only 30 of the 281 patients who did not develop diabetic nephropathy died during the observation period.

We model the disease histories of the patients by the Markov illness–death model with the states 0 and 1 corresponding to "alive without diabetic nephropathy" and "alive with diabetic nephropathy", respectively, and with diabetes duration as time-scale. Figure 2 shows $\hat{P}_{01}(5, t)$, i.e. the estimated probability of being alive with diabetic nephropathy for patients without this complication five years after the onset of the disease. Pointwise 95% (log-transformed) **confidence intervals** based on the approximate normality of the Aalen–Johansen estimator (cf. below) are also shown. It is seen that the probability of being alive with diabetic nephropathy (among the group of patients we consider) first increases up to an estimated value of 17% after 23 years of diabetes duration, and then declines due to the high mortality among these patients.

It should be realized that Figure 2 is based on two crude assumptions. First, calendar time trends in mortality and incidence of diabetic nephropathy are not taken into account. Secondly, by using a Markov process to model the disease histories, the effect on mortality of the duration of diabetic nephropathy has been neglected. A point of less importance is that the exact times of onset of diabetic nephropathy were not known for nine of the 93 patients with this complication. For these nine patients, predicted times for the occurrence of diabetic nephropathy were used. A further discussion and analysis of the data are given, e.g. by Borch-Johnsen et al. [4]. The data were used for illustrative purposes by Andersen et al. [3] who also describe how the nine predicted times have been calculated.

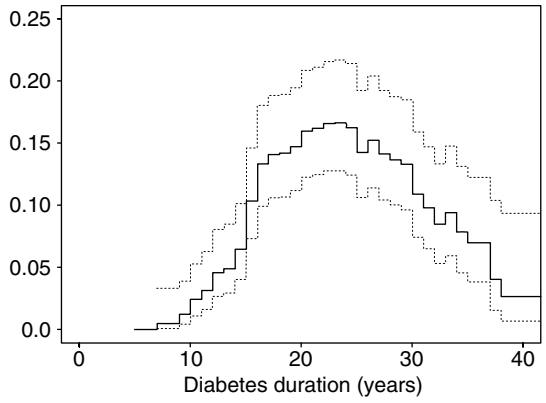

Figure 2 Aalen–Johansen estimate of the probability of being alive with diabetic nephropathy for female patients with diabetes onset before 10 years of age and with no sign of diabetic nephropathy five years after the onset of the disease (————). Pointwise 95% log-transformed confidence intervals are also shown (· · · · · · ·)

The General Case

We then consider a general Markov process with a finite number of states that may be used to model the life histories of individuals from a homogeneous population. Let $\mathcal{I} = \{0, 1, \ldots, k\}$ be the state space of the Markov process, and denote by $\alpha_{gh}(t)$ the transition intensity from state $g \in \mathcal{I}$ to state $h \in \mathcal{I}$, $g \neq h$. The transition intensities describe the instantaneous risks of transitions between the states, so $\alpha_{gh}(t)\,\mathrm{d}t$ is the probability that an individual who is in state g just before time t will make a transition to state h in the small time interval $[t, t + \mathrm{d}t)$. Furthermore, for all $g, h \in \mathcal{I}$, we let $P_{gh}(s, t)$ denote the probability that an individual who is in state g at time s will be in state h at a later time t, and we write $\mathbf{P}(s, t)$ for the $(k + 1) \times (k + 1)$ matrix of these transition probabilities. Only for simple Markov processes, like the competing risks and illness–death models considered earlier, is it possible to give explicit expressions for the $P_{gh}(s, t)$ in terms of the transition intensities, cf. (1), (2) and (6)–(8). We will see later, however, that the transition probability matrix $\mathbf{P}(s, t)$ itself can be expressed in terms of the $(k + 1) \times (k + 1)$ matrix $\boldsymbol{\theta}(t)$ of the transition intensities. First, we review the Aalen–Johansen estimator for $\mathbf{P}(s, t)$ and discuss the estimation of (co)variances.

Suppose that we have a sample of n individuals from the population under study. The individuals may be followed over different periods of time, so our observations of their life histories may be subject to left truncation and/or right censoring. A crucial assumption, however, is that truncation and censoring are independent so that the entry and censoring times do not carry any information on the risks of transitions between the states; cf. Andersen et al. [3, Sections III.2– 3] for a general discussion. We assume that exact times for transitions between the states are recorded, and denote by $t_1 < t_2 < \cdots$ the times when transitions between any two states are observed. Furthermore, for $g, h \in \mathcal{I}$, $g \neq h$, we

let d_{ghj} be the number of individuals who experience a transition from state g to state h at t_j, and introduce $d_{gj} = \sum_{h \neq g} d_{ghj}$ for the number of transitions out of state g at that time. Finally, we let r_{gj} be the number of individuals in state g just prior to time t_j. Then, the Aalen–Johansen estimator takes the form

$$\hat{\mathbf{P}}(s,t) = \prod_{s<t_j \leq t} (\mathbf{I} + \hat{\boldsymbol{\theta}}_j). \tag{13}$$

Here, $\mathbf{I}$ is the $(k+1) \times (k+1)$ identity matrix, $\hat{\boldsymbol{\theta}}_j$ is the $(k+1) \times (k+1)$ matrix with entry (g,h) equal to $\hat{\alpha}_{ghj} = d_{ghj}/r_{gj}$ for $g \neq h$ and entry (g,g) equal to $\hat{\alpha}_{ggj} = -d_{gj}/r_{gj}$, and the matrix product is taken in the order of increasing t_js. For simple models like the competing risks model and the illness–death model considered earlier, we are able to give explicit expressions for the elements of (13), cf. (3), (4), and (9)–(11). In general, however, this is not possible. But, in any case, a direct implementation of (13) is simple using software that can handle matrix multiplications (*see* **Matrix Computations**).

For any $g,h,m,r \in \mathcal{I}$, the covariance between $\hat{P}_{gh}(s,t)$ and $\hat{P}_{mr}(s,t)$ may be estimated by

$$\begin{aligned}
&\widehat{\mathrm{cov}}[\hat{P}_{gh}(s,t), \hat{P}_{mr}(s,t)] \\
&\quad = \sum_{i=0}^{k} \sum_{l \neq i} \sum_{s<t_j \leq t} \hat{P}_{gi}(s,t_{j-1}) \hat{P}_{mi}(s,t_{j-1}) [\hat{P}_{lh}(t_j,t) \\
&\qquad - \hat{P}_{ih}(t_j,t)][\hat{P}_{lr}(t_j,t) - \hat{P}_{ir}(t_j,t)] \\
&\qquad \times (r_{ij}-1) r_{ij}^{-3} d_{ilj},
\end{aligned} \tag{14}$$

provided that there are no ties in the data or that a small number of tied observations have been broken at random. Formulas (5) and (12) given earlier are special cases of (14). As an alternative to (14), or to handle ties in a systematic manner, one may use the recursion formula:

$$\begin{aligned}
&\widehat{\mathrm{cov}}[\hat{P}_{gh}(s,t_j), \hat{P}_{mr}(s,t_j)] \\
&\quad = \sum_{i=0}^{k} \sum_{l=0}^{k} \widehat{\mathrm{cov}}[\hat{P}_{gi}(s,t_{j-1}), \hat{P}_{ml}(s,t_{j-1})] \\
&\qquad \times (\delta_{ih} + \hat{\alpha}_{ihj})(\delta_{lr} + \hat{\alpha}_{lrj}) + \sum_{i=0}^{k} \hat{P}_{gi}(s,t_{j-1}) \\
&\qquad \times \hat{P}_{mi}(s,t_{j-1}) \widehat{\mathrm{cov}}(\hat{\alpha}_{ihj}, \hat{\alpha}_{irj}),
\end{aligned} \tag{15}$$

which describes how the estimated (co)variances are updated at the times of the observed transitions. (The estimates are constant between the t_js.) Here, δ_{ih} is a Kronecker delta, while $\widehat{\mathrm{cov}}(\hat{\alpha}_{ihj}, \hat{\alpha}_{irj})$ equals $(\delta_{hr} r_{ij} - d_{ihj}) r_{ij}^{-3} d_{irj}$ when $h \neq i, r \neq i$; it equals $-(r_{ij} - d_{ij}) r_{ij}^{-3} d_{irj}$ when $h = i \neq r$; and it equals $(r_{ij} - d_{ij}) r_{ij}^{-3} d_{ij}$ when $h = r = i$. When there are no ties in the data (14) and (15) give identical results.

Product–Integral Representation and Relation to the Nelson–Aalen Estimator

We now review how the transition probability matrix may be derived from the transition intensities $\alpha_{gh}(t)$ and describe how the Aalen–Johansen estimator is related to the Nelson–Aalen estimators for the cumulative transition intensities. To this end, we introduce $\alpha_{gg}(t) = -\sum_{h \neq g} \alpha_{gh}(t)$ and write $\boldsymbol{\theta}(t)$ for the $(k+1) \times (k+1)$ matrix with element (g,h) equal to $\alpha_{gh}(t)$. Then, the transition probability matrix $\mathbf{P}(s,t)$ is the unique solution to the Kolmogorov forward differential equation $(\partial/\partial t)\mathbf{P}(s,t) = \mathbf{P}(s,t)\boldsymbol{\theta}(t)$ with initial condition $\mathbf{P}(s,s) = \mathbf{I}$. By a general result for product–integrals (Volterra's equation), this solution takes the form $\mathbf{P}(s,t) = \prod_{(s,t]} [\mathbf{I} + \boldsymbol{\theta}(u)\,\mathrm{d}u]$. Alternatively, if we introduce the $(k+1) \times (k+1)$ matrix $\mathbf{A}(t)$ with elements $A_{gh}(t) = \int_0^t \alpha_{gh}(s)\,\mathrm{d}s$, we may write

$$\mathbf{P}(s,t) = \prod_{(s,t]} [\mathbf{I} + \mathrm{d}\mathbf{A}(u)]. \tag{16}$$

This product–integral representation of the transition probability matrix of a Markov process is not restricted to the situation where transition intensities exist. In fact (16) assumes only the existence of cumulative transition intensities $A_{gh}(t)$, which do not need to be absolutely continuous.

For $g \neq h$ we may estimate the cumulative transition intensity $A_{gh}(t)$ by the Nelson–Aalen estimator $\hat{A}_{gh}(t) = \sum_{t_j \leq t} \hat{\alpha}_{ghj}$, while $\hat{A}_{gg}(t) = -\sum_{h \neq g} \hat{A}_{gh}(t) = \sum_{t_j \leq t} \hat{\alpha}_{ggj}$. Let $\hat{\mathbf{A}}(t) = \sum_{t_j \leq t} \hat{\boldsymbol{\theta}}_j$ be the $(k+1) \times (k+1)$ matrix with these elements. By (16) it is reasonable to estimate the transition probability matrix by $\hat{\mathbf{P}}(s,t) = \prod_{(s,t]} [\mathbf{I} + \mathrm{d}\hat{\mathbf{A}}(u)]$. But since $\hat{\mathbf{A}}(t)$ is a matrix of step functions with a finite number of jumps on $(s,t]$, this is nothing but the Aalen–Johansen estimator (13).

Thus, the Aalen–Johansen and Nelson–Aalen estimators are related in exactly the same way as are the transition probability matrix and the cumulative transition intensities themselves. This suggests that the Aalen–Johansen estimator is the canonical nonparametric estimator for the matrix of transition probabilities in a Markov process with a finite number of states. This statement is supported by the fact that it may also be given a **nonparametric maximum likelihood** interpretation [8].

Martingale Representation and Statistical Properties

The product–integral formulation of the Aalen–Johansen estimator is useful for the study of its statistical properties. We here indicate a few main steps and refer to Andersen et al. [3, Section IV.4] for a detailed account. For each $g \in \mathcal{I}$ we introduce an indicator $J_g(t)$, which is one if there is at least one individual in state g just before time t, and zero otherwise. Furthermore, for all $g, h \in \mathcal{I}$ define $A^*_{gh}(t) = \int_0^t J_g(u)\,\mathrm{d}A_{gh}(u)$, and let $\mathbf{A}^*(t)$ be the $(k+1) \times (k+1)$ matrix with these elements. Finally, we introduce $\mathbf{P}^*(s,t) = \prod_{(s,t]}[\mathbf{I} + \mathrm{d}\mathbf{A}^*(u)]$, and note that this is almost the same as $\mathbf{P}(s,t)$ (cf. (16)) when there is only a small probability that one or more states will be empty at times u between s and t. By a general result for product–integrals (Duhamel's equation), we may then write

$$\hat{\mathbf{P}}(s,t)\mathbf{P}^*(s,t)^{-1} - \mathbf{I} = \int_{(s,t]} \hat{\mathbf{P}}(s,u-)\,\mathrm{d}(\hat{\mathbf{A}} - \mathbf{A}^*)(u)\mathbf{P}^*(s,u)^{-1}. \quad (17)$$

Here, $\hat{\mathbf{A}} - \mathbf{A}^*$ is a $(k+1) \times (k+1)$ matrix of square integrable martingales (*see* **Nelson–Aalen Estimator**). It follows that the right-hand side of (17) is a matrix-valued stochastic integral, and therefore itself a $(k+1) \times (k+1)$ matrix of mean zero square integrable martingales. As a consequence of this

$$\mathrm{E}[\hat{\mathbf{P}}(s,t)\mathbf{P}^*(s,t)^{-1}] = \mathbf{I},$$

so the Aalen–Johansen estimator is almost **unbiased**. Furthermore, the predictable variation process of the matrix-valued martingale (17) suggests an estimator for the covariance matrix of $\hat{\mathbf{P}}(s,t)\mathbf{P}^*(s,t)^{-1}$, and based on this the (co)variance estimators (14) and (15) may be derived.

The martingale representation (17) is also key to the study of the large sample properties of the Aalen–Johansen estimator. For fixed s it may be shown that $\hat{\mathbf{P}}(s,\cdot)$, properly normalized, converges weakly to a matrix-valued Gaussian process. In particular, when also t is given, the Aalen–Johansen estimator (13) is asymptotically multinormally distributed, a fact that was used earlier in connection with the construction of confidence intervals.

ØRNULF BORGAN

Absolute Risk

Absolute risk is defined as the probability that a disease-free individual will develop a given disease over a specified time interval given current age and individual risk factors, and in the presence of **competing risks**. In mathematical terms, the absolute risk of developing a disease of interest c_1 in the age interval $[a_1, a_2)$ in the presence of competing risks c_2 for a person of age a_1 and with initial **covariates** x is given by

$$\pi(a_1, a_2; x) = \frac{\displaystyle\int_{a_1}^{a_2} h_1(u;x) \exp\left\{-\int_0^u [h_1(v;x) + h_2(v;x)]\mathrm{d}v\right\} \mathrm{d}u}{\displaystyle\exp\left\{-\int_0^{a_1} [h_1(v;x) + h_2(v;x)]\mathrm{d}v\right\}}, \tag{1}$$

where $h_1(v;x)$ and $h_2(v;x)$ are, respectively, the cause-specific **hazards** of developing c_1 and c_2 for an individual with current age v and level x of covariates X. In this formula, the numerator represents the probability of developing the disease of interest c_1 between ages a_1 and a_2 in the presence of competing risks c_2 while the denominator represents the probability of being at risk at age a_1, namely free of c_1 and c_2. This formulation underscores the conditional nature of absolute risk. However, a simpler and equivalent formulation can be obtained as

$$\pi(a_1, a_2; x) = \int_{a_1}^{a_2} h_1(u;x) \times \exp\left\{-\int_{a_1}^{u} [h_1(v;x) + h_2(v;x)]\,\mathrm{d}v\right\} \mathrm{d}u. \tag{2}$$

The hazard $h_1(u;x)$ can be expressed as a function of both the baseline hazard $h_1(u)$ (i.e. the hazard in subjects at baseline level of covariates x) and the level x of covariates X. For instance, if the covariates X have a **multiplicative** effect on the hazard, then the multiplicative relationship $h_1(u;x) = h_1(u)rr(u;x)$ is obtained, where the multiplier $rr(u;x)$ is the relative rate, also termed the rate ratio, **incidence density ratio**, **hazard ratio** (the term which is used throughout this article), instantaneous relative risk or, loosely, **relative risk** (see the section "Related Quantities" below). If the covariates X have an **additive** effect on the hazard, then the additive relationship $h_1(u;x) = h_1(u) + d(u;x)$ is obtained, where the additive term $d(u;x)$ is the rate difference or hazard difference or incidence density difference. Upon considering such expressions, one can note that the value of absolute risk depends on both the incidence of disease in the population and the strength of the relationship between covariates and disease. One consequence is that, while the hazard ratio is often portable from one population to another (portability being more questionable for the rate difference), portability is not a property of absolute risk, as the baseline incidence rate of disease may vary widely among populations that are separated in time and location or even among subgroups of populations, possibly because of differing genetic patterns or differing exposure to unknown risk factors. Additionally, competing causes of death (competing risks) may also have different patterns among different populations which might also influence values of absolute risk.

An important consideration is that covariates X may be time-dependent (*see* **Time-dependent Covariate**), in which case one must rely on a more general formulation of (1) and (2) obtained by (i) replacing initial covariate value x in $\pi(a_1, a_2; x)$ by covariate history in interval $[a_1, a_2)$, namely $\{x(v), a_1 \leq v < a_2\}$, and (ii) by using generalized versions of cause-specific hazards, namely $h_1(v; x(v))$ and $h_2(v; x(v))$, in the right-hand terms of (1) and (2). Eqs. (1) and (2) correspond to the special case in which covariates X remain constant throughout the interval. However, unless it is possible to predict (in a probabilistic or deterministic manner) the future variation of covariates over time, estimation is based on (1) or (2) in their original form, and relies on the initial covariate value x and the assumption that it remains constant. This approach is likely to underestimate absolute risk if covariates the associated risks of which can only increase with time are considered. Such variables include, for instance, family history of breast cancer and number of previous breast biopsies for benign breast disease, which are used in estimating the absolute risk of breast cancer from the Breast Cancer Detection and Demonstration Project [47] (see the section "Estimation From Population-Based or Nested Case–Control Studies" below).

Range

Absolute risk is a probability and therefore lies between 0 and 1 and is dimensionless. A value of 0, while theoretically possible, would correspond to very special cases such as a purely genetic disease for an individual not carrying the disease gene. A value of 1 would be even more unusual and might again correspond to a genetic disease with a **penetrance** of 1 for a **gene** carrier (but, even in this case, the value should be less than 1 if competing risks cannot be ignored).

Synonyms

The term *absolute risk* or *absolute cause-specific risk* has been used by several authors, including Dupont [35], Benichou & Gail [13, 14], Benichou [11], and Langholz & Borgan [62]. However, it is not a universally accepted term. Alternative terms include risk [59], individualized risk [47], individual risk [94], crude probability [28], crude incidence [60], **cumulative incidence** [49], cumulative incidence risk [75] and absolute incidence risk [76]. It should be noted that the definition of the two latter terms [75, 76] ignores the concept of competing risks.

Interpretation and Usefulness

Absolute risk provides an individual measure of the probability of disease occurrence, and can therefore be useful in counselling. It is well suited to predicting **risk** for an individual, unlike the hazard ratio or the relative risk, which quantify the increase in the probability of disease occurrence relative to subjects at the baseline level of risk factors, but do not quantify that probability itself. Moreover, individualized absolute risk estimates over specific time intervals are often more useful than general statements about risk such as "one in nine women will develop breast cancer during her lifetime" [3].

Absolute risk has been used as a tool for individual counseling in breast cancer. Indeed, a woman's decision to embark on a program of intensive surveillance with mammography or even to undergo prophylactic mastectomy depends on her awareness of the medical options, on personal preferences, and on absolute risk. A woman may have several risk factors and an elevated hazard ratio, but if her absolute risk of developing breast cancer over the next 10 years is small, she may be reassured and she may be well advised simply to embark on a program of surveillance. Conversely, she may be very concerned about her absolute risk over a longer time period, such as 30 years, and she may decide to undergo prophylactic mastectomy if her absolute risk is very high [92]. An assessment of absolute risk (and its range of uncertainty) can help the woman understand the extent of the risk and can therefore be useful in helping the woman and her doctor define an acceptable medical plan [17, 44, 47].

Absolute risk is also useful in designing trials of interventions to prevent the occurrence of a disease (*see* **Prevention Trials**) because the sample sizes required for these studies (*see* **Sample Size Determination for Clinical Trials**) depend importantly on the absolute risk of developing the disease during the period of study [8]. Absolute risk has also been used to define **eligibility criteria** in such studies. For example, women were enrolled in a preventive trial to decide whether the drug Tamoxifen can reduce the risk of developing breast cancer. Because Tamoxifen is a potentially toxic drug and because it was to be administered to a healthy population, it was decided to restrict eligibility to women with somewhat elevated absolute risks of breast cancer. Only women over age 59 and younger women whose absolute risks were estimated to equal or exceed that of a typical 60-year-old woman were eligible to participate [8, 93].

Absolute risk can also be important in decisions affecting public health. For example, in order to estimate the absolute reduction in lung cancer incidence that might result from measures to reduce exposure to radon, one could categorize a general population into subgroups based on age, sex, smoking status, and current radon exposure levels, and then estimate the absolute reduction in lung cancer incidence, in the presence of competing risks, that would result from lowering radon levels in each subgroup [13, 42]. Such an analysis would complement estimation of population **attributable risk** and generalized impact fractions.

The concept of absolute risk is also useful in a clinical setting as a measure of the individualized probability of an adverse event, such as a recurrence or death in diseased subjects. In that context, absolute risk depends on **prognostic factors** of

recurrence or death, rather than on factors influencing the risk of incident disease, and the time-scale of interest is usually time from diagnosis or from surgery rather than age. Absolute risk is a useful tool to help define individual patient management and, for instance, the absolute risk of recurrence in the next three years might be an important element in deciding whether to prescribe an aggressive and potentially toxic treatment regimen. Such an application is discussed in Benichou & Gail [13], who consider the absolute risk of recurrence as a function of cell type and TN staging in patients with resected lung cancer. Korn & Dorey [60] provide other examples. Note that in such a setting, 1 minus the absolute risk of recurrence differs from the standard disease-free survival probability (obtained from the disease-free interval distribution or time to recurrence distribution) in that absolute risk takes into account competing risks (deaths from other causes than the disease under study). The difference is particularly large if competing death rates are high compared to the disease-related adverse event rate, as among older people.

Properties

Two main points need to be emphasized. First, as is evident from its definition, absolute risk can only be estimated in reference to a specified time interval. One might be interested in short time spans (e.g. five years), long time spans (e.g. 30 years), or even lifetime absolute risk. Of course, absolute risk increases as the time span increases. In the clinical setting, the time span might also vary with the context and the severity of the disease.

Absolute risk can be strongly influenced by the intensity of competing risks (typically competing causes of death). Absolute risk varies inversely as a function of death rates from other causes (denoted by $h_2(v;x)$ in (1) and (2)). The same result in the clinical setting may lead to differences between 1 minus the absolute risk and the disease-free survival probability (see the section "Interpretation and Usefulness" above). Indeed, disease-free survival applies best in the situation in which no competing causes (unrelated to the disease under study) are acting to kill the patient before the occurrence of the disease or adverse event of interest [13].

Estimability

It follows from its definition that absolute risk is estimable if and only if cause-specific hazard rates for the disease (or event) of interest c_1 as well as death rates from competing causes c_2 are estimable (*see* **Estimation**). Therefore, absolute risk is directly estimable from **cohort** and **case–cohort studies**, but **case–control** and **cross-sectional studies** have to be complemented with follow-up data. Absolute risk is estimable from nested **case–control studies** or **population-based case–control studies**, in which the cohort or the specified population from which cases and controls are selected provides the necessary complementary information on incidence rates. While the theoretic possibility exists to complement cross-sectional studies with follow-up data, such designs do not seem to have been implemented.

An important feature of absolute risk is that it takes into account competing risks, that is the possibility for an individual to die of an unrelated disease before developing the disease (or disease-related event) of interest. Absolute risk is identifiable without any unverifiable competing risk assumptions, such as the assumption that competing risks act independently of the cause of interest because, as Prentice et al. [86] emphasize, all functions of the cause-specific hazards in (1) and (2) are estimable. Chiang [28] used the term "crude" probability to describe absolute risk, the probability of experiencing c_1 *in the presence* of competing risks c_2. This quantity is relevant for individual predictions and other applications discussed above rather than the underlying (or "net" or "latent") probability of experiencing c_1 in the absence of competing risks. One minus the standard disease-free survival represents that underlying probability of experiencing c_1 in the absence of competing risks or under the (unverifiable) assumption of independence between time to c_1 and time to c_2 (see [13, 27, 28, 43, 55, 60] and [86] for more details). The only competing risk assumption needed to estimate absolute risk concerns subjects lost to follow-up, who are assumed to be randomly selected from those at risk at the time of loss (independent noninformative **censoring**) [13].

Sometimes, estimates of competing hazards h_2 are based on external sources such as **vital statistics**. For instance, Gail et al. [47] developed breast cancer absolute risk estimates and used mortality rates from year 1979 for all causes except breast cancer

(see also [11, 13, 14] and [60]). Although (1) and (2) allow for competing risk hazards h_2 to depend on covariate level x, it is frequently assumed that h_2 does not depend on x. It could also be assumed that h_2 depends on a set of covariates X' that are different from covariates X.

Estimation from Cohort Studies

Since all cause-specific hazards can be estimated from cohort studies, it follows that absolute risk can also be directly estimated from cohort studies. Estimation of cause-specific hazards from cohort data is a standard topic and details can be found in epidemiology or survival analysis textbooks (*see* **Survival Analysis, Overview**). However, the details of absolute risk estimation have been worked out under several models, and properties of absolute risk estimates have been studied and compared. A review is given here.

Covariate-free Estimates of Absolute Risk

The following methods are appropriate for a homogeneous study population. They are also used to provide estimates of composite absolute risk in populations; namely, overall estimates of absolute risk that do not distinguish among levels of covariates X. Parametric and **nonparametric** estimators are presented.

The "density method" [59, 76, 77] estimates absolute risk $\pi(a_1, a_2)$ by the cumulative (incidence) risk given by $1 - \exp\{-\Lambda(a_1, a_2)\}$, where $\Lambda(a_1, a_2)$ is the cumulative hazard for the event of interest, c_1. This formulation ignores competing risks. The term x is omitted in Λ because an overall rather than an exposure-specific absolute risk is considered. This approach is parametric, as it relies on a piecewise **exponential** distribution of time to c_1, which corresponds to a piecewise constant hazard of developing c_1. It ignores competing risks, and therefore applies only in the absence of competing risks, which constitutes an important limitation.

Benichou & Gail [13] developed direct parametric estimators of absolute risk. They derived direct estimators of $\pi(a_1, a_2)$ based on (1) or (2) (still ignoring covariates X) under exponential and piecewise exponential models. Under the exponential assumption, hazards h_1 and h_2 are constant, while under the piecewise exponential assumption, hazards h_{1i} and h_{2i} are piecewise constant. The expression for $\pi(a_1, a_2)$ under the piecewise exponential assumption is given by [13]

$$\pi(a_1, a_2) = \sum_i h_{1i}(h_{1i} + h_{2i})^{-1} \times [1 - \exp\{-(h_{1i} + h_{2i})\Delta_i\}]A(i), \quad (3)$$

with $A(i) = \prod_j \exp\{-(h_{1j} + h_{2j})\Delta_j\}$. In (3), the sum is taken over all time intervals included in $[a_1, a_2)$, i is the corresponding index, h_{1i} (respectively h_{2i}) denotes the (constant) hazard for cause c_1 (respectively c_2) in interval i, Δ_i is the width of interval i, and the product in $A(i)$ is taken over all time intervals in $[a_1, a_2)$, but the last one and indexed by j. For simplicity, a_1 and a_2 are taken to correspond to interval bounds.

Hazard rates h_{1i} can easily be estimated by d_{1i}/t_i, where d_{1i} and t_i, respectively, denote the observed number of events and **person-years** in interval i. Analogous estimates of competing hazards h_{2i} are given by d_{2i}/t_i, where d_{2i} denotes the observed number of events in interval i. Corresponding point estimates of $\pi(a_1, a_2)$ can be obtained by replacing hazards by their estimates in (3). Under the simple exponential assumption, no separate intervals are considered as the hazards h_1 and h_2 are considered constant throughout time. Eq. (3) simplifies, as the sum includes only one term and $A(i)$ equals 1. Estimates of hazards are obtained as for the piecewise exponential model with a single interval.

Unlike estimates with the density method, direct estimates of absolute risk with the exponential and piecewise exponential assumptions do not ignore competing risks, therefore providing estimates of the absolute risk of developing c_1 *in the presence* of competing risks. Moreover, as for the density method, absolute risk can be estimated for a much longer duration than the actual follow-up of individuals in the study if age is the time scale (open cohort), provided that there is no secular trend in age-specific disease incidence.

Variance estimates of the absolute risk estimate are obtained using the **delta method** [87], and corresponding **confidence intervals** follow. Details are given in Benichou & Gail [13] for the exponential and piecewise exponential models. Properties of point and variance estimators were studied by Benichou & Gail [13] for the case of a closed cohort. When the simple exponential model was correct,

simulations showed no or very little **bias** in point estimates of $\pi(a_1, a_2)$, and analytic and simulation results showed that substantial gains in efficiency could be achieved with a simple exponential analysis. **Simulations** showed that exponential and piecewise exponential analyses yielded nearly nominal coverage with better results under the log **transformation** of $\pi(a_1, a_2)$. When a **Weibull** model with a large shape parameter of 2 was correct, simulations showed that only the piecewise exponential analysis with a sufficient number of intervals achieved little or no bias as well as good coverage, while simpler models led to serious bias and consequent failure of coverage.

The **actuarial method** or **life table** method [23, 33, 39, 41, 59] is an approach that shares similarities with the piecewise exponential approach, although it was derived from a less parametric viewpoint. As with the piecewise exponential approach, time is split into intervals (indexed by i in this presentation). In each time interval i, the probability for an individual at risk at the beginning of the interval to survive the interval without developing c_1 is expressed as

$$S_i = \frac{\left(\frac{n_i - w_i}{2 - d_i}\right)}{\left(\frac{n_i - w_i}{2}\right)}, \tag{4}$$

where n_i denotes the number of subjects in the cohort at the beginning of interval i, d_i the number of events occurring in interval i, and w_i the number of subjects either lost to follow-up or developing c_2 (competing risks) in interval i. The actuarial approach is most appropriate when grouped data are available and the actual follow-up in each interval is not known. The person-years of follow-up for subjects lost to follow-up or developing c_2 in interval i is not used but, if one assumes that the **mean** withdrawal time occurs at the midpoint of the interval, then the denominator in (4) can be regarded as the effective number of persons at risk of developing the disease. That is, it represents the number of disease-free persons that would be expected to produce d_i events if all persons could be followed for the entire interval [38, 59, 66]. It can be regarded as a refinement of the simple cumulative method [59, 77] that ignores quantity w_i. Absolute risk is estimated by the cumulative (incidence) risk which, from the formulation in (4), is obtained as

$$1 - \prod_i S_i. \tag{5}$$

Since (5) ignores competing risks, the actuarial method applies in the absence of competing risks, which constitutes an important limitation, in an analogous manner as the density method. Moreover, as shown by several authors [33, 41], the actuarial method results in biased estimates of risks even in the unlikely and most favorable event (in terms of bias) of all withdrawals occurring at the interval midpoints. Alternative approaches based on different choices of the quantity to subtract from n_i (choices different from $w_i/2$) are not subject to less bias [38]. The problem can be improved best by using narrower intervals, but this is done at the expense of a larger **random error**.

Unlike the piecewise exponential models, the actuarial method does not require knowledge of follow-up time in each interval but only knowledge of the number at risk and the number of withdrawals. The piecewise exponential approach could, however, be used without knowledge of follow-up time by assigning a follow-up time of half the interval width to subjects who are lost to follow-up or who develop c_1 or c_2, in an analogous fashion as with the actuarial method [13]. The piecewise exponential approach has several advantages over the actuarial method. Bias is less of a problem with it, it takes competing risks into account, it applies naturally to open cohorts, and it extends easily to **regression**-based estimators (see below).

When individual follow-up times are all known, it is possible to estimate absolute risk nonparametrically as in Aalen [1], by substituting $\hat{\overline{G}}(t_1-)$, the right continuous **Kaplan–Meier estimate** [56] of surviving both c_1 and c_2 to time a_1 into the denominator of (1) and by replacing the numerator by $\sum \hat{\overline{G}}(t-)R^{-1}(t)$, where $R(t)$ is a left continuous process defining the number of subjects at risk just before t. The summation is over distinct times in $[a_1, a_2)$ at which events c_1 occur. The same estimator is discussed by Aalen & Johansen [2], Kay & Schumacher [57], Gray [49], Matthews [73], Keiding & Andersen [58], Benichou & Gail [13], and Korn & Dorey [60].

While nonparametric point estimates are easy to obtain, variance estimates are more complex and can be obtained in several ways. Results in Aalen [1, Theorem 2] can be used, as discussed in Benichou & Gail [13] and Korn & Dorey [60]. Alternatively, results in Aalen & Johansen [2, Theorem 4.3] can be used, as discussed by Keiding & Andersen [58]. Confidence intervals can then be obtained, based on

the log transformation, as suggested by Benichou & Gail [13] and Keiding & Andersen [58], or based on results of Dorey & Korn [34], who treat the lower and upper limit differently, a procedure that they claim is advantageous under heavy censoring.

Analytic and simulation results in Benichou & Gail [13] under exponential survival distributions show that the loss of efficiency of the nonparametric method is very small compared to a detailed piecewise exponential model and that nearly nominal coverage is obtained with the log transformation as for the piecewise exponential model. In simulations under a Weibull model with a large shape parameter of 2, very little bias and near nominal coverage was observed as with the piecewise exponential model [13]. These results suggest that properties of the piecewise exponential model and the nonparametric approach agree closely. The nonparametric approach does not make any assumption on the form of the hazards, but the piecewise constant assumption can be made less stringent by increasing the number of intervals. The piecewise exponential model has the advantage of simplicity of computation, in that it uses grouped data rather than individual data. Moreover, it is well suited to open cohorts.

These approaches yield an overall composite absolute risk and ignore covariates X. In order to obtain estimates that depend on the level of covariates, the cohort can be subdivided into subcohorts, and these approaches applied to resulting subcohorts defined by levels of X. This approach yields absolute risk estimates with low precision, however, if the subcohorts are small and have few events, as can happen if several risk factors have to be considered jointly (see [47] for further discussion and illustration, and [7] and [82] for further illustration with the actuarial method and breast cancer data). In order to remedy this problem, a natural approach is to model incidence rates h_1 and h_2 through regression models.

Covariate Models

Regression-based parametric methods are a direct extension of parametric methods for composite estimates. For instance, Benichou & Gail [13] studied exponential and piecewise exponential models. Under the piecewise exponential model, it is assumed that hazards for c_1 are products of a baseline hazard in interval i and a function of the covariates, usually (but not necessarily) expressed as $\exp(\beta^{\mathrm{T}} x)$. Baseline hazards as well as hazard ratio parameters β can be jointly estimated by maximizing the piecewise exponential **likelihood**. That likelihood is the same as that obtained by assuming that the number of events in each combination of time interval and level of X has a **Poisson distribution** with mean given by the product of the hazard times the corresponding number of person-years, that latter number being assumed constant [52, 61] (*see* **Poisson Regression in Epidemiology**). It is possible to include time by exposure **interactions** in covariates X so that the **proportional hazard** assumption is not required. Furthermore, hazards for cause c_2 are estimated separately. They are also assumed to be piecewise constant and can be assumed to depend on the set of covariates X, a different set X' if needed, or on no covariates. A point estimate of $\pi(a_1, a_2; x)$ is obtained by replacing quantities h_{1i} in (3) by quantities $h_{1i} \exp(\beta^{\mathrm{T}} x)$, where h_{1i} denotes the baseline hazard in the latter expression, and by plugging in **maximum likelihood** estimates of the parameters. Corresponding parameter estimates for competing hazards are estimated separately and also plugged in (3). A similar approach to point estimation can be taken for other parametric models such as a simple exponential model or a Weibull model [13].

As described in Benichou & Gail [13], variance estimates can be obtained by applying the delta method [87] and relying on the observed **information matrix** for all parametric models. Finite sample properties were studied by Benichou & Gail [13] through simulations based on a **clinical trial** of lung cancer [48]. Simulations used 392 patients, an accrual period of three years, and an additional follow-up of two years. Time to c_1 was assumed to be exponentially distributed and to depend on two covariates forming six joint levels, while time to c_2 was assumed to be exponential and not to depend on any covariates. Point estimates had little bias with piecewise exponential and exponential analyses. Variance estimates were also little biased and coverage was nearly nominal with all analyses except for the level of X with the fewest patients (12 patients) in which variance estimates and corresponding coverage were too small. Loss of efficiency could be appreciable when a detailed piecewise exponential was used compared to the simple exponential model.

Finally, a **semiparametric** estimator of absolute risk can be obtained, as outlined in Benichou & Gail [13]. The difference with the piecewise

exponential approach is that the hazard for c_1 is the product of an unspecified function of time (the baseline hazard) times a function of the covariates which is also usually of the form $\exp(\beta^T x)$ [31]. As for the piecewise exponential model, X may include time by exposure interaction and competing hazards can be assumed to depend on covariates X or X' or on no covariates (in the latter case, corresponding survival is estimated nonparametrically using the Kaplan–Meier product-limit estimator).

The expression for a semiparametric estimate of absolute risk is given in Benichou & Gail [13, formula (3.1)] and is a function of **partial likelihood** estimates [32] of hazard ratio parameters β and related **Nelson–Aalen estimates** of cumulative baseline hazards [6]. From results in Tsiatis [95] and Andersen & Gill [5] on the joint distribution of these parameter estimates, Benichou & Gail [13] derived an asymptotic variance estimator. No formal study of its finite sample properties has been undertaken.

These regression methods yield estimates of absolute risk with acceptable precision for several covariates. Regression-based methods are therefore well suited for individual prediction. Parametric or semiparametric approaches can be used. The piecewise exponential estimator seems to provide a good compromise between bias and precision, while being easy to implement both for open and closed cohorts.

Estimation from Population-based or Nested Case–Control Studies

Case–control studies provide data on the distributions of exposure respectively in diseased subjects (cases) and nondiseased subjects (controls) for the disease under study. These data are used to estimate hazard ratios or relative risks through the estimation of odds ratios, but are not sufficient to estimate exposure-specific incidence rates (the terms "hazard" and "incidence rate" are used indiscriminately in the remainder of the text) and absolute risks. In order to do so, case–control data have to be complemented by follow-up data. Either the cases and controls are selected from a follow-up study (*see* **Case–Control Study, Nested**) that provides either grouped data or individual data with survival-type information, or they are selected from a specified population in which an effort is made to identify all **incident cases** diagnosed during a fixed time interval (*see* **Case–Control Study, Population-based**) usually in a grouped form (number of cases and number of persons by age group). In both situations, full information on exposure is obtained only for cases and controls, but the complementary data provide information on composite incidence that can be combined with hazard ratio estimates to obtain exposure-specific incidence rates, as has long been recognized [29, 30, 68, 75, 76, 80].

The main estimation problem regards estimation of exposure- and age-specific hazards or incidence rates (age is the usual time scale in this context). Absolute risk estimates are then obtained from (1) or (2), and the delta-method [87] can be used to obtain the variance of absolute risk estimates based on the **covariance matrix** of incidence rate estimates. Parametric methods based on the piecewise exponential model (also termed the **Poisson regression** model) and the **logistic** model have been derived under a full likelihood approach, a **pseudo-likelihood** approach, and a hybrid approach. That latter approach will be described fully, because it has been used to obtain absolute risk estimates in practice. The former two approaches will be reviewed more briefly, because they have not yet been used to derive absolute risk estimates and fewer results are available. Finally, a semiparametric estimate of absolute risk based on partial likelihood has been proposed for nested case–control studies with time-matching of cases and controls, and will also be reviewed.

Parametric Approaches

The hybrid approach has been proposed by Gail et al. [47] as a multivariate extension of earlier work by Miettinen [75]. It relies on the possibility of estimating composite incidence rates h^*_{1i} from the population or follow-up data for each age group i or, in a more general fashion, for each stratum i defined by age and other factors observed in the follow-up or population data such as sex and region. Under a piecewise exponential assumption, the quantity h^*_{1i} is estimated by the ratio d_{1i}/t_i of the number of incident cases of disease c_1 to the number of person–years. Although information on exposure is obtained on cases and controls only, and not on the whole cohort or population, baseline incidence rates h_{1i} (for subjects at the baseline level of all exposure factors considered) can be obtained through the relationship [47, 75]:

$$h_{1i} = h^*_{1i}(1 - AR_i), \tag{6}$$

where AR_i is the attributable risk for disease c_1 in age group i or, more generally stratum i, for all exposure factors jointly, a quantity estimable from the case–control data. Gail et al. [47] suggested using the model-based approach of Bruzzi et al. [25], that incorporates **odds ratios** from **logistic regression**, for estimating attributable risk, and obtained a point estimate for h_{1i}. Upon multiplying that estimate by the corresponding odds ratio from logistic regression, they obtained an estimate of the incidence rate for each joint age and exposure level. Finally, incidence rates for competing risks can be obtained from the follow-up or population data, provided that those rates are assumed not to be influenced by the exposure factors for c_1. The latter assumption stems from the fact that it would be impossible to estimate hazard ratios for c_2 from case–control data for disease c_1. In fact, Gail et al. [47] used external data on national US mortality rates to estimate h_{2i} and obtained absolute risk estimates from the piecewise exponential model in formula (3).

Variance estimators are complex since incidence rate estimates involve odds ratio parameters obtained through logistic regression from the case–control data and counts of incident cases from the follow-up or population data. Estimators of variances and covariances of age- and exposure-specific incidence rates have been fully worked out by Benichou & Gail [14] for **simple random sampling**, **stratified random sampling**, **frequency matching** and individual **matching** in a simple setting. The approach relies on an extension of the delta-method to implicitly related **random variables** [12]. It takes into account all sources of variability; namely, the variance of hazard ratio estimates and of baseline incidence rate estimates, as well as the covariance between the two. Variance estimates of absolute risk estimates are then obtained through the delta-method [87] and take into account the variance of competing hazard estimates unless they are estimated from external sources and considered fixed, as in Gail et al. [47].

The hybrid approach can be regarded as relying on two models; namely, the piecewise exponential model and the logistic model (the **conditional logistic** model for individual matching and the unconditional logistic model for the three other ways of sampling controls). The baseline incidence rates are obtained by combining follow-up (or population) data and case–control data. Benichou & Gail [14] performed simulations based on the Breast Cancer Detection Demonstration Project (BCDDP) [9], a large follow-up study of 284 780 women, from which about 3000 cases and 3000 controls were selected (case–control study within a cohort or case–control study). They used a sample size of 100 000 women in each replication and generated piecewise exponentially distributed times to breast cancer occurrence by considering four age groups and two exposure factors forming six levels. A follow-up of five years was considered, and the possibility of dying from other causes (piecewise constant competing hazards not influenced by any covariates) was taken into account. Incident cases and frequency-matched controls were selected from the follow-up data. They found a small upward bias in absolute risk estimates due to the small upward bias incurred by using odds ratios to estimate hazard ratios when the rare disease assumption is violated in the context of such a study. Complete variance estimates had very little bias and yielded confidence intervals with near nominal coverage. Coverage was improved with the logit transform. Incomplete variance estimates that took into account only the variance of hazard ratio estimates from the case–control data were too small for small values of absolute risk, because they ignored the variances of baseline incidence rate estimates, and too large for larger values of absolute risk, because they ignored the negative covariances between hazard ratio estimates and baseline incidence rate estimates.

The hybrid approach was applied to the estimation of absolute risk of breast cancer from the BCDDP data as a function of age and four risk factors [47]. Details regarding variance estimation can be found in Benichou [11], who took into account special subsampling of cases and controls. Indeed, not all incident cases were used to estimate composite hazards and not all selected cases and controls were used to estimate hazard ratios. In order to implement these results and estimate absolute risk for new subjects, tables for point estimation were given by Gail et al. [47]. Practical implementation has been greatly facilitated by the development of the computer program RISK [10] and of graphs [17] that yield point estimates and confidence intervals of the absolute risk of developing breast cancer. Absolute risk is a widely used tool in individual counseling for breast cancer [17].

A pseudo-likelihood approach and a full likelihood approach have been proposed as alternatives to the hybrid approach [15]. They also rely on the piecewise exponential (or Poisson) model or logistic

model, although other parametric models could be used. They yield exposure-specific incidence rate estimates, but have not been fully developed to obtain absolute risk estimates, although this extension would be straightforward. Indeed, it would consist in (i) substituting in (1) or (2) age- and exposure-specific hazard estimates for disease c_1 and competing hazard estimates in order to obtain point estimates of absolute risk and (ii) using the delta-method [87] to derive variance estimates.

The pseudo-likelihood approach was presented by Benichou & Wacholder [15] in the context of a Poisson model (piecewise exponential model) and rests on the following principles. A full likelihood for the entire cohort or population could be written and maximized if information on exposure were available for all subjects in the population or cohort rather than just for the cases and controls. However, one can combine follow-up or population information in the form of number of events d_i and person-years t_i for each stratum i with the observed distribution of exposure in the case–control data to obtain estimates of number of events d_{1ij} and person-years t_{ij} for joint stratum level i and exposure level j. This is simply done by multiplying quantities d_{1i} (respectively t_i) by the observed proportion of cases (respectively controls) at exposure level j in stratum i. The rare disease assumption is used to obtain person-years from the conditional distribution of exposure in controls only. Substituting these estimated quantities, one obtains a Poisson pseudo-likelihood which is then maximized to obtain maximum pseudo-likelihood estimates of incidence rate parameters (baseline incidence rates and hazard ratios for a multiplicative model). Variance estimation relies on sandwich variance estimators [64] which allow for taking into account the additional component of variability incurred by the use of estimates of quantities d_{1ij} and t_{ij}.

The full likelihood approach differs from the pseudo-likelihood approach in that a full likelihood is written as a function of the incidence rate parameters to be estimated *and* a set of **nuisance parameters** for the conditional distribution of exposure given the stratum in the population. Rather than using the observed conditional distributions in cases and controls as with the pseudo-likelihood approach, the nuisance parameters are estimated jointly with the incidence rate parameters by maximization of the likelihood [15]. One obtains fully efficient maximum-likelihood estimates (rather than maximum pseudo-likelihood estimates) of all parameters (incidence rate and nuisance parameters), and variance estimates of the incidence rate parameters are obtained directly from the observed information matrix. In the context of a Poisson model, this approach is faced with the potential problem of a large number of parameters if several risk factors and stratum levels are considered. Even in the simple example of Benichou & Wacholder [15], with nine strata and eight exposure levels only, 60 nuisance parameters had to be estimated. This problem can be alleviated if one is willing to consider the logistic rather than the Poisson model, as pointed out by Greenland [50]. A prospective logistic model can be applied to the case–control data and yields maximum likelihood estimates of hazard ratio parameters. Furthermore, maximum likelihood estimates of baseline incidence rates are obtained by adding to the stratum parameter estimates from the logistic model a term corresponding to the logarithm of the ratio of sampling fractions among cases and controls in the stratum [50, 85]. The covariance matrix of estimates of baseline incidence rates and hazard ratios is obtained as described in Prentice & Pyke [85].

Upon comparing the pseudo-likelihood, full likelihood and hybrid approach on population-based case-control data of bladder cancer [51], Benichou & Wacholder [15] found that the hybrid approach seemed to be less efficient for incidence rate estimation than the other two approaches, which were themselves equally efficient. This efficiency loss might be due to the following conceptual difference regarding estimation of baseline incidence rates and hazard ratios among the three approaches. With the maximum likelihood and pseudo-likelihood approaches, these quantities are jointly estimated and their negative correlations fully accounted for in variance estimates. With the hybrid approach, crude incidence rates and hazard ratios are estimated separately and then combined to obtain stratum- and exposure-specific incidence rates and, as a consequence, negative correlations between estimates of baseline incidence rates and hazard ratios are not as strong, which results in larger variances [15]. Another potential advantage of the full likelihood and pseudo-likelihood approaches is that they directly estimate hazard ratios rather than odds ratios. Furthermore, if the Poisson (but not the logistic) model is used, they can be applied to more general models of risk; for example, models with an additive form using

rate difference parameters rather than hazard ratio parameters [15]. Finally, all three approaches require that cases and controls be selected at random [67] and that incident cases or at least a known proportion of them be fully identified [15].

Semiparametric Approach

The three parametric approaches described above apply to situations in which controls are not individually matched to cases. The hybrid approach can handle special cases of individual matching [14] but not time-matching, which characterizes **nested case–control studies** [24, 65, 71]. In that context, Langholz & Borgan [62] developed a semiparametric approach which can be regarded as an extension of the semiparametric approach for cohort studies described above (see the section "Estimation from Cohort Studies" above). The context is that of a nested case–control study (case–control within a cohort), in which cases develop from a cohort, and controls are selected from subjects still at risk. Therefore, individual follow-up times are needed and grouped data are not sufficient.

Incidence rates are expressed as the product of baseline incidence rates of an unspecified form times a function of the covariates representing the hazard ratio [31]. Hazard ratio parameter estimates are obtained from maximizing the partial likelihood of the **Cox regression model** for nested case–control data [81, 84]. Absolute risk estimates are obtained by combining partial likelihood hazard ratio parameter estimates and corresponding cumulative hazard estimates. Langholz & Borgan [62] showed that their proposed semiparametric estimate is asymptotically **normal** and provided a variance estimator based on results in Aalen & Johansen [2], Andersen et al. [6], and Borgan et al. [21]. Point estimates and corresponding variance estimates are based on simple sums or products of information from the case–control study, the estimated hazard ratio parameters, and the number at risk at the failure times. Competing risks can be taken into account provided that it is assumed that occurrence of c_2 is not influenced by the risk factors for occurrence of disease c_1. Finite sample properties of this approach have not been studied. A direct comparison with parametric approaches presented above is not possible because the semiparametric approach applies only to time-matched data, which the parametric approaches cannot handle. The semiparametric approach requires observation of individual follow-up time of each subject in the original cohort in order to form the risk sets for each failure time, and enable control selection. It is therefore potentially less widely applicable than the parametric approaches but makes no assumption on the baseline hazard. Finally, it has the advantage over the available parametric approaches of being able to handle continuous covariates.

Special Problems

Case–Cohort and Cross-sectional Designs

In the **case–cohort design**, information on exposure is gathered only in a subcohort of subjects randomly selected from the original cohort and among subjects who develop the disease [83]. It is therefore possible to estimate exposure-specific incidence rates and absolute risk directly from case–cohort data. However, the details of absolute risk estimation have not been worked out in the literature. **Cross-sectional studies** would need to be complemented by follow-up or population data in order to allow for incidence rate and absolute risk estimation, but such designs do not seem to have been implemented (*see* **Case–Control Study, Prevalent**).

Two-stage Case–Control Studies

In **two-phase case–control studies** [22, 98, 99], cases and controls are selected from a cohort or a population, as in a case–control study within a cohort or a population-based case–control study. Furthermore, a nested subsample of cases and controls is selected from original cases and controls on which information is gathered on exposure factors which are more difficult to obtain, such as X-ray data or **genetic markers**. Several parametric approaches have been developed to allow for hazard ratio and incidence rate estimation by an extension of the pseudo-likelihood approach for two-stage case–control data [16], pseudo-conditional likelihood methods [22, 90], and weighted likelihood methods [40, 54, 88, 89]. From incidence rate estimates from these various methods, it would be easy to obtain absolute risk estimates from (1) or (2).

Continuous Risk Factors

Absolute risk can be expressed as a function of both continuous and categorical risk factors. Model-based estimation methods presented above for cohort data (see the section "Estimation from Cohort Data" above) accommodate both types of variables. For case–control data however, the situation is different. Among parametric approaches, the hybrid approach yields point estimates that apply to both types of variables, but variance estimators have been developed only for categorical covariates. The full likelihood and pseudo-likelihood approach only apply to categorical covariates. The semiparametric approach is more flexible, in that it fully allows for continuous risk factors for point and variance estimation.

Time-dependent Risk Factors

Most estimation procedures presented above can be adapted to take into account **time-dependent covariates**. However, when absolute risk is used for individual prediction, estimation of absolute risk over time interval $[a_1, a_2)$ is based on the initial value of the covariates (i.e. the value at time a_1) and assumes that it stays constant over the whole interval, unless it is possible to predict (in a probabilistic or deterministic manner) the future variation of covariates over time (see the opening text).

Secular Trend

An important feature of the estimation methods described for cohort and case–control studies is that, by combining hazard estimates from different age intervals, absolute risk can be estimated for a much longer age interval than the actual follow-up of individuals in the study. To combine these hazard estimates into a single estimate of absolute risk, one must assume that there is no secular trend in disease incidence [59, Chapter 6].

Misclassification of Exposure

Misclassification of exposure could affect the validity of absolute risk estimates, but this problem, which has been studied for estimation of other measures (e.g. odds ratio, hazard ratio, and population attributable risk; *see* **Measurement Error in Epidemiologic Studies**) has not been studied for absolute risk estimation.

Use of Two Time Scales

In some applications, it may be important to consider two time scales, such as time from entry in the cohort (e.g. time from surgery, diagnosis, or first exposure) and age. Korn & Dorey [60] give guidelines and examples for that situation.

Selection of Risk Factors and Model Misspecification

Selection of risk factors on which to base absolute risk estimation is a difficult task. Complex multivariate models containing many risk factors will usually appear to describe the variation of risk in the data used to fit the model better than simpler models. Yet the simpler models often perform as well or better in predicting risk in other populations [37]. This is because complex models fit the statistical anomalies of the given sample as well as the reproducible features, whereas the simpler models tend to reflect the reproducible features only. It might therefore be preferable to choose factors for inclusion in the model that have been previously demonstrated to be important rather than to rely solely on the current data sample to select factors for inclusion [44].

A related problem is model **misspecification** which can lead to severe bias in absolute risk estimates and has to be considered carefully. Model misspecification can come from an inappropriate selection of risk factors, but also from incorrectly modeling the effect of included risk factors, from selecting the wrong model for time to event distribution, or from incorrectly assuming proportional hazards. Benichou & Gail [13] illustrate the potential severity of the problem in an example which suggests that using unsaturated rather than saturated models for covariate effects can lead to a **systematic error** that is potentially larger than **random error** (*see* **Generalized Linear Model**).

Validation

Given the potentially severe effects of model misspecification on absolute risk estimation, it is important to validate models used for absolute risk estimation. For instance, from internal validation results and two studies of external validation based on independent cohorts [20, 94] (*see* **Validation Study**), it appeared that the model developed by

Gail et al. [47] to estimate absolute risk of breast cancer from the BCDDP as a function of age and four risk factors produces valid estimates of absolute risk for women in regular screening as in the BCDDP, but yields estimates that tend to be too high when applied to unscreened or sporadically screened populations [20, 44, 45, 94], as had been cautioned in the initial paper [47].

Absolute Risk and Treatment Comparison

It might be useful to use absolute risk as a means of testing for treatment effect, especially given the availability of tests for comparing k treatment groups based on absolute risk [49]. However, use of absolute risk alone may be misleading. For example, if a cancer treatment increases h_2 but leaves h_1 unaffected, absolute risk will diminish in the treated group; yet overall survival is reduced and c_1-specific survival is unchanged. Instead, one should compare overall survival and estimates of the cause-specific survival curves in the treated and untreated groups, as is common practice. If h_2 is not affected by treatment, however, the change in absolute risk is a more realistic gauge of treatment benefit than a comparison of c_1-specific survival curves. If both h_1 and h_2 are affected, absolute risk gives useful descriptive information for summarizing the burden of recurrence in each group [13].

Overall Adjusted Absolute Risk

In order to obtain an overall measure of absolute risk at the population level, one might combine individualized estimates to obtain a direct adjusted value for the entire population by summing estimated values of absolute risk for a given level of the covariates over the distribution of the covariates in the reference population [13]. This procedure would yield a different estimate than that obtained by covariate-free estimation of absolute risk from the same population (see the section "Estimation from Cohort Studies" above). The adjusted procedure would be analogous to the methods for direct adjustment of survival curves described by Murphy & Haywood [79], Makuch [70], and Chang et al. [26], and the variance estimation methods of Gail & Byar [46] could be adapted.

Related Quantities

Attack Rate

In the investigation of a local outbreak of a **communicable disease**, a measure of interest is the absolute risk of developing the disease for the duration of the epidemic or the time during which primary cases occur. In this situation, absolute risk is often called an attack rate [59, 69].

Hazard Ratio and Relative Risk

As discussed above (see the section "Interpretation and Usefulness"), the hazard ratio, also called the relative rate, rate ratio, incidence density ratio, or instantaneous relative risk, is a useful measure in etiologic research that quantifies the strength of the relationship between exposure and disease, while absolute risk is more useful in individual prediction as a measure of the actual probability of disease for a given risk profile. Large hazard ratios may correspond to small absolute risks if the disease is rare and conversely.

Since incidence rates are a function of hazard ratios in multiplicative models, absolute risk is also a function of hazard ratios (and of baseline incidence rates) in those models. Alternatively, additive models can be used with the rate difference, also called hazard difference or incidence density difference, being the relevant parameter instead of the hazard ratio to measure the effect of covariates.

The term "relative risk" is frequently used to represent a hazard ratio or its estimator. Strictly speaking, however, relative risk refers to the ratio of absolute risks and not of incidence rates [59]. A synonym is "risk ratio" [76].

Incidence Rate

Absolute risk is a direct function of incidence rates, as is apparent from (1) and (2) that define absolute risk. As was mentioned above (see the sections "Estimability" and "Estimation" above), the problems of absolute risk estimability and estimation essentially reduce to those of incidence rate estimability and estimation.

Cumulative Risk and Cumulative Hazard

The relationships between absolute risk and cumulative risk and hazard have been defined in the section "Estimation from Cohort Studies" above.

Excess Risk

Excess risk [91], also called excess incidence [18, 69, 74], is defined as the difference between the incidence rates in the exposed and the unexposed. Like absolute risk, it takes into account the incidence of the disease in the unexposed and the strength of the association between exposure and disease. It can be expressed as the product of the baseline incidence rate times the hazard ratio minus 1, and it quantifies the difference in incidence that can be attributed to exposure at the individual level. Other terms have been used to denote this quantity; namely, "Berkson's simple difference" [96], "incidence density difference" [76], "excess prevalence" [96], and even "attributable risk" [72, 91].

Population Attributable Risk and Generalized Impact Fraction

Population **attributable risk** [63] and the generalized impact fraction [97] are measures that assess the public health consequences of an association between exposure and disease and the potential impact of prevention measures aimed at eliminating (population attributable risk) or reducing (generalized impact fraction) exposure in the population. As was mentioned above (see the section "Interpretation and Usefulness" above), absolute risk can be used to estimate the absolute reduction in incidence that would result from prevention measures in each subgroup of exposure, and can therefore be regarded as a useful complement to population attributable risk and the generalized impact fraction.

Floating Absolute Risk

The term "floating absolute risk", introduced by Easton et al. [36], refers to a concept unrelated to absolute risk, which may introduce some confusion. The purpose of those authors was to remedy the standard problem that hazard ratios are estimated in reference to a baseline group which in turn causes hazard ratio estimates for different levels of exposure to be correlated and may lead to lack of precision in hazard ratio estimates if the baseline group is small. The authors proposed a procedure to obtain hazard ratio estimates unaffected by these problems. They termed their proposed hazard ratio estimates "floating absolute risks" to indicate that their **standard errors** were not estimated in reference to an arbitrary baseline group.

Prospects and Conclusions

Despite the substantial development of methods for estimating absolute risk, there remain important research issues, including point and variance estimation for parametric case–control estimators when continuous risk factors are considered, the study of finite sample properties of nonparametric and semiparametric estimators and their comparison with parametric estimators, the comparison of the three main parametric approaches in case–control studies, the study of the effect of exposure misclassification on absolute risk estimation, and research issues regarding special problems (see the section "Special Problems" above).

An important issue is the development of tools to implement methods for absolute risk estimation. For instance, a graphic approach has been developed to convert relative to absolute risk [35]. Graphs [17] and a computer program [10] have been developed to estimate absolute risk of breast cancer as a function of age and four risk factors. More general programs would be worth developing.

Finally, an important challenge is to increase awareness of the proper interpretation and use of absolute risk in practice (e.g. in counseling, see [4, 17, 19, 53] and [78]), as well as of correct estimation techniques.

JACQUES BENICHOU

Accelerated Failure-time Models

Accelerated failure-time models can be simply illustrated in the following way. Let T_0 be the survival time, under control conditions, from some origin to the occurrence of an event of interest, and suppose that application of a treatment, or exposure to a risk factor, modifies the survival time to $T = T_0/\theta$ for some fixed scaling parameter θ. Then the **median survival time** under the treatment or risk factor is $1/\theta$ times the median under the control, and indeed the time to reach *any* percentile of the treatment group will be $1/\theta$ times the time to reach the corresponding percentile of the controls. This proportional adjustment of the time-scale represents the simplest form of the accelerated failure-time assumption.

The term *accelerated failure time* derives from accelerated life testing, particularly in engineering and similar applications. In these, extrapolation is often required from high stress levels, designed to induce rapid failure under laboratory conditions, to lower stress levels which operate under normal conditions. The assumed link between the effects of the different levels is provided by the adjusted time-scale. Corresponding biostatistical applications include situations such as carcinogenicity or toxicity experiments, in which doses of a high level are applied under experimental conditions and the results extrapolated to lower doses via the accelerated failure-time assumption (*see* **Extrapolation, Low Dose**).

The Models

Let the proportion of cases in the control group surviving beyond time t be denoted by $S_0(t)$ (the *survival function*), and let the survival function under the treatment or exposure be $S(t)$. Then according to the accelerated failure-time model the two survival functions are related by

$$S(t) = S_0(\theta t),$$

and the *hazard functions* (*see* **Hazard Rate**) by

$$\lambda(t) = \theta\lambda_0(\theta t)$$

(*see* **Survival Distributions and Their Characteristics**). Under this assumption,

$$\Pr(\log T > t - \log\theta) = S_0(\mathrm{e}^t),$$

giving a location shift model on the log scale, namely

$$\log T = \beta_0 + \log\theta + \varepsilon,$$

where ε is a zero mean **residual**.

More general models are obtained by incorporating **covariates** or **explanatory variables** into θ. If $\mathbf{x}$ is a vector of covariates associated with an individual, then the survival function, given $\mathbf{x}$, is assumed to be of the form

$$S(t|\mathbf{x}) = S_0[\theta(\mathbf{x})t]$$

for an underlying survival function S_0 and function $\theta(\cdot)$, with hazard function

$$\lambda(t|\mathbf{x}) = \theta(\mathbf{x})\lambda_0[\theta(\mathbf{x})t].$$

Correspondingly, $\log T = \beta_0 + \log\theta(\mathbf{x}) + \varepsilon$. A particularly useful form is the **loglinear** regression model in which $\theta(\mathbf{x}) = \exp(\boldsymbol{\beta}'\mathbf{x})$, which leads to the linear model $\log T = \beta_0 + \boldsymbol{\beta}'\mathbf{x} + \varepsilon$. Inferences concerning the regression parameters and the ways in which they influence survival can therefore be made using log survival times and **linear regression** methods, including methods that allow for **censored** survival times, where the survival time may be known only to exceed or be smaller than a given value. This may result from loss to follow-up, withdrawal for causes unrelated to the end point of interest (*see* **Competing Risks**), survival beyond the end of a trial, and so on.

Parametric Models

Parametric models under the accelerated failure-time assumption are obtained by specifying the underlying distribution S_0 and the form of dependence on $\mathbf{x}$ through $\theta(\cdot)$. Some important special cases of the underlying distribution include the *Weibull*, when $S_0(t) = \exp(-kt^\alpha)$, the **lognormal**, when $\log T$ has a normal distribution, and the *log-logistic*, when $S_0(t) = 1/(1 + kt^\alpha)$. The last model has received considerable attention, since one is often interested in the probability of survival beyond a fixed time (e.g.

five-year survival rates). If $\theta(\mathbf{x}) = \exp(\boldsymbol{\beta}'\mathbf{x})$, then the logistic transform or log **odds ratio** is

$$\log\left\{\frac{S(t|\mathbf{x})}{[1-S(t|\mathbf{x})]}\right\} = -\log k - \alpha \log t - \alpha\boldsymbol{\beta}'\mathbf{x},$$

which is linear in the covariates $\mathbf{x}$, and for fixed t represents the familiar linear **logistic regression** model.

Estimation and Analysis

If we assume a fully parametric form for the accelerated failure-time model, then standard parametric inference procedures such as the use of **likelihood** methods are applicable, allowing for the possible presence of censored observations. With right-censored failure times and i indexing the individuals, provided the censoring and survival mechanisms are independent, the likelihood function is given by

$$l = \prod_i \lambda(y_i|\mathbf{x}_i)^{\delta_i} S(y_i|\mathbf{x}_i),$$

where y_i is the observed failure time or the time at which censoring occurs for the ith individual and δ_i is an indicator of censoring taking the value 1 if the failure time is observed and 0 if censored. Large-sample estimates of standard errors can be obtained from the observed Fisher **information**, since the presence of censoring will generally preclude the taking of expectations.

The Expectation-Maximization **(EM) algorithm** of Dempster et al. [6] often provides a convenient method of maximizing the likelihood with censored data (e.g. [5, Chapter 11]). This method is particularly useful if the distribution of $Z_i = \log T_i$ is a member of the regular **exponential family** in the mean parameter μ_i with variance V_i. Then the likelihood equations corresponding to derivatives of the log likelihood with respect to the parameters β_j in the mean take the simple form

$$\sum_i \frac{\tilde{z}_i - \mu_i}{V_i}\frac{\partial \mu_i}{\partial \beta_j} = 0,$$

where $\tilde{z}_i$ is z_i if the failure time is observed or $\mathrm{E}(Z_i|T_i > y_i)$ if the failure time T_i is censored at y_i. This is of the same form as the likelihood equations when all data are uncensored but with the censored values replaced by their conditional means. The E-step in the EM algorithm thus consists of replacing the censored responses by their estimated conditional means given the existing parameter estimates and the time at which censoring occurs, while the M-step corresponds to parameter updating by solving the likelihood equations treating the estimated values as if they were uncensored. The process is iterated until convergence. In general there will also be other parameters involved in the model which need to be estimated. For a discussion of the EM approach with (log)-normal responses see Aitkin [1].

Buckley & James [2] adopted a similar approach to deriving a semiparametric procedure in which the residual distribution remains unspecified. Suppose that the residuals ε_i are independent with common distribution and that $\mu_i = \beta_0 + \boldsymbol{\beta}'\mathbf{x}_i$. The likelihood equations then become

$$\sum_i (\tilde{z}_i - \beta_0 - \boldsymbol{\beta}'\mathbf{x}_i)x_{ij} = 0.$$

In the method of Buckley & James the conditional expectations for the censored responses are replaced in the equations by their estimates based on the **Kaplan–Meier** product-limit estimator of the residual distribution. An iterative estimation scheme analogous to the EM procedure therefore consists of starting with estimates of the β_j, obtaining the Kaplan–Meier residual distribution, replacing the censored responses by their estimated conditional means using the estimated residual distribution, and solving the normal equations, assuming these were the true responses, to update the parameter estimates. Some modifications are needed to account for the possibility of the Kaplan–Meier means being undefined when the largest residual is censored, and this will typically introduce some biases into the intercept estimates for small samples.

Unlike the fully parametric EM algorithm this iterative scheme need not converge, nor need the estimating equations have a unique nor exact solution due to discontinuities and nonmonotonicity. In these cases zero crossings or values closest to zero can be used. Extensions to **nonlinear regressions** or M-estimators [16] (*see* **Robustness**) are conceptually straightforward.

Whilst the method is simple to describe, obtaining theoretic properties has proved difficult, in part due to the issues of censored data in the right-hand tail of the distribution. Asymptotic properties have been

obtained under some conditions by Ritov [16] and Lai & Ying [10], who introduce a smooth weighting function to overcome instability due to censorship. Practical issues in the estimation of standard errors have been addressed by Weissfeld & Schneider [27], Smith [21], and Lin & Wei [11]. Approximations based on imputation via the data augmentation algorithm were proposed by Wei & Tanner [24] but, as noted by James [7], they do not appear to offer many advantages over the Buckley–James approach (*see* **Missing Data**).

Other semiparametric estimation methods have been proposed by Miller [13] and by Koul et al. [9]. The former is based on minimizing the weighted sum of squared residuals $\int \varepsilon^2 \, \mathrm{d}\hat{F}(\varepsilon)$, where $\hat{F}$ is the Kaplan–Meier estimator of the residual distribution function, while the latter is based on the observation that the quantities $\delta_i Z_i / [(1 - G(Z_i|\mathbf{x}_i)]$ have mean $\beta_0 + \boldsymbol{\beta}'\mathbf{x}_i$, where G is the censoring distribution. Koul et al. use a **Bayesian** estimator of G, thus obtaining observable quantities which form the basis of **estimating functions**. Both the Miller and Koul et al. estimators appear to be sensitive to the relationship between the censoring times and the covariates – the former requiring that censorship relate linearly with the same slope parameters $\boldsymbol{\beta}$, the latter that there be no relationship (Miller & Halpern [14]). A comparison of semiparametric methods based on application to the Stanford heart transplant data is provided by Miller & Halpern.

Estimates of parameters and derivation of their properties can be based generally on appropriate test statistics. In the case of accelerated failure-rate models the **linear rank test** statistics with right-censored data introduced by Prentice [15] provide a basis for estimation and testing using **ranks** of the data. Similar rank procedures have been introduced by Louis [12], Tsiatis [23], and Wei et al. [26]. Ritov [16] discusses the asymptotic equivalence of the method of Tsiatis and the Buckley–James-type estimators.

Bayesian methods of analysis in the accelerated failure-time models are considered by Christensen & Johnson [3].

Comparison with the Proportional Hazards Model

It is instructive to compare the accelerated failure-time model with the **proportional hazards** model or **Cox model**. In the proportional hazards model the survival function is related to the underlying survival function S_0 by

$$S(t|\mathbf{x}) = S_0(t)^{\phi(\mathbf{x})},$$

and the hazards are related by

$$\lambda(t|\mathbf{x}) = \phi(\mathbf{x})\lambda_0(t)$$

for some function ϕ and covariates $\mathbf{x}$. The Cox model takes the loglinear form $\phi(\mathbf{x}) = \exp(\boldsymbol{\beta}'\mathbf{x})$. In practice, whether it is the accelerated failure-time model or the proportional hazards model that is appropriate (if either) will depend on the mechanisms operating on the survival times through the covariates. The only distributions that satisfy both the accelerated failure-time and proportional hazards conditions are the Weibull distributions with underlying hazard functions of the form $\lambda_0(t) = \alpha k t^{\alpha-1}$, in which case $\phi(\mathbf{x}) = \theta(\mathbf{x})^{\alpha}$.

Ciampi & Etezadi-Amoli [4] suggested that both accelerated failure-time and proportional hazards models could be embedded into an extended model of the form

$$\lambda(t|\mathbf{x}) = h(\boldsymbol{\alpha}'\mathbf{x})\lambda_0[h(\boldsymbol{\beta}'\mathbf{x})t]$$

for some function h. Then, if $\boldsymbol{\alpha} = \boldsymbol{\beta}$ we have an accelerated failure-time model, while if $\boldsymbol{\beta} = \mathbf{0}$ the model is proportional hazards. Comparing the two thus reduces to testing the values of the parameters in this embedded model provided the underlying distribution is not Weibull.

Extensions and Further Reading

In many applications the covariates used for adjustment may also vary with time. Examples include calendar period effects, immunodeficiency status which changes over time, indicators of receipt of additional treatments at time t, and so on. Extensions of regression models to include **time-dependent covariates** have become relatively routine in many areas of application. Their incorporation into accelerated failure-time models leads to

$$S[t|\mathbf{x}(t)] = S_0\{\theta[\mathbf{x}(t)]t\},$$

where the notation $\mathbf{x}(t)$ now reflects the dependence of the covariates on the time under consideration. Fully parametric analyses in which both

the underlying distribution and the nature of the dependence of the covariates on time are completely specified may be carried out using, for example, likelihood methods. Robins & Tsiatis [18] and Robins [17] study an approach to the analysis of models with time-dependent covariates which is semiparametric in the sense that the dependence of the covariates on time is fully specified but where the underlying distribution S_0 remains unspecified.

Useful accounts of accelerated failure-time models can be found in Kalbfleisch & Prentice [8] and Cox & Oakes [5]. Wei [25] provides a comprehensive overview of nonparametric methods of estimation in accelerated failure-time models, and compares them with proportional hazards models.

In the econometric literature accelerated failure-time models are typically referred to as *tobit* models.

Software

Comprehensive parametric analyses of accelerated failure-time regression models are available in widely used packages such as **S-PLUS** [22] and *SAS* [19], as well as many other commercially available packages (*see* **Software, Biostatistical**). These incorporate response distributions such as the lognormal, Weibull, log-logistic, and Rayleigh (*see* **Parametric Models in Survival Analysis**) plus their transforms, and with various forms of censoring. More specialized survival analysis packages such as *Egret* [20] also accommodate censored regression models. Specific procedures for semi- and nonparametric analyses do not appear to be widely available.

IAN JAMES

Accident and Emergency Medicine

Accident and emergency medicine is that specialty of medicine whose practitioners offer immediate medical care to people with major and minor injuries and illnesses presenting as emergencies to departments of Accident and Emergency (A&E) in general hospitals.

The specialty of A&E medicine and A&E departments in the UK have their counterparts in other countries. For example, in the United States of America (US), Canada, Sweden, Australia, New Zealand, and Spain, there are emergency rooms in general hospitals that provide the same service as A&E departments in the UK. The crucial functions of this service are the formulation of an early diagnosis, the institution of immediate therapies, and the timely referral if needed to the most appropriate specialty or agency to allow maximum chance of optimum recovery to be achieved. The conditions with which people present can vary widely. At one end lie true emergencies, where lifesaving treatment is needed within the first hour of onset. At the other end are a vast range of minor injuries and illnesses that could be managed in primary care or by individuals themselves.

Historical Development

In the UK, prior to the inception of the National Health Service (NHS) in 1948, free medical care for the poor had been varyingly available for several centuries from infirmaries run by local councils and from independent hospitals funded by charity. Most conditions seen would have been, as now, minor illnesses and injuries. This pattern of free care for the poor was followed in other countries. The debate about whether these minor conditions should be seen in A&E departments is not new. It was first described in the *Lancet* in 1849 [7]. Casualty departments primarily saw people with injuries caused by trauma. The report of the Medical Advisory Committee of the Central Health Services Council on Accident and Emergency Services in 1962, known as the Platt Report, recommended centralizing casualty services in general hospitals where all specialties were represented. They were to become receiving departments and be managed by orthopedic surgeons because of the predominance of trauma cases. They were to be called Accident and Emergency departments. There was an increasing realization that most of the real emergencies were medical cases with presenting conditions such as heart attacks and severe asthmatic or epileptic attacks. There was also much debate, as now, about whether the main role of such services should be to manage major emergency cases or anyone who presented. Parallel developments have occurred elsewhere. Early concern about the growth in the use of emergency departments was raised in the US in 1966 [22] and in the UK in the 1980s [13]. For example, the annual rate of first attendance at such departments per 1000 population in England rose from 105 in 1961 to 218 in 1984 [13]. This upward trend seems to have finally peaked in 1989 at a rate of 233 attendances per 1000 population [24]. A&E departments are now an integral part of general hospitals in the UK. But the debates about their true role (managing only emergency cases or offering an alternative to primary care) and their relation to trauma centers still rage in many countries [2, 24].

Different Types of Study

Descriptive and Analytical Epidemiology

Many researchers have tried to understand the determinants of the large geographical and temporal variation in first attendance. Some of these, and many others, have striven to show either the inappropriateness of much of the attendance at A&E departments or that much of it could be managed in general practice, or both. There have been a very large number of studies of single departments looking at these issues. Most of these have just used simple descriptive statistics with occasional use of the **chi-square test** and simple parametric tests (*see* **Hypothesis Testing**). One of the earliest was reported by Weinerman et al.in 1966 [22]. Many of these studies are referenced in [24] and in the report of the Anglia and Oxford emergency health care project steering group [2]. Fairley et al. [5] undertook one of the first studies of more than one department. They found that rates of use were highest for the age range 15–44 years, sex-specific rates were higher for males, and about 10% of attenders are admitted. These results have been replicated by many others. In general, the large majority of cases are due to trauma [5], although medical cases are relatively more common in inner city areas. Reilly [18] was one of the first to

show that general practitioners (*see* **General Practice**) could do much of the work undertaken by A&E departments. Holohan [8] was the first to describe the concept of social predicament as a key determinant in a large proportion of cases. The concept of inappropriateness has been much described. But the first systematic attempt to produce a classification scheme was in 1960 by the Nuffield Provincial Hospitals Trust.

Milner et al. [13] used **correlation** analysis, **multiple linear regression**, multiple **logistic regression** and a nonparametric test for the analyses of variance (*see* **Nonparametric Methods**) in their studies on temporal and geographical use. They found an eighteen-fold difference among health districts in the mean annual new attendance rates at A&E departments in England over the period 1974–1985. There was a rising trend in these rates which was statistically significant ($P < 0.05$) for 89% of districts. There was also a twenty-six-fold difference in the extent to which new attenders were reviewed [12]. The ratio of return attendances to first attendances (reattendance ratio) had declined significantly ($P < 0.05$) in 70% of districts. Investigation of the variation in the reattendance ratio among eight A&E departments showed that it was booked reattendance which largely determined sample reattendance ratios [12].

There is now an NHS common minimum data set for A&E departments in the UK [16]. This should facilitate comparative research among A&E departments.

Clinical Research

Discriminant analysis has been used very successfully for producing survival probabilities using logistic functions and regression weightings to allow the systematic audit of emergency care for cases of major trauma. This began in the US in the early 1980s with the Major Trauma Outcomes Study [3] and was later adopted in the UK [21]. The mortality rate in A&E departments in the UK is much less than 1% and trauma accounts for less than one-fifth [20]. Most of the deaths are due to medical emergencies such as myocardial infarction, stroke, or asthma [19]. **Randomization** has proven very difficult in care for life-threatening emergencies. There have been no randomized controlled trials (RCTs) (*see* **Clinical Trials, Overview**) of major trauma centers or emergency helicopter medical services. Major well-designed comparative studies of these have been undertaken in the UK without random allocation by the Medical Care Research Unit in Sheffield [17]. The major obstacle to randomization was the organization of care. The emergency nature of cases interacted with the ability to randomize responsively and quickly. The Medical Care Research Unit in Sheffield is currently running a randomized controlled trial in the UK of paramedical assistance as the first emergency contact which randomizes the paramedics rather than the patients. For the less urgent conditions, informed consent in randomized controlled trials has usually been sought (*see* **Ethics of Randomized Trials**).

A search of the nine emergency journals on Medline for 1995 found only 4% of articles described RCTs. These were usually studies of minor clinical developments.

Health Technology Assessment

Weinerman et al. [23] used descriptive statistics and χ^2 analysis to describe the possibilities of medical triage in 1963 in a pilot study. There have been many similar subsequent studies which claimed to have evaluated nurse triage and shown it to be beneficial. Apart from one, they have all either excluded a comparative arm, not used valid **outcome measures**, or been pilot studies. George et al. [6] in 1992 used a comparative design with triage being alternately on and off. They showed that triage patients waited on average longer than nontriaged. This was especially so for those most in need of urgent medical care.

Health technology assessment (*see* **Health Services Organization in the US**) came of age in accident and emergency medicine with the publication of an RCT with a cost-effectiveness analysis by Murphy et al. [15]. This group used valid intermediary outcome measures and found that general practitioners (GPs) were more cost effective than hospital doctors or nurses for managing primary care cases which presented to an A&E department.

The debate about trauma centers rages on. There is a shortage of good quality research evidence on the relative costs and benefits of the alternative forms of care for patients suffering major trauma. The UK Department of Health has funded a major comparative study of this [17] which shows, according to the

Department, that trauma centers are not cost effective in the shire counties of England.

Laboratory and Basic Sciences

There are many investigations undertaken in A&E departments in the UK. X-ray testing is the most common, followed by blood testing [12]. The opportunities for such tests are great. Head injuries, for example, are very common, as are twisted ankles. New technologies, such as MRI scanning or near-patient testing, are constantly being developed, which could have a major impact on A&E clinical practice. So far none of these technologies has been evaluated as rigorously as new drugs are. The lack of rigorous evaluation of tests is a general finding in health care. A recent **Cochrane Collaboration** has been established to try to rectify this. Details about its work and testing methodologies can be found on the World Wide Web at `http://wwwsom.fmc.flinders.edu.au FUSA/COCHRANE/sadtdoc.htm`.

In the nine emergency care journals found on Medline in 1995, the vast majority of original articles contained descriptive statistics. Correlation and predictive analysis were much less common.

Statistical Models

In the vast majority of studies only standard statistical methods have been used. **Time series** analysis was used recently to estimate the staffing requirements of A&E departments at various times depending on the **case-mix** presenting [14]. Milner had previously used the autoregressive integrative moving average (ARIMA) process (*see* **ARMA and ARIMA Models**) using the Box–Jenkins procedure to estimate future workloads in the Trent region of England [11]. Three time series were forecast. These were the first attendance rate, the ratio of return to first attendances, and the local resident population forecasts. These forecasts were then combined to produce forecasts for the district numbers of first, return, and total attendances. The theoretical ARIMA methods were applied without modification. There were two other examples of studies of emergency departments in the statistical literature on Medline in the period 1985–1996. The first was the 1992 National Ambulatory Medical Survey from the US **National Center for Health Statistics**. This was a descriptive survey of a random sample of attendances at hospital emergency and outpatient departments [10]. The second described the use of **correspondence analysis** as a screening method for indicants for clinical diagnosis through the application of the independent **Bayesian method** [4].

The proximity of the place of residence of an individual to a health care facility predicts its use by that individual. This general relationship has been found to hold for the use of A&E departments by Ingram et al. [9] and others.

Landmark Studies

Major Trauma Outcomes Studies

The Major Trauma Outcome Studies in the US [3] and UK [21] have allowed the quality of emergency care to be examined thoroughly by health care professionals as well as by purchasers and providers. These confidential studies allowed mortality rates for departments to be compared after adjusting for the nature and severity of the injury by means of the Revised Trauma Score and the Injury Severity Score and the patient's age.

Deaths in A&E Departments

The battle for the heart and soul of A&E medicine has long since been won. History and trauma favored orthopedic surgery. Technology and the diseases of affluence favored general medicine. The Platt Report started the revolution in the UK and various learned bodies continued it. But it was Shalley & Cross who stopped the debate with their study using descriptive statistics which showed in 1984 that most preventable deaths in A&E departments were due to medical conditions [19].

Inappropriate Attendance

Weinerman relaunched the debate in 1966 about inappropriate attendance in the US with a descriptive study of a case series of 2028 patients [22]. This followed the Nuffield Provincial Hospitals Study of casualty services in 1960 and the Platt Report in 1962. We have still not answered the question about appropriateness. We do however understand much better the policy and health service issues (*see* **Health Services Research, Overview**).

Reattendance

Reattendance of a patient at A&E departments was thought to be determined by the diagnosis and need for treatment. Milner et al. [12] showed using multiple logistic regression in 1992 that these were minor influences. The crucial factor was whether the doctor booked a patient to return. This propensity varied in an idiosyncratic manner among departments.

Particular Statistical Concepts, Problems, and Techniques

Accurate, population-based information on the **incidence rates** of minor injuries and illnesses is not available in the UK, unlike the US where the National Health Interview Survey reports this annually [1]. A similar regular survey from time to time in the UK would help to assess the appropriateness of the great geographical variation in the use of A&E departments.

There is a need to develop valid quantitative **health status instruments** for common A&E conditions such as twisted ankles, lacerations, head injuries, and strains and sprains, as well as the uncommon ones such as burns, and ear, nose, throat and eye disorders. They will have to be simple to administer. This will allow cost-effectiveness studies of the various alternative models of care to be undertaken.

Anticipated Developments

The central issue on the use of A&E departments in the UK is not discovering the determinants of such use. It is to secure an agreed policy on the basis of research evidence on the role of A&E departments. Currently they are providing a combination of services for hospital emergencies, minor injuries, alternative primary care, major trauma, and/or a fail-safe system for healthcare. There are two basic options for coping with the out-of-hours emergency problems and the overlap between general practice and A&E departments.

One model is to develop emergency primary health care centers for out-of-hours work or for a 24-hours-a-day service. The second model is to develop primary care within the A&E department. We need to know the cost effectiveness of these options. When there is agreement in a locality about the respective roles of hospital emergency services and general medical services, then there is an obligation to inform local people about using these health services appropriately.

The Cochrane Collaboration is systematically reviewing the literature by health problem through a world-wide collaboration based on Cochrane Centers and health problem collaborative groups (`http://cochrane@mcmaster.ca`). There will be a systematic attempt to bring together knowledge on emergency care from the collaborative groups.

Accident Proneness

Research into the concept of accident proneness was motivated by the desire to find effective ways of reducing accidents. The initial hope was to identify the individuals most "prone" to have accidents and to nullify their problems in some way. Accident proneness was viewed as a personal psychological factor which affected the individual's probability of suffering an accident. The original context was industrial accidents during the 1914–1918 war. A very substantial research literature grew up over the succeeding half-century, especially as road accidents became a serious social and economic problem.

The concept of an accident as a purely random event had led Bortkiewicz [2, 3] to develop the **Poisson distribution** as a model for the number, X, of fatal accidents at work in a given time interval

$$\Pr(X = x) = \mathrm{e}^{-\lambda}\frac{\lambda^x}{x!}, \quad x = 0, 1, 2, \ldots, \quad 0 < \lambda. \tag{1}$$

His data sets included the well-known data on deaths from cavalry horse kicks. The Poisson model assumes that all individuals have the same probability (proportional to λ) of having an accident. The model implies that if you remove from the population under consideration those members who have had the highest number of accidents over a period of time, then this will have no effect whatsoever on the distribution of accidents in the population in subsequent periods.

Greenwood & Woods [5] and Greenwood & Yule [6] challenged the idea of pure randomness in their investigation into factory accidents. They put forward three competing hypotheses:

1. *Pure chance*, leading to the Poisson distribution, (1).
2. *True contagion*, i.e. the hypothesis that all individuals initially have the same probability of having an accident, but that this probability changes each time an accident is incurred. This led to their "biased distribution". If the probability of an accident remains unchanged after the occurrence of the first accident, then they described the outcome as the "burnt fingers distribution".
3. *Apparent contagion*, i.e. the hypothesis that individuals have constant but unequal probabilities of having an accident. This became known as accident proneness in the literature. It gives rise to a mixed Poisson distribution. Greenwood & Yule's well-known model for accident data assumes that the probability of an accident varies from individual to individual according to a gamma (c, k) distribution (*see* **Gamma Distribution**); the outcome is that the overall distribution of accidents in the population is a **negative binomial distribution** with

$$\begin{aligned}\Pr(X = x) &= \int_0^\infty \mathrm{e}^{-\lambda}\frac{\lambda^x}{x!}\frac{\mathrm{e}^{-c\lambda}c^k\lambda^{k-1}\,\mathrm{d}\lambda}{\Gamma(k)} \\ &= \binom{k+x-1}{x}\left(\frac{1}{c+1}\right)^x\left(\frac{c}{c+1}\right)^k, \\ &\qquad x = 0, 1, 2, \ldots, \ 0 < c, \ 0 < k\end{aligned} \tag{2}$$

(*see* **Contagious Distributions**).

However, it is easy to construct a *true contagion* model which also leads to the negative binomial distribution of (2) – a good empirical fit of the negative binomial distribution to population accident data cannot therefore distinguish between true contagion and accident proneness.

During the 1950s a number of authors (including Arbous & Kerrich [1]) tried to detect accident proneness by examining individuals' accident records in two consecutive periods. The general finding was that in practice this bivariate approach requires very large data sets. Arbous & Kerrich gave a good review of contemporary theories of accident occurrence.

Cresswell & Froggatt [4] in their study of bus driver accidents rejected the idea of accident proneness in favor of a fourth model:

4. *Spells*; here each driver is assumed to be susceptible to random spells (periods of time) during which accidents may befall him/her randomly with a probability that is the same for all drivers. They called the outcome distribution "long" or "short" according to whether further accidents might not or might occur randomly outside a spell. For their long model

$$\begin{aligned}\Pr(X = x) &= \sum_{j=0}^{\infty}\frac{\mathrm{e}^{-j\lambda}(j\lambda)^x}{x!}\frac{\mathrm{e}^{-\phi}\phi^j}{j}, \\ &\qquad x = 0, 1, 2, \ldots, \ 0 < \lambda, \ 0 < \phi.\end{aligned} \tag{3}$$

There is no simple expression for these probabilities. The distribution is better known in the statistical literature as the Neyman type A.

It soon became apparent that the problems of distinguishing between the various hypotheses are very severe. The Neyman type A distribution can easily be given a proneness interpretation [7] and, similarly, the negative binomial distribution can be given a spells interpretation.

A major problem which has bedevilled accident proneness as a concept is its exact definition – how is proneness to be distinguished from other aspects of personal risk, e.g. age or experience? This does not seem to have been resolved satisfactorily.

Prior to 1968, accident models assumed constant environmental risk as opposed to personal risk. Irwin [8] criticized this assumption and introduced a fifth type of model:

5. *Accident liability and accident proneness*; this incorporates the concept of accident liability resulting from varying environmental exposure. Irwin developed a three-parameter "Generalized Waring" distribution that assumes randomness while taking into account varying accident liability as well as varying accident proneness. He set $\theta = 1/(c+1)$ in (2) and assumed that θ has a **beta(a,b)** distribution, giving

$$\begin{aligned}\Pr(X = x) &= \int_0^1 \binom{k+x-1}{x} \theta^x (1-\theta)^k \\ &\quad \times \frac{\theta^{a-1}(1-\theta)^{b-1}\,\mathrm{d}\theta}{B(a,b)} \\ &= \frac{(b+k-1)!(a+b-1)!}{(b-1)!(k-1)!(a-1)!} \\ &\quad \times \frac{(k+x-1)!(a+x-1)!}{(a+b+k+x-1)!x!}, \\ &\quad x = 0, 1, 2, \ldots, \end{aligned} \tag{4}$$

where $0 < k$, $0 < a$, $0 < b$. The theory underlying this model has been studied in depth by Xekalaki [11, 12] both for a single time period and for a subdivided time period. Discrimination between proneness and liability is theoretically possible but it is difficult to achieve this in practice.

Most of the work on proneness and related concepts has involved accident count data and hence discrete distributions. An alternative approach is to examine interaccident times (involving continuous distributions). This has received some attention but it runs into problems similar to those with count data – it is particularly difficult to get reliable large-scale data on interaccident times.

There are two major books on the statistical analysis of accident data. Both involve large data sets. The two books display strongly contrasting views on accident theory – Cresswell & Froggatt [4] favor the spells hypothesis while Shaw & Sichel [10] strongly endorse the accident-proneness approach. Kemp [9] gave a detailed review of work on proneness and related topics from 1920 to 1970. He concluded that "from a practical point of view (e.g. in terms of its contribution to accident prevention), the concept of accident proneness had proved singularly ineffectual". Nevertheless, the study of accident proneness was valuable in the development of statistical methodology.

By the early 1980s the golden age of accident proneness theorizing was over. Very little theoretical research appears to have taken place since then. Attention had moved towards **risk** evaluation and analysis. This may well reflect the view that whether or not proneness in a narrow sense does exist, in practice there are other very important factors that contribute to a particular individual's accident record.

Actuarial Methods

Historically, probability theory and statistical methods have played a central part in actuarial science, in both theory and practice. Indeed, the motto of the Institute of Actuaries, the professional body in England and the first to be established worldwide is *certum ex incertis*. Furthermore, the early development of these subjects was inextricably linked, with many of the principal contributors to actuarial theory also making notable contributions to probability and statistics – for example, **John Graunt**, Abraham de Moivre, Thomas Simpson, Daniel and Nicholas **Bernoulli**, and Erastus de Forest. Also, some modern statistical models have little-known actuarial antecedents, e.g. Böhmer's development in 1912 of the product limit estimator of **Kaplan–Meier**, and Du Pasquier's analysis in 1913 of multiple state and **competing risk** models; see Haberman & Sibbett [28] for further discussion.

We begin our review with a brief consideration of the nature of actuarial science. Actuarial science is concerned with the financial management of financial security systems – these can be defined as "mechanisms for reducing the adverse financial impact of random events that prevent the fulfillment of reasonable expectations" [3]. These systems have the important characteristics of **risk** transfer and risk pooling [12] but certain fundamental limitations. For example, they are restricted to reducing the consequences of random events that create losses that can be measured in monetary terms. Secondly, such systems do not directly reduce the probability of a loss occurring.

Examples of situations where random events may cause financial losses would include the following:

1. The destruction of property by fire or natural catastrophe (storm, hail, flood, landslide, earthquake, volcanic eruption) is usually considered a random event in which the loss can be measured in monetary terms.
2. A damage award imposed by a court as a result of a negligent event is often considered a random event with resulting monetary loss.
3. Prolonged illness may occur unexpectedly and result in financial losses in terms of reduced income and extra health care expenses.
4. Death of a young adult may occur while long-term family and business commitments remain unfulfilled.
5. Survival to an advanced age may deplete an individual's resources for meeting the cost of living, including long-term care.

One of the key tasks for an actuary advising financial security systems is the management of uncertainty. This process can be broken down into a number of distinct stages; for example, one classification would be: identification of information sources; collection of data; analysis; model construction (*see* **Model, Choice of**); **sensitivity analysis**; **prediction**; monitoring the model assumptions in the light of emerging experience (*see* **Model Checking**); updating the model.

Survival Model (or Life Table): Structure

The **survival** model is concerned with representing the mortality of individuals. Here, we consider single lives, although the extension to contingencies involving multiple lives is straightforward [3, 21]. The initial assumption is that the time from birth to death can be represented by a continuous **random variable** T_0. We define the distribution function of T_0 and the survival function of T_0 as follows:

$$F_0(t) = \Pr(T_0 \le t); \tag{1}$$

$$S_0(t) = \Pr(T_0 > t) = 1 - F_0(t). \tag{2}$$

If we consider an individual aged $x(> 0)$ currently, then we can define a random variable T_x to be his/her future lifetime, conditional on him/her having survived to age x. Then the distribution function of T_x is defined as

$$F_x(t) = \Pr(T_x \le t) = \Pr(T_0 \le x + t | T_0 > x), \tag{3}$$

which is written as ${}_tq_x$ in actuarial notation (and as q_x in the special case when $t = 1$), and the survival function is defined as

$$S_x(t) = \Pr(T_x > t) = \Pr(T_0 > x + t | T_0 > x), \tag{4}$$

which is written as ${}_tp_x$ in actuarial notation.

It is then straightforward to demonstrate the connection between F_x and F_0, and between S_x and S_0, namely

$$F_x(t) = \frac{F_0(x + t) - F_0(x)}{1 - F_0(x)} \tag{5}$$

and

$$S_x(t) = \frac{S_0(x+t)}{S_0(x)}. \tag{6}$$

The force of mortality at age x, μ_x, is defined as

$$\mu_x = \lim_{h \to 0} \left[\frac{\Pr(x < T_0 \leq x + h | T_0 > x)}{h} \right]. \tag{7}$$

The force of mortality is also described as the **hazard rate**.

The probability density function of T_x, $f_x(t)$, is defined by

$$f_x(t) = \frac{\mathrm{d}}{\mathrm{d}t} F_x(t),$$

and is linked to the force of mortality through the following relationship which follows from this definition:

$$f_x(t) = {}_t p_x \mu_{x+t}, \tag{8}$$

so that

$$\mu_{x+t} = \frac{f_x(t)}{S_x(t)}.$$

This gives rise to a differential equation for ${}_t p_x$,

$$\frac{\mathrm{d}}{\mathrm{d}t} {}_t p_x = -{}_t p_x \mu_{x+t}, \tag{9}$$

which can be integrated with the boundary condition ${}_0 p_x = 1$ to give the following useful and important formula:

$${}_t p_x = \exp\left(- \int_0^t \mu_{x+s} \, \mathrm{d}s \right). \tag{10}$$

In numerical applications of the survival model it is common to impose simplifying assumptions on the distribution of T_x within a particular year of age. The two most commonly used such assumptions are:

1. a **uniform distribution** of deaths, i.e.

$$f_x(t) = \text{constant for } 0 \leq t \leq 1;$$

2. a constant force of mortality, i.e.

$$\mu_{x+t} = \text{constant for } 0 \leq t \leq 1.$$

An important modification to the survival model is the development of a select survival model, for use in many applications, in particular life insurance. The survival model is constructed from observations for certain population groups, differentiated by characteristics such as sex, geographical area, and type of insurance purchased. The age at entry to the group under consideration can have a significant influence on the resulting probabilities.

To focus the discussion, we consider an individual who has just purchased life insurance at age x. Since life insurance is carefully underwritten and only lives in good health are accepted (sometimes after a medical examination), it is reasonable to expect that a person who has just purchased insurance at, say, age x will be in better health than a person who bought insurance t years ago, say, at age $x - t$, and is now also aged x (*ceteris paribus*). This dependence of health status on t and x will have an impact on the probabilities of survival and is allowed for by a select survival model. Specifically, the probabilities of death are graded according to age at entry and duration of membership. The notation is to represent the one-year conditional probability of death for a person who entered at age x and who is now aged $x + t$ as $q_{(x)+t}$. Then the selection effect is represented by the sequence of inequalities:

$$q_{(x)} < q_{(x-1)+1} < q_{(x-2)+2} < \cdots, \tag{11}$$

where each probability refers to the conditional probability of death for a person aged x with different periods of membership. Empirically, we find that the selection effect becomes negligible some years, say r, after entry. We represent this feature by requiring that

$$q_{(x-r)+r} = q_{(x-r-1)+r+1} = \cdots = q_x.$$

r is then called the select period and q_x is called the ultimate probability of death at age x.

Selection arises in other practical circumstances, for example for persons purchasing life annuities and for those retiring after disablement. This latter case provides an example of negative selection for which the inequalities in (11) would be reversed.

The survival model can be traced back to Graunt's landmark contribution with the setting up of the first **life table** in 1662. The first authors to have used this life table were the Huygens brothers, who corresponded on the probabilistic interpretation of various life table indices. The first life table in the modern sense is widely attributed to **Halley** in 1693. Further historical details can be found [28, 29].

Survival Model and the Life Table: Actuarial Applications

In general, life insurance policies involve benefits payable by the insurer to the policyholder contingent on the policyholder's status and, in return, premiums are payable by the policyholder while he or she is alive. The benefits may consist of a single payment or a series of payments, and may be dependent on the policyholder having just died (as in life insurance) or being alive (as in an annuity). The financial management and control of life insurance depends critically on the survival model (and life table) which is used by actuaries in the calculations of premiums, reserves, surrender values, and other functions; see [3, 21] for further discussion.

Life insurance mathematics was developed by de Moivre (with his book of 1725, which was the first text on this subject) and Simpson (with his book of 1742), although their prime focus was on annuity rather than insurance contracts. Dodson was the first to demonstrate (in 1755) how modern life insurance could be operated with level annual premiums calculated on the basis of age at entry, and how this level charge for an increasing risk leads to the build-up of a reserve.

Survival Model: Estimation of Parameters

Estimation of $F_x(t)$, $S_x(t)$, $f_x(t)$, or μ_{x+t} will enable us to specify the distribution of T_x, given certain mildly restrictive conditions.

The simplest experiment would be to observe a large number of individuals, born in a particular time interval: then the proportion alive at age $t > 0$ would provide an estimate of $S_0(t)$. This is a nonparametric approach (*see* **Nonparametric Methods**), leading to a step function which would become more regular if the sample size were increased. Such an approach is not practicable because of the length of time it would take to specify fully the survival function and because it may not be possible to observe the deaths of all the lives in the study, because of censoring (*see* **Censored Data**). In medical statistics, however, this type of experiment is widely used, and estimators like the Kaplan–Meier (product limit) and the **Nelson–Aalen estimators** have been developed which allow for censored observations. The so-called *actuarial estimator* also enjoys wide use when the data are in grouped form [16]. We consider a partition of the survival period as follows:

$$0 = t_0 < t_1 < \cdots < t_n < t_{n+1} = \infty,$$

and assume that the total population of lives at time t_0, N_0, is of the same exact age (and suppress age in the notation). Let d_i be the observed number of deaths and w_i the number of right-censored observations (or losses) during the interval (t_i, t_{i+1}). Let N_i be the number of lives at risk at the start of the interval (t_i, t_{i+1}), i.e. just after time t_i.

Then $N_{i+1} = N_i - d_i - w_i$, and the *actuarial estimate* of $F(t)$ is

$$\hat{F}(t) = 1 - \prod_{\substack{j\geq 0 \\ t_{j+1}\leq t}} \left(1 - \frac{d_j}{N_j - \frac{1}{2}w_j}\right). \qquad (12)$$

In actuarial practice, it is normal to use a different experimental plan and base estimation on data gathered within a short time interval – for example, four calendar years for the standard life tables prepared by the UK Continuous Mortality Investigation Bureau (CMIB). As a consequence, we observe several cohorts within a well-defined *window* rather than one cohort over its full life history (see Figure 1). As a result, we might not be sampling from the same distribution and it may be necessary to impose further assumptions on our model (for example, that survival probabilities are constant with respect to calendar time). Limiting the observation time to a rectangle defined by a specific period of time and an age interval, say x to $x + 1$, also introduces censoring: lives enter observation at a known time and survivors leave observation at a known time (when the investigation period ends or on attaining age $x + 1$), while

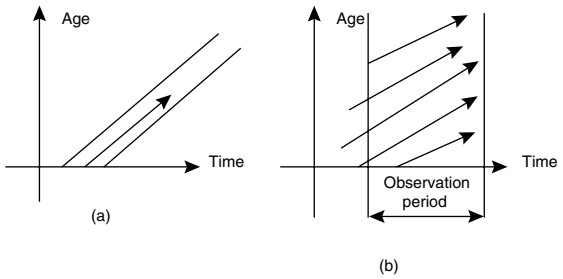

Figure 1 Lexis diagrams illustrating different experimental plans. (a) Cohort-based; (b) fixed period

for deaths and other types of exit (for example, surrenders of a policy), the time of exit will be random. Further discussion of censoring is provided by [1].

To take the actuarial approach further, we follow Broffit [5] and consider one particular form of censoring. We consider N lives to be observed between ages x and $x+1$. For the ith life we let $x+a_i$ be the age at which observation starts and $x+b_i$ the age at which observation must cease if the life survives to that age. Then $b_i = \min(1, a_i + c_i - e_i)$, where e_i and c_i are the dates of entry into the study and of the end of the study. The key point is that a_i, e_i, and c_i, and hence b_i, are known in advance.

We define two random variables

$$D_i = \begin{cases} 1, & \text{if the } i\text{th life is observed to die,} \\ 0, & \text{if the } i\text{th life is not observed to die,} \end{cases}$$

and T_i such that $x + T_i =$ age at which observation of the ith life ceases.

We also define $W_i = T_i - a_i$, the waiting time or time spent under observation for the ith life.

We note that

$$D_i = \begin{cases} 0, & \text{if and only if } W_i = b_i - a_i, \\ 1, & \text{if and only if } 0 < W_i < b_i - a_i. \end{cases}$$

The outcome of observing these random variables is a sample (d_i, w_i), and we define $w = \sum_{i=1}^{N} w_i$ and $d = \sum_{i=1}^{N} d_i$, the total waiting time and total number of deaths observed, respectively.

The **maximum likelihood** estimator for μ is then

$$\hat{\mu} = \frac{D}{W}, \tag{13}$$

where $D = \sum_{i=1}^{N} D_i$ and $W = \sum_{i=1}^{N} W_i$, and the corresponding estimate is $\tilde{\mu} = d/w$.

In many applications the randomness of W_i is ignored and it is usual to write the realized value w as E_x^c, the central *exposure* to risk. Assuming a constant force of mortality as before, the assumption that D has a **Poisson distribution** with parameter μE_x^c leads to the estimator

$$\hat{\mu} = \frac{D}{E_x^c}. \tag{14}$$

The Poisson model is not exact given the above experimental design, but it is a good approximation in many applications.

Given the estimated values of μ from (13) or (14), it is then possible to construct a survival model, using the standard results described earlier. By using estimates from successive ages and time periods, it is also possible to construct a cohort life table, as depicted schematically in Figure 1(a).

Many of the early life tables were based on the experience of individuals who purchased annuities (usually from the government) or who participated in tontines: for example, those constructed by Struyck in 1740, Kersseboom in 1742, and Deparcieux in 1746. These life tables were based on the cohort design of Figure 1(a). In 1749, the Swedish General Register Office was established and the first national set of population data started to be collected from that date. Wargentin combined death registration data for 1755–1763 and the triennial censuses of 1757, 1760, and 1763 (used to approximate exposed to risk figures) to estimate values of q_x (1766). This procedure was taken up and developed further by Price in 1783 to produce the first modern life tables based on the experimental design of Figure 1(b). The first published life table in 1828 based on the mortality experience of an insurance company was reported by Morgan in 1828.

Multiple State and Multiple Decrement Models: Structure

The survival model can be regarded as a two-state model (Figure 2), with two states "alive" and "dead" and transitions permitted in one direction only. This model can be extended to include any number of states, with transitions between them in either direction. Two examples with important applications in actuarial work, are the multiple decrement model (Figure 3, widely used in pensions applications) and the three-state disability model (Figure 4, widely used in disability insurance applications).

We consider initially the case where there are n possible states. Let $S(x)$, $0 \le x \le \infty$, be a continuous-time, time-inhomogeneous **Markov process** with a finite state space ($n < \infty$), and suppose that we interpret "$S(x) = 1$" to mean "the individual is in state 1 at age/time x".

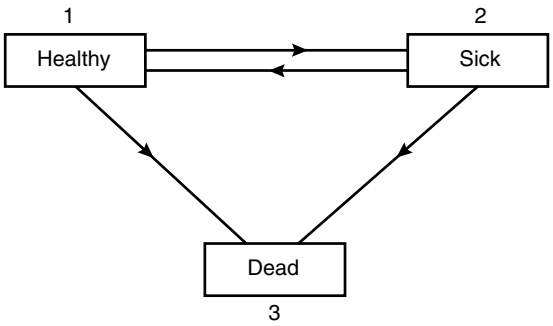

Figure 4 Three-state multiple state model

We define the conditional transition probability

$$ {}_tp_x^{ab} = \Pr[S(x+t) = b | S(x) = a], $$

and the occupancy probability

$$ {}_tp_x^{\overline{aa}} = \Pr[S(x+u) = a, \quad \text{for all } u \in (0,t) | S(x) = a]. $$

Corresponding to the definition of the force of mortality, (7), in the survival model, we define the transition intensity from state a to state b at age x by

$$ \mu_x^{ab} = \lim_{h \to 0+} \left(\frac{{}_hp_x^{ab}}{h} \right), \quad \text{for } a \neq b. $$

Then, we can derive the Chapman–Kolmogorov forward differential equations:

$$ \frac{\partial}{\partial t} {}_tp_x^{ab} = \sum_{j \neq b} {}_tp_x^{aj} \mu_{x+t}^{jb} - {}_tp_x^{ab} \mu_{x+t}^{bj} \tag{15} $$

and

$$ \frac{\partial}{\partial t} {}_tp_x^{\overline{aa}} = -{}_tp_x^{\overline{aa}} \sum_{j \neq a} \mu_{x+t}^{aj}, \tag{16} $$

which are generalizations of (9). Given estimates of the transition intensities, this set of equations (15) can be solved numerically (see, for example, [8, 31]) or analytically in certain special cases (see [42] for a discussion of piecewise constant transition intensities). Eq. (16) can be integrated directly, in a similar manner to (9), leading to

$$ {}_tp_x^{\overline{aa}} = \exp\left(-\int_0^t \sum_{j \neq a} \mu_{x+s}^{aj} \, ds \right), \tag{17} $$

which plays an important role in the estimation of the transition intensities from observed data.

Semi-Markov Model

In the above discussion, the Markov assumption has been made: that transition intensities (and probabilities) at time t depend (at least explicitly) on the current state at that time only. More realistic, and possibly more complex, models can be constructed considering, for example:

1. the dependence of some intensities (and probabilities) on the age x at time 0, corresponding, for example, to the issue of an insurance policy
2. the dependence of some intensities (and probabilities) on the time spent in the current state since the latest transition to that state
3. the dependence of some intensities (and probabilities) on the total time spent in some states since the policy issue.

The consideration of point 1 implies the use of issue-select intensities, corresponding to $\mu_{(x)+t}$ for the survival model and life table. This extension does not imply the use of more complex models since it is implicitly allowed for by the Markov assumption for the process $S(t)$.

With point 2, the Markovian property of the process $S(t)$ is lost. Nevertheless, there are practicable ways of dealing with this assumption, which is of practical importance in disability insurance where transitions from the disabled state would depend on the duration of the current disability. One general (and complex) approach leads to **semi-Markov** processes [8, 11], while a simpler approach requires the "splitting" of some states [11, 31].

The aim of point 3 is to stress the individual's life history. This assumption can lead to intractable models. (However, particular aspects of this assumption can be introduced without a dramatic increase in complexity.)

Multiple State Models: Actuarial Applications

As for the survival model, multiple state models are used for the determination of premiums and reserves for insurance policies, operating in a multiple state environment – for example, income protection insurance policies in the UK which provide an annuity while the individual is "sick or disabled" subject to certain qualifying conditions [40]. For a further discussion, see [25].

Correspondingly, the multiple decrement model is widely used in applications in defined pension schemes where the actuary's objective is to determine the contribution rate for current members and to calculate reserves at regular intervals and to monitor the financial health of the scheme.

In some practical applications, it is important to allow for the effects of selection arising from the effect of different transitions. For example, where withdrawals are associated with lower than average mortality rates, increased mortality in the continuing population results; where early retirements are associated with higher than average mortality, the result is decreased mortality in the continuing population.

Multiple State Models: Estimation of Parameters

For illustration we consider the three-state model of Figure 4; extensions to the more general case are straightforward. We consider an observation period of perhaps several calendar years and assume that each individual represents an independent realization of the underlying **stochastic process**, $S(y)$, where y is the individual's age. We assume that, while under observation, we can observe the time and type of each transition that an individual makes. We focus, for inference purposes, on the age interval $(x, x+1)$, over which we assume that the transition intensities are constants, μ_x^{12}, μ_x^{13}, μ_x^{21}, μ_x^{23}.

The observations in respect of a single life are now:

1. the times between successive transitions
2. the numbers of transitions of each type.

The form of the **likelihood** means that it suffices to record the total waiting time spent in each state. Following Sverdrup [51], we then define

C_j = waiting time of the jth life in the healthy state
W_j = waiting time of the jth life in the disabled state
S_j = number of transitions from healthy $\longrightarrow$ disabled by the jth life
R_j = number of transitions from disabled $\longrightarrow$ healthy by the jth life
D_j = number of transitions from healthy $\longrightarrow$ dead by the jth life
U_j = number of transitions from disabled $\longrightarrow$ dead by the jth life,

and totals $C = \sum_1^N C_j$ (and so on). It can then be shown that the maximum likelihood estimators are, respectively,

$$\hat{\mu}_x^{13} = \frac{D}{C}, \quad \hat{\mu}_x^{23} = \frac{U}{W},$$
$$\hat{\mu}_x^{12} = \frac{S}{C}, \quad \hat{\mu}_x^{21} = \frac{R}{W}. \tag{18}$$

We note that each estimator is the ratio of two random variables: number of transitions and waiting time (or central exposed to risk).

It may be important to be able to estimate the **moments** of these estimators, for example when comparing the results of two sets of observations or comparing one experience with a given standard experience. It is a well-known result of maximum likelihood theory that the asymptotic distribution of each $\hat{\mu}$ is **normal** with mean μ and variance $\mu/E(C)$ or $\mu/E(W)$, as appropriate.

The history of the development of multiple state models has been fully described by [13] and [46].

These models can be traced back to **Bernoulli's** memoir of 1766, in which he applied the methods of differential calculus to a problem involving a three-state decrement model and then solved the resulting differential equations under certain constraints. The problem was concerned with the incidence of smallpox in the population and measuring the efficacy of inoculation. Bernoulli's ideas were developed by a number of authors, in particular Lambert in 1772, Cournot in 1843, Makeham in 1867, Karup in 1875, and Du Pasquier in 1912.

Du Pasquier's work is very significant, presenting an early application of Markov processes and laying the foundations for modern actuarial applications to disability insurance, long-term care insurance, and critical illness policies, *inter alia* [40].

Projections

Almost all aspects of the actuarial management of financial security systems like insurance companies and pension funds require the projection forward of the financial status and the underlying cash flows using a survival model, multiple state model, or multiple decrement model, as appropriate.

The methods used are essentially those of the component method of population projection, and can be traced back to Webster's early calculations for the Scottish Ministers' Widows Fund set up in 1743. Techniques, which were originally deterministic, have now been extended to allow for stochastic projections, based on **simulations**, of portfolios of policies and ultimately of companies.

In life insurance, financial projections require, *inter alia*, estimates of mortality rates and withdrawal rates. For pension schemes, the projections require estimates of rates of mortality, withdrawal, disability, and retirement. For health insurance, a multiple-state model with rates of incidence of disability, recovery, withdrawal, and mortality would be used. In these cases, it would be normal to attempt to model the variation of the probabilities with secular time (as well as age, for example), so that **extrapolations** can be made. The forecasting methods receiving most attention consist of regression based methods (using generalized linear models: for example [48]) and methods based on the Lee-Carter method (for example, [34, 35, 44].

In the case of financial calculations associated with annuities and pensions, it is important to note that the improving **life expectancy** and the downward secular trend in mortality rates (observed in many countries) (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**) need to be allowed for explicitly in the calculation of premiums and reserves. Failure to make such an allowance can have serious financial consequences for an insurer because improving life expectancy would mean that benefits would have to be paid for longer than anticipated. An example of modeling the impact of mortality trends as insurance portfolios is [38].

Similarly, where an upward trend in mortality is suspected, it is important to recognize this in life insurance calculations. This has been an important feature of recent discussions in respect of the impact of **AIDS** (see [14]).

For health insurance (based on the model in Figure 4), we would note the likely relationship between the probability of recovery and the employment prospects for the individual and the economic environment [24]. An important area of recent development has centered on the modeling of dependence between demographic risks and between demographic and financial risks. This application has been based on copulas [18, 49].

Graduation

Graduation may be regarded as the principles and methods by which a set of observed probabilities is adjusted to provide a suitable basis for inferences and further practical calculations to be made.

We consider for the moment a set of age-specific crude probabilities of death, $\mathring{q}_x$, or forces of mortality (i.e. hazard rates), $\mathring{q}_x$, which have been calculated from a set of observations. These values can each be regarded as a sample from a larger population and thus contain some random fluctuations. If we believed that the true q_x (or μ_x) were independent, then the crude values would be our final estimates of the true, underlying rates. However, a common, prior opinion about the form of these true rates is that each is closely related to its neighbors. This relationship is expressed by the belief that the true rates progress smoothly from one age to the next. So the next step is to graduate the crude rates to produce smooth estimates, $\tilde{q}_x$ (or $\tilde{\mu}_x$) of the true rates. This is done by systematically revising the crude values to remove the random fluctuations. This can be considered as a

cheaper and more practicable alternative to increasing the size of the original investigation.

The graduation process is an essential step in the construction of a survival model in ensuring that the model displays the required degree of smoothness. Then, the functions of practical importance calculated from the model (and leading to insurance premiums, reserves, surrender values, etc.) have results that share this important property of smoothness.

Graduation methods tend to fall under the categories *parametric* (*see* **Parametric Models in Survival Analysis**) and *nonparametric*. For a full review, readers should consult [2] and [36].

Parametric methods involve the fitting of a mathematical function to $\mathring{q}_x$ or $\mathring{\mu}_x$, with the parameters being determined by a formal procedure such as maximum likelihood estimation. Although in the context of the assumed function such methods are efficient (*see* **Efficiency and Efficient Estimators**), they are always liable to some degree of **bias** since no preassigned function will represent exactly the true (and unknown) values of q_x or μ_x. Nonparametric methods aim to give more stable estimates than the crude values by combining data at different values of x, but without presupposing any particular mathematical form for q_x or μ_x. Like parametric methods, they are liable to give biased estimates, but in such a way that it is possible to balance explicitly an increase in bias with a decrease in sampling variation. With nonparametric methods, like kernel methods (*see* **Density Estimation**), the amount of smoothing of the crude data can be varied continuously over a continuous range (e.g. by the choice of bandwidth). In contrast, the smoothness of parametric methods can only be regulated in discrete steps, for example by increasing the degree of the polynomial or by increasing the number of knots in a cubic **spline**. The properties of such curves will also tend to change abruptly. However, parametric methods are able to achieve higher degrees of smoothness than nonparametric methods through their use of explicit mathematical formulae, and may be more useful for extrapolation beyond the data range available.

Parametric Methods

We consider initially the graduation of an index of mortality like q_x or μ_x with respect to age.

Forfar et al. [17] give a comprehensive description of the methodology used in the UK to graduate survival models. We reformulate the methodology using the framework of **generalized linear models** (GLMs); for a full review see [27].

A GLM is characterized by independent response variables (Y_u with $u = 1, 2, \ldots, n$) with distribution specified by

$$\mathrm{E}(Y_u) = m_u, \quad \mathrm{var}(Y_u) = \frac{\phi V(m_u)}{\omega_u} \tag{19}$$

comprising a variance function V, a scale parameter $\phi(> 0)$, and prior weights ω_u. **Covariates** enter via a linear predictor,

$$\eta_u = \sum_{j=1}^{p} x_{uj}\beta_j, \tag{20}$$

with specified structure (x_{uj}) and unknown parameters β_j linked to the mean response through a known, differential, monotonic link function g with

$$g(m_u) = \eta_u. \tag{21}$$

The suffices or units u have a structure which is either intrinsic or imposed. The data comprise realizations (y_u) of the independent response variables, matched to the structure of the units. Generally, in any one study, the detail of the distribution and link are fixed, while the predictor structure may be varied.

Model fitting is by maximizing the quasi log likelihood (*see* **Quasi-likelihood**), leading to a system of equations in the unknown β_js which need to be solved numerically. Full details can be found in [37], which also describes the calculation of the **standard errors** for the parametric estimators, based on standard statistical theory. For members of the exponential family of distributions (*see* **Parametric Models in Survival Analysis**), the quasi log likelihood equates to the log likelihood.

The raw data would normally comprise the number of recorded deaths a_x accruing from matching exposures (or **person-years at risk**) r_x over a range of ages x, in a specific calendar period.

The approach would then be to model the actual numbers of deaths A_x as Poisson variables when targeting μ_x and as **binomial** variables when targeting q_x. Thus, for μ_x graduations with responses (A_x),

$$m_x = \mathrm{E}(A_x) = r_x\mu_{x+1/2},$$
$$V(m_x) = m_x, \quad \omega_x = 1, \quad \phi = 1,$$

and for q_x graduations with responses (A_x),

$$m_x = r_x q_x, \quad V(m_x) = m_x\left(1 - \frac{m_x}{r_x}\right),$$
$$\omega_x = 1, \quad \phi = 1.$$

The formulas underpinning a (parametric) graduation can be presented as predictor–link relationships with age x as the sole covariate.

The most common choice for η_x is to use polynomial predictors, or a set of orthogonal polynomials (*see* **Orthogonality**) for reasons of convenience of computing and interpretation. Splines and break-point predictors have also been used.

Parametric models of mortality have a long history, dating from Gompertz's "law" of 1825,

$$\mu_x = \exp(b_0 + b_1 x),$$

Makeham's modification of 1860,

$$\mu_x = a_0 + \exp(b_0 + b_1 x),$$

and Thiele's proposal of 1872,

$$\mu_x = \exp(b_0 - b_1 x) + a_1 \exp\left[-\frac{(x-c)^2}{2b_2}\right] + \exp(b_3 + b_4 x).$$

Later suggestions include the use of a **logistic** family of curves [39] and Heligman & Pollard's model involving a combination of double-exponential and **lognormal** curves for representing the odds function $[q_x/(1-q_x)]$ [30]. These mark progress towards a parametric model for the full age range.

Nonparametric Methods: Moving Weighted Average Graduation

Moving weighted average graduation methods (*see* **Moving Average**) were among the first nonparametric methods to be developed. The adjusted average formulae were largely developed by de Forest in the 1870s in a series of rather obscure papers which were rescued from oblivion and the results extended by Wolfenden [55]. For comments on the importance of de Forest's contributions see [50]. In this approach a weighted average of consecutive crude values is taken, i.e.

$$\hat{q}_x = \sum_{s=-m}^{s=m} a_s \mathring{q}_{x+s}. \tag{22}$$

The most successful formulas have symmetric coefficients $a_s = a_{-s}$. When considering the optimality of the coefficients a_s, it is useful to consider the crude rate as a random variable and express it as

$$\mathring{q}_x = q_x + r_x,$$

where q_x is the true rate and r_x is the residual error. An essential feature of any graduation is that the graduated rates should be smooth in some sense. With moving weighted averages (MWA), one approach is to choose weights that give the smoothest graduations, *ceteris paribus*. London [36] provides a fuller discussion of this approach.

The problems caused by MWA methods failing to give smoothed values of the first and last m observations have recently been addressed by Greville [23], among others.

Nonparametric Methods: Kernel Methods

Kernel estimation methods are used for estimating a probability density function (*see* **Density Estimation**). Thus, if $x_1, x_2, \ldots, x_n$ are some observed values of the random variable X, then the kernel estimate of the density at x is

$$\hat{f}(x) = \frac{1}{nb}\sum_{i=1}^{n} k_b(x - x_i), \tag{23}$$

where $k_b(x) \equiv k(x/b)$ is a kernel function which satisfies

$$\int_{-\infty}^{\infty} k(x)\,\mathrm{d}x = 1.$$

The bandwidth b governs the amount of smoothing which is applied. The larger the value of b is, the more smooth is the resulting estimate. In effect, a kernel density estimate is formed by placing a kernel function at each data point and then summing these functions to form the estimate. A more complete discussion of kernel density estimation is given in [45, 47].

We assume that for a set of ages x_i, $i = 1, \ldots, n$, we are given a measure of the exposed to risk e_i and the observed number of deaths d_i.

Two kernel estimators have been suggested, both of which are closely related to MWA graduation,

namely

$$\hat{q}_x^{\mathrm{CH}} = \frac{\sum_{i=1}^{n} d_i k_b(x - x_i)}{\sum_{i=1}^{n} e_i k_b(x - x_i)} \tag{24}$$

and

$$\hat{q}_x^{\mathrm{NW}} = \frac{\sum_{i=1}^{n} \mathring{q}_{x_i} k_b(x - x_i)}{\sum_{i=1}^{n} k_b(x - x_i)}. \tag{25}$$

In the context of graduation, $\hat{q}^{\mathrm{CH}}$ was introduced by Copas & Haberman [9] and $\hat{q}^{\mathrm{NW}}$ by Ramlau–Hausen [41]. The latter is related to the Nadaraya–Watson estimator and can be viewed as a continuous analogue of MWA graduation [19]. The choice of bandwidth is discussed in some detail in [20].

Nonparametric Methods: Whittaker–Henderson Methods

The nonparametric methods described above can be regarded as local, in the sense that the graduated value at a given age depends only on the observed values for arguments within a stipulated distance from the given argument. Global methods allow each graduated value to depend on all the observed data. The principal such method is Whittaker–Henderson graduation, devised by Whittaker [54].

The approach is based on a minimization of

$$S = \sum_{i=1}^{n} w_{x_i}(u_{x_i} - y_{x_i})^2 + h \sum_{i=1}^{n-s} (\Delta^s u_{x_i})^2, \tag{26}$$

where y_{x_i} denotes the crude values and u_{x_i} denotes the resulting graduated values at age x_i, with $i = 1, 2, \ldots, n$. S combines a measure of goodness of fit of the graduation and a measure of the smoothness of the sequence of graduated values, moderated by a positive parameter h chosen by the user to reflect the relative importance that they wish to attach to these conflicting characteristics. It is common to choose $s = 2$ or 3.

When $h = 0$, S is minimized when $u_{x_i} = y_{x_i}$ so that no graduation is needed. As h tends to 0, fit is emphasized over smoothness. When h becomes large, the second term dominates and in the limit the graduating curve becomes the least squares fitted polynomial of degree $s - 1$.

(w_{x_i}) is a set of positive weights chosen by the user, although it is common to choose for w_{x_i} the reciprocal of an estimate of the variance of the observation y_{x_i}. Then, the graduated values u_{x_i} are constrained to be close to the more reliable observations (i.e. those with smaller variances) and to be approximately a polynomial of degree $s - 1$, where the observations are less reliable.

We can rewrite (26) in matrix notation,

$$\mathbf{S} = (\mathbf{u} - \mathbf{y})' \mathbf{W} (\mathbf{u} - \mathbf{y}) + \boldsymbol{h} (\mathbf{K}\mathbf{u})' \mathbf{K}\mathbf{u}, \tag{27}$$

where $\mathbf{y}$ is the vector of observed values, $\mathbf{u}$ is the vector of graduated values, and $\mathbf{W}$ is the $n \times n$ diagonal matrix with successive diagonal elements equal to w_{x_i}. $\mathbf{K}$ is an $(n - s) \times n$ matrix with entries k_{ij}, where

$$k_{ij} = (-1)^{s+i-j} \binom{s}{j-i}.$$

It is then straightforward to show that $\mathbf{S}$ is minimized by $\mathbf{u}$ satisfying

$$(\mathbf{W} + \boldsymbol{h}\mathbf{K}'\mathbf{K})\mathbf{u} = \mathbf{W}\mathbf{y}. \tag{28}$$

As an extension, the loss function in (26) has been adapted to the fitting of a continuous curve, namely the smoothing spline of DeBoor [15]. This is discussed in more detail in [22].

A **Bayesian** interpretation of Whittaker–Henderson graduation has been provided by Taylor [52], and Verrall [53] has shown that the approach is equivalent to a dynamic **regression** analysis in which one parameter of the fitted line is allowed to vary stochastically. A two-dimensional version of Whittaker–Henderson graduation has been introduced by Knorr [33].

Other Nonparametric Methods

Related global methods include Bayesian [32] and information theoretic methods [4].

Tests of a Satisfactory Graduation

Two characteristics of a graduation require examination: smoothness and **goodness of fit** to the

observed data. These qualities are in competition, as is formalized in the criterion S for Whittaker–Henderson graduation; see (26).

The degree of smoothness required of a graduation is subjective and depends on the use to be made of the results; for applications in life insurance, it is essential that the resulting functions (e.g. premiums) are smooth. A parametric function (not a piecewise function) may, of course, be assumed to be smooth. In other cases, it has become customary to examine low-order finite differences of the graduated values and to consider their size and progression with respect to age.

For measuring the goodness of fit, it is common practice to tabulate the residuals, defined as the difference between the graduated value and the observed value at the relevant ages. The **diagnostics** are augmented by a variety of residual plots (*see* **Residuals for Survival Analysis**), including the normal and **half-normal** plots, and a battery of tests (including the standardized deviations test, cumulative deviations test, **serial correlations** test, **sign test**, changes of sign tests, and grouping of sign tests; see [2] for a full discussion).

Risk Classification and Regression

An important feature of insurance systems is the classification of risks for the purposes of fixing premiums. The classic economic argument in favor of risk classification is to combat **adverse selection**, the tendency of high risks to be more likely to buy insurance or to buy larger amounts than low risks [12].

In this context, the **proportional hazards** model of Cox [10] has become widely used for the modeling of the dependence of the force of mortality on a range of covariates (e.g. sex, blood pressure, weight). Following the notation of statistics, we let λ denote the force of mortality (or hazard rate) and then propose

$$\lambda(t, z_i) = \lambda^*(t) \exp\left(\sum_{j=1}^{p} z_{ij}\beta_j\right), \qquad (29)$$

where $\lambda(t, \mathbf{z}_i)$ is the hazard rate at time t for a person with known covariates given by the vector $\mathbf{z}_i$ (with elements z_{ij}), (β_i) is a set of parameters to be estimated, and $\lambda^*(t)$ is a baseline hazard rate at time t. Then each factor $\mathbf{z}_i$ enters the hazard in a multiplicative fashion. In this formulation, only $\lambda^*(t)$ depends on time, but the model can be adapted to feature time-dependent covariates.

If we assume that the $\lambda^*(t)$ values are known, then we can formulate the model as a GLM and hence produce parameter estimates for the (β_j); examples are provided by [26, 43].

Results from such studies of insurance mortality have demonstrated that the total mortality risk can be represented by a statistical model involving a linear combination of a number of factors (possibly with **interactions**). The results have proved very useful for insurance purposes. Further, the major medico-actuarial studies of mortality and survival experience of insured lives characterized by a range of covariates have been of considerable importance in public health terms – for example, the link between build, blood pressure, and mortality demonstrated by the Build and Blood Pressure Studies in the US [6, 7].

Adaptive and Dynamic Methods of Treatment Assignment

The simplest design of a randomized clinical trial is to enter a predetermined number of patients (i.e. use a fixed sample size) and to assign treatment by randomization with equal probability for each patient. In practice, trials are rarely conducted in this fashion. More commonly, both the manner in which patients are allocated a treatment, and the decision to terminate the study, are based on patient-specific information that accumulates during the progress of the trial. The terminology used to identify the different kinds of methods has not been consistent. However, in this article the following taxonomy will be used to classify the methods. A *dynamic* allocation method is one in which information on patient covariates that predict the clinical outcome is used to determine the treatment assignment. By contrast, an *adaptive* allocation method is one that uses accumulating outcome data to affect the treatment selection. In the broad context of adaptive designs, *sequential* designs (*see* **Sequential Analysis**) are prespecified analytic rules that guide the decision to terminate the trial on the grounds that the evidence favoring one of the treatments has become persuasive.

Dynamic Treatment Allocation

A completely randomized design (*see* **Experimental Design**) is relatively simple to implement and prevents selection bias. It also ensures that all hypothetical permutations of the treatment assignments are equiprobable, under the null hypothesis, and thus forms the basis for a conventional permutation test, if this is the analysis of choice. The disadvantages of complete randomization include inefficiency in small trials, due primarily to the risk of imbalanced treatment totals, and the possibility that important prognostic factors may also be imbalanced by chance, reducing the credibility of the results of the trial. The simplest way to avoid imbalance in treatment totals is to randomize groups of individuals in "blocks", with equal numbers of each treatment in each block (*see* **Randomized Treatment Assignment**). Imbalance in important prognostic factors can be reduced by allocating randomly permuted blocks within the strata (*see* **Stratification**) defined by the factors [26]. This method, randomly permuted blocks in strata, is probably the most widely used randomization method, and it is easily implemented, since all of the allocation sequences can be prescribed before the start of the trial, by creating sequences of blocks for each stratum. That is to say, the dynamic aspects of this method are embedded in the stratum-specific sequences of allocations, and so no dynamic calculations are necessary in the course of the trial to determine the next treatment allocation.

The method of randomly permuted blocks in strata rapidly degenerates as the number of strata increases. For example, a trial with five stratification factors, and three categories for each factor, would have $3^5 = 243$ distinct strata. Therefore, in the course of the trial many of the strata will accrue few, if any, patients (unless the sample size is very large), rendering the blocking ineffective. In effect, the method reduces to complete randomization as the number of strata increases. To offset this problem there are a number of methods that balance the factors individually, i.e. marginally, without requiring balance within all factor combinations.

Suppose that there are f factors, and l_f levels in factor f. At any given point in the trial the treatment allocations of the previous patients will have created some amount of imbalance among the factors. Let t_{ijk} be the total number of patients in the jth level of factor i that have been allocated to treatment $k, i = 1, \ldots, f, j = 1, \ldots, l_f, k = 1, \ldots, r$, where r is the number of treatments. The trial is balanced for factor i level j to the extent that $t_{ij1}, \ldots, t_{ijr}$ are similar. If the next patient to be randomized possesses factor i at the jth level, then one can consider the effect that each of the possible treatment allocations would have on this balance. Balance must be characterized by a mathematical function. Taves [21] proposed the popular minimization method, where balance is characterized by the range of treatment totals, and the treatment is selected by minimizing the sum of the ranges across all of the factors. Pocock & Simon [18] proposed a more general version of this method in which the treatment is selected by a biased coin randomization, with the biased coin probabilities determined by the balancing function. They suggested the use of either the range or the variance as balancing functions. Their overall balancing function

involves a weighted sum of the balancing functions of the individual factors, where the weights could be assigned on the basis of the relative importance of the prognostic factors. That is, if $t^*_{ijk}(k)$ represents the treatment totals if treatment k is allocated, and if $F_{ij}[t^*_{ijk}(k)]$ is the balance for the jth level of the ith factor under these circumstances, then the overall balance is

$$B_k = \sum_i \sum_j w_i F_{ij}[t^*_{ijk}(k)].$$

Note that only the unique levels of each factor for the new patient are affected by the choice of k. The values of B_k are especially easy to update and compute if the variance is used as the balancing function [11]. The biased coin probabilities are then determined on the basis of B_k. For example, if the r treatment assignments are ranked from the one that would lead to the least imbalance, $k = 1$, to the one that would lead to the greatest imbalance, $k = r$, then one of the formulas suggested by Pocock & Simon is to select $p_1 > r^{-1}$, and set $p_k = (1 - p_1)/(r - 1)$ for $k = 2, \ldots, r$. In this case the degree of randomization is inversely related to p_1, and the design is fully randomized if $p_1 = r^{-1}$. The use of biased coins in this context, rather than deterministic allocations, was originally proposed by Efron [10], in part to ensure that the trial is truly "randomized", enabling the calculation of an appropriate reference distribution for a permutation test (making use of the biasing probabilities), and in part to reduce the risk of **selection bias**.

Numerous other treatment allocation schemes have been proposed. Notably, it has been shown that balance is a characteristic of design optimality for the linear model [7], and efficient designs have been developed in the context of the theory of **optimal design** [3]. Various simulation studies and general empirical evidence demonstrate that all of these algorithms are effective at balancing stratification factors, even very early in the trial when there is a risk that the trial might have to be terminated unexpectedly. The numerous proposed methods have been reviewed in detail [14].

The validity of conventional statistical tests subsequent to the use of stratified or minimization-type schemes has been a topic of debate. In general, stratification has the effect of making the treatment groups more alike that would be expected by chance. This tends to make the unadjusted estimator of the treatment effect more precise, but the variance estimator is positively biased, and thus unadjusted statistical tests are conservative. Simon provides a review of historical discussion of this issue in the context of agricultural experiments in the 1930s [19]. To correct for this effect, it is necessary to perform a stratified analysis, stratified by the same factors employed in the design. This may be inconvenient if numerous factors were used in a minimization-type scheme. However, the distortion of the p values is only substantial for strong prognostic factors, and so it will typically be unnecessary to adjust for all factors in the analysis. Biased-coin designs affect the validity of standard permutation tests owing to the fact that different allocation sequences are not equiprobable, and it is possible in theory to correct this problem by simulating the correct reference distribution [19].

Adaptive Designs

Adaptive designs, i.e. designs which depend on the accumulating outcome data, have been researched and discussed extensively since the 1950s. Pioneering work in this area was accomplished by Armitage, who adapted the sequential probability ratio test for application to medical trials [2]. Such a scheme allows for a formal termination rule at any time based on a global significance level. That is to say, it accounts for the fact that multiple analyses of the data will increase the chances of a false positive finding, and so the stopping boundaries are adjusted to offset this multiplicity problem. For many years this methodology appears to have been well known but little used. However, a series of papers in the late 1970s and early 1980s succeeded in popularizing the concept, via the development of group sequential stopping rules, in which a relatively small number of pre-specified interim analyses are envisaged (*see* **Data and Safety Monitoring**). These new methods were developed in recognition of the fact that large multicenter trials are usually subject to regular analyses by data-monitoring committees (*see* **Data Monitoring Committees**). The simplest method involves setting a single significance level for each analysis [17]. However, it appears that methods with very strict criteria early in the trial, and a final criterion close to the nominal level (e.g. 5%), such as the O'Brien and Fleming rule, are more popular [15].

An entirely different formulation of this problem also led to much research and debate, stemming

from the ideas of Anscombe [1] and Colton [9]. This approach is designed to optimize the stopping rule on the basis of an appropriate **loss function**, in contrast to the arbitrariness inherent in using significance tests. To do this, it is necessary to construct a "patient horizon", i.e. the total number of patients either on the trial or affected by the trial results in the future via the choice of the best treatment. In this model the responses to each treatment are assumed normally distributed with equal variances, and patients are randomized until the boundary is crossed, after which all remaining patients are assigned to the superior treatment up to the patient horizon. The optimal boundary is evaluated by trading the losses incurred by randomizing half the patients to the inferior treatment, and the losses incurred by making the wrong decision and assigning all future patients, up to the horizon, to the inferior treatment. Tabulated boundaries for this problem are provided by Chernoff & Petkau [8]. Even greater optimization is theoretically possible by optimizing the proportions randomized to the treatments on the basis of the emerging data [5, 13]. A perceived problem with this kind of approach is that the formulation is considered by most experts to be too simplistic to be a credible approximation to the realities of clinical research [16]. The patient horizon is a spuriously precise expression of a vague concept. As a result, this approach is not used widely.

A closely related formulation is the two-armed bandit problem [20]. Zelen popularized this concept in the context of medical trials, calling it the play-the-winner rule [25]. Conceptually this rule involves randomly selecting treatments using urn-sampling, where the numbers of balls in the urn are changed as outcomes are recorded. If outcomes are recorded immediately, i.e. before the next allocation, then a modified play-the-winner rule assigns the subsequent patient to the same treatment following a successful outcome, and to the opposite treatment following a failure. Generalizations to this idea have been studied by numerous investigators, especially randomized versions that do not allow deterministic allocations [24]. The basic rationale presented for play-the-winner (or biased coin) adaptive designs is that it is preferable on ethical grounds to assign more patients to the treatment that appears to be generating the superior outcomes, and indeed it has been shown that such designs do allocate fewer patients to the "inferior" treatment compared with an equal allocation design, after fixing the probability of a correct selection [25]. Although this method has not been used frequently in practice, it was employed in a highly controversial study of extracorporeal membrane oxygenation therapy (ECMO) in newborn infants [4]. This trial was concluded after 12 patients were treated, only one of whom was allocated the control treatment (the only failure in the study). The subsequent permutation-based analysis, calculated on the basis of the biased-coin design, led to a marginally significant result [23]. However, the methodology received much criticism [6], and a subsequent confirmatory trial involving a randomized consent design (*see* **Ethics of Randomized Trials**) also led to great controversy [22].

The decision to continue or terminate a clinical trial on the basis of the available evidence is a highly charged issue that continues to engender debate among statisticians, clinical investigators, and ethicists, and even the role of randomization continues to be disputed. Frequently, in the course of a trial, relevant data from a related trial or a meta-analysis (*see* **Meta-analysis of Clinical Trials**) become available, and this may influence the decision to continue or terminate the study. The merits of formalizing the use of such information have been debated at length [12].

Adaptive Designs for Clinical Trials

If investigators planning a clinical trial knew all that was necessary to design it, they would select an optimal statistical procedure to test the primary hypothesis of interest. In practice, however, one rarely has sufficient information available at the time one designs a trial – the variability of the primary outcome measure may be unknown, the effect size uncertain, and the expected compliance to therapy, a conjecture. Particularly for a long-term study, modifications to standard medical practice that may occur as the trial progresses may produce unanticipated changes that affect parameters used to design the trial. Lacking firm estimates for parameters integral to the design of a study, the investigators may choose to sacrifice statistical optimality in exchange for an adaptive design that provides flexibility. This section discusses a variety of such adaptive designs for clinical trials.

One can imagine many different types of adaptations. Some adaptive designs, by changing the allocation ratio during the course of the trial (play the winner trials or drop the loser trials) aim to increase the probability of assigning the best treatment to the participants in the trial (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). Other adaptive designs incorporate aspects of both a *dose-finding* and *confirmatory study*; others may allow change in endpoint or modifications of entry criteria. This article discusses a class of adaptive designs that modify sample size during the course of the trial. Two types of such designs are available – those whose purpose is to end a study early if the answers are clear and those whose purpose is to increase the information in a trial, either by increasing sample size or length of follow-up, to maintain desired statistical power. We deal here primarily with two-stage adaptive designs. For a general description of the theoretical underpinnings of two-stage adaptive designs, see [16].

The types of designs considered in this article encompass the classes of design with an experimental and control arm (*see* **Clinical Trials, Overview**), a preselected primary endpoint, and a criterion specifying the requirement to preserve, or nearly preserve, the preselected *Type I error* rate. These designs aim to prevent bias, not only the technical bias defined by inflation of the Type I error rate, but also bias that may creep into the study by loosening the protective firewalls that separate the blinded data from those involved in the conduct of the study. In particular, the article addresses **sequential analysis**, *futility analysis*, conditional power (*see* **Cooperative Heart Disease Trials**), and designs that permit changes to sample size or follow-up time in response to internal estimates of either variability or effect size. Designs that allow changes to sample size on the basis of these internal estimates are called "internal pilot" designs [23]. Some authors reserve the word "adaptive" for the special case of internal pilot designs that use effect size to modify the sample size. This article does not discuss more general adaptive designs that allow such changes as dropping a study arm during the course of the trial, redefining the primary endpoints, selecting a different test statistic, modifying the study population, or changing the allocation ratio during the study.

The oldest type of adaptive design goes by the name "sequential analysis". These methods, now part of the standard tools of biostatistics, have been widely used for several decades and experienced clinical trialists understand their properties well. While sequential designs are less efficient than the optimal fixed sample design, most schemes in common use incur only small losses in **efficiency**. They allow a trial to stop early with the declaration of statistically significant benefit for the treated group. Many clinical investigators expect to see a sequential plan as part of a clinical trial, especially a long-term trial or a trial with a clinical outcome. In designing such trials, biostatisticians should think not only of the primary endpoint, but also about supportive endpoints and subgroups of potential importance. Stopping a trial early may allow declaration of success for the primary endpoint, but if the sample size is small at the time the study ends, the observed effect size may considerably overestimate the true effect. Moreover, the results may have ambiguous interpretations for other important questions.

A second type of adaptive approach that permits early termination with protection of Type I error rate is the so-called futility analysis. A trial may be declared futile if the experimental therapy is not so bad as to be unsafe, but if the probability of showing benefit is low. In this type of design, the group watching the trial, often the **Data Monitoring Committee**, may recommend ending the trial early if

it assesses that continuing is "futile". The method of assessing futility may be based on conditional power [13] and the B-value [14]; it may be based on a **confidence limit**, or a boundary for excluding a specific effect [8]. The criterion for defining futility often depends on the secondary objectives of the trial. A trial examining proof-of-concept may stop early for futility if the concept appears unfounded; similarly, a confirmatory trial, or a trial that follows an unsuccessful one, may have a low threshold for stopping early and declaring futility. Designers of a first Phase 3 trial (*see* **Clinical Trials, Overview**) however, may be reluctant to stop for futility because they intend to use data from the trial to learn a lot about the new therapy and early stopping produces too little information for rich exploration of the data. By the same token, designers of a trial of a therapy in common use may wish to continue the trial even if the chance of finding benefit is low because clear evidence of no efficacy is important for the public health. Futility analyses that are based on conditional power rely on the stochastic independence of nonoverlapping periods of the trial [14].

Internal pilot designs, unlike sequential analysis and futility analysis, incorporate the possibility of increased sample size. Two classes of such designs are available: those that use data internal to the trial to reestimate one or more **nuisance parameters** and those that reestimate the effect size. In both cases, the new estimate provides the basis for recalculating sample size. All these designs provide a hedge against having made poor estimates of parameters in designing the trial; however, this hedge can be costly. Midcourse estimates, which are based on a fraction of the total sample size originally projected, are often imprecise. This imprecision is more serious for designs that aim to estimate effect size than they are for those that estimate nuisance parameters.

The simplest approaches use data from the first, or internal pilot phase, to estimate **variance**, and then apply this new estimate to a **sample size** formula. A paper by Stein spawned these methods [22]. Many variants are available. Some use unblinded data [3, 22, 23], some **blinded** [11]. Some use formulas that do not correct for potential inflation of Type I error rate, and some address the inflation directly. Methods are available for **normal** [3–5, 7, 11, 23, 24, 26] and **binomial** [10, 12] tests as well as for repeated measures (*see* **Multiplicity in Clinical Trials**) [25].

The blinded and unblinded approaches have different properties. From the point of view of statistical operating characteristics, the blinded versions are generally preferable when the specified effect size is close to the true effect [26]. Especially for binomial and time-to-failure outcomes (*see* **Survival Analysis, Overview**), choosing between blinded and unblinded assessment requires balancing the risk of overestimating the sample size, which can occur in the blinded cases, with providing too much information to the investigators, which can occur in unblinded cases. For example, consider a trial designed to demonstrate a difference in proportion of failure from 0.4 to 0.3. In the blinded case, one would expect a pooled event rate of 0.35. Seeing a rate lower than that would prompt an increase in sample size. If, however, the observed rates were 0.4 and 0.1, that is, a 75% reduction at the first stage, the observed pooled rate of 0.25 would lead to a considerable, and unnecessary, increase in sample size. A method based on the estimated **placebo** rate alone would leave the sample size unchanged.

Both blinded and unblinded methods protect the Type I error rate quite well. In fact, even naïve estimates that simply calculate the sample size at the second stage using the estimated rate in the placebo without any correction for having made an interim look at the data incur only minimal inflation in Type I error rate [23]. Other methods, for example, [5] correct for the look and hence preserve Type I error rate more precisely. Thus, the criterion for selecting a method for increasing sample size on the basis of internal estimates of information (variance, proportion, or **hazard** should be based less on the operating characteristics (*see* **Animal Screening Systems**) of the procedures and more on practical contingencies. If the study team can separate the estimates from the operation of the study, then unblinded assessments based on the placebo rates may be appealing; if they cannot, then blinded methods are preferable.

Several very different methods are available for internal pilot designs that use effect size as the basis for changing sample size. Some approaches combine ***p*-values** from the two stages [1]; some base sample size on conditional power [19]; some rely on unequal weighing of data from the two phases of the study [6, 15, 20].

Procedures that allow increasing the sample size to control the conditional power implicitly permit increasing the sample size if the effect size at

the interim look is low. The procedure calculates the conditional power at the first stage and then increases the sample size to maintain desired conditional power. Consider a two-stage trial that tests a one-sided (*see* **Alternative Hypothesis**) **null hypothesis** H_0. At each stage one calculates p-values, p_1 and p_2. If $p_1 \leq \alpha_1 < \alpha$, the trial stops and rejects H_0. If $p_1 > \alpha_0 > \alpha$, the trial stops for futility. If $\alpha_1 \leq p_1 < \alpha_0$, the trial continues to the second stage and the final decision is based on a combination function $C(p_1, p_2)$ that rejects (does not reject) H_0 if $C(p_1, p_2) \leq c(> c)$. If $\alpha_0 = 1$, the trial will not stop for futility and if $\alpha_0 = 1$, the trial will not stop early [2]. The conditional error function [19], $CE(p_1) = \text{Prob}(\text{reject } H_0|p_1)$, is the probability of rejecting the null hypothesis conditional on observing a p-value of p_1 at the first stage. Let $A(p_1)$ be a monotonic function such that $\alpha_1 + \int_{\alpha_1}^{\alpha_0} A(p_1)\,\mathrm{d}p_1 = \alpha$. A rule that rejects H_0 when $p_1 \leq \alpha_1$ or when $\alpha_1 < p_1 \leq \alpha_0$ and $p_2 \leq A(p_1)$ controls the Type I error rate. If $\alpha_1 < p_1 \leq \alpha_0$ then $A(p_1)$ is the conditional error function [18]. For a description of various conditional error functions, see [19].

One simple, very flexible, two-stage method calculates the z-statistic (*see* **Standard Normal Deviate**), z_1 halfway though the trial [20]. The investigators decide on the basis of z_1 whether to increase the sample size (decreases are not allowed). If they decide not to change the sample size, the study continues to its planned end. If they change the sample size, they may use any method to calculate the second stage sample, n_2. The rejection region is $z^* = (z_1 + z_2)/2^{1/2} > z_\alpha$ and the p-value is $1 - \Phi\{(z_1 + z_{2)}/2^{1/2}\}$. Because Z_1 and Z_2 are independent **standard normal variates** for any sample size function $n_2(z_1)$, z^* also has a standard normal distribution. If the sample size remains unchanged, then the loss of efficiency is very small because z^* is only slightly larger than the usual fixed-sample z-score.

An option for one-sided tests uses a variance-spending sequential method [9], a technique that allows one to change sample size in response to an effect size different from expected. In these designs, one constructs a final test statistic using a weighted average of the sequentially collected data, where the observed data prior to each stage determines the weight function for that stage [21]. The goal is to terminate a trial early when the treatment effect is large or when the new therapy is harmful but to ensure an adequate sample size when the true effect is small. The final test statistic is a weighted average of the test statistics at each stage. One selects the weights to maintain the variance of the final test statistic in order to preserve the Type I error rate. Thus, in general, not all observations have equal weight.

Two other approaches combine sequential analysis with potential increases in sample size [6, 15]. These methods, like the variance-spending sequential methods above, maintain the Type I error rate by assigning different weights to different stages of the study. Consider a trial with K planned interim analyses. At interim analyses $1, 2, \ldots, L$, perform the prespecified group sequential test. At the Lth interim analysis, if the monitoring boundary is not crossed, then adjust the sample size, up or down, by the factor $N(\delta/\Delta_L)$ where N is the original sample size per group and Δ_L the observed treatment difference at the Lth analysis. Both approaches [6] and [15], though slightly different in theory and implementation, have similar properties.

While the ability to modify one's study on the basis of an observed effect has considerable appeal (you *can* have your cake and eat it), the methods are not problem free. The estimate of effect size can be quite biased, so special estimators must be employed. The estimated treatment effect at the end of the first stage may be imprecise, so the recalculated sample size may be either too large or too small and there is some question about the propriety of changing the effect size one wants to detect. Moreover, such designs can be extremely inefficient relative to comparable fixed sample size designs or classical sequential designs [17].

None of these methods should substitute for a careful design. Classical sequential analysis, futility analysis, and sample size recalculation on the basis of reestimated nuisance parameters incur little loss of efficiency; however, adaptive methods that use effect size to change sample size may be very inefficient, requiring much larger sample sizes than a well-designed sequential plan. Thus, one should be cautious in the use of this type of adaptation. During the design phase, one should identify the parameters projected with greatest uncertainty and select midcourse changes specifically to address those uncertainties. A strategy that deliberately chooses a low sample size in the hope that an adaptive design will bail one out courts serious inefficiency. On the other hand, failing to modify one's plans when the

data from a trial show important deviations from the expected may render the results of a trial ambiguous.

JANET WITTES

Adaptive Sampling

Animal populations are often highly clustered (*see* **Clustering**). For example, fish can form large, widely scattered schools with few fish in between. Even rare species of animals may form small groups that are hard to find. Applying standard sampling methods such as **simple random sampling** of plots to such a population could yield little information, with most of the plots being empty. Adaptive cluster sampling, the most well-known form of adaptive sampling, is based on the simple idea that when some animals are located on a sample plot, the neighboring plots (and possibly their neighbors as well) are added to the sample. The hope is to find the whole cluster.

Methods of estimation were initially developed in the three pioneering papers of Thompson [27–29] and the sampling book by Thompson [30]. The methodology is described in detail by Seber & Thompson [38], and by Thompson & Seber [51].

Adaptive Methods

With adaptive sampling, the selection of sampling units (or plots) at any stage of the process depends on information from the units already selected. **Sequential** sampling could therefore be regarded as an adaptive method of sampling, but with the sample size rather than the method of selecting the units being adaptive. We note that the **network** (multiplicity) **sampling** introduced by Sirken and colleagues [39] (see [21] for references) is different from adaptive sampling, though they both use the idea of a network.

Adaptive cluster sampling, which we discuss in detail below, is the most common adaptive method. It is a form of biased sampling, technically known as unequal probability sampling, which arises when sampling clusters of different sizes. The probability of selecting a plot will depend on the size of the animal cluster in which the plot is embedded. We find, not surprisingly, that the standard **Horvitz–Thompson** (HT) and Hansen–Hurwitz (HH) estimators for unequal probability sampling (cf. [16] and [18]) can be modified to provide **unbiased** estimators.

Another adaptive method, which has been described as adaptive allocation, can be used when the population is divided up into strata or primary units, each consisting of secondary units. An initial sample of secondary units is taken in each primary unit. If some criterion is satisfied, for example the average number of animals per sampled unit in the primary unit is greater than some prechosen number, then a further sample of units is taken from the *same* primary unit. Kremers [22] developed an unbiased estimator for this situation. If the clumps tend to be big enough so that they are spread over several primary units, we could use what is found in a particular primary unit to determine the level of the sampling in the next unit. This is the basis for the theory developed by Thompson et al. [49]. Other forms of augmenting the initial sample which give biased estimates are described by Francis [14, 15] and Jolly & Hampton [19, 20].

Adaptive Cluster Sampling

As indicated briefly above, adaptive cluster sampling begins with an initial sample and, if individuals are detected on one of the selected units, then the neighboring units of that unit are sampled as well. If further individuals are encountered on a unit in the neighborhood, then the neighborhood of that unit is also added to the sample, and so on, thus building up a cluster of units. If the initial sample includes a unit from a clump, then the rest of the clump will generally be sampled. Such an approach will give us a greater number of individuals.

To set out the steps involved in adaptive cluster sampling, we begin with a finite population of N units (plots) indexed by their "labels" $(1, 2, \ldots, N)$. With unit i is associated a variable of interest y_i for $i = 1, 2, \ldots, N$. Up till now we have referred to y_i as the number of animals on the ith unit. However, as well as counting numbers of individuals, we may wish to measure some other characteristic of the unit, for example plant biomass or pollution level, or even just note the presence or absence of some characteristic using an indicator variable for y_i. In addition to rare species and pollution studies, we can envisage a wide range of populations that would benefit from adaptive sampling, for example populations which form large aggregations such as fish, marine mammals, and shrimp. It has also been used for sampling animal habitats [28], and we can add mineral deposits and rare infectious diseases in human populations (e.g. **AIDS**) to our list. Having defined y_i, our aim is to select a sample, observe the

y values for the units in the sample, and then estimate some function of the population y values such as the population total $\sum_{i=1}^{N} y_i = \tau$ or the population mean $\mu = \tau/N$. Before sampling begins we need to do three things.

The first is to define, for each unit i, a neighborhood consisting of that unit and a set of "neighboring" units. For example we could choose all the adjacent units with a common boundary which, together with unit i, form a "cross". Neighborhoods can be defined to have a variety of patterns; the units in a neighborhood do not have to be contiguous. However, they must have a "symmetry" property, that is if unit j is in the neighborhood of unit i, then unit i is in the neighborhood of unit j. We assume, for the moment, that these neighborhoods do not depend on y_i.

The next step is to specify a condition C (for instance, $y > c$ where c is a specified constant), which determines when we add a neighborhood or not, and the third step is to decide on the size of the initial sample size n_1.

We begin the sampling process by taking an initial **random sample** of n_1 units selected, usually without replacement (*see* **Sampling With and Without Replacement**), from the N units in the population. Whenever the y value of a unit i in the initial sample satisfies C, all units in the neighborhood of unit i are added to the sample. If, in turn, any of the added units satisfies the condition, still more units are added. The process is continued until a cluster of units is obtained which contains a "boundary" of units called *edge* units that do not satisfy C. If a unit selected in the initial sample does not satisfy C, then there is no augmentation and we have a cluster of size one. The process is demonstrated in Figure 1 where the units are plots and the neighborhood forms a cross. Here y_i is the number of animals on plot i and $c = 0$ so that a neighborhood is added every time animals are found. In Figure 1(a) we see one of the initial plots which happens to contain one animal. As it is on the edge of a "clump" we see that the adaptive process leads to the cluster of plots in Figure 1(b).

We note that even if the units in the initial sample are distinct, as in sampling without replacement, repeats can occur in the final sample as clusters may overlap on their edge units or even coincide. For example, if two nonedge units in the same cluster are selected in the initial sample, then that whole cluster occurs twice in the final sample. The final sample

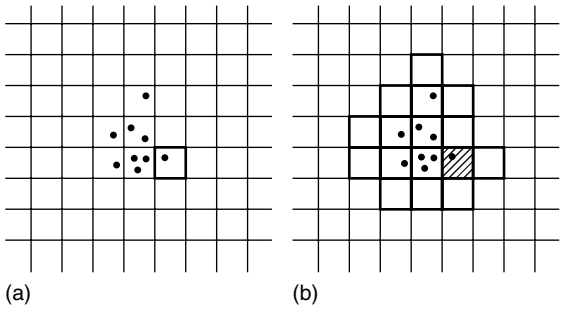

Figure 1 (a) Initial sample plot; (b) cluster obtained by adding adaptively

then consists of n_1 (not necessarily distinct) clusters, one for each unit selected in the initial sample.

Unbiased Estimation

Although the cluster is the natural sample group, it is not a convenient entity to use for theoretical developments because of the double role that edge units can play. If an edge unit is selected in the initial sample, then it forms a cluster of size 1. If it is not selected in the initial sample, then it can still be selected by being a member of any cluster for which it is an edge unit. We therefore introduce the idea of the network A_i for unit i which is defined to be the cluster generated by unit i but with its edge units removed. In Figure 1(b) we get the sampled network by omitting the empty units from the sampled cluster. Here the selection of *any* unit in the network leads to the selection of *all* of the network. If unit i is the only unit in a cluster satisfying C, then A_i consists of just unit i and forms a network of size 1. We also define any unit which does not satisfy C to be a network of size 1 as its selection does not lead to the inclusion of any other units. This means that all clusters of size 1 are also networks of size 1. Thus any cluster consisting of more than one unit can be split into a network and further networks of size 1 (one for each edge unit). In contrast to having clusters which may overlap on their edge units, the distinct networks are *disjoint* and form a *partition* of the N units.

Since the probability of selecting a unit will depend on the size of the network it is in, we are in the situation of unequal probability sampling and the usual estimates based on equal probability sampling will be biased. However, as already mentioned,

we can consider the Horvitz–Thompson (HT) and Hansen–Hurwitz (HH) estimators, the latter being used in sampling with replacement. These estimators, however, require that we know the probability of selection of each unit in the final sample. Unfortunately these probabilities are only known for units in networks selected by the initial sample, and not for the edge units attached to these networks. For example, the probability π_i that an initial sampling unit falls in the network containing unit i is

$$\pi_i = 1 - \binom{N - m_i}{n_1} \Big/ \binom{N}{n_1},$$

where m_i is the number of units in this network.

Therefore, in what follows, we ignore all edge units that are not in the initial sample and use only network information when it comes to computing the final estimators. Motivated by the HT estimator for the population **mean** μ, we consider

$$\hat{\mu} = \frac{1}{N} \sum_{i=1}^{N} y_i \frac{I_i}{\mathrm{E}[I_i]},$$

where I_i takes the value 1 if the initial sample intersects network A_i, and 0 otherwise. It is clear that $\hat{\mu}$ is an unbiased estimator for sampling with or without replacement.

Another possible estimator (motivated by the HH estimator) that is also obviously unbiased for sampling, with or without replacement, is

$$\tilde{\mu} = \frac{1}{N} \sum_{i=1}^{N} y_i \frac{f_i}{E[f_i]},$$

where f_i is the number of times that the ith unit in the final sample appears in the estimator, that is the number of units in the initial sample which fall in (intersect) A_i determined by unit i. We note that $f_i = 0$ if no units in the initial sample intersect A_i. It can be shown that

$$\tilde{\mu} = \frac{1}{n_1} \sum_{i=1}^{n_1} w_i = \overline{w},$$

say, where w_i is the mean of the observations in A_i, i.e. $\overline{w}$ is the mean of the n_1 (not necessarily distinct) network means. Di Consiglio & Scanu [12] studied the asymptotic behaviors of $\hat{\mu}$ and $\tilde{\mu}$. They proved that, under suitable conditions, Hajek's theorem [17] for asymptotic normality distribution can be applied to both estimators. However, confidence intervals based on asymptotic approximations may not be appropriate when the sample size is relatively small. Christman & Pontius [9] used several bootstrap percentile methods for constructing confidence intervals under adaptive cluster sampling. They showed, in a simulation study, that the coverage by the bootstrap method was closer to nominal coverage than the normal approximation.

In addition to the above two types of estimator, there is a third type of estimator that can be used. Since a network can be selected more than once, a more efficient design might be to "remove" a network from further consideration once it has been selected, i.e. select networks without replacement. We can than use an estimator due to Murthy [26]; details are given by Salehi & Seber [33]. Salehi & Seber [35] gave a direct proof of Murthy's estimator which extends the use of this estimator to sequential and some adaptive sampling schemes.

Rao–Blackwell Modification

In the above unbiased estimates that we introduced, we did not make use of the y values from the edge units. With this loss of information we would expect to be able to find more efficient estimates using all the sample data. We now show how we can do this.

An adaptive sample can be defined as one for which the probability of obtaining the sample depends only on the distinct unordered y observations in the sample, and not on the y values outside the sample. In this case d, the set of distinct unordered labels in the sample together with their associated y values, is minimal **sufficient** for μ. This is proved for "conventional designs" by Cassel et al. [7] and Chaudhuri & Stenger [8], and their proofs readily extend to the case of adaptive designs. (This extension is implicit in [2] and it is given in [51].) This means that an unbiased estimator that is not a function of d can be "improved" by taking the expectation of the estimator conditional on d to give an estimator with smaller **variance**. For example, consider three unbiased estimators of μ, namely $\overline{y}_1$ (the mean of the initial sample of n_1 units), $\hat{\mu}$, and $\tilde{\mu}$. Each of these depends on the order of selection as they depend on which n_1 units are in the initial sample; $\tilde{\mu}$ also depends on repeat selections; and when the

initial sample is selected with replacement, all three estimators depend on repeat selections. Since all three estimators are not functions of the minimal sufficient statistic d we can apply the **Rao–Blackwell theorem**. If T is any one of the three estimators, then $E[T|d]$ will give a better unbiased estimate, i.e. one with smaller variance. We find that this estimator now uses all the units including the edge units. Salehi [30], using an approach based on the inclusion–exclusion formula, has derived analytical expressions for the Rao–Blackwell version of the modified HH and HT estimators and their variance estimators. Felix-Medina [13], using a different approach, has also derived analytical expressions for their variances.

Applications and Extensions

In applications, other methods are sometimes used for obtaining the initial sample. For instance, in forestry the units are trees, and these are usually selected by a method of unequal probability sampling where the probability of selecting a tree is proportional to the basal area of a tree (the cross-sectional area of a tree at the basal height – usually 4.5 feet in the US). Roesch [29] described a number of estimators for this situation and derivations are given in [51].

In ecology, larger sample units other than single plots are often used. For example, a common sampling unit is the strip transect, which we might call the primary unit. In its adaptive modification, the strip would be divided up into smaller secondary units, and if we find animals in one of its secondary units we would sample units on either side of that unit, with still further searching if additional animals are sighted while on this search. Strips are widely used in both aerial and ship surveys of animals and marine mammals.

Here the aircraft or vessel travels down a line (called a line transect) and the area is surveyed on either side out to a given distance. Thompson [44] showed how the above theory can be applied to this sampling situation. He pointed out that a primary unit need not be a contiguous set of secondary units. For example, in some wildlife surveys the selection of sites chosen for observation is done systematically (with a random starting point) and a single systematic selection then forms the primary unit (*see* **Systematic Sampling Methods**). We can then select several such primary units without replacement and add adaptively as before. Such a selection of secondary units will tend to give better coverage of the population than a simple random sample. Acharya et al. [1] used sstematic adaptive cluster sampling (SACS) to sample three rare tree species in a forest area of about 40 ha in Nepal. They checked its applicability and showed that, for some cases, its efficiency of density estimation relative to conventional systematic sampling, increased by up to 500%.

Clearly other ways of choosing a primary unit to give better coverage are possible. Munholland & Borkowski [24, 25] and Borkowski [3] suggest using a **Latin square** $+1$ design selected from a square grid of secondary units. The Latin square gives a secondary unit in every row and column of the grid, and the extra (i.e. $+1$) unit ensures that any pair of units has a positive probability of being included in the initial sample. The latter requirement is needed for unbiased variance estimation. Salehi [31] suggested using a systematic Latin square sampling $+1$ design selected from a rectangular grid of secondary units.

In some situations it is hard to know what c should be for the condition $y > c$. If we choose c too low or too high we end up with a feast or famine of extra plots. Thompson [48] suggested using the data themselves, in fact the **order statistics**. For example, c could be the rth largest y value in the initial sample statistic so that the neighborhoods are now determined by the y values. This method would be particularly useful in pollution studies where the location of "hot spots" is important. In a study of contaminated sites, the advantages and disadvantages of this sampling scheme, when used along with composite sampling, have been discussed briefly by Correl [11].

Another problem, regularly encountered with animal population studies, is that not all animals are detected. Thompson & Seber [50] developed tools for handling incomplete detectability for a wide variety of designs including adaptive designs thus extending the work of Steinhorst & Samuel [42]. In the presence of incomplete detection, Pollard and Buckland [27] developed an adaptive sampling method in shipboard line transect survey. The survey effort is increased when the number of observation exceeds some limit. This increase is achieved by zigzagging for a period, after which the ship returns to the nominal (straight line) cruise track. They use distance sampling theory (see [6] to find the estimator.

Often we are in a **multivariate** situation where one needs to record several characteristics or measurements on each unit, e.g. the numbers of different species. Thompson [47] pointed out that any function of the variables can be used to define the criterion C, and obtained unbiased estimates of the mean vector and **covariance matrix** for these variables.

We can use any of the above methods in conjunction with **stratification**. If we do not allow the clusters to cross stratum boundaries, then individual stratum estimates are independent and can be combined in the usual fashion. However, Thompson [45] extended this theory to allow for the case where clusters do overlap. Such an approach makes more efficient use of sample information.

Finally we mention the "model-based" or **"superpopulation"** approach (cf. Särndal et al. [37], for example). Here the population vector $\mathbf{y}$ of y values is considered to be a realization of a random vector $\mathbf{Y}$ with some joint distribution F, which may depend on an unknown parameter ϕ. In a **Bayesian** framework ϕ will have a known **prior distribution**. For this model-based approach, Thompson & Seber [51] indicate which of the results for conventional designs carry over to adaptive designs and which of those do not. They also show in their Chapter 10 that **optimal designs** tend to be adaptive.

Relative Efficiency

An important question one might ask about adaptive sampling is "How does it compare with, say, simple random sampling?" This question is discussed by Thompson & Seber [51, Chapter 5] and some guidelines are given. Cost considerations are also important. Simple examples given by them throughout their book suggest that there are large gains in efficiency to be had with clustered populations. Clearly, it will depend on the degree of clustering in the population. Two **simulation** studies that shed some light on this are given by Smith et al. [40] and Brown [4]. These two studies suggested that the HT estimator is more efficient than the HH estimator. Salehi [32] found some support for this analytically, and recommended use of the HT estimator despite the HH estimator being easier to compute.

Adaptive cluster sampling is an efficient method for sampling rare and clustered populations when cluster sizes are large relative to unit sizes. Smith et al. [41] used adaptive cluster sampling for estimating the density of freshwater mussel populations. Since some of the populations were rare and clustered, but with small cluster sizes, adaptively added units were mainly edge units, with little or no gain in efficiency.

Designing an Adaptive Survey

There are several problems associated with adaptive sampling. First, the final sample size is random and therefore unknown. Furthermore, as we saw above, the unit selection probabilities depend on the initial sample size n_1. How then can we use a pilot survey, for example, to design an experiment with a given efficiency or expected cost – an approach which is used for conventional designs such as simple random sampling? Secondly, if an inappropriate criterion C for adding neighborhoods is used, then there may be a "feast or famine" of sampling units. If too many units are being added at each initially selected unit then we end up sampling too many units. Alternatively we might not get enough units. Thirdly, a lot of effort can be expended in locating initial units as we must travel to the site of each such unit.

Recently, a two-stage scheme has been developed by Salehi & Seber [34] which helps us to deal with all three problems in a reasonably optimal manner. To use this scheme, we divide the population of (secondary) units into, say, M primary sampling units (PSUs), each containing $N_0 = N/M$ secondary units. A simple random sample of m primary units is then taken and adaptive cluster sampling is carried out in each of the selected primary units using an initial sample of n_0 units. We again have two schemes, depending on whether networks are allowed to cross PSU boundaries or not, and two estimators (HT and HH) for each scheme. To design such an experiment, we use the HT estimator with nonoverlapping boundaries and choose a pilot sample of m_p PSUs but with the *same* initial sample size of n_0 units in each of the selected primary units. The theory based on the pilot survey now works, that is, we can now determine m to achieve a given efficiency or cost. The reason for this is that the network selection probabilities in a PSU are the same for both the pilot survey and the survey planned; both depend on n_0.

Another method of controlling the overall sample size is to use a method called restricted adaptive

cluster sampling, proposed by Brown & Manly [5]. Here the units are selected sequentially for the initial sample until a desired sample size is reached. The sampling therefore "restricts" the initial sample to one that produces a final sample size that is either at or just over the defined limit. The HT and HH estimators are now biased but under some circumstances the bias can be estimated well by **bootstrapping**. Lo et al. [23] used the restricted method to estimate Pacific hake larval abundance.

Salehi & Seber refno36 provided an unbiased estimator for the restricted method. Using a simulation study, they showed that the unbiased estimator has a smaller **mean square error** than the biased estimators. They also considered a restricted method when the networks are selected without replacement and obtained its unbiased estimator. Christman and Lan [10] introduced inverse adaptive cluster sampling, which is a especial case of restricted adaptive cluster sampling.

Additive Hazard Models

While most modern analyses of survival data focus on **multiplicative models** for **relative risk** using **proportional hazards** models, some work has been done on the development of additive hazard models. **Aalen's additive regression model** [1, 2, 6, 8] is a general nonparametric additive hazard model of the form:

$$\sum \lambda_i(t)x_i, \tag{1}$$

where the λ_i are nonparametric hazard functions associated with **covariate** x_i, which may be **time-dependent**. Andersen & Væth [3] discuss a special case of this model of the form

$$\beta(t)\mu^*(t) + \gamma(t), \tag{2}$$

where $\gamma(t)$ and $\beta(t)$ are functions to be estimated and $\mu^*(t)$ is a known function describing rates in some reference population. McKeague & Sasieni [8] discuss a partly parametric version of (1). For inference and other issues related to models (1) and (2) see **Aalen's additive regression model**. In what follows we discuss a class of parametric additive hazard models that are of special interest in studies in which we want to describe data on survival in terms of how the excess risk (or rate) depends on one or more "exposures", and how these exposure-specific risks depend on other factors, such as sex, age at exposure, or time since exposure. These models are used extensively in studies of **radiation** effects on cancer [10, 11] and are applicable in a wide variety of **occupational** and other studies.

In many applications it is useful to consider additive hazard models of the form:

$$\lambda_0(t, \beta_0, z_0) + \lambda_1(t, \beta_1, z_1), \tag{3}$$

$$\lambda_0(t, \beta_0, z_0)[1 + \lambda_1(t, \beta_1, z_1)]. \tag{4}$$

In these models, $\lambda_0(\cdot)$ represents a background **hazard (rate)** function that depends on time (t), and other covariates, z_0, with parameters β_0, while $\lambda_1(\cdot)$ describes the excess hazard (excess absolute rate) (3) or excess relative risk (4) as a function of time and covariates, z_1, with parameters β_1. In general, covariates affecting the excess risk will include some measure of exposure and may be time-dependent. It is also common for some covariates, e.g. sex, to affect both the background and excess risks. That is, some covariates may appear in both z_0 and z_1.

When working with parametric additive hazard models one must specify functional forms for the background and excess risks. In many problems **log-linear models** provide an adequate description of the background rates. Commonly used models for the logarithm of the background rate are linear or polynomial functions of t or $\log(t)$, though linear or quadratic **splines** in t or $\log(t)$ can also be useful. Other covariates, such as sex or **birth cohort**, may affect the intercepts or slopes in such models.

For an exposure, d, it is often useful to consider **excess risk** models of the form

$$\lambda_1(\cdot) = \rho(d, \beta_d)\gamma(t, z, \beta_1),$$

where we assume that other factors act multiplicatively on the shape of the **dose–response** function $\rho(\cdot)$. Dose–response functions may be described using linear, quadratic, linear spline, categorical, or other functions of dose, while **effect modification** is often modeled using loglinear functions of other covariates.

For example, in an analysis of mortality from cancers other than leukemia in Japanese atomic bomb survivors over a 40-year period it was found that the effect of radiation could be described quite well using an additive **excess relative risk** model in which the linear dose effect depends on sex and decreases loglinearly with increasing age at exposure ($agex$) with no significant effects of age. One way to write this model for the excess relative risk is

$$\lambda_1(\cdot) = \beta_1 dose \times \exp(\beta_2\, female + \beta_3\, agex),$$

where *female* is an indicator variable that is 1 for women and 0 for men. An alternative model describing excess absolute cancer death rates for atomic bomb survivors cancer data in terms of age at death (age) is

$$\begin{aligned}\lambda_1(\cdot) &= \beta_1\, dose \times \exp[\beta_2 \ln(age)] \\ &= \beta_1\, dose \times (age)^{\beta_2}.\end{aligned}$$

These two models were found to describe the excess cancer risks equally well.

Generalizing the Models

There are a number of useful generalizations and extensions of models (3) and (4). An important extension, which is closely related to model (1), generalizes the simple standardized mortality ratio (SMR) (*see* **Standardization Methods**) used in many epidemiologic studies. In particular, external data on background rates can be incorporated into either model by inclusion of these rates as a covariate in the background term, which may also include additional parameters to describe the ratio of the external background rates and the rates in the study population. We can write this background rate model as

$$\lambda_0(t, z_0, \beta_0) = \mu^*(t, z_0)\gamma(z_0, \beta_0).$$

Breslow et al. [5] discuss this multiplicative SMR model in some detail; extension to additive hazard models is straightforward.

Models (3) and (4) can also be extended to investigate the joint effects (*see* **Synergy of Exposure Effects**) of multiple exposures by the inclusion of additional excess hazard terms (for independent additive effects) or by allowing **interactions** between different exposure effects in a single excess hazard term.

Several authors (e.g. [4] and [9]) have proposed hybrid parametric families with a continuous index parameter γ such that models like (3) and (4) correspond to specific values of γ. The method of Aranda-Ordaz [4] involves the use of a hybrid family that includes complementary log–log and negative complementary log models to analyze survival data grouped into equal length intervals. This family includes models in which the excess hazard or the log relative risk are modeled as linear functions of the covariates. Muirhead & Darby [9] proposed a hybrid model of the form

$$\{\lambda_0(t, \beta_0, z_0)^\gamma + [1 + \lambda_1(t, \beta_1, z_1)]^\gamma - 1\}^{1/\gamma}.$$

When γ equals 1 this corresponds to the excess hazard model (4) and, in the limit as γ approaches 0, it corresponds to the excess relative model (3).

The primary use of these hybrid models is to compare how well the data of interest are described by models in which either the relative or absolute excess risk is constant over time. It is generally easier and more informative to address this question through a simple comparison of the fits of time-constant excess hazard and excess relative risk models, together with analyses of the effect of allowing the excess hazards or relative risks to depend on time. When excess risks are allowed to depend on time there is usually little difference in the fit of models (3) and (4). In this case, the hybrid models contain little information about the index parameter (i.e. the **profile likelihood** function for γ is quite flat).

Parameter Estimation and Inference

It is generally impractical to develop likelihood-based **estimating function** equations for the use of fully specified parametric models based on (3) and (4) with ungrouped survival data. However, parameter estimation for both of these classes of models is relatively straightforward when done using **Poisson regression** methods for grouped survival data. With suitable Poisson regression **software** it is possible to fit a version of model (4) in which the background hazard is modeled using separate multiplicative parameters for each time period, possibly, with stratification on other factors. This model, which is closely related to the stratified semiparametric proportional hazards model, can be written

$$\lambda_0(t, z, \beta) = \eta_{st}\lambda(z, \beta), \tag{5}$$

where the η_{st} is a parameter describing the hazard for the tth time period in a stratum, s, defined by other factors.

Since model (4) is a proportional hazards model, parameter estimation can also, in principle, be carried out using **partial likelihood** or **counting process methods**; in which case, the background rate would be replaced by, or include, a nonparametric baseline hazard function. Lin & Ying [7] outline a method for fitting simple semiparametric additive excess rate models (3) (*see* **Semiparametric Regression**) to ungrouped data using counting process methods.

Unfortunately, since the additive models of interest are almost always not simple linear or loglinear functions of the covariates, standard Poisson regression and proportional hazards modeling software is of little use in fitting these models. However, the Epicure software package, which was designed for working with general parametric and semiparametric additive risk models, can compute **maximum likelihood** estimates for a broad range of additive hazard models.

Since parameter estimation for additive hazard models is generally carried out using **likelihood** or partial likelihood methods, inference about parameters of interest can be carried out using the standard asymptotic methods, including Wald, score, and **likelihood ratio tests**. However, because of the nonlinear nature of the models and, in many applications, the limited information on excess risks, asymptotic standard errors and, hence, hypothesis tests and confidence intervals based on Wald tests can be quite misleading. Likelihood ratio tests and profile likelihood-based confidence intervals are the preferred methods of inference when working with additive hazard models.

Hazard functions are, by definition, nonnegative. This constraint is addressed implicitly by multiplicative hazard models. However, for additive hazard models it is possible that one of the components of the hazard (usually the "excess") can be negative. The implicit constraint in model (3) is that $\lambda_1(\cdot) > -\lambda_0(\cdot)$, while that for model (4) is $\lambda_1(\cdot) > -1$. These implicit constraints can make it difficult to fit additive hazard models for some data sets. In simple excess risk models, these constraints can be addressed by the choice of the parameterization (e.g. modeling the log of the linear dose–response slope) or by restricting the range of some parameters (e.g. restricting a linear dose–response slope in a simple linear excess relative risk model to be greater than minus one over the maximum dose). However, these approaches are inadequate for every problem.

Summary

Parametric additive hazard functions such as those described in (3) and (4) are useful and, in some settings, natural, alternatives to the semiparametric multiplicative hazards that have come to dominate the analysis of survival data in recent years. These models are especially useful for dose–response analyses in which one is primarily interested in the characterization of excess risks and how the excess depends on other factors. Parameter estimation and inference for additive hazard models is most easily carried out using nonlinear models and Poisson regression methods for **grouped survival data**.

Additive Model

It is common, though potentially confusing, in discussions of risks and rates to make a distinction between additive and **multiplicative risk models** (e.g. [1, Chapter 4]). Under the additive or **excess risk** (rate) model the risk is described as

$$R = R_0 + E(z), \tag{1}$$

where R_0 is the background risk and $E(z)$ is an excess risk function associated with "exposure", z. Under the multiplicative or **relative risk model**, "exposure" is assumed to have a multiplicative effect on the rates:

$$R = R_0 \times RR(z), \tag{2}$$

where $RR(z)$ is the **relative risk** function.

The confusion in referring to (1) and (2) as additive and multiplicative models arises because the functions used to describe the excess risk in (1) or the relative risk in (2) can include both additive and multiplicative components. In particular, the simple **excess relative risk** model $RR(z) = 1 + \beta z$ is often called an additive model. To make a clear distinction between the form of the risk function and the nature of the functions used to model the components of risk, it is best to describe (1) and (2) as excess risk and relative risk models, respectively. If this is done, then the term additive model can be used to refer to excess or relative risk models that involve additive components. With this definition of additive models, excess risk models are intrinsically additive because they always include the sum of background and excess risks, while relative risk models may be either multiplicative, e.g. $RR(z) = \exp(\beta z)$, or additive, e.g. $RR(z) = 1 + \beta z$. Thomas [4] and Breslow & Storer [2] describe general relative risk functions that include both additive and multiplicative models. Realistic excess risk models often involve sums of multiplicative models for the background and excess risk functions. For example, in a **dose–response** analysis it might be appropriate to allow the excess risk associated with a given dose (d) to depend on sex (s) or time since exposure (t) by considering a multiplicative model for the excess risk of the form

$$E(d, s, t) = \beta_{1s} d \times t^{\theta}.$$

Preston et al. [3] describe a general class of additive models that are useful in working with either excess or relative risks.

The articles on **Parametric Models in Survival Analysis** and **Poisson Regression in Epidemiology** describe some specific additive models and discuss methods for parameter estimation and inference with such models.

Additive–Multiplicative Intensity Models

Introduction

The **proportional hazards** model introduced by Cox (*see* **Cox Regression Model**) has been so dominant in **survival analysis** that other models have had a hard time getting the attention they deserve. The Cox model is extremely useful and has many desirable properties, but obviously also has some shortcomings. One important shortcoming is that the model has a hard time describing **time-varying** effects (non-proportional effects), and although some work has been aimed at extending the model to overcome this problem [7, 9, 15], there is still some way to a fully satisfactory apparatus to deal with time-varying effects. Also, some **covariates** will have effects that are not well described as being multiplicative, and some of the available tests may reveal this [13].

One important alternative to the proportional hazards model is the **additive hazard model** and, in particular, **Aalen's additive hazard regression model**. Aalen's additive hazard regression model is completely **nonparametric** and includes covariates additively in the model thus leading to an **excess risk** interpretation. The Aalen model is very flexible and will estimate all covariate effects as time-varying effects. A **semiparametric** version of the model was suggested by McKeague and Sasieni [8] and in a special case by Lin and Ying [4] (*see* **Aalen's Additive Regression Model**). One advantage of the additive models is that time-varying effects are easy to estimate (with explicit estimators) and that inferential procedures for making conclusions about the time-varying effects exist. The semiparametric version of the model has not received much attention in practical work but has the advantage that explicit estimators are given and that the flexibility of the Aalen model can be used only for those covariate effects where it is needed, whereas other covariate effects can be described by parameters.

The additive and multiplicative models postulate different relationships between the hazard and covariates, and it is seldom clear which of the models should be preferred. The models may often be used to complement each other and to provide different **summary measures**. Sometimes, however, covariate effects are best modeled as multiplicative and other covariate effects are best modeled as being additive, and then one must combine the additive and multiplicative models.

Sometimes the data will only give little guidance on whether a covariate effect should be described as multiplicative or additive, but then the choice of additive or multiplicative effects will not be critical for the interpretation of the data. We illustrate in the example how certain tests can be used to decide if a covariate has an additive or multiplicative effect.

The additive and proportional hazard models may be combined in various ways to achieve flexible and useful models. We shall here consider two models that are based on either adding or multiplying the multiplicative Cox model and the additive Aalen model. This leads to two quite different models that are both quite flexible and useful. When the models are added, it leads to the proportional excess hazard models. Several parametric versions of such models exist (*see* **Additive Hazard Models**). For the version of the proportional excess hazard model considered here, the additive part can be thought of as modeling the baseline mortality, whereas the multiplicative part describes the excess risk due to different exposure levels. When the models are multiplied, it leads to a flexible model termed the Cox–Aalen model below. For this model, some covariate effects are believed to result in multiplicative effects, whereas other effects are better described as additive. In the article on **additive hazard models**, an example from cancer mortality is used to illustrate structures similar to those in the Cox–Aalen model.

Some notation is needed. We here use the **counting process** formulation. Assume that i.i.d. subjects are observed over some observation period $[0, \tau]$ and give rise to counting process data $N_i(s)$ with at risk indicator $Y_i(s)$, excess risk indicator $\rho_i(t)$, and $(p+q)$-dimensional covariates $(X_i^{\mathrm{T}}(s), Z_i^{\mathrm{T}}(s))$. Let $\boldsymbol{N}(t) = (N_1(t), \ldots, N_n(t))^{\mathrm{T}}$ be an n-dimensional counting process and define matrices $\boldsymbol{X}(t) = (Y_1(t)X_1(t), \ldots, Y_1(t)X_n(t))^{\mathrm{T}}$, $\boldsymbol{X}_\rho(t) = (\rho_1(t)X_1(t), \ldots, \rho_1(t)X_n(t))^{\mathrm{T}}$, and $\boldsymbol{Z}(t) = (Y_1(t)Z_1(t), \ldots, Y_1(t)Z_n(t))^{\mathrm{T}}$. Finally, let $\mathrm{diag}(w_i)$ denote an $n \times n$ diagonal matrix with elements $w_1, \ldots, w_n$, $\boldsymbol{\phi}(t) = (\phi_1(t), \ldots, \phi_n(t))^{\mathrm{T}}$, where $\phi_i(t) = \rho_i(t) \exp(Z_i^{\mathrm{T}}(t)\beta)$ and define $\tilde{\boldsymbol{X}}(\beta, t) = (\boldsymbol{X}_\rho(t), \boldsymbol{\phi}(t))$, an $(p+1) \times n$ matrix (*see* **Matrix Algebra**).

Proportional Excess Hazard Models

Lin and Ying [5] considered the following additive–multiplicative intensity model

$$\lambda(t) = Y(t)\left[g(Z^{\mathrm{T}}(t)\beta) + \lambda_0(t)h(X^{\mathrm{T}}(t)\gamma)\right], \quad (1)$$

where $Y(t)$ is an at risk indicator, $(X(t), Z(t))$ is a $p+q$ dimensional covariate vector, $(\beta^{\mathrm{T}}, \gamma^{\mathrm{T}})$ is a $p+q$ dimensional vector of regression coefficients and $\lambda_0(t)$ is an unspecified baseline hazard. Both h and g are assumed known. One problem with this model is that only the baseline is time-varying and therefore data with time-varying effects will often not be well described by the model. When additional time-varying effects are included in the model, the model will get added flexibility and it turns out that it is relatively simple to extend the model to deal with time-varying effects such as in the flexible additive–multiplicate intensity model [6], where the intensity is of the form

$$\lambda(t) = Y(t)\left[X^{\mathrm{T}}(t)\alpha(t)) + \rho(t)(\lambda_0(t)\exp\{Z^{\mathrm{T}}(t)\beta\}\right], \quad (2)$$

where both $Y(t)$ and $\rho(t)$ are at risk (excess risk) indicators, $\alpha(\cdot)$ is a q-vector of time-varying regression functions, $\lambda_0(t)$ is the baseline hazard of the excess risk term, and β is a p-dimensional vector of **relative risk** regression coefficients. The at risk indicators $Y(t)$ and $\rho(t)$ may be equivalent as in the Lin and Ying model, but sometimes one will have a baseline group where there is no excess risk. It should be verified that the model is **identifiable**. The model is an extension of the Lin and Ying model when $g(x) = x$ and $h(x) = \exp(x)$ and the model is the sum of an additive Aalen model and a Cox model. Sasieni [10] considered the special case of this model where $\alpha^{\mathrm{T}}(t)X_i(t)$ is replaced by a known function of $X_i(t)$. We shall consider estimation of the unknown parameters β, $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$ and $\Lambda(t) = \int_0^t \lambda_0(s)\,\mathrm{d}s$; see [6] for additional theoretical details. Essentially, the model reduces to Aalen's additive risk model for known β and this may be utilized to obtain a score equation (*see* **Likelihood**) for β that only depends on observed quantities. Zahl [14] illustrated the use of the model with examples from breast and colon cancer.

Using the matrix notation introduced above, we can write an unweighted version of the score equation for β as

$$U(\beta) = \int_0^\tau \boldsymbol{Z}^{\mathrm{T}}(t)\mathrm{diag}(\phi_i(t))[I - \tilde{\boldsymbol{X}}(\beta, t) \times \{\tilde{\boldsymbol{X}}^{\mathrm{T}}(\beta, t)\tilde{\boldsymbol{X}}(\beta, t)\}^{-1}\tilde{\boldsymbol{X}}^{\mathrm{T}}(\beta, t)]\,\mathrm{d}\boldsymbol{N}(t) = 0, \quad (3)$$

where $\phi_i(t) = \rho_i(t)\exp(Z_i(t)^{\mathrm{T}}\beta)$.

Now, denoting the solution to the score equation as $\hat{\beta}$, we estimate $B = (A(t), \Lambda(t))$ by

$$\widehat{B}(t) = \int_0^t \left\{\tilde{\boldsymbol{X}}^{\mathrm{T}}(\hat{\beta}, t)\tilde{\boldsymbol{X}}(\hat{\beta}, t)\right\}^{-1}\tilde{\boldsymbol{X}}^{\mathrm{T}}(\hat{\beta}, t)\,\mathrm{d}\boldsymbol{N}(t). \quad (4)$$

An alternative estimation strategy is to iterate between fitting the model with β or $A(t)$ known [14].

The model extends both the Cox and the Aalen model and may have potential use to investigate **goodness of fit** for these models.

The Multiplicative Cox–Aalen Model

A different way of combining additive and multiplicative models are given by the Cox–Aalen model [11, 12]

$$\lambda_i(t) = Y_i(t)\left[X_i^{\mathrm{T}}(t)\alpha(t)\right]\exp(Z_i^{\mathrm{T}}(t)\beta). \quad (5)$$

The Cox–Aalen allows a very flexible (additive) description of covariate effects of $X_i(t)$ while allowing other covariate effects to act multiplicatively on the hazard. One alternative way of thinking about the model is to consider it as an approximation to the general stratified hazard model $\lambda(t, X_i(t))\exp(Z_i^{\mathrm{T}}(t)\beta)$ suggested by Dabrowska [1]. Compared to the Dabrowska model, some structure is introduced to make the estimation easier and to help facilitate the interpretation of the covariate effects.

To estimate the parameters of the model, an approximate **maximum likelihood** score equation is suggested and the estimators are studied in [11, 12]. The key to solving the model is to notice that for known β we have a usual Aalen model where the nonparametric terms can be estimated.

To estimate the regression parameter β, we solve the score equation

$$U(\beta) = \int_0^\tau \boldsymbol{Z}^{\mathrm{T}}(t)[I - \boldsymbol{W}(t, \beta)\boldsymbol{X}(t) \times \{\boldsymbol{X}^{\mathrm{T}}(t)\boldsymbol{W}(t, \beta)\boldsymbol{X}(t)\}^{-1}\boldsymbol{X}^{\mathrm{T}}(t)]\,\mathrm{d}\boldsymbol{N}(t) = 0, \quad (6)$$

where $\boldsymbol{W}(t, \beta) = \text{diag}(\exp(Z_i(t)^{\mathrm{T}}\beta))$. This score equation reduces to Cox's partial score equation when $\boldsymbol{X}(t) \equiv (Y_1(t), \ldots, Y_n(t))^{\mathrm{T}}$. An estimator of the cumulative baseline $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$ is

$$\hat{A}(t) = \int_0^t \left\{ \boldsymbol{X}^{\mathrm{T}}(t)\boldsymbol{W}(t, \hat{\beta})\boldsymbol{X}(t) \right\}^{-1} \boldsymbol{X}^{\mathrm{T}}(t)\,\mathrm{d}\boldsymbol{N}(t). \tag{7}$$

Note the strong resemblance with the Aalen estimator. These estimators may be improved by the use of weight matrices.

Effect-modification

For models where effects are modeled solely as either multiplicative or additive, effect-modification is just another word for **interaction** (*see* **Effect Modification**) on the chosen scale. For the additive–multiplicative models considered in the sections "Proportional Excess Hazard Models" and "The Multiplicative Cox–Aalen Model", however, this is no longer valid.

Generally, multiplicative effects will lead to some interaction on the hazard, and additive effects will lead to interaction on the log-hazard. For the proportional excess model, both the multiplicative and additive effects will lead to interaction on the overall log-hazard. The model is constructed to give multiplicative effects on the excess risk. The multiplicative effects of the Cox–Aalen model are linear on the log-hazard and lead to interaction on the hazard, and vice-versa for the additive effects of the model.

Assume, for example, that gender has a multiplicative effect on some hazard, with males having relative risk θ compared to that of females, and that some treatment has an additive (or multiplicative) effect, with treated having intensity $\lambda_1(t)$ and untreated having intensity $\lambda_0(t)$. Then the treated females will have excess risk $e(t) = \lambda_1(t) - \lambda_0(t)$, whereas the excess risk for males will be modified by the effect of gender to $\theta e(t)$. Note that these properties refer specifically to the chosen scale at which one considers covariate effects.

The Cox–Aalen model has the useful property that it allows effect-modification of the covariates included in the proportional part of the model; some examples of the use of such a model is given under **additive hazard models**. Note, that the effect-modification, however, must be the same for all effects in the additive part of the model (just as in the Cox model). The model may be extended to allow different effect-modification for the different effects in the additive model.

Example

To illustrate the use of the Cox–Aalen model, we consider the data that was also used to illustrate the use of the Aalen model (*see* **Aalen's Additive Regression Model**). The data are given in [2] and gives the survival on 418 patients with primary biliary cirrhosis. The source of our data set is the survival package of S-Plus/R (*see* **S-PLUS and S**; **R**). The following covariates were used for the modeling: age, log(albumin), bilirubin (dichotomized as 0 when bilirubin is less than 3.25 mg/dL and 1 otherwise), edema (present/not present), and log(prothrombin). To resemble the analysis for the additive risk model as closely as possible, we only consider the data for the first 3000 days.

First, considering the Cox model to fit the data, a modified version of the cumulative score test [3] (see [12]) showed that log(prothrombin) had a nonproportional effect with a ***P* value** at 0.001. We therefore included log(prothrombin) in the additive part of the model. With log(prothrombin) in the additive part of the model, a similar score test revealed that edema had nonproportional effects ($p = 0.04$). So even though the test statistic is not dramatic, it seems preferable with a more flexible description of the effect of edema.

We therefore consider the Cox–Aalen model with baseline, edema and log(prothrombin) as additive components and age, log(albumin), bilirubin as multiplicative effects. The score test for proportional effects gave P values 0.12 for bilirubin, 0.91 for age and 0.81 for log(albumin). The covariates age and log(albumin) were centered to give a meaningful interpretation of the additive part of the model. The log-relative risk estimates (standard error) were 1.46 (0.19) for bilirubin, 0.033 (0.0073) for age, and −2.58 (0.57) for log(albumin).

Figure 1 gives the cumulative effect of edema, whose shape resembles that of the estimate from Aalen's additive risk model. Denote the cumulative effect of edema as $A_e(t)$. Now, for a subject with mean age and mean log(albumin) and bilirubin (less

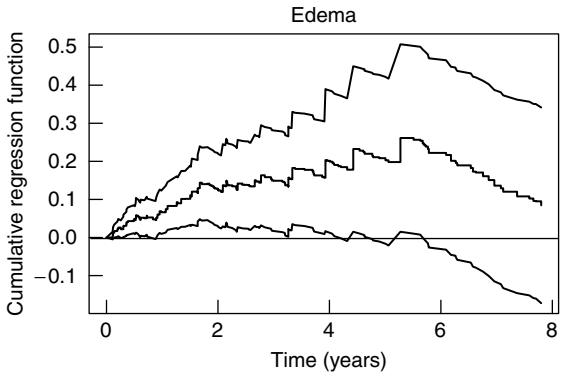

Figure 1 Cumulative regression function for time-varying excess risk effect of edema with 95 % pointwise confidence intervals

than 3.25), the presence of edema leads to a survival that lowered by $\exp(-A_e(t)$ (relative survival). For a subject with proportional effects leading to a total relative risk at R, however, the relative survival is $\exp(-R \cdot A_e(t))$.

Software

Software to fit the models using R (S-plus) is available from `www.biostat.ku.dk/~ts`

Administrative Databases

Administrative databases are derived from information routinely and systematically collected for purposes of managing a health care system [8]. Over the last few years, hospitals and insurers have often used such data to examine admissions, procedures, and lengths of stay. Because of new technologies allowing linkages between databases (*see* **Record Linkage**) and the increasing availability of comprehensive population information, studies using administrative data no longer need focus just on the amount and type of care. Instead, the accessibility and breadth of administrative data have made them a more general resource for the study of both health and health care (*see* **Health Services Research, Overview**) [56].

Questions such as the following can be approached using population-based administrative data:

1. How does the use of procedures, medications, and other health services vary with personal characteristics, such as age, gender, race, income, and health status (*see* **Descriptive Epidemiology**; **Health Care Utilization Data**)?
2. How does the use of these services vary with the source or mechanism of payment (*see* **Health Care Financing**)?
3. How does the use of these services vary across hospitals, communities, and regions (*see* **Small Area Variation Analysis**)?
4. How do the short-term and long-term outcomes of health care vary with personal, payer, and geographic or system characteristics (*see* **Outcomes Research**)?
5. How do total health care costs, and the distribution of component costs, vary with personal, payer, and geographic or system characteristics?
6. Is high use of specific health services associated with better outcomes? Are unhealthy populations "underserved" by the health care system?
7. How have the use of health services and the outcomes of care changed over time?
8. What is the appropriate level of health care resources for a population or region?
9. In what areas is the health care system consuming excess resources and, therefore, deserving of regulatory or market constraints?
10. How are the outcomes and processes of health care related? Which physicians, hospitals, nursing facilities, and health plans have the best outcomes and processes of care? How can the quality of care provided elsewhere be improved?
11. How does the natural history of disease vary with personal and geographic characteristics? How has it changed over time?
12. Are diagnostic or therapeutic methods as effective in the community as they are in randomized controlled trials (*see* **Clinical Trials, Overview**)?

Figure 1 presents a view of an ideal administrative database with a research registry playing a central role. Such a registry, with its ability to generate meaningful information on each individual's life course, helps multiply the number of health and health care studies that can be performed. Nonetheless, each of the associated files – alone or in conjunction with others – may permit important research.

This article provides an overview of the use of administrative databases for research on **clinical epidemiology**, health services, and population health. We wish to present a framework for understanding how administrative data can accurately and cost-effectively generate health and health care information for communities and populations.

Common Types of Administrative Data

The inclusiveness of administrative databases is strongly related to the requirements of health insurance plans and regulatory agencies. In Canada, where the population of each province is covered by a single insurance plan, health care data are comprehensive. The more complicated situation in the US has resulted in a loss of important utilization data associated with the Medicare and Medicaid programs [73]. In other developed countries, many administrative data files hold information about eligibility or enrollment, life events, claims and services, special programs, and providers. We present a brief overview of each type of file in what follows.

Registries

A population registry incorporates information on birth, death, mobility within a catchment area (such as

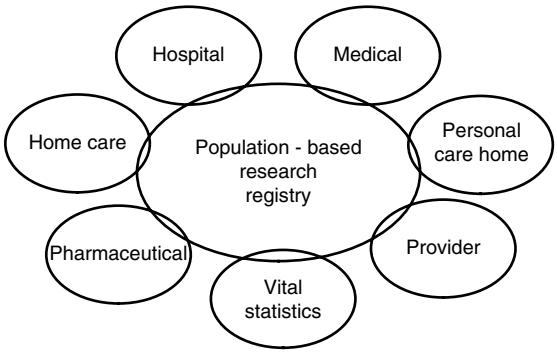

Figure 1 An ideal administrative database

a province), and in- and out-migration for all people enrolled with an insurance or benefit plan. A registry is essential for following a study cohort (*see* **Cohort Study**), providing denominators for analyses of **rates**, and updating data for each enrolled individual. When administrative registries are compared and combined into a research registry which accurately defines the health insurance status for each resident over many years the value of the tool is enhanced [64].

A research registry permits extensive checks on "subject misidentification". If an individual's identifiers are incorrect, utilization, loss to follow-up, and mortality may be misassigned. In one study, a lack of adjustment for women who were not appropriately identified, because they either left the province or changed their health care number, led to a serious underestimate of the number of women who may have developed cancer following breast augmentation [4].

Standardized systems for updating and reviewing the quality of registry data are critical. Typical checks on the accuracy of a population registry rely on other sources of information (**disease registers, vital statistics** files, **census** data, etc.). Such checks include comparisons between the number and characteristics of individuals in particular categories (such as age/gender/place of residence) with aggregate statistics from organizations such as the census [28, 64]. Often, there are opportunities to compare registry information on individual mortality and loss to follow-up with primary data collection; these comparisons are particularly useful in uncovering errors affecting a small percentage of the population.

Life Events

Acquiring and maintaining up-to-date demographic information generally requires integrating files from different sources. Life events such as birth (date and place), marriage (date and place), and death (date, place, and cause) are typically recorded in vital statistics files. In Canada, vital statistics files need to be better coordinated with utilization data maintained by provincial health departments to provide a standard health registration number on all death records.

In the US, linkages between vital statistics and health care utilization files (*see* **Record Linkage**) are rather unusual. However, the Medicare Provider Analysis and Review dataset from the Health Care Financing Agency is linked to an enrollment file indicating the date of death. Some states, such as California, have also linked patient discharge data to birth and death records. Both Canadian (through the Statistics Canada Mortality File) and American statistical agencies (through the **National Center for Health Statistics'** National Death Index) provide an additional route for funded investigators to access mortality data.

Claims and Services

Physician services recorded in an administrative database may include information regarding physician visits, surgical procedures, immunizations, prescription drugs, and diagnostic tests such as Papanicolaou tests. Descriptive fields identify the patient, the physician, and, where relevant, the institution. Typically, each claim describes a single service or event for a specific patient by a specific provider on a single date. If a single visit results in several billable services, more than one computer record may be generated; attention to detail is critical so that a single test or service is not counted twice (*see* **Drug Utilization Patterns**).

Documentation requirements affect the extent to which any recording system captures a population's ambulatory care patterns. In Manitoba, neither visits to the provincial cancer foundation (after the first) nor visits to health care providers other than physicians are recorded. However, because of the frequency of fee-for-service care and the requirement that salaried physicians submit "dummy" claims, from 90% to 98% of all physician-provided ambulatory care is captured in the existing system.

Administrative files describing hospital or nursing home stays are often maintained by regulatory agencies or provider associations. Each hospital discharge abstract describes services provided to a patient during a specified period in that facility. Most hospital discharge files are similar, including patient identifiers, demographic information such as gender and age or birth date, dates of admission and separation (discharge), diagnostic codes, payer source and charges, and procedure codes for all surgery (*see* **Classifications of Medical and Surgical Procedures**). Files for nursing home stays are similar but usually include little, if any, diagnostic and surgical information.

Although many private and government programs maintain files that describe individuals' use of their services, the agency managing the data must be willing to permit linkage (*see* **Record Linkage**). Service files may be maintained by nutrition programs (e.g. the Women, Infants, Children program in the US), immunization programs, local public health programs, education and rehabilitation programs, special programs for children with developmental disorders, and various voluntary agencies.

Provider Data

Physician information will obviously depend on the requirements of the relevant insurer or registrar. Items such as age, sex, education, specialty, and experience are likely to be available. Such data are particularly useful for physician manpower planning (*see* **Health Workforce Modeling**) and for comparisons of practice patterns among different types of physicians.

Health care organizations often submit data about their organizational, structural, and financial characteristics to trade associations and regulatory agencies. This information can be linked to individual-level data, so that differences in the utilization, costs, and outcomes of health care can be correlated with institutional characteristics. This permits testing hypotheses related to the impact of hospital size, ownership, teaching status, financial health, intensive care availability, and nurse staffing levels. Provider information collected by trade associations may be relatively difficult to obtain or may be incomplete because participation in the data system is typically voluntary.

Uses of Administrative Data

As fiscal restraint and organizational change continue, administrative databases can help to answer questions regarding the complex interplay among population characteristics, health status (*see* **Quality of Life and Health Status**), and health care utilization patterns. Such analyses can target health reform efforts, highlight the correlates of apparent overuse or underuse, and identify low-variation and high-variation services for which discretion plays a greater role (*see* **Health Care Utilization Data**; **Drug Utilization Patterns**). Differences in utilization can be related to:

1. Individual characteristics, such as age, gender, race, income, education, medical history, and comorbidity.
2. Payer characteristics, such as the source and method of payment [15, 42].
3. Characteristics of health care organizations, such as teaching status, size, ownership, location, and staffing levels [20].
4. Characteristics of small areas, states and provinces, and countries [22, 74].

Studies comparing the use of specific health services may provide important information for managing the delivery of preventive health services to an entire population (e.g. opthalmologic examination of diabetic patients), for directing additional resources to generally underserved individuals, and for redesigning health care organizations to deliver higher priority services [72]. Administrative data are particularly important for evaluating the impact of changes in the health care system, such as capitating physician payment, restricting pharmaceutical formularies, and closing hospital beds.

Profiling physician use of health services is a popular application in the 1990s [3]. Hospitals profile their physicians' length of stay pattern and their prescribing of high-cost medications. Health plans describe physician choice of screening tests, as well as their subspecialty referral rates and hospitalization rates. Such studies have revealed, for example, that physicians vary considerably in their use of Papanicolaou testing, with some overtesting and others markedly undertesting relative to current guidelines [65]. Physicians also vary in their management of breast cancer and in their proclivity to hospitalize, even after controlling for patient characteristics [21, 61]. Disease-specific utilization measures that assess

ambulatory care quality and access have several uses: to reward physicians who use preventive services appropriately, to counsel physicians who do not, and to channel patients away from primary care physicians who overuse technology-intensive and subspecialty services [46].

In the US, administrative data are also being used to profile health care delivery systems, such as health maintenance organizations (HMOs) and independent practice associations (IPAs). Large employers and employer coalitions have pressured health insurance plans to produce information on quality as well as on price. In response, the National Committee for Quality Assurance [48] developed a Health Plan Employer Data Information System (HEDIS) which includes a set of quality indicators representing use of various preventive procedures. To promote more comprehensive measures, several major purchasers and managed care advocates established the Foundation for Accountability [76]. Many of these measures may be based on administrative data, although operational definitions were not released by early 1997.

Costs

Because of global budgeting, Canadian hospital databases typically do not include direct cost data. Most administrative databases in the US, however, include data on total charges and/or charges for selected components of care (e.g. pharmacy, laboratory, supplies). Databases maintained by payers, such as state Medicaid programs and insurance companies, also include information on allowable charges or actual payments to providers. Although these payments sometimes represent only a fraction of the billed charges, payments by government health insurance programs represent a better measure of public investment than billed charges. These financial data can be used for five general types of research:

1. Cost-profiling studies to show the mean costs incurred by specific physicians, hospitals, and other health care providers. Similar to the utilization profiles discussed above, cost profiles can be used by health plans to "delist" individual providers and offer incentives for improved financial performance.
2. Cost-of-illness studies to estimate the aggregate cost of medical and nonmedical care for a specific condition. This aggregate cost may be stratified by payer or by demographic characteristics to show how the condition's economic impact is distributed.
3. Cost-containment studies to evaluate the effects of various strategies, such as pharmacy benefit caps, mandatory second-opinion programs, and preauthorization for hospital care.
4. Cost-effectiveness studies to compare the costs of various diagnostic or therapeutic strategies to achieve a given health benefit (e.g. quality-adjusted life year gained or cancer death prevented).
5. Benefit–cost studies to compare the total economic costs and benefits of a health-related intervention (*see* **Health Economics**).

Outcomes

Administrative data can unobtrusively provide useful information about selected health outcomes. Death is perhaps the best example, being well defined, clearly documented, and easily verified. However, some administrative data sets only capture in-hospital deaths, while others suffer from delayed or inexact reporting of death. In-hospital or 30-day death has been used as a measure of quality of care for such high-risk conditions as myocardial infarction, stroke, pneumonia, and congestive heart failure.

Recently, researchers have refined **risk-adjustment** models that use administrative data to estimate expected and risk-adjusted mortality rates for physicians, hospitals, and health systems. These risk-adjustment models have been developed by American government agencies such as the Health Care Financing Administration [39] and the California Office of Statewide Health Planning and Development [41], provider organizations such as the Hospital Research and Educational Trust, proprietary organizations such as 3M Health Information Systems and MediQual Systems [30], and independent investigators [10, 11]. For most conditions, these risk-adjustment models do not discriminate between decedents and survivors as well as those that include detailed clinical data [31, 39]. This has been most clearly demonstrated for stroke, pneumonia [33, 34] and coronary artery bypass surgery [25]. Administrative and clinical data allow

comparable discrimination only when post-admission complications are used in estimating the probability of death [32, 41].

When administrative data are used to estimate indirectly standardized mortality ratios (*see* **Standardization Methods**) or mortality z scores for hospitals, the results correlate reasonably well with those of more sophisticated models based on either clinical data or more carefully abstracted data (e.g. $r = 0.75$ to 0.87) [25, 32, 39, 59]. In practice, however, hospitals frequently shift above or below any **outlier** threshold (e.g. $P < 0.05$, $P < 0.01$) when clinical data are added to, or substituted for, administrative data. The **predictive value** of being labeled as a mortality outlier using administrative data may be as low as 50%–64% [25, 39].

The validity of risk-adjusted mortality estimates based on administrative data is supported by some, but not all, studies linking outcomes and processes of care. Two studies found significant hospital-level correlations between risk-adjusted mortality measures and quality problem rates determined by peer review organizations, although these correlations varied across states and across conditions [26, 71]. Physician-rated preventable deaths for pneumonia and stroke (but not myocardial infarction) occurred more often at high-mortality than at low-mortality hospitals, although explicit process scores did not differ [12]. Hospitals with low risk-adjusted mortality after myocardial infarction (based on administrative data) administered aspirin more quickly and were more aggressive with catheterization and revascularization than high-mortality hospitals [41]. These studies suggest that administrative data can be used to help identify process deficiencies.

For conditions that cause significant morbidity but are rarely fatal, death has limited utility as a measure of quality of care. Other measures developed from administrative data focus on adverse events and event-free survival, but their validity has not been well established. These are:

1. Post-operative complications can be identified using **International Classification of Diseases (ICD)**-9-CM diagnoses and procedures. Early measures suffered from **misclassification** bias because they were limited to diagnoses explicitly labeled as complications; such diagnoses are likely to be poorly documented by physicians and undercoded by hospitals, [10, 40]. More recent measures, developed both for specific conditions and for broader categories of patients, demonstrate better face and content validity, but still lack construct validity (*see* **Health Status Instruments, Measurement Properties of**) [30, 58, 67]. One promising "comorbidity-adjusted complication risk" measure incorporates physicians' consensus estimates of the probability that any secondary diagnosis is a complication of a given admitting diagnosis, but this has only been validated to a limited extent [2].
2. Post-operative length of stay may be an indicator of post-operative complications, especially if one identifies long-stay outliers instead of just comparing mean lengths of stay. This measure is free from coding bias and may be more predictive of true complications than measures based on ICD-9-CM diagnoses [40, 60]. However, length of stay may be heavily influenced by social factors, such as marital status and homelessness, and by the local availability of skilled nursing beds.
3. Post-discharge readmissions can be identified using linked hospital discharge or claims data. Being more common than death for most conditions, readmission is a promising measure of quality [77]. Panels of specialists convened by the US Health Care Financing Administration have developed lists of readmission diagnoses that indicate adverse events after orthopedic, cardiac, and general surgery [53]. Some investigators have found that "unplanned" readmissions are related to unresolved concerns at discharge, but others found no association with physician quality-of-care ratings (at one hospital) or quality problems determined by peer review organizations [1, 27, 70]. Readmission rates may well be associated with hospital-bed availability, complicating efforts to link readmissions with quality measures [17].
4. After certain procedures, such as hip fracture repair and elective discectomy, reoperations may represent treatment failures. However, reoperations tend to be low-frequency events and, for many conditions, may reflect disease progression more than quality of care. The validity of reoperation rates as a quality measure is unknown.
5. Emergency room visits and unscheduled physician visits after hospital discharge can be ascertained using claims data, but the reliability and validity of such measures are unknown. Given

the poor quality of outpatient diagnostic coding, separating routine visits from complications may be impossible.

In general, administrative data may be a less biased source of outcomes data than **case series** reported from prominent institutions or randomized controlled trials with rigid **eligibility and exclusion criteria**. Such information about mortality and other patient outcomes in the "real world" may help patients choose among therapeutic options. Given the universality of administrative data, differences in outcomes can be related to individual characteristics, such as age, gender, race, income, education, medical history, and comorbidity. These analyses can identify unusual but powerful risk factors for adverse outcomes and sort out the independent effects of multiple variables to facilitate clinical decision making.

Studies of characteristics of health care organizations (teaching status, size, ownership, location, and staffing levels) can highlight the general features of high-quality organizations and promote the regionalization of treatments having a clear association between hospital/surgeon volume and outcomes (e.g. coronary bypass surgery, angioplasty [37]). Relatively little research has studied the influence of payer characteristics, such as the source and method of payment. Analyses of small areas, states and provinces, and countries (*see* **Mortality, International Comparisons**) can elucidate the separate impact of physiologic and sociocultural factors. For example, American–Canadian studies suggest that a one- to four-day preoperative delay after hip fracture is associated with mortality simply by being a marker of preoperative morbidity [62].

Studies using administrative data to evaluate the comparative effectiveness of specific treatments suffer from the limitations of **nonrandomized** designs (*see* **Observational Study**), such as **confounding** because of self-selection into treatment groups (*see* **Selection Bias**), and potential misclassification of risk factors and outcomes. However, they appear useful when a randomized controlled trial is too costly, impractical, or unethical (because a therapy has already been adopted as the "standard of care"). Through careful subset analyses, for example, incidental appendectomy during open cholecystectomy was found to increase the risk of death [78].

New techniques from economics and epidemiology may also help control for differences in pretreatment health status. By using instrumental variables to account for selection bias, McLellan and colleagues found care within the first 24 hours to have more effect on myocardial infarction mortality in the elderly than later invasive procedures [43]. The **rate** ratio approach takes an epidemiologic perspective, using temporal profiles of death rates in the year after surgery to adjust for preoperative death risk [66].

Administrative data can support both randomized and nonrandomized designs. For example, administrative data external to, and independent of, a randomized trial were used to construct health histories of breast disease prior to entry in the controversial Canadian National Breast Screening Study; no definitive evidence supporting a nonrandom allocation of women was found [7]. A nonrandomized, but controlled, approach to introducing competing vaccines (e.g. acellular pertussis) (*see* **Vaccine Studies**) could generate product-specific estimates of clinical effectiveness and serious adverse reactions. Administrative data could be incorporated into a system to provide early warning of adverse events following administration of vaccines, antibiotics, antiarrhythmics, and other medications (*see* **Surveillance of Diseases**; **Postmarketing Surveillance of New Drugs and Assessment of Risk**). Many hospitals already use such systems internally, but they could be expanded on a regional or national scale.

Interventions

Administrative data can actually be used to carry out health interventions (if **confidentiality** constraints permit contacting individual patients) (*see* **Confidentiality in Epidemiology**). Client-oriented interventions (e.g. reminder postcards) and provider-oriented interventions (e.g. targeted feedback) both appear promising [69]. Although trials of reminder systems have apparently never been performed for an entire population, they would not be difficult to implement from guidelines published by various task forces on preventive services [52]. Some American health plans are already using enrollment lists to generate reminders. There are many unanswered questions about the optimal number, timing, and type of reminders for preventive care (*see* **Screening Benefit, Evaluation of**).

Other interventions might focus on identifying candidates for a randomized controlled trial or patients who seem to have "fallen between the

cracks" in the health care system. For example, claims data could be used to identify **AIDS** patients who have experienced an episode of Pneumocystis pneumonia but are not receiving prophylaxis to prevent recurrence. Administrative data could be used to identify persons with possible drug–drug interactions and those who might benefit from home care services because of their high risk of institutionalization (*see* **Pharmacoepidemiology, Adverse and Beneficial Effects**).

Characteristics of Administrative Data

Strengths

The unique advantages of administrative data derive largely from their accessibility, inclusiveness, and flexibility [19]:

1. Using data that have already been collected instead of primary data provides an opportunity to conduct research relatively quickly and cost-effectively.
2. The natural, real-world setting maximizes external validity. Observed outcomes of care using an experimental design may be less representative of "real-world" care than measures derived from administrative data. The inclusiveness of administrative data facilitates selection of representative samples of people, health care providers, and institutions for study.
3. Large sample sizes make small effect sizes detectable.
4. Standards or benchmarks (e.g. for defining an adequate level of care) can be established empirically.
5. Long-term demographic trends (e.g. aging population), changes in utilization, and cost increases can be disentangled as factors influencing system-wide costs [9].
6. Unique person-specific identifiers facilitate both **cohort** and **case–control studies** by the capacity to create comparison groups, to track individuals over time, and to construct histories of prior utilization and events [51, 64].
7. Utilization and mortality rates can be compared across communities to understand better the relationships among such variables [75].
8. Linkage with other databases creates opportunities for cost-effectively adding information collected using other methodologies or by other investigators [49].
9. The absence of the **recall bias** often associated with **surveys** increases the validity of the constructs or measures generated from administrative data.
10. The reliability and validity of many data sets are known and monitored; additional studies can be carried out by comparing records from several independent sources.

Limitations

Some of the limitations of administrative databases, and the extent to which they can be overcome, are presented in the following discussion.

1. *Reliability:* Maintaining data quality in medical, hospital, and nursing home files is an ongoing challenge. Variation in training and supervision leads to differences in coding styles. Information on intensive care and emergency room visits is often not standardized across hospitals. Definitions may be vague or difficult to apply. States and provinces differ in their definitions of institutions (particularly rehabilitation, long-term care hospitals, and extended care units). Ethnicity (*see* **Ethnic Groups**) presents particular problems. In Canada, a definition of Indians with rights specified by treaty has not been coordinated between different levels of government. Defining racial categories has also been problematic in the US, where patients with the same ethnic heritage may self-identify differently.
2. *Validity:* Reimbursement using **diagnosis-related groups (DRGs)** and public comparisons of **risk-adjusted** outcomes may result in bias because of pressures on reporting entities and fear of bad publicity [68].
3. *ICD-9-CM coding:* The lack of operational criteria for defining each disease compromises the quality of data generated by the International Classification of Diseases (ICD) system [16]. Variability among clinicians in diagnosing the same condition differently can produce unreliable statistics [38]. The extent to which shifts in disease rates over time are due to changes in occurrence, or to technological advances that generate improved diagnostic methods, can be difficult to discern. Illness severity and disease

progression affect both prognosis and therapy, but these factors can rarely be recorded using ICD-9-CM.

4. *Personal identifiers:* Many databases do not have personal identifiers that permit reliable record linkage or tracking of individuals over time.
5. *Timeliness:* Delays in submission and processing hinder time-dependent studies, leading to criticisms that one-or two-year-old data do not reflect current practices.
6. *Scope:* Populations of interest, such as the uninsured in the US, may not be included. Generally, only certain categories of billable services can be ascertained. Information on conditions (e.g. the common cold) that do not usually require contact with the health care system may be incomplete. Information on activities (e.g. immunizations) performed by nonmedical health care professionals may not be collected [54]. Similarly, hospital outpatient care was once relatively unimportant and some information systems still do not capture these data. Finally, as insurers move away from fee-for-service payment and toward capitated contracts with medical groups, they should establish incentives to ensure accurate recording of contact data.
7. *Content:* Many important data elements are not collected. For example, a lack of physiologic data (e.g. blood pressure, laboratory values) limits clinical risk-adjustment. Less specific and less standardized cost data are available in Canada, where hospitals receive global budgets, than in the US.

Database Issues: Problems and Opportunities

Reliability and Validity

Concerns about accuracy can be addressed by assessing the agreement among several data sources. In Manitoba, agreement among patient surveys, physician claims, and clinical measures is relatively high for diabetes and hypertension; this is reflected in both overall prevalence and case identification [47, 55]. The flexibility of administrative data easily permits such **sensitivity analysis**; varying the number of years in a patient history or using more stringent inclusion criteria (for example, requiring more than one diagnosis) is relatively easy. As histories of physician visits or hospital stays are incorporated into statistical models, the availability and quality of such data will become increasingly important [45, 51].

Discharge abstracts from the index hospitalizations typically fail to identify many patients with such conditions as angina, congestive heart failure, cerebrovascular disease, and prior acute myocardial infarction, although high agreement between abstracts and hospital records has been observed for diabetes [36, 64]. The number of co-morbid conditions (*see* **Co-morbidity**) identified can be increased by adding more diagnostic fields to the hospital discharge abstract, reviewing abstracts from earlier hospital stays, and using physician claim histories. In practice, however, increasing the number of co-morbidities available for each patient has only moderately improved the prediction of outcomes [63].

ICD-9-CM Coding

Using multiple ICD-9-CM codes to capture all cases of interest addresses problems that arise from use of a single code [16]. Enumerating asthma diagnoses on physician claims, along with possibly associated diagnoses (e.g. bronchitis, chronic obstructive pulmonary disease), helped estimate the extent to which an increase in the apparent prevalence of asthma was real or due to changed diagnostic coding [13]. This is especially important when a nonspecific ICD-9-CM code (e.g. unspecified intracranial hemorrhage) may substitute for a more specific code. Associated codes may clarify the presentation or severity of the condition of interest. For example, the severity of a liver injury may be estimated from the associated surgical repair codes [56].

Researchers should be familiar with techniques for assessing the quality of ICD-9-CM coding and with some of the important findings. Diagnoses are coded more reliably at the three-digit level than at the four- or five-digit level, while some diagnoses and procedures are markedly undercoded [35]. In general, coding quality in the US has improved over the past two decades [18], major procedures are coded more reliably than minor procedures [57], diagnoses that affect DRG assignment are coded more reliably than those that do not [23], and any diagnosis (e.g. mitral regurgitation, congestive heart failure) is more likely to be coded when clinically severe than when mild [36]. Truncation of the data at five or fewer diagnosis fields leads to systematic underreporting of co-morbidities

among patients who die [57]. American hospitals appear to resequence physicians' diagnoses to optimize reimbursement, so the principal diagnosis may not always be the cause of admission [29]. Because of substantial variation in coding quality across facilities [44], hospitals with implausibly low prevalences of major co-morbidities may legitimately be excluded from comparative studies [41].

New Directions

Several promising approaches to increasing the scope and content of research using administrative data are under way. Record linkage, performed with stringent controls to protect confidentiality, is critical both for expanding available data content and facilitating studies of reliability and validity. Because having identifiers to permit following individuals and linking files is so important for research that can benefit the public, efforts to persuade the jurisdictions that do not allow such tracking to do so are clearly in order [50].

Primary data collection should be targeted to fill in gaps in administrative data; for example, public health nurses can enter childhood immunization data to supplement physician claims and provide a picture of population coverage. Since routinely collected patient information about symptoms and functional ability might facilitate outcomes research, several American medical centers have created systems that include such functional measures as well as traditional administrative variables.

As noted in the earlier section on reliability and validity, health status information on individuals and areas from physician and hospital data can be compared fruitfully with that produced using other methodologies [6]. Registry, vital statistics, and census data are all being used to construct small area measures of premature mortality, **life expectancy**, and cause-specific mortality [5, 14]. Census data provide community-level socioeconomic information; in special circumstances, Canadian individual utilization data may be linked to the census [28].

Having a single payer with universal coverage facilitates developing integrated systems with population-wide scope. Comparing a Canadian population health information system to what might be done in the US, Greenfield [24] noted: "Just beginning to collect similar information on those who have health care coverage or can provide it for themselves in our disorganized multipayer system would require a significant expenditure of funds." Although lack of data on the American uninsured will remain a major obstacle to generating a true population health information system, at least one state (Minnesota) is building a state-wide data system on all aspects of health care (*see* **Health Services Data Sources in the US**).

This ability to use multiple files suggests new ways to look at problems. Thus, the integrated system in Manitoba has permitted the examination of physician supply and hospital bed supply within a population health context [62]. Ongoing research is directed toward examining rural hospital performance using two types of indicators: **population-based** (to describe the characteristics of the people living in the area served by each hospital) and hospital-based (to "describe the activities at each rural hospital"). Such contextually sensitive work represents just one new approach to using administrative data to further our knowledge of health and health care.

Admixture in Human Populations

Human society is stratified primarily because of linguistic and cultural differences. This stratification has resulted in restrictions on free interbreeding. There is usually much more interbreeding within a linguistic/cultural stratum than between such strata. Breeding between members of different strata results in an exchange of **genes**. Sometimes, because of large-scale migration, there is a sudden infusion of genes from one population to another. For example, because of slave trading from Africa to North America in the eighteenth century, there has been an exchange of genes between the African Black and American White gene pools. Since children of marriages between Blacks and Whites were socially regarded as belonging to the Black population, this flow of genes was unidirectional – from Whites to Blacks. Exchange of genes has effects on disease profiles, especially in respect of those diseases that are primarily genetic. Human geneticists have long been interested in estimating extents of admixture between populations based on genetic data. This is an important problem, especially because statistics pertaining to migration and other demographic parameters are often unavailable.

Statistical Models and Estimation Procedures

One Biallelic Locus

Consider a specific allele at a codominant biallelic genetic locus. (Codominance is assumed for algebraic simplicity. If there is dominance, minor modifications in formulas are necessary.) Suppose $p_1, p_2, \ldots, p_p$ are the frequencies of this allele in P populations. Consider a hybrid population formed by admixture of these P parental populations in proportions μ_1, $\mu_2, \ldots, \mu_P (0 \leq \mu_i \leq 1; \sum_{i=1}^{P} \mu_i = 1)$. Then, in the hybrid population, the frequency of the allele will be [2]

$$p_{\mathrm{H}} = \sum_{i=1}^{P} \mu_i p_i. \tag{1}$$

The problem is to obtain estimates of the μ_is.

For simplicity, suppose $P = 2$. Then, (1) reduces to

$$p_{\mathrm{H}} = \mu_1 p_1 + (1 - \mu_1) p_2. \tag{2}$$

Assuming that p_1 and p_2 are known without error,

$$\mu_1 = \frac{p_{\mathrm{H}} - p_2}{p_1 - p_2}. \tag{3}$$

The above assumption is crucial and unrealistic since allele frequencies are, in practice, not known without error and are estimated from samples of individuals drawn from the parental and hybrid populations. If $x_1, x_2, \ldots, x_P$, and x_{H} denote the estimates of $p_1, p_2, \ldots, p_P$, and p_{H}, then an estimate m_1 of μ_1 is

$$m_1 = \frac{x_{\mathrm{H}} - x_2}{x_1 - x_2}, \tag{4}$$

$$\mathrm{var}(m_1) \approx \frac{\mathrm{var}(x_{\mathrm{H}}) + m_1^2 \mathrm{var}(x_1) + (1 - m_1)^2 \mathrm{var}(x_2)}{(x_1 - x_2)^2}, \tag{5}$$

where $\mathrm{var}(X_i) = x_i(1 - x_i)/n_i$ = sampling variance of x_i (*see* **Sampling Distributions**), and n_i = number of individuals sampled from the ith population; $i = H, 1, 2, \ldots, P$.

In the above we have made another crucial assumption: there are no other sources (e.g. genetic drift (*see* **Population Genetics**)) contributing to the variances of allele frequencies. In what follows, we continue to make this assumption. Some references to studies relaxing this assumption are, however, provided later.

Several Biallelic Loci

If data on $L(> 1)$ biallelic loci are available, then one can obtain estimates $m_1^{(l)}$ and $\mathrm{var}(m_1^{(l)})$ for the lth locus ($l = 1, 2, \ldots, L$) using (4) and (5). Cavalli-Sforza & Bodmer [3] suggest the following combined estimate:

$$\overline{m_1} = \frac{\sum_{l=1}^{L} \left[m_1^{(l)} \Big/ \mathrm{var}\left(m_1^{(l)}\right) \right]}{\sum_{l=1}^{L} \left[1 \Big/ \mathrm{var}\left(m_1^{(l)}\right) \right]}, \tag{6}$$

with

$$\mathrm{var}(\overline{m_1}) = \frac{1}{\sum_{i=1}^{L} \left[1 \Big/ \mathrm{var}\left(m_1^{(l)}\right) \right]}. \tag{7}$$

Multiallelic Loci

As in (1), a single allele provides a single equation. Thus, if $P > 2$, estimation of the μ_is is not possible without generalizing the model. Roberts & Hiorns [17] provide the generalization. Let $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_P) = ((x_{ij}))_{k\times P}$, where x_{ij} denotes the estimated frequency of the ith allele $(i = 1, 2, \ldots, k)$ at a codominant locus in the jth parental population $(j = 1, 2, \ldots, P)$. Let $\mathbf{y}_{k\times 1} = (y_1, y_2, \ldots, y_k)'$ denote the estimated allele frequencies in the hybrid population formed by admixture of the P parental populations in proportions $\boldsymbol{\mu}_{P\times 1} = (\mu_1, \mu_2, \ldots, \mu_P)'$. Then, if the x_{ij}s are known without error (that is, are actually known values of the corresponding population parameters), then

$$\mathrm{E}(\mathbf{y}) = \mathbf{X}\boldsymbol{\mu}. \tag{8}$$

Hence, the ordinary **least squares** estimate, $\mathbf{m}$, of $\boldsymbol{\mu}$ is:

$$\mathbf{m} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}. \tag{9}$$

Unfortunately, because $\sum_{i=1}^{k} x_{ij} = 1$, for all $j = 1, 2, \ldots, P$, $\mathbf{X}'\mathbf{X}$ is a singular matrix. Roberts & Hiorns [17, 18] suggest eliminating data on one allele chosen arbitrarily, so that $\mathbf{X}'\mathbf{X}$ becomes nonsingular. However, in that case, the estimates of the admixture proportions become dependent on which allele is eliminated.

Elston [7] instead suggests a generalized least squares solution:

$$\mathbf{m} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}, \tag{10}$$

where $\mathbf{V}$ is the dispersion matrix of $\mathbf{y}$, which is the dispersion matrix of the underlying **multinomial distribution**. Of course, because of the constraint that $\sum_{i=1}^{k} y_i = \sum_{i=1}^{k} x_{ij} = 1$, $\mathbf{V}$ is singular. Therefore, as suggested by Roberts & Hiorns [17, 18], in the present case too, data on one allele need to be eliminated arbitrarily to ensure nonsingularity of $\mathbf{V}$ and $\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}$. However, the advantage in using the generalized least squares approach is that the estimate $\mathbf{m}$ remains the same irrespective of the allele that is eliminated [7].

In addition to the problem of singularity, unconstrained least squares estimation (ordinary or generalized) does not guarantee $m_j \geq 0$, for all $j = 1, 2, \ldots, P$, and $\sum_{j=1}^{P} m_i = 1$. Elston [7] shows that the estimates

$$\mathbf{m}^* = (\mathbf{X}^{*'}\mathbf{X}^*)^{-1}\mathbf{X}^{*'}\mathbf{y}^*, \qquad m_P = 1 - \sum_{j=1}^{P-1} m_j, \tag{11}$$

where $\mathbf{y}^*_{k\times 1} = \mathbf{y} - \mathbf{x}_P$, $\mathbf{X}^*_{k\times(P-1)}$ is the matrix whose jth column is $\mathbf{x}_j - \mathbf{x}_P$ and $\mathbf{m}^*_{(P-1)\times 1} = (m_1, m_2, \ldots, m_{P-1})'$, satisfy $\sum_{j=1}^{P} m_j = 1$. However, there is still no guarantee that $m_j > 0$, for all $j = 1, 2, \ldots, P$. Elston [7] suggests that, in practice, if any of the m_js is <0, the $\mathbf{m}$ should be recomputed with the smallest m_j set equal to 0.

The procedure for **maximum likelihood** estimation of $\boldsymbol{\mu}$ was suggested by Krieger et al. [10] and improved upon by Elston [7] to accommodate the constraint $\sum_{j=1}^{P} \mu_j = 1$. Under this model (Eq. (8)), the **likelihood** L that n_h alleles of type h are observed in a random sample of $2n$ alleles (that is, n individuals) from the hybrid population is

$$L \propto \prod_{h=1}^{k} (\mathbf{x}_h'\boldsymbol{\mu})^{n_h}, \tag{12}$$

since the n_hs follow a multinomial distribution with parameters $(\mathrm{E}(\mathbf{y});\ 2n)$. In practice, the likelihood is numerically maximized to obtain the mle of $\boldsymbol{\mu}$ (see [7] for details).

Generalizations of these procedures when allele frequency data on several loci are available are straightforward under the assumption that the allele frequencies are known without error. However, when we take into account fluctuations due to sampling a finite number of individuals to estimate allele frequencies in parental and hybrid populations, the procedure for estimating admixture proportions becomes statistically more complicated. Long & Smouse [13] have proposed a maximum likelihood estimation procedure taking sampling fluctuations into account. In addition to contemporary sampling fluctuations, there is another source of stochastic fluctuation of allele frequencies in each generation due to finiteness of population sizes (*genetic drift*). The effect of genetic drift is more difficult to take into account. Some attempts, albeit not completely satisfactory, have been made in this direction, notably by Thompson [19] and Wijsman [20].

Estimating Admixture from Genetic Similarities

Pollitzer [16] first formalized the intuitive notion that when there is differential gene flow from parental populations to a hybrid population, there will be a direct relationship between the amounts of gene flow and genetic similarities of the hybrid population from the parental populations. Thus, in principle, it should be possible to estimate admixture proportions from observed genetic similarity (or **genetic distance**) values. The initial statistical attempt made by Balakrishnan [1] has come under strong criticism [9, 6]. Chakraborty [4, 5] proposes an estimation procedure based on Nei's [14] gene identity coefficient. This coefficient, J_{ij}, is defined as the probability that two genes drawn at random, one from the ith population and the other from the jth population, are identical ($i, j = H, 1, 2, \ldots, P$). A **consistent estimator** of J_{ij} is [16]:

$$\hat{J}_{ij} = \frac{\sum_{l=1}^{L} \sum_{k=1}^{r_l} x_{ikl} x_{jkl}}{L}, \tag{13}$$

where x_{ikl} is the frequency of the kth allele at the lth locus in the ith population; r_l is the number of alleles at the lth locus; and L is the total number of randomly selected loci from the genome for which data are available. Chakraborty [5] shows that

$$\mathrm{E}(\mathbf{D}_{\mathrm{H}}) = \mathbf{D}\boldsymbol{\mu}^*, \tag{14}$$

where $\mathbf{D}_{\mathrm{H}} = (J_{1\mathrm{H}} - J_{1P}, J_{2\mathrm{H}} - J_{2P}, \ldots, J_{P\mathrm{H}} - J_{PP})'$, $\mathbf{D} = ((J_{ij} - J_{iP}))_{P\times(P-1)}$, $\boldsymbol{\mu}^* = (\mu_1, \mu_2, \ldots, \mu_{(P-1)})'$. Hence, the ordinary least squares estimator of $\boldsymbol{\mu}^*$ is:

$$\mathbf{m}^* = (\mathbf{D}'\mathbf{D})^{-1}\mathbf{D}'\mathbf{D}_{\mathrm{H}}. \tag{15}$$

While nonsingularity of $\mathbf{D}'\mathbf{D}$ is assured in this approach, there is no guarantee that the m_js will be nonnegative. When negative estimates are encountered, the strategy mentioned earlier may be adopted. By considering the dispersion matrix of $\mathbf{D}_{\mathrm{H}}$, evaluated empirically using formulas given in [15] and [12], generalized least squares estimators of $\boldsymbol{\mu}^*$ are obtained in a straightforward way.

Dynamics of Admixture

In the formulations above we have implicitly assumed that the admixture is a static, one-time phenomenon. In reality, there is usually a continued, long-term exchange of genes among populations. For example, as we mentioned in the beginning, migration of Africans to North America continued for more than a century. The total period of slave trading was about three centuries (from about 1650 to 1950), although the trading predominantly took place in the eighteenth century. Because of interbreeding with Whites, in each generation a fraction of the gene pool of African Blacks brought to North America was replaced by genes of Whites. Let b_0 denote the original frequency of an allele in Black Africans prior to any interbreeding with Whites, w denote the frequency of this allele among American Whites and μ denote the fraction of the gene pool of Blacks replaced per generation by genes of Whites. (Both w and μ are assumed to remain constant over generations.) Then, as in (2),

$$b_i = (1 - \mu)b_{i-1} + \mu w, \tag{16}$$

where b_i denotes the frequency of the allele among Blacks after i generations of interbreeding.

Thus, from (16), we obtain:

$$(1 - \mu)^i = \frac{b_i - w}{b_0 - w}. \tag{17}$$

Using (17), Glass & Li [8] estimated that the accumulated amount of White genes in the American Black gene pool was 30.6% ($\hat{\mu} = 0.0358$) based on the R^o allele frequency of the Rh **blood group** system and $i = 10$ generations (period of admixture $\approx$300 years; generation time $\approx$30 years). (This estimate has subsequently been questioned and revised. See [6] for a discussion, further references, examples and a detailed review.)

Data on frequencies of "private" alleles (i.e. unique alleles present in one population but not in others) are very helpful for admixture estimation. However, estimation procedures using such data need modifications from those presented above [11].

A Caveat

One of the major impediments to admixture estimation in humans has been the lack of accurate identities of parental populations of a hybrid population. All

the estimators presented above are quite sensitive to fluctuations of parental allele frequencies. Therefore, unless identities of, and allele frequencies in, parental populations are known accurately, estimates of admixture may be quite unreliable.

Admixture Mapping

The mapping of genes that control a trait or a disease is usually carried out by **linkage analysis** of family data on the trait/disease and **markers** [6]. However, there are other ways of mapping genes. One of these is by studying hybrid populations, that is populations that have arisen as a result of the admixture of two or more populations. The suggestion that hybrid populations can provide useful information about **linkage** was first pointed out by Rife [7]. Linkage between two loci results in the nonrandom **association** of alleles at the loci [8]. When two diallelic loci with alleles (A_1 and A_2) and (B_1 and B_2), respectively, are unlinked, then the frequency (f_{ij}) of the gamete A_iB_j ($i, j = 1, 2$) in the population will be

$$f_{ij} = p_i q_j,$$

where p_i and q_j denote, respectively, the frequencies of the alleles A_i and B_j in the population. If $D = f_{11}f_{22} - f_{12}f_{21}$ is used as a measure of the association of alleles at the two loci in gametes, which is known as **linkage disequilibrium**, then D is expected to be zero if the two loci are unlinked. However, if the two loci are linked and if θ denotes the recombination fraction between the two loci, then in a random-mating population,

$$D^{(t)} = (1-\theta)^t D^{(0)}, \tag{1}$$

where $D^{(0)}$ denotes the initial value of linkage disequilibrium in the population and $D^{(t)}$ denotes the value of linkage disequilibrium in the population after t generations of random mating [8]. It is clear from (1) that linkage disequilibrium will decay rapidly unless the two loci are closely linked, that is unless θ is close to zero.

The admixture between populations also leads to linkage disequilibrium between loci [1, 5]. Consider a population (Z) that is formed by the admixture of two populations X and Y, in proportions m ($\neq 0$) and $(1-m)$, respectively. Assume that no further admixture has taken place in the population Z. Then,

$$D_Z^{(t)} = (1-\theta)^t D_Z^{(0)}, \tag{2}$$

where $D_Z^{(t)}$ is the linkage disequilibrium in the admixed population Z in generation t and $D_Z^{(0)}$ is the linkage disequilibrium in population Z immediately after its formation by the admixture of populations X and Y, which is given by [2]

$$D_Z^{(0)} = mD_X^{(0)} + (1-m)D_Y^{(0)} + m(1-m) \times [p_1^{(x)} - p_1^{(Y)}][q_1^{(x)} - q_1^{(Y)}], \tag{3}$$

where $D_X^{(0)}$ and $D_Y^{(0)}$ are the initial linkage disequilibria in populations X and Y, respectively, $p_1^{(x)}$ and $q_1^{(x)}$ are the frequencies of alleles A_1 and A_2, respectively, in population X, and $p_2^{(Y)}$ and $q_2^{(Y)}$ are these frequencies in population Y. Equation (3) shows that even if the parental populations X and Y are in linkage equilibrium, if the allele frequencies in the parental populations X and Y are different, then there will be linkage disequilibrium in the admixed population. If the values of m, t, $[p_1^{(x)} - p_1^{(Y)}]$ and $[q_1^{(X)} - q_1^{(Y)}]$ are known, then θ can be estimated from (2) and (3). Appropriate likelihood ratio tests have been formulated [2] to test whether an observed value of linkage disequilibrium in the admixed population is due to linkage or due to admixture.

As was pointed out by Rife [7], in situations where the parental populations are of opposite homozygous **genotypes** ($A_1A_1B_1B_1 \times A_2A_2B_2B_2$ or $A_1A_1B_2B_2 \times A_2A_2B_1B_1$), then linkage from data from the admixed population may be detected in much the same way as from data on experimental crosses. This idea has been further extended. Since these extensions are similar to linkage analysis in experimental crosses, the term "admixture mapping" has been proposed [10].

With information about the ancestry of alleles at marker loci in individuals in the admixed population, one approach [3, 4] has been to test for association with states of ancestry on chromosomes drawn from the admixed population, conditioning on parental admixture. At each locus on each gamete there are two possible states of ancestry: X or Y. It has been shown [3] that from **Mendel's law** of independent assortment, conditional on parental admixture, there is no association between the ancestry of alleles at different loci if the loci are unlinked. Thus, the null hypothesis of no linkage is that, conditional on parental admixture, the odds ratio for the association between states of ancestry at any two loci on the same gamete is 1. Rejection of the **null hypothesis** is an indication of linkage between the loci under consideration. Using Bayesian statistical methodology, McKeigue et al. [4] have shown that the posterior distribution of parental admixture and ancestry at each marker locus, conditional on the observed

marker genotype data, can be generated by **Markov chain** simulation. They have also provided a statistical method of detecting linkage and of detecting misspecification of ancestry-specific allele frequencies within the admixed population under study.

A second approach [10] is based on an extension of the transmission-disequilibrium test (TDT) [9] (*see* **Disease-marker Association**). However, it should be noted that the usual TDT is not a special case of the multipoint TDT proposed [10] for this purpose. In this approach, a statistical method has been developed by conditioning on the ordered multilocus genotypes of parents and testing for association of marker **haplotypes** with the trait/disease under study. One major difference between this approach and the approach described in the previous paragraph is that the conditioning in this approach is on parental genotype, while in the other approach it is by parental admixture. Another major difference is the nature of data. While in McKeigue et al.'s [4] approach genotype data on parents are not essential, Zheng & Elston's [10] approach relies on nuclear family data. In both approaches, association arises only in the presence of linkage. Modeling in the second approach [10] is done through frequency distributions of haplotypes in the admixed population as a function of population history. Thus, probabilities of haplotypes on specific trait allele-carrying gametes that are derived from each of the two parental populations are calculated taking into account various modalities of multilocus recombination and the history of admixture. Using these probabilities, a "multipoint TDT" is derived. Unlike the usual TDT [9], in the present approach, what is scored is whether a *haplotype* in a parent is a transmitted one or a nontransmitted one to an offspring. The data therefore comprise counts of transmitted and nontransmitted haplotypes, the **likelihood** of which have been derived under various assumptions and scenarios [10]. A permutation test has been proposed as a test of significance [10].

While both approaches described above seem to perform well in a statistical sense, it remains unclear which of these two approaches is statistically more efficient.

PARTHA P. MAJUMDER

Adoption Studies

Adoption usually refers to the rearing of a nonbiological child in a family. This practice is commonplace after wars, which leave many children orphaned, and is moderately frequent in peacetime. Approximately 2% of US citizens are adoptees.

Historically, adoption studies have played a prominent role in the assessment of genetic variation in human and animal traits [10]. Most early studies focused on cognitive abilities [9], but there is now greater emphasis on psychopathology [5] and physical characteristics, such as body mass [20]. Adoption studies have made major substantive contributions to these areas, identifying the effects of genetic factors where they were previously thought to be absent [3, 12, 15].

In recent years the adoption study has been overshadowed by the much more popular twin study [17] (*see* **Twin Analysis**). Part of this shift may be due to the convenience of twin studies and the complex ethical and legal issues involved in the ascertainment and sampling of adoptees. Certain Scandinavian countries – especially Denmark, Sweden and Finland [8, 13, 14] – maintain centralized databases of adoptions and thus have been able to mount more representative and larger adoption studies than elsewhere.

The adoption study is a "natural experiment" that mirrors cross-fostering designs used in genetic studies of animals, and therefore has a high face validity as a method to resolve the effects of genes and environment on individual differences. Unfortunately, the adoption study also has many methodological difficulties. First, is the need to maintain **confidentiality**, which can be a problem even at initial ascertainment, as some adoptees do not know that they are adopted. Recent legal battles for custody fought between biological and adoptive parents make this a more critical issue than ever. Secondly, in many substantive areas, e.g. psychopathology, there are problems with sampling, in that neither the biological nor the adoptive parents can be assumed to be a random sample of parents in the population. For example, poverty and its sequelae may be more common among biological parents who have their children adopted into other families than among parents who rear their children themselves. Conversely, prospective adoptive parents are, on average, and through self-selection, older and less fertile than biological parents. In addition, they are often carefully screened by adoption agencies, and may be of higher socio-economic status than nonadoptive parents. Statistical methods (see below) may be used to control for these sampling biases if a random sample of parents is available. Some studies indicate that adoptive and biological parents are quite representative of the general population for demographic characteristics and cognitive abilities [19], so this potential source of bias may not have substantially affected study results.

Thirdly, selective placement is a common methodological difficulty. For statistical purposes, the ideal adoption study would have randomly selected adoptees placed at random into randomly selected families in the population. Often there is a partial **matching** of the characteristics of the adoptee (e.g. hair and eye color, religion and ethnicity) to those of the adopting family. This common practice may improve the chances of successful adoption. Statistically, it is necessary to control for the matching as far as possible. Ideally, the matching characteristics used should be recorded and modeled. Usually, such detailed information is not available, so matching is assumed to be based on the variables being studied and modeled accordingly (see below). In modern adoption studies, these methods are used often [18, 19].

Types of Adoption Study

Nuclear families in which at least one member is not biologically related to the others offer a number of potential comparisons that can be genetically informative (see Table 1). Of special note are monozygotic (MZ) twins reared apart (MZ_A) (*see* **Zygosity Determination**). Placed into uncorrelated environments, the correlation between MZ twins directly estimates the proportion of variation due to all genetic sources of variance ("broad **heritability**"). Estimation of heritability in this way is statistically much more powerful than, e.g. the classical twin study that compares MZ and dizygotic (DZ) twins reared together (MZ_T and DZ_T). With MZ_A twins the test for heritability is a test of the null hypothesis that the correlation is zero, whereas the comparison of MZ_T and DZ_T is a test of a difference between correlations. Environmental effects shared by members of a twin pair (known as "common", "shared" or "family" environment or "C") are excluded by design. If this source of variation is of interest, then additional groups of relatives, such as unrelated individuals reared together,

Table 1 Coefficients of genetic and environmental variance components quantifying resemblance between adopted and biological relatives, assuming random sampling, mating and placement

Relationship	Variance component

V_A – additive genetic; V_D – dominance genetic; V_{AA} – additive × additive interaction; V_{AD} – additive × dominance interaction; V_{DD} – dominance × dominance interaction; E_S – environment shared by siblings; E_P – environment shared or transmitted between parent and child. Relationships are: MZ – monozygotic twin; DZ – dizygotic twin; BP – biological parent; BC – biological child; AP – adoptive parent; AC – adopted child. The subscripts T and A refer to reared together and reared apart, respectively.

are needed to estimate it. Similar arguments may be made about across-generational sources of resemblance. Heath & Eaves [11] compared the power to detect genetic and environmental transmission across several twin-family (twins and their parents or twins and their children) adoption designs.

Methods of Analysis

Most modern adoption study data are analyzed with Structural Equation Models (SEM) [2, 17]. SEM is an extension of **multiple linear regression** analysis that involves two types of variable: *observed variables* that have been measured, and *latent variables* that have not. Two variables may be specified as causally related or simply correlated from unspecified effects. It is common practice to represent the variables and their relationships in a path diagram (*see* **Path Analysis in Genetics**), where single-headed arrows indicate causal relationships, and double-headed arrows represent correlations. By convention, observed variables are shown as squares and latent variables are shown as circles.

Figure 1 shows the genetic and environmental transmission from biological and adoptive parents to three children. Two of the children are offspring of the biological parents (sibs reared together) while the third is adopted. This diagram may also be considered as multivariate, allowing for the joint analysis of multiple traits. Each box and circle then represents a vector of observed variables. Multivariate analyses (*see* **Multivariate Analysis, Overview**) are particularly important when studying the relationship between parental attributes and outcomes in their offspring. For example, harsh parenting may lead to psychiatric disorders. Both variables should be studied in a multivariate genetically informative design such as an adoption or twin study to distinguish between the possible direct and indirect genetic and environmental pathways.

From the rules of path analysis [22, 23] we can derive predicted covariances among the relatives, in terms of the parameters of the model in Figure 1. These expectations may, in turn, be used in a structural equation modeling program such as Mx [16] to estimate the parameters using **maximum likelihood** or some other **goodness-of-fit** function. Often, simpler models than the one shown will be adequate to account for a particular set of data.

A special feature of the diagram in Figure 1 is the dotted lines representing delta-paths [21]. These represent the effects of two possible types of selection: assortative mating, in which husband and wife correlate; and selective placement, in which the adoptive and biological parents are not paired at random. The effects of these processes may be deduced from the Pearson–Aitken selection formulas [1]. These formulas are derived from **linear regression** under the assumptions of multivariate linearity and homoscedasticity. If we partition the variables into selected variables, X_S, and unselected variables X_N, then it can be shown that changes in the covariance of X_S lead to changes in covariances among X_N and the cross-covariances (X_S with X_N). Let the original (preselection) covariance matrix of X_S be **A**, the original covariance matrix of X_N be **C**, and the covariance between X_N and X_S be **B**. The preselection matrix may be written

$$\left(\begin{array}{c|c} \mathbf{A} & \mathbf{B} \\ \hline \mathbf{B}' & \mathbf{C} \end{array}\right).$$

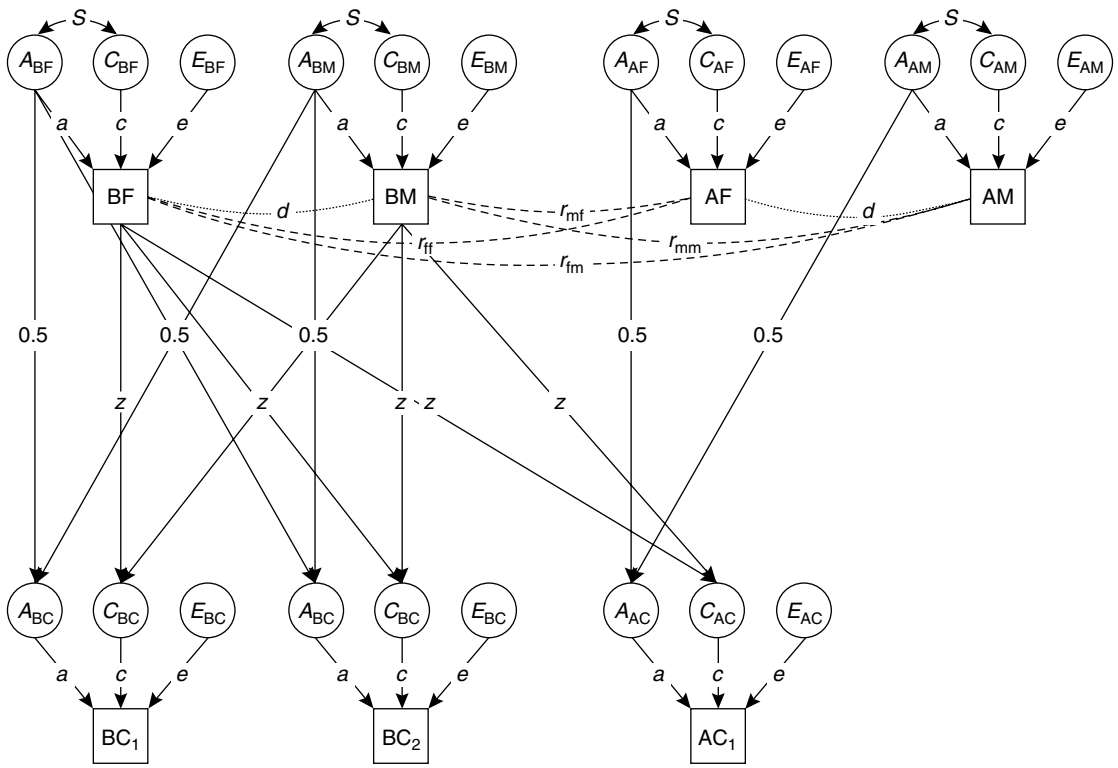

Figure 1 Path diagram showing sources of variation and covariation between: adoptive mother, AM; adoptive father, AF; their own biological children, BC_1 and BC_2; a child adopted into their family, AC_1; and the adopted child's biological parents, BF and BM

If selection transforms **A** to **D**, then the new covariance matrix is given by

$$\left(\begin{array}{c|c} \mathbf{D} & \mathbf{DA}^{-1}\mathbf{B} \\ \hline \mathbf{B}'\mathbf{A}^{-1}\mathbf{D} & \mathbf{C}-\mathbf{B}'(\mathbf{A}^{-1}-\mathbf{A}^{-1}\mathbf{DA}^{-1})\mathbf{B} \end{array}\right).$$

Similarly, if the original means are $(\mathbf{x}_s : \mathbf{x}_n)'$ and selection modifies $\mathbf{x}_s$ to $\tilde{\mathbf{x}}_s$, then the vector of means after selection is given by

$$[\mathbf{x}_s : \mathbf{x}_n + \mathbf{A}^{-1}\mathbf{B}(\mathbf{x}_s - \tilde{\mathbf{x}}_s)]'.$$

These formulas can be applied to the covariance structure of all the variables in Figure 1. First, the formulas are applied to derive the effects of assortative mating, and secondly, they are applied to derive the effects of selective placement. In both cases, only the covariances are affected, not the means. An interesting third possibility would be to control for the effects of nonrandom selection of the biological and adoptive relatives, which may well change both the means and the covariances.

Selected Samples

A common approach in adoption studies is to identify members of adoptive families who have a particular disorder, and then examine the rates of this disorder in their relatives (*see* **Ascertainment**). These rates are compared with those from control samples. Two common starting points for this type of study are (i) the adoptees (the adoptees' families method) and (ii) the biological parents (the adoptees study method). For rare disorders, this use of selected samples may be the only practical way to assess the impact of genetic and environmental factors.

One limitation of this type of method is that it focuses on one disorder, and is of limited use for examining **co-morbidity** between disorders. This

limitation is in contrast to the **population-based** sampling approach where many characteristics – and their covariances or co-morbidity – can be explored simultaneously.

A second methodological difficulty is that ascertained samples of the disordered adoptees or parents may not be representative of the population. For example, those attending a clinic may be more severe or have different risk factors than those in the general population who also meet criteria for diagnosis, but do not attend the clinic.

Genotype × Environment Interaction

The natural experiment of an adoption study provides a straightforward way to test for **gene–environment interaction**. In the case of a continuous phenotype, interaction may be detected with linear regression on

1. the mean of the biological parents' phenotypes (which directly estimates **heritability**)
2. the mean of the adoptive parents' phenotypes
3. the product of points 1 and 2.

Significance of the third term would indicate significant G × E interaction. With binary data such as psychiatric diagnoses, the rate in adoptees may be compared between subjects with biological or adoptive parents affected, vs. both affected. G × E interaction has been found for alcoholism [7] and substance abuse [6].

Logistic regression is a popular method to test for genetic and environmental effects and their interaction on **binary** outcomes such as psychiatric diagnoses. These analyses lack the precision that structural equation modeling can bring to testing and quantifying specific hypotheses, but offer a practical method of analysis for binary data. Analysis of binary data can be difficult within the framework of SEM, requiring either very large sample sizes for asymptotic weighted **least squares** [4] or integration of the **multivariate normal** distribution over as many dimensions as there are relatives in the pedigree, which is numerically intensive.

Adverse Selection

Some health care providers (e.g., clinicians, hospitals, or HMOs) and insurers serve populations that are substantially sicker or more difficult to care for than average. A provider or insurer with sicker than average patients experiences adverse selection; one with healthier than average patients has favorable selection. Action taken to achieve favorable selection is called "skimming" or "cream skimming".

Biased selection (either favorable or adverse is not necessarily a problem, if such differences are recognized and accounted for when paying for care or holding providers accountable for their patients' health outcomes. However, when providers are paid a fixed price for each patient, or they are penalized for expending more resources than their peers for patient care, or for not achieving as good outcomes, providers will compete to treat healthy patients and will be discouraged from caring for those with complex problems.

Age-of-onset Estimation

Age-of-onset estimation refers to the estimation of the distribution, as a function of age, of the time a trait first appears. Typically, the time of first occurrence is measured by the age at diagnosis. Many diseases exhibit variable age of onset where subjects carrying a susceptibility **gene** for a disease develop the disease at an earlier age. Consequently, interest is in estimating the age of disease onset as a function of **genotype** and characterizing how the distribution may vary across subpopulations, or in the presence of gene–gene or **gene–environment interactions**. Other names for the age-of-onset distribution include the age-specific **penetrance**, age-specific risk, cumulative risk, or cumulative incidence.

For many diseases, such as cancer, age is the primary risk factor; the risk of developing disease increases with age. However, not all subjects will develop a specific disease or trait in their lifetime. Therefore age of onset is studied among living subjects who are at risk for the trait of interest, in the presence of death from other causes. Observations are censored for participants on whom the event is not observed, either because the subjects are unaffected at time of observation or because they die without ever having developed the trait. In the literature this has been approached using two different modeling philosophies. One assumes the population is a mixture of susceptible and nonsusceptible individuals, nonsusceptible individuals being subjects who would never develop the trait no matter how long they lived [6, 7, 14]. This is the approach that we describe below. The other philosophy assumes all individuals are susceptible and would eventually become affected if they only lived long enough [1, 4, 13, 22, 24].

Let g denote genotype and x a vector of exposures. Then the cumulative risk at age a_1 for a carrier of genotype g can be expressed using the improper distribution function

$$F_g(a_1;x) = 1 - S_g(a_1;x) = \phi_g \left\{ 1 - \exp\left[- \int_0^{a_1} \lambda_g(a;x)\ \mathrm{d}a \right] \right\}, \quad (1)$$

where ϕ_g estimates the proportion of subjects who will develop the trait in their lifetime and $\lambda_g(a;x)$ is the hazard, the instantaneous probability of the trait developing among subjects at risk, given their genotype and exposures, as a function of age. For an individual who is unaffected at age a_0, the risk of developing the trait by age a_1 is

$$\pi(a_0, a_1; x) = \frac{\int_{a_0}^{a_1} h_g(a;x)\, S_g(a;x)\, S_c(a;x)\ \mathrm{d}a}{S_g(a_0;x)\, S_c(a_0;x)}, \quad (2)$$

where $h_g(a;x) = \partial/\partial a F_g(a;x)/S_g(a;x)$ and $S_c(a;x)$ is the probability of surviving up to age a due to causes of death unrelated to the trait of interest. For designing prevention studies or for the purpose of risk management in unaffected individuals, this latter quantity may be more relevant than the "pure" trait-specific cumulative risk given above.

The variability in age of onset as a function of other exposures, X, can be modeled through the hazard. The hazard is expressed in two parts: the hazard of disease onset in subjects with the baseline levels of exposure, $\lambda_g(t)$, and a term involving the level of exposure, x. Several models may be proposed. The most common is the proportional hazards model, $\lambda_g(t;x) = \lambda_g(t)RR(t;x)$, where the exposures have a multiplicative effect on the baseline hazard. The multiplicative term of the covariates is often called the hazard ratio or the **relative risk**. Alternatively, the effect on the hazard could be additive as in the additive hazard model, $\lambda_g(t;x) = \lambda_g(t) + RD(t;x)$, where $RD(t;x)$ is the risk difference. A third paradigm is an accelerated failure time model, $\lambda_g(t;x) = \lambda_g(t \cdot w(t;x))w(t;x)$, where the effect of the covariates is multiplicative on age.

Alternative formulations for the age-of-onset distribution use **regressive** logistic or regressive linear models. These approaches model the probability that an individual is affected at age a by $\phi_g w_g(a,x)$, and the probability that an individual is unaffected at age a by $1 - \phi_g W_g(a,x)$. The function w_g is the logistic or normal density and is modeled as a regressive function of age a and covariates x; W_g is its corresponding cumulative distribution function.

Uses

Estimating age of onset is important in studies of disease etiology. Allowing for variable age of onset in segregation analysis can help find evidence for new major genes and the use of age-of-onset estimates in **linkage analysis** can assist in the localization of

putative susceptibility genes. Additionally, estimates of the proportion of cases explained by a gene as a function of age of onset may guide the development of new studies for identifying other risk factors for disease. For example, the genes BRCA1 and BRCA2 explain a large proportion of breast cancer among early onset cases but do not explain the majority of cases among women with late onset disease. Therefore studies for identifying new risk factors may focus on cases with late onset breast cancer.

Accurate estimates of age of onset are also important for individual **genetic counseling** and for the planning of future prevention studies. A subject's age-specific cumulative risk for developing disease may influence the recommended age at which regular screening should begin or the length of time between visits. Also, it may influence preventive measures a subject may take. For a woman who has a low risk of developing breast cancer, regular surveillance may be her selected regimen. However, a woman having a high lifetime risk of breast cancer may opt for a prophylactic mastectomy. Accurate risk estimates and their variability will help a patient in determining her own course of action.

In the design of prevention trials, accurate estimates of age of disease onset are needed for estimating sample size. Another use, shown by a trial for studying the drug Tamoxifen as a chemopreventive agent for breast cancer, is for screening eligible study participants. Owing to the potential toxicities related to the administration of the drug to a healthy population, investigators enrolled subjects at high risk of breast cancer. Eligible women were either over the age of 59 or younger but having the same age-specific risk as an average 60-year-old woman [18].

Study Design

A careful study design is critical for obtaining good estimates of age-specific penetrance [7, 20]. First, the disease may be uncommon. For instance, among women in the US who live to age 85, one in nine (11%) will develop breast cancer [2]. Other cancers such as colon cancer occur less frequently. Four percent of the US population are expected to develop colon cancer in their lifetime. A second reason why a study design is important is that the genes that are strong risk factors for disease, BRCA1 and BRCA2 for breast cancer and MLH1 and MSH2 for colon cancer, are rare. Standard cohort and case–control studies would need prohibitively large sample sizes to study these genes. As a result, family studies have been implemented. Family studies have the advantage that they can be completed relatively quickly. Disease status on all family members can be obtained in a single interview and data for several diseases can be collected at the same time. However, a possible source of **bias** includes the differential participation rates of probands (*see* **Ascertainment**) based on **family history** of disease [7, 8]. A second source of bias is reporting error on the disease status of relatives. Although reporting error is not specific to family studies, it could occur at a higher frequency.

The following completed or ongoing family study designs are proposed for estimating age-specific cumulative risk.

Case–Control Family Study

In a **case–control** family study, affected study participants ("cases") are selected during a fixed time period from a population-based sample of newly identified diseased subjects. Unaffected study participants ("controls") are selected, generally by frequency matching to the cases based on age, sex, and geographic region of residence. Data are collected from the study participants on the history of disease in a specified group of relatives (e.g. first-degree relatives). Blood samples for genotyping may or may not be obtained from the participants or relatives. When genotypes on the participants are available, the design is named the genotyped–proband design [7].

Studies that have published estimates of age-specific penetrance of breast cancer from a case–control family study include a study of breast cancer in the Cancer and Steroid Hormone Study (CASH) [3] and a study of three US case–control studies with cases selected for ovarian cancer [23]. Additional estimates using data from breast cancer (case-only) families were reported from a population-based study in Australia [10].

Kin–Cohort Design

In the kin–cohort design, study participants are volunteers. They provide a blood sample and complete a short, self-administered questionnaire reporting on risk factors and family history of disease in first- and second-degree relatives. The relatives ("kin")

form a **cohort** from which age-specific cumulative risk is estimated. A **kin–cohort study** of Ashkenazi Jews living in Washington DC provided age-specific cumulative risk estimates for three BRCA1 **mutations** [19].

Multistage Sampling

Multistage sampling designs have been proposed for estimating the penetrance of rare genes in families. In order to increase the frequency of the gene variants in the sample, investigators have proposed to oversample probands with a positive family history of disease. In stage 1, participants are stratified based on their family history of disease in first-degree relatives. Subjects are then randomly sampled, conditional on their family history. The University of Southern California (USC) Consortium Colorectal Cancer Family Registry applied a multistage design in developing a registry of colorectal cancer cases and their families. They select all cases with a positive family history of disease and 16% of cases with a negative family history.

High-risk Families

Samples of high-risk families that were originally collected for the purpose of linkage analysis have also been used to characterize age of disease onset. Such families, generally collected in clinics, have a large number of affected relatives and variable family structure. In addition to the usual trait information on relatives, **marker** genotypes are measured on a large number of family members. The Breast Cancer Linkage Consortium has used a collection of families having multiple cases of breast and/or ovarian cancer to characterize age of disease onset. One analysis focused on families with four or more cases of either breast or ovarian cancer that reported linkage to marker D17S579, a genetic marker $\sim$2 cM distal to BRCA1 [5].

Estimation Methods

Many approaches have been developed for estimating age-specific penetrance from family studies. These include **likelihood** [1, 6, 7, 9, 14], **pseudo-likelihood** [13], **marginal likelihood** [4], weighted score [17, 24], and method of moments [22] approaches. We introduce the different methods for each of the above-mentioned designs. We begin by describing the likelihood for the data from a population-based case–control family study.

Case–Control Family Study. Let g_0 denote the proband's disease susceptibility genotype and $y_0 = (a_0, \delta_0)$ the phenotype, where a_0 is age at diagnosis if affected or current age if unaffected, and δ_0 is disease status (1 = affected, 0 = unaffected). The phenotypes and susceptibility genotypes of J relatives are given by $\mathbf{y}_1 = (y_{11}, \ldots, y_{1J})$ and $\mathbf{g}_1 = (g_{11}, \ldots, g_{1J})$. For relatives who died without ever developing the trait, a_{1j} is their age at death. The likelihood is conditioned on the disease status of the proband to adjust for their selection conditional on disease status. Assuming that phenotypes are conditionally independent within a family given genotypes, the likelihood contribution from a single family is

$$L(\boldsymbol{\Omega}, q; \mathbf{y}_1 | y_0) = \frac{\sum_{g_0, \mathbf{g}_1} p(g_0, \mathbf{g}_1; q)\, f(y_0 | g_0; \boldsymbol{\Omega}) \prod_{j=1}^{J} f\left(y_{1j} | g_{1j}; \boldsymbol{\Omega}\right)}{\sum_{g_0} p(g_0; q)\, f(y_0 | g_0; \boldsymbol{\Omega})}, \tag{3}$$

where the parameter q denotes the susceptibility allele frequency, $p(g_0, \mathbf{g}_1; q)$ is the probability of the unobserved family genotypes, and $f(y|g; \boldsymbol{\Omega})$ is the density function characterized by the age of onset parameters $\boldsymbol{\Omega}$. This density can be from a logistic function [6, 14]. Alternatively, and the case we describe in more detail below, it can be based on a hazard function. The genotype probabilities are computed under the usual assumptions of **Hardy–Weinberg equilibrium**, random mating, and a known mode of inheritance. To incorporate measured susceptibility genotypes on relatives into a joint likelihood, the observed genotypes are removed from the sum in the numerator of (3).

Both parametric and semiparametric models for the hazard function have been proposed. Gail et al. [7] parameterize the cumulative risk function using an improper Weibull function, $F_g(a) = \phi_g\{1 - \exp[-(\gamma_g a)^{\alpha_g}]\}$. Assuming that censoring is unrelated to genotype, they write the density as

$$f_g(a) = \lambda_g(a)^{\delta} S_g(a) G(a), \tag{4}$$

where $\lambda_g(a) = \phi_g \alpha_g \gamma_g^{\alpha_g} a^{\alpha_g - 1} \exp[-(\gamma_g a)^{\alpha_g}]/S_g(a)$ and $G(a)$ is the probability of surviving all causes of death unrelated to the disease of interest. Since $G(a)$ does not depend on genotype, it does not affect the penetrance estimates. For a semiparametric modeling approach, Moore et al. [13] propose a piecewise exponential survival model. A common set of age cut-points is selected and age intervals created for estimating separate hazard functions in gene carriers and noncarriers, e.g. less than 30 years old, 30–39 years, 40–49 years, 50–59 years, 60–69 years, 70–79 years, 80 or more years. Then they estimate a constant hazard function for each separate age interval.

For relatively simple family structures and parametric models, the loglikelihood can be directly maximized or an **EM algorithm** approach may be used. For more complex structures a **Monte Carlo** EM method may be preferred [12]. Moore et al. [13] present a pseudolikelihood alternative for estimating the age-specific risk estimates for their semiparametric model. All these approaches are analogous to estimating penetrance parameters in a **segregation analysis**. When measured genotypes are incorporated into the likelihood, it may be referred to as a modified segregation analysis. These methods assume conditional independence of disease given genotype which, if violated, can lead to biased penetrance estimates. Alternative methods that allow for residual familial correlation have been developed for randomly sampled families. These are described below for the kin–cohort design.

Kin–Cohort Design. Wacholder et al. [22] proposed a method of moments approach to estimate age of onset for the kin–cohort design. Using Kaplan–Meier methods they estimated the proportion of kin who develop disease separately for carrier participants and noncarrier participants. Noting that relatives form a mixture of carriers and noncarriers, they presented a method to decompose the risk estimates from kin into its genotype-specific parts. Under dominant gene action, the first-degree relatives of participants who carry a disease mutation are approximately a 50 : 50 mixture of carriers and noncarriers. For first-degree relatives of noncarrier participants the mixture is $\pi : (1 - \pi)$, where π is the population frequency of carrying the variant gene. Similar to the likelihood-based methods, this analysis assumes a known mode of inheritance of disease, a constant **gene frequency** across age (i.e. censoring due to the competing risk of death from an unrelated cause is not a function of the genotype under study), and homogeneity of risk given the genetic variant of interest. The primary critique of the analysis is that the estimates of cumulative risk from the use of Kaplan–Meier methods can be nonmonotonic. Whenever a noncarrier kin has an event at a time that the carrier kin does not, the cumulative risk will decrease. Also, it does not utilize the disease status of the proband.

These criticisms can be overcome by a likelihood-based analysis. Risk estimates derived from likelihood-based approaches are always monotonically increasing. Furthermore, the likelihood includes information on the proband's disease status. In the kin–cohort design, probands are volunteers from the population, so it is not necessary to condition (3) on the proband's phenotype. However, an added assumption is necessary, namely that there is no differential survival of cases by genotype before the time that they are selected into the study [7]. Gail et al. [7] showed that the kin–cohort design allows a modest reduction in necessary sample sizes compared with standard epidemiologic cohort or case–control designs. Larger reductions are possible if additional genotypes from relatives can be obtained [7].

Other strengths of a likelihood approach are that it allows for additional modeling of **covariates** and also allows the likelihood to be extended to include the disease status of more distant relatives. However, these estimates can suffer from their own **biases** under model misspecification. As mentioned earlier, **maximum likelihood** relies on a conditional independence assumption of disease given genotype and covariates [7] which, if violated, can result in biased risk estimates. To allow for the residual familial aggregation of disease arising from shared genetic and/or environmental effects, a **marginal likelihood** approach has been proposed [4]. Alternatively, one could add a family-specific random effect [12, 16]. Currently, these two approaches are limited to designs where the study participants are randomly sampled from a general population.

Multistage Sampling. A weighted score approach has been proposed for estimating risk from multistage sampled families [17, 24]. For a two-stage design, the analysis weights the score contribution of the data in stage 2 by the inverse of the proportion of

participants sampled in that stratum. Specifically, if S_k denotes stratum k $(k = 1, 2)$, then the weighted score equation is

$$U_W(\mathbf{\Omega}) = \sum_{k=1}^{2} \frac{1}{f_{S_k}} \sum_{y \in \text{stage } 2} \frac{\partial}{\partial \mathbf{\Omega}} \ln L(\mathbf{\Omega}, q; \mathbf{y}_1, g_0 | y_0), \tag{5}$$

where f_{S_k} denotes the fraction sampled in stratum S_k. In using this approach to design the USC Colorectal Cancer Family Registry, Siegmund et al. [17] found that over-sampling probands with a positive family history of disease could improve the efficiency of the penetrance estimates in gene carriers.

High-risk Families. The retrospective likelihood is used for estimating penetrance when families are sampled based on the occurrence of multiply affected individuals. This approach is also known as maximizing the lod score, or the mod score approach [9]. In this likelihood, marker genotypes (**m**) are measured on a large number of relatives, and their distance from the susceptibility locus is modeled using a recombination fraction (θ). The contribution to the retrospective likelihood from a single family is proportional to the probability of the family marker genotypes given all phenotypes:

$$L(\mathbf{\Omega}, q, \theta; \mathbf{m}|\mathbf{y}) \propto \frac{\sum_{\mathbf{g}} f(\mathbf{y}|\mathbf{g}; \mathbf{\Omega})\, p(\mathbf{g}|\mathbf{m}; q, \theta)}{\sum_{\mathbf{g}} f(\mathbf{y}|\mathbf{g}; \mathbf{\Omega})\, p(\mathbf{g}; q)}, \tag{6}$$

where $p(\mathbf{g}|\mathbf{m}; q, \theta)$ is the probability of unobserved susceptibility genotypes in the family given the observed marker genotypes as a function of the susceptibility allele frequency q and the distance between the marker and the susceptibility locus, θ. Random mating and Hardy–Weinberg equilibrium are assumed. Parameters are estimated using maximum likelihood and the same conditional independence of phenotype given genotype assumptions are needed. Vieland & Hodge [21] point out that for general pedigree structures the retrospective likelihood does not provide an exact ascertainment correction. However, the adjustment based on phenotype is believed to yield, in general, essentially unbiased penetrance estimates.

For a discussion of bias and efficiency based on different likelihood approaches, see Kraft & Thomas [11].

Populations

The experience of estimating the age-of-onset distribution for breast cancer shows the large variability that can exist across study populations. Early estimates from a large population-based case–control study in the US found a 67% risk of breast cancer by age 70 for women who carried a susceptibility gene [3]. Cases were young women, aged 20–54, with newly diagnosed breast cancer. After the cloning of BRCA1 identified that the gene was a risk factor in families carrying excess cases of breast and ovarian cancer, a similar study was undertaken using incident ovarian cancer cases. That study reported a 69% risk of breast cancer by age 70, supporting the earlier estimates [23]. Neither of these studies measured specific genetic variants in their samples.

In studies that have measured specific BRCA1 variants or a linked marker locus, a range of risk estimates for carriers has emerged. The analysis of high-risk families identified by the Breast Cancer Linkage Consortium reported an 85% risk of breast cancer (confidence interval 51%–91%) by age 70 [5]. The kin–cohort study of Ashkenazi Jews in Washington DC estimated a risk of 56% [19]; a population-based sample of Australian women selected for having onset prior to the age of 40 reported a risk of 40% [10].

The large variability accompanying many of these estimates (±15%–20%) does not on its own appear sufficient to explain the apparent inconsistencies of the estimates from the high-risk and population-based samples. One possible explanation for the higher risk estimates from the multiple-case families is ascertainment bias due to the selection of families showing linkage to BRCA1 (lod > 1.0). The general practice of selecting families based on lod scores depends on the marker distribution in the family and can lead to overestimates of penetrance in carriers from the retrospective likelihood [15]. The authors report that their estimates are not sensitive to this cut-point so they believe such bias is negligible in their data. Another possibility is that the increased risk estimates are capturing a **correlation** of disease due to unmeasured risk factors shared among the relatives. This is biologically plausible and can explain the experience

of genetic counselors that gene carriers in families having a strong history of disease appear to be at increased risk of disease over carriers from the general population. For this reason, genetic counselors prefer to counsel subjects based on estimates derived from families with a similar family history. Estimates derived from clinic-based families are used for counseling individuals with a strong family history of disease and estimates derived from population-based samples are preferred for counseling negative family history subjects.

Conclusions

Accurate estimates of age of onset are crucial to clinical management and designing disease prevention studies. They are also valuable in studies of disease etiology. More work is needed on understanding the subtleties of applying simple genetic models to complex traits and on extending current methods to fit more complex models. It will be very important to characterize how risks vary across different populations, and their possible modification by exposure, both environmental and genetic.

Age–Period–Cohort Analysis

Age–period–cohort analysis refers to a family of statistical techniques for understanding temporal trends of an outcome, such as cancer **incidence**, in terms of three related time variables: the subject's age, the subject's date of birth (birth cohort), and calendar period. The fundamental ideas underlying these three perspectives of time have been understood by social scientists and public health researchers for many years. Early applications of these ideas employed innovative graphical presentations of data, but more recently investigators have also employed modeling and more formal **hypothesis testing** to understand better the separate contributions of each of these factors. Attempts to quantify the contributions of each factor have forced analysts to address the fact that age, period, and cohort are linearly dependent factors whose main effects cannot be uniquely and simultaneously estimated. This phenomenon is referred to as the **identifiability** *problem*. Available data do, however allow one to estimate the degree of curvature or departure from overall trends.

Suppose that we are interested in whether a **screening** program for breast cancer has had an impact on the **incidence rates** in a defined population. Such a program would identify cases at an earlier stage when the disease can be more effectively treated. However, shortening the time to detection would also be expected to result in a temporary rise in the calendar year (period) effect before returning to the long-term time trend. One approach we might try is to estimate the difference in the period effect before and immediately after the screening program, but we shall see that this is not an estimable quantity when we try to adjust for effects of age and year of birth. However, we can estimate a change in slope immediately before and after the program began, because this depends on curvature, and thus it is estimable. In fact, it may be reasonable to test the hypothesis that the screening program changes the slope by deflecting an ongoing trend.

Temporal Perspectives for Events

To understand the rationale for age–period–cohort analysis, as well as its inherent limitations, we first define the different time perspectives that give rise to the dynamic changes in a population, and then indicate the logical problems that arise when we try to consider all three factors simultaneously.

Definitions of Age, Period, and Cohort

Age refers to time since birth or, more generally, to time since a subject entered a study. *Period*, on the other hand, refers to the calendar date at which the outcome was determined. Finally, *cohort* identifies the calendar time when an individual was born, or entered a study; cohort thus provides an index for generational effects. The purpose of age–period–cohort analyses is to determine the separate contributions of age, period, and cohort to the outcome under consideration.

Vital statistics are often analyzed for age, period, and cohort effects. These data are readily available, and sometimes yield early hints on the etiology of a disease.

Age often influences risk of disease and socioeconomic outcomes. Hence, it would usually be essential to consider this factor in any analysis.

Period effects tend to be factors that impact all individuals under observation on a particular date, regardless of their age. For example, because everyone breathes essentially the same air, if disease incidence is affected by ambient air pollution in all age groups, and if levels of pollutants have changed over time, then we might expect to see period effects for each age group. However, not all period effects need be due to changes in causative agents. Artifacts, such as changes in medical diagnostic practice, or technology can introduce changes in disease incidence that would be manifested in the data as period effects.

Cohort effects can be attributed to factors related to the year of birth. A disease that is associated with poor nutrition in the mother might be expected to have higher incidence in cohorts born during a war or a famine. However, cohort effects may not be limited to events around the time of birth, because the cohort can also be thought of as a generational identifier. For example, cigarette smoking most commonly begins in late teens or early twenties, so that major changes in the marketing of cigarettes would affect primarily the generations who happened to be in the vulnerable age group on the date at which such marketing changes occurred. Hence, we might expect to see an effect due

to cohort for diseases that are strongly associated with the smoking of cigarettes in populations that have experienced major shifts in cigarette sales.

Early analyses of period and cohort relied mainly on descriptive plots of the data. More recently, investigators have tried to formalize the study of disease trends by fitting models that include time effects, or by considering **nonparametric** approaches to the analysis. These attempts have forced a recognition of the inherent limitation in these analyses, namely a nonidentifiability of some model parameters.

Collinearity of Age, Period, and Cohort

Figure 1 gives a **Lexis diagram**, showing the only possible diagonal paths that may be traversed by an individual under study, and it also demonstrates the relationship among the three temporal measures under consideration. The diagonal paths represent individual cohorts, c. If an event occurs to an individual of age a in year p, then a particular cohort $c = p - a$ must be involved. Hence, $a - p + c = 0$, and these time measures are linearly dependent. This dependence leads to aliasing of parameters, i.e. a fundamental inability to identify completely the separate contributions for each of the individual time factors. We usually think of an effect due to a particular factor as the contribution from that factor if other factors are held constant. However, this concept is clearly nonsensical when the factors are functionally related, as they are here.

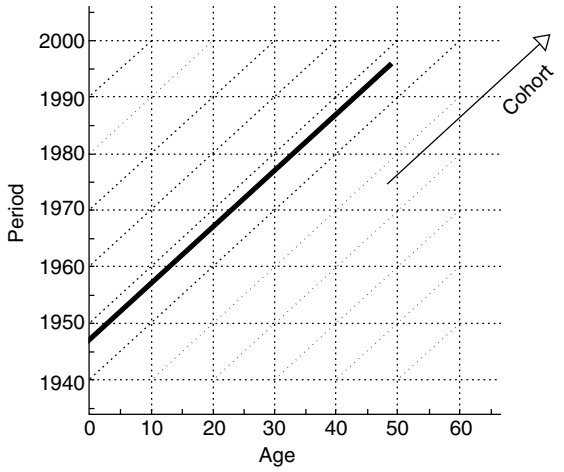

Figure 1 A Lexis diagram showing the relationship between age, period, and cohort

Interval Divisions

Population-based data are usually tabulated for the calculation of rates, by grouping age and period into categorical intervals, as seen in Table 1. Five- or 10-year intervals are most commonly used, although for large regions these rates are often reported annually, which implies one-year intervals for period. Because the grouping results in a somewhat crude measure for age and period, there remains some ambiguity when one tries to identify a corresponding cohort. For example, if a death occurred in someone aged 50–54 in 1990–94, then that individual could have been born as early as January 1, 1935, or as late as December 31, 1945, a span of 10 years, which is twice the width of the age and period interval. In addition, the intervals are overlapping, as we can see from the fact that for the next age group, 55–59, an individual could have been born between January 1, 1940, and December 31, 1950. From the Lexis diagram shown in Figure 1 we can see the pattern of age and period intervals traversed by different cohorts. While age and period uniquely define a cohort, we have lost that uniqueness in cohort definition when time has been categorized. Hence, the same cohort may pass through different age groups during a particular period interval. The same problem arises for the third time factor, when any of the other two time factors are categorized. Tarone & Chu [37] have suggested using a finer grid when possible. For example, in their analysis of breast cancer mortality they employ two-year intervals for age and period. Nevertheless, smaller overlaps remain.

If we know the cohort for each individual, then we can obtain nonoverlapping cohort categories, along with the other two time measures, by further grouping the data along the diagonal, as shown in Figure 1 [32]. When the age and period intervals are of equal width, identical width cohort intervals can be selected so that each square is divided into two triangles along the diagonal, thus achieving the same degree of precision as age and period, and avoiding the overlap at the same time.

Table 1 Observed number of cases, denominators and rates for lung cancer incidence in Connecticut males, 1935–1984

Age	1935–44	1945–54	1955–64	1965–74	1975–84

80–89	41.34	111.51	246.14	420.56	582.71

Graphical Displays of Temporal Trends

Graphical displays offered the first approach for analyzing the effects of age, period, and cohort. One may plot the **response surface** against two time axes, such as the graph showing lung cancer incidence rates for women in Connecticut plotted on the age × period plane shown in Figure 2. The vertical axis shows the natural logarithm of the rate per 100 000 person-years experience, and we shall use this outcome to demonstrate each graphical method. While such graphs convey a broad picture of relationships, it is harder to extract some essential details. It is not easy, and sometimes impossible, to pick out the magnitude of the incidence in a particular surface plot. Other features are also unclear in two-dimensional representations of a three-dimensional figure, including whether the rates are changing on one axis, at a fixed value of the other axis. This is especially difficult for the missing time axis, i.e. cohort, in this figure. Obvious alternatives to this particular graph would entail the use of the age × cohort plane or even the period × cohort plane, although the latter is not used when, as usual, there is good reason to believe that age exerts a strong effect on the response.

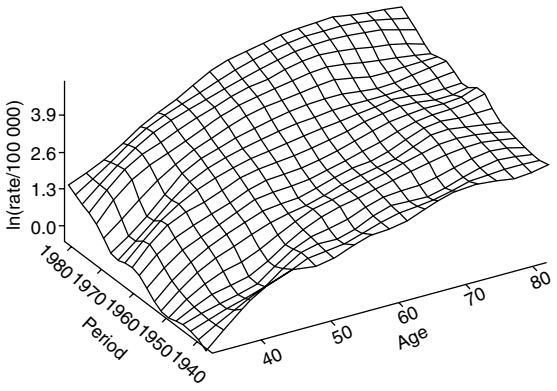

Figure 2 Natural log of the lung cancer incidence rates for Connecticut women plotted against age and period

An alternative display projects this response surface onto the age × response plane, as shown in Figure 3. Such figures were used by Korteweg [23] and others to recognize the effect of birth cohort on disease incidence. In this graph, solid lines connect

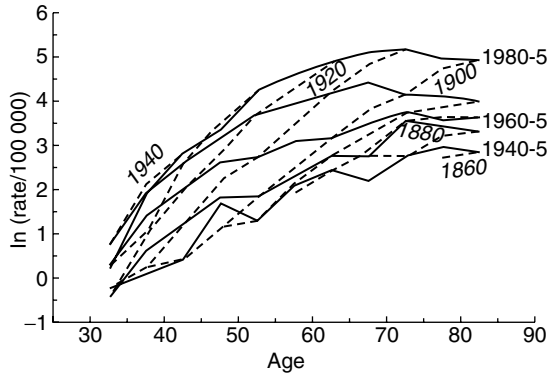

Figure 3 Natural log of the lung cancer incidence rates for Connecticut women by age (solid lines with regular font connect constant periods, broken lines with italic font connect constant cohorts)

the age-specific rates for the identical periods, and broken lines for specific cohorts. Note that the age-specific rates decline at older ages for the solid lines corresponding to fixed periods. The constant cohort (broken) lines increase monotonically with age, consistent with a belief that lung cancer risk increases with age. Because it is biologically implausible that rates should decline with age, we are led to reject the age–period model and, instead, to consider age and cohort as explanatory factors for disease trends. Similar reasoning was used by earlier investigators to suggest cohort as an important factor for some diseases. The cohort lines also tend to be more nearly parallel than the period lines, a feature that is especially relevant for the more formal models that can be fitted to these rates, as discussed below.

Projections of the response surface on the two remaining time axes can also be used (Figure 4). Each line shows either the period or the cohort trend for a particular age group. Because age so dominates these trends, these graphs better highlight some of the more subtle features for period and cohort trends. If these lines are more nearly parallel for either the period or the cohort axes, then that factor offers a more **parsimonious** description of the age-specific rates. We use the same scale for period and cohort so that the bend in a line will have the same visual impact for either period and cohort. Otherwise, the period axis would be more spread out, thus visually diluting some of the curvatures, as we can see in a period plot of the same data in a typically proportioned graph in Figure 5. By stretching the period axis, curves

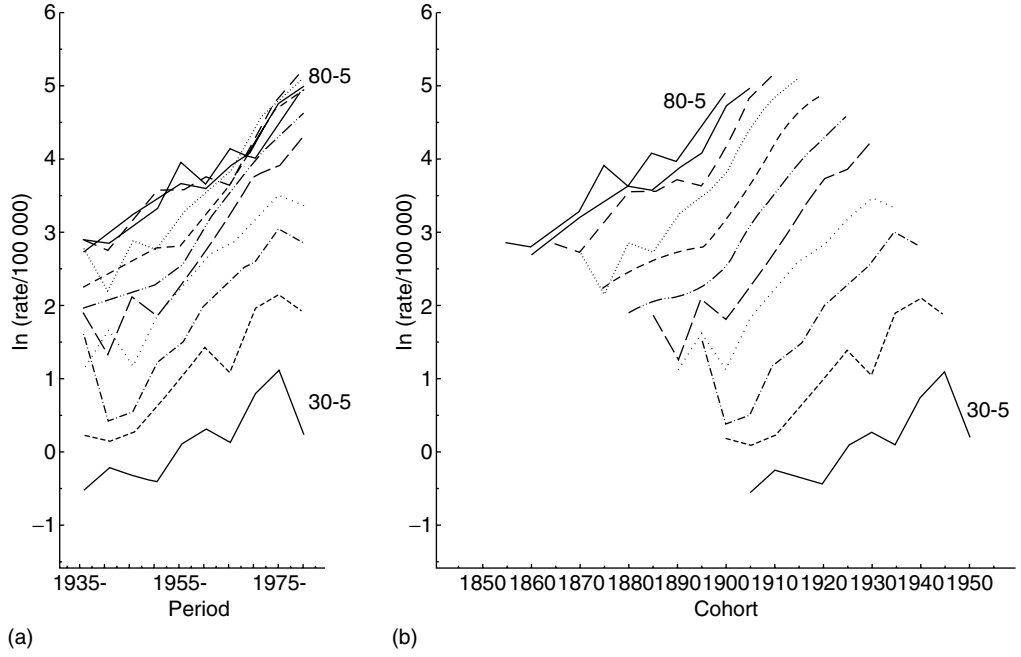

Figure 4 Natural log of the lung cancer incidence rates for Connecticut women by (a) period and (b) cohort

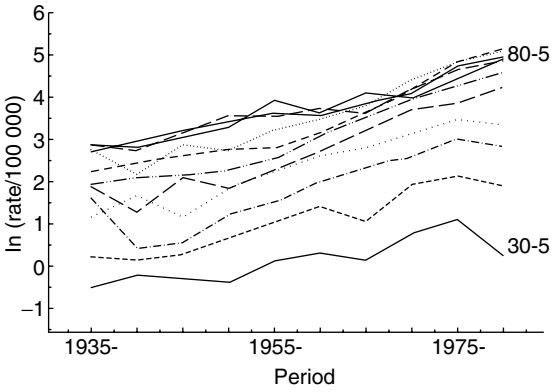

Figure 5 Natural log of the lung cancer incidence rates for Connecticut women by period

begin to appear more nearly straight and more nearly parallel. Because there are generally more cohorts than periods, the period trends will tend to look straighter unless we show the axes on the same scale. Hence, to facilitate the comparison of period and cohort effects, it is important to use the same abscissal scale.

Contour plots offer yet another approach for displaying features of the response surface by projecting lines producing the same response onto the age × period plane, as shown in Figure 6. The contours represent lines of constant lung cancer incidence, and are labeled according to ln(incidence/100 000). Similar graphs can be produced using the age × cohort or period × cohort planes [22]. Following the lines parallel to the age (period) axis, we can tell the rate at which the surface is increasing by how rapidly we cross the contour lines. Regions where the contours are parallel to the age (period) axis do not exhibit a change in incidence with age (period). Figure 6 also shows the constant cohorts as diagonal dotted lines, and we can make similar interpretations with respect to cohort by observing whether the contours are crossed or are parallel to this axis. These graphs can be especially useful when trying to understand complex patterns, such as the contour graph for Hodgkin's disease shown in Figure 7, in which there is more than one mode.

Another refinement that can assist in the interpretation of trends is to smooth the rates before preparing the contour plot. For example, Cislaghi et al. [7] give contour plots on the age–cohort plane for observed rates, fitted rates using a **polynomial regression** model, and residuals that show the adequacy of the model over the entire plane. Other variations include the use of models with period effects, or **spline functions**, in place of polynomials.

The cohort lines shown in Figure 6 have a different scale because they are diagonals on a rectangular age × period grid. Weinkam & Sterling [40] propose the use of a triangular lattice that represents the plane consisting of the locus of possible combinations of age, period, and cohort in three-dimensional age–period–cohort space. In this way they are able to present an identical scale for each time element, while at the same time using a two-dimensional time plane. This approach emphasizes that there are really only

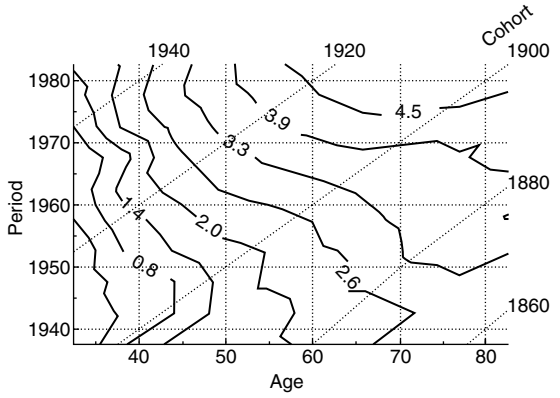

Figure 6 Contour plot for natural log of the lung cancer incidence rates for Connecticut women by age and period (cohorts are shown by the diagonal broken lines)

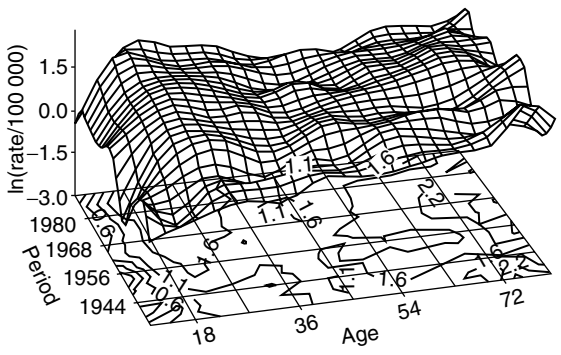

Figure 7 Surface and contour plot for the natural log of Hodgkin's disease incidence rates for Connecticut women by age and period

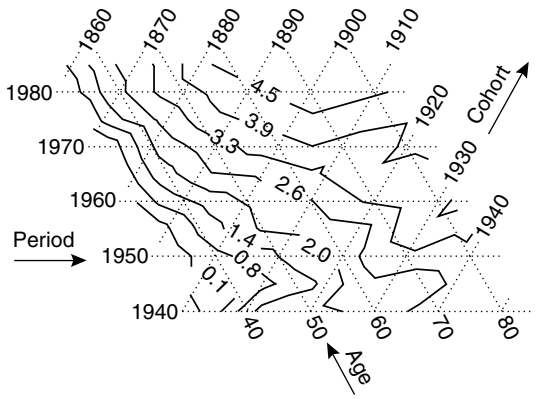

Figure 8 Contour plot for the natural log of the lung cancer incidence rates for Connecticut women on an age–period–cohort triangular lattice

two time dimensions that underlie an age–period-cohort analysis. Figure 8 shows the contours for the lung cancer example using this approach. Interpretation of the graph is similar to that of the contour plots discussed earlier.

Modeling Temporal Effects

In this section we consider age–period–cohort analyses that arise from fitting models to data. Because of the identifiability problem that arises from the **collinearity** among the time factors, it is impossible to determine parameters uniquely in models based on a linear combination of age, period, and cohort factors. We discuss several proposals to overcome this difficulty.

Vital statistics are often presented as **rates**, found by taking the ratio of the number of events divided by the total person-years experience. It is common to assume that the numerator has a **Poisson distribution**, and that the log rate is a linear function of specified regressor variables. Models of this form belong to the class of generalized linear models, which can be readily fitted using standard statistical software (*see* **Software, Biostatistical**).

Additive Effects

To formulate a linear model for the temporal effects, we first consider the case where data have been tabulated by dividing age and period into categories of equal width. This is the most common situation in practice, and instances where the interval widths are different for age and period actually give rise to still further complications [13, 15]. Let $i(= 1, \ldots, I)$ represent the age groups, $j(= 1, \ldots, J)$ the periods and $k(= 1, \ldots, K = I + J - 1)$ the cohorts. In a typical table, i represents the row index, j the column index, and k the upper-left to lower-right diagonals, beginning with the cell in the lower-left corner of the table. These indices are also linearly dependent, $k = j - i + I$, so the issue of collinearity remains. A typical **additive model** can be given by

$$Y_{ijk} = \phi_0 + \phi_{\mathrm{a}i} + \phi_{\mathrm{p}j} + \phi_{\mathrm{c}k} + \varepsilon_{ijk},$$

where Y_{ijk} represents the response (perhaps the log rate), ϕ_0 is an intercept, other parameters in the model ($\phi_{\mathrm{a}i}$, $\phi_{\mathrm{p}j}$ and $\phi_{\mathrm{c}k}$) represent age, period, and cohort effects, and ε_{ijk} is a **random error**. This equation has the same general form as **analysis of variance** models, and additional constraints must be made. One approach is to set the parameters arbitrarily at one level to zero, $\phi_{\mathrm{a}1} = \phi_{\mathrm{p}1} = \phi_{\mathrm{c}1} = 0$, say. Alternatively, we can adopt the usual constraints, $\sum_i \phi_{\mathrm{a}i} = \sum_j \phi_{\mathrm{p}j} = \sum_k \phi_{\mathrm{c}k} = 0$, which will be used in the remainder of this discussion. Unfortunately, forcing the parameters to satisfy these constraints does not entirely resolve the identifiability problem; a further constraint is necessary if one is to obtain a unique set of parameter estimates. Many regression packages allow for the possibility of a linear dependence among the **covariates** by employing a generalized inverse when fitting a model, which results in additional arbitrary constraints. The results can differ widely depending on the constraints used in the analytical software, and the order in which the factors are assigned to the model [15].

Linear Dependencies in the Design Matrix. Parameters under the usual constraints can be determined by setting up a **dummy variable** design matrix. Let the age columns of the design matrix be given by

$$\mathbf{A} = (\mathbf{A}_1 \quad \mathbf{A}_2 \ldots \mathbf{A}_{I-1}),$$

where the ith column is defined as

$$A_i = \begin{cases} 1, & \text{if } i\text{th age group,} \\ -1, & \text{if } I\text{th age group,} \\ 0, & \text{otherwise,} \end{cases}$$

thus yielding the parameters ϕ_{ai}, $i = 1, \ldots, I-1$, and $\phi_{aI} = -\sum_{i=1}^{I-1} \phi_{ai}$. The period, **P**, and cohort, **C**, components of the design matrix are similarly defined. Kupper et al. [24, 25] show that the columns of the overall design matrix formed by concatenating all three components satisfy

$$\sum_{i=1}^{I-1}\left[i - \frac{I+1}{2}\right]\mathbf{A}_i - \sum_{j=1}^{J-1}\left[j - \frac{J+1}{2}\right]\mathbf{P}_j + \sum_{k=1}^{K-1}\left[k - \frac{K+1}{2}\right]\mathbf{C}_k = 0.$$

Thus, these columns are linearly dependent. A condition for the existence of a unique set of parameter estimates in a regression model is that the design matrix be of full column rank. Hence, a model that simultaneously includes age, period, and cohort effects does not yield a unique set of estimates, which is referred to as the identifiability problem.

Partitions into Linear and Curvature Effects. One convenient way of representing trends for a particular factor is to include the overall trend or slope and the departure from that trend, namely the curvature. This approach represents the age effects obtained under the usual constraints as

$$\phi_{ai} = \left(i - \frac{I+1}{2}\right) \times \beta_a + \gamma_{ai},$$

where β_a is the overall slope, and γ_{ai} is the curvature. Period and cohort parameters can be represented in a similar way. Holford [17] proposed using the usual **least squares** estimate of the slopes, which can be expressed as a linear **contrast** among the age parameters $\beta_a = \mathbf{C} \times \phi_a$, where the contrast vector has elements

$$C_i = \left[i - \frac{I+1}{2}\right] \times \frac{12}{I(I-1)(I+1)}$$

for equally spaced intervals. This is the first-order **orthogonal** polynomial contrast (*see* **Polynomial Approximation**). We call β_a the "least squares linear component". Alternatively, Clayton & Schifflers [8] use the **mean** of the successive differences to represent the slope, which reduces to $(\phi_{aI} - \phi_{a1})/(I-1)$, and thus depends only on parameters in the first and last age groups. Both of these approaches for defining slopes can also be modified by restricting the range over which the slope is determined, either by defining the contrast appropriately in the case of using least squares, or by choosing groups other than the first and last when calculating the mean differences, i.e. using $(\phi_{ai} - \phi_{ai'})/(i - i')$.

Curvature terms can be determined by taking the difference between the estimated parameters and the fitted value from a **simple linear regression**, i.e. the residuals. If the least squares linear component is used, then these residuals are

$$\gamma_{ai} = \phi_{ai} - \left[i - \frac{I+1}{2}\right] \times \beta_a.$$

Identifiability Problem for Parameters. Because of the collinearity among the three temporal factors, a unique set of parameter estimates cannot be obtained without further constraints. Using different constraints can change not only the magnitude of the parameters, but the direction of trend for each time factor, thus profoundly influencing the conclusions from an analysis. The partitioning of the temporal effects into linear and curvature components provides one useful way of reducing the number of parameters involved in the collinearity, leading to a better understanding of its effect. It has been shown that the curvature parameters, such as γ_{ai}, are invariant, regardless of the parameterization or constraints on linear components [15, 33]. The same is not the case for the slopes (β_a, β_p, and β_c), which can arbitrarily take any value, $\beta_\cdot \in (-\infty, \infty)$. While each slope parameter may vary widely, all these parameters can only do so while maintaining a specific relationship among themselves. This constrained relationship suggests the use of estimable functions of the parameters, i.e. functions that do not depend on the constraints adopted to find a particular set of parameter estimates.

For an arbitrary pair of numbers, (r, s), the linear function, $r\beta_a + s\beta_p + (s-r)\beta_c$ is invariant to the particular set of parameters obtained, i.e. it is an estimable function of the slopes [15]. For example, by setting $r = s = 1$, we see that $\beta_a + \beta_p$ is estimable. Likewise, $r = 0$ and $s = 1$ demonstrate that $\beta_p + \beta_c$ is estimable, and in a similar fashion we can find other combinations of the slopes that are not affected by arbitrary constraints applied to obtain a particular set of parameters.

The completely unlimited range of values that can be arbitrarily assigned to an individual slope is certainly a serious drawback of these analyses. But

through the use of estimable functions we can see that if any one slope is determined, then the other two are immediately identified as well. With this in mind, any underlying quantity representing the individual slopes can be expressed as

$$\beta_a^* = \beta_a + \nu,$$
$$\beta_p^* = \beta_p - \nu,$$
$$\beta_c^* = \beta_c + \nu,$$

where β_a, β_p, and β_c are the true slopes and ν is an indeterminant parameter. For example, if we are particularly interested in period trends, β_p, then it is disconcerting that the estimated slope might be either increasing or decreasing depending on the unknown ν. However, β_a^* also depends on the same indeterminant constant, so that if it is implausible on substantive grounds for rates to decrease with age, then the values for ν that make the age slope negative must be implausible for β_p^* and β_c^* as well. If one can somehow show that ν lies within a particular range, then there is a corresponding range of values that must hold for the period and cohort effects as well.

We can observe the effect of nonidentifiability of the linear terms by considering a model in which we ignore the curvature components

$$Y = \mu + a \times \beta_a + p \times \beta_p + c \times \beta_c.$$

Because of the linear dependence between the time factors, we can add $0 = \nu \times (a - p + c)$ to the right-hand side, yielding

$$\begin{aligned} Y &= \mu + a(\beta_a + \nu) + p(\beta_p - \nu) + c(\beta_c + \nu) \\ &= \mu + a \times \beta_a^* + p \times \beta_p^* + c \times \beta_c^*, \end{aligned}$$

which is the model based on parameters obtained using a particular set of constraints.

Example. To illustrate the result from fitting age–period–cohort models, consider the data on lung cancer incidence in Connecticut men shown in Table 1. An analysis of deviance for a **loglinear model** fitted to these incidence rates is shown in Table 2, suggesting that the model does give a good fit to the data overall, and that each of the time components is statistically significant. The adequacy of the model can be further confirmed by an analysis of the residuals. Notice that the change in the scaled deviance (*see* **Model, Choice of**) attributable to age has $7 - 2 = 5$ **degrees of freedom**. The additional reduction in degrees of freedom arises because a model that includes period and cohort includes terms that are completely aliased with linear age. Hence, the test for the age effect when period and cohort are included in the model is only a test of age curvature. Likewise, the contribution for each of the factors is one less than the usual degrees of freedom that result from including a categorical factor in a model.

Table 2 Summary of analysis of deviance from fitting a loglinear model to the data in Table 1

Source	df	Scaled deviance	*P*
Goodness of fit	15	15.99	0.3825
Age|period, cohort	5	2907.06	<0.0001
Period|age, cohort	3	118.15	<0.0001
Cohort|age, period	9	464.87	<0.0001

We can observe the alternative sets of parameters from fitting the various models in Table 3. Despite the large discrepancies among these models, they each give identical fitted values. The second column was obtained by simply including age, period, and cohort in the regression model. In this instance the program set a parameter to zero when it discovered the first column of the design matrix that identified it as not being of full rank. Hence, the last two cohort effects are zero.

The third column includes linear age and cohort terms (period is not included because of the linear dependence), followed by dummy variables which constrain the first and last curvatures to be zero. The coefficients for the age and period terms correspond to net trends identified by considering the mean of successive differences, and the linear age effect estimates $\beta_a + \beta_p$, and cohort $\beta_c + \beta_p$. By dropping the curvatures we can readily see the source of the degrees of freedom for each effect, because we have applied two constraints on the components not accounted for by linear trend.

The final column shows the results of partitioning the effects into a least squares slope, and the corresponding residuals. These can be determined by: (i) simple linear regression on the parameters where the slope identifies the linear component and the residuals are the curvature; (ii) estimating a contrast using the approach described below; or (iii) forming a design matrix that is orthogonal to the linear component [21].

Approaches to Identifiability

By its very nature there cannot be a solution to the identifiability problem in the usual sense. We have already seen that alternative constraints can yield very different parameter trends, as we see from a graph of the age, period, and cohort effects in Figure 9. Notice that we can rotate the period slope 180° without affecting the fit of the model, but as we rotate period in a clockwise direction, there is a corresponding counterclockwise rotation for age and cohort. Proposals for ways to obtain a particular set of parameter estimates are necessarily arbitrary, and must be subject to critical evaluation when trying to interpret the results from an analysis. A variety of solutions have been proposed, but each has potentially serious limitations. Alternatively, we can limit our summaries to estimable functions of the parameters, thus avoiding the arbitrariness of any particular solution.

Parameter Constraints. A unique set of parameter estimates for a model of time trends is obtained by setting constraints on the parameters. Sometimes these are selected arbitrarily by a regression program that makes use of a particular generalized inverse when finding **maximum likelihood** estimates. However, it is better for the analyst to specify the constraint and to understand the implications of that constraint.

Drop a Factor. Perhaps the simplest approach to nonidentifiability is the attempt to avoid it by not considering all three factors simultaneously. When fitting such a two-factor model, the interpretation of the results seems quite straightforward, and it may in fact be a very reasonable approach if such a model gives a good fit to the data. However, implicit in any model that drops one of the factors is that it has no effect, i.e. there is neither curvature nor a linear effect due to the factor. As we have already seen, the latter cannot be addressed from the data so that there may still be a lingering source of **bias** in the parameters – the unidentifiable constant ν – which could have influence even if the model shows a good fit to the data.

Equate Two Effects. A second approach to finding a unique set of parameters is to equate just two of the effects for one of the model factors [3, 4, 13], rather than equating all effects for one factor to zero. For instance, two adjacent period effects may be set equal to each other because there is reason to believe that no changes occurred during that epoch, e.g. $\phi_{p1} = \phi_{p2}$. A variation on this approach is an assumption that the mean of the successive differences is zero, which reduces to $\phi_{p1} = \phi_{pJ}$ in the case of period. This is actually the constraint automatically specified by some regression programs for the last factor specified for a model. This constraint is very simple to apply, and it forces the parameters to return to their original level, which can yield parameters that are similar to those obtained by setting the period slope to zero, as discussed below.

The advantage of this approach to the nonidentifiability problem is that it is quite simple to understand

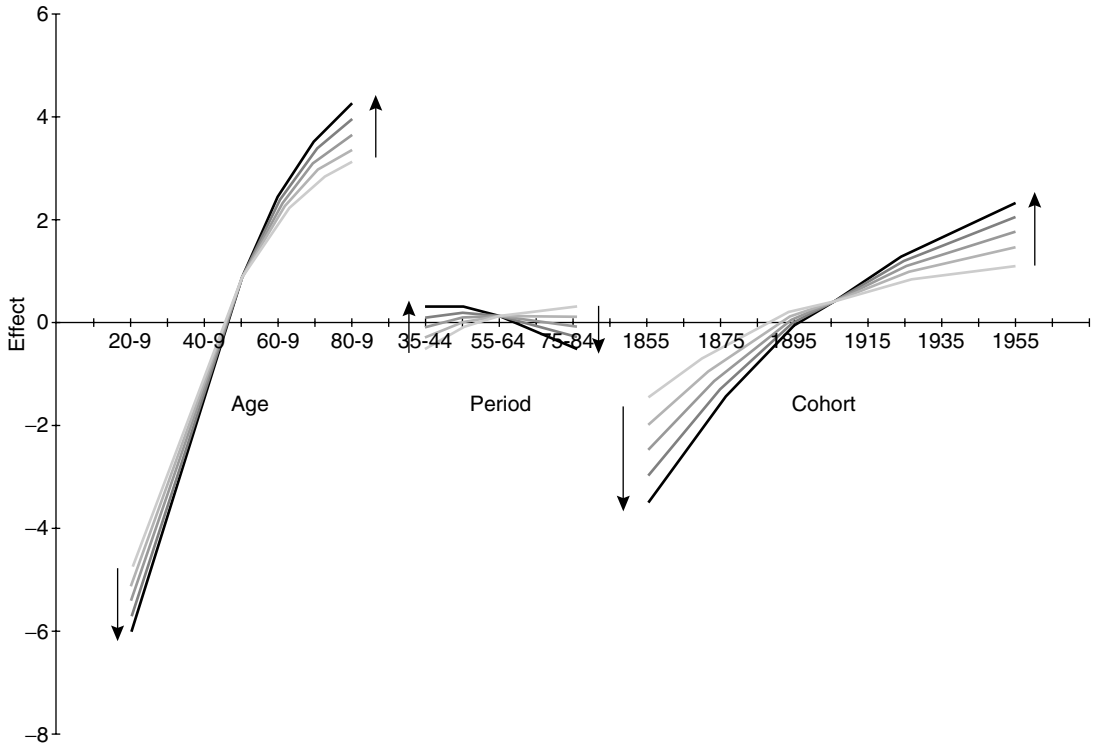

Figure 9 Age, period, and cohort effects in which the period slope takes values $-0.2(0.1)0.2$.

and apply. In addition, it does not force equality for all the effects, as is the case when one of the factors is dropped entirely from the model. Unfortunately, there is usually no more solid basis for equating two effects than reasoning such as: "There is no reason to expect a change during these years; therefore, they will be assumed to be equal." It is often true that equality of the fourth and fifth periods is just as logical as the first and second in a particular situation, and the resulting parameter estimates can vary considerably for these equally plausible assumptions.

Minimize Euclidean Distance to Two-factor Models. Osmond & Gardner [31] propose an approach that estimates the unidentifiable parameter, ν. Their criterion uses the Euclidean distance between the parameters from the age–period–cohort model, and a corresponding model that drops one of the factors, e.g. $\|\phi(\nu) - \phi_{(c)}\|$ in the case of a model that drops cohort. Because age plays a vital role in most responses, it is not eliminated entirely; but rather the fitted values from an age-only model are introduced as offset terms. The estimation criterion is to minimize

$$g(\nu) = \frac{\|\phi(\nu) - \phi_{(c)}\|}{\rho_c} + \frac{\|\phi(\nu) - \phi_{(p)}\|}{\rho_p} + \frac{\|\phi(\nu) - \phi_{(a)}\|}{\rho_a},$$

where ρ_c, ρ_p, and ρ_a are the residual mean squares from the respective models.

While this approach has the advantage of offering a unique set of model parameters, there is some question about whether the criterion is appropriate in general. At one level it seems sensible to give parameters from two-factor models with poor fit (high residual mean squares) less weight, until we recall that we can only estimate curvature in a three-factor model. A factor with a great deal of curvature will result in a relatively large residual mean square for the reduced model, thus receiving less weight according to the estimation criterion. But it is not clear why the parameter that identifies linear trend should be

related to curvature, or indeed to parameters from a two-factor model that may give a poor fit to the data. Alternative underlying models for the overall trends for the time factors can give rise to the same responses, as we have seen, and this approach does not guarantee that we will find the "correct" underlying trend.

Set a Slope to Zero. An alternative to excluding a factor altogether is to assume that its slope is zero. For example, we might specify that there is no period slope, $\beta_p = 0$ [15]. This approach is an immediate extension of the deletion method in that both assume that the overall slope for one factor is zero; however, this approach does not also require that all the curvature terms be set to zero. There may still be unidentifiable bias for all three slopes. Another variation on this theme is to fix the slope over a shorter span of time, rather than the entire span. For example, we might assume that there is no trend with period for the years 1940–1969, a span of three 10-year periods.

Roush et al. [34, 35] undertook a systematic study of cancer incidence using data from the Connecticut Tumor Registry. This analysis focused primarily on the curvature effects for each of the time factors, but in the summary graphs a period slope of zero was specified, $\beta_p = 0$. The rationale for this approach was that: (i) there is a strong biologic basis for an age effect on cancer, so that if only one factor is unimportant it is likely to be either period or cohort; (ii) empirical results strongly suggest that cohort has a stronger association with cancer incidence than period; and (iii) the assumption that $\beta_p = 0$ was less restrictive than ignoring the effect of period altogether.

Restrict the Range of the Slopes. Another way to select constraints on the parameters is to employ theoretical knowledge about the underlying process with respect to one of the time factors. Wickramaratne et al. [41] analyzed the effects of age, period, and cohort on risk of major depression in five US communities. Although a specific assumption about the overall trends with period and cohort was not imposed, it seemed reasonable to assume that there was not a decreasing trend with either period or cohort, i.e. $\beta_p \geq 0$ and $\beta_c \geq 0$. Adding β_c to both sides of the first inequality, and β_p to the second gives $\beta_p + \beta_c \geq \beta_c \geq 0$ and $\beta_p + \beta_c \geq \beta_p \geq 0$. Note that the upper bounds are estimable in each case. Similarly, the age slope must satisfy the inequality $\beta_a + \beta_p \geq \beta_a \geq \beta_a - \beta_c$, which also has estimable upper and lower bounds. Using these bounds, Wickramaratne et al. [41] were able to obtain the qualitative result that there was an increasing trend in the risk of major depression in the cohort born during the years 1935–1944, even though it was not possible to obtain a point estimate for the trend.

Estimable Functions. To avoid the adoption of arbitrary assumptions, estimable functions of the parameters offer summaries that are identical for any particular set of model parameters. In this section we discuss several estimable functions that have been found to be useful.

Forecasting Based on Age–Period–Cohort Models. The problem of **forecasting** trends is one that is difficult because one must necessarily make assumptions regarding trends beyond the range of existing data, which in general cannot be verified. For example, we might assume that the trends of the past will continue into the future, an albeit strong assumption [7, 25] which may well be unwarranted in a particular instance. Nevertheless, it is an assumption that is commonly made in other contexts, and it is one that seems reasonable in the absence of contradictory information. If we make a linear **extrapolation** for all three time parameters, then the resulting projected rates are identifiable [16, 30]. This property can be demonstrated by using a model that only includes linear terms, remembering that more complicated models that include curvature terms present no new problems, because the curvature parameters are estimable. The resulting model for the ith age, jth period, and kth cohort is

$$Y_{ijk} = \mu + i \times \beta_a + j \times \beta_p + k \times \beta_c.$$

Following the same cohort in time by increasing the age and the period index by one unit, gives

$$Y_{i+1,j+1,k} = \mu + (i+1)\beta_a + (j+1)\beta_p + k \times \beta_c,$$

and the difference between the two rates,

$$Y_{i+1,j+1,k} - Y_{i,j,k} = \beta_a + \beta_p,$$

which is an estimable function of the slopes, as we have already seen.

Drift Based on Mean of Successive Differences. We have already noted Clayton & Schifflers' [8, 9] suggestion of using the mean of successive differences as an estimate of overall trend for a particular factor. They also proposed the sum of the period and cohort slopes, $\beta_p + \beta_c$, as an indicator of the overall trend for the outcome during the span of time covered by the data, which they call the net drift. This is an estimable function of the model parameters, and hence it is unique. We can estimate the net drift for any set of parameter estimates by taking the contrast

$$\frac{\phi_{pJ} - \phi_{p1}}{J-1} + \frac{\phi_{cK} - \phi_{c1}}{K-1}.$$

Alternatively, we can estimate the drift for any range of periods and cohorts by using the contrast

$$\frac{\phi_{pj^*} - \phi_{pj}}{j^* - j} + \frac{\phi_{ck^*} - \phi_{ck}}{k^* - k}.$$

Drift Based on Slopes. As an alternative to determining drift on the basis of the mean of first differences, we can use the sum of the least squares estimates of the slopes. This can be expressed in terms of a linear contrast among the period and cohort parameters, $\beta_p + \beta_c = (\mathbf{C}_p'|\mathbf{C}_c') \cdot (\boldsymbol{\phi}_p'|\boldsymbol{\phi}_c')'$, where the elements of contrast vectors are the first-order orthogonal polynomial contrasts defined previously. We accomplish this by concatenating the slope contrasts for period and cohort. The variance for the contrast can be estimated from $\text{var}(\beta_p + \beta_c) = (\mathbf{C}_p'|\mathbf{C}_c') \times \text{var}(\boldsymbol{\phi}_p'|\boldsymbol{\phi}_c')(\mathbf{C}_p'|\mathbf{C}_c')'$.

Curvature Estimates. While nonidentifiability of the slope for a time factor implies that we cannot identify the overall trend, there remains useful information in the curvatures or departures from linear trend which are estimable. In fact, any contrast that is orthogonal to the first-order contrast for linear trend is estimable when the equal age and period intervals are used. Hence, we can determine any aspect of the shape of the curves, including information on whether the trends are concave upward or downward.

This approach can also be applied when looking for spikes in the overall trend lines by considering second differences, such as $D_k = \phi_{c,k} - 2\phi_{c,k+1} + \phi_{c,k+2}$ in the case of cohort [8, 36]. Tango & Kurashina [36] studied such effects by comparing mortality from diabetes, ischemic heart disease, liver cirrhosis, and suicide around the Showa Era, 1925–1940. They found that men born in this era had a higher than expected risk compared with the overall trend among men born in surrounding cohorts. This particular cohort experienced nutritional deprivation in adolescence during World War II, and they contributed extensively to the rapid economic expansion during the 1960s which introduced profound changes to Japanese society.

Because of the overlapping of cohort intervals, Tango & Kurashina [36] also suggested estimating the average of second differences, $(D_k + D_{k+1})/2$.

If we think of second differences as comparing slopes between adjacent points, then a natural extension is to consider changes in slopes over longer spans of time [38]. Suppose that we wish to consider slopes for two such cohort epochs, ϕ_{c1} and ϕ_{c2}, respectively. We already know that because of the identifiability problem, we can only estimate slopes that are aliased, $\phi_{c1}^* = \phi_{c1} + \nu$ and $\phi_{c2}^* = \phi_{c2} + \nu$. However, the difference is estimable because the indeterminant constant, ν, is canceled out.

The change in slope can be estimated using a contrast matrix formed by subtracting vectors that give slopes over the corresponding epochs. For example, if $\mathbf{C}_1$ is the cohort contrast for the slope during the first epoch, and $\mathbf{C}_2$ during the second, then the change in slopes is determined by $(\mathbf{C}_1 - \mathbf{C}_2)$. To illustrate this using the 11 cohorts represented in Table 1, suppose we wish to determine whether there is a significant change in cohort trend for men born from the turn of the century until 1925, and men born in the years following 1925. The resulting contrast would be

$$\begin{aligned}
&(0\ \ 0\ \ 0\ \ 0\ \ 0\ \ -0.5\ \ 0\ \ 0.5\ \ 0\ \ 0\ \ 0)\\
&-(0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ -0.3\ \ -0.1\ \ 0.1\ \ 0.3)\\
&\quad =(0\ \ 0\ \ 0\ \ 0\ \ 0\ \ -0.5\ \ 0\ \ 0.8\ \ 0.1\ \ -0.1\ \ -0.3),
\end{aligned}$$

which yields a Wald statistic of 1.39 on 1 df, and a contrast estimate of 0.172 (se = 0.149).

Autoregressive Models for Time Effects. We have already noted the identifiability of second differences. Berzuini & Clayton [6] propose an autoregressive model for the time effects (*see* **ARMA and ARIMA Models**) in which successive parameters are given by

$$\phi_{c,k} = 2\phi_{c,k-1} - \phi_{c,k-2} + \varepsilon_{ck}$$

in the case of cohort, with similar expressions for age and period. Each term is clearly related to the two previous parameters, along with an added random perturbation, $\varepsilon_{ck} \sim \mathrm{N}(0, \sigma_c^2)$. Berzuini & Clayton describe a **Bayesian method** for estimating the model parameters that employs a Markov chain Monte Carlo algorithm. One of the interesting extensions that this approach offers is Bayesian forecasting of rates, which is also an estimable function of the model parameters, as noted above. This is in contrast to the use of an autoregressive model for the cohort effect by Lee & Lin [26], who used this model to obtain a unique set of parameter estimates. As always, unique estimates for the nonestimable functions of the parameters depend on strong, unverifiable assumptions.

Design Matrices. An alternative to the use of contrasts for parameter estimates is to construct a design matrix with linearly independent columns which will yield a set of parameter estimates that are unique. Of course, the usual approach of constructing a design matrix using dummy variables for each level of age, period, and cohort will necessarily contain a linear dependence because of the dependence among the indices noted above.

A partitioned design matrix that will partition the effects into the linear and curvature components described above can be written as

$$\mathbf{X} = [\mathbf{1}|\mathbf{A}_\mathrm{L}|\mathbf{A}_\mathrm{C}|\mathbf{P}_\mathrm{L}|\mathbf{P}_\mathrm{C}|\mathbf{C}_\mathrm{L}|\mathbf{C}_\mathrm{C}],$$

where each row corresponds to the rate in a particular age and period group. The columns represented by $\mathbf{A}_\mathrm{L}$ and $\mathbf{A}_\mathrm{C}$ are the linear and curvature components for age, and the remaining elements of the design matrix are the corresponding terms for period and cohort. Regression parameters that correspond to the components of this design matrix are given by the vector

$$\boldsymbol{\Theta} = (\phi_0|\beta_\mathrm{a}|\gamma_\mathrm{a}|\beta_\mathrm{p}|\gamma_\mathrm{p}|\beta_\mathrm{c}|\gamma_\mathrm{c})'.$$

The column vector for the age slope, $\mathbf{A}_\mathrm{L}$, may be defined as having the elements $A_{\mathrm{L}i} = i - [I + 1]/2$ for the ith age group. For period and cohort, the slope columns, $\mathbf{P}_\mathrm{L}$ and $\mathbf{C}_\mathrm{L}$, are similarly defined. The linear dependence in this design matrix is readily apparent because $\mathbf{P}_\mathrm{L} = \mathbf{A}_\mathrm{L} + \mathbf{C}_\mathrm{L}$. Thus, a model that includes $\mathbf{A}_\mathrm{L}$ and $\mathbf{C}_\mathrm{L}$ would have already effectively included $\mathbf{P}_\mathrm{L}$. The resulting regression parameter associated with the remaining $\mathbf{A}_\mathrm{L}$ will actually estimate the sum of the age and period slopes, $\beta_\mathrm{a} + \beta_\mathrm{p}$. Likewise, the $\mathbf{C}_\mathrm{L}$ parameter would estimate $\beta_\mathrm{c} + \beta_\mathrm{p}$. These are two of the estimable functions of the slopes noted earlier.

Curvature elements of the design matrix are given by the remaining regressor variables that saturate the effect. If the first and last columns for age in a design matrix containing a 0–1 indicator variable for each category are dropped from the model, then we are effectively constraining $\phi_{\mathrm{a}1} = \phi_{\mathrm{a}I}$, which ultimately yields slopes that correspond to those obtained by considering means of successive differences. However, if we choose to represent the curvatures using variables that are orthogonal to the linear term, then we obtain slopes that correspond to the least squares slopes.

Summary of Estimable Effects. We now summarize the effect of the nonidentifiability problem on our ability to address questions of scientific interest. Without making strong assumptions, we cannot estimate overall changes for age, period, and cohort. This is a severe limitation because some of the most interesting scientific questions relate to whether trends are increasing or decreasing. However, there remain a number of questions that can still be addressed using quantities that are estimable, including:

1. predicted values;
2. slope changes or a deflection of an overall trend;
3. temporary spikes or departures from overall trend; and
4. net drift or combined period and cohort changes.

Interesting scientific questions can often be framed in terms of quantities that are estimable, although it may require us to conceptualize a problem in a different way. Ultimately, we want to produce valid estimates, and if we wish to do that without making strong assumptions about the model parameters, then we need to limit ourselves to estimable functions.

Nonlinear Effects. The difficulty caused by the nonidentifiability problem has led some to consider the use of intrinsically **nonlinear** models. One example is the model used by Moolgavkar et al. [29]:

$$Y_{ijk} = \mu + \phi_{\mathrm{p}j} + \phi_{\mathrm{c}k} + \phi_{\mathrm{a}i} \cdot \delta_j + \varepsilon_{ijk},$$

which was also considered by James & Segal [21]. In this model, $\phi_{\mathrm{p}j}$ and $\phi_{\mathrm{c}k}$ represent the effects due to

period and cohort, respectively. The effect of age, ϕ_{ai}, is included along with a multiplicative factor involving period, δ_j, which can modify the effect of age. Even though a unique set of parameters can result from this model, the parameters can be difficult to estimate and they can be inherently unstable. A special case occurs when

$$\delta_j = 1, \quad \text{for all } j,$$

which is identical to the usual model, and in instances where this gives a good fit to data the parameters are likely to be unstable [9, 36].

Another approach that sometimes leads to nonlinear models involves the theoretical introduction of external information for one of the parameters, thus specifying its functional form. For example, Holford et al. [19] discuss the use of various forms of the multistage carcinogenesis model described by Armitage & Doll [1] for use in the analysis of lung cancer incidence. In this case the effect of age has the same form as a **Weibull hazard**

$$A(a) \propto a^{\omega},$$

where the parameter ω represents the number of stages minus one. If the response represents the log hazard, then the functional form for the age effect becomes

$$\phi_{ai} = \omega \times \ln(a_i),$$

which is no longer linear in age. This and related nonlinear models for age do yield a unique set of model parameters, thus avoiding the adoption of a constraint. However, the unique set of parameters relies heavily on the success of a particular mathematical model in describing the effect of age. Even so, the parameters can be extremely unstable and difficult to estimate using the usual maximum likelihood approach. In addition, the estimates of overall trend can vary widely depending on the model chosen for the effect of age [27, 28].

Replace Temporal Variables. Underlying most studies of time trends is the idea that the effect of time is related to some factor that will affect the outcome. If this is correct, then a better analysis will include a more direct measure of the factor, rather than using time as a surrogate measure. A problem in using a model that employs information on causative agents is that we must have population data on exposure over time. Lung cancer is one instance where such a study is feasible, because we know that cigarette smoking is by far the leading cause of the disease [12, 39], and exposure information is available. Even so, there are several additional facts that must be kept in mind when developing a model, including: (i) smokers often begin in their late teens or early twenties, a fairly narrow age range, so that a change in cigarette consumption primarily affects individuals in these age groups; (ii) there can be a long lag (over 20 years) between the time one starts to smoke until cancer is diagnosed; (iii) not everyone has the same exposure, because some consume more cigarettes, and some cigarettes pose a greater risk; (iv) there is a cumulative effect of smoking, so that individuals who consume the same number of cigarettes per day at one point in time would have different cumulative exposures if they began at different times; and (v) individuals who quit smoking have a risk intermediate between current smokers and those who never smoked [11].

The contribution to risk from beginning to smoke is clearly identifiable with birth cohort [see (i) above]. However, the introduction of filters and other manufacturing changes in cigarettes would be associated with a period effect. Other factors could have components that are identified with both cohort and period. For instance, certain generations may be more health conscious and thus able to quit smoking more readily, a cohort effect, but the overall population might also be influenced by a report from the Surgeon General or an antismoking television advertising campaign, a period effect.

Brown & Kessler [5] fitted a model to US lung cancer mortality that used US data on cigarette composition over time, which would be expected to affect primarily the period parameters. The period effect was expressed as a linear function of a measure of tar, so that the log rate became

$$Y_{ijk} = \phi_0 + \phi_{ai} + \beta X_j + \phi_{ck} + \varepsilon_{ijk},$$

where X_j is a measure of the population's tar exposure for the jth period. While estimates of the prevalence of smoking were not included in the model, the pattern in the estimated cohort effects was similar to the temporal pattern of smoking prevalence, estimated from sample surveys in men and women. The successful use of information on changes in cigarette composition in this particular instance does not necessarily imply that the approach

will be uniformly successful. If there were a strictly linear trend in the mean tar content over time, then the X_j would be linearly dependent on I and k, resulting once again in nonidentifiability. Along similar lines, Holford et al. [20] used population information on the prevalence of smokers, ex-smokers, and mean years smoked to model incidence rates in Connecticut (*see* **Smoking and Health**).

Higher-order Models

Thus far we have only addressed models that include main effects for age, period, and cohort. We now consider work on higher-order models that allow for **interactions**, either with the time factors themselves, or with other groups. The identifiability problem continues to manifest itself in these more complex models; nevertheless, it is possible to address some substantive questions.

Interactions with Temporal Factors. Each of the models considered above assumes that the effect of a time factor is not modified by the level of the others, i.e. there are no interactions. Part of the problem with considering interactions between these temporal variables arises because in any two-factor model the incorporation of an interaction results in a saturated model. For example, if we only consider age and period the model becomes

$$Y_{ij} = \mu + \phi_{\mathrm{a}i} + \phi_{\mathrm{p}j} + \phi_{\mathrm{ap},ij} + \varepsilon_{ij},$$

where $\phi_{\mathrm{a}i}$ and $\phi_{\mathrm{p}j}$ are the main effects for age and period, and $\phi_{\mathrm{ap},ij}$ is the interaction. Comparing this model with the age–period–cohort model, we can see that the only difference between the two is that the first model includes a cohort effect, $\phi_{\mathrm{c}k}$, and the second an age–period interaction, $\phi_{\mathrm{ap},ij}$. Because the interactions saturate the model that only includes main effects due to age and period, we can think of the cohort effect as a particular type of age–period interaction [25]. In a similar way we can describe the period effect as a particular type of age–cohort interaction or the age effect as a particular type of period–cohort interaction, both of which are saturated models. Fienberg & Mason [14] have studied polynomial models for the three time factors, and have indicated which interactions can be identified. The interpretation of interactions in higher-order polynomial models is difficult under the best of circumstances, without complicating things still further with the nonidentifiability problem. Hence, considerable care is needed when introducing interactions into these models.

An alternative to polynomial interactions among temporal factors is simply to split times as, for example, in the comparison of cohort trends in breast cancer among women younger and older than 50 [18]. In one study this division was used because of a suggestion that breast cancer trends may differ between pre- and postmenopausal women [2]. In this instance the model may be written as

$$\log \lambda_{ijk} = \begin{cases} \mu + \phi_{\mathrm{a}i} + \phi_{\mathrm{p}j} + \phi_{\mathrm{c}k} + \phi_{\mathrm{ac},k} + \varepsilon_{ijk}, \\ \quad \text{if } i < i_0, \\ \mu + \phi_{\mathrm{a}i} + \phi_{\mathrm{p}j} + \phi_{\mathrm{c}k} - \phi_{\mathrm{ac},k} + \varepsilon_{ijk}, \\ \quad \text{if } i \geq i_0, \end{cases}$$

where $\phi_{\mathrm{ac},k}$ represents the difference from the mean log rate, and i_0 is the age category where the split is made. This type of interaction would cause no additional difficulties if we were only considering an age–period model, but another complication does arise when cohort is involved. If we follow the cohort diagonals in a typical table of rates, we see that by changing the row or age group at which the interaction occurs, we are at the same time changing the set of cohorts involved in making inferences about the interaction.

Interactions with Nontemporal Factors. Nonidentifiability also affects our ability to compare trends among groups by testing for interactions with the temporal variables. Once again it is convenient to partition the trends into linear and curvature components and, as before, only the linear terms are affected by the identifiability problem. We can express the differences between two groups by

$$(\beta^*_{\mathrm{a}1} - \beta^*_{\mathrm{a}2}) = (\beta_{\mathrm{a}1} - \beta_{\mathrm{a}2}) + (\nu_1 - \nu_2),$$
$$(\beta^*_{\mathrm{p}1} - \beta^*_{\mathrm{p}2}) = (\beta_{\mathrm{p}1} = \beta_{\mathrm{p}2}) - (\nu_1 - \nu_2),$$
$$(\beta^*_{\mathrm{c}1} - \beta^*_{\mathrm{c}2}) = (\beta_{\mathrm{c}1} - \beta_{\mathrm{c}2}) + (\nu_1 - \nu_2),$$

which are clearly aliased. In some circumstances we may be able to assume that the trends for one of the factors are identical for the groups. For example, we may be willing to assume that the age effect reflects an underlying biological process that is the same for all populations, i.e. $\beta_{\mathrm{a}1} - \beta_{\mathrm{a}2} = 0$. Hence, equating the two age linear trends identifies $\nu_1 - \nu_2$, and thus the remaining slope differences.

To illustrate how this result can be used in practice, consider the comparison of lung cancer trends for men and women in Connecticut. We can force the age trends to be equivalent for males and females by fitting a model that includes A, P, C, S, S·P and S·C, where S represents sex and where a dot indicates interaction terms. However, we might question whether it is reasonable to equate the age trends, because there is a variety of biological factors that might result in differences between men and women, including the possible effects of hormonal changes resulting from the menopause. Hence, we may have to settle for comparing the estimable interactions, such as those with curvature trends or drift. Equating age effects may be more reasonable when comparing rates for the same gender among different geographic regions [10]. However, Clayton & Schifflers [9] indicate that there is still the danger of regional differences in age-specific exposure to risk factors which can affect the age parameters.

Polynomials and Splines. In the analyses above, the time factors are treated as categoric, which allows for complete curvature flexibility for the trends. However, in some instances the variances for the individual responses may be large, such as the case when rates are based on small numbers of cases. In these circumstances it may be desirable to smooth the curvature, either by representing the effects by polynomials or by using **spline functions**. For age, these can represented by

$$\phi_{ai} = \left(i - \frac{I+1}{2}\right)\beta_a + X_{a2i}\beta_{a2} + \cdots + X_{api} \times \beta_{ap},$$

where X_{api} represents a regressor variable for a pth-order polynomial or a particular term in a spline function. The usual representation of these regressor variables is highly collinear with the first-order linear term, $i - (I+1)/2$. Thus, the identifiability problem can result in parameters that are difficult to interpret, unless an effort is made to identify the separate components of trend using the principles discussed above.

We can partition the effects into least squares linear components and the remaining curvature by defining regressor variables that are orthogonal to the linear components of trend. In the case of polynomials, this can be accomplished by employing orthogonal polynomials, which give rise to underlying slope parameters that can be interpreted in much the same way as in the models described earlier. Likewise, alternative representations of curvature, such as spline functions, can be constructed by defining variables that are orthogonal to the linear term. This can be accomplished for age by using

$$\mathbf{X}_a^* = \mathbf{X}_a - \mathbf{L}_a(\mathbf{L}_a' \times \mathbf{L}_a)^{-1} \times \mathbf{L}_a' \times \mathbf{X}_a,$$

where $\mathbf{L}_a$ is a vector of linear regressors, $\mathbf{X}_a$ is a matrix or regressor variable, and $\mathbf{X}_a^*$ is the matrix or regressor variable that is orthogonal to $\mathbf{L}_a$. A similar method can be applied to the period and cohort effects. An example of this method is shown in an analysis of thyroid cancer incidence in Connecticut [42].

Nonparametric Methods

A **nonparametric** approach to the analysis of period and cohort trends has been developed by Tarone & Chu [37]. To address the question of a cohort effect, age-specific rates are compared between adjacent cohorts and the total number of decreases is used to construct a permutation test. The **null hypothesis** is that there is no trend with cohort, and the mean and variance of the number of decreases expected out of n comparisons between successive cohorts in the same age group are $n/2$ and $(n+2)/12$ respectively. In a typical rectangular age–period matrix of rates, not all cohorts are represented by the same number of age groups. For example, in the data shown in Table 1 only one age group can be compared for the 1855 and 1955 cohorts, but four each can be made for the four cohorts from 1885 to 1915. The expected number of decreases is

$$\frac{1+2+3+4\times 4+3+2+1}{2} = 14,$$

and the sum of the corresponding variances is 4. Only three decreases are observed in the table, yielding the test statistic $z = (3-14)/4 = -2.75$, which may be compared with a **standard normal deviate**. In this case we can conclude that the rates are not constant across the cohorts.

A similar analysis can be conducted across periods, which results in the same observed and expected numbers of decreases; only the total variance has changed. In the example from Table 1, four comparisons are made in each of seven age groups, resulting

in a total variance of $7 \times (4 + 2)/12 = 3.5$, instead of 4.

Additional refinements offered by Tarone & Chu [37] include the consideration of blocks of cohorts for analysis to address the possibility that cohort effects may only be important during certain epochs and not others (*see* **Blocking**). This raises the issue of **multiple comparisons** that must be taken into account when trying to interpret the results. They also suggest comparing the results of analyses obtained by forming blocks of cohorts with blocks of periods to determine whether one factor predominates in the overall direction of the trends.

THEODORE R. HOLFORD

Aging Models

Models for aging, senescence, and biologic lifespan have come under intensive scrutiny in recent years due to increasing general scientific and medical interest in aging [7]. Projections of "oldest-old mortality", i.e. the mortality of those aged 85 or more in human populations, are important to plan for the future of society. The future of health care, pension, and social security systems critically depends on an assessment of oldest-old mortality and lifespan [9, 22, 25]. Currently, the most long-lived, well-documented person was Jeanne Calmont of France, who died at age 122 in 1997, providing an example of how far human lifespan can extend. Of particular interest recently has been the study and analysis of an observed slowing of mortality that occurs for the survivors into the ranks of the oldest-old (see [5, 15, 29, 32]).

Characteristic features of lifetime data in aging and **demographic** research [14], which distinguish such data from typical survival data such as obtained in cancer clinical trials, include the following. (i) All individuals in a **cohort** enter the study simultaneously (no staggered entry). Entry into the study occurs at a fixed age, often at birth. (ii) A cohort is observed until the last member is dead, and lifetime normally refers to the entire lifespan of each individual. (iii) **Censoring** and **truncation** are only seldom encountered. (iv) The data are usually aggregated in a **life table**. The exact time of death is rarely recorded. The aggregation intervals vary between days (as in biodemographic studies) to five year intervals (as in some human studies). The aggregated nature of the data must be taken into account for model fitting and inference. (v) The behavior of mortality in the right tail, including the study of extreme lifetimes, is of particular interest (oldest-old mortality). (vi) Large initial total cohort sizes are necessary to assure a sufficiently large group of oldest-old. In some studies, this is achieved by simultaneously observing many smaller cohorts, a fact that needs to be taken into account in the analysis. (vii) Individual-level Covariates and events may be recorded at irregular observation intervals before death.

In spite of these particular features, the quantification of aging and mortality is based on the same concepts as are used in survival analysis (*see* **Survival Distributions and Their Characteristics**). The dynamics of mortality in dependence on age are usually measured in terms of the force of mortality, also referred to as instantaneous death rate, **hazard rate**, or hazard function. The hazard rate or force of mortality at age t is defined as

$$\lambda(t) = \lim_{\Delta \to 0} \frac{1}{\Delta} P(t + \Delta > T \geq t | T \geq t),$$

where T denotes lifetime (assumed to be a continuous random variable). The force of mortality $\lambda(t)$ describes the instantaneous risk of dying at age t.

Other functions which equivalently characterize the lifetime distribution (see Cox [6]) are:

1. The survival function

$$\overline{F}(t) = P(T \geq t), \quad t \geq 0,$$

which is related to $\lambda(t)$ via

$$\overline{F}(t) = \exp\left[- \int_0^t \lambda(u)\, \mathrm{d}u \right],$$

$$\lambda(t) = -\frac{\mathrm{d}}{\mathrm{d}t} \log[\overline{F}(t)].$$

2. The probability density function

$$f(t) = \lim_{\Delta \to 0} \frac{1}{\Delta} \Pr(t \leq T < t + \Delta), \quad t \geq 0,$$

which is related to $\lambda(t)$ via

$$f(t) = \lambda(t) \exp\left[- \int_0^t \lambda(u)\, \mathrm{d}u \right],$$

$$\lambda(t) = \frac{f(t)}{\displaystyle\int_0^t f(u)\, \mathrm{d}u}.$$

3. The remaining **life expectancy** function, also referred to as expected residual life function,

$$r(t) = \mathrm{E}(T - t | T \geq t), \quad t \geq 0,$$

where $\mathrm{E}(\cdot|\cdot)$ denotes conditional expectation. The remaining life expectancy function is related to $\lambda(t)$ via

$$r(t) = \int_t^\infty \exp\left[- \int_t^u \lambda(v)\, \mathrm{d}v \right] \mathrm{d}u,$$

$$\lambda(t) = \left\{ \frac{\mathrm{d}}{\mathrm{d}t}[r(t)] + 1 \right\} \Big/ r(t).$$

Note that $r(0)$ is the expected lifetime from birth for individuals. The relative merits of hazard function estimates and remaining life expectancy function estimates are discussed below in the context of a data example.

Mortality data typically are in the form of a life table $(n_i, d_i), i \geq 1$, where for time intervals $[\Delta(i-1), \Delta i]$ of length Δ, n_i is the number of subjects alive and under observation at the beginning of the interval, and d_i is the number of observed deaths in the interval. For data exploration, one usually computes and plots the central death rate or actuarial estimate for such data. Evaluated at $t_i = \Delta(i - 1/2)$, the central death rate is

$$\tilde{q}_c(t_i) = \frac{2d_i}{\Delta(n_i + n_{i+1})}.$$

The central death rate has a rapidly rising variance as the numbers of subjects at risk n_i declines.

A common approach for further analysis is to fit a parametric model to the data, using the maximum likelihood method (*see* **Parametric Models in Survival Analysis**). Given a parametric model with hazard rate (force of mortality) $\lambda(t, \boldsymbol{\theta})$, where $t \geq 0$ denotes age and $\boldsymbol{\theta} \in \mathcal{R}^p$, $p \geq 1$, is a parameter vector, the likelihood function is found to be

$$L(\boldsymbol{\theta}) = \prod_{i=1}^{\infty} \{F(\Delta i, \boldsymbol{\theta}) - F[\Delta(i-1), \boldsymbol{\theta}]\}^{d_i},$$

where $F(t, \boldsymbol{\theta}) = 1 - \exp[-\int_0^t \lambda(u, \boldsymbol{\theta})\, \mathrm{d}u]$ is the distribution function. The maximum likelihood estimator is then, as usual, $\hat{\boldsymbol{\theta}} = \arg\max_{\boldsymbol{\theta} \in \mathcal{R}^p} L(\boldsymbol{\theta})$. Modified versions of L are used for censored data or special sampling schemes, such as occur in the nematode study of Brooks et al. [3].

The standard parametric model for aging and mortality data is the Gompertz model [10], which stipulates that the force of mortality rises exponentially,

$$\lambda(t) = \beta_0 \exp(\beta_1 t), \quad \beta_0, \beta_1 > 0, t > 0,$$

or linearly on the log scale, $\log[\lambda(t)] = \log \beta_0 + \beta_1 t$. This is the hazard rate of an extreme value distribution. The Gompertz model can be motivated in various ways. It is, for instance, obtained as a special case in random walk models of aging, considering physiological age states in a state space [33].

The Gompertz model can also be derived via the "disposable soma theory" of aging, which assumes that reproduction takes away resources for repair and thus leads to faster senescence [2]. Biological consequences and comparisons of Gompertz and Weibull models were studied in [23].

Fitting the Gompertz model to mortality data from various sources, some authors found that, when considering a sample of fitted parameters, the linear relationship $\log \hat{\beta}_0 = c_0 - c_1 \hat{\beta}_1$ with positive constants c_0, and c_1 [24] appears to hold. While this indicates simply a negative correlation between the two fitted parameters, far-reaching consequences have been claimed, including the existence of an upper limit to human lifespan [8].

Other fairly flexible parametric aging models which can be derived from various assumptions are the two-parameter Weibull model [31]

$$\lambda(t) = \frac{\beta_0}{\beta_1} \left(\frac{t}{\beta_1}\right)^{\beta_0 - 1}, \quad \beta_0 > 1, \beta_1 > 0, t > 0,$$

with

$$\log(\lambda(t)) = \log \beta_0 - \beta_0 \log \beta_1 + (\beta_0 - 1) \log t,$$

and the Gompertz–Makeham model [16]

$$\lambda(t) = \beta_0 + \beta_1 \exp(\beta_2 t), \quad \beta_0, \beta_1, \beta_2 > 0.$$

The latter is an extension of the Gompertz model, adding a baseline mortality.

Many other parametric distributions may reasonably be fitted to lifetime data; for instance, a shock model in which the force of mortality is composed of a sum of parameterized Gaussian-type peaks [35]. Examples of Gompertz and Gompertz–Makeham hazard rates (force of mortality) are shown in Figure 1.

Extensions of Gompertz, Gompertz–Makeham, and other models have been proposed [27] by assuming that the individuals vary randomly in their **frailty**, a variation that could be rooted in genetics or environment. Such random effects models are also referred to as heterogeneous or compositional models. An example is the Gompertz model with frailty,

$$\lambda(t|Z) = Z \exp(\beta_1 t), \quad \beta_1 > 0,$$

where Z is a random variable with a **gamma** or **inverse Gaussian distribution**. This model has been discussed by various authors [1, 13].

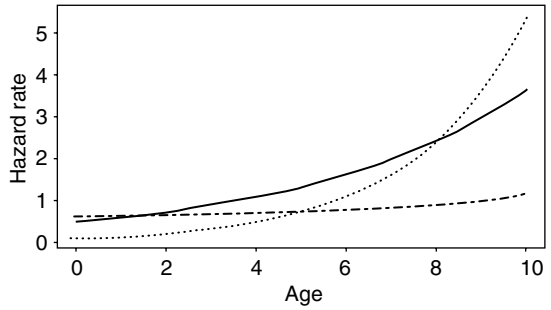

Figure 1 Force of mortality shown for two Gompertz models with parameters $(\beta_0, \beta_1) = (0.5, 0.2)$(———) $(\beta_0, \beta_1) = (0.1, 0.4)$(· · · ·), and a Gompertz–Makeham model with parameters $(\beta_0, \beta_1, \beta_2) = (0.5, 0.1, 0.2)$ (– · – · –)

The idea underlying the frailty approach is that each individual is following its own frailty-determined trajectory of mortality. The ensemble of these random forces of mortality determines the population force of mortality. It is important to note that one cannot conclude that an individual force of mortality is the same as the population force of mortality. This mistake has been made many times in the literature, starting with Gompertz [10]. Indeed, it was demonstrated by Vaupel & Yashin [26] that even if all individuals in a cohort have monotone increasing force of mortality, the population force of mortality may nevertheless be decreasing. The distinction between population and individual force of mortality is of great importance for an understanding of the biologic determinants of aging.

The problems of overfitting and lack of interpretability associated with parametric modeling of aging and mortality have led to recent renewed interest in nonparametric modeling. This requires primarily the nonparametric estimation of the force of mortality from life table data. This problem has a history of more than a century, starting with Gram [11] and important contributions by Hoem [12]. Denote a generic smoother S, like a smoothing **spline** or local linear fit or kernel smoother, based on weight functions W_i and smoothing scatterplot data (t_i, Y_i), by

$$S(t, (t_i, y_i)_{i=1,\ldots,n}) = \sum_{i=1}^{n} W_i(t) Y_i.$$

Letting $\hat{q}(t) = S[t, (t_i, \tilde{q}_i)_{i=1,\ldots,n}]$, which is a smoothed version of the central death rate, a reasonably smoothed force of mortality can be obtained as ([19, 30])

$$\hat{\lambda}(t) = -\log[1 - \hat{q}(t)].$$

An analogous estimate for the remaining life expectancy function is obtained by

$$\hat{r}(t) = S\left\{t, \left(t_i, \frac{1}{n_i}\sum_{j \in N_i}(T_j - t_i)\right)_{i=1,\ldots,p}\right\},$$

where T_j is the lifetime of the jth subject, N_i is the index set of those subjects still at risk at t_i, $N_i = \{j : T_j \geq t_i\}$, and n_i is the number of elements of N_i. The implementation of such smoothers requires choice of a smoothing parameter [18].

As an example for the application of these nonparametric procedures, and to demonstrate how force of mortality and remaining life expectancy function complement each other, consider data on cohorts of female medflies. For details of these data and their analysis, see Müller et al. [20]. Force of mortality and remaining life expectancy function estimates are shown in Figure 2. They have been computed for two groups of medflies: a protein-deprived group (solid lines) and a full-diet group (dashed lines).

A striking finding is a prominent peak in the force of mortality at around day ten, which appears for the protein-deprived group only. This peak corresponds

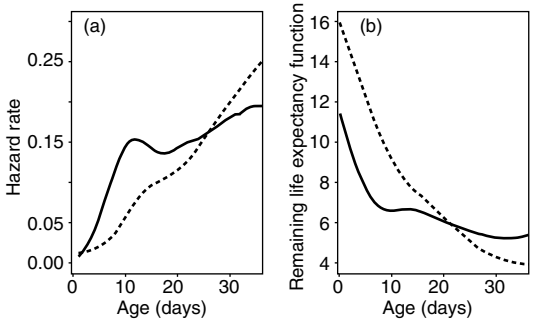

Figure 2 Nonparametric function estimates for force of mortality and remaining life expectancy, based on data of two cohorts of protein-deprived (———) and full diet (- - - -) female medflies of more than 100 000 medflies each. Estimates of hazard rate (force of mortality) (a) and of remaining life expectancy function (b): (a) is a modified version of Figure 1 of Müller et al. [20]

to a sharp drop in the remaining life expectancy function at around the same time. It can be interpreted as the signature of a vulnerable period for female medflies at reproduction. Since such a phenomenon would be hard to anticipate with parametric aging models, this example demonstrates that nonparametric modeling, properly implemented, is capable of establishing novel features by letting the data speak for themselves.

Future work on modeling of aging data is needed to address a multitude of open questions. This is an area of research with impact for society, medicine, and life sciences, in which statisticians can and should make important contributions. Open problems concern the further development of dynamic stochastic models [17, 34], and the incorporation of life history and **covariate** information for lifetime data [4] Addressing these problems requires the development of innovative lifetime regression models, that extend the classical tools of models for the deceleration of aging of the oldest–old [28] and models that include and predict secular trends in mortality, in particular the continuing increases in life expectancy [21, 28].

Agreement, Measurement of

Reliability of measurements taken by clinicians or diagnostic devices is fundamental to ensure efficient delivery of health care. Consequently, clinicians and health professionals are becoming more aware of the need for evaluating the extent to which measurements are error-free and the degree to which clinical scores might deviate from the truth. Specifically, the recorded ratings or findings made during clinical appraisal need to be consistent, whether recorded by the same clinician on different occasions or by different clinicians within a short period of time. The consistency of the ratings reflect agreement, which is a distinct type of association. A clearly defined measure of agreement describes how consistent one clinician's rating of a patient is with what other clinicians have reported (interclinician reliability), or how consistently a clinician rates a patient over a number of occasions (intraclinician reliability). High agreement is indicative of how reproducible the results might be at different times or at other laboratories [9].

Investigators often have some latitude on the choice of how to measure the characteristics of interest in assessing agreement between raters. One practical aspect of this decision may relate to the implications of measuring the characteristic on a continuous or categorical scale. For categorical measurements, or when the levels of a continuous characteristic are categorized, the **kappa** coefficient and its variants seem to be appropriate tools to measure agreement among raters. The kappa coefficient gives an estimate of the proportion of agreement above chance [12]. For interval or continuous scale measurements, we estimate interclinician reliability with the "intraclass correlation coefficient" (ICC) (*see* **Correlation**).

In this paper we review some of the well-known indices of agreement, the conceptual and statistical issues related to their estimation, and interpretation for both categorical and interval scale measurements.

Cohen's Kappa and Darroch's Measure of Category Distinguishability

Let n subjects be classified into c **nominal** scale categories $1, \ldots, c$ by two clinicians using a single rating protocol, and let π_{jk} be the joint probability that the first clinician classifies a subject as j and the second clinician classifies the subject as k. Let $\pi_{j\cdot} = \sum_k \pi_{jk}$, and $\pi_{\cdot k} = \sum_j \pi_{jk}$. There are two questions that need to be addressed; the first is related to the interclinician **bias**, or the difference between two sets of **marginal probabilities** $\pi_{j\cdot}$ and $\pi_{\cdot j}$, while the second is related to the magnitude of $\sum \pi_{jj}$, or the extent of agreement of the two clinicians about individual subjects or objects.

Cohen [12] proposed that a coefficient of agreement be defined by

$$\kappa = \frac{\sum_{j=1}^{c} (\pi_{jj} - \pi_{j\cdot}\pi_{\cdot j})}{1 - \sum_{j=1}^{c} \pi_{j\cdot}\pi_{\cdot j}} \tag{1}$$

as a measure of agreement between two raters or clinicians. Cohen's justification was that the sum of the diagonal probabilities, $\pi_0 = \sum \pi_{jj}$, is the percentage of agreement between the two raters. Since $\pi_e = \sum \pi_{j\cdot}\pi_{\cdot j}$ is the probability of random or chance agreement, it should be subtracted from π_0. The division by $1 - \pi_e$ results in a coefficient whose maximum value is 1, which is attained when $\pi_{jk} = 0$, $j \neq k$. An estimate of κ is obtained by substituting n_{jk}/n for π_{jk}, where n_{jk} is the observed frequency for the j, kth cell.

The definition of κ given in (1) is suitable for $c \times c$ tables with nominal response categories. For ordinal response, Cohen [13] introduced the weighted kappa, κ_w, to allow each cell j, k to be weighted according to the degree of agreement between the jth and kth categories. Assigning weights $0 \leq d_{jk} \leq 1$ to the j, k cell with $d_{jj} = 1$, Cohen's weighted kappa is

$$\kappa_w = \frac{\sum_{j=1}^{c}\sum_{k=1}^{c} d_{jk}(\pi_{jk} - \pi_{j\cdot}\pi_{\cdot k})}{1 - \sum_{j=1}^{c}\sum_{k=1}^{c} d_{jk}\pi_{j\cdot}\pi_{\cdot k}}. \tag{2}$$

The large sampling distribution of the estimated κ_w has been investigated by Everitt [24] and Fleiss et al. [35]. The equivalence of κ_w to the ICC was shown by Fleiss & Cicchetti [32], Fleiss & Cohen [33], Krippendorff [46], and Schouten [61, 62].

In many circumstances the categories into which subjects are classified do not have clear objective definitions. As a result, clinicians may interpret the category definitions differently and the categories may not be completely distinguishable from each other, even by the same clinician. Darroch & McCloud [16] defined the degree of distinguishability from the joint classification probabilities for two clinicians. They derived an average measure of degree of distinguishability, δ, as

$$\delta = 2\sum_{j<k} \frac{\pi_{jj}\pi_{kk} - \pi_{jk}\pi_{kj}}{\pi_{jj}\pi_{kk}} \Big/ c(c-1). \qquad (3)$$

We estimate δ by substituting n_{jk}/n for π_{jk}.

Aickin's Alpha for Nominal Responses

It is evident from the definition of κ that it represents a fraction of subjects not classified in some category by chance; that is, they are classified for reasons other than chance. Aickin [2] attempted to make the notion of "agreement for cause" concrete by introducing another measure of agreement termed "α-measure", later referred to as Aickin's α. He based his argument on the idea that subjects to be classified are drawn from a population which is a mixture of two subpopulations. The first subpopulation consists of subjects which are difficult to classify, so that agreement between the two raters will be by chance alone. The second subpopulation consists of subjects that are easy to classify, so the raters will always agree (agreement for cause). The proposed parameter α is defined as the fraction of the entire population that consists of items that are classified identically for cause rather than by chance.

Interestingly, a case for Aickin's α can be made from reviewing the literature on the reliability of clinical methods. Koran [43] reported a study by Conn et al. [14] on physicians' agreement in diagnosing varices by esophagoscopy. In that study, two "experienced endoscopists" examined 39 male cirrhotic patients for esophageal varices during the same esophagoscopic examination. When the physicians disagreed, the one not reporting varices usually reported prominent mucosal folds, with which varices may be confused. The authors noted that "most diagnostic difficulties occur in the patients in whom esophageal varices are small". Clearly, the more prominent a sign, the easier it should be to recognize. One may argue, then, that in the population of male cirrhotic patients, the fraction with prominent signs is α (those which are easy to classify), while $1-\alpha$ have less prominent signs and therefore are difficult to diagnose.

According to Aickin's setup, let $\pi_{\mathrm{r}}(j)$ and $\pi_{\mathrm{c}}(j)$, $j = 1, 2, \ldots, c$, be any two probability distributions on the classification categories. The joint distribution π_{jk}, governing the classification of a subject by the first clinician in category j, and the second clinician in category k, is defined by

$$\pi_{jk} = (1-\alpha)\pi_{\mathrm{r}}(j)\pi_{\mathrm{c}}(k) + \alpha s^{-1} d_{jk}\pi_{\mathrm{r}}(j)\pi_{\mathrm{c}}(k), \qquad (4)$$

where $d_{jk} = 1$ if a row classification of j and column classification of k are considered to be in agreement; $d_{jk} = 0$ otherwise, and $s = \sum d_{jk}\pi_{\mathrm{r}}(j)\pi_{\mathrm{c}}(k)$.

This can be seen as a mixture of two discrete distributions. The first occurs with probability $1-\alpha$, and is a distribution under which the two classifications are independent with marginal probabilities $\pi_{\mathrm{r}}(j)$ and $\pi_{\mathrm{c}}(k)$ for the two raters. The second which occurs with probability α is a distribution under which there can only be perfect agreement. In this manner the parameter α acquires its meaning as the fraction of the population that produces "agreement for cause" between the two clinicians. A consequence of (4) is

$$\alpha = \frac{\sum_{jk} d_{jk}\pi_{jk} - \sum_{jk} d_{jk}\pi_{\mathrm{r}}(j)\pi_{\mathrm{c}}(k)}{1 - \sum_{jk} d_{jk}\pi_{\mathrm{r}}(j)\pi_{\mathrm{c}}(k)}. \qquad (5)$$

This shows that the parameter α follows the pattern of kappa-like statistics given in (1). The fundamental difference lies in the fact that $\pi_{\mathrm{r}}(j)$ and $\pi_{\mathrm{c}}(k)$ are not marginal table probabilities, but rather the marginal probabilities of the subpopulation of difficult-to-classify patients.

The above model contains $2(c-1)$ marginal probabilities and the α parameter (total of $2c-1$ parameters). Since the saturated model (*see* **Generalized Linear Model**) contains $c^2 - 1$ parameters, the number of **degrees of freedom** are $(c^2-1) - (2c-1) = c(c-2)$. For model fitting by **maximum likelihood** with application to cancer registry data (*see* **Disease Registers**), see Aickin [2].

Monotonic Agreement

Other measures of agreement for ordinal data, which do not involve any assumptions concerning the exact size of the interval between pairs of ordinal classes, are Kendall's τ [42] and **Goodman and Kruskal's** γ [37]. These two statistics measure monotonic agreement. The basic building blocks of most ordinal measures are the concepts of concordant and discordant pairs of observations. For example, select two subjects at random from the $c \times c$ table and let X_l and Y_l represent the lth subject's score by the first and the second rater; X_m and Y_m stand for the corresponding score for the mth subject. A pair is said to be concordant if one of the two subjects is higher (or lower) on both X and Y than the other person. Specifically, if $X_l > X_m$ and $Y_l > Y_m$, or $X_l < X_m$ and $Y_l < Y_m$, then the pair $(X_l, Y_l)(X_m, Y_m)$ is concordant. The simplest way to calculate the total number of concordant pairs, N_C, is to multiply each cell frequency, n_{jk}, by the total number of subjects falling in cells lying to the right and below it and then summing the results. If, on the other hand, $X_l > X_m$ and $Y_l < Y_m$, or $X_l < X_m$ and $Y_l > Y_m$, then the pair is discordant. The total number of discordant pairs in a table, N_D, is obtained by multiplying each cell frequency, n_{jk}, by the total number of subjects in the cells lying to the left and below it, and then summing the results. If there are tied observations, they are given the average of the ranks they would have received if there had been no ties. The formula for τ is

$$\tau = \frac{N_C - N_D}{\left\{\left[\binom{n}{2} - T_1\right]\left[\binom{n}{2} - T_2\right]\right\}^{1/2}}, \qquad (6)$$

where $T_1 = \frac{1}{2}\sum_{j=1}^{c} n_{j\cdot}(n_{j\cdot} - 1)$, $n_{j\cdot}$ being the number of tied observations on the jth group of ties of rater 1, and $T_2 = \frac{1}{2}\sum_{j=1}^{c} n_{\cdot j}(n_{\cdot j} - 1)$, $n_{\cdot j}$ being the number of tied observations in the jth group of ties of rater 2.

Binary Responses: Agreement in the 2 × 2 Table

One of the most familiar and extensively studied types of cross-classification in medical research is the **2 × 2 table**, as shown in Table 1.

Table 1 Classification probabilities into two categories by two raters

		Clinician 1		
		Disease	No disease	
Clinician 2	Disease	π_{11}	π_{12}	$\pi_{1\cdot}$
	No disease	π_{21}	π_{22}	$\pi_{2\cdot}$
		$\pi_{\cdot 1}$	$\pi_{\cdot 2}$	

In addition to the simplicity of computing measures of agreement in such tables, many such measures reduce to functions of the cross-product ratio, $\Phi = \pi_{11}\pi_{22}/\pi_{12}\pi_{21}$, which is the most widely known measure of association in epidemiologic studies.

Recall that a crude measure of agreement is $\pi_0 = \pi_{11} + \pi_{22}$, which is estimated by $\hat{\pi}_0 = (n_{11} + n_{22})/n$. This measure is equivalent to Dunn & Everitt's [22] "matching coefficient of numerical taxonomy". If the clinicians are diagnosing a rare condition, the fact that they agree on the absence of the condition (the frequency, n_{22}) may be considered uninformative. A better measure of agreement in this case is estimated by

$$s = \frac{n_{11}}{n_{11} + n_{12} + n_{21}}. \qquad (7)$$

This is the Jaccard coefficient of numerical taxonomy [20, 22]. Before we discuss other indices of agreement for **binary data**, we show the relationship between **association** and agreement. Such a relationship is harder to demonstrate when the number of categories is larger than two.

First, the Pearson product moment **correlation** in a 2×2 table is

$$\rho = \frac{\pi_{11}\pi_{22} - \pi_{12}\pi_{21}}{(\pi_{1\cdot}\pi_{2\cdot}\pi_{\cdot 1}\pi_{\cdot 2})^{1/2}}, \qquad (8)$$

and its sample estimate is

$$\hat{\rho} = \frac{n_{11}n_{22} - n_{12}n_{21}}{(n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2})^{1/2}}. \qquad (9)$$

The value of ρ varies between -1.0 and 1.0. It equals zero if the two sets of ratings are independent. From Eq. (8), $\rho = 1.0$ if $\pi_{12} = \pi_{21} = 0$, and $\rho = -1.0$ if $\pi_{11} = \pi_{22} = 0$. In this sense, the correlation coefficient gives both the direction and strength of association.

If we standardize the 2×2 table so that both row and column marginal totals are (1/2, 1/2) while the cross-product ratio ϕ remains unchanged, the adjusted cell probabilities are

$$\pi_{11}^* = \pi_{22}^* = \frac{1}{2}\left(\frac{\phi^{1/2}}{\phi^{1/2}+1}\right)$$

and

$$\pi_{12}^* = \pi_{21}^* = \frac{1}{2}\left(\frac{1}{\phi^{1/2}+1}\right)$$

[7, p. 379]. It can be shown that

$$\rho = \frac{\phi - 1}{(\phi^{1/2}+1)^2}.$$

Another well-known measure of association is Yule's Q. It is defined as

$$Q = \frac{\pi_{11}\pi_{22} - \pi_{12}\pi_{21}}{\pi_{11}\pi_{22} + \pi_{12}\pi_{21}} = \frac{\phi - 1}{\phi + 1}. \tag{10}$$

Clearly, the cell probabilities in Table 1 can be reparameterized and rewritten as functions of any of the above measures of association. In terms of ρ we have

$$\begin{aligned}
\pi_{11} &= \pi_{1\cdot}\pi_{\cdot 1} + \rho\omega, \\
\pi_{22} &= \pi_{2\cdot}\pi_{\cdot 2} + \rho\omega, \\
\pi_{12} &= \pi_{1\cdot}\pi_{\cdot 2} - \rho\omega, \qquad (11)
\end{aligned}$$

and

$$\pi_{21} = \pi_{\cdot 1}\pi_{2\cdot} - \rho\omega,$$

where $\omega = (\pi_{1\cdot}\pi_{2\cdot}\pi_{\cdot 1}\pi_{\cdot 2})^{1/2}$. Shoukri et al. [66] showed that Cohen's kappa can be written as

$$\kappa = \frac{2\rho\omega}{\pi_{1\cdot}\pi_{\cdot 2} + \pi_{\cdot 1}\pi_{2\cdot}} \tag{12}$$

$$= \frac{2(\pi_{11}\pi_{22} - \pi_{12}\pi_{21})}{\pi_{1\cdot}\pi_{\cdot 2} + \pi_{\cdot 1}\pi_{2\cdot}}. \tag{13}$$

Note that, when the two raters are **unbiased** relative to each other, i.e. $\pi_{1\cdot} = \pi_{\cdot 1}$, then $\kappa = \rho$. It is also noted that perfect association ($\rho = 1$) does not generally imply perfect agreement (unless $\pi_{1\cdot} = \pi_{\cdot 1}$).

Rogot & Goldberg [59] proposed another index of agreement based on the **conditional probabilities** $\pi_{11}/\pi_{1\cdot}$, $\pi_{11}/\pi_{\cdot 1}$, $\pi_{22}/\pi_{2\cdot}$, $\pi_{22}/\pi_{\cdot 2}$. Their proposed index is

$$A_1 = \frac{1}{4}\left[\frac{\pi_{11}}{\pi_{1\cdot}} + \frac{\pi_{11}}{\pi_{\cdot 1}} + \frac{\pi_{22}}{\pi_{2\cdot}} + \frac{\pi_{22}}{\pi_{\cdot 2}}\right]. \tag{14}$$

The chance expected value of A_1 was shown by Fleiss [28] to be 1/2. Hence, their chance corrected measure is

$$M(A_1) = \frac{A_1 - \frac{1}{2}}{1 - \frac{1}{2}} = \frac{2(\pi_{11}\pi_{22} - \pi_{12}\pi_{21})}{\left(\frac{1}{\pi_{1\cdot}\pi_{2\cdot}} + \frac{1}{\pi_{\cdot 1}\pi_{\cdot 2}}\right)}.$$

Recently, Hirji & Rosove [40] argued that an ideal measure of agreement should have the following characteristics:

1. In the case of perfect agreement, it should yield a standard value, usually 1.
2. In the case of perfect disagreement, it should also yield a standard value, of -1.
3. When the two raters are independent, it should return a value of 0.

They proposed an index of agreement that satisfies the above characteristics. They defined λ_i such that

$$1 + \lambda_i = \frac{\pi_{ii}}{\pi_{i\cdot}} + \frac{\pi_{ii}}{\pi_{\cdot i}}. \tag{15}$$

Clearly, $1 + \lambda_1$ is the sum of the conditional probabilities of agreement given that the first rater classifies a patient as diseased and the conditional probability of agreement given that the second rater classifies the patient as diseased, and λ_2 has a complementary interpretation. Note that $-1 \le \lambda_i \le 1$. Hirji & Rosove [40] defined an overall measure of agreement, λ, as

$$\begin{aligned}
\lambda &= \frac{\lambda_1 + \lambda_2}{2} \\
&= 2A_1 - 1. \qquad (16)
\end{aligned}$$

It is easy to see that the chance corrected value of λ is 0, and that it satisfies the above three characteristics. The maximum likelihood estimate of λ is obtained by replacing π_{ii} by n_{ii}/n. Hirji & Rosove [40] extended their index of agreement to the case of multiple categories.

Armitage et al. [3] proposed, as another index of agreement, the **standard deviation** of the subject's total scores, where a subject scores 2 if both raters judged them positive, 1 if one observer judged a subject positive and the other negative, and 0 if both observers judged a subject negative. Their index of agreement is easily shown to be

$$\mathrm{SD}^2 = \pi_{11} + \pi_{22} - (\pi_{11} - \pi_{22})^2. \tag{17}$$

Fleiss [28] noted that the above measure is inadequate since it does not have the range of values required by the traditional index. He suggested rescaling SD^2 to become

$$RSD^2 = \frac{\pi_{11} + \pi_{22} - (\pi_{11} - \pi_{22})^2}{1 - \left(\frac{\pi_{1\cdot} + \pi_{\cdot 1}}{2} - \frac{\pi_{2\cdot} + \pi_{\cdot 2}}{2}\right)^2}, \quad (18)$$

which will have the desired range of variation. In fact, $RSD^2 = 1$ if $\pi_{12} = \pi_{21} = 0$ and $RSD^2 = 0$ if $\pi_{11} = \pi_{22} = 0$. As before, a **consistent estimator** of RSD can be obtained by replacing π_{ij} by n_{ij}/n.

Under marginal homogeneity ($\pi_{1\cdot} = \pi_{\cdot 1} = \pi$), or when the raters are deemed unbiased relative to each other (as in test–retest reliability studies), Table 1 can be rewritten as Table 2.

Thus, (11) becomes

$$\pi_{11}(\kappa) = \pi^2 + \kappa\pi(1-\pi),$$
$$\pi_{22}(\kappa) = (1-\pi^2) + \kappa\pi(1-\pi), \quad (19)$$

and

$$\pi_{12}(\kappa) = \pi_{21}(\kappa) = \pi(1-\pi)(1-\kappa).$$

The maximum likelihood estimates of π and κ are given, respectively, as

$$\hat{\pi} = \frac{2n_{11} + n_{12} + n_{21}}{n} \quad (20)$$

and

$$\hat{\kappa} = \frac{4(n_{11}n_{22} - n_{12}n_{21}) - (n_{12} - n_{21})^2}{(2n_{11} + n_{12} + n_{21})(2n_{22} + n_{12} + n_{21})}. \quad (21)$$

This estimator of κ is identical to the estimator of an intraclass correlation coefficient for 0–1 data [72, pp. 294–296; [9]], and was proposed by Scott [63] as a measure of agreement between two clinicians when their underlying base rates are the same (i.e. marginal homogeneity). Bloch & Kraemer [9] derived a $\sin^{-1}$ transformation (*see* **Delta Method**) to stabilize the variance of $\hat{\kappa}$. Calculations of confidence intervals are eased using such a transformation.

Table 2 2×2 table with marginal homogeneity

		Clinician 1		
		Disease	No disease	
Clinician 2	Disease	π_{11}	π_{12}	π
	No disease	π_{21}	π_{22}	$1-\pi$
		π	$1-\pi$	

The observed frequencies n_{11}, n_{12}, and n_{22} follow a **multinomial distribution** conditional on $n = n_{11} + n_{12} + n_{21} + n_{22}$, with estimated probabilities $\hat{\pi}_{11}(\kappa)$, $\hat{\pi}_{12}(\kappa)$, and $\hat{\pi}_{22}(\kappa)$, where we obtain $\hat{\pi}_{ij}(\kappa)$ by replacing π by $\hat{\pi}$ in (20). It follows that

$$\chi^2_G = \frac{[n_{11} - n\hat{\pi}_{11}(\kappa)]^2}{n\hat{\pi}_{11}(\kappa)} + \frac{[n_{12} - n\hat{\pi}_{12}(\kappa)]^2}{n\hat{\pi}_{12}(\kappa)} + \frac{[n_{22} - n\hat{\pi}_{22}(\kappa)]^2}{n\hat{\pi}_{22}(\kappa)} \quad (22)$$

has a limiting **chi-square distribution** with one **degree of freedom**.

Donner & Eliasziw [19] obtained corresponding two-sided **confidence limits** on κ by finding the admissible roots $(\hat{\kappa}_L, \hat{\kappa}_U)$ to the equation $\chi^2_G = \chi^2_{(1,1-\alpha)}$, which is cubic in $\hat{\kappa}$, where $\chi^2_{(1,1-\alpha)}$ is the $100(1-\alpha)$ percentile point of the chi-square distribution with one degree of freedom. They provided explicit expressions for $\hat{\kappa}_L$ and $\hat{\kappa}_U$; this method of estimation was referred to as the **goodness-of-fit** (GOF) method.

The **simulation** study conducted by Donner & Eliasziw [18] showed that the coverage levels associated with the GOF procedure are close to nominal over a wide range of parameter values (π, κ) in samples having as few as 25 subjects.

Some Remarks on the Use of Kappa

The purpose of this Section is to bring to the reader's attention some of the conceptual issues that arise when the kappa coefficient is used as an index of quality of measurements for a binary variable. Some of these issues have received attention; we mention, among others, Carey & Gottesman [11], Spitznagel & Helzer [69], Feinstein & Cicchetti [25, 26], and Thompson & Walter [70, 71].

Since the device by which subjects can be correctly classified may not be available, then neither of the two raters is a valid indicator of the true state of the subject to be classified. However, the magnitude of the simple index of chance corrected agreement between the two raters may provide a valid

interpretation of the true state of a subject. Thompson & Walter [70] showed that the kappa coefficient depends not only on the **sensitivity** and **specificity** of the two raters, but also on the true **prevalence** of the condition. They showed that, under the assumption that the classification errors are conditionally independent (an assumption that may hold if the two raters have a different biological basis for classifying subjects), kappa is given by

$$\text{kappa} = \frac{2\pi(1-\pi)(1-\theta_1-\eta_1)(1-\theta_2-\eta_2)}{p_1(1-p_2)+p_2(1-p_1)}, \tag{23}$$

where π is the true proportion having the condition, $\theta_i = 1 - \textit{specificity}$ for the ith rater, $\eta_i = 1 - \textit{sensitivity}$ for the ith rater, and $p_i = \pi(1-\eta_i) + (1-\pi)\theta_i$ is the proportion classified as having the condition according to the ith rater ($i = 1, 2$). The strong dependence of kappa on the true prevalence π complicates its interpretation as an index of agreement. Thompson & Walter [70] stated that it is not appropriate to compare two or more kappa values when the true prevalences of the conditions compared may differ. For further discussion on misinterpretation and misuse of kappa, we refer the reader to Bloch & Kraemer [9], Thompson & Walter [71], and Maclure & Willett [52]. Other issues related to modeling of kappa can be found in recent reviews by Kraemer [45] and Agresti [1].

Agreement of Multiple Raters Per Subject

In the previous section we discussed indices of agreement for present/absent characteristics as measured by two raters. Here we discuss the issue of agreement when more than two raters classify groups of subjects for dichotomous data. We distinguish between two situations: (i) when the subjects are evaluated by the same group of clinicians. This situation occurs in practice when a group of clinicians are presented with samples of slides, X-rays, or radiograms, and based on some clearly identified protocol each item is classified as having/not having the characteristic; (ii) when subjects are classified by different (possibly unequal) numbers of raters. For example [34], the subjects may be hospitalized mental patients, the studied condition may be the presence or absence of some psychological disorder, and the raters may be those psychiatry residents, out of a much larger pool, who happen to be on call when a patient is newly admitted. Not only may the particular residents responsible for one patient be different from those responsible for another, but different numbers of residents may provide diagnoses on different patients.

Let Y_{ij} represent the assessment of the ith subject by the jth rater, $(i = 1, \ldots, n; j = 1, \ldots, k)$, with $Y_{ij} = 1$ if the ith subject is judged by the jth rater to have the condition, and 0 otherwise. Let $Y_{i\cdot}$ represent the total number of raters who judged the ith subject to have the condition, and let $y_{\cdot j}$ represent the total number of subjects the jth rater judges to have the condition. Finally, let $Y_{\cdot\cdot}$ represent the total number of subjects for which the condition is judged to be present.

Since the raters differ in their sensitivities and specificities, it may be of interest to test whether these differences are statistically significant. This test is equivalent to testing the equality of the observed marginal probabilities. The appropriate test of marginal homogeneity for binary data is the use of Cochran's Q statistic [27; 20, pp. 141–142].

If we make the a priori assumption of no rater bias, then an estimate of the reliability kappa can be obtained from the **analysis of variance** (ANOVA) just as if the results were interval scores. From the ANOVA table a **variance components** estimate of reliability is

$$\hat{\rho}_{1\omega} = \frac{\text{MSBS} - \text{MSE}}{\text{MSBS} + (k-1)\text{MSE}}, \tag{24}$$

where MSBS is the between-subject mean square, MSE is the mean square error, and k is the number of raters. For a reasonably large number of subjects, $\hat{\rho}_{1\omega}$ is approximately equivalent to

$$R_1 = \frac{\text{SSBS} - (\text{SSBR} + \text{SSE})}{\text{SSBS} + \text{SSBR} + \text{SSE}}, \tag{25}$$

where SSBR is the sum of squares due to raters, SSBS is the sum of squares due to subjects, and SSE is the error sum of squares. Fleiss [28] demonstrated that, for $k = 2$, R_1 in (25) is mathematically identical to $\hat{\kappa}$ in (21). Therefore the assumption of marginal homogeneity in the calculation of chance-corrected kappa is equivalent to that of ignoring rater bias using the one-way ANOVA model for derivation of the variance component estimate of the intraclass reliability coefficient. If one were not prepared to

assume the lack of rater bias, then the appropriate model would either be a two-way **random effects** ANOVA, or a two-way mixed model [20, p. 146] (*see* **Experimental Design**). For the random effects model, the appropriate intraclass correlation can be estimated by

$$\hat{\rho}_{2\omega\mathrm{R}} = \frac{\hat{\sigma}_{\mathrm{g}}^2}{\hat{\sigma}_{\mathrm{g}}^2 + \hat{\sigma}_{\mathrm{c}}^2 + \hat{\sigma}_{\mathrm{e}}^2}, \tag{26}$$

where

$$\hat{\sigma}_{\mathrm{g}}^2 = \frac{\mathrm{MSBS} - \mathrm{MSE}}{k},$$
$$\hat{\sigma}_{\mathrm{c}}^2 = \frac{\mathrm{MSBR} - \mathrm{MSE}}{n},$$
$$\hat{\sigma}_{\mathrm{e}}^2 = \mathrm{MSE},$$

and MSBR is the "between raters" mean square. $\hat{\sigma}_{\mathrm{g}}^2, \hat{\sigma}_{\mathrm{c}}^2$, and $\hat{\sigma}_{\mathrm{e}}^2$, are, respectively, the variance component estimates for subjects, raters, and error. Fleiss [28] demonstrated that (26) is approximately the same as

$$R_2 = \frac{\mathrm{SSBS} - \mathrm{SSE}}{\mathrm{SSBS} + \mathrm{SSE} + 2\mathrm{SSBR}}. \tag{27}$$

For $k = 2$, R_2 is mathematically equivalent to the estimated value of kappa in (13), i.e.

$$R_2 = \hat{\kappa} = \frac{2(n_{11}n_{22} - n_{12}n_{21})}{n_{1\cdot}n_{\cdot 2} + n_{\cdot 1}n_{2\cdot}}. \tag{28}$$

In the second situation, when subjects are assigned different numbers of patients, Fleiss & Cuzick [34] extended the definition of the estimate of kappa to

$$\hat{\kappa} = 1 - \frac{1}{n(\overline{k} - 1)\hat{\pi}(1 - \hat{\pi})} \sum_{i=1}^{n} \frac{R_i(k_i - R_i)}{k_i}, \tag{29}$$

where

$$\overline{k} = \frac{1}{n}\sum_{i=1}^{n} k_i, \quad R_i = \sum_{j=1}^{k_i} y_{ij} \quad \text{and} \quad \hat{\pi} = \frac{1}{n\overline{k}} \sum_{i=1}^{n} R_i.$$

They also showed that $\hat{\kappa}$ is asymptotically (as $n \to \infty$) equivalent to the estimated intraclass coefficient

$$\hat{\kappa} = \frac{\mathrm{MSBS} - \mathrm{MSE}}{\mathrm{MSBS} + (k_0 - 1)\mathrm{MSE}}, \tag{30}$$

where

$$k_0 = \frac{1}{n-1}\left[\sum k_i - \frac{\sum k_i^2}{\sum k_i}\right]$$

(see Fleiss [30]).

Another estimate of the reliability kappa was constructed by Mak [53], and was given as

$$\tilde{\kappa} = 1 - \frac{2}{n(n-1)} \times \left[\sum_i \frac{R_i}{k_i} \sum_i \frac{k_i - R_i}{k_i} - \sum \frac{R_i(k_i - R_i)}{k_i^2}\right]. \tag{31}$$

When all the k_i are equal, the estimators $\hat{\kappa}$ of (30) and $\tilde{\kappa}$ are asymptotically equivalent as $n \to \infty$.

Agreement of Multiple Readings with Unanimous and Majority Rules

In this Section we discuss agreement from a different direction. If a single observation per subject does not produce a satisfactory value for kappa, then a sufficient number of repeated observations on each subject may produce a score close to the consensus score. Kraemer [44] has shown that, if there are k independent raters, then the reliability of the proportion of positive ratings is

$$R \simeq \frac{k\hat{\kappa}}{1 + k\hat{\kappa}}, \tag{32}$$

where $\hat{\kappa}$ is the estimated kappa when each subject is measured once by each rater.

Lachenbruch [47] introduced a **sequential** strategy for the use of the k tests. The tests are assumed to be given in a fixed order: the second test is applied after the results of the first are known, the third test is applied after the results of the second are known, and so on. We may consider one of two rules for the combination of the individual test results. To declare a subject as positive, the unanimity rule requires that all of the individual tests yield positive results. The majority rule requires that the majority of the individual tests yield positive results (which means an odd number of diagnostic tests being administered).

For example, if we have three diagnostic tests which are given in a fixed order, the unanimity rule implies that the negative individuals give the results

$(-)$, $(+-)$, $(++-)$, while the positives are $(+++)$. Assuming, for simplicity, that each of the three tests has the same specificity η and also the same sensitivity θ, then the specificity of the unanimous rule is given by

$$\text{SPEC} = 1 - (1 - \eta)^3,$$

and its sensitivity is

$$\text{SENS} = \theta^3.$$

Clearly, SENS $< \theta$, while SPEC $> \eta$.

The above derivations are based on the assumption that θ and η are constant across subjects. Lachenbruch [47] considers cases when this assumption is relaxed. Note also that the above derivations are dependent on the assumption of independence of the diagnostic tests. Lui [51] assessed the effect of the intraclass correlation ρ under the unanimity rule. When $\rho = 1$, the multiple reading procedure will yield the same sensitivity and specificity as those of a single reading. For small values of ρ, SENS $< \theta$ and SPEC $> \eta$, as stated above.

Interval Scale Agreements

In the first part of this review we were concerned with measures of agreement for categorical responses. Categories may be nominal, ordinal, or the result of categorizing a continuous variable. The advantage of such categorization makes the index of agreement easier to comprehend and interpret; a disadvantage is the dependence of the value of the index of agreement on the number of categories. Hermann & Kliebsch [39] demonstrated that quadratically weighted kappa coefficients tend to increase with the number of categories. Their findings contrast with findings by MacLure & Willett [52] for unweighted kappa coefficients, which decrease with the number of categories.

In the second part of this article, we discuss agreement for inherently continuous measurement, whereby categorization may not be advantageous. For example, if two trained nurses measure the weight of an infant to the nearest milligram, experience shows us that the two measurements will usually not be identical, and that differences of 10–20 g are not uncommon. Differences may, in part, be due to the effect of the rater and in part due to **measurement error**. Dunn [21] reported that it is not uncommon among clinical psychologists, for example, to use **linear regression** to associate the two sets of measurements, which is not appropriate when the two rating devices commit measurement error. Moreover, product–moment correlation coefficients are measures of association and should not be used as indices of agreement.

In his recent review, Dunn [21] classified reliability studies into two types. The first involves the comparison of two or more raters (or measuring instruments) and the second explicitly examines the sources of variability in measurements. The distinction between the two is not always clear-cut.

The simplest design used to assess the reliability or the agreement between sets of scores is the one-way random effects model. Suppose that we have n patients and we would like to take several measurements by a single device. How can we assess the consistency of the set of measurements taken from each patient? The one-way model stipulates that

$$Y_{ij} = \mu + s_i + e_{ij}, \tag{33}$$

where Y_{ij} is the jth measurement taken on the ith subject, μ is the bias, s_i is the subject effect, and e_{ij} is a random measurement error, assumed independent of s_i, where $s_i \sim \text{N}(0, \sigma_\text{s}^2)$ and $e_{ij} \sim \text{N}(0, \sigma_\text{e}^2)$.

The reliability estimate of R is defined as

$$R = \frac{\hat{\sigma}_\text{s}^2}{\hat{\sigma}_\text{s}^2 + \hat{\sigma}_\text{e}^2} \tag{34}$$

(see [23, 54, 31], and [4]). Here, $\hat{\sigma}_\text{s}^2$ and $\hat{\sigma}_\text{e}^2$ are the estimates of the corresponding variance components and are obtained from the one-way random effects ANOVA. This reliability estimate is the familiar estimate of the intraclass correlation coefficient (ICC) (Snedecor & Cochran [68]). It is clear, then, that a precise estimate of R depends on the precision of estimating σ_s^2 and σ_e^2. It is noted by Dunn [21] that R is not a fixed characteristic of a measuring device–it changes with the population of subjects being sampled. This is analogous to the effect of prevalence on the kappa statistic. However, the estimate is useful as an indicator of how a particular device will perform in a particular clinical setting. As can be seen from the definition of the ICC estimate in (34), low ICC occurs when the variation between subjects is low relative to that within subjects. This means that, in a typical **reliability study** it is desirable to have low differences between readings

for a given subject and large differences between subjects. Large between-subject differences usually reflect the condition where the raters are given the chance to test their skills with a full range of a measurement scale. Normal subjects, or subjects with predefined severity, are examples of a narrow range study where raters' reliability is a test only of agreement on the absence of the condition or a subsection of the disease scale, and not a test of the instrument on the full range (see [5]).

Rater Comparison

Two Raters

Bland & Altman [8] described the following clinical experiment. Data on cardiac stroke volume or blood pressure using direct measurement without adverse effects are difficult to obtain. The true values remain unknown. Instead, indirect methods are used, and a new method has to be evaluated by comparison with an established technique. If the new method agrees sufficiently well with the old, then the old may be replaced. When the two methods are compared, neither provides an unequivocally correct measurement. We need to assess the degree of agreement.

Bland & Altman [8] recommended plotting the difference between the two measurements $(Y_{i1} - Y_{i2})$ against their mean $(Y_{i1} + Y_{i2})/2$. This plot can be useful in detecting systematic bias, **outliers**, and whether the variance of the measurements is related to the mean.

Alternatively, we can simply plot Y_{i1} against Y_{i2}. We would like to see, within tolerable error, that the measurements fall on a 45° line through the origin. Lin [49] provided several graphs demonstrating how the Pearson correlation coefficient fails to detect any departure from the 45° line. For example, if the measurement taken by rater $2(Y_{i2})$ has systematic bias relative to rater 1, i.e. $Y_{i1} = Y_{i2} - c$, where c is a fixed constant, then Pearson's correlation will attain its maximum value of 1 while there is little or no agreement between Y_{i1} and Y_{i2}. The **least squares** approach may fail to detect departure from the intercept equal to 0 and slope equal to 1 (see [48; 65, p. 37].

Based on a **random sample** of n subjects, where the ith subject provides the pairs of measurements (Y_{i1}, Y_{i2}) taken by the two raters, Lin [49] constructed a measure of agreement between readings which he called "concordance correlation" (CC). Assuming that $(Y_{i1}, Y_{i2}), i = 1, 2, \ldots, n$, have a **bivariate normal distribution** with means μ_1, μ_2 and **covariance matrix**

$$\begin{bmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{bmatrix}, \tag{35}$$

where ρ is Pearson's correlation, then the concordance correlation is defined as

$$\rho_c = \frac{2\rho\sigma_1\sigma_2}{\sigma_1^2 + \sigma_2^2 + (\mu_1 - \mu_2)^2}. \tag{36}$$

Let $\beta_1 = \rho\sigma_1/\sigma_2$ and $\beta_0 = \mu_1 - \beta_1\mu_2$. Then,

$$\rho_c = \frac{2\beta_1\sigma_2^2}{(\sigma_1^2 + \sigma_2^2) + [(\beta_0 - 0) + (\beta_1 - 1)\mu_2]^2}, \tag{37}$$

and thus the sample estimate of ρ_c is

$$\hat{\rho}_c = \frac{2s_{12}}{s_1^2 + s_2^2 + (\overline{y}_1 - \overline{y}_2)^2}. \tag{38}$$

The concordance correlation has the following properties:

1. $-1 \le -|\rho| \le \rho_c \le |\rho| < 1$
2. $\rho_c = 0$ if and only if $\rho = 0$
3. $\rho_c = \rho$ if and only if $\sigma_1 = \sigma_2, \mu_1 = \mu_2$
4. $\rho_c = \pm 1$ if and only if $\rho = \pm 1, \sigma_1 = \sigma_2, \mu_1 = \mu_2$.

It is also clear from (36) that the magnitude of ρ_c is inversely related to the bias $= |\mu_1 - \mu_2|$.

As an alternative procedure for assessing agreement between the two raters, Bradley & Blackwood [10] suggested regressing $Y_i = (Y_{i1} - Y_{i2})$ on $X_i = (Y_{i1} + Y_{i2})/2$. A simultaneous test of $\mu_1 = \mu_2$ and $\sigma_1^2 = \sigma_2^2$ is conducted using the F statistic,

$$F(2, n-2) = \frac{\sum Y_i^2 - \text{SSReg}}{2\text{MSReg}},$$

where SSReg and MSReg are the residual sum of squares and the mean square with $n - 2$ degrees of freedom, respectively, from the regression of Y on X.

Suppose now, as in Bland & Altman [8], that each of the two raters or methods provides two replicates, as in Table 3.

Let

$$x_{ij} = \mu + s_i + \xi_{ij} \tag{39}$$

Table 3 Comparing two raters with two replicates per subject

Rater	Subject 1	2	...	n
1	x_{11}	x_{21}		x_{n1}
	x_{12}	x_{22}		x_{n2}
2	y_{11}	y_{21}		y_{n1}
	y_{12}	y_{22}		y_{n2}

and

$$y_{ij} = \mu + s_i + \eta_{ij}, \quad i = 1, 2, \ldots, n; j = 1, 2. \tag{40}$$

It is assumed that $s_i \sim \mathrm{N}(0, \sigma_s^2)$, $\xi_{ij} \sim \mathrm{N}(0, \sigma_\xi^2)$, and $\eta_{ij} \sim \mathrm{N}(0, \sigma_\eta^2)$, and that s_i, ξ_{ij}, and η_{ij} are mutually independent. As can be seen, the relative bias between the two raters, μ, is assumed constant. The above equations represent regression models where both variables are measured with error.

Dunn [21] suggested that the analysis starts with estimating the within-subjects mean squares by fitting two separate one-way ANOVAs – one for each rater. The estimated reliabilities are

$$R = \frac{\mathrm{BSMS} - \mathrm{WSMS}}{\mathrm{BSMS} + \mathrm{WSMS}} \tag{41}$$

(see [31]), where BSMS is the between subjects mean square and WSMS the corresponding within subjects mean square.

Let $x_i^* = (x_{i1} + x_{i2})/2$ and $y_i^* = (y_{i1} + y_{i2})/2$. Grubbs [38] showed that the maximum likelihood estimates of σ_s^2, σ_ξ^2, and σ_η^2 are given, respectively, as $\hat{\sigma}_s^2 = s_{xy}, \hat{\sigma}_\xi^2 = 2(s_{xx} - s_{xy})$, and $\hat{\sigma}_\eta^2 = 2(s_{yy} - s_{xy})$, where $(n-1)s_{\mathrm{ab}} = \sum_{i=1}^n (a_i - \overline{a})(b_i - \overline{b})$ and $\overline{a} = 1/n \sum_{i=1}^n a_i$.

The **null hypothesis** that the two raters are equally precise ($\mathrm{H}_0 : \sigma_\xi^2 = \sigma_\eta^2$) can be tested using a result due to Shukla [67], who showed that H_0 is rejected whenever $t_0 = r[(n-2)/(1-r^2)]^{1/2}$ exceeds $|t_{n-2,\alpha/2}|$, where $t_{\alpha/2}$ is the cutoff point in the t-table at $100(1-\alpha/2)\%$ confidence and $n-2$ degrees of freedom, and r is Pearson's correlation between u_i and v_i, $u_i = x_i^* + y_i^*$, $v_i = x_i^* - y_i^*$. Approximate $100(1-\alpha)\%$ confidence limits on the relative precision $q = \sigma_\xi^2/\sigma_\eta^2$ are

$$q_{\mathrm{U}} = \frac{b + \sqrt{c}}{a - \sqrt{c}}, \qquad q_{\mathrm{L}} = \frac{b - \sqrt{c}}{a + \sqrt{c}},$$

with $a = \hat{\sigma}_\eta^2/2$, $b = \hat{\sigma}_\xi^2/2$, and $c = [t_{\alpha/2}^2(s_{ss}s_{yy} - s_{xy}^2)]/(n-2)$.

Regression models with **errors in variables**, or **structural equations** to assess reliability of two raters, have received considerable attention from many researchers. For example, we refer the reader to Kelly [41], Linnett [50], Nix & Dunston [56], and the earlier work of Deming [17].

Example

Table 4 provides measurements derived from an experiment in microbiology. The primary aim was to determine the number of colonies of the *E. coli* 0157:H7 pathogen in contaminated fecal samples collected from 12 beef carcasses. For a given faecal sample, the number of colonies was determined by a new test (Petrifilm HEC) and by a "standard test" in two subsamples; results are recorded as the logarithm of the number of colonies (Table 4). The first two rows correspond to the repeated determinations based on the use of the standard test, and the second two rows correspond to the repeated determinations of the new test. (These data were kindly provided by Dr Christine Power from the Ontario Veterinary College, Guelph, Ontario.)

We begin the analysis by first investigating the repeatability of each of the two tests separately. Following the recommendations of Bland & Altman [8], we plotted the difference between the two against their sum (Figure 1).

Table 4 Logarithm of the number of colonies of *E. coli* 157:H7 in samples taken from 12 beef carcasses

Test (subsample)		1	2	3	4	5	6	7	8	9	10	11	12
Standard	1	2.356	2.149	2.452	2.255	2.694	2.43	2.322	2.322	2.491	2.322	2.322	2.491
	2	2.384	2.263	2.417	2.299	2.684	2.44	2.491	2.041	2.322	2.322	2.491	2.785
New test	1	2.283	2.061	2.322	2.162	2.068	2.322	2.491	2.041	2.322	2.491	2.041	2.785
	2	2.265	1.987	2.316	2.127	2.111	2.28	2.491	2.041	2.041	2.71	2.322	2.322

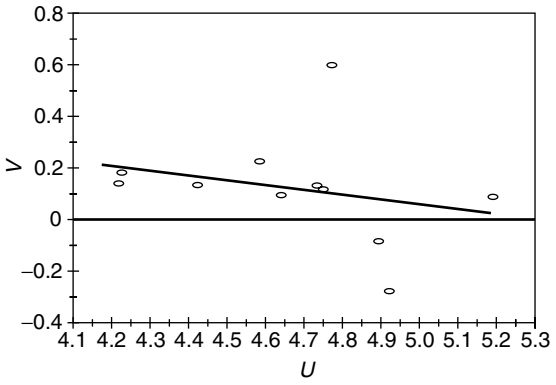

Figure 1 Plot of the difference, V, vs. the sum, U, with regression line imposed

Dunn [21] pointed out that the graph can be extremely useful in (i) allowing us to detect systematic bias and (ii) looking for outliers. The regression of the difference on the sum shows that observation #5 has a large standardized **residual**. We subsequently produced a one-way ANOVA to obtain estimates of the corresponding test–retest reliabilities using the intraclass correlation (41). The results are given in Table 5.

As can be seen, the two tests have equivalent test–retest reliability estimates. The models (39) and (40) assume that the relative biases of the two estimates are constant. This allows us to estimate the error variances using the Grubbs [38] method. If X represents the mean of the standard test log counts, and Y the mean of the new test log counts, then $\hat{\sigma}_s^2 = 0.010$, $\hat{\sigma}_\xi^2 = 0.026$, and $\hat{\sigma}_\eta^2 = 0.057$. It appears that the standard test is almost twice as precise as the new test.

Table 5 ANOVA of the logarithm of the number of colonies for the standard test and the new test

(a) Standard test (intraclass correlation = 0.61)

Source of variation	Sum of squares	df	Mean square
Cow	0.500	11	0.045
Residual	0.134	12	0.011
Total	0.634	23	

(b) New test (intraclass correlation = 0.62)

Source of variation	Sum of squares	df	Mean square
Cow	0.837	11	0.076
Residual	0.215	12	0.018
Total	1.052	23	

We now proceed to test the significance of the difference $(\sigma_\xi^2 - \sigma_\eta^2)$. Using the results of Shukla [67], we have $s_{xx} = 0.023$, $s_{yy} = 0.038$, and $s_{xy} = 0.010$. The Pearson correlation between $U = X + Y$ and $V = X - Y$ is $r = -0.27$ and $t_0 = -0.87$. We are unable to detect a significant difference between σ_ξ^2 and σ_η^2. This may be because the sample size was insufficient.

Multiple Raters

The simplest reliability study involves having each member of a sample of n subjects rated once by each member of a sample of k raters. Raters might be considered as fixed, or as a random sample drawn from a potentially larger population of raters. If raters are assumed fixed, the estimate of reliability can be obtained from the two-way mixed effects ANOVA model,

$$Y_{ij} = \mu + s_i + r_j + e_{ij}, \tag{42}$$

where Y_{ij} is the score of the jth rater on the ith patient, μ is the bias, $s_i \sim \mathrm{N}(0, \sigma_s^2)$, $e_{ij} \sim \mathrm{N}(0, \sigma_e^2)$, and the $r_i, \ldots, r_k$ are the raters effects such that $\sum r_j = 0$. Both s_i and e_{ij} are independent. From Fleiss [31], the appropriate reliability estimate is

$$R_f = \frac{n(\mathrm{BSMS} - \mathrm{WSMS})}{n(\mathrm{BSMS}) + (k-1)\mathrm{BRMS} + (k-1)(n-1)\mathrm{WSMS}}. \tag{43}$$

The components of (43) are as defined in (41), with BRMS as the between-raters mean square. If raters are assumed random, then the added assumptions that $r_j \sim \mathrm{N}(0, \sigma_r^2)$ and that r_j, s_i, and e_{ij} are mutually independent give an estimate of reliability identical to $\hat{\rho}_{2\omega R}$ in (26); simplified, this becomes

$$R_r = \frac{n(\mathrm{BSMS} - \mathrm{WSMS})}{n(\mathrm{BSMS}) + k(\mathrm{BRMS}) + (nk - n - k)\mathrm{WSMS}}. \tag{44}$$

Remarks

It is evident that **estimation** of indices of agreement for interval scale measurements is tied to estimation of variance components. The total variance is decomposed into subjects effect, raters effect (if raters are considered random), and the error component. The

traditional ANOVA, either one-way or two-way, is used when the data are balanced and/or complete (no missing data). For unbalanced data, one may use the maximum likelihood (ML) and **restricted maximum likelihood** (REML) [57, 64]. The advantage of ML or REML methods is that we obtain estimates of the **standard errors** of the estimates. Depending on the nature of the study, more complex designs other than the ANOVA may be used. Bassin et al. [6] used **crossover designs** for method comparisons. Other designs such as **balanced incomplete block designs** [27, 29] and hierarchical designs [36] can be used for nested reliability studies (*see* **Hierarchical Models**).

We emphasize that there is no single procedure which can be used to assess raters' reliability agreement. Bartko [5] pointed out that procedures for exploring agreement should be based upon the nature of the study and the purposes of various agreement measures. Table 6 summarizes the basic formulas mentioned in this article.

Computer Programs

Cyr & Francis [15] provided a menu-driven PASCAL program to compute Cohen's kappa and weighted kappa using the two types of weights, d_{jk}.

$$\text{(i) } d_{jk} = 1 - \frac{(j-k)^2}{(c-1)^2}, \quad \text{(ii) } d_{jk} = 1 - \frac{|j-k|}{c-1},$$

and other user-defined weights.

The SAS software (*see* **Software, Biostatistical**) [60] has a number of procedures referred to as "PROC" statements. PROC FREQ provides estimates of a variety of measures of association in $c \times c$ contingency tables, including an unweighted estimate of kappa. As an illustration, using Dunn's [20, p. 24] data, PROC FREQ in SAS provides the following estimates of kappa: unweighted Cohen's kappa ($= 0.21$) and weighted kappa ($= 0.58$), using the weights as described in (ii) above. Alternately, Cyr & Francis's, [15] program which uses the quadratic weights in (i), gives 0.80 as an estimate of weighted kappa. For multiple raters and the 0–1 category, estimates of kappa, in (24), (26), and (30), are obtainable using PROC ANOVA or PROC GLM in SAS. The SAS procedures provide the appropriate sum of squares and the corresponding mean squares to calculate reliability kappa estimates. It is also possible to use **StatXact** [55] to calculate Cohen's kappa or a weighted kappa statistic.

Estimates of variance components from the balanced one-way random effects, two-way random effects, and mixed effects models can be obtained using either PROC ANOVA with the RANDOM statement or PROC VARCOMP in SAS. For more complex designs with multiple levels of nesting and crossing, PROC MIXED in SAS may be used to estimate the components of variance. For unbalanced data or when some data points are missing, Robinson's [58] REML program can be used to obtain estimates of variance components and hence the intraclass correlations. With little programming experience in SAS, PROC UNIVARIATE, PROC CORR, and PROC REG are quite easy to implement and may be used to calculate the concordance correlation and Bradley & Blackwood [10] statistics.

Table 6 Summary of basic formulas

Parameter	Interpretation
Eq. (1)	Cohen's kappa – nominal-scale measure of agreement between two raters
Eq. (2)	Cohen's weighted kappa – used as an ordinal scale measure of agreement between two raters
Eq. (3)	Darroch & McCloud measure of category distinguishability
Eq. (14)	Rogot & Goldberg index of agreement
Eq. (18)	Armitage et al.index of disagreement
Eq. (24)	Intraclass kappa – obtained from the one-way random effects model under the assumption of no interrater bias
Eq. (26)	Reliability kappa – obtained from the two-way random effects model accounting for rater's effect
Eq. (36)	Concordance correlation – measures the departure from the 45° line

Agreement, Modeling of Categorical

In many situations two observers evaluate and classify each of n subjects into one of K mutually exclusive categories. For $K = 2$ a common measure of chance-corrected agreement between the two raters is Cohen's **kappa** (κ) statistic [6]. The measure has been extended to $K > 2$, where the K categories may be ordered [7] (*see* **Kappa and its Dependence on Marginal Rates**). Some authors, e.g. Agresti [1], argue that a single measure of agreement may be too simple for some situations. For example, one may want to model agreement after adjustment for chance agreement and ordinal association [1, 2] (*see* **Ordered Categorical Data**). Additionally, **covariates** may influence the probabilities of classification and may need to be considered prior to assessment of agreement [3]. Below we discuss models that address these issues.

Assumption of Marginal Homogeneity

Let p_{ij} be the probability of a subject being classified in category i by the first rater and category j by the second rater. Then the marginal probability of classification into category i for the first rater is $p_{i\cdot} = \sum_j p_{ij}$ and similarly $p_{j\cdot} = \sum_i p_{ij}$ for classification into category j by the second rater. Some models of agreement assume that $p_{i\cdot} = p_{\cdot i}$ for $i = 1, \ldots, K$. This assumption of marginal homogeneity is stringent, but is consistent with the definition of intraclass **correlation** for continuous data that assumes equal means and variances for the two variables [14]. Note that marginal homogeneity may be a prerequisite for high agreement [2]. Quite simply, one would not expect agreement to be high when the marginal totals are discrepant because the raters are probably not using the same underlying classification scheme. In the **loglinear model** described below, the assumption of marginal homogeneity is testable.

2 × 2 Tables

For the usual kappa statistic, the row and column marginal totals in **2 × 2 tables** are considered fixed. Since sample sizes may be small in studies of agreement, the number of discordant observations may be small. In this case computing a ***P* value** based on the exact permutation distribution (with marginals fixed) may be preferable (e.g. as implemented in **StatXact** 3 for Windows, Cambridge, MA; (*see* **Exact Inference for Categorical Data**). Alternatively, one can assume marginal homogeneity and compute an intraclass correlation [5, 9] as discussed below. The corresponding permutation distribution would be conditional on the overall number of positive and negative responses, but allow the cell frequencies in Table 1 to vary.

The marginal probability of classification for a particular subject may depend on one or more subject-specific covariates as well. For example, a radiologist may be more likely to classify a mammographic abnormality as breast cancer in the presence of known breast cancer risk factors, such as a family history of breast cancer or advanced age. A stratified kappa (*see* **Stratification**) can be used with weights determined by the sample size for each covariate combination comprising the strata [4]. Failure to account for these **confounders** (i.e. collapsing across strata) may lead to inflated estimates of agreement [4].

As the number of confounders becomes large, the stratified kappa would be based on sparse tables and would exhibit poor asymptotic behavior. Therefore, it is desirable to adjust directly for subject-specific covariates that may influence the raters in their classification of the subject. For the $K = 2$ case one can use a **logistic regression** model for linking subject-specific covariates to the marginal probability of classification and include a term for the intraclass correlation θ [3]. The model does assume marginal homogeneity, with the subject-specific covariates influencing each rater's marginal probability in the same way.

Let n_{ij} be the frequency in the ith row (rater 1) and the jth column (rater 2). Assuming marginal homogeneity leads to the trinomial distribution given in Table 1. This model (without covariates) is discussed elsewhere [5, 11]. Note that the model gives θ as the marginal probability of a positive response for each rater. **Maximum likelihood** estimates of ρ and θ are

$$\hat{\rho} = \frac{4n_{11}n_{22} - (n_{12} + n_{21})^2}{(2n_{11} + n_{12} + n_{21})(2n_{22} + n_{12} + n_{21})}$$

and

$$\hat{\theta} = \frac{2n_{11} + n_{12} + n_{21}}{2n},$$

Table 1 Trinomial model

Classification	Both positive	Discordant	Both negative
Frequency	n_{11}	$n_{12} + n_{21}$	n_{22}
Probability	$\theta^2 + \rho\,\theta(1-\theta)$	$2(1-\rho)\,\theta\,(1-\theta)$	$(1-\theta)^2 + \rho\,\theta(1-\theta)$

with estimated variance estimate for $\hat{\rho}$ given by [5, 9]:

$$\text{var}(\hat{\rho}) = \frac{1-\hat{\rho}}{n}\left[(1-\hat{\rho})(1-2\hat{\rho}) + \frac{\hat{\rho}(2-\hat{\rho})}{2\hat{\theta}(1-\hat{\theta})}\right].$$

Using the modeling approach derived below, a score test of $H_0 : \rho = 0$ can be derived. Without covariates, the score test is simply $n\hat{\rho}^2$, assumed to be distributed as χ^2 (1 df) under the **null hypothesis**. The estimate $\hat{\rho}$ is the intraclass correlation for dichotomous outcomes. If the formula for the intraclass correlation for continuous data is applied to the dichotomous data, then the estimate $\hat{\rho}$ is obtained [14]. In practice, $\hat{\rho}$ will be quite close to the kappa statistic and equal to it when $n_{12} = n_{21}$.

Inclusion of Covariates

To include subject-specific covariates, let $\mathbf{x}_i = (1, x_{i1}, x_{i2}, \ldots, x_{ip})$ be the $p+1$ vector of covariates for subject i. Assume a logit link function (*see* **Generalized Linear Model**) between the **mean** θ_i and the covariate vector $\mathbf{x}_i$, i.e. logit $(\theta_i) = \mathbf{x}_i\boldsymbol{\beta}$, with $\boldsymbol{\beta}$ a parameter vector to be estimated. This **multinomial** model may be fitted as a conditional logistic regression model with a generalized **relative risk** function [3].

$$r_i = \exp(z_i\beta) + w_i\rho - \frac{w_i - 1}{3},$$

where $\mathbf{x}_i$ and w_i are functions of the covariates and the observed outcome for person i. This additive risk function decomposes into a part that incorporates the covariates, a part that depends on the intraclass correlation, and an "offset". **Confidence limits** for θ may be derived using either a standard Wald interval or a **profile likelihood** interval. Alternatives to the asymptotic bounds are desirable for establishing a confidence interval for ρ since Wald-based confidence intervals have poor coverage probabilities for estimates of agreement [4].

The model also allows for easy derivation of a score test of $H_0 : \rho = 0$. Let Y_{ij} indicate whether the ith person has been classified into the jth cell of Table 1, $i = 1, \ldots, n$; $j = 1, 2, 3$. Let $\tilde{\boldsymbol{\beta}}$ be an estimate of $\boldsymbol{\beta}$ assuming $\rho = 0$, i.e. breaking the pairing and estimating $\boldsymbol{\beta}$ using a standard logistic regression model for the $2n$ observations. If the risk (denoted $\tilde{r}$) is based on $\tilde{\boldsymbol{\beta}}$, then a one-step estimate of ρ is

$$\hat{\rho}_{1-\text{step}} = \frac{1}{\text{n}}\sum_i\left(\frac{Y_{i1}}{\tilde{r}_{i1}} - \frac{2Y_{i2}}{\tilde{r}_{i2}} + \frac{Y_{i3}}{\tilde{r}_{i3}}\right)$$

and the score test (χ^2 with 1 df; *see* **Likelihood**) of $H_0 : \rho = 0$ is $n\hat{\rho}^2_{1-\text{step}}$. Limitations of the model include the marginal homogeneity assumption and restriction to $K = 2$.

Extension to $K \times K$ Tables

In many situations ratings are made on a **nominal** or ordinal scale with $K > 2$. Tanner & Young [15] proposed a loglinear model for nominal scales. Suppose that Y_{ij} is the number classified into row i and column j by raters 1 and 2, respectively. Assume a **Poisson distribution** for Y_{ij} with the loglink function $\log \mu_{ij} = z_{ij}^{\text{T}}\boldsymbol{\beta}$. A possible model would be $\log \mu_{ij} = \mu + \alpha_i + \beta_j + \delta_{ij}$, where the $\boldsymbol{\theta}$ and $\boldsymbol{\beta}$ parameters correspond to the marginal distributions for raters 1 and 2, respectively, and δ_{ij} is zero for $i \neq j$ and equal to δ_i otherwise. A test of statistically significant agreement is given by the difference in deviances between this model and the independence model, $\log \mu_{ij} = \mu + \alpha_i + \beta_j$. The **likelihood ratio test** is assumed to have a **chi-square distribution** with K degrees of freedom for $K > 2$. This particular model is called the "**quasi-independence** model" because raters 1 and 2 are assumed to be independent given they disagree. The model forces the fitted values on the diagonal to be equal to the observed values. An intermediate model is given by constraining $\delta_1 = \delta_2 = \ldots \delta_K = \delta$. This model does not constrain the diagonals to equal the observed values

and can be tested against both the independence and quasi-independence models by likelihood ratio tests.

The above model does not assume marginal homogeneity, but it is not difficult to make this assumption and test its validity. The difference in deviances between models $\log \mu_{ij} = \mu + \alpha_i + \beta_j + \delta_{ij}$ and $\log \mu_{ij} = \mu + \alpha_i + \alpha_j + \delta_{ij}$ has a chi-square distribution on $K - 1$ degrees of freedom. The α parameters for the latter model are estimated using covariates $X_l = I(l = i) + I(l = j)$ for $l = 2, \ldots, K$, where I is an indicator function. When $K = 2$ the likelihood ratio test of $H_0 : \delta = 0$ under marginal homogeneity is identical to that for $H_0 : \rho = 0$ in the first section.

For ordinal categories it is likely that if there is disagreement the two raters choose ratings that are more similar rather than more distant. A weighted kappa may be used with weights determined by linear or squared differences between the scores corresponding to the categories [7]. However, these models can accommodate covariates only by stratification and may be too simple for most situations. Accordingly, Agresti [1] proposed a generalization of the loglinear model intended to accommodate the association between the two ordinal scales. The discussion below is based largely on Agresti's generalization of loglinear models of nominal association [10, 15].

Suppose that u_i is the score associated with the ith category of the ordinal scale with $u_1 < u_2 < \ldots < u_K$. In most cases $u_i = i$, but the scores could depend on midpoints of categorized values or on subjective a priori experience. A possible model is

$$\log \mu_{ij} = \mu + \alpha_i + \beta_j + u_i u_j \theta + \delta_{ij},$$

where θ indexes the linear-by-linear association and δ_{ij} indexes residual agreement between the raters. A comparison of deviances for this model vs. $\log \mu_{ij} = \mu + \alpha_i + \beta_j + u_i u_j \theta$ gives a test of agreement on K degrees of freedom. Unlike the weighted kappa statistic, "partial credit" for being similar rather than identical is attributed primarily to association rather than agreement. Agresti [1] recommends a slightly simpler model with $\delta_1 = \delta_2 = \cdots = \delta_K = \delta$, since the diagonal elements are not constrained to be equal to the observed values. This model has $(K - 1)^2 - 2$ df for assessing **goodness of fit** and allows a direct test of agreement $H_0 : \delta = 0$ and/or linear association $H_0 : \theta = 0$.

This model may also be modified to assume marginal homogeneity:

$$\log \mu_{ij} = \mu + \alpha_i + \alpha_j + u_i u_j \theta + \delta_{ij},$$

with δ_{ij} either a scalar (δ) or a **K**-vector on the diagonal. The latter model again imposes a perfect fit on the diagonal. Finally, one can include categorical subject-level covariates that may influence the marginal probabilities. For example, the subjects may be grouped into m age groups, and the $m(K \times K)$ tables fit by a common model with age entering as a main effect. Furthermore, age may be tested as an **effect modifier** of δ using **interaction** terms. Controlling for several **confounders** simultaneously will often not be possible due to sparseness of the tables, however.

Multiple Raters

In many cases several raters will rate all or some of the subjects and classify them into the K categories. In this situation extensions to kappa have been proposed [8, 13]. If all pairwise tables are considered, the tables are correlated since a rater may appear in several tables. Schouten [13] proposes using a **jackknife** variance estimator to assess significance in this setting. A unified loglinear model of agreement across multiple raters is not yet available. Tanner & Young [15] discuss a loglinear model for comparison of several raters to a standard.

If marginal probabilities are allowed to vary with each rater, the number of parameters tends to infinity when the number of raters does. In this case marginal homogeneity may be required. One might consider all pairwise tables in a loglinear model under marginal homogeneity. It would be necessary to correct the standard errors using a **generalized estimating equations** approach [12]. Alternatively, confidence limits could be found by **bootstrapping** the contributions from each rater.

Example

An agreement and accuracy study was performed to study the ability of radiologists to classify screening mammograms. The research was supported by the National Cancer Institute (CA63731, PI Stephen Taplin, MD). We consider

only a subset of the data here. Ten radiologists classified 113 screening mammograms into five categories: (i) normal; (ii) normal with benign findings; (iii) probably benign; (iv) suspiciously abnormal; and (v) highly suspicious of malignancy. The 113 mammograms included a mix of negative and positive mammograms. Table 2 shows the distribution for a single pair of raters and Table 3 shows the classification for all possible pairing of raters (45) classifying each of the 113 subjects, yielding a total of 5085 paired ratings.

Data for the two raters in Table 2 were analyzed using a loglinear model, though sparseness in the Table may be problematic. The Agresti [1] linear association model fits well (deviance $\chi^2 = 15.71$ on 14 df), but is not significantly different from a model that assumes marginal homogeneity that also provides a reasonable fit (deviance $\chi^2 = 21.64$ on 18 df). Under the two models, the estimates of the scalar δ are 1.065 (se 0.466) and 0.862 (se 0.448), respectively. For the marginal homogeneity model, both the Wald test ($z = 1.923$) and likelihood ratio test ($\chi^2 = 3.38$ on 1 df) show weak (one-tailed) significance for agreement beyond linear association. By comparison the unweighted and linear weighted kappas are quite high – 0.620 and 0.774, respectively.

Table 2 Classification by two raters of 113 screening mammograms

	Rater 1					
Rater 2	1	2	3	4	5	Total
1	75	1	3	1	0	80
2	1	1	0	0	1	3
3	5	2	4	0	1	12
4	0	0	2	1	3	6
5	0	0	0	0	12	12
Total	81	4	9	2	17	113

Table 3 Pairwise classification by 10 raters of 113 screening mammograms

Lower rating	Higher rating				
	1	2	3	4	5
1	3073	178	631	32	15
2		24	109	13	3
3			217	127	76
4				68	178
5					341

The loglinear model dissects the apparent interrater agreement into a strong linear association and weak residual agreement.

If all 45 pairwise tables are considered, then the median estimate of δ is 0.244 when not assuming marginal homogeneity and 0.093 under this assumption. In 43 of 45 tables, marginal homogeneity resulted in a smaller estimate of agreement. Finally, if one models all 45 tables simultaneously (assuming marginal homogeneity), then the overall δ estimate is 0.103, but the standard error needs to be corrected for the induced correlations among pairings.

Conclusions

Agreement between two fixed raters may be modeled using either a conditional logistic regression model ($K = 2$) or a loglinear model ($K \geq 2$). The former allows for continuous or categorical covariates, while the latter can incorporate only categorical covariates. More complex models are needed for more than two raters. Marginal homogeneity may be a prerequisite for strong agreement to be observed.

WILLIAM BARLOW

AIDS and HIV

The human immunodeficiency virus (HIV) can be transmitted from person to person. The immune system of individuals infected with HIV deteriorates, leaving them susceptible to infection and the development of various diseases. Certain conditions of poor health in HIV infected individuals qualify for a diagnosis of acquired immune deficiency syndrome (AIDS). Statistical issues associated with data from the HIV epidemic and HIV/AIDS related studies emerged soon after AIDS was formally defined in 1982. At that time the number of cases began to increase alarmingly and early concerns were with **forecasting** the incidence of AIDS diagnosis, estimating the distribution of the survival time with AIDS and estimating the distribution of the time from infection until diagnosis with AIDS. The latter time period is often called the **incubation period**.

The area of AIDS and HIV data has been a rich source of statistical challenges, which are reported in an extensive literature. Fusaro et al. [8] give an annotated bibliography of the early literature. Jewell [11] reviews some statistical issues associated with the study of HIV and AIDS data, and some of these are described in detail in the book by Brookmeyer & Gail [6].

Extrapolating AIDS Incidence

The rising number of AIDS diagnoses and the devastating consequence for its victims naturally generated an interest in the current trend of AIDS incidence and the likely number of cases in the near future. Owing to the lack of knowledge about the way AIDS cases arose, early attempts at forecasting AIDS incidence were based on fitting curves of a simple algebraic form to the observed AIDS incidences and then extrapolating these curves into the future. More specifically, **polynomial regression** models in time were fitted to the AIDS counts, or logarithms of the counts, and then **extrapolated**. The basis for making projections of AIDS incidences by extrapolating fitted polynomials is weak. Furthermore, the approach does not give an estimate of the rate of development of new infections over time, i.e. the HIV infection curve, which is of considerable interest. For these reasons, there soon developed an interest in using models that contain at least some aspects of the way AIDS cases arise.

Transmission Models for HIV

Only models that describe the way HIV is transmitted from person to person contain all aspects of the way AIDS cases are generated. There is a substantial body of work on infectious disease models (*see* **Communicable Diseases**), and attempts were soon made to adapt these models to HIV transmission.

There are several features that distinguish the HIV epidemic from epidemics of other communicable diseases. First, several different modes of transmission are identified for HIV, such as sexual transmission, injecting drugs with contaminated needles, and receiving contaminated blood or blood products during medical therapy. This means that comprehensive models contain many parameters that need to be estimated, from data that are personal, highly sensitive, and sparse. The models of Hethcote & Van Ark [9] illustrate this. To keep models simple it is common to restrict attention to a single risk category with the assumption that transmission within that group occurs without significant transmission from infective individuals in other risk categories.

Another distinguishing feature is that the incubation period usually has a duration of several years, with the consequence that knowledge about the disease, therapy, and behavior change significantly during the course of the epidemic. In statistical terms this means that model parameters do not remain constant.

These difficulties give rise to considerable uncertainty about conclusions reached by the use of transmission models. As a consequence the preferred methods for assessing the size of the HIV epidemic and making projections of AIDS incidence are based on the method of **back-calculation**, which is now described.

Reconstructing the HIV Infection Curve

This topic has been a major focus of statistical studies in the HIV/AIDS area. Reconstruction of the realized, but unobserved, HIV incidences is of interest because they indicate the size of the epidemic and are useful for predicting future AIDS incidences and the health care costs resulting from AIDS cases.

Let H_t and A_t denote the number of HIV infections and AIDS diagnoses in the discrete time unit t, typically a quarter, and let τ be the last time unit for which reliable data are available. We can relate $\mu_t = \mathrm{E}(A_t)$, the mean AIDS incidence in time unit t, to the HIV incidences at earlier times by

$$\mu_t = \sum_{s=1}^{t} \lambda_s f_{t-s}, \quad t = 1, 2, \ldots, \tag{1}$$

where $\lambda_s = \mathrm{E}(H_s)$ and f_r is the probability that the duration of the incubation period is r time units. This convolution equation holds for any transmission model, relying only on subjects having independent incubation periods.

The method of back-calculation, or back-projection, uses (1) to reconstruct the HIV infection curve, by a method that ignores the fact that HIV cases arise by infection. Most versions of the method of back-projection reconstruct the $H_1, H_2, \ldots, H_\tau$ by estimates of $\lambda_1, \lambda_2, \ldots, \lambda_\tau$, assuming that a precise estimate of the incubation period distribution $f_0, f_1, \ldots$ is available from data of large **cohort studies**.

Typically, the $H_1, H_2, \ldots, H_\tau$ are assumed independent Poisson variates (*see* **Poisson Processes**). This produces a very convenient working model, because with independent incubation periods it makes the AIDS incidences independent observations of Poisson variates with means given by (1), making **maximum likelihood** estimation an option for $\lambda_1, \lambda_2, \ldots, \lambda_\tau$. Rosenberg & Gail [24] show that for large epidemics this model assumption gives similar results to some other model assumptions. Simulation results show that this model gives sensible reconstructed HIV incidences even when data are generated by a transmission model [3].

Leaving the λ_s as separate parameters, in the spirit of functional estimation, makes their estimates overly sensitive to minor perturbations in the AIDS incidence data, so some form of smoothing (*see* **Nonparametric Regression**) needs to be imposed. When they first proposed back-projection in the AIDS context, Brookmeyer & Gail [6] assumed a piecewise constant form for λ_s, $s = 1, 2, \ldots, \tau$; that is, the λ_s take only a small number of distinct values. However, a smooth parametric form has also been used for the λ_s [27], while Isham [10] uses a smooth parametric form for the μ_t and deconvolutes (1).

A preference has evolved for leaving the λ_s as separate parameters but constraining them to a smooth form, because no simple natural parametric form is apparent for the HIV infection curve. Another, possibly more important, reason for this preference is a concern that with the use of parametric models we may not get an appropriate reflection of how the precision of the reconstructed HIV infection curve varies over time.

A variety of methods have been explored for reconstructing the HIV infection curve by smoothing a nonparametric estimate, including use of the **EM algorithm** with a smoothing step added to each iteration of the usual E- and M-steps for maximum likelihood estimation [5]. This method is very easy to program because the iterations involve only simple explicit expressions. Another approach is to estimate the λ_s by **penalized maximum likelihood**:

$$L(\boldsymbol{\lambda}; \mathbf{a}) - \gamma \Psi(\boldsymbol{\lambda}).$$

Here $L(\boldsymbol{\lambda}; \mathbf{a})$ is the **likelihood** function corresponding to the observed AIDS cases and $\Psi(\boldsymbol{\lambda})$ is a function that penalizes any estimate that is not sufficiently smooth. For example, $\Psi(\boldsymbol{\lambda}) = \sum_j (\lambda_{j+1} - 2\lambda_j + \lambda_{j-1})^2$ is used by Bacchetti et al. [2].

Bayesian methods seem natural for reconstructing the HIV infection curve, since posterior probabilities are appropriate descriptions of likely realizations of unobserved incidences, and these have been used to get smooth back-projections [18]. **Ridge regression** [21] and **splines** [24] have also been applied to obtain smooth reconstructions.

AIDS counts alone contain very little information about HIV infections in the recent past so that, naturally, reconstruction of the HIV incidences for recent time units is less precise than reconstruction for the distant past.

The large number of variations in the methods of back-projection are matched by an equally wide range of ways in which changes in the incubation distribution, over time, have been incorporated. These changes are needed because the incubation period has changed over time as a result of both therapy effects and changes in the definition of AIDS. Early methods for incorporating the dependence of the f_r on the time of infection were simple and crude, but there were soon a variety of ways in which these effects were incorporated in a more descriptive way [6].

Methods for incorporating auxiliary information into back-projections have been developed to

improve the precision of reconstructed HIV infection curves. For example, age at AIDS diagnosis is usually observed and its inclusion as a **covariate** improves precision and enables the estimation of age-specific **relative risks** of infection [4].

Estimating the Incubation Distribution from Retrospective Ascertainment Data

Estimation of the probability distribution for the incubation period has also been a major focus of statistical studies in the HIV/AIDS area. It is of interest because this distribution is needed to advise patients, to monitor disease progression, and for back-projection. Its estimation presents difficulties because the time of infection is usually unknown.

For individuals infected with HIV by a single blood transfusion it is possible to determine the time of infection. However, even for data on these subjects, estimation requires new methodology, because subjects usually enter the study sample only when they have been diagnosed with AIDS. At this point their time of infection can only be ascertained retrospectively. Shorter incubation periods are overrepresented when subjects are sampled in this way, so it is important that the method of estimation takes account of the way the data arise. Lui et al. [19] estimated the incubation distribution by ignoring the infection process that led to the data, considering each retrospectively ascertained incubation time as an observation from a truncated Weibull distribution. Medley et al. [20] allow for HIV infections to occur according to a Poisson process with the rate having a parametric form $\lambda(t;\boldsymbol{\beta})$ at time t and taking a parametric form $f(x;\boldsymbol{\theta})$ for the incubation distribution. They consider the forms

$$\lambda(t;\boldsymbol{\beta}) = \exp(\beta_0 + \beta_1 t) \quad \text{and} \quad \lambda(t;\boldsymbol{\beta}) = \beta_0 + \beta_1 t$$

for the infection rate and consider both the gamma and the Weibull distributions for f.

As pointed out by Kalbfleisch & Lawless [13], there is an **identifiability** problem when we try to estimate both the Poisson rate, λ, and the incubation distribution, f, nonparametrically, and this reflects itself even in the parametric setting by making the estimates of certain parameters imprecise. Nonparametric estimation of the shape of the incubation distribution is facilitated by a reparameterization to reverse-time **hazard rates** [17].

If it were possible to follow up a random sample of subjects infected by a blood transfusion, then the analysis of data on incubation periods would be a standard problem of **survival analysis**. Retrospective ascertainment data is the extreme case when information on the incubation period is available only for AIDS cases. Between these two extremes is the situation where the incubation periods are known for those who have developed AIDS and we also know the time since infection for some of those infected but still without AIDS. Analysis of such data requires modeling of the way the HIV infected individuals are detected.

The effect of covariates on the incubation distribution can be studied by focusing on the reverse-time hazard $h(x) = f(x)/F(x)$, where f is the density and F the distribution function. The analysis resembles survival analysis [17], and a **proportional hazard** regression analysis can be applied in reverse time [14].

Estimating the Incubation Distribution from Other Data

Estimation of the incubation distribution from prospective cohort studies has contributed to the development of a methodology for **interval censored** data. The time of infection is usually unknown, but tests for antibodies to HIV on subjects over time produce a time of last seronegative and a time of first seropositive. This has motivated extensions of known self-consistency algorithms to deal with doubly **censored data** [7], as well as truncation (*see* **Truncated Survival Times**) [26].

With a method analogous to the method of back-projection, Bacchetti & Jewell [1] use the convolution equation, (1), to estimate the incubation distribution by using the λ_s as estimated from data on a large cohort study. They obtain a smooth nonparametric estimate by using a penalized likelihood approach.

Monitoring Markers of the Immune System in Subjects

Numerous markers of the state of the immune system have been considered for monitoring disease progression. Of these the $CD4^+$ count seems the best indicator of disease progression. These counts are

highly variable, and the count declines at a rate that differs between individuals. The typical analysis fits a model that is linear in time, using **random effects**, to some transformation of the $CD4^+$ counts. The five papers in Jewell et al. [12, Section 3] give a good overview of the relevant statistical methodology.

Reporting Delays

Surveillance systems are usually prone to delays in the registration of cases, and AIDS surveillance reports are no exception. The number of AIDS cases in a surveillance report is usually less than the number of AIDS cases that have actually been diagnosed by the time of its publication, because of random delays until dates of AIDS diagnoses are entered onto the surveillance register (*see* **Surveillance of Diseases**).

AIDS surveillance data must be appropriately corrected for reporting delays before they can be used either for reconstruction of the HIV infection curve or for forecasting of AIDS incidence. This was recognized quite early, and the public access data on AIDS incidence in the US contain an adjustment for reporting delays.

Such adjustments require knowledge of the probability distribution of reporting delays. This distribution needs to be estimated from data on dates of diagnosis and subsequent dates of entry onto the surveillance register. A feature of these data is that both the date of diagnosis and the date of entry onto the register usually become available only at the time of entry onto the register. In other words, the available data have the same form as retrospective ascertainment data on the incubation periods of transfusion-acquired HIV infection, with the consequence that the methods of analysis carry over to reporting delay data. In particular, the methods of nonparametric estimation described in Kalbfleisch & Lawless [13] and Lagakos et al. [17] can be used.

A comprehensive analysis of reporting delay data, involving covariates, is a useful way of identifying weaknesses in the reporting system and of detecting changes in the reporting delay distribution over time. Methods for testing the **stationarity** of reporting delays over time, using a proportional reverse-time hazards model, are described by Kalbfleisch & Lawless [13] and Pagano et al. [21]. The use of **generalized linear models** for identifying significant factors, such as geographic region for example, is described by Zeger et al. [29].

Forecasting AIDS Incidence

Before using AIDS surveillance data to predict future AIDS incidence the available data must be corrected for reporting delays. Rosenberg [23] describes a simple way to do this.

All methods of forecasting extrapolate a curve like the convolution equation, (1), beyond the period for which data are available. For example, a prediction of the AIDS incidence for time unit τ', where $\tau' > \tau$, is given by

$$\mu_{\tau'} = \sum_{s=1}^{\tau'} \lambda_s f_{\tau'-s}. \qquad (2)$$

If a parametric form is assumed for the λ_s, then its smaller number of parameters have been estimated from the available data and extrapolating the time argument presents no difficulty, but relies on the assumed parametric form remaining appropriate for time points in the future. When the λ_s have been estimated as separate parameters, i.e. nonparametrically, then (2) contains $\lambda_{\tau+1}, \ldots, \lambda_{\tau'}$, which are not known. Some assumptions need to be made about those values. These assumptions are not crucial for short-term predictions since their multipliers $f_{\tau'-\tau-1}, \ldots, f_0$ will then be very small, because short incubation periods are rare.

The f_r contained in (2) are assumed known but are in fact estimated from available data. This means that knowledge about probabilities f_r is very imprecise for large r, adding to the uncertainty of predictions.

Infectivity

Rates of transmission between individuals are a central concern for infectious diseases. HIV can be transmitted between sexual partners. Estimating the risk of transmission between partners and determining the factors that affect this risk has been a focus of some studies.

To gain an understanding of sexual transmission of HIV, fundamental questions have had to be addressed with new statistical methodologies. Kaplan [15] used simple Bernoulli process models to investigate whether the number of partners alone can explain sexual transmission of HIV or whether the number of sex acts must be counted. Shiboski & Jewell [25] extend the investigation to whether the infectivity changes during the course of a partnership and

identify factors which influence the infectiousness of the initial infective partner and the susceptibility of uninfected partners. Analysis is complicated by limitations in the data, which include uncertainty in the times of infection of HIV positive individuals. Their methodology is akin to those of survival analysis.

When there is uncertainty about which partner is the source of infection, the EM-algorithm can be used to estimate the probabilities of transmission between partners.

Methods for Studying Intervention

Treatments intended to delay disease progression in HIV infected subjects are often therapies for just one or two of the many AIDS-defining illnesses. **Competing risk** models are therefore a natural tool for the assessment of the effectiveness of therapy in **clinical trials**. Another issue requiring statistical consideration is the assessment of drug **compliance** during clinical trials [16], because drugs tend to be self-administered and have undesirable side-effects.

Trials for determining the efficacy of vaccines (*see* **Vaccine Studies**), often aimed at preventing the onset of disease rather than preventing infection with HIV, present special challenges in the HIV/AIDS context [22]. One major issue of concern, which also has relevance to trials that assess other therapies of disease progression, is that the long incubation period means that estimation of the vaccine efficacy, with adequate precision, requires a very long trial. To avoid such delays there is interest in the use of **surrogate endpoints**. In particular, a reduction in the loss of $CD4^+$ cells during HIV infection is considered a promising sign of vaccine impact.

A second issue of concern is that subjects are able to determine, by being tested, whether they are receiving a vaccine rather than a placebo. This may induce a feeling of security in individuals who know they are receiving the vaccine, with a possible change in behavior to less safe sexual practices. This may obscure a modest protection offered by the vaccine.

Statistical methods have also been used to evaluate needle exchange programs.

Screening for HIV Infection

The seroprevalence of HIV infection is low in many parts of the population. In low **prevalence** regions there will tend to be more **false positives** than real positives. Furthermore, large samples are needed to obtain a nonzero estimate of the prevalence. This prompts the pooling of sera samples and performing tests on the pooled samples. Statistical studies have shown that not only does this result in cost saving, but the estimate of the seroprevalence can be improved significantly [28].

Akaike's Criteria

Two of the criteria that have been widely used for model-choice are associated with H. Akaike.

FPE

If a (not necessarily true) p-parameter linear model is fitted by unweighted **least squares** to n observations $y_1, \ldots, y_n$, giving fitted values $\hat{y}_1, \ldots, \hat{y}_n$ and Residual Sum of Squares (*see* **Analysis of Variance**) $(n-p)s_p^2$, say, then the Final Prediction Error criterion (FPE) may be defined by

$$\text{FPE} = \left(1 + \frac{p}{n}\right) s_p^2.$$

This formula was derived by Jones [6] as the "full model" value of a model-choice criterion equivalent to C_p, for observations uncorrelated and homoscedastic (*see* **Scedasticity**) with variance σ^2 (*see* **Mallows' C_p Statistic** Statistic). Jones showed that

$$\text{E(FPE)} \geq \text{E}\left\{\frac{\sum[\hat{y}_i - y_i']^2}{n}\right\},$$

where y_i' is an independent replication of y_i, with equality if $\text{E}(s_p^2) = \sigma^2$ (which almost requires the model to be true after all). The FPE formula was independently derived by Akaike [1] in the context of autoregression (*see* **ARMA and ARIMA Models**), as a model-choice criterion in its own right. Provided p/n and C_p/n are small, FPE and C_p give the same model ranking: for then, denoting equivalence or approximate equivalence by $\cong$,

$$\text{FPE} \cong \left(1 + \frac{2p}{n}\right) \text{RSS}_p \cong 1 + \frac{C_p}{n}.$$

AIC

For a (not necessarily true) model $\mathcal{M}$ with p parameters $\theta = (\theta_1, \ldots, \theta_p)$ and **likelihood** function $L(\theta|y)$ (taken as a rewritten probability density function (pdf)), the Akaike Information Criterion [2] is

$$\text{AIC} = -2\log L[\hat{\theta}(y)|y] + 2p,$$

where $\hat{\theta}$ maximizes $L(\theta|y)$. Under conditions on the likelihood functions in $\mathcal{M}$ that involve their regularity and high informativeness, AIC is an approximately unbiased estimate of

$$\text{E}^{\mathcal{M}} = \text{E}_y\{\text{E}_Y[-2\log L[\hat{\theta}(y)|Y]\},$$

in which Y has, independently, the same unknown true distribution as the data y. Since the inner expectation over Y is a respected **information** theory index of the discrepancy between the pdf of Y (in $\mathcal{M}$) for $\theta = \hat{\theta}(y)$ and its true pdf, AIC has been well received as a model-choice criterion.

When $\mathcal{M}$ is a normal linear model with independent observations with *known* variance σ^2 and we take $L(\theta|y) = \exp\{-\sum[y_i - \text{E}(y_i)]^2/2\sigma^2\}$,

$$\text{AIC} = \frac{(n-p)s_p^2}{\sigma^2} + 2p = C_p + n$$

so that AIC and C_p are then equivalent. If σ^2 is one of the estimated parameters in $\mathcal{M}$ and we take $L(\theta|y) = \sigma^{-n}\exp\{-\sum[y_i - \text{E}(y_i)]^2/2\sigma^2\}$, then

$$\text{AIC} = n\log(\hat{\sigma}_p^2) + 2p + n + 2,$$

where $\hat{\sigma}_p^2 = (1 - p/n)s_p^2$ is the maximum likelihood estimate (mle) of σ^2 in $\mathcal{M}$. When p/n is small,

$$\text{FPE} \cong \log \text{FPE} \cong \log(\hat{\sigma}_p^2) + \frac{2p}{n}$$

and FPE and AIC are then approximately equivalent (which therefore extends to C_p when C_p/n is small too).

The asserted equivalences or approximate equivalences are purely functional and therefore *operationally* effective. "An asymptotic equivalence" of a different sort was proved by Stone [9] between AIC and a particular (not necessarily attractive) choice A of the **cross-validatory** criterion. The connection is of limited interest, since it is an operational, approximate equivalence (for small p/n) only when the model $\mathcal{M}$ used to generate both AIC and A is actually true.

Applications of AIC select models with the smallest value of AIC, a practice labeled MAICE. This practice has been widely criticized for its asymptotic inconsistency in selecting true models, meaning that it has been *theoretically* established that, *for large n and small* p/n, MAICE may have a high probability of picking an "over-fitting" model in which there is

a sharply defined, simpler submodel truly generating the data. This criticism is misplaced, given that AIC was designed to optimize, for ordinarily sized data sets, the approximation of an essentially unidentifiable true distribution, by an almost inevitably untrue model selected by MAICE from some merely reasonable family of distributions.

This is not to say that there is no room for improvement in the performance of MAICE in fulfilling its objective. Most sets of data are not big enough for the complex inferences that scientists wish to draw from them. So the practical effectiveness of model selection methods often depends on their capacity to handle cases where p/n is not small. Since the penalty term $2p$ in AIC was derived for small p/n, there must be doubts whether AIC can handle such cases (see p. 83 of the application-oriented book of Sakamoto et al. [8]). A modification of AIC to deal with moderate to large p/n has been proposed by Hurvich & Tsai [5] which has been generalized to multivariate **y** by Bedric & Tsai [3] and Fujikoshi & Satoh [4].

The book by Linhart & Zucchini [7] gives a useful, nonpartisan overview of the whole area of model choice, including applications.

Algorithm

An algorithm is a sequence of instructions for carrying out a well-defined task. The term is generally used to describe a series of logical steps that, when implemented within a computer program, will perform a desired computational task. This article will discuss issues that are generally important in finding or choosing such an algorithm.

The task must be specified precisely. The algorithm should then do the task correctly and do it economically (i.e. with acceptably small computational and memory cost). These, and several related points, will be illustrated with reference to some common tasks. We observe that there are tasks whose computational demands are so severe that they are not tractable, on current computers or on any currently imaginable digital computer.

The sorting of a set of numbers into numerical order is an unambiguous task. But suppose that the permutation (rearrangement) that places the numbers in order is at the same time applied to a second list of numbers. For example, the permutation of the numbers in the first row is at the same time applied to the numbers in the second row.

$$\begin{array}{ccc} 311 & 311 & 231 \\ 7 & 6 & 9 \end{array}$$

There are then two solutions. In one of these, the columns are placed in the order 3, 1, 2. In the second solution, the columns are placed in the order 3, 2, 1. There are several possibilities:

- Either result may be acceptable.
- Whenever there is a choice, the original order is preserved. Thus column 1 would precede column 2.
- Whenever there is a choice, the numbers in the second column appear in numerical order.

In file compression, different algorithms will lead to different compressed files. What is important is not to obtain the same compressed files, but to make a substantial reduction in the size of the file, with modest computational effort. The basis for comparing algorithms that perform reliably is the trade-off that they offer between computational requirements for compression and decompression, and the amount of compression achieved. For information on widely used file compression programs and formats, see the web page `http://www.programmersheaven.com/zone22/cat208/`.

Because different **internet** search engines use different algorithms, they will not always find the same sites and they will rank them differently. Some engines are better for some types of search, for example, searching for papers that have been published on the web, and others for other types of search, for example, searching for travel information.

The calculation of a variance and linear least squares are examples of **floating point** calculations, that is, calculations with decimal numbers that are stored using the floating point format that is standard on modern digital computers. Since these calculations will be carried out on computers that have limited floating point precision, two distinct algorithms that ostensibly solve the same numerical problem will almost inevitably differ in the precision that they achieve on an actual computer.

Finally, note the idea of computational complexity. This has to do, not with the complexity of the code that will carry out the computation, but with the number of operations that are required. Two algorithms that handle the same task can have very different demands; additionally, there are tasks that, irrespective of the algorithm used, make heavy or perhaps impossible demands on computer resources.

For example, one way to assess the significance of a one-sample t-statistic (*see* **Student's *t* Statistics**) is to refer it to its permutation distribution, that is, to the distribution of the statistic that arises from all the 2^n possible assignments of sign ($+$ or $-$) to the n values (*see* **Randomization Tests**). With $n = 20$, there are 1 048 576 possible assignments of sign, and the calculation is tractable. With $n = 50$, however, and assuming a computer that can handle the calculation for 10^6 of the 2^{50} t-statistics in each second, it will take more than 35 years to complete the calculations. Thus, this calculation is not tractable, for any except quite small values of n. Additionally, storage of all the 2^{50} t-statistics would require a little more than a million gigabytes, and might seem an issue for this calculation. Storage problems can however be sidestepped by building up information on the distribution as calculations proceed. Fortunately, calculation of all 2^{50} t-statistics is for practical purposes unnecessary. By taking a sufficient number of random samples from the distribution, the distribution can be estimated with high accuracy.

Algorithm Design

Where several alternative algorithms are available for a task, there are various criteria that may be important in comparing them. Typically, some algorithms will be preferred on one criterion (e.g. high numerical accuracy), and others on other criteria (e.g. computational time and/or storage requirements).

Strategies for algorithm design vary greatly from one problem area to another. The issues involved in designing algorithms for **matrix** computations are different from those for the design of sorting algorithms. Hence the differences in style and content found between Cormen et al. [7] who examine algorithms that are widely important in computing, Higham [11] whose interest is numerical algorithms, and Monahan [15] who examines algorithms that are important for statistical calculations.

A widely applicable general strategy is, in essence, that of top-down programming – complex problems are broken down into simpler subproblems, which are then further broken down. It is sometimes possible to break the problem down into smaller instances of the same problem, in what is called *recursion*. Sorting algorithms are among those that are suited to the use of recursion [7]. Another widely used device is *iteration*, which involves repeated execution of the same set of statements. Recursive algorithms can be attractive because of the initial simplicity and elegance of the code. An iterative version is often more efficient for the final implementation.

The design of a good algorithm will typically involve the use of theoretical insights, heuristic arguments that suggest (but do not establish beyond doubt) effective ways to proceed, trial and error, and the use of insights from the scrutiny of other algorithms that have a similar purpose.

Specific criteria will now be noted that are important for algorithm design. Note that assessment with respect to such criteria as optimality and accuracy can depend strongly on the particular **computer architecture** and organization. Tuning, that is, adaptation of implementation details, is often required to get the best performance on a particular computing system.

Optimality

Optimality has to do with computational cost. Often, the cost is dominated by one particular operation, for example, multiplication, or number of comparisons made. Or it may be dominated by sets of operations that are closely linked, for example, comparisons made and exchange of elements. Analysis of optimality aims to get results that, as far as possible, are independent of the different relative costs, on different computers, of operations that may be of interest. Often it is possible to identify operations or sets of operations that increasingly dominate the cost as the size of the problem (e.g. the number of elements that are to be sorted) increases. These are then the focus of attention. The relative costs of different sorting algorithms, for the sorting of 10 numbers, are of no consequence. For sorting a million numbers, the difference does matter.

Computer Memory or Storage Requirements

Not only do algorithms differ in computational complexity, but also in the amount of storage space that is required. For example, the usual implementations of the *Mergesort* algorithm that I discuss below require the use of two auxiliary arrays, of total length equal to the length of the vector that is to be sorted. By contrast, the *Quicksort* algorithm sorts in place, that is, no additional storage is required. This may be a consideration in choosing between the algorithms.

Simplicity

Simple forms of description make it easier to understand an algorithm, to verify correctness, and to ensure that the algorithm is robust against unusual or extreme inputs. In the choice between computational efficiency and simplicity, the more efficient algorithm will usually be preferred.

Accuracy and Precision

Questions of accuracy and precision arise because calculations with real numbers are carried out using **floating point arithmetic**. A key issue is to ensure that inaccuracies do not accumulate unreasonably; (*see* **Matrix Computations**).

Languages for Describing Algorithms

Computer languages, because they trade off ease of human comprehension against computational efficiency and demands that arise from the tradition of

the language, may not be ideal for the communication of algorithms to other humans. This has been a reason for the use of various forms of pseudocode, where simplicity, ease of description, and communication are the major considerations. The syntax may be modeled on a widely used computer language.

Benefits from using a computer language for describing as well as for implementing algorithms include:

- Implementation on actual machines forces resolution of language ambiguities.
- The description is immediately accessible, without explanation of language conventions, to the community of individuals with skills in the language or in a related language.
- The algorithm can be directly exposed to a range of checks on a computer.
- Changes to the implemented code can be immediately reflected in the description of the algorithm. Such changes may be required to correct bugs, to reduce execution time, to allow the program to handle a wider range of inputs, or to handle illegal inputs.
- Once carefully tested, the implementation is immediately available for incorporation into computer programs.

If a computer language is used, it is important to choose a language whose primitives, that is, the set of abilities that are immediately available in the language, are appropriate for algorithms of this general type. The Matlab language and associated syntax has been popular with numerical analysts. For statistical algorithms, the S language, whether as implemented in **S-PLUS** or as in **R**, may be a good choice. Functions that the algorithm writer may add to the language extend the set of "primitives" that are available for the coding of algorithms. The Perl and Python languages are widely regarded as versatile tools for text manipulation, string, and general-purpose programming.

Practical implementations of computer languages encode a large number of algorithms, which users of those languages take for granted. These include algorithms for parsing source language statements and turning them into more immediately executable code, algorithms for handling addition, subtraction, multiplication, and division, algorithms for extracting square roots, for calculating logarithms, and so on. Already, in the implementation of the statements of the computer language that will be used, algorithms are pervasive. Algorithms for handling such "primitive" operations are primarily a matter for compiler writers and other specialists, and will not be discussed further in this article.

Visual Devices

Visual devices can be helpful in the development and description of algorithms. The best known of these are flowcharts and structure diagrams. Flowcharts emphasize the sequence of operations within the algorithm or, more generally, within a computer program. Structure diagrams emphasize the command structure of the code. The master routine delegates tasks to a succession of lower level routines that, in their turn, delegate tasks to routines that are further down the hierarchy. There is a preference for algorithmic descriptions that are associated with simple forms of structure diagram.

Computational Complexity

Optimality, that is, keeping computational time to a minimum, is a serious issue for operations that must be carried out a large number of times. Hence the emphasis on *computational complexity*, that is, the investigation of how the number of operations of the predominate type increases with the size of the problem. This has led to attention to the asymptotic behavior of algorithms, that is, to the behavior as the size of the problem increases. Sorting algorithms will be used for illustration.

Bubblesort is a simple comparison-based algorithm. While it is not recommended for practical use, it is a useful point of reference, in making comparisons with more satisfactory algorithms. A first pass though the data uses the comparison and perhaps the exchange of adjacent elements to bring the largest element into the final position. The next pass then brings the next largest element into the second last position, and so on. The algorithm requires $N(N-1)/2$ comparisons and, on average, half that number of exchanges. In order to simplify the discussion, exchanges are commonly treated as a tax on comparisons, with the tax rate varying from one algorithm to another and from one computer implementation to another.

It follows from the discussion above that the computational cost of the *Bubblesort* algorithm is

$cN(N-1)$, where c is a suitably chosen constant, so that the algorithm is $O(N^2)$. For certain special inputs, there are sorting algorithms, not based on comparisons, that are $O(N)$. The relevant constant c_0 will be different, and, indeed, the operations that dominate the computational cost are not comparisons. What is important is that for sufficiently large N, in this example for $N > c_0/c$, the inequality $c_0 N < cN^2$ is satisfied. Recall the earlier remark that the interest is in computational cost when N is "large". Algorithms that are $O(N)$ or better are said to be *scalable* [5].

Two efficient and widely used sorting algorithms are *Mergesort* and *Quicksort*. *Mergesort* has best-case, average-case, and worst-case performance that is $O(N \log N)$. Most implementations require the use of an auxiliary array for storage of intermediate results, which can be a disadvantage relative to *Bubblesort* and *Quicksort*. As usually described, *Quicksort* has best-case and average-case performance that is $O(N \log N)$, with $O(N^2)$ worst-case performance. The algorithm can however be modified to be $O(N \log N)$, even in the worst case [7]. Depending on the computing implementation, the factor by which $N \log(N)$ must be multiplied to give a realistic time can be smaller than for *Mergesort*.

More than Polynomial Complexity

An algorithm that is $O(N^p)$ for some p has polynomial complexity. If an algorithm is not $O(N^p)$ for any p, then the computational cost will make the calculation intractable for any except relatively small N. An algorithm that is $O(N^{500})$ would be just about as intractable as an algorithm that is exponential in N, that is, an algorithm that is $O(e^{aN})$ for some $a > 0$. In practice, however, when polynomial complexity can be achieved, p is typically quite small, no more than 3.

In order to illustrate the reach of computational complexity, consider the naive use of **maximum likelihood** methods such as are described in [8], for the estimation of evolutionary trees from nucleic acid sequence data, in what is known as phylogenetic reconstruction. With n taxa, the number of unrooted bifurcating trees with n labelled tips is $(2n-5)!/[(n-3)!2^{n-3}]$. It can be shown that this makes the problem, without accounting for the increase in computation per tree as n increases, at least $O(n^{n-2})$. Examination of all likelihoods is possible only for n less than about 12; for larger n, it is necessary to resort to one of a number of probabilistic and/or heuristic methods that seem likely to give a good approximation to the maximum likelihood solution.

A problem with approximate methods is that it is often impossible to be sure that the problem has been "solved", and there has been a continuing search for "better" methods. The website `http://evolution.genetics.washington.edu/phylip/software.html` is an interesting source of information on the large variety of software and methods that have been developed for the estimation of evolutionary trees.

There is an important special class of problems that are said to be NP-complete. For details of the definition, see [6, 7]. Several are problems of considerable practical importance. For these problems, no polynomial time algorithm is known. All are suspected to require more than polynomial time; however, this has not been proved. Several of them have polynomial time approximate solutions that are adequate for most practical purposes (Cormen et al.[7]). One of the best-known examples is the traveling salesman problem: Given the array of $n(n-1)/2$ distances between n cities that a salesman must visit, find the minimum distance route that passes through all n cities. Cook[6] presents an overview of computational complexity.

Algorithms and Models

Many algorithms that are in practical use lack a totally convincing theoretical basis. They may be developed using a *heuristic* approach, effectively a trial and error approach that tries what seems to make sense, then testing it to see whether it works. When such approaches are used in statistical data analysis, they lead to the use of models that may be fairly described, following Breiman [4], as algorithmic. Although Breiman does not explain how algorithmic models arise, some of the motivations are:

- Extensions of algorithms, for example, normal theory statistical models, into contexts where the theory that motivated the models is no longer plausible.
- Algorithms for models of a learning process, leading to the use of the term *machine learning*. **Neural networks** have this character.

- Algorithms that mimic processes that have been found useful in taxonomic identification or medical diagnosis (*see* **Computer-aided Diagnosis**. **Tree-structured Statistical Methods**, often called decision tree methods (*see* **Decision Analysis in Diagnosis and Treatment Choice**), mimic the creation of a botanical or other taxonomic key.

If the purpose of the model is prediction, then the key issue is the ability to make accurate predictions for data that are different from those used for the development of the model. It is important to devise realistic tests. Further discussion would take us outside of the scope of this present article. See, in particular, the contributions of Cox and Efron to the discussion that followed [4].

Parallel Algorithms

Clustered computing systems, with multiple processors that can be used in parallel, are now relatively cheap and straightforward to build; *see* **Computer Architecture and Organization**. The structuring of algorithms to take advantage of such multiple processor systems and their associated software is, in general, much less straightforward. Problems where the major part of the computation splits cleanly into distinct subproblems, so that the structuring is simple, are said to be *embarrassingly parallel*. Thus, for a parallel sort, the data are split into parts, the parts are sorted separately, and then, as in *Mergesort*, the separate parts are merged. Modern computational power, and such developments as parallel processors, encourage the contemplation of methods for which the computations were formerly prohibitive; for example, **computer-intensive** statistical methods, virtual reality systems, three-dimensional medical imaging (*see* **Image Analysis and Tomography**), global climate models, and so on. Growth in computational power continually extends the range of computations and their associated algorithms that are of practical interest.

Future Reading and References

The books by Knuth [12–14] are classics. Harel [10] has extensive bibliographic notes, useful in indicating where to look for additional information on published algorithms or associated literature. Cormen et al. [7] is encyclopedic in its coverage. As with Harel, the focus is on nonnumerical algorithms. For numerical and matrix algorithms, see [2, 11, 20]. Thisted [21] and Monahan [15] are useful sources of information on statistical algorithms. For algorithm design and analysis, see [1, 3, 17, 19]. Algorithm design is a creative problem-solving activity, to which the discussion in Pólya [16] is relevant. On algorithms for parallel computing, see [9, 18, 22, 23]; (*see also* **Computer Architecture and Organization**).

Sources of information on algorithms and computation include *ACM Transactions on Mathematical Software, Communications of the ACM, Computational Statistics, Computer and Mathematics with Applications, IEEE Transactions on Computers, Journal of Computational and Graphical Statistics, Journal of the ACM, SIAM Journal on Computing*, and *Statistics and Computing*, where research articles appear regularly.

Allometry

Allometry is the study of shape differences associated with size. Shape changes in growing organs or whole organisms may be triggered by either biological or physical needs. For example, a simple spherical organism may use its entire surface area for nutrient intake and respiration. If the organism doubles in diameter, then there is a fourfold increase in surface area, A, and an eightfold increase in volume, V. Food requirements are likely to be roughly proportional to volume. Spherical shape can only be maintained if additional nutrient requirements are met by increasing the efficiency of intake or by the inclusion of an increasing amount of inactive organic matter (akin to the woody structure in trees). To both of these there must be an upper limit at which the organism must either stop growing or increase its *effective* A/V ratio either by (i) convolution or branching, or (ii) alteration in shape, implying a different growth rate in some directions or in some parts of the organism. Animals and plants must also adapt their structure to meet physical demands. For example, the strength of a bone is proportional to its cross-sectional area.

The term *allometry* is used by some writers with more specific meanings usually relating to differences in proportions correlated with changes in absolute magnitude of the total organism, or of specific parts under consideration [2]. Variables measured may be morphological, physiological, or chemical. Gould also proposed, and this is now widely accepted, that the term be used regardless of the mathematical expression used to characterize the relationship between variables. We emphasize this point because many bivariate studies have been concerned with the so-called equation of *simple allometry* where two size variables, x and y, satisfy approximately a relationship of the form

$$y = \alpha x^{\beta}, \tag{1}$$

or equivalently

$$\ln\, y = \ln\, \alpha + \beta\, \ln\, x. \tag{2}$$

Relationships of the form (1) or (2) hold between many pairs of size measurements, e.g. between $x =$ *head height* and $y =$ *total height* for individuals in man and many other species from a few weeks after conception to maturity. The ratio x/y decreases with age because head height decreases as a proportion of total height. This is allied to the brain being a larger proportion of total body mass at birth than it is at maturity, because a relatively large brain is needed at birth to ensure that essential bodily functions to maintain life and stimulate growth are possible, but as the individual grows, other parts of the body (e.g. arms and legs) grow at a faster rate than the brain so as to make possible new activities by the developing individual.

Intuitively we think of size measurements x and y like lengths and masses as measures of absolute magnitude, and proportions such as x/y as shape indicators. If the latter remain constant in time, then this implies no shape change with respect to the particular size measurements and this situation is often described as *isometry* and corresponds to $\beta = 1$ in (1). Eq. (1) was proposed by Huxley [5] and has been used in a variety of contexts since.

Extensions from a **bivariate distribution** ($p = 2$) to a **multivariate distribution** ($p > 2$), where p size measurements are made on organs or parts of an organism, have received considerable attention. A diversity of approaches to suitable generalizations from the case $p = 2$ have been advocated by Teissier [9], Jolicoeur [6], Hopkins [4], and others, who recommended analyses of size and shape on the basis of either **factor analysis** or **principal components analysis**. Their approaches were basically empirical and often required assumptions which, although intuitively reasonable, were not readily amenable to statistical verification.

Mosimann [8] made a major breakthrough in the p-variate case by defining *size variables* and *shape vectors* associated, for example, with a set of distances between specified points. He defines sameness of shape in terms of vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ of distances by a relationship $\mathbf{x}_2 = c\mathbf{x}_1$, where c is a constant. Subject to certain axioms, he proved several theorems about size and shape. However, in this context, definitions of equality of shape of two organisms depend critically on how many and what measurements are made. For example, if an animal is 100 cm long from snout to tail, stands 80 cm high at its back legs, and the top of its head is 160 cm above ground, then we may argue on this evidence that it has the same shape as an animal with corresponding measurements 125 cm, 100 cm, and 200 cm, where $c = 1.25$. However, if we know also that the torso length of the

animals are, respectively, 50 cm, and 40 cm, then we would no longer consider the animals to be the same shape.

Bookstein [1] recognized the fundamental weakness in the above approaches to be the linearity implied by distance vectors and the constraints imposed by Euclidean geometry. He proposed two approaches to make the analysis of shape and shape changes more realistic. The first was by introducing concepts of curvature and tangent directions at a series of what he called landmark points. The second was a formalization of the concept of coordinate transformations first proposed by Thompson [10] using biorthogonal grids, and this is relevant also to more general aspects of morphometrics such as comparisons of shapes of corresponding parts of different species. His analyses are essentially mathematical rather than statistical in nature although he recognizes the statistical element in the interpretation of his results. A summary of the recent work on shape analysis using Euclidean distance matrix analysis can be found in [7].

For a review of conceptual and statistical difficulties associated with classic bivariate and multivariate allometry, see [3].

Alternative Hypothesis

An *alternative hypothesis* (usually symbolically represented as H_a: or H_1:) is a statement about a population or set of populations. It stands in contradistinction to the **null hypothesis**, stating what the conclusion of the experiment would be if the null hypothesis were rejected. While the null hypothesis usually expresses what the result of the experiment would indicate if nothing statistically significant results (a negative conclusion), the alternative hypothesis is stated in positive terms, i.e. something of significance is noted. The alternative hypothesis may be *two-sided* or *one-sided*. A *two-sided* alternative hypothesis would conjecture that if the null hypothesis is not acceptable, then the findings might indicate either a larger *or* smaller value for a parameter (for one population), or a difference (direction unspecified) among values for the parameter across the several populations. Notationally, a *two-sided* alternative hypothesis would take the form H_a: $\theta \neq \theta_0$ for a one-population setting, or H_a: not all θ_j are equal, for a setting with several populations. To illustrate, if μ is the population mean for one population and μ_0 is the value specified by the null hypothesis, then H_a: $\mu \neq \mu_0$; and if μ_1 and μ_2 are the means for two populations, then the alternative hypothesis might be H_a: $\mu_1 \neq \mu_2$.

The alternative hypothesis is *one-sided* when a directional relationship is indicated; that is, the value of a parameter (for one population) is smaller or larger (but only one direction is hypothesized), e.g. H_a: $\theta < \theta_0$. If several populations are being studied, a one-sided alternative would indicate specific directional relationships among the values of the parameter for the several populations, e.g. H_a: $\theta_1 < \theta_2$, if $k = 2$.

To illustrate, if μ_1 is the mean length of hospitalization for a population of males following coronary artery bypass surgery (CABG), and μ_2 is the comparable parameter for a population of females, then, if H_0: $\mu_1 = \mu_2$, the one-sided alternative hypothesis might be H_a: $\mu_1 < \mu_2$, i.e. that females have on the average a shorter postoperative hospitalization than males. A specific alternative might state how much shorter, say H_a: $\mu_2 = \mu_1 - 2$; i.e. females average 2 days less than males.

Additional terminology about the null and alternative hypothesis is sometimes used, to indicate the number of possible choices for the parameter under hypothesis. For example, for one population H_0: $\theta = \theta_0$ would be called a *simple* hypothesis because it specifies only a single choice for θ. On the other hand, H_a: $\theta \neq \theta_0$, would be termed a *composite* alternative hypothesis because there are many possible choices for θ (i.e. all values $\neq \theta_0$).

Alternative Medicine

Alternative medicine is not an entity easy to define. The **World Health Organization (WHO)** has defined alternative medicine as all forms of health-care provision which "usually lie outside the official health sector" [2], and the US **National Institutes of Health** Office of alternative medicine defines it as "therapies that are unproven" [3]. This last definition has the advantage that a proper evaluation of a therapy demonstrating its efficacy would move this therapy from alternative to orthodox. The problem with the word "alternative" is that most so-called alternative procedures are not offered as an alternative but rather as a complement to orthodox medicine; complementary medicine is therefore an expression which is often used and has been recommended. However, restricting the problem to complementary therapies ignores the fact that some proponents of alternative methods do reject orthodox medicine, and claim to offer truly alternative medical systems. The list of procedures that are considered as complementary medicine is very long and the most prevalent forms of therapy are acupuncture, homeopathy, and manipulation, i.e. osteopathy and chiropractic [4].

The proportion of the population reporting use of complementary medicine varies in Europe between 49% in France and 20% in the Netherlands [5], and is equal to 34% in the US [3]. Complementary therapies are generally used because they have fewer side effects than conventional therapies and with the aim to control symptoms. Despite this wide use, these practices remain outside of the mainstream of medicine without being completely accepted nor completely rejected, and their efficacy has not been properly evaluated.

Most alternative therapies have been in use for centuries. Ayur Veda, a traditional healing system from India, currently popular in the US is 5000 years old. The first Chinese text on acupuncture is more than 2000 years old, Hahnemann defined the principles of homeopathy 200 years ago, and Still developed a system of osteopathy in 1874 [14].

Types of Studies

A substantial number of randomized controlled trials (*see* **Clinical Trials, Overview**) evaluating alternative medical practice have been conducted, but few trials used an adequate methodology. The Groupe de Recherches et d'Essais Cliniques en Homoeopathie (GRECHO) trial of homeopathy in post-operative ileus [12] gives a good illustration of a well conducted trial. Six hundred patients undergoing planned abdominal surgery were randomized into four groups (*see* **Randomization**), one being left untreated and the other three receiving, under double blind conditions (*see* **Blinding or Masking**), either opium plus raphanus or opium plus raphanus placebo or a double placebo. Opium was at a dilution of 10^{30} and raphanus at a dilution of 10^{10}. The outcome (*see* **Outcome Measures in Clinical Trials**) was the time to recovery of bowel movements after surgery. The sample size was 600, to have a 95% chance to demonstrate a reduction in the time to recovery of bowel movements from 100 hours to 80 hours assuming a standard deviation equal to 40 hours for this measure (type I error of 5%) (*see* **Sample Size Determination for Clinical Trials**). There were no significant differences between any of the groups ($P > 0.30$). The conclusion of the trial was that the resumption of intestinal transit is not affected by placebo or by opium, either alone or associated with raphanus, in the concentrations studied.

Most studies are not that carefully designed. It is not often that the placebo effect is evaluated by comparing a placebo-treated group with a group left untreated. Some trials are described as randomized but show an obvious misconception of randomization [1]. The sample size is rarely based on statistical considerations and is much too small. The analysis is often biased by exclusion of patients. The main conclusion is often based on results observed on a subgroup of patients.

Proper quantitative **meta-analyses of clinical trials** are very difficult if not impossible to perform because of the heterogeneity between studies both in terms of patient selection and, more importantly, in terms of outcome. Nevertheless, qualitative literature reviews are feasible although they do not provide a synthetic measure of the efficacy of the therapy under study. Meta-analyses of trials evaluating alternative therapies are also difficult since many trial results are published in journals not listed in common databases, and in journals having limited resources to review clinical trial reports.

Landmark Studies

Trials of homeopathy have been reviewed by Hill & Doyon [6] and by Kleijnen et al. [7]. Hill & Doyon's review is restricted to 40 randomized trials, and excludes trials which are described as randomized but show obvious misconception of randomization, whereas Kleijnen et al.'s review includes 107 trials of which only 68 are said to be randomized. The two reviews reach different conclusions: Hill & Doyon concluding that their review failed to provide acceptable evidence that homeopathic treatments are effective, and Kleijnen et al. concluding that the evidence of clinical trials is positive, but not sufficient.

Shekelle et al. [16] reviewed studies of the safety and efficacy of spinal manipulation. Twenty-five controlled trials were identified. The conclusion is that spinal manipulation is of short-term benefit in the subgroup of patients with uncomplicated, acute low-back pain. Data are insufficient concerning the efficacy of spinal manipulation for chronic low-back pain. This review failed to report the results on the overall 25 trials.

Richardson & Vincent [15] and Vincent & Richardson [17] reviewed studies of acupuncture in the relief of pain including both randomized and nonrandomized studies. Their conclusion, based on a selection of studies including those described by the authors themselves as seriously flawed, is that there is good evidence for short-term effectiveness but weaker evidence for longer-term effectiveness.

Kleijnen et al. [8] identified 13 trials described as randomized or double-blind evaluating the efficacy of acupuncture in asthma. They conclude that no studies of high quality seem to have been published, and that claims of the efficacy of acupuncture in the treatment of asthma are not supported by the results of well-performed clinical trials.

Law & Tang [9], in a review of randomized controlled trials of smoking cessation interventions including eight trials of acupuncture on 2759 patients, concluded that acupuncture is ineffective. Li et al. [10] reviewed studies evaluating the effect of acupuncture on gastrointestinal function and disorders, and identified five trials published in China, two being described as randomized. The conclusion is that "more systematic, carefully designed and properly controlled studies are needed".

In conclusion, there does not seem to be any sound evidence of the efficacy of the alternative therapies considered here.

Problems and Solutions

Numerous arguments have been brought forward by practitioners and proponents of alternative therapies for *not* evaluating rigorously alternative therapies, and these therapies have been considered for a long time as very difficult, if not impossible, to evaluate. In 1986, the British Medical Association published a report [14] which concluded that an assessment of the value of alternative therapies

> would be *feasible* in the sense of not being totally impossible. For many therapies a formal trial would be quite inappropriate. In some cases... because the treatment was alleged to be necessarily different for each individual patient, it clearly would rule out any trial based on comparisons between patients.

We think that, in most instances, placebo-controlled trials are feasible and constitute a necessary first step since their aim is to establish the efficacy of the treatment. Placebo-controlled trials are feasible, and indeed have been conducted to study homeopathy, acupuncture, and chiropractic, using placebo drugs for homeopathy and sham acupuncture or a sham manipulation.

For acupuncture and chiropractic, double-blind trials are not recommended since a truly blind procedure would have to be carried out by a naive inexperienced practitioner who may not produce an adequate standard of treatment. Single-blind trials with independent outcome assessment are recommended. For homeopathy, double-blind trials are recommended. The argument that the treatment has to be adapted to each case is not a problem if one uses a whole placebo pharmacopoeia. Contrary to what is stated by Long & Mercer [11], blinding of the therapist does not prevent the monitoring of progress and the alteration of treatment; it is perfectly possible to adapt a placebo treatment.

Practitioners of alternative medicine have argued that trials were not possible because they thought that the methodology of trials imposed a strict selection of the patient population, this selection being based on a classification of diseases that was not relevant to them. We think that **eligibility and exclusion criteria** may be broadly defined, should correspond

to the practice of the therapists, and should respect the uncertainty principle [18].

In the same spirit, alternative therapies usually imply a flexible and individualized treatment. In principle this is not an obstacle to a placebo-controlled randomized trial, but varied sham manipulations may be difficult to organize, and the lack of conviction of the manipulator performing a sham treatment may be associated with a poorer outcome, leading to biased results.

According to Mercer et al. [13], complementary therapists insist on including both subjective and objective measures. We argue that the evaluation of the efficacy of alternative therapies must be based on a main outcome measure, defined uniquely and clinically meaningful. The analysis must be unbiased, based on the **intention to treat** principle, and include all randomized patients. The results should not be based on a subgroup analysis.

In conclusion, alternative therapies must be evaluated as rigorously as conventional therapies: trials should be designed, conducted, and analyzed with adequate methods, and should also comply with the principles of the complementary therapy studied.

Meta-analyses, having the quality of the trials they include, should be avoided because of the poor quality of the trials performed so far. Overviews are preferable. They imply a critical review of the methodology of each trial. They should include nothing but properly randomized trials. Studies where the treatment assigned to the next patient is predictable are not considered as adequately randomized. If possible, the efficacy of the therapy must be evaluated in an objective manner. It is not adequate to summarize the result of each trial by the conclusion it claims to have reached, without any discussion of the validity of this conclusion.

Anticipated Developments and Unresolved Problems

It is amazing that these therapies have been in use for such a long time without ever being properly evaluated. A meta-analysis of 12 surveys studying how physicians perceive complementary medicine in six countries concluded that it may be useful but that randomized controlled trials were urgently needed [4]. Despite this conclusion there does not seem to be any pressure to perform these evaluations.

Because alternative medicine has a cost, the only incentive for a rigorous evaluation will come, if it ever comes, from the regulatory authorities or from health insurance systems, unless the strong lobbies of practitioners and of manufacturers of homoeopathic treatments succeed in maintaining the status quo of wide use without any evidence of efficacy.

CATHERINE HILL & FRANÇOISE DOYON

American Public Health Association

The American Public Health Association (APHA) is the largest organization of public health professionals in the world, numbering over 31 000 members in 1997 organized into 31 sections and forums representing the major scientific disciplines and programmatic concerns of public health. Headquartered in Washington, DC, the main objective of APHA is the protection and improvement of public health by exercising leadership in the development of health policy and action.

APHA programs include publications, conferences, and advocacy and action on public health issues. The *American Journal of Public Health* is a monthly peer-reviewed scientific journal and *The Nation's Health* is a monthly newsletter reporting on legislation and policy issues. Professional publications include *Control of Communicable Diseases in Man* (15th Ed.), *Chronic Disease Epidemiology and Control, Standard Methods for the Examination of Water and Wastewater* (18th Ed.), *Compendium of Methods for the Microbiological Examination of Foods* (3rd Ed.), and *Standard Methods for the Examination of Dairy Products* (16th Ed.). The Annual Meeting and Exhibition, featuring more than 500 scientific and special theme sessions, has been attended by 10 000 to 15 000 public health professionals in recent years. Through its Governing Council and an array of standing and *ad hoc* committees, the Association makes recommendations on public health policy, establishes standards in a variety of public health areas, provides educational material for professional and lay use, collaborates in research projects, and enhances the professional stature of public health workers.

Since its founding in 1872, APHA has been a vigorous advocate for improving public health programs, strengthening the legislative and organizational infrastructure of community programs, and providing adequate resources to improve the health of disadvantaged groups. Much of its initial impact devolved around the control of yellow fever at the end of the nineteenth century, but it was also a leading force for international health activities, promoting a national health board (which finally resulted in the establishment of the US Department of Health, Education, and Welfare in 1953) and advocating sanitation and disease surveillance programs (*see* **Surveillance of Diseases**). Over the years it helped establish appropriate standards for the investigation and control of **communicable diseases**, especially tuberculosis and venereal diseases, nutritional disorders, and maternal and child health programs. The Association was at the forefront in advocating fluoridation of water supplies, limiting tobacco use, reduction of occupational and environmental hazards, control of drug abuse, vaccination programs, and wider choices in reproductive health and family planning. Recent issues addressed by the Association include national health care reform, state and federal funding for health programs, model community health standards, air pollution control, injury and violence, and HIV/**AIDS** programs.

The Statistics Section of the APHA

The Vital Statistics Section was founded in 1908 and renamed the Statistics Section in 1948. When established, the Section accounted for about 13% of the Association's membership, but with the growth of the size of APHA and the scope of public health disciplines and activities, the Section constituted only 1.7% of primary section affiliations in 1997. Following a period of steady growth from about 1911 with 93 members until 1971, when it reached 698 members, the size of the Statistics Section had declined to 539 in 1997. The membership in the early twentieth century was dominated by physicians who had responsibilities for state vital registration systems (*see* **Vital Statistics, Overview**), and by staff of the Bureau of the Census and of insurance companies (*see* **Actuarial Methods**). By the 1930s, academicians became a prominent portion of the membership, and this group has tended to dominate in recent years as biostatistical issues and health research have come to the forefront of statistical activities. In keeping with the evolving issues in public health and the interests of its membership, the Section was first primarily concerned with establishing a national vital statistics program (which was first considered complete for births and deaths in 1932) and in the classification of causes of death (*see* **Cause of Death, Underlying and Multiple**). Subsequently the Section's activities have involved setting standards in statistical practice including definitions used in vital registration records,

tabular presentation, contents of statistical reports of city and state health departments, and use of age adjustment (*see* **Standardization Methods**). In the 1960s, the Section embarked on a project for the APHA to produce a set of monographs on mortality and morbidity for a variety of conditions. The 16 Vital and Health Statistics Monographs were a milestone in health statistics reporting. The Section has maintained interest in, and support for, the National Health Surveys conducted by the **National Center for Health Statistics** and was an advocate for the formation of the National Death Index to aid epidemiologic research (*see* **Health Services Data Sources in the US**). In recent years the Section has dealt with issues at the cutting edge of health statistics including increased use of computers and large databases (*see* **Administrative Databases**), linking of data files (*see* **Record Linkage**), and statistical aspects of **clinical trials** and **health services research**.

The Statistics Section sponsors an annual award in honor of **Mortimer Spiegelman** to recognize outstanding young statisticians working in the public health arena.

MANNING FEINLEIB

American Statistical Association

The American Statistical Association (ASA) is a unique organization among professional associations. ASA's strength comes from the diversity of its membership, which includes different educational levels, disciplines, and types of employers. Members include professionally trained B.S., M.S., and Ph.D. level statisticians, users of statistics, government and industry statisticians, economists, psychologists, chemists, sociologists, and other scientists who use statistical techniques, as well as policy makers who have an interest in data. This diversity creates interaction among members that fosters ASA's continuous evolution, including the creation of new Chapters, Sections, Committees, publications, meetings, and events.

Diversity has been a consistent theme of the ASA since its beginning in 1839, when five men in Boston founded the group whose interest was in gathering and reporting data. Statistics, as a discipline in itself, was not known at that time. Yet these founders had an interest in seeing and analyzing data reported by medical societies, census takers, occupational groups, and others. Much of their interest was in getting facts in front of the public for policy debates and research.

The five founders had different backgrounds – ministry, law, medicine, journalism, and politics. They were interested in **vital statistics**, mortality data, accurate **censuses**, and analyzing data for guidance in diagnosing problems. In fact, an early ASA focus was in the accuracy of the US census. Edward Jarvis, ASA president from 1852 through 1882, worked with the census to improve classifications. Early ASA members helped develop the standards for classification and data presentation.

Much more active advocacy by the ASA took place then than occurs now. One of the first things the ASA did after its creation was to launch a critique of the 1840 census. An interesting debate on how questions are asked and answered was an ongoing part of the critique. The ASA was also active in promoting the creation of a permanent Bureau of the Census in 1902.

Many other professional societies were begun between 1860 and 1900, but today most of them have disbanded. The ASA continued its activities, expanding its growth and influence throughout the twentieth century. ASA moved to New York in the 1920s, then to Washington, DC in 1934. The office is now located in Alexandria, Virginia.

In the beginning, ASA held quarterly meetings with an invited membership. Those small meetings grew into an annual meeting that attracts large numbers of members and guests; in fact there were over 5500 participants in 2003. Initially, there was no ASA national office, as the President and Secretary handled most ASA business in rented office space in Boston. The ASA now has a staff of 37 led by an appointed Executive Director.

As ASA grew to include national and international members in every field of statistical practice, ASA organized into Sections, Chapters, and Committees. Chapters are arranged geographically, representing 77 areas across the United States and Canada. Sections are subject-area and industry-area interest groups covering 22 subdisciplines. Over 60 Committees coordinate meetings, publications, education, careers, and special-interest topics involving statisticians.

To bring together geographically diverse members, ASA created local Chapters. Though there are many Chapters that vie for the honor of being the first, Los Angeles was the first chartered ASA Chapter. Other groups called themselves Chapters and had local meetings, but neglected the official chartering. Chapters provide various services for their local members, depending on their size, constituency, and needs. Each has at least one meeting a year, but many have monthly meetings and the Washington Statistical Society, the Washington DC Chapter, has meetings almost on a weekly basis. Many of the Chapters offer short courses, some have social gatherings, and some publish newsletters posting job openings and updating members on news and upcoming events. Chapter members appreciate the opportunities to hear about new techniques and job opportunities and keep up with the world of statistics. A Council of Chapters, which includes a representative from each of the Chapters, was established in 1984 to govern the Chapters. Nearly half of ASA's membership belongs to at least one Chapter.

ASA membership also has vast subject-area diversity – statisticians work in medicine, education, biometrics, business and economics, government statistics, engineering, quality control, computing, consulting, marketing, sports, the environment, and many

other areas. To be sure that the ASA was meeting the needs of working statisticians, it began establishing Sections. The first was the Biometrics Section, established in 1938. Though the **International Biometric Society** began shortly thereafter, the activity of the Biometrics Section increased. Indeed, the relationship between the Biometrics Section and the Society was strong and continues today. The Biometrics Section is one of the ASA Sections involved in the program for the Eastern North American Region's (ENAR) Spring Meeting of the Biometric Society. In the mid-1940s, a Section on the Training of Statisticians, later renamed the Section on Statistical Education, was formed. Sections did not proliferate at the rate that Chapters did. One reason may have been that Sections were represented on the ASA Board of Directors, and a second may have been that there was little encouragement to form new Sections. However, by the mid-1980s, there was a demand by members to form more Sections. One vital service of Sections is their role in formulating the program for the annual meeting. Each Section has a representative on the Program Committee and organizes a certain number of sessions for the annual meeting. In addition, Sections hold short courses, maintain electronic bulletin boards and email lists for their members, write newsletters, and keep their members informed of new developments in their fields of interest. There are now 22 active Sections in the ASA, with two-thirds of the ASA membership belonging to at least one Section. A Council of Sections, consisting of one representative from each group, governs the Sections.

Unlike Chapters and Sections, which are responses to members' professional interests, Committees are working groups for ASA internal policies and functions. There are many different kinds of Committees, some of which take care of internal business such as ethics, fellows, nominations, and planning. Others are concerned with minority groups, international participation, budgeting, ASA's relations to other professional organizations, or management of the ASA's growing array of journals and magazines. Committees are usually appointed by the President and report to the Board of Directors. There are now over 60 active Committees in the ASA.

Another important service the ASA offers to its members is its publications. In 1888, ASA established the ***Journal of the American Statistical Association*** (*JASA*), which has long been considered the premier journal of statistical science and is now the most widely cited journal in all mathematical sciences. Though the types of articles in it have changed over time, it is a strong link to members' interests, presenting articles describing new theories and applications. *JASA* is primarily seen as an outlet for the publication of academic members' articles, though members who work in government and industry also publish there. *The American Statistician* is aimed at a broader audience. It has articles on theory as well, but also contains commentary on statistical issues of the day, book reviews, software reviews, and a teaching corner. *Amstat News* is a monthly magazine with news about the profession, the activities of the ASA, and its members.

ASA has expanded its publications over the years to include eight professional journals, three magazines, and various brochures and information kits. Many ASA professional journals are sponsored jointly with other associations. *Technometrics* was developed in the l950s with the now named American Society for Quality. The *Current Index to Statistics* is published with the Institute of Mathematical Statistics. The *Journal of Computational and Graphical Statistics* is produced with the Institute of Mathematical Statistics and the Interface Foundation of North America. The *Journal of Agricultural, Biological, and Environmental Statistics* is published jointly with the International Biometric Society. The *Journal of Educational and Behavioral Statistics* is produced with the American Educational Research Association. ASA also offers a book series in conjunction with the Society for Industrial and Applied Mathematics.

As the ASA began working more with people who used data and were interested in statistics but were not trained statisticians, the idea for a publication more of interest to the general public was advanced. *Chance* came into being as a publication of Springer-Verlag, but is now jointly published by Springer-Verlag and ASA, with all editorial content determined by ASA. This publication is popular with a large group of people, but especially among those who teach statistics at the community college and undergraduate level. Another publication of more general interest is *Stats: The Magazine for Students of Statistics*.

ASA offers many of its journals and magazines on the Internet. Members have access to the JSTOR online database of the *Journal of the American Statistical Association* and *The American Statistician* as a benefit of ASA membership. Access to JSTOR

allows members to search all ASA journals, including over 100 years of *JASA* in full-text format. *JASA* is available through JSTOR from 1888, the inaugural year of the journal, through the volume published five years prior to the current year. Other journals and magazines publish abstracts or selected whole articles on the ASA web page or publication-specific sites.

The ASA has always been interested in education. The second Section formed was on the training of statisticians. For many years, the emphasis was on educational opportunities for members, or for statisticians. In the last 20 years, the ASA has expanded its view to include education for nonstatisticians, with a special emphasis on teaching statistics in grade schools and high schools. The ASA has developed workshops, with funding from the National Science Foundation, for teachers who help transfer knowledge about the collection, analysis, and presentation of data. Those workshops for teachers of both mathematics and science have been very effective. ASA also offers educational opportunities for members to include short courses beyond those offered at the annual meeting.

Similarly, the ASA has expanded its meetings. The Joint Statistical Meetings (JSM) is the largest gathering of statisticians held. It is jointly sponsored by the American Statistical Association, International Biometric Society (ENAR and WNAR), the Institute of Mathematical Statistics, and the Statistical Society of Canada. Attended by more than 5500 people in 2003, activities of the meeting include oral presentations, panel sessions, poster presentations, continuing education courses, an exhibit hall with state-of-the-art statistical products and opportunities, a career placement service, society and Section business meetings, Committee meetings, social activities, and networking opportunities. The location of JSM changes every year to ensure all members have an equal opportunity to attend.

Though an annual meeting for the entire membership is a cornerstone, the ASA has other regular meetings. About every other year there is a conference on **radiation** and health, sponsored by one or more federal agencies, depending on the exact topic. There is also a workshop cosponsored by ASA and the **Food and Drug Administration** that takes place each year. Certain Sections, including the Survey Methods Research Section, Health Policy Statistics Section, and Biopharmaceuticals Section, have meetings or conferences every other year on topics of interest to their members. Books that have been highly useful to practitioners have followed these conferences. In recent years, the ASA has cosponsored many different kinds of meetings, ranging from those focused on teaching statistics in business schools to those focused on undergraduate research. The ASA works with its Sections and Chapters to help in setting up meetings.

Over the years, the ASA has set up a series of awards. The most widely known is its selection of Fellows. Each year, members are elected for this honor, recognizing their achievements in statistics and service to the ASA. An annual Founders Award was established to recognize a few members for their exceptional service to the ASA. In total, there are 10 awards given by the national office, plus those given by individual Chapters, Sections, and Committees. Most awards are given on an annual or biannual basis.

The changing needs of the ASA membership keep pushing the Association forward, developing new services and products for its members. The diversity that was present at the beginning of ASA has been responsible for its growth and success as a professional association.

For those interested in more information about the ASA, please contact ASA, 1429 Duke Street, Alexandria, VA 22314-3402, USA; `www.amstat.org`, or email *asainfo@amstat.org*.

BARBARA BAILAR, WILLIAM B. SMITH &
MEGAN R. KRUSE

Analysis of Covariance

Analysis of covariance (ANCOVA), in modern usage, describes statistical models in which a model to compare groups (which usually involves indicator or **dummy variables** such as discussed under **analysis of variance**), incorporates a continuous **covariate** or covariates obtained at the level of the basic measurement unit. The primary focus is usually assumed to be on potential group differences, not on the continuous covariate(s). Snedecor & Cochran [3] describe four basic uses for analysis of covariance models. These include the increase of precision in designed experiments, the adjustment for sources of **bias in observational studies**, to throw light on treatment effects in randomized experiments (*see* **Randomized Treatment Assignment**), and the study of **regression** in multiple classifications. In what follows, we discuss these basic uses and the statistical modeling involved. We also discuss the estimation of adjusted treatment means, and the interpretation and pitfalls associated with the technique.

Increasing Precision in Designed Experiments

As discussed in the article on **Analysis of Variance**, an experimenter can often group experimental units into homogeneous sets by **blocking** on factors related to the response. The levels of the treatment can then be assigned, randomly, to the units within a block. This blocking reduces experimental error, and increases the precision with which we can make statements about the treatment effects. However, blocking on all factors related to the response is not feasible, and even after blocking on major factors, there may be other variables related to the response, which can be measured on the experimental units. The analysis of covariance is a statistical technique developed originally to allow experimenters to incorporate information on a factor or factors which varied across experimental units, and which thus contributed to the experimental error term in the analysis of variance models. In agricultural experiments, for example, by using fields as blocks, a number of climate variables could be controlled. However, even within a field, there could be variation in fertility from plot to plot. If the effect of that fertility variable could be captured in an appropriate statistical model, then the unexplained variability would be reduced and, thus, more precise statements about the effects of the treatments could be made.

In a study of the effects of drug treatment on blood pressure, we may determine that age, gender and treatment center may be important blocking variables because of their potential relationship to blood pressure, and the feasibility in a controlled trial of assigning patients to blocks defined by levels of these factors. However, a subject's blood pressure at pretest will very likely be related to posttest blood pressure. If we can incorporate information on pretest blood pressure into the analysis of variance model, then we should be able to reduce the experimental error term and make more precise comparisons of the effects of the drug (*see* **Baseline Adjustment in Longitudinal Studies**). Cox [1] calls such supplementary observations, which may be used to improve precision, *concomitant variables*.

It is important to consider the scientific requirements, or assumptions, on concomitant observations [1] in order that comparisons between treatments "adjusted" for levels of the covariate are meaningful. These requirements are given below, along with the consequences of a violation of the assumptions. In general, if there is a constant difference in the response between the treatment groups for all values of the concomitant variable(s), then the adjusted treatment effect is this constant difference. However, because we have not had control of the values of the concomitant variable, we must rely on a statistical model to make the adjustment. The following are the requirements for these concomitant observations.

1. The concomitant observation is assumed to represent a factor (or a constellation of factors, e.g. fertility) at the level of the experimental unit which is *unaffected by the treatment*. It can be measured *before* the treatments are assigned or applied (e.g. pretest blood pressure), *before* the effect of the treatment has had time to develop, or on some part of the process which is *not* related to the assignment of the treatment (e.g. the time of day that the measurement is taken). Randomization should ensure that the covariate does not differ significantly between treatment groups; however, this can be checked. If the groups differ with respect to the covariate, they

will be compared at a value of the covariate which is not typical of either group. Further, the statistical model will need to **extrapolate** beyond the region where there is the most data for both groups, and this makes an assumption that the statistical model is correct in that region, for both groups. If the treatment *does* affect the concomitant variable, then adjusting for differences in the concomitant variable may well "adjust away" the actual treatment differences.

2. The relationship between the response and the covariate must be the same for all groups. That is to say, there is no **interaction** between the treatments and the covariate (*see* **Treatment-covariate Interaction**). If there is an interaction, then it does not make sense to compare the groups at a single value of the covariate, since any difference noted will not apply for other values of the covariate. This assumption is equivalent to saying that the relationship between the response and the concomitant variable(s) should appear as parallel curves, one for each treatment group [1]. Again, the assumption of parallel curves can be checked at the time of modeling.

Adjustment for Bias in Observational Studies

In **observational studies**, groups may differ on factors related to the response because of naturally occurring phenomena that lead to self-selection into groups, or historical differences in how groups have developed. Snedecor & Cochran [3] give the example of a study examining the relationship between obesity and physical activity on the job. Since obesity is related to age, and there may be differences between the age structures for different occupations, adjusting for age differences between the workers in the study by analysis of covariance will help model the response and adjust for the age bias. However, for the reasons noted above, considerable care needs to be taken in the interpretation of such models for the following reasons.

1. If the occupations differ significantly with respect to age, then we will obtain a comparison of the relationship between high and low activity occupations for an individual of a fixed age. There may be few individuals of that age in either occupation, so the comparison may be meaningless, and will necessarily involve an extrapolation of the statistical model.
2. The observational nature of the data make it impossible to determine if it is the physical inactivity on the job which leads to the obesity, or whether individuals who are obese select certain occupations. While the analysis of covariance may allow for a comparison adjusting for age, it cannot answer this very basic question.

The Nature of Treatment Effects in Designed Experiments

In many investigations there will be variables that can be measured on the experimental units which can help elucidate the mechanisms responsible for the treatment effects. For example, in the blood pressure study mentioned earlier, we could also measure a subject's pretest and posttest weight. A natural question is whether the posttest blood pressure can be explained by the change in weight which might have occurred over the course of treatment. Analysis of covariance provides a modeling approach to examine the differences between groups in posttest blood pressure using pretest blood pressure and weight change as covariates. It is important to note that adjusting for weight change may, in fact, remove the difference between groups; however, to claim on this basis that the drug had no effect would be misleading if the effect of the drug was to increase weight loss. In this latter case we might report that there was a difference between the two groups in posttest blood pressure (adjusting for pretest differences in blood pressure), and that, at the same time, there was a difference in weight loss; the loss of weight was associated with a reduction in blood pressure.

Again, this example points out the need to be very careful in interpreting the differences (or lack thereof) between adjusted means. Cox [1] presents a thorough discussion of this type of situation, in which he interprets a series of possible data patterns.

Regression in Multiple Classification

Suppose we wished to model and examine the relationship between blood pressure and physical activity across several socioeconomic strata, and age groups. We could develop a regression model with indicator variables which coded for socioeconomic

status and age group, and a continuous variable which provides the measure of physical activity for each individual. By adding regression variables which code for the interaction between socioeconomic status and physical activity, say, we could assess whether the relationship between blood pressure and physical activity was the same for all socioeconomic strata. If there was no interaction, the significance of the indicator variables coding for socioeconomic status would assess whether there are significant differences in blood pressure between levels of socioeconomic status, after adjusting for physical activity differences through the statistical model (i.e. when we compare two different individuals with the same level of activity).

Again, the caveats discussed above apply. We should determine whether physical activity differs significantly between groups and whether the response curves are parallel, before proceeding to discuss these adjusted means.

The Model

To illustrate the technique, we consider a randomized block experiment (*see* **Randomized Complete Block Designs**) in which t treatments are randomly assigned to experimental units in each of b blocks. Furthermore, assume that for each experimental unit, we have a measurement on an explanatory variable (e.g. pretest blood pressure). If we define the covariate measurement from the plot in the jth block which received the ith treatment as x_{ij}, we can write the model as

$$Y_{ij} = \mu + \alpha_i + \beta_j + \gamma(x_{ij} - \overline{x}_{..}) + \varepsilon_{ij},$$

$$\text{with constraints } \sum_{i=1}^{t} \alpha_i = 0, \sum_{j=1}^{b} \beta_j = 0.$$

(Note that the subscript dot indicates that averaging has been taken over the relevant subscript(s), so $\overline{x}_{..}$ is the average of the covariate over all tb experimental units.)

In the model, μ represents the overall mean effect, α_i and β_j represent the effect of the ith treatment and jth block, respectively, and ε_{ij} represents the unexplained variation in Y_{ij}. We usually assume $\varepsilon_{ij} \sim \mathrm{N}(0, \sigma^2)$, independently.

In addition, we add the term $x_{ij} - \overline{x}_{..}$ to reflect the variation in the covariate about its average; γ is the regression coefficient associated with that covariate. If $\gamma = 0$, then the covariate information is not related to the response after adjusting for treatments and blocks, i.e. there is no increase in precision resulting from adjusting for the covariate. The transformation of the covariate from x_{ij} to $x_{ij} - \overline{x}_{..}$ is useful to produce a regression variable which is **orthogonal** to the mean. Furthermore, note that if $x_{ij} = \overline{x}_{..}$, then the expected value of the ith treatment mean is $\mathrm{E}\left(\sum_{j=1}^{b} Y_{ij}/b\right) = \mu + \alpha_i$. That is, "adjusting for the covariate" provides an estimate, via the statistical model, for the treatment mean for a hypothetical plot with $\overline{x}_{..}$ as covariate value (see subsequent discussion).

Estimates of Parameters

From this model, the **least squares** estimates (**maximum likelihood** estimates under the above model for the ε_{ij}s) are

$$\hat{\mu} = \overline{y}_{..};$$

$$\hat{\alpha}_i = (\overline{y}_{i.} - \overline{y}_{..}) - \hat{\gamma}(\overline{x}_{i.} - \overline{x}_{..});$$

$$\hat{\beta}_j = (\overline{y}_{.j} - \overline{y}_{..}) - \hat{\gamma}(\overline{x}_{.j} - \overline{x}_{..});$$

and

$$\hat{\gamma} = \frac{\sum_{i=1}^{t}\sum_{j=1}^{b}(Y_{ij} - \overline{y}_{i.} - \overline{y}_{.j} + \overline{y}_{..})(x_{ij} - \overline{x}_{i.} - \overline{x}_{.j} + \overline{x}_{..})}{\sum_{i=1}^{t}\sum_{j=1}^{b}(x_{ij} - \overline{x}_{i.} - \overline{x}_{.j} + \overline{x}_{..})^2}.$$

If we define E_{yy}, and E_{xx} to be the Residual Sum of Squares from a randomized block model for the Y_{ij}s and x_{ij}s, respectively, and E_{xy} to be the Residual Sum of Cross-Products, then we have

$$\hat{\gamma} = \frac{E_{xy}}{E_{xx}}.$$

Note the similarity between the above expression for $\hat{\gamma}$ and the expression for the least squares estimate of the slope in a simple **linear regression** model. Thus, the estimate of γ is equivalent to that obtained from a simple linear regression of the **residuals** from a randomized block model for the Y_{ij}s on the residuals from a randomized block model for the x_{ij}s. The estimate will be different from zero when

there is residual variation in the Y_{ij}s explained by the x_{ij}s.

The estimate of σ^2 can be obtained as usual from the $\hat{\varepsilon}_{ij}$s; that is,

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^{t}\sum_{j=1}^{b}(Y_{ij} - \hat{\mu} - \hat{\alpha}_i - \hat{\beta}_j - \hat{\gamma}(x_{ij} - \overline{x}_{..}))^2}{(t-1)(b-1)-1} = \frac{(E_{yy} - E_{xy}^2/E_{xx})}{((t-1)(b-1)-1)}.$$

We note that the first term in the numerator is the Residual Sum of Squares from the randomized block model for the Y_{ij}s. The second term, which must be positive, will significantly reduce the randomized block Residual Sum of Squares for the Y_{ij}s whenever $\hat{\gamma}$ is significantly different from zero.

The extension to additional covariates, or to **transformations** of the covariates [e.g. adding $(x_{ij} - \overline{x}_{..})^2$ to the above model] requires no new theory. It will become more difficult to compute the required quantities as the model becomes more complex, but with existing **software** these computations are easily performed.

Adjusted Treatment Means: Estimation and Testing

As discussed above, the analysis of covariance allows us to estimate treatment means which are adjusted for the covariate via the statistical model (i.e. estimated at $x_{ij} = \overline{x}_{..}$). For example, for the randomized block design above, the adjusted treatment mean for treatment i is

$$\sum_{j=1}^{b}\frac{\hat{Y}_{ij}}{b} = \hat{\mu} + \hat{\alpha}_i = \overline{y}_{i.} - \hat{\gamma}(\overline{x}_{i.} - \overline{x}_{..}).$$

Thus, if $\hat{\gamma}$ is positive (i.e. in general, large values of Y_{ij} are associated with large values of x_{ij}), and $\overline{x}_{i.} > \overline{x}_{..}$ (reflecting the fact that, on average, treatment i was applied to units with larger values of the covariate), then the observed mean for treatment i will be adjusted downwards, as required. The ith adjusted treatment mean has variance

$$\text{Variance}_{\text{Adjusted Treatment Mean}} = \sigma^2\left[\frac{1}{b} + \frac{(\overline{x}_{i.} - \overline{x}_{..})^2}{\sum_{i=1}^{t}\sum_{j=1}^{b}(x_{ij} - \overline{x}_{i.} - \overline{x}_{.j} + \overline{x}_{..})^2}\right],$$

and, using the estimate for σ^2 given earlier, we can obtain **confidence intervals** for any adjusted mean; the relevant reference distribution being $t_{(t-1)(b-1)-1}$, i.e. **Student's *t*** with $(t-1)(b-1)-1$ **degrees of freedom**.

Likewise, we can test an hypothesis based on a **contrast** in the adjusted treatment means. If $\boldsymbol{c}_k$ is a $t \times 1$ vector of constants with $\sum_{i=1}^{t} c_{ik} = 0$, then, similarly to the development given in the analysis of variance entry, the ratio

$$F = \frac{\left(\sum_{i=1}^{t} c_{ik}\,\text{Adjusted Treatment Mean}_i\right)^2 \Big/ \sum_{i=1}^{t} c_{ik}^2}{\text{Residual Mean Square}_{\text{Full Model}}},$$

will follow the $F_{1,(t-1)(b-1)-1}$ distribution (i.e. ***F* distribution** with 1 and $(t-1)(b-1)-1$ degrees of freedom) under the hypothesis that the contrast in the (adjusted) treatment means is zero.

To test the global hypothesis that the adjusted treatment effects are zero, the extra sum of squares principle F test (*see* **Analysis of Variance**) can be employed. That is, under the hypothesis H: $\alpha_i = 0, i = 1, \ldots, t$, the model becomes

$$Y_{ij} = \mu + \beta_j + \gamma(x_{ij} - \overline{x}_{..}) + \varepsilon_{ij},$$

which is the model for a completely randomized design (one-way classification) with a covariate observed on each plot.

If T_{yy} represents the "Treatments Sum of Squares" for the response variable under the randomized block design, and T_{xx} and T_{xy} are defined analogously for the x_{ij}s and the cross-products of the response and covariate, then, following the discussion of the randomized block design, we can estimate γ in the

hypothesized model as

$$\hat{\hat{\gamma}} = \frac{\sum_{i=1}^{t}\sum_{j=1}^{b}(Y_{ij} - \overline{y}_{.j})(x_{ij} - \overline{x}_{.j})}{\sum_{i=1}^{t}\sum_{j=1}^{b}(x_{ij} - \overline{x}_{.j})^2} = \frac{(E_{xy} + T_{xy})}{(E_{xx} + T_{xx})}.$$

The Residual Sum of Squares from the hypothesized model is

$$\text{Residual Sum of Squares}_{\text{H: }\alpha_i=0} = \sum_{i=1}^{t}\sum_{j=1}^{b}((Y_{ij} - \overline{y}_{.j}) - \hat{\hat{\gamma}}(x_{ij} - \overline{x}_{..}))^2 = E_{yy} + T_{yy} - \frac{(E_{xy} + T_{xy})^2}{(E_{xx} + T_{xx})}.$$

Then, the difference in the Residual Sum of Squares between the hypothesized model and the full model forms the basis for the extra sum of squares principle F test. Thus, if

$$\Delta = \text{Residual SS}_{\text{H: }\alpha_i=0} - \text{Residual SS}_{\text{Full Model}},$$

then the extra sum of squares principle F test statistic is

$$F = \frac{\Delta/(t-1)}{\text{Residual SS}_{\text{Full Model}}/((t-1)(b-1)-1)}.$$

The resulting value can be compared with tables of the $F_{(t-1),(t-1)(b-1)-1}$ distribution.

The difference between the two Residual Sums of Squares in the numerator is

$$\Delta = T_{yy} - \left(\frac{(E_{xy} + T_{xy})^2}{(E_{xx} + T_{xx})} - \frac{E_{xy}^2}{E_{xx}}\right),$$

which we note is the Treatment Sum of Squares for the response, T_{yy}, adjusted for the covariate.

With certain software packages (e.g. SAS [4]), the programs that fit normal linear models will compute type III sums of squares and mean squares (*see* **Analysis of Variance**). The type III sums of squares provide, for each source, the sum of squares after adjusting for all other terms in the model. Thus, if the covariate is included in a model, the type III mean square for treatments will be the relevant numerator for the F test, and the F test will be provided in the table. For interactive modeling, such as that provided by GLIM [2] (*see* **Software, Biostatistical**), the change in deviance when the "factor" coding for treatments is dropped from the full model, divided by $(t-1)$, will give the numerator for the test, the denominator being the deviance for the full model divided by its degrees of freedom.

Checking Assumptions on the Covariate

In this section we briefly discuss how the important issues surrounding the meaning of "adjusting for the covariate" can be assessed. For a discussion of methods for checking other aspects of the fit of the model, see **Model Checking, Diagnostics,** and **Residuals**.

The first concern described above is that if the covariate is significantly different for different treatments, then the adjustment may require extrapolation beyond the data on which the model was developed to covariate/treatment combinations which did not (or may not) occur. This raises both scientific and statistical concerns. Related to this, if the treatment affects the covariate, then we may adjust away the effect of the treatment on the response by adjusting the treatment means to the same value of the covariate. An analysis of variance conducted on the x_{ij}s will help address this concern. If there are significant treatment effects for the x_{ij}s, we must be very careful in interpreting the results of the analysis of covariance.

The second issue was that the relationship between the response and the covariate should be a set of parallel curves, one for each treatment, in order that we get the same treatment difference at all values of the covariate. In the linear relationship case, we can address this issue by adding $t-1$ columns to the X matrix, representing the product of the covariate and each of the $t-1$ columns coding for the treatments. If adding (deleting) these $t-1$ interaction columns to (from) the model reduces (increases) the Residual Sum of Squares significantly, we have evidence that the curves are not parallel. If the model contains m columns in X to represent the effect(s) of the covariate(s), we require $m \times (t-1)$ additional columns to assess fully the interactions. These should be added (deleted) in sets of $t-1$.

Thus, we should:

1. Check the covariate(s), via analysis of variance, for significant treatment effects.
2. Fit the analysis of covariance model, and the model with interactions between treatments and the covariate(s). Check the significance of the interactions of the covariate and treatments.
3. If there is no difference between treatment groups in the covariate, and no interaction between treatments and the covariate in the augmented analysis of covariance model, proceed to the analysis of covariance as described earlier. If problems are identified, refer to scatter plots (*see* **Graphical Displays**) of the relationship between the response and the covariate to determine the type of statement which can be made safely.

Comparison with other Modeling Strategies

Consider the experiment described earlier. Subjects with high blood pressure are randomly assigned (m per group) to a drug group or a placebo group. A pretest measure of blood pressure is taken and then blood pressure is reassessed at posttest. We have (at least) three choices for the analysis.

1. Take the difference in blood pressure for each subject (posttest−pretest), and analyze these differences via a **paired *t* test**. This analysis investigates whether the mean blood pressure change is the same for the two groups.
2. Treat the two measures of blood pressure as the response, and analyze the data as for a repeated measures design (*see* **Longitudinal Data Analysis, Overview**). This is an example of the class of designs described in the analysis of variance entry where there are two sources of experimental error to consider: *between* subjects and *within* subjects. The relevant question is whether there is an interaction between treatment and test. That is, is the relationship between pre- and posttest measures the same for both groups?
3. Use the pretest measure as a covariate, and then conduct an analysis of covariance with the posttest measure as response. This analysis compares the mean posttest blood pressure at the average pretest blood pressure for the two groups.

To compare these analyses, define Y_{ijk} to be the measured value of blood pressure for the kth test on the jth subject in the ith group. A model for the first analysis can be written as

$$Y_{ij2} - Y_{ij1} = \mu^* + \alpha_i + \varepsilon^*_{ij},$$

or

$$Y_{ij2} = \mu^* + \alpha_i + Y_{ij1} + \varepsilon^*_{ij},$$

where μ^* is the overall mean, α_i is the effect of the ith group, and ε^*_{ij}, the experimental error term, reflects the effects of uncontrolled factors which differ from pretest to posttest for the same subject. We note that this model is just a special case of the model developed above for the analysis of covariance. Specifically, if $\gamma = 1$, and $\mu = \mu^* + \overline{y}_{..1}$, we get the above model from the analysis of covariance model. Thus, the analysis of covariance provides a more general analysis of these data.

A model for the second analysis can be written

$$Y_{ijk} = \mu + \alpha_i + \delta_{ij} + \tau_k + (\alpha\tau)_{ik} + \varepsilon_{ijk},$$

where δ_{ij} and ε_{ijk} are the between-subjects and within-subjects experimental error terms, respectively, τ_k represents the effect of the kth test time, and $(\alpha\tau)_{ik}$ represents the effect of the interaction of the ith level of treatment group and the kth test time.

In this model, the relevant hypothesis is $\mathrm{H}: (\alpha\tau)_{ik} = 0, i = 1, 2; j = 1, 2,$ which states that the effect of test time is the same for both groups. This test is algebraically equivalent to the test of no difference between the adjusted treatment means as provided by the analysis of covariance. Consequently, we could model this situation using either approach. However, the analysis of covariance may be easier to interpret and explain, and by considering the assumptions of no differences in pretest measures, and parallel curves for the different treatments, we are more naturally led to assess whether, for instance, the difference in posttest blood pressure for each treatment is the same at all levels of pretest blood pressure. Furthermore, it provides the additional information concerning the relationship between the pretest and posttest blood pressures.

Concluding Remarks

The above discussion has concentrated on the analysis of covariance in designs in which there is estimation of a single source of experimental error. More complicated designs, such as those discussed in the analysis of variance entry, allow for the estimation of two or more sources of error, such as between-subjects variation due to differences in the subjects, and within-subjects variation due to differences between the test times for multiple measurements on the same subject. In such designs, covariate information could be available on the subjects (e.g. age) and/or on the test times (e.g. temperature). The analysis and interpretation of treatment differences will need to consider the relevant covariates. Again, this requires very careful modeling to ensure that the appropriate estimates of error are used in assessing treatment differences.

This same modeling strategy can be applied beyond the normal linear model described above to **generalized linear models**, allowing for the adjustment for covariates in a wide range of models.

Since the analysis of covariance models are just regression models in which there are both indicator variables and continuous covariates, the theory of model fitting, and inference about regression parameters is not different than that discussed elsewhere for **multiple linear regression** models. However, as with any statistical modeling, it is essential that the interpretation of the model be correct and clearly presented. The discussion of these models in Cox [1] provides an excellent overview of the issues involved in interpretation.

Analysis of Variance for Longitudinal Data

Analysis of variance (ANOVA) methods are some of the most commonly used techniques for the analysis of sources of variation in both experimental and observational studies. It therefore seems quite natural to ask how they might be adapted for use on **longitudinal data**. Typically, one might recognize data coming from a longitudinal study as coming from a nested design (a **split-plot** experiment, for example), with the serial measurements (subplots) being nested within each of the subjects (plots). Designs involving repeated or serial measurements differ from the typical nested experiment, however, in that the times of observation must by their very nature follow a strict temporal sequence and that, in general, measurements made on occasions close together will be more highly correlated than those further apart. Be warned: *an analysis that ignores* **serial correlation** *will almost certainly be invalid.*

This article briefly introduces the use of ANOVA methods for longitudinal data – typically, repeated measures experiments – and then discusses assumptions necessary for their validity, methods of testing for departures from these assumptions and, finally, methods for the adjustment of F tests to compensate for these departures. In case the reader feels that, after reading about the pitfalls of the use of ANOVA, it would be better to use other methods of analysis, these other methods (particularly **multivariate analysis of variance** (MANOVA) and random effects models for longitudinal data) are briefly mentioned. We will illustrate the methods for two simple repeated measures designs. In the first, each member of a single group of subjects provides measurements on each of k separate occasions. The second design involves the use of two or more groups of subjects, and again each subject within these groups provides measurements on k occasions. For both designs it will be assumed that the timing of the measurements is the same for all subjects, but the spacing between successive measurements does not, necessarily, remain constant. The more complex repeated measures designs involving changing treatment conditions over time (**crossover designs**) will not be discussed here.

Growth Curves in a Single Group of Subjects

In this design each member of a group of n subjects is observed on each of k occasions. The structure of the data is analogous to that arising from a randomized blocks experiment, with the times corresponding to treatments and the subjects being the blocks. Beware of the differences, however. The order of the successive measurements in the longitudinal data is fixed, but the allocation of treatments within blocks is randomized. There will be serial correlation in the longitudinal data that will not be present in the data arising from randomized blocks. The aim of the analysis, however, is similar. We wish to test for differences in the means for the different occasions (treatments), having first allowed for overall subject (block) differences.

The Assumed Model

The statistical model for the repeated measures data is given by

$$Y_{ij} = \mu + \alpha_j + \omega_i + \varepsilon_{ij},$$

where Y_{ij} is the measurement for the ith subject on the jth occasion, μ is the grand mean, α_j is the effect associated with the jth occasion, ω_i the effect associated with the ith subject and, finally, ε_{ij} is the error term for the ith subject on the jth occasion. Note that as there is no replication of measurements on each occasion we have to assume that there is no time-by-subject interaction (analogous to the assumption of no treatment-by-blocks interaction in the randomized blocks experiment) – this interaction being completely confounded with the error term in the following ANOVA model. It is very straightforward to carry out a routine two-way analysis of variance and construct an F test for the null hypothesis that $\alpha_j = 0$ for all j. The resulting F statistic for a test of time trends will have $(k-1)$ and $(n-1)(k-1)$ degrees of freedom. Note in passing that if $k = 2$, the above analysis is equivalent to carrying out the much simpler **paired *t* test** on the changes between the first and second occasions. The F test from one is the square of the t statistic from the other, and the resulting P values are therefore identical.

Necessary Assumptions for a Test of Time Trends

As in any analysis of variance, in order for the above F test to be valid we need to make a series of assumptions. We assume that the repeated measures are measured on an interval or ratio scale of measurement (*see* **Measurement Scale**). We also make the usual assumptions concerning random sampling from the population, independence of subjects, and normality. There is also a homogeneity assumption similar to that required for between-subjects designs. This is the assumption that for any two occasions – say r and s – the difference $Y_r - Y_s$ must have the same population variance for every pair of occasions. The variance of the difference $Y_r - Y_s$ can be written as

$$\begin{aligned}\sigma^2_{Yr-Ys} &= \sigma^2_{Yr} + \sigma^2_{Ys} - 2\text{cov}(Y_r, Y_s)\\ &= \sigma^2_{Yr} + \sigma^2_{Ys} - 2\rho_{rs}\sigma_{Yr}\sigma_{Ys},\end{aligned}$$

where ρ_{rs} is the population correlation for measurements taken on occasions r and s. Huynh & Feldt [4] and Rouanet & Lépine [8] showed that this homogeneity of the time-difference variance assumption is equivalent to the assumption that the population covariance has a certain form, referred to as **sphericity** or *circularity*. A special case of sphericity is *compound symmetry*. A covariance matrix possesses compound symmetry if and only if all the variances are equal to each other and all the covariances are equal to each other. An equivalent statement is that all the repeated measures have the same variance ($\sigma^2_r = \sigma^2_s = \sigma^2$, for all r and s) and that the correlations between measures for all pairs of occasions are equal ($\rho_{rs} = \rho$, for all r and $s, r \neq s$). Under the assumption of compound symmetry, the variance of the difference between Y_r and Y_s becomes $2\sigma^2(1-\rho)$ for any r and $s, r \neq s$. In summary, compound symmetry implies sphericity, but not vice versa. In practice, however, one is unlikely to come across data demonstrating sphericity but not compound symmetry. One exception is in a simple follow-up study with $k = 2$. In this situation, the sphericity assumption always holds (there being only two variances and a unique correlation) but compound symmetry very often will not (the variation at follow-up being higher than at the start of the experiment, for example). When $k = 2$, the sphericity assumption is not needed and the F test is always valid, provided, of course, that the other assumptions are true.

Several tests of sphericity are available, the most commonly used being that according to Mauchly [6]. These sphericity tests are of limited value, however, because of their sensitivity to nonnormality. The Mauchly test seems to be poor for detecting small departures from sphericity despite the fact that these small departures can produce substantial bias in the standard F tests. Several authors, including Hand & Crowder [3] and Maxwell & Delaney [7], for example, recommend making the more realistic assumption that sphericity does *not* hold and automatically adjust the F tests accordingly (see below). The reader can find a brief discussion of the Mauchly test in [3]. For tests of departure from compound symmetry, see [8].

Adjustments to the F tests

When the assumption of sphericity is false, it is possible to perform an adjusted F test of the equality of means over time. Box [1] derived a measure, usually denoted by ε, which measures the departure of the covariance matrix from sphericity. A matrix that displays sphericity always has an ε-value of one and departure from sphericity leads to a lowering of ε, with an absolute minimum of $1/(k-1)$. Box [1] showed that if one calculates the required F statistic and compares it with the critical values from an $\boldsymbol{F}$ **distribution** with numerator and denominator degrees of freedom given by $\varepsilon(k-1)$ and $\varepsilon(n-1)(k-1)$, respectively, then the results will be approximately correct. On its own, however, this information is of limited value since we do not know the true value of ε. One solution to the problem is to use an estimate of ε, based on the observed covariance matrix – see [3] for further details. This is the so-called Greenhouse–Geisser estimate provided by many software packages. A more refined estimate of ε, due to Huynh & Feldt [5], is also produced by these software packages, although Maxwell & Delaney [7] recommend the routine use of the Greenhouse–Geisser estimate because the former can occasionally fail to control properly the Type 1 error rate. A final option is to use the known lower bound for ε in the adjustments rather than its estimated value – see [2]. Here, the adjustment factor is simply $1/(k-1)$. This is a conservative procedure, but if the F test is still significant after making this adjustment we can at least feel fairly safe in the validity of the result. Note that the use of any of these three adjustments does not need any change in

the analysis of variance – the observed F statistics remain unchanged – but simply a change in the degrees of freedom of the theoretical F variate in order to obtain a valid ***P* value**.

Comparison of Two or More Groups

Typically, we have the results of a randomized controlled trial in which n patients have each been randomly allocated to one of m treatments. Let us assume that each treatment group has exactly r patients allocated to it, and that there are no drop-outs. Each patient then provides regular follow-up measurements, yielding a total of k repeated measures per patient. Here, the analogy is with a traditional **split plot** design where the patients are equivalent to plots and the measures repeated over time are the subplots. This analogy implies the allocation of the degrees of freedom in an analysis of variance as in Table 1. The test of real interest in this context is that for the treatments by occasions interaction: are the time trends constant across the m groups? The F statistic for this interaction is compared to an F distribution with $(m-1)(k-1)$ and $m(r-1)(k-1)$ degrees of freedom. Despite the analogy, however, the data from this repeated measures design should *not* be treated as if it were from a split-plot experiment. The degrees of freedom should be adjusted using the appropriate Greenhouse–Geisser ε estimate in order to take into account the likely serial correlation in the data (although, as before, when $k = 2$ we do not have a problem). Note again that the adjustments are made to the theoretical F variate, with no adjustment whatsoever to the observed value of the test statistic. This is done automatically in many readily available software packages. Full details are provided in [7]. It is also important to remember that even these adjusted F tests are dependent on the additional assumption necessary for the analysis of data from this design: the covariance matrices are the same (apart from sampling fluctuations) across the m treatment groups.

Table 1

Between patients	$mr-1$
Treatments	$m-1$
Residual	$m(r-1)$
Within patients	$mr(k-1)$
Occasions	$k-1$
Treatments by occasions	$(m-1)(k-1)$
Residual	$m(r-1)(k-1)$

Advantages and Problems with the Use of ANOVA

The main advantage of the traditional ANOVA approach to the analysis seems to be both familiarity (amongst the data analysts and the readers of the resulting reports) and availability of easy-to-use software. It is difficult to think of any others! An alternative, which is quite popular in the social and behavioral sciences (including psychiatry), is to drop the assumptions concerning the correlational structure of the repeated measures and move on to use explicitly multivariate tests through the use of MANOVA. Both the adjusted ANOVA and the MANOVA approaches depend on the assumption of homogeneity of covariance matrices across groups, however. The multivariate approach involves the construction and testing of a set of transformed variables representing the within-subject differences for the within-subject factor (here, occasions) – typically a set of $k-1$ orthogonal polynomial **contrasts**. When $k = 2$ the univariate and multivariate methods are identical. One can carry out tests on the contrasts separately (is there a significant linear trend, for example, or is this trend the same in the m groups?) or as part of a multivariate test (using **Hotelling's T^2** statistic, for example).

Both the ANOVA and MANOVA approaches are dependent on complete data. If there are gaps or drop-outs, the patients with missing data have to be dropped from the analysis. This might be a source of considerable bias in the results. Another, although less common, problem is the collection of haphazardly spaced data instead of the measurements being made at fixed times for everyone in the study. One possible approach is to use random effects models with either **maximum likelihood** (ML) or **restricted maximum likelihood** (REML) estimation.

One obvious alternative to the use of ANOVA is to calculate a measure of change for each subject in the study – the summary measures approach to the analysis of repeated measures. In the context of the designs discussed above, this might be an estimate of linear trend. For the first design (k observations on each of n subjects) one can simply use a single-sample t test to assess whether this trend

is statistically significant. It is also very straightforward to produce confidence intervals for this trend. For the m-group design we can enter the summary statistics themselves into a simple one-way ANOVA to test for group differences. The advantage of the latter approach is that it is extremely simple to carry out and the results even easier to interpret than the output from split-plot design (with or without the almost obligatory adjustments). Although we are still using ANOVA, we are avoiding the pitfalls arising from serial correlation by replacing the k repeated measures by a simple, single, response feature of primary interest.

GRAHAM DUNN

Analysis of Variance

Analysis of variance (ANOVA) is one of the most commonly used statistical techniques, with applications across the full spectrum of biostatistics. The first reference to the technique appeared in the work of **R.A. Fisher** [5] in which he discussed the analysis of causes of human variability under a Mendelian scheme of inheritance (*see* **Mendel's Laws**). The first reference in Fisher's published work to the analysis of variance table was in 1923 [7], in a paper on the response of 12 different varieties of potato to the application of six manure treatments. The technique was fully discussed in Fisher's 1925 book [6].

Overview

One of the principal uses of statistical models is to attempt to explain variation in measurements. This variation may be due to a variety of factors, including variation from the measurement system, variation due to environmental conditions which change over the course of a study, variation from individual to individual (or experimental unit to experimental unit), etc. Factors which are not controlled from observation to observation can introduce variation in measured values. In designed experiments, the experimenter deliberately changes the levels of experimental factors to induce variation in the measured quantities, to lead to a better understanding of the relationship between experimental factors and the response (*see* **Experimental Design**). Other factors related to the response, called **blocking** factors, can be held fixed at one level to create a block of homogeneous experimental units which, in the absence of the effects of other factors, might be expected to produce measured responses with small variability. The experimental factors can then be manipulated on the units within the block. In a second block, the blocking factors can be held fixed at other levels and the experimental factors manipulated on the units within the block, etc. Effective blocking on factors related to the response can produce more precise estimates of the differences between the levels of experimental factors, while, at the same time, allowing more generalizable conclusions. To ensure that unnecessary variation in the measured responses is not introduced, other factors may be deliberately held fixed throughout the experiment (e.g. use of a standardized measurement system). Finally, **randomization** of the experimental factors to the experimental units serves to balance the effects of uncontrolled factors across the levels of the experimental factors to avoid the conscious or subconscious **confounding** of uncontrolled factors with those the experimenter is manipulating (*see* **Randomized Treatment Assignment**).

In **observational studies**, factors are typically not controlled – the data are obtained the way nature provides them. However, modeling and understanding the relationship between the observed values of the response and the observed values of explanatory variables collected with the response remains an important aim. The lack of control of extraneous factors either by blocking on levels of factors related to the response, or through randomization, makes the interpretation of models for observational data difficult, even if the basic analysis techniques are the same.

Analysis of variance is a commonly used technique for analyzing the relative contributions of identifiable sources of variation to the total variation in measured responses. Understanding the potential sources of variation prior to the development of a statistical model is very important. To develop an effective experimental design and/or to aid in the development and understanding of a statistical model, factors related to the response can be listed under categories such as measurement, environment, individual, method, etc. The cause and effect diagram, from the statistical process control literature (e.g. [8]), is an effective way to summarize potential sources of variation.

In a designed experiment, those variables which are to be experimentally manipulated, those which are used to define homogeneous sets of units (blocks), and those which are carefully controlled at fixed levels (e.g. measurement system variables) can be identified. Variables which have not been identified as experimental, blocking, or controlled factors may be contributing to variation in the response; however randomization will offer some insurance that their effects on the response are not systematically linked to the levels of the experimental factors.

For data from an observational study, the identification of such sources of variation can lead to the development of a statistical model in which variation in the response variable, associated with available explanatory variables, is "explained" through

inclusion of appropriate terms in the model. Again, variation from observational unit to observational unit in variables which are not included in the model can contribute to the "unexplained" (and possibly systematic) variation in the response. Finally, as described above, because the analyst cannot exert control over the process which gave rise to the data, unequivocal interpretations of the findings are very difficult, if not impossible.

The Model

In the description of the model, it will be assumed that there are n measurements on a response variable, Y, (i.e. $Y_1, Y_2, \ldots, Y_n$), and that associated with each measured response, there is a (row) vector of **explanatory variables** measured on, or related to the same unit as the response. Denote the elements of the vector associated with the ith response, Y_i, as $x_{i1}, x_{i2}, \ldots, x_{ip}$.

The elements of the vector of explanatory variables related to the response can be of several types. These include variables (assumed interval or ratio scaled; *see* **Measurement Scale**) such as age, height, or fitness score, and possibly higher powers of such variables (e.g. age^2), or other transformations (e.g. ln age). They can also include indicator or **dummy variables** which identify the levels of a nominal variable such as city or gender, or allow the distinction between the levels of an ordinal scale variable (e.g. satisfaction coded from "highly satisfied" to "completely dissatisfied"). Finally, an intercept term is usually required in the model. A variable, say x_{i1}, with $x_{i1} = 1$, for $i = 1, \ldots, n$ allows for the intercept term.

The **general linear model** links the response variable for the ith unit, Y_i, to the vector of variables related to the response. The form of this model is

$$Y_i = \beta_1 x_{i1} + \beta_2 x_{i2} + \cdots + \beta_p x_{ip} + \varepsilon_i,$$
$$i = 1, \ldots n(p < n).$$

In matrix form, the model can be written

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon},$$

where $\mathbf{Y}$ is an $n \times 1$ vector of response variables, $\mathbf{X}$ is an $n \times p$ matrix which has the (row) vectors of variables as rows, $\boldsymbol{\beta}$ is a $p \times 1$ vector of unknown parameters, and $\boldsymbol{\varepsilon}$ is the $n \times 1$ vector of residuals.

The role of the ε_is is to represent all sources of variation in the response which have not been accounted for by the variables included in the model. Thus, this vector represents the residual, or unexplained, variation in the measured response Y_i not accounted for by the model. This variation can be due to the effects of variables not included in the model, or to the misspecification of the form of their effects.

In the design of experiments literature, the ε_i term is often called the "experimental error" term to represent the combined effects of all those factors not controlled by the experimenter. For example, variation introduced by the measurement system, variation due to factors such as temperature or diet which the experimenter has not controlled, or variation in how the same treatment was applied to different subjects or units will contribute to this term. Randomization and **blinding** are designed to ensure, as far as possible, that the uncontrolled effects are not systematically related to terms in the model.

In observational studies, similar factors contribute to the residual term. However, unlike experiments in which randomization has been used to assign treatments to experimental units, it is often not reasonable to assume that such factors are unrelated to terms in the model.

In what follows we make the usual general linear model assumptions on the distribution of the ε_is. That is, it will be assumed that ε_i is a random variable with

$$\mathrm{E}(\varepsilon_i) = 0, \quad \mathrm{var}(\varepsilon_i) = \sigma^2; \quad i = 1, \ldots, n,$$

and $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_n$ independent.

These assumptions state that, on average, the residual terms are neither positive or negative so that the model does not systematically under- or overpredict; that the variation in these terms is the same for all experimental units and does not depend on the size of Y_i, and that the value of the ith residual term is not predictive of the value of any other residual term. These model assumptions can be checked using techniques discussed elsewhere (e.g. [2], and [4]) (*see* **Residuals**).

For tests of hypotheses (*see* **Hypothesis Testing**) about terms in the model, or for the calculation of **confidence intervals** for specific model parameters $(\beta_1, \beta_2, \ldots, \beta_p; \sigma^2)$, an additional assumption which describes the probability distribution of the ε_is is required. By far the most commonly used assumption

is that

$$\varepsilon_i \sim \mathrm{N}(0, \sigma^2).$$

Taken together, these assumptions imply that the residual (error) terms behave like an independent sample from a **normal distribution**, with mean 0 and common variance σ^2.

Estimation of Parameters

If the columns of the $\mathbf{X}$ matrix are linearly independent (i.e. $\mathbf{X}$ is of rank p), then the **least squares** estimate of the $p \times 1$ vector $\boldsymbol{\beta}$ which is equivalent to the maximum likelihood estimate of $\boldsymbol{\beta}$ under the normal distribution model described above is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}.$$

The values of the response variable *predicted* by the model can then be obtained as

$$\hat{Y}_i = \hat{\beta}_1 x_{i1} + \hat{\beta}_2 x_{i2} + \cdots + \hat{\beta}_p x_{ip},$$

or, in matrix terms,

$$\hat{\mathbf{Y}} = \mathbf{X}\hat{\boldsymbol{\beta}}.$$

The difference between the measured value of the response variable, Y_i, and the predicted value of the same variable, $\hat{Y}_i$, is called the ith estimated residual $\hat{\varepsilon}_i = Y_i - \hat{Y}_i$. If the model describes the data well, then we would expect $Y_i - \hat{Y}_i$ to be "small". However, if the model is not providing a good description of the data, then $Y_i - \hat{Y}_i$ will be "large". It is these estimated residuals which form the basis for the model **diagnostics**, discussed elsewhere, used to assess the form and fit of the model. Furthermore, the quantity $\sum \hat{\varepsilon}_i^2/(n-p)$, which provides a measure of the departures from the model, is the usual estimate of σ^2, the variance of the residuals.

The Analysis of Variance Table

For the analysis of variance, we start with a measure of the variation in the measured response variables *before* any model is established for the Y_is. A convenient measure of the total variation in the measured response variables is given by the Total Sum of Squares

$$\text{Total SS} = \sum (Y_i - \overline{y})^2, \quad \text{where } \overline{y} = \sum \frac{Y_i}{n},$$

which is just $(n-1)$ times the estimated sample variance of the Y_is. If we have chosen an appropriate form for the model and have included the important predictors of the response, we expect $\hat{Y}_i$ to be close to Y_i. Thus, we will have "explained" a "large" portion of this variation. In fact, the variation left *unexplained* by the model can be summarized by the quantity

$$\text{Residual SS} = \sum (Y_i - \hat{Y}_i)^2,$$

which is just $n - p$ times the estimate of the variance of ε_i.

Thus, the variation in the response "explained" by the model will be the difference between the measure of the total variation in the response and the variation unexplained by the model. We have

total variation in the response
= variation explained by the model
+ variation unexplained by the model.

The "explained variation" is called the Model Sum of Squares (or Regression Sum of Squares). Algebraically, we can show that

$$\begin{aligned}\text{Model SS} &= \text{Total SS} - \text{Residual SS} \\ &= \sum (Y_i - \overline{y})^2 - \sum (Y_i - \hat{Y}_i)^2 \\ &= \sum (\hat{Y}_i - \overline{y})^2.\end{aligned}$$

In matrix terms, the split of the Total Sum of Squares into the Model Sum of Squares and Residual Sum of Squares can be written as

$$\mathbf{Y}'\mathbf{Y} - n\overline{y}^2 = \hat{\boldsymbol{\beta}}'\mathbf{X}'\mathbf{X}\hat{\boldsymbol{\beta}} - n\overline{y}^2 + (\mathbf{Y} - \mathbf{X}'\hat{\boldsymbol{\beta}})'(\mathbf{Y} - \mathbf{X}'\hat{\boldsymbol{\beta}}).$$

It is this decomposition of the total sum of squares (as a measure of the total variation in the data prior to model fitting) into that portion "explained" by the model and that portion left "unexplained" that is the basis of the analysis of variance.

It is common practice to summarize the results of the analysis of variance in an *analysis of variance table*. The standard format of the table is given in Table 1. There are columns identifying the source of the variation, the degrees of freedom associated with each source, the corresponding sum of squares, and the mean square (sum of squares divided by degrees of freedom). Another column, headed "F", which gives the ratio of the Model Mean Square and the

Table 1 The analysis of variance table

Source	df	Sum of squares	Mean square	F
Model	$p-1$	$\hat{\boldsymbol{\beta}}'\mathbf{X}'\mathbf{X}\hat{\boldsymbol{\beta}} - n\overline{y}^2$	$(\hat{\boldsymbol{\beta}}'\mathbf{X}'\mathbf{X}\hat{\boldsymbol{\beta}} - n\overline{y}^2)/(p-1)$	$\frac{\text{Mean Square}_{\text{Model}}}{\text{Mean Square}_{\text{Residual}}}$
Residual	$n-p$	$(\mathbf{Y}-\mathbf{X}'\hat{\boldsymbol{\beta}})'(\mathbf{Y}-\mathbf{X}'\hat{\boldsymbol{\beta}})$	$(\mathbf{Y}-\mathbf{X}'\hat{\boldsymbol{\beta}})'(\mathbf{Y}-\mathbf{X}'\hat{\boldsymbol{\beta}})/(n-p)$	
Total	$n-1$	$\mathbf{Y}'\mathbf{Y} - n\overline{y}^2$		

Residual Mean Square is usually added. This column is used for tests of hypotheses associated with sources of variation which will be discussed later.

As discussed, the Residual Mean Square in the analysis of variance table provides an estimate of σ^2, the (assumed constant) variance of the distribution of the ε_is.

Tests of Hypotheses – The Extra Sum of Squares Principle *F* Test

In most applications of the analysis of variance, interest will focus on the testing of hypotheses concerning the regression parameters (i.e. the β_is in the above model). In particular, tests of hypotheses of the form

$$\text{H: } \beta_k = 0,$$

or, more generally,

$$\text{H: } \beta_{q+1} = \beta_{q+2} = \cdots = \beta_p = 0,$$

are the most common. Each of the above is equivalent to asking whether the variable or variables associated with the β parameter(s) in the statement of the hypothesis are related to the response, *after adjusting for the effects of other variables included in the model*.

Intuitively, if we fit the full model and compute the Residual Sum of Squares, and then refit a reduced model without the variables corresponding to the β_is specified in the hypothesis, we should be able to judge the appropriateness of the hypothesis by examining the increase in the Residual Sum of Squares. If the increase is "large", then the variables we removed were important in explaining the variation in the response, after considering the effect of the variables remaining in the model. The assessment of whether this increase in the Residual Sum of Squares is "large" can be conducted by a statistical test based on the size of the increase in the Residual Sum of Squares, standardized by the Residual Sum of Squares from the full model.

Consider the hypothesis

$$\text{H: } \beta_{q+1} = \beta_{q+2} = \cdots = \beta_p = 0,$$

and define

$$\Delta = \text{Residual SS}_{\text{Reduced Model}} - \text{Residual SS}_{\text{Full Model}}.$$

Then the test statistic

$$F = \frac{\Delta/(p-q)}{\text{Residual SS}_{\text{Full Model}}/(n-p)}$$

assesses the change in the Residual Sum of Squares per variable removed from the model, relative to the residual mean square from the full model. That is, large values of the test statistic occur whenever the increase in the Residual Sum of Squares is "large" with respect to what might be expected by chance alone.

If the full model is assumed to be an adequate description of the variation in the response, and if the residuals are assumed to follow the normal distribution as described above, then under the hypothesis, H:$\beta_{q+1} = \beta_{q+2} = \cdots = \beta_p = 0$, the quantity F behaves like a random variable from the $F_{(p-q),(n-p)}$ distribution (i.e. ***F* distribution** with $p-q$ and $n-p$ **degrees of freedom**). Consequently, a test of significance can be performed in which the observed value of F, F_{observed}, is compared to the tables of the $F_{(p-q),(n-p)}$ distribution. The significance level of the data with respect to the hypothesis is, then, $\Pr(F_{(p-q),(n-p)} > F_{\text{observed}})$ (*see* **Level of a Test**). *Small* values of the significance level are associated with *large* values of the observed test statistic, and cast doubt on the hypothesis.

One important application of this principle involves assessing whether the independent variables, collectively, explain a significant portion of the

variability in the response. In a model with an intercept term (i.e. $x_{i1} = 1, i = 1, \ldots, n$) this involves testing

$$\text{H: } \beta_2 = \beta_3 = \cdots = \beta_p = 0.$$

The reduced model under the hypothesis is

$$Y_i = \beta_1 + \varepsilon_i, \quad i = 1, \ldots, n.$$

In this reduced model, $\hat{\beta}_1 = \overline{y}$, and the Residual Sum of Squares is

$$\text{Residual SS}_{\text{Model With Intercept Only}} = \sum (Y_i - \overline{y})^2,$$

which is just the Total Sum of Squares for the Y_is.

Then if

$$\begin{aligned} \Delta &= \text{Residual SS}_{\text{Model With Intercept Only}} \\ &\quad - \text{Residual SS}_{\text{Full Model}} \\ &= \text{Total SS} - \text{Residual SS}_{\text{Full Model}} \\ &= \text{Model SS}, \end{aligned}$$

then the extra sum of squares principle F test statistic is

$$\begin{aligned} F &= \frac{\Delta/(p-1)}{\text{Residual SS}_{\text{Full Model}}/(n-p)} \\ &= \frac{\text{Model Mean Square}}{\text{Residual Mean Square}}. \end{aligned}$$

The column headed "F" in the analysis of variance table contains this ratio. When compared with the $F_{(p-1),(n-p)}$ tables, this statistic provides a test of whether the combined effect of all independent variables, and hence the fitted model, explains a significant portion of the variability in the response.

Partitioning the Model Sum of Squares

In many applications, interest will focus on examining various submodels of the fitted model. For example, in a **polynomial regression** model

$$Y_i = \beta_1 + \beta_2 x_i + \beta_3 x_i^2 + \varepsilon_i,$$

an obvious question is whether the model involving only the linear term would describe the data almost as well as the more complicated quadratic model. Since the linear model is a special case of the quadratic model (i.e. $\beta_3 = 0$), the residual sum of squares for the best fitting linear model cannot be smaller than that for the best fitting quadratic model. The difference,

$$\begin{aligned} &\text{Residual SS}_{(\text{linear})} - \text{Residual SS}_{(\text{linear, quadratic})} \\ &\quad = \text{Model SS}_{(\text{linear, quadratic})} - \text{Model SS}_{(\text{linear})} \\ &\quad = \text{Model SS}_{(\text{quadratic}|\text{linear})}, \end{aligned}$$

if large, indicates that the quadratic model is "explaining" much more of the variation in the measured response variable than is the linear model. The extra sum of squares principle F test provides one means of testing whether the variation explained by the quadratic term is significant, over and above that which is explained by the linear term.

Similarly, if the measured response is systolic blood pressure, $x_{i1} = 1$ codes for the intercept, x_{i2} represents *weight* and x_{i3} represents *age* for the ith subject, then the difference

$$\begin{aligned} &\text{Residual SS}_{(\text{Model with weight})} \\ &\quad - \text{Residual SS}_{(\text{Model with weight and age})}, \end{aligned}$$

represents the additional portion of the variation "explained" when age is added to a model involving weight, over that explained by a model involving weight alone. If this difference is large, it suggests that age is an important variable in the explanation of the variability in systolic blood pressure even when the effect of weight has been modeled in this fashion.

If we define Model $\text{SS}_{(\text{weight, age})}$ to be the Model Sum of Squares for a model containing both weight and age, and Model $\text{SS}_{(\text{weight})}$ as the model sum of squares for a model containing only weight, then we can define

$$\begin{aligned} \text{Model SS}_{(\text{age}|\text{weight})} &= \text{Model SS}_{(\text{weight, age})} \\ &\quad - \text{Model SS}_{(\text{weight})}, \end{aligned}$$

as the "additional" sum of squares explained by age when added to a model containing weight.

Then, we can modify the Model Sum of Squares entries in the analysis of variance table to allow us to look at this partitioning of the Model Sum of Squares. Since,

$$\begin{aligned} \text{Model SS}_{(\text{weight, age})} &= \text{Model SS}_{(\text{weight})} \\ &\quad + \text{Model SS}_{(\text{age}|\text{weight})}, \end{aligned}$$

Table 2 Analysis of variance table for the blood pressure example

Source	df	Sum of squares	Mean square	F
Model (weight, age)	2	Model $SS_{(\text{weight, age})}$	Model $SS_{(\text{weight, age})}/2$	$\frac{\text{Model } MS_{(\text{weight, age})}}{\text{Residual MS}}$
Model (weight)	1	Model $SS_{(\text{weight})}$	Model $SS_{(\text{weight})}/1$	$\frac{\text{Model } MS_{(\text{weight})}}{\text{Residual MS}}$
Model (age|weight)	1	Model $SS_{(\text{age}\mid\text{weight})}$	Model $SS_{(\text{age}\mid\text{weight})}/1$	$\frac{\text{Model } MS_{(\text{age}\mid\text{weight})}}{\text{Residual MS}}$
Residual	$n-2$	Residual $SS_{(\text{weight, age})}$	Residual $SS_{(\text{weight, age})}/(n-2)$	
Total	$n-1$	$\mathbf{Y}'\mathbf{Y} - n\overline{y}^2$		

we have the analysis of variance table shown in the Table 2.

Then F ratios, reading down the column, test respectively, the hypotheses:

1. The model involving weight and age does not explain a significant portion of the variation in blood pressure.
2. The model involving weight alone does not explain a significant portion of the variation in blood pressure.
3. After adjusting for weight, age does not explain a significant portion of the variation in blood pressure. That is, for individuals of the same weight, there is no significant linear relationship between blood pressure and age.

It is important to note that we could also have decomposed the Model Sum of Squares as:

$$\text{Model } SS_{(\text{weight, age})} = \text{Model } SS_{(\text{age})} + \text{Model } SS_{(\text{weight}\mid\text{age})}.$$

The interpretation of the F tests is analogous to that described above, with the role of weight and age reversed. Because of the observational nature of many data sets, the explanatory variables may be highly correlated. In such cases, it will often be very difficult to obtain an unequivocal interpretation of the results of these F tests. For example, the model involving both age and weight may be highly significant, but both Model $SS_{(\text{age}\mid\text{weight})}$ and Model $SS_{(\text{weight}\mid\text{age})}$ may be small. Conversely, neither age nor weight on its own may explain a significant portion of the variation in blood pressure, but the model involving both may be highly significant. A class of techniques known as **variable selection** methods (e.g. [3, 4]) is often used to attempt to untangle the relationships between the response variable and correlated predictor variables.

In some software packages (e.g. SAS [12]), the analysis of variance table output will contain reference to type I and type III sums of squares. (Types II and IV are also available but will not be discussed here.) In brief, with type I sums of squares, the Model Sum of Squares is decomposed in the order that the terms are specified in the model. Thus, if the model is specified as

$$Y_i = \beta_1 + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i,$$
$$(\text{i.e. } Y = \text{Weight} + \text{Age}),$$

we get

$$\text{Model } SS_{(\text{weight, age})} = \text{Model } SS_{(\text{weight})} + \text{Model } SS_{(\text{age}\mid\text{weight})},$$

and the two sums of squares terms on the right of the equation are provided as the type I sums of squares.

A type III sum of squares is the contribution to the Model Sum of Squares due to a term in the model after adjusting for *all other* terms specified in the model. Thus, in the example above, the type III sums of squares would be Model $SS_{(\text{age}\mid\text{weight})}$ and Model $SS_{(\text{weight}\mid\text{age})}$. Note that type I sums of squares will total the Model Sum of Squares, whereas the type III sums of squares will not unless the columns of the $\mathbf{X}$ matrix are orthogonal, as described in the next section.

Orthogonality

A very special case of partitioning the Model Sum of Squares occurs when the columns of the $\mathbf{X}$ matrix

are orthogonal (perpendicular) (*see* **Orthogonality**). In general, if two $n \times 1$ (column) vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ are orthogonal, then

$$\mathbf{x}_1'\mathbf{x}_2 = 0.$$

If the columns of the matrix $\mathbf{X}$ are mutually orthogonal (i.e. each pair of columns is orthogonal), then $\mathbf{X}'\mathbf{X}$ will be a diagonal matrix. In particular, the entry in position (j, j) is $\mathbf{x}_j'\mathbf{x}_j$, where $\mathbf{x}_j$ is the jth column of $\mathbf{X}$. The least squares estimate of $\boldsymbol{\beta}_j$ (equivalent to the maximum likelihood estimate under the assumption of a common normal distribution for the $\varepsilon_i s$), will be

$$\hat{\beta}_j = \sum_{i=1}^{n} x_{ij} Y_i \Bigg/ \sum_{i=1}^{n} x_{ij}^2,$$

and this estimate will not change as orthogonal columns are added or deleted from the $\mathbf{X}$ matrix.

Further, when the columns of $\mathbf{X}$ are orthogonal, the Model Sum of Squares decomposes into $p - 1$ components, with the jth component given by

$$\left(\sum_{i=1}^{n} x_{ij} Y_i\right)^2 \Bigg/ \sum_{i=1}^{n} x_{ij}^2.$$

(Note that the term $n\overline{y}^2$ which has been used to correct the Total and Model Sums of Squares for the intercept term, is just

$$n\overline{y}^2 = \left(\sum_{i=1}^{n} 1 \times Y_i\right)^2 \Bigg/ \sum_{i=1}^{n} 1^2,$$

consistent with the above.)

Thus, the Model Sum of Squares can be written

$$\begin{aligned}
&\hat{\boldsymbol{\beta}}'\mathbf{X}'\mathbf{X}\hat{\boldsymbol{\beta}} - n\overline{y}^2 \\
&\quad = \sum_{j=1}^{p} \left(\left(\sum_{i=1}^{n} x_{ij} Y_i\right)^2 \Bigg/ \sum_{i=1}^{n} x_{ij}^2 \right) - n\overline{y}^2 \\
&\quad = \sum_{j=2}^{p} \left(\left(\sum_{i=1}^{n} x_{ij} Y_i\right)^2 \Bigg/ \sum_{i=1}^{n} x_{ij}^2 \right),
\end{aligned}$$

and we have a complete decomposition of the Model Sum of Squares into $p - 1$ one-degree-of-freedom sums of squares.

The ratio of any of these one-degree-of-freedom sums of squares to the Residual Mean Square provides an F test of the hypothesis that the relevant β_i term is zero. Because of the complete orthogonality, the sum of squares associated with any column in the $\mathbf{X}$ matrix will not change as columns orthogonal to it are added to or deleted from the model. Note that in such cases the type I and type III Sums of Squares (e.g. SAS [12]) will be equal.

This result is very important to the design of experiments. As discussed, in the designed experiment, the investigator has freedom to choose the levels of factors to be manipulated, the combinations of factors to be used in the experiment, and the number and construction of blocks which will be used to produce homogeneous units on which to experiment. With the proper choice of levels of experimental factors, and the proper attention to balance of the experimental factors across blocks, it is possible to design orthogonality into the experiment. This makes the analysis of the results relatively straightforward. More importantly, the interpretation of the results is clear since the orthogonality of the design ensures protection against the confounding of the experimental factors. For example, by randomly assigning predetermined levels of exercise to the same number of younger and older subjects, and measuring blood pressure at a later time, it would be possible to estimate the effects of exercise on blood pressure independently of age (and vice versa).

With observational studies, no such balance is guaranteed. Consequently, it is common to find explanatory variables which are highly correlated. The interpretation of the results is difficult. If younger subjects have lower blood pressure and exercise more than do older subjects, it may be difficult to separate the roles of exercise and age on blood pressure.

Analysis of Variance in Designed Experiments

In this section, we briefly describe the analysis of variance in designed experiments. The design of experiments is a very broad topic, and specific designs are described elsewhere (e.g. [1] and [11]) (*see* **Randomized Complete Block Designs**; **Latin Square Designs**; **Factorial Experiments**). However, we will discuss the use of the analysis of variance technique with reference to some simple designs to illustrate the basic features of the technique.

Consider a randomized block experiment in which t treatments are to be studied in an experiment involving b blocks. That is, the experimenter has isolated b sets of t units each on which to experiment. The units within a block are similar with respect to factors thought to be related to variability in the response. Units in different blocks may well be quite different with respect to factors thought to be related to the response. The t treatments are randomly assigned to the units within a block, and one measurement is taken from each unit. Thus, we have $n = t \times b$ measurements on the response variable to analyze.

Note that by assigning different treatments to relatively homogeneous units, the experimenter has deliberately introduced variation into the experiment. However, the sources of this variation are known and, thus, can be dealt with at the time of analysis.

In what follows, we will assume a **fixed effects** model. That is, the inference about the effects of the treatments, and about the effects of the blocks is relevant only for the treatments and blocks used in the particular experiment. Later, we will briefly describe **random effects** models in which the treatments (and/or blocks) are assumed to be a random sample from a population of treatments (blocks). In such cases, the inference will apply to the population of treatments (blocks) from which the actual treatments (blocks) were a sample.

To better describe the model, we change notation slightly. Define Y_{ij} to be the measured response of treatment i in block j. Then we describe the measured value as composed of an effect common to all observations, the effect due to the treatment applied, and the effect due to the block which contains the unit as follows:

$$Y_{ij} = \mu + \alpha_i + \beta_j + \varepsilon_{ij}, \quad i = 1, \ldots, t; \quad j = 1, \ldots, b.$$

In this model, μ represents an effect common to all observations, α_i represents the effect of the ith treatment relative to μ, β_j represents the effect of the jth block relative to μ, and ε_{ij} represents the uncontrolled variation (experimental error) from the unit in the jth block receiving the ith treatment.

While this model may seem different from the model defined earlier, there is a correspondence between them which is useful to keep in mind. If we write the measured values in a $tb \times 1$ column vector such that the observation on treatment i in block j is in location $i^* = (j-1)t + i$, then we have "strung out" the observed values so that the first observation is on treatment 1 in block 1, the second is on treatment 2 in block 1, ..., the tth observation is on treatment t in block 1. Then observation $t+1$ is the observation on treatment 1 in block 2, etc. We can then define a matrix $\mathbf{X}$ which will contain indicator variables to code for the different treatments and the different blocks in the experiment.

For example, define a $tb \times 1$ column vector $\mathbf{x}_1$ such that $x_{i1} = 1$, for $i = 1, \ldots, tb$, to provide for an intercept term (μ).

Define t $tb \times 1$ column vectors $\mathbf{x}_2, \mathbf{x}_3, \ldots, \mathbf{x}_{t+1}$ such that the kth entry of $\mathbf{x}_{1+i}$ is 1 if the kth observation is on treatment i; otherwise the kth entry of $\mathbf{x}_{1+i}$ is 0.

Likewise, define b $tb \times 1$ column vectors $\mathbf{x}_{t+2}, \ldots, \mathbf{x}_{t+b+1}$ such that the kth entry of x_{t+1+j} is 1, if the kth observation is from block j; otherwise the kth entry of $\mathbf{x}_{t+1+j}$ is 0.

Then we form the matrix $\mathbf{X}$ with columns given by $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_{t+b+1}$. For example, if $t = 2$ and $b = 3$, then we get the $\mathbf{X}$ matrix shown in Table 3.

With this definition for $\mathbf{X}$, we could write the model in matrix form as

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\gamma} + \varepsilon,$$

where $\mathbf{Y}$ is the $tb \times 1$ vector of observations "strung out" as described above, $\mathbf{X}$ is given in Table 3, and $\boldsymbol{\gamma}$ is a $t + b + 1$ vector of parameters with

$$\boldsymbol{\gamma}' = (\mu, \alpha_1, \alpha_2, \beta_1, \beta_2, \beta_3).$$

However, in this model, $\mathbf{X}$ is not of full rank; the columns of $\mathbf{X}$ are not linearly independent. For example, column 1 is the sum of columns 2 and 3, and also the sum of columns 4, 5, and 6. Thus, we cannot obtain unique estimates of the parameters.

Table 3 $\mathbf{X}$ matrix for the randomized block design for $t = 2$, $b = 3$ with no constraints

$$\begin{pmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 1 \end{pmatrix}$$

However, if we place some restrictions or constraints on the parameters, we can arrive at estimates which are useful for describing the variation in the measured response. There are two commonly used sets of constraints for models of this type; these will be briefly described. It is important to note that these different systems of constraints will lead to different estimates of the parameters in the model, and the interpretation of the estimates will depend on the type of constraint applied. However, tests of hypotheses about the overall effect of treatments or blocks will be the same under both sets of constraints.

Indicator Variable Constraints

The simplest way to resolve the issue of linear dependence in the columns of **X** is to remove columns to produce a set which is linearly independent but which still allow for the estimation of meaningful quantities. In the example in Table 3, dropping the second and fourth columns of **X** gives a matrix which has linearly independent columns. Dropping these columns is equivalent to the set of constraints

$$\alpha_1 = 0; \quad \beta_1 = 0.$$

Under this model, the parameter μ is an estimate of the mean response from the unit in block 1 which received treatment 1. The parameter α_2 measures the difference in mean response between units *in the same block* which received treatment 2 and those which received treatment 1. Similarly, β_2 represents the difference in mean response between units in block 2 and units in block 1 *which received the same treatment*. A test of the hypothesis that $\alpha_2 = 0$ is then a test of no difference between treatments, adjusting for the differences in blocks, as required.

These constraints are used in many computing packages (e.g. GLIM [9]). Their major disadvantage is that, since the columns of **X** are not orthogonal, when the parameters related to treatments (blocks) are dropped from the model, the estimated values of the other parameters in the model will change, requiring a refit of the model. However, this disadvantage is only minor with modern computing packages.

Of course the choice of which columns to drop is arbitrary. In general, setting up the model so that natural reference categories are formed has some advantage for interpreting the results of the analysis.

Analysis of Variance Constraints

An alternative set of constraints which allows for hand calculation of all quantities required is

$$\sum_{i=1}^{t} \alpha_i = 0; \quad \sum_{j=1}^{b} \beta_j = 0.$$

Under these constraints, the parameter μ represents the overall mean response across all units used in the experiment. The parameter α_i represents the difference in mean response for units treated with treatment i, relative to the overall mean response. Similarly, the parameter β_j represents the difference in mean response for units in block j, relative to the overall mean response.

If we write the model in terms of α_2, β_2, and β_3 using these constraints (i.e. $\alpha_1 = -\alpha_2; \beta_1 = -\beta_2 - \beta_3$), we have the new **X** matrix, $\mathbf{X}^*$, given in Table 4, and the model can be written as

$$\mathbf{Y} = \mathbf{X}^* \boldsymbol{\gamma}^*,$$

where $\boldsymbol{\gamma}^{*\prime} = (\mu, \alpha_2, \beta_2, \beta_3)$.

In this model the column coding for the mean effect is orthogonal to those coding for treatment effects and to those coding for block effects. Similarly, the columns coding for treatment effects are orthogonal to those coding for the block effects. This orthogonality is a natural result of the balance in the design (each treatment appears the same number of times in each block), and the parameterization of the model. It follows that if this model is fitted and then the columns coding for the treatment effects are deleted and the model refitted, the estimates of the parameters for the mean and for the blocks will be unchanged. It further follows that we can get an easy decomposition of the Model Sum of Squares into a source due to treatments and a source due to blocks.

Table 4 $\mathbf{X}^*$ matrix for the randomized block design for $t = 2$, $b = 3$ with analysis of variance constraints

$$\begin{pmatrix} 1 & -1 & -1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & -1 & 0 & 1 \\ 1 & 1 & 0 & 1 \end{pmatrix}$$

These sources will have $t-1$ and $b-1$ degrees of freedom respectively due to the single constraint on the $t(b)$ treatment (block) parameters.

Further it is quite easy to show that the least squares estimates (maximum likelihood estimates under the common normal errors model) of the parameters in the model are

$$\hat{\mu} = \overline{y}; \quad \hat{\alpha}_i = \overline{y}_{i.} - \overline{y}. \quad \text{and} \quad \hat{\beta}_j = \overline{y}_{.j} - \overline{y}_{..};$$
$$i = 1, \ldots, t; \quad j = 1, \ldots, b,$$

where $\overline{y}_{i.} = \sum_{j=1}^{b} Y_{ij}/b$, and $\overline{y}_{.j} = \sum_{i=1}^{t} Y_{ij}/t$ are the average responses for all units which received treatment i, and the average response for all units in block j, respectively. The Residual Sum of Squares for this model is then

$$\begin{aligned}
&\text{Residual SS}_{\text{Full Model}} \\
&= \sum_{i=1}^{t}\sum_{j=1}^{b} \hat{\varepsilon}_{ij}^2 \\
&= \sum_{i=1}^{t}\sum_{j=1}^{b} (Y_{ij} - \hat{\alpha}_i - \hat{\beta}_j)^2 \\
&= \sum_{i=1}^{t}\sum_{j=1}^{b} (Y_{ij} - \overline{y}_{i.} - \overline{y}_{.j} + \overline{y}_{..})^2 \\
&= \sum_{i=1}^{t}\sum_{j=1}^{b} (Y_{ij} - \overline{y}_{..})^2 - b\sum_{i=1}^{t} (\overline{y}_{i.} - \overline{y}_{..})^2 \\
&\quad - t\sum_{j=1}^{b} (\overline{y}_{.j} - \overline{y}_{..})^2.
\end{aligned}$$

The quantities $b\sum_{i=1}^{t}(\overline{y}_{i.} - \overline{y}_{..})^2$ and $t\sum_{j=1}^{b}(\overline{y}_{.j} - \overline{y}_{..})^2$ are called the Treatments and Blocks Sum of Squares, respectively. For example, if there is considerable variability of the $\overline{y}_{i.}$s about their mean $(\overline{y}_{..})$, there is evidence that not all the treatments are producing the same average response and the Treatments Sum of Squares will be large. Since each treatment appears in each block, differences between blocks cannot be accounting for the differences between the treatment averages. Similar conclusions will obtain in examining the Blocks Sum of Squares.

The Analysis of Variance Table for the Randomized Block Design

To develop the analysis of variance table for the randomized block design, we adopt the analysis of variance constraints parameterization, and note that the hypotheses of interest are usually that there is no difference between the treatments, or no difference between the blocks; i.e.

$$\text{H: } \alpha_1 = \alpha_2 = \cdots = \alpha_t = 0 \quad \text{or}$$
$$\text{H: } \beta_1 = \beta_2 = \cdots = \beta_b = 0.$$

Under the first hypothesis above, the model becomes

$$Y_{ij} = \mu + \beta_j + \varepsilon_{ij}; \quad i = 1, \ldots, t; \quad j = 1, \ldots, b,$$

and we again have, due to the orthogonality of the columns representing the block parameters and the column representing the mean parameter, that

$$\hat{\mu} = \overline{y}_{..}; \quad \hat{\beta}_j = \overline{y}_{.j} - \overline{y}_{..}, \quad j = 1, \ldots, b;$$

and

$$\begin{aligned}
\text{Residual SS}_{\text{H:}\alpha_i=0} &= \sum_{i=1}^{t}\sum_{j=1}^{b} (Y_{ij} - \overline{y}_{..})^2 \\
&\quad - t\sum_{j=1}^{b} (\overline{y}_{.j} - \overline{y}_{..})^2.
\end{aligned}$$

Then, to test H: $\alpha_1 = \alpha_2 = \cdots = \alpha_t = 0$, we compute the Extra Sum of Squares Principle F test statistic.

Let

$$\begin{aligned}
\Delta &= \text{Residual SS}_{\text{H:}\alpha_i=0} - \text{Residual SS}_{\text{Full Model}} \\
&= \text{Treatments SS}.
\end{aligned}$$

Then

$$\begin{aligned}
F &= \frac{\Delta/(t-1)}{\text{Residual SS}_{\text{Full Model}}/(t-1)(b-1)} \\
&= \frac{\text{Treatments MS}}{\text{Residual MS}_{\text{Full Model}}}.
\end{aligned}$$

We compare the observed value of the test statistic to the tables of the $F_{(t-1),(t-1)(b-1)}$ distribution.

The above can be summarized in the analysis of variance Table given in Table 5.

Table 5 Analysis of variance table for a randomized block design

Source	df	Sum of squares	Mean square	F
Model	$t+b-2$			
Treatments	$t-1$	$b\sum_{i=1}^{t}(\overline{y}_{i.}-\overline{y}_{..})^2$	Treatments SS/$(t-1)$	$\dfrac{\text{Treatments MS}}{\text{Residual MS}}$
Blocks	$b-1$	$t\sum_{j=1}^{b}(\overline{y}_{.j}-\overline{y}_{..})^2$	Blocks SS/$(b-1)$	$\dfrac{\text{Blocks SS}}{\text{Residual MS}}$
Residual	$(t-1)(b-1)$	Residual $SS_{\text{Full Model}}$	Residual $SS_{\text{Full Model}}/(t-1)(b-1)$	
Total	$n-1$	$\mathbf{Y}'\mathbf{Y}-n\overline{y}_{..}^2$		

Orthogonal Contrasts for Planned Comparisons

In many experiments in which t treatments are to be compared, there may be some a priori (i.e. planned) comparisons which the investigator has in mind. For example, suppose that $t = 3$, and that the three treatments represent three doses (0, 10, and 20 units) of a drug. Rather than whether there are differences between the doses, the question of interest might be whether the response to the drug changes linearly with dose.

Factorial designs (*see* **Factorial Experiments**; **Factorial Designs in Clinical Trials**) provide another important example. Suppose $t = 8$ and the eight treatments represent all combinations of three drugs (Q, R, and S), each of which has two levels (0 and 20 units). Questions involving comparing the high and low doses of each drug, and determining whether the effect of one drug depends on the level of another drug (i.e. whether there is an interaction between the drugs), are likely to be more relevant than whether there is a difference between the eight treatments.

Consider the t means, $\overline{y}_{1.}, \overline{y}_{2.}, \ldots, \overline{y}_{t.}$, as a vector of t responses, and define a $t \times (t-1)$ matrix $\mathbf{C}$ such that the columns of $\mathbf{C}$ are mutually orthogonal and such that the sum of the t entries in each column is zero. The columns of $\mathbf{C}$ thus defined are called **contrasts**. While there may be many ways to define a set of orthogonal contrasts, generally there will be a main set which provides the answers to the relevant analysis questions.

For example, for the question of linearity described in the first experiment above, we order the means so that they correspond to the averages on units receiving 0, 10, and 20 units, respectively. If we define the contrast, $\mathbf{c}_1' = (-1, 0, 1)$, then $\sum_{i=1}^{t} c_{i1}\overline{y}_{i.}$ will be close to zero whenever the first mean and third mean are of the same size. If this were the case, there would be no suggestion that the means were increasing linearly. The contrast $\mathbf{c}_2' = (-1, 2, -1)$ is orthogonal to $\mathbf{c}_1$, and if $\sum_{i=1}^{t} c_{i2}\overline{y}_{i.}$ is close to zero, it suggests that there is no parabolic (quadratic) relationship between the means and dose.

For the 2^3 factorial design described above, let $\overline{y}_{qrs}$ represent the mean of all observations when the qth level of drug Q, the rth level of drug R, and the sth level of drug S are administered ($q, r, s = 1, 2$). Consider the matrix $\mathbf{C}$ shown in Table 6. If the treatment means are arranged in the vector $(\overline{y}_{111}, \overline{y}_{211}, \overline{y}_{121}, \overline{y}_{221}, \overline{y}_{112}, \overline{y}_{212}, \overline{y}_{122}, \overline{y}_{222})'$, then the first column of $\mathbf{C}$ is a contrast which, when applied to the vector of means, assesses whether the observations on the high and low levels of Q are equal. Similarly, columns 2 and 4 assess the *main effects* of R and S; i.e. whether observations on the high and low levels of R and S, respectively, are equal. Column 3 examines whether the difference between high and low levels of drug Q are different for the levels of drug R. Similarly, columns 5 and 6 assess the *interactions* of drugs Q and S, and R and S, respectively. The final column assesses the three-way interaction, i.e. whether the interaction of

Table 6 Matrix of contrasts, $\mathbf{C}$, for the 2^3 factorial design

$$\begin{pmatrix} -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}$$

Q and R depends on the levels of S. In each case, if $\sum_{i=1}^{t} c_{ik}\overline{y}_{i.}$ is close to zero, we can conclude that the particular effect is not important.

Because of the orthogonality, the Treatment Sum of Squares can be decomposed into $t-1$ one-degree-of-freedom sum of squares, each of which can be used to test whether the corresponding sum is significantly different from zero. We have

$$\sum_{i=1}^{t}(\overline{y}_{i.}-\overline{y}_{..})^2=\sum_{k=1}^{t-1}\left(\left(\sum_{i=1}^{t}c_{ik}\overline{y}_{i.}\right)^2\Big/\sum_{i=1}^{t}c_{ik}^2\right),$$

where c_{ik} is the ith entry in the kth column of $\mathbf{C}$. This result has exactly the same form and follows directly from the result given earlier on the decomposition of the Model Sum of Squares when the columns of $\mathbf{X}$ are orthogonal. Here, the "Model Sum of Squares" from the regression of the vector of means on the columns of $\mathbf{C}$ will be equivalent to the "Total Sum of Squares" of the means since we have t means and have defined $t-1$ columns in $\mathbf{C}$. Again, there is a one-degree-of-freedom sum of squares for the "intercept" term. Indeed, the requirement that the columns of $\mathbf{C}$ sum to zero is to ensure orthogonality with the overall mean.

Thus, the Treatment Sum of Squares (which for the randomized block design is just b times the expression on the left above) can be decomposed into $t-1$ one-degree-of-freedom sums of squares. (For the randomized block design, the kth such sum of squares would be $b(\sum_{i=1}^{t} c_{ik}\overline{y}_{i.})^2/\sum_{i=1}^{t} c_{ik}^2$.) Each of these sums of squares can be used to test certain comparisons among the treatment means, by forming the F statistic with the sum of squares as numerator and residual mean square as denominator.

Note that the development given here assumes that there are the same number of observations on each treatment, as would be the case in most designs, including the randomized block design described above. If the design is unbalanced, this breakup of the Treatment Sum of Squares may still be possible, but the $\mathbf{C}$ matrix needs to be constructed based on the original vector of responses, taking the different numbers of observations into account.

Designs Involving More Than One Source of Error

In the discussion above, we have considered models in which, because of the design, it was only possible to estimate a single measure of experimental error. As discussed initially, there are many potential sources of variation in any statistical investigation. Often through the design used, we may be able to separate sources of variation (*see* **Variance Components**) and arrive at different error terms for different comparisons. We illustrate this briefly with a simple example. Suppose we are interested in the effect of a drug on heart rate during exercise. We randomly assign m individual subjects to one of three levels of the drug (0, 10, or 20 units). The experimental procedure involves measuring heart rate, for each subject, under two exercise conditions (moderate and extreme), using a standard protocol. Thus, we have $6m$ measurements in total.

If we consider the factors associated with variation in heart rate, some of these are factors which vary from individual to individual (e.g. age, fitness level, weight, etc.). Others are factors which would vary between test times on the same individual (e.g. temperature, fatigue, etc.) In fact, we could measure the *within-subject* variation by taking repeat measurements on the same subject under similar conditions, and measure the *between-subject* variation by taking measurements on different subjects under similar conditions. It is reasonable to think that under similar conditions there will be more variation from individual to individual than from test time to test time within a single subject (*see* **Longitudinal Data Analysis, Overview**; **Split Plot Designs**).

The design described above allows us to estimate the between-subject and within-subject contributions to the overall experimental error. The between-subject contributions provide the benchmark against which to test treatments applied at the level of the subject (i.e. the levels of the drug). The within subjects contributions provide the baseline variability against which to compare treatments applied within subjects (i.e. the differing exercise regimes, and their interaction with the dose of the drug).

A model for this experiment includes two sources of error, which, for this design, are separable. A model is

$$Y_{ijk}=\mu+\alpha_i+\varepsilon_{ij}+\beta_k+(\alpha\beta)_{ik}+\delta_{ijk},$$

where Y_{ijk} represents the observation on exercise level k for the jth subject in the ith drug group; μ is the overall mean; α_i represents the effect of drug level $i\,(i=1,2,3)$; β_k represents the effect of exercise level $k(k=1,2)$; and $(\alpha\beta)_{ik}$ represents the effect of the interaction of drug level i and exercise

level k. Furthermore, ε_{ij} gives the between-subjects experimental error term for subject j in the ith drug group, and δ_{ijk} represents the within-subjects experimental error term for the measurement on exercise regimen k, for the jth subject in group i.

For the purposes of estimation, we make the usual "fixed" effects assumptions, i.e.

$$\sum_{i=1}^{3}\alpha_i = 0; \quad \sum_{k=1}^{2}\beta_k = 0;$$

$$\sum_{i=1}^{3}(\alpha\beta)_{ik} = \sum_{k=1}^{2}(\alpha\beta)_{ik} = 0.$$

Furthermore, we assume

$$\varepsilon_{ij} \sim \mathrm{N}(0, \sigma_{\mathrm{I}}^2), \quad \text{independently;}$$

and

$$\delta_{ijk} \sim \mathrm{N}(0, \sigma_{\mathrm{II}}^2),$$

independently, and independent of ε_{ij}.

Under this model, we obtain the following estimates:

$$\hat{\mu} = \overline{y}_{...}; \quad \hat{\alpha}_i = \overline{y}_{i.} - \overline{y}_{...}; \quad \hat{\beta} = \overline{y}_{.j.} - \overline{y}_{...};$$

and

$$(\alpha\hat{\beta})_{ik} = \overline{y}_{i.k} - \overline{y}_{i..} - \overline{y}_{..k} + \overline{y}_{...},$$

where the notation again implies averages are taken over the subscript denoted by a subscript dot. The sums of squares associated with each of the fixed effects are obtained as before. That is, the Drug Groups Sum of Squares is just

$$\text{Drugs SS} = \sum_{k=1}^{2}\sum_{j=1}^{m}\sum_{i=1}^{3}(\overline{y}_{i..} - \overline{y}_{...})^2$$

$$= 2m\sum_{i=1}^{3}(\overline{y}_{i..} - \overline{y}_{...})^2.$$

There are two sources of experimental error to estimate here. The between-subjects residual sum of squares is obtained by combining both measurements on the exercise regimen, and measuring the variation between subjects within drug groups. Thus we obtain,

$$\text{Residual SS}_{\text{Between Subjects}}$$

$$= \sum_{k=1}^{2}\sum_{i=1}^{3}\sum_{j=1}^{m}(\overline{y}_{ij.} - \overline{y}_{i..})^2,$$

which is based on $3(m-1)$ degrees of freedom (i.e. $m-1$ degrees of freedom in each of three drug groups).

The within-subjects residual sum of squares is the overall residual sum of squares from the model. It can be thought of as the measure of the total variation between the measurements made on the same individual (the total within-individual variation which has $3m$ degrees of freedom) less the variation which the experimenter deliberately induced within individuals; that is, less the exercise sum of squares (one degree of freedom) and the drug–exercise interaction sum of squares (two degrees of freedom). Thus, it could be calculated as:

$$\text{Residual SS}_{\text{Within Subjects}}$$

$$= \sum_{i=1}^{3}\sum_{j=1}^{m}\sum_{k=1}^{2}(Y_{ijk} - \overline{y}_{ij.})^2$$

$$- \sum_{i=1}^{3}\sum_{j=1}^{m}\sum_{k=1}^{2}(\overline{y}_{..k} - \overline{y}_{...})^2$$

$$- \sum_{i=1}^{3}\sum_{j=1}^{m}\sum_{k=1}^{2}(\overline{y}_{i.k} - \overline{y}_{i..} - \overline{y}_{..k} + \overline{y}_{...})^2,$$

and it will have $3m - 1 - 2$ degrees of freedom.

Then, to test the between-subject effects (i.e. drug levels) or contrasts involving the means for the drug groups, we use the residual mean square from the between-subjects portion of the analysis in the F test. For the within-subjects sources of variation (i.e. exercise and the drug–exercise interaction), we use the residual mean square from the within-subjects part of the analysis in the F test. An abbreviated analysis of variance table is shown in Table 7.

Random Effects and Expected Mean Squares

In our discussion to this point we have assumed we were interested only in making statements about the treatments and blocks actually used in the experiment, and not some larger population of treatments or blocks from which those actually used were a random sample. The theory behind the analysis of variance allows us to deal with this latter situation. Note that in designed experiments it is very rare that

Table 7 Analysis of variance table for the drug–exercise example

Source	df	Sum of squares	F
Between Subjects	$3m-1$		
Drugs	2	$2m\sum_i(\overline{y}_{i..}-\overline{y}_{...})^2$	$\dfrac{\text{Drugs MS}}{\text{Residual MS}_{\text{Between Subjects}}}$
$\text{Residual}_{\text{Between Subjects}}$	$3(m-1)$	$2\sum_i\sum_j(\overline{y}_{ij\cdot}-\overline{y}_{i..})^2$	
Within Subjects	$3m$		
Exercise	1	$3m\sum_k(\overline{y}_{..k}-\overline{y}_{...})^2$	$\dfrac{\text{Exercise MS}}{\text{Residual MS}_{\text{Within Subjects}}}$
Drug × Exercise	2	$m\sum_i\sum_k(\overline{y}_{i.k}-\overline{y}_{i..}-\overline{y}_{..k}+\overline{y}_{...})^2$	$\dfrac{\text{Drug} \times \text{Exercise MS}}{\text{Residual MS}_{\text{Within Subjects}}}$
$\text{Residual}_{\text{Within Subjects}}$	$3m-3$	Subtraction from total	
Total	$6m-1$	$\mathbf{Y}'\mathbf{Y}-n\overline{y}_{..}^2$	

either treatments or blocks are chosen randomly from a larger population. Blocks used in an experiment may be thought to be representative of the larger population of blocks; however, it is common for blocks to be deliberately chosen to span the range of possible situations in which the treatments may be applied, and the assumption, at least, that the blocks are a simple random sample of all blocks is unlikely to be true.

In sample survey applications it may be more realistic to think of random samples of blocks (e.g. towns), and then further random samples within towns. In such cases we would like the inference to be made across the population of towns, and not just those actually used in the data collection.

A full treatment of this topic is not possible here. However, we illustrate the ideas in a simple example. For a thorough treatment of the subject of fixed, random and mixed effects models, see [1] and [10].

Consider a model for a randomized block experiment

$$Y_{ij}=\mu+\alpha_i+\beta_j+\varepsilon_{ij},$$
$$\text{with } \varepsilon_{ij}\sim \text{N}(0,\sigma^2), \text{ independently,}$$

and assume the blocks used in the experiment represent a random sample of blocks from a larger population. If this population is large relative to the number of blocks used in the experiment, it may be reasonable to assume that the block effects have a distribution which can be described by a normal probability model. That is, the β_js are randomly distributed according to the model

$$\beta_j\sim \text{N}(0,\sigma_{\text{B}}^2),\quad j=1,\ldots,b,\quad \text{independently,}$$
$$\text{and independently of the } \varepsilon_{ij}\text{s.}$$

Under this model, $Y_{ij}\sim \text{N}(\mu+\alpha_i,\sigma^2+\sigma_{\text{B}}^2)$, and the model induces a **correlation**, termed the intra-class correlation $(\sigma_{\text{B}}^2/(\sigma^2+\sigma_{\text{B}}^2))$, between observations in the same block, while maintaining the independence of observations in different blocks. The relevant hypothesis for the lack of block effects is, then, H: $\sigma_{\text{B}}^2=0$. Interestingly, this hypothesis can be tested in the same manner as in the fixed effects case, although the interpretation is different.

For example, consider the Block Mean Square, $t\sum_{j=1}^b(\overline{y}_{.j}-\overline{y}_{..})^2/(b-1)$. Then with the fixed effects assumptions on the α_is (i.e. $\sum_{i=1}^t\alpha_i=0$), and using the fact that $\text{var}(\sum_{i=1}^t Y_{ij})=t(\sigma^2+(t-1)\sigma_{\text{B}}^2)$, due to the correlation between observations in the same block, we can derive the expected value of the Blocks Mean Square as follows:

$$\begin{aligned}
&\text{E}(\overline{y}_{.j}-\overline{y}_{..})^2\\
&=\text{var}(\overline{y}_{.j}-\overline{y}_{..})+(\text{E}(\overline{y}_{.j}-\overline{y}_{..}))^2\\
&=\text{var}(\overline{y}_{.j})+\text{var}(\overline{y}_{..})-2\text{cov}(\overline{y}_{.j},\overline{y}_{..})+0\\
&=\frac{\sigma^2+t\sigma_{\text{B}}^2}{t}+\frac{\sigma^2+t\sigma_{\text{B}}^2}{tb}-\frac{2t(\sigma^2+t\sigma_{\text{B}}^2)}{t^2b}\\
&=\frac{(b-1)(\sigma^2+t\sigma_{\text{B}}^2)}{tb}
\end{aligned}$$

So,

$$\mathrm{E}\left(t\sum_{j=1}^{b}\frac{(\overline{y}_{\cdot j}-\overline{y}_{\cdot\cdot})^2}{b-1}\right)=\sigma^2+t\sigma_{\mathrm{B}}^2.$$

In this manner, we can construct expected mean squares for other sources in the analysis of variance table. In many designs, these can be useful to indicate the appropriate mean squares for tests of hypotheses about effects in the model. For example, for the randomized block design discussed earlier, Table 8 gives the expected mean squares for the design in which treatment is a fixed effect and blocks are assumed to be a random effect.

The table suggests that if $\sigma_{\mathrm{B}}^2=0$, the ratio of the Blocks Mean Square to the Residual Mean Square should be close to one, and that large values of this ratio will cast doubt on H: $\sigma_{\mathrm{B}}^2=0$. In fact, under this hypothesis, the ratio will have the $F_{(b-1),(t-1)(b-1)}$ distribution, as before. Similarly, the ratio of the Treatment Mean Square to the Residual Mean Square will be large when $\sum\alpha_i^2$ is large; that is, when there is evidence against H: $\alpha_1=\alpha_2=\cdots=\alpha_t=0$. The F test applies in this case, as well.

There has been much written on the estimation of the individual variance terms in models involving random effects. It is clear that the residual mean square is an unbiased estimate of σ^2. Further, in the model discussed above, an unbiased estimate of σ_{B}^2 is given by

$$\widehat{\sigma_{\mathrm{B}}^2}=\frac{\text{Block MS}-\text{Residual MS}}{t},$$

although it is possible for the estimate to be negative when calculated in this manner. The intra-class correlation discussed above can likewise be estimated from these quantities.

While there is no difference in the test statistics for hypotheses about treatment or block effects between this simple mixed model and the fixed effects model discussed above, there are differences when one wishes to make confidence interval statements about, say, the expected value of an observation or treatment mean taken at a future time. For the fixed effects model, this will involve specifying both the treatment and the block since both α_i and β_j are involved in the expression for the expected value. The variance term, $\mathrm{var}(Y_{ij})$, involves just σ^2 and constants; that is

$$\mathrm{var}(\hat{\mu}+\hat{\alpha}_i+\hat{\beta}_j)=\sigma^2\left(\frac{1}{b}+\frac{1}{t}-\frac{1}{tb}\right).$$

For the mixed model described above, only specification of the treatment is required; the assumption is that the observation will be taken from a randomly selected block. Thus, the block effect appears in the variance expression. So

$$\mathrm{var}(\hat{\mu}+\hat{\alpha}_i)=(\sigma^2+\sigma_{\mathrm{B}}^2)\left(\frac{1}{b}\right)$$

is the variance of a future observation on the ith treatment.

The development of the expected mean squares for complicated designs, including mixed effects designs and designs with more than one source of error, is beyond the scope of this article. Discussions and algorithms for determining these expected mean squares can be found in [1, 10], and [11]. The SAS computing package [12] will also generate expected mean squares for a given model specification.

Table 8 Expected mean squares for the randomized block design with treatment effects fixed and block effects random

Source	df	Expected mean square
Model	$t+b-2$	
Treatments	$t-1$	$\sigma^2+b\sum\alpha_i^2/(t-1)$
Blocks	$b-1$	$\sigma^2+t\sigma_{\mathrm{B}}^2$
Residual	$(t-1)(b-1)$	σ^2
Total	$n-1$

Analytic Hierarchy Process

Among the most important decisions made in society today are those relating to the life and health of people. How does one make a decision when faced with many conflicting factors that determine the best choice among the available alternatives of that decision? Most of these factors may be intangibles and the choice is not simply a matter of making financial trade-offs. How does one pool the judgments of doctors and other experts with their varying degrees of expertise to obtain the best decision? Who should bear the costs, and how much control should there be, what should be legal and what should not, who should receive an organ in transplant operations, and what is the best treatment for a certain type of disease? If we have standard measurements for how average people score on medical tests and if the readings of an individual on several tests do not meet these standards, how far off do they have to be before that individual is suspected of having a disease? These are examples of decision making that occur in the health and medical professions (*see* **Decision Analysis in Diagnosis and Treatment Choice**; **Decision Theory**).

Procedures for finding the answers to such questions are found in the new and rapidly spreading field of multicriteria decision making. An application of this decision-making theory is the analytic hierarchy process (AHP), which is defined below and also illustrated with an example of choosing a hospice.

The Analytic Hierarchy Process (AHP)

The analytic hierarchy process [3, 4, 6, 8] subdivides a complex decision-making problem or planning issue into its components or levels, and arranges these levels into an ascending hierarchic order. At each level of the hierarchy, the components are compared relative to each other using a pairwise comparison scheme. The components of a given level are related to an adjacent upper level and thereby generate an integration across the levels of the hierarchy. The result of this systematic process is a set of priorities or relative importance, or method of scaling between the various actions or alternatives. The relative priority weights can provide guidelines for the allocation of resources among the entities at the lower level.

Structuring any decision problem hierarchically is an efficient way to deal with and identify the major components of the problem. There is no single hierarchic structure to use in every problem. When hierarchies are designed to reflect likely environmental scenarios, corporate objectives, current and proposed product/market alternatives, and various medical strategy options, the AHP can provide a framework and methodology for the determination of a number of key decisions.

The AHP allows its users flexibility in constructing a hierarchy to fit their needs. The AHP also provides an effective structure for group decision making by imposing a discipline on the group's thought processes. The necessity of assigning a numerical value to each variable of the problem helps decision makers to maintain cohesive thought patterns by deriving the relative weight of each component of the hierarchy: criteria and alternatives. In this manner, one determines the optimum alternative. The AHP has been applied successfully to a variety of problems in planning [10], prioritization [6], resource allocation [10], conflict resolution [9], decision making, and forecasting or prediction [11], as well as in health care [1, 2, 7]. The AHP is a special case or subset of the analytic network process (ANP), which uses a network structure that allows dependence and feedback instead of a hierarchy.

The AHP focuses on dominance matrices and their corresponding measurement in contrast with the proximity, profile, and conjoint measurement approaches [12]. It goes beyond the Thurston [13] comparative judgment approach by relaxing the assumption of **normality** on the parameters, e.g. equal **variance**, zero covariance, and restriction of the type of comparisons. It is based on a trade-off concept whereby one develops the trade-off in the course of structuring and analyzing a series of simple reciprocal pairwise comparison matrices.

Some Detail

A measurement methodology is used to establish priorities among the elements within each level or stratum of the hierarchy. This is accomplished by asking the decision maker to evaluate each set of elements in a pairwise fashion with respect to their

parent element in the adjacent higher stratum. This measurement methodology provides the framework for data collection and analysis and constitutes the heart of the analytic hierarchy process. The degree of importance of the elements at a particular level over those in the succeeding level is measured by the paired comparisons. To ensure meaningful comparisons the elements are placed in homogeneous groups of a few elements in each to ensure consistency, with a pivot element from one group to the next. Each paired comparison made by a decision maker providing the judgments requires estimating how many times more one element has the property than the other element. The judgments are expressed verbally as equal, moderate, strong, very strong, and extreme. With these judgments are associated the absolute numbers (how many times more): 1, 3, 5, 7, 9. The numbers 2, 4, 6, 8 are used for compromise between the verbal judgments. In addition, reciprocals are used to represent the inverse comparison. This scale is used to compare any homogeneous set. When the elements are not homogeneous, a pivot element is used to link one cluster to an adjacent cluster. The choice of scale values to correspond to feelings and judgments is founded in both theory and in considerable experimental work, and is not to be taken lightly. When applied to comparisons of things whose measurements are already known, using this scale gives very close values when the judgments are given by an expert. For the mathematics behind the AHP and numerous applications, see [3], [5], and [6].

Unlike traditional ways of measurement that begin with a scale and apply it to measure things, in the AHP, we begin with things, measure them in pairs by using the lesser object as the unit, and then derive a scale of relative values from the pairwise measurements. The scale comes after and not before the objects. In this case, we do not need a unit, we only want relative values and it turns out that both the comparisons and the derived scale belong to the strongest possible kind of scale like the real numbers. It is known as an absolute scale, invariant under multiplication by the identity.

At each level, a set of priorities is obtained which numerically corresponds to the relative importance of the elements of that level relative to an element at an upper level. For a given level in the hierarchy if there are n elements, the solution technique will result in an n-element **eigenvector** of local priorities by solving the principal **eigenvalue** problem $(A - \lambda I)X = 0$. The components of the principal eigenvector correspond to the relative importance of each element. These priorities are now used as weighting factors for the eigenvectors generated at the next lower level in the hierarchy until all levels are completed. Applying this procedure at each level and weighting the next level and so on to the lowest level will result in a composite priority vector for the alternatives at the bottom level of the hierarchy.

One needs to use the eigenvector to derive the ratio scale priorities. Other techniques such as the method of **least squares** can minimize error but do not capture the dominance expressed numerically by the judgments. The eigenvalue process can determine the true order of dominance despite any inconsistencies or intransitivities that may occur in the judgments [5].

Example: the Hospice Problem

The following application is explained in greater detail in [6]. A hospital is concerned with the costs of the facilities and staffing involved in taking care of terminally ill patients. Often these patients do not need as much medical attention as do other patients. Those who best utilize the limited resources in a hospital are patients who require the medical attention of its specialists and advanced technology equipment–whose utilization depends on the demand of patients admitted into the hospital. The terminally ill need medical attention only episodically. Most of the time such patients need psychological support. For the mental health of the patient, home therapy may be most beneficial. From the medical standpoint, especially during a crisis, the hospital provides a greater benefit. Costs include economic costs as well as intangibles, such as inconvenience and pain. The planning association of the hospital wanted to develop alternatives for caring for terminally ill patients and to choose the best one from the standpoint of the patient, the hospital, the community, and society at large. To study the problem, one needs to deal with the benefits and costs of the decision separately (*see* **Health Economics**).

Approaching the Problem

The problem was which hospice to choose. There were three possible models under consideration: in Model I, the hospital provides full care to the

patients; in Model II, the family cares for the patient at home, and the hospital provides only emergency treatment (no nurses go to the home); and in Model III, the hospital and the home share patient care (with visiting nurses going to the home).

Two hierarchies were created by the decision makers: one for benefits and one for costs (Figures 1 and 2). For both hierarchies, the goal was to choose the best hospice. That goal is placed at the top of each hierarchy. The two hierarchies descend from the more general criteria in the second level to secondary subcriteria in the third level, then to tertiary subcriteria in the fourth level, and on to the alternatives at the bottom or fifth level.

For the benefits hierarchy (Figure 1) we decided that the decision should benefit the recipient, the institution, and society as a whole. We located these three elements on the second level of the benefits hierarchy. As the decision would benefit each party differently, it was thought important to specify the types of benefits for the recipient and the institution. Recipients want physical, psychosocial, and economic benefits. We located these benefits in the third level of the hierarchy. Each of these in turn needed further decomposition into specific items in terms of which of the decision alternatives could be evaluated. For example, while the recipient measures economic benefits in terms of reduced costs and improved productivity, the institution needed the more specific measurements of reduced length of stay, better utilization of resources, and increased financial support from the community. There was no reason to decompose the societal benefits into third-level subcriteria, and hence societal benefits

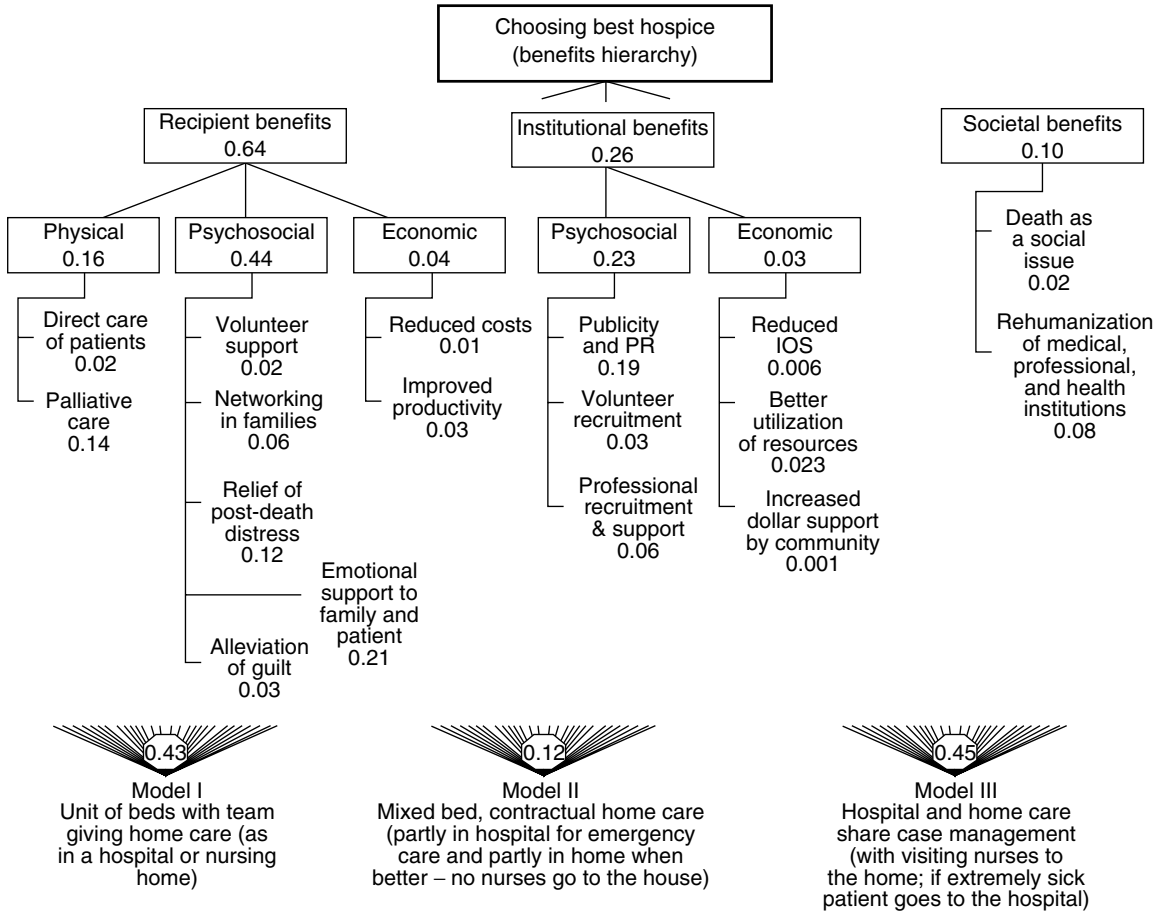

Figure 1 Benefits of choosing best hospice

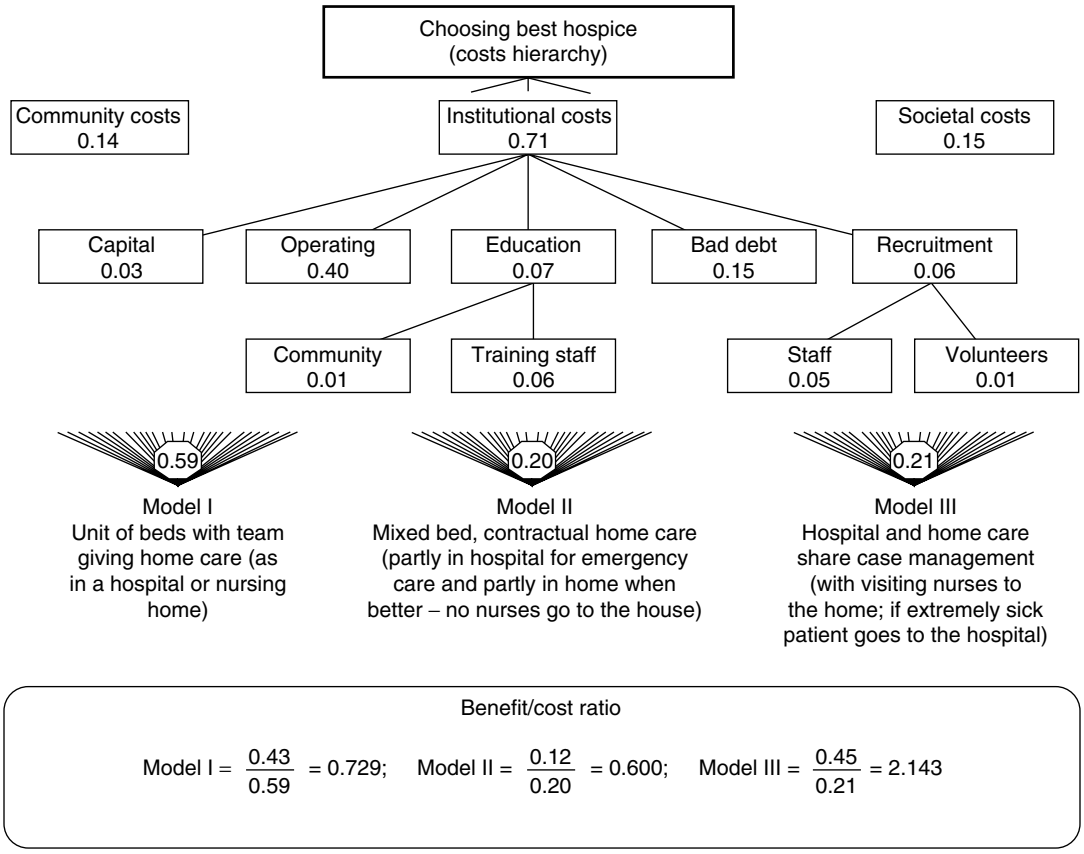

Figure 2 Costs of choosing best hospice

connect directly to the fourth level. The three hospice models are located on the bottom or fifth level of the hierarchy.

In the costs hierarchy there were also three major interests that would incur costs or burdens: community, institution, and society. In this decision the costs incurred by the patient were not included as a separate factor. Patient and family could be thought of as part of the community. We thought decomposition was necessary only for institutional costs. We included five such costs in the third level: capital costs, operating costs, education costs, bad debt costs, and recruitment costs. Educational costs apply to staff and volunteers. Since both the costs hierarchy and the benefits hierarchy concern the same decision, they both have the same alternatives in their bottom levels, even though the costs hierarchy has fewer levels.

Note that, even before preference judgments are introduced, this method of structuring the problem has changed an unformed problem into a structured problem.

Judgments and Comparisons

For both the cost and the benefit models, we compared the criteria and subcriteria according to their relative importance with respect to the parent element in the adjacent upper level. For example, one judges the importance of the three benefits criteria, as shown in Table 1. Recipient benefits were determined to be moderately more important than institutional benefits, and are assigned the absolute number 3 in the (1, 2) or first-row second-column position. The reciprocal value is automatically entered in the (2, 1) position, where institutional benefits on the left are compared with recipient benefits at the top. Similarly, a 5, corresponding to strong dominance or importance, is assigned to recipient benefits over social

Table 1 Comparing benefits of the hospice major benefit criteria

Choosing best hospice	Recipient	Institutional benefits	Social benefits	Priorities
Recipient benefits	1	3	5	0.64
Institutional benefits	1/3	1	3	0.26
Societal benefits	1/5	1/3	1	0.10

benefits in the (1, 3) position, and a 3, corresponding to moderate dominance, is assigned to institutional benefits over social benefits in the (2, 3) position, with corresponding reciprocals in the transpose positions of the matrix.

The priorities column at the right in Table 1 is the normalized eigenvector of the matrix of priorities. A matrix $A = (a_{ij})$ is consistent if and only if $a_{ij}a_{jk} = a_{ik}$ for all i, j, and k. If all the judgments were consistent, the priorities would be equivalent to the normalized sum of the elements in each row. In this case they were not. For example, institutional benefits should dominate social benefits by 5/3 and not 3. The eigenvalue solution, which handles inconsistency, must be used because, in general, people, though knowledgeable, are somewhat inconsistent. The software based on the AHP can show which judgment is the most inconsistent, and suggest the value that best improves consistency. The program determined that $a_{13} = 5$ is the most inconsistent judgment in this matrix, and suggested that instead of 5, 9 should be used. However, this recommendation may not lead to priorities in harmony with one's understanding of the real world. One might prefer to leave it at 5 and focus on the second most inconsistent judgment instead, or change the 5 to a 6 or a 7.

Similar tables were constructed for each of the other parent nodes in the model. The results of these tables are weighted and added to derive the overall priorities of the subcriteria just above the alternatives – the three models being evaluated. The first column of Table 2 shows these synthesized priorities, which sum to one for the benefits and for the costs.

The decision makers also rated each of the three hospice models with respect to each covering benefit and each covering cost. Those ratings are shown in columns 2, 3, and 4 of Table 2. For example, the first row shows that Model I provided the most direct care to the patient and Model II the least. Each of these rows sums to 1. The synthesis numbers are the sum of the product of the priorities of the subcriteria and the model weights.

The benefit/cost ratio in the last row of Table 2 is simply the quotient of the corresponding synthesis for each model. Model III would be chosen because it has the highest expected ratio of benefit to cost. This model – shared management between the hospital and home care with visiting nurses on a day-to-day basis, with hospital care for emergencies – was adopted for the community. Rounding off decimals gives slightly different numbers from the Benefit to cost ratios shown in Figure 2.

Finally, we performed a **sensitivity analysis** by varying the priorities of the criteria to determine the stability of the best alternative. We asked, for example, what would happen if the priority for institutional costs was less than the 0.71 value it received (Figure 2). The resulting ranking of the three models was fairly stable to small or realistic perturbations in the relative weights of the criteria.

Absolute Measurement–Rating Alternatives One at a Time

Cognitive psychologists have recognized for some time that people are able to make two kinds of comparisons–absolute and relative. In absolute comparisons, people compare alternatives with a standard in their memory that they have developed through experience. In relative comparisons, they compared alternatives in pairs according to a common attribute, as we did throughout the hospice example.

People use absolute measurement (sometimes also called rating) to rank independent alternatives one at a time in terms of rating intensities for each of the criteria. An intensity is a range of variation of a criterion that enables one to distinguish the quality of an alternative for that criterion. An intensity may be expressed as a numerical range of values if the criterion is measurable or in qualitative terms.

For example, if ranking students is the objective and one of the criteria on which they are to be ranked

Table 2 Synthesis

		Distributive mode		
Benefits	Priorities	Model I	Model II	Model III
Direct care of patient	0.02	0.64	0.10	0.26
Palliative care	0.14	0.64	0.10	0.26
Volunteer support	0.02	0.09	0.17	0.74
Networking in families	0.06	0.46	0.22	0.32
Relief of postdeath stress	0.12	0.30	0.08	0.62
Emotional support of family and patient	0.21	0.30	0.08	0.62
Alleviation of guilt	0.03	0.30	0.08	0.62
Recipient economic reduced costs	0.01	0.12	0.65	0.23
Improved productivity	0.03	0.12	0.27	0.61
Publicity and PR	0.19	0.63	0.08	0.29
Volunteer recruitment	0.03	0.64	0.10	0.26
Professional recruitment and support	0.06	0.65	0.23	0.12
Reduced length of stay	0.006	0.26	0.10	0.64
Better utilization of resources	0.023	0.09	0.22	0.69
Increased financial support	0.001	0.73	0.08	0.19
Death as a social issue	0.02	0.20	0.20	0.60
Rehumanization of institutions	0.08	0.24	0.14	0.62
Synthesis		0.428	0.121	0.451
Costs				
Community costs	0.14	0.33	0.33	0.33
Institutional capital costs	0.03	0.76	0.09	0.15
Institutional operating costs	0.40	0.73	0.08	0.19
Institutional costs educating community	0.01	0.65	0.24	0.11
Institutional costs training staff	0.06	0.56	0.32	0.12
Institutional bad debt	0.15	0.60	0.20	0.20
Institutional costs recruiting staff	0.05	0.66	0.17	0.17
Institutional costs recruiting volunteers	0.01	0.60	0.20	0.20
Societal costs	0.15	0.33	0.33	0.33
Synthesis		0.583	0.192	0.224
Benefit/cost ratio		0.734	0.630	2.013

is performance in mathematics, the mathematics ratings might be: excellent, good, average, below average, poor; or, using the usual school terminology, A, B, C, D, and F. Relative comparisons are first used to set priorities on the ratings themselves. If desired, one can fit a continuous curve through the derived intensities. This concept may go against our socialization. However, it is perfectly reasonable to ask how much an A is preferred to a B or to a C. The judgment of how much an A is preferred to a B might be different under different criteria. Perhaps for mathematics an A is very strongly preferred to a B, while for physical education an A is only moderately preferred to a B. So the end result might be that the ratings are scaled differently. For example, one could have the following scale values for the ratings:

	Math	Physical education
A	0.50	0.30
B	0.30	0.30
C	0.15	0.20
D	0.04	0.10
E	0.01	0.10

The alternatives are then rated or ticked off one at a time on the intensities.

I will illustrate absolute measurement with an example. A firm evaluates its employees for raises. The criteria are dependability, education, experience, and quality. Each criterion is subdivided into intensities, standards, or subcriteria (Figure 3). The managers set priorities for the criteria by comparing them in pairs. They then pairwise compare the intensities according to priority with respect to their parent criterion (as in Table 3) or with respect to a subcriterion if they are using a deeper hierarchy. The priorities of the intensities are divided by the largest intensity for each criterion to put them in ideal form (second column of priorities in Figure 3).

Table 3 shows a paired comparison matrix of intensities with respect to dependability. The managers answer the question: which intensity is more important and by how much with respect to dependability. Finally, the managers rate each individual (Table 4) by assigning the intensity rating that applies to him or her under each criterion. The scores of these intensities are each weighted by the priority of its criterion and summed to derive a total ratio scale score for the individual (shown on the right of Table 4). These numbers belong to a ratio scale, and the managers can give salary increases precisely in proportion to the ratios of these numbers. Adams gets the highest score and Kessel the lowest. This approach can be used whenever it is possible to set priorities for intensities of criteria; people can usually do this when they have sufficient experience with a given operation. This normative mode requires that alternatives be rated one by one without regard to how many there may be and how high or low any of them rates on prior standards. Some corporations have insisted that they no longer trust the normative standards of their experts and that they prefer to

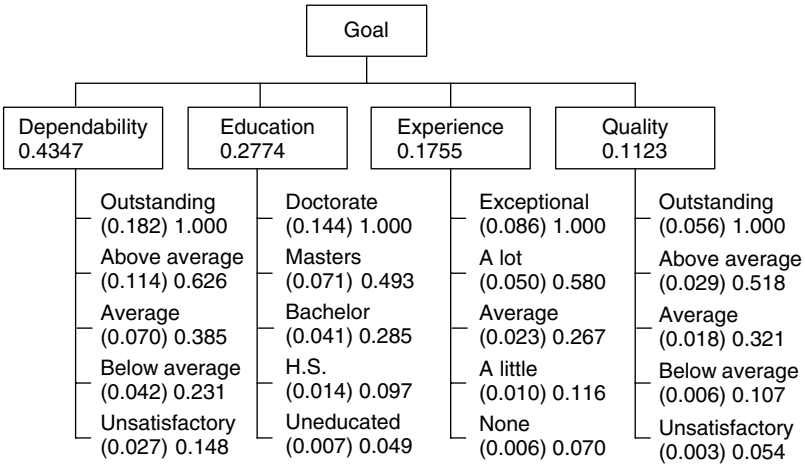

Figure 3 Criteria with priorities and their intensities both prioritized and idealized

Table 3 Ranking intensities: Which intensity is preferred most with respect to dependability and how strongly?

Intensities	Outstanding	Above average	Average	Below average	Unsatisfactory	Priorities
Outstanding	1.0	2.0	3.0	4.0	5.0	0.419
Above av	1/2	1.0	2.0	3.0	4.0	0.263
Average	1/3	1/2	1.0	2.0	3.0	0.160
Below av	1/4	1/3	1/2	1.0	2.0	0.097
Unsatisfact	1/5	1/4	1/3	1/2	1.0	0.062
						C.R. = 0.015

Table 4 Ranking alternatives. The priorities of the intensities for each criterion are divided by the largest one and multiplied by the priority of the criterion. Each alternative is rated on each criterion by assigning the appropriate intensity. The weighted intensities are added to yield the total on the right

Alternatives	Dependability 0.4347	Education 0.2774	Experience 0.1775	Quality 0.1123	Total
1. Adams, V.	Outstanding	Bachelor	A little	Outstanding	0.646
2. Becker, L.	Average	Bachelor	A little	Outstanding	0.379
3. Hayat, F.	Average	Masters	A lot	Below average	0.418
4. Kessel, S.	Above av	H.S.	None	Above average	0.369
5. O'Shea, K.	Average	Doctorate	A lot	Above average	0.605
6. Peters, T.	Average	Doctorate	A lot	Average	0.583
7. Tobias, K.	Above av	Bachelor	Average	Above average	0.456

make paired comparisons of their alternatives. Still, when there is wide agreement on standards, the absolute mode saves time in rating a large number of alternatives.

Other applications for AHP in the health care environment are as follows:

1. Choosing the most efficient hospital management information supply order system. The main criteria in this application were cost, speed, simplicity, flexibility, quality, and security. Most of these criteria had two or more subcriteria which were used to choose the best of the three alternatives: manual, computer, and Wand system, with the highest priority going to the last alternative.
2. Choosing a corporate health plan from among five options: fee for services (FFS), and Health Maintenance Organization (HMO), which has the three options: Physician Provider Organization (PPO), Individual Practice Association (IPA), and Staff and Group.
3. Selecting the best way to provide health care for everyone.
4. Performing a benefit/cost analysis to decide on an infant formula policy: sell to industrial countries, sell to Third World countries, stop selling.
5. Conducting a benefit/cost analysis as to whether drugs should be legalized in the US (No was nearly double Yes).
6. Doing a benefits (B), opportunities (O), costs, (C) and risks (R) called BOCR analysis to determine the best of the following five alternatives for solving a physicians heart problem: bypass operation, medicinal treatment, angioplasty, transplant, and doing nothing. When one does costs and risks, one needs to ask which is more costly and which is more risky because the smaller element is used as the unit and the larger one is estimated as a multiple of that unit. It cannot be done the other way by estimating the smaller as a fraction of the larger without using the smaller first as the unity. The importance of each of the four BOCR merits is determined by finding the best of the alternatives with respect to each one. Because there may be several criteria for each merit and because the alternatives are put into ideal form for each criterion, the winning or ideal alternative may not receive an overall value of one for that merit. That alternative is then rated as a representative of its merit using a set of strategic criteria and

their priorities used to evaluate all the decisions made for this type of problem. Here, the strategic criteria or subcriteria are prioritized as in a hierarchy and are then each assigned different intensities like high medium and low, or excellent, very good, average, and poor that are prioritized, then idealized by dividing by the largest value thus making the priority 1 as the standard and then assigning an alternative one intensity for each criterion and finally, multiplying the idealized priorities of the intensities by the priorities of their corresponding criteria and adding to obtain the overall importance rating of that alternative and hence, also of the merit it represents. In this manner, one obtains a rating for each of the four BOCR merits. These ratings are then normalized by dividing each value by their sum to obtain their priorities that are used to weight the priorities of the alternatives under each and then take the sum of the benefits and opportunities and subtract from it the sum of the costs and the risks for each alternative. We note that the outcome for some or all the alternatives may be negative and we have negative priorities.

7. Choosing a treatment for breast cancer, based on both physician and patient values.

In conclusion, the AHP and its generalization to feedback networks the Analytic network Process (ANP) (there is a book on the ANP and its applications by this author, 2001, RWS Publications) are finding increasing uses in the medical field. The software package Super Decisions, enables users to implement easily the AHP/ANP in decision-making. It can be downloaded from creativedecisions.net. The ANP has powerful predictive content as has been demonstrated in many examples involving market share and in predicting turn around in the US economy, and the presidential elections since 1976.

Analytic Epidemiology

Analytic epidemiology denotes epidemiologic studies, such as **cohort studies**, **cross-sectional studies**, and **case–control studies**, that obtain individual-level information on the **association** between disease status and exposures of interest. Such analytic studies often include individual-level information on potential **confounders** and **effect modifiers**. Usually such studies are designed to evaluate predetermined hypotheses concerning possible causal relationships between exposure and risk of disease (*see* **Causation**). Analytic epidemiology is distinguished from **descriptive epidemiology**, which focuses on quantifying trends and rates of disease in populations and on **ecologic studies** that attempt to correlate rates of disease in populations with average levels of exposure in such populations. Descriptive studies are often used to generate etiologic hypotheses that are tested in subsequent analytic studies.

MITCHELL H. GAIL

Ancillary Statistics

In a parametric model $f(\mathbf{y};\boldsymbol{\theta})$ for a **random variable** or vector $\mathbf{Y}$, a statistic $\mathbf{A} = a(\mathbf{Y})$ is ancillary for $\boldsymbol{\theta}$ if the distribution of $\mathbf{A}$ does not depend on $\boldsymbol{\theta}$. As a very simple example, if $\mathbf{Y}$ is a vector of independent, identically distributed random variables each with mean $\boldsymbol{\theta}$, and the sample size is determined randomly, rather than being fixed in advance, then $\mathbf{A}$ = number of observations in $\mathbf{Y}$ is an ancillary statistic. This example could be generalized to more complex structure for the observations $\mathbf{Y}$, and to examples in which the sample size depends on some further parameters that are unrelated to $\boldsymbol{\theta}$. Such models might well be appropriate for certain types of sequentially collected data arising, for example, in clinical trials.

Fisher [5] introduced the concept of an ancillary statistic, with particular emphasis on the usefulness of an ancillary statistic in recovering **information** that is lost by reduction of the sample to the **maximum likelihood** estimate $\hat{\boldsymbol{\theta}}$, when the maximum likelihood estimate is not minimal **sufficient**.

An illustrative, if somewhat artificial, example is a sample $(Y_1, \ldots, Y_n)$, where now n is fixed, from the uniform distribution on $(\theta, \theta + 1)$. The largest and smallest observations, $(Y_{(1)}, Y_{(n)})$, say, form a minimal sufficient statistic for θ. The maximum likelihood estimator of θ is any value in the interval $(Y_{(n)} - 1, Y_{(1)})$, and the **range** $Y_{(n)} - Y_{(1)}$ is an ancillary statistic. In this example, while the range does not provide any information about the value of θ that generated the data, it does provide information on the precision of $\hat{\theta}$. In a sample for which the range is 1, $\hat{\theta}$ is exactly equal to θ, whereas a sample with a range of 0 is the least informative about θ.

A theoretically important example discussed in Fisher [5] is the location model (*see* **Location–Scale Family**), in which $\mathbf{Y} = (Y_1, \ldots, Y_n)$, and each Y_i follows the model $f(y - \theta)$, with $f(\cdot)$ known but θ unknown. The vector of **residuals** $\mathbf{A} = (Y_1 - \overline{Y}, \ldots, Y_n - \overline{Y})$, where $\overline{Y} = n^{-1} \sum Y_i$, has a distribution free of θ, as is intuitively obvious, since both Y_i and $\overline{Y}$ are centered at θ. The uniform example discussed above is a special case of the location model, and the range $Y_{(n)} - Y_{(1)}$ is also an ancillary statistic for the present example. In fact, the vector $\mathbf{B} = (Y_{(2)} - Y_{(1)}, \ldots, Y_{(n)} - Y_{(1)})$ is also ancillary, as is $\mathbf{C} = (Y_1 - \hat{\theta}, \ldots, Y_n - \hat{\theta})$, where $\hat{\theta}$ is the maximum likelihood estimate of θ. A *maximal* ancillary provides the largest possible conditioning set, or the largest possible reduction in dimension, and is analogous to a minimal sufficient statistic. **A**, **B**, and **C** are maximal ancillary statistics for the location model, but the range is only a maximal ancillary in the location uniform.

An important property of the location model is that the exact conditional distribution of the maximum likelihood estimator $\hat{\theta}$, given the maximal ancillary $\mathbf{C}$, can be easily obtained simply by renormalizing the **likelihood** function:

$$p(\hat{\theta}|\mathbf{c};\theta) = \frac{L(\theta;\mathbf{y})}{\int L(\theta;\mathbf{y})\,\mathrm{d}\theta}, \tag{1}$$

where $L(\theta;\mathbf{y}) = \prod f(y_i;\theta)$ is the likelihood function for the sample $\mathbf{y} = (y_1, \ldots, y_n)$, and the right-hand side is to be interpreted as depending on $\hat{\theta}$ and $\mathbf{c}$, using the equations $\sum \partial\{\log f(y_i;\theta)\}/\partial\theta|_{\hat{\theta}} = 0$ and $\mathbf{c} = \mathbf{y} - \hat{\theta}$.

The location model example is readily generalized to a **linear regression** model with nonnormal errors. Suppose that, for $i = 1, \ldots, n$, we have independent observations from the model $Y_i = \mathbf{x}_i'\boldsymbol{\beta} + \sigma\varepsilon_i$, where the distribution of ε_i is known. The vector of standardized residuals $(Y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}})/\hat{\sigma}$ is ancillary for $\boldsymbol{\theta} = (\boldsymbol{\beta}, \sigma)$ and there is a formula similar to (1) for the distribution of $\hat{\boldsymbol{\theta}}$, given the residuals.

It is possible, and has been argued, that Fisher's meaning of ancillarity included more than the requirement of a distribution free of $\boldsymbol{\theta}$: that it included a notion of a physical mechanism for generating the data in which some elements of this mechanism are "clearly" not relevant for assessing the value of $\boldsymbol{\theta}$, but possibly relevant for assessing the accuracy of the inference about $\boldsymbol{\theta}$. Thus, Kalbfleisch [7] makes a distinction between an experimental and a mathematical ancillary statistic. Fraser [6] developed the notion of a structural model as a physically generated extension of the location model. Efron & Hinkley [4] gave particular attention to the role of an ancillary statistic in estimating the variance of the maximum likelihood estimator.

Two generalizations of the concept of ancillary statistic have become important in recent work in the theory of **inference**. The first is the notion of approximate ancillarity, in which the distribution of $\mathbf{A}$ is not required to be entirely free of $\boldsymbol{\theta}$, but free of $\boldsymbol{\theta}$ to some order of approximation. For example, we might require that the first few

moments of $\mathbf{A}$ be constant (in $\boldsymbol{\theta}$), or that the distribution of $\mathbf{A}$ be free of $\boldsymbol{\theta}$ in a neighborhood of the true value $\boldsymbol{\theta}_0$, say. The definition used by Barndorff-Nielsen & Cox [1] is that $\mathbf{A}$ is qth order locally ancillary for $\boldsymbol{\theta}$ near $\boldsymbol{\theta}_0$ if $f(\mathbf{a};\boldsymbol{\theta}_0 + \delta/\sqrt{n}) = f(\mathbf{a};\boldsymbol{\theta}_0) + O(n^{-q/2})$. Approximate ancillary statistics are also discussed in McCullagh [9] and Reid [11]. The notion of an approximate ancillary statistic has turned out to be rather important for the asymptotic theory of statistical inference, because the location family model result given in (1) can be generalized, to give the result

$$p(\hat{\boldsymbol{\theta}}|\mathbf{a};\boldsymbol{\theta}) \doteq c(\boldsymbol{\theta},\mathbf{a})|j(\hat{\boldsymbol{\theta}})|^{1/2}\frac{L(\boldsymbol{\theta};\mathbf{y})}{L(\hat{\boldsymbol{\theta}};\mathbf{y})}, \qquad (2)$$

where c is a normalizing constant, $j(\boldsymbol{\theta}) = -\partial^2 \log L(\boldsymbol{\theta})/\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}'$ is the observed Fisher information function, $\mathbf{a}$ is an approximately ancillary statistic, and in the right-hand side $\mathbf{y}$ is a function of $\hat{\boldsymbol{\theta}}, \mathbf{a}$. This approximation, which is typically much more accurate than the normal approximation to the distribution of $\hat{\boldsymbol{\theta}}$, is known as Barndorff-Nielsen's approximation, or the p^* approximation, and is reviewed in Reid [10] and considered in detail in Barndorff-Nielsen & Cox [1]. In (2) the likelihood function is normalized by a slightly more elaborate looking formula than the simple integral in (1), but the principle of renormalizing the likelihood function has still been applied. A distribution function approximation analogous to (2) is also available: see Barndorff-Nielsen & Cox [1] and Reid [11].

Suppose that the parameter $\boldsymbol{\theta}$ is partitioned as $\boldsymbol{\theta} = (\boldsymbol{\psi}, \boldsymbol{\lambda})$, where $\boldsymbol{\psi}$ is the parameter of interest and $\boldsymbol{\lambda}$ is a **nuisance parameter**. For example, $\boldsymbol{\psi}$ might parameterize a regression model for survival time as a function of several covariates, and $\boldsymbol{\lambda}$ might parameterize the baseline **hazard** function. If we can partition the minimal sufficient statistic for $\boldsymbol{\theta}$ as $(\mathbf{S}, \mathbf{T})$, such that

$$f(\mathbf{s},\mathbf{t};\boldsymbol{\theta}) = f(\mathbf{s}|\mathbf{t};\boldsymbol{\psi})f(\mathbf{t};\boldsymbol{\lambda}), \qquad (3)$$

then $\mathbf{T}$ is an ancillary statistic for $\boldsymbol{\psi}$ in the sense of the above definition. Factorizations of the form given in (3) are the exception, though, and we more often have a factorization of the type

$$f(\mathbf{s},\mathbf{t};\boldsymbol{\theta}) = f(\mathbf{s}|\mathbf{t};\boldsymbol{\psi})f(\mathbf{t};\boldsymbol{\psi},\boldsymbol{\lambda}) \qquad (4)$$

or

$$f(\mathbf{s},\mathbf{t};\boldsymbol{\theta}) = f(\mathbf{s}|\mathbf{t};\boldsymbol{\psi},\boldsymbol{\lambda})f(\mathbf{t};\boldsymbol{\lambda}). \qquad (5)$$

An example of (4) is the **two-by-two table**, with ψ the log **odds ratio**. The conditional distribution of a single cell entry, given the row and column totals, depends only on ψ: this is the basis for **Fisher's exact test** (*see* **Conditionality Principle**). Although it is sometimes claimed that the row total is an ancillary statistic for the parameter of interest, this is in fact not the case, at least according to the definition of ancillarity discussed here. Some more general notions of ancillarity have been proposed in the literature, but have not proved to be widely useful in theoretical developments. Further discussion of ancillarity and conditional inference in the presence of nuisance parameters can be found in Liang & Zeger [8] and Reid [10].

Ancillary statistics are defined for parametric models, so would not be defined, for example, in Cox's **proportional hazards** regression model (*see* **Cox Regression Model**). Cox [2] did originally argue, though, that the full likelihood function could be partitioned into a factor that provided information on the regression parameters $\boldsymbol{\beta}$ and a factor that provided no information about $\boldsymbol{\beta}$ in the absence of knowledge of the baseline hazard: the situation is analogous to (4) but, as was pointed out by several discussants of [2], the likelihood factor that is used in the analysis is not in fact the conditional likelihood for any observable random variables. Cox [3] developed the notion of **partial likelihood** to justify the now standard estimates of $\boldsymbol{\beta}$.

N. REID

Animal Screening Systems

Animal screening systems are experimental protocols designed primarily to screen substances in laboratory animals for possible adverse effects in humans. It is necessary to use animals as surrogates for humans because of ethical concerns associated with the intentional exposure of human subjects to potentially harmful substances in a controlled experiment and the frequent lack of comprehensive epidemiology data associated with unintentional exposures. The most important of the animal screening systems are discussed below.

Long-term Rodent Toxicity/Carcinogenicity Studies

The objective of long-term rodent carcinogenicity experiments is to determine if the administration of a test substance to laboratory animals will alter the normal pattern of tumor development (*see* **Tumor Incidence Experiments**). The test substance may be given in the diet or administered by other routes, such as inhalation, skin paint, or oral gavage. A typical experiment uses male and female rats and mice, with three dosed groups and a control, each group containing 50 animals. These animals are given the test substance for most of their natural lifespan (generally two years). Following necropsy, tissues taken from a number of different organ sites are examined microscopically for evidence of carcinogenic effects.

Important statistical issues that arise in the design, analysis, and interpretation of long-term toxicity/carcinogenicity studies include: (i) selecting the number, magnitude, and spacing of doses [3, 20] (ii) use of survival-adjusted methods in the evaluation of tumor data [13, 17] (iii) **multiple comparison** adjustments for the large number of tumor sites and types evaluated [11, 15, 36] (iv) use of **historical control** data [16, 17] and (v) adjustment for potentially **confounding** factors such as body weight that may be correlated with tumor incidence [31]. For further discussion of these issues, see **Tumor Incidence Experiments**. Studies of this type are often called **bioassays** although this term is more properly applied to experiments for the estimation of relative potency (*see* **Biological Assay, Overview**).

The carcinogenicity screening assay is the first step (often denoted the hazard identification phase) of a broader risk assessment effort to determine the magnitude of human risk that may be associated with exposure to the test substance. Thus, another major statistical issue in this area is the development of appropriate methodology to permit an extrapolation of experimental results (i) from high to low doses and (ii) from species to species [26] (*see* **Extrapolation, Low Dose**; **Extrapolation**). Critical in this evaluation is the proposed mechanism of action for the development of tumors and the effective dose of the chemical reaching the target site [27].

Short-term Toxicity Studies

The long-term rodent bioassay is generally preceded by short-term (generally 90 day) toxicity studies, which evaluate variables such as body and organ weights, histopathology, clinical pathology (hematology, clinical chemistry, and urinalysis data), sperm morphology and vaginal cytology, and immunotoxicology and neurobehavioral effects [4]. In related studies, the metabolism and distribution of the test substance are also evaluated. The objectives of these experiments are: (i) to assess chemical toxicity to permit an appropriate dose selection for the long-term study; (ii) to identify possible target organs for adverse effects; and (iii) to understand better the mechanism which may be responsible for the adverse effects observed. Statistical issues that arise in the evaluation of these studies include the multiplicity of parameters evaluated (*see* **Simultaneous Inference**), adjustment for **covariates** that may be affecting the observed responses, and choice of an appropriate model relating adverse effect to dose.

Screens for Anti-carcinogenesis

While chemically related decreases in tumor incidence frequently occur in long-term rodent carcinogenicity studies [18], animal studies can also be designed specifically to screen for anti-carcinogenic effects. Typically, a known carcinogen (such as dimethylbenzanthracene) is used to induce site-specific tumors in a short period of time, and the test compound is then administered to determine if it can counteract the development of these induced tumors [2]. Tamoxifen, now commonly used in

humans in adjuvant therapy for breast cancer [5], was first discovered to suppress the growth of chemically induced mammary tumors in rodents [21]. The knowledge gained from anti-carcinogenesis studies may also be useful in the design of human **clinical trials**. The statistical issues that arise in the design, analysis, and interpretation of anti-carcinogenesis screens are similar to those discussed above for toxicity/carcinogenicity studies.

A procedure for the mass screening of compounds for anti-tumor activity should aim to select the small proportion of active materials, and to reject the higher proportion of inactive materials, as economically and reliably as possible. Studies of the operating characteristic curve [22, 29] (*see* **Power**) and application of **decision theory** [6, 9], support the use of a multistage screen, in which unpromising materials can be rejected quickly, while more promising ones are tested further before acceptance.

Reproductive and Developmental Toxicology Experiments

These studies are designed to evaluate the impact of chemical exposure or other test agents on the developing fetus [24] (*see* **Teratology**). The objectives of these experiments are: (i) to assess reproductive performance; (ii) to identify developmental defects due to exposure to chemicals; (iii) to study the biologic mechanisms of developmental toxicants; and (iv) to establish "safe" conditions for their use or consumption by humans [14]. Typically, pregnant dams are administered the agent of interest during the period of gestation, and the animals are later sacrificed and examined to determine whether or not they exhibit chemically related effects on fetal implantation, mortality, and malformations [19].

The most important statistical issue associated with the evaluation of developmental toxicity data is how to take litter effects into account [12, 19]. That is, fetuses sampled from the same female represent multiple observations on a single experimental unit (the litter), and it is likely that the individual fetal responses will be correlated. If this correlation is not taken into account, any calculated test statistics or confidence intervals could be adversely affected (*see* **Correlated Binary Data**; **Multilevel Models**). Other important statistical issues include the development of tests for multiple binary factors such as different types of malformations [23], and the development of mathematical models for low dose risk estimation [14] (*see* **Dose–Response Models in Risk Analysis**).

Skin Corrosion Tests

The potential for chemicals to cause skin effects such as corrosion is a concern of industrial toxicologists in their assessments of possible worker and consumer safety issues, and animal models have often been used to screen substances for corrosive effects [25]. One protocol used for this purpose is the Draize test [8], in which the test substance is tested on the skin of albino rabbits. A material is considered corrosive if the structure of the tissue at the site of contact is destroyed or changed irreversibly after an exposure period typically ranging from four hours to 48 hours.

Because of concerns regarding the humane treatment of laboratory animals, one important statistical issue in this area is to devise a testing strategy that minimizes animal use. In addition, a high priority research activity is to develop *in vitro* methods for assessing corrosivity that do not require direct exposure of laboratory animals. Several promising new *in vitro* methods have been proposed [25, 37].

New Alternative Methods for Screening

Laboratory animal researchers are currently seeking new screening systems that are as (or more) predictive of human health hazard as the current methods, but can be conducted in a shorter time frame, with less expense, and requiring fewer animals. The 1993 NIH Revitalization Act in the US directed the various NIH Institutes to develop and validate alternate methods for acute and chronic safety testing that will reduce animal use, replace animals with nonanimal methods or lower species, or refine animal use to decrease or eliminate pain or distress. Certain of these alternative methods are discussed below.

Transgenic Animals

One of the potentially most important new alternative screening systems is the use of transgenic mouse lines, which provides the opportunity to develop relatively short-term *in vivo* models to identify carcinogens and other toxic agents. Such models include

transgenic mice carrying reporter genes that may serve as targets for mutagenic events, or mice carrying specific oncogenes or inactivated tumor-suppressor genes that are important factors contributing to the **multistage process of carcinogenesis** [7]. Mouse lines with defined genetic alterations that result in overexpression or inactivation of a gene intrinsic to carcinogenesis, but that are insufficient alone for neoplastic conversion, are promising models for chemical carcinogen identification and evaluation. Such studies may provide advantages in shortening the time required for bioassays and improving the accuracy of carcinogen identification [33]. One important statistical issue in this area is to develop appropriate model validation procedures.

Fish Models for Carcinogenicity Studies

The US National Toxicology Program (NTP) recently initiated studies to evaluate the feasibility of using two small fish models – Medaka and guppy – to determine the toxic and carcinogenic potential of selected chemicals. This project will include a comparative evaluation of molecular lesions in both the rodent and fish tumors to identify similarities and differences in activated oncogenes and/or mutations in tumor-suppressor genes. The greatest screening potential for fish at this time appears to be as a mid-tier carcinogenesis screen that could be conducted in a shorter time frame and less expensively than the two-year rodent bioassay [32].

Frog Embryo Teratogenesis Assay (FETAX)

This assay is a 96-hour whole-embryo developmental toxicity test that utilizes embryos of the South African clawed frog. Embryos are exposed to the test chemical continuously from the early blastula to free-swimming larvae stages. FETAX endpoints can potentially detect all four manifestations of mammalian developmental toxicity: growth retardation, structural malformations, death and functional deficits. An NTP multilaboratory validation study with 20 coded chemicals (including strong, weak, and nonteratogens) has recently been completed to determine further the repeatability and reliability of the FETAX system [32].

Computer-based Prediction Systems

Another method of reducing the number of animals used in screening tests is to derive computer-based systems to predict the outcome of such tests. In the area of carcinogenicity, a number of different methods have been proposed, some based on chemical structure [10, 30] and others based on the activity of the test compound in surrogate biological test systems such as **mutagenicity** and short-term toxicity studies [1, 34]. These approaches typically employ **multiple linear regression** techniques, **discriminant analysis**, and/or artificial **neural network**/decision tree strategies to identify important predictor variables for the endpoint of interest (*see* **Tree-structured Statistical Methods**). For an overview of these various methods, see Richards [28]. For the results of an application of these prediction systems to actual carcinogenicity data, see [35].

JOSEPH K. HASEMAN

Anthropometry

That the ancient world was involved in measuring the human body is not in doubt, although little has survived in the form of data. The Egyptians measured the stature of their kings, the Chinese measured height and head circumference, and in Mesopotamia they could measure weight on a balance. Sculptors have always necessarily been aware of body proportions; Greek sculptors worked to a ratio of one full male height to $7\frac{1}{2}$ head heights in general and to eight head heights on occasion, the justification being that the former reflects the true physical proportion but the latter the proportion as it appears from eye level. Aristotle noted that the human body gains in length between birth and five years about the same amount as it gains during the rest of its life, an approximation as valid today as it was in 300 BC.

The Renaissance rediscovered the glories of ancient Greece, so it is perhaps not surprising that although Leon Battista Alberti constructed an instrument for measuring the human body around 1450, its sole purpose was the making of better statues.

The term Anthropometry can be ascribed to Johann Sigismund Elsholtz (1623–1688), a German physician, who entitled his graduation thesis *Anthropometria*. He described an anthropometer for measuring heights and parts of heights of the human body. A 72 in. man should ideally measure 28 in. down to the navel, 36 in. to the pubic bone, etc. and Elsholtz's interest lay in discerning whether divergences from these proportions could be ascribed to various diseases.

The eighteenth century witnessed a surge of interest in human measurement, led mainly by the military, who preferred tall soldiers to short ones. But scientific interest also flourished, and among those active was George LeClerc, Count of Buffon (1707–1788), of Buffon's needle (*see* **Stereology**), who measured the length and weight of a number of fetuses and newborns. J.G. Roederer (1726–1763) also measured the length and weight of newborn infants but with a view to detecting immaturity in the baby, an early example of the use of measurement as a diagnostic tool. A particular high-water mark was provided by Buffon's friend Count Philibert Guéneau de Montbeillard (1720–1785) who measured his son's height some 38 times between birth and age 19 years and so provided the first known longitudinal study of human height. Graphs, based on these data, of height and height velocity – the latter clearly showing the pubertal growth spurt – can be seen in Tanner [20], who provides a comprehensive history of human growth.

Lambert Adolphe Jacques Quetelet (1796–1874) also made longitudinal measurements of his son and daughter and two daughters of a friend. Furthermore, by analyzing very large samples of measurements made on the military, he concluded that height, as well as other dimensions such as chest circumference, were **normally distributed** (Gaussian) in a population. An unfortunate consequence of this was that he concocted the idea of "l'homme moyen" – the average man – who represented the *type* or standard in the population although, as others have pointed out, such a person was thereby rather dull. Quetelet constructed tables of **mean** heights and weights for children based on **cross-sectional** data although the sample size at each age was rather small. Moreover, his interest in shape led to his definition of the Quetelet index, now the body mass index (see below).

The *cephalic index* (head width to length ratio) was an early nineteenth-century invention for use by anthropologists in characterizing ethnic and racial groups.

Sir Francis Galton (1822–1911) collected measurements of height, weight, and the circumferences of chest, upper arm, and head in his study of family likeness and inherited characteristics that led to the concept of **regression**. However, an important impetus to measuring children in the nineteenth century was social concern about the effects that dismal living and working conditions were having on the health of the poor, and much of the work, particularly around the 1830s, was done in association with the various Factory Acts. Similar investigations at this time were carried out in France. Later in the century the British Association for the Advancement of Science set up a number of Anthropometric Committees to collect data on heights, weights, etc. and height surveys, particularly in schools and colleges, were carried out in Boston, USA, and Italy.

At the beginning of the twentieth century, longitudinal studies, often measuring many physical variables, were set up in several centers in Europe and America. The twentieth century later saw the clinical measuring of several dimensions of the human body for diagnostic purposes while, in quite different

areas, measurements were required by the clothing industry for the making of garments and in the field of ergonomics for the design of tools and equipment in the workplace.

Direct Measures

Height (Length)

Height is measured by a stadiometer, on which a horizontal board is brought into contact with the top of the head and its distance then measured from the footplate. The Harpenden stadiometer contains a dial that displays the height and needs calibrating at regular intervals. A number of inexpensive plastic instruments are now available with built-in scales. Some of these need careful positioning and calibration. During measurement, the subject's head should be placed in the Frankfurt plane; that is, with an imaginary line drawn from the center of the ear hole to the lower border of the eye socket set horizontally. A number of experiments have been carried out with these instruments, the conclusions being that they are about equally reliable. In particular Voss et al. [24], after measuring children and wooden poles, concluded that a child contributes at least 90% of the error **variance** when using one of these instruments, the remainder originating with the measurer and the instrument. They also concluded, in agreement with other workers, that the **standard deviation** of a single height measurement is about 0.25 cm. This is an average value over children, the standard deviation varying from child to child, with some children being almost static in their posture while others are rather springy. Subsequent experiments suggest that this value also obtains for adults.

Up to age 2 years, it is usual to measure supine length, rather than height, on a calibrated measuring mat. The standard deviation of a single measurement is estimated to be about 0.3 cm in newborn infants and about 0.4 cm at 6 weeks and 8 months [7].

There are problems in trying to measure a subject more than once and then averaging the observations to reduce the effect of **measurement error**. Several minutes of activity need to elapse between measurements for them to be independent, and the scale on the instrument needs to be read by an independent observer to avoid the very strong **bias** that can result when a measurer remembers a previous reading.

In 1724 the Royal Society of London was told of the Reverend Joseph Wasse's experiment with a nail in the wall that he could touch in the morning but not later in the day owing to diurnal shrinkage of the human body (*see* **Circadian Variation**). This has been investigated since by many researchers [17], who have found that daily shrinkage can be greater than 2 cm, and has led to a stretching method of measuring height that involves gentle upward pressure on the mastoid processes. This reduces only partly the effects of diurnal shrinkage and the variable posture of the subject. However, as shown in [24], different measurers stretch by different amounts so that, in clinical practice, subjects should be measured on repeated visits to the clinic by the same measurer and at the same time of day. Seasonal variation in growth and catch-up growth after illness are also well known. Hall [12] discusses clinical considerations in measuring height (as well as weight and head circumference).

The end of the nineteenth century saw the first attempts at producing centile charts (*see* **Quantiles**) for height based on cross-sectional data consisting of a number of heights made at each age. Their purpose was merely to describe the population, but later such charts were used for clinical diagnostic purposes or for **screening**. Any child with height below some threshold level, say the 3rd centile, can be referred and investigated further for possible pathology. To this end the charts of Tanner et al. [23], modified by Tanner & Whitehouse [22], were published and served as the standard in the UK for the next 30 years. They give smoothed 3rd, 10th, 25th, 50th, 75th, 90th, and 97th height (supine length to age 2) centiles from birth to age about 19 years for boys and girls separately. The corresponding charts for the US standards for height were given by Tanner & Davies [21]. Standards and charts also exist for several other countries, while much of the developing world uses charts prepared by the **World Health Organization** (**WHO**), although these are based on US data.

Charts of height velocity are also given in [21–23]. If H_1 is the height of a subject at time 1 and H_2 the height at a later time 2, then $D = H_2 - H_1$ is the incremental change in height which, when measured over the interval of a year, is known as the *height velocity*. This can be used for diagnostic purposes, in particular to detect a child who, although at an acceptable height, has a growth rate that starts

to fall. It is, however, subject to a larger measurement error than height.

Height, but not height velocity, standards for the UK have now been updated and the corresponding charts published by the Child Growth Foundation (CGF), but see Freeman et al. [10] for a full description. As explained by Cole [4], nine centiles are shown, against the original seven, these being spaced two-thirds of a standard deviation score (see below) apart. Data from seven sources were used in the construction of the charts, which were plotted by means of the LMS method and **penalized maximum likelihood** of Cole & Green [5]. In this, if $H(t)$ is the height, say, of a male at t years, $M(t)$ is its **median**, and $S(t)$ its coefficient of variation (*see* **Standard Deviation**), then $L(t)$ can be found from a Box–Cox **power transformation** of $H(t)$ so that

$$Z = \frac{\left[\frac{H(t)}{M(t)}\right]^{L(t)} - 1}{L(t)S(t)}$$

has approximately a standard normal distribution. Once estimates of $L(t)$, $M(t)$, and $S(t)$ have been obtained, the $C_{100\alpha}(t)$ centile of the height distribution at age t is given by

$$C_{100\alpha}(t) = M(t)[1 + L(t)S(t)z_\alpha]^{1/L(t)},$$

where z_α is the **standard normal deviate** corresponding to the centile ($z_\alpha = 1.341$ for the 91st centile, etc.). In fact, $L(t)$ was not found to differ significantly from 1 at any age and so was set uniformly to 1.

It has been suggested that when a child is measured on two separate occasions, the height observed on the second occasion should be assessed conditionally on the height obtained on the first. If height H, at a particular age, has mean μ and standard deviation σ, and h is an observed value of H, then $h^{\mathrm{SDS}} = (h - \mu)/\sigma$ is known as the *standard deviation score* (SDS) of h. If H is also normally distributed, then the centile of h^{SDS} can be determined from the standard normal distribution. Moreover, the conditional SDS of h_2 given h_1 can be found from the relation

$$(h_2|h_1)^{\mathrm{SDS}} = \frac{(h_2^{\mathrm{SDS}} - \rho h_1^{\mathrm{SDS}})}{(1 - \rho^2)^{1/2}},$$

where ρ is the coefficient of **correlation** between h_1 and h_2. This is well over 0.9 in the years approaching puberty [1].

Note that if $D = H_2 - H_1$ is a height velocity, then the observed velocity conditional on h_1 is given by $d|h_1 = h_2|h_1 - h_1$, so that **inferences** based on conditional height at time 2 and conditional velocity up to time 2 are equivalent.

Weight

Much of what has been written about height also applies to weight. Modern measuring instruments are highly reproducible with repeated observations differing by only a few grams. The main source of variability lies in the subject but is not so short term, being dependent on the contents of the stomach, bowel, and bladder. Moreover, the weight distribution in a population at any age is not generally normally distributed, although log (weight) is often sufficiently nearly normal for practical purposes (*see* **Lognormal Distribution**). The charts of Tanner & Whitehouse [22] have provided the weight and weight velocity standards for the UK since the 1960s although the weight standards have now been updated by Freeman et al. [10] and the corresponding charts published by the CGF. The LMS method was again used, but the values of $L(t)$ were found significantly different from 1. The charts of the US weight standards can be found in Hamill et al. [14].

The human body often is regarded as made up of two components, lean body mass and fat. In view of the latter, body weight can decrease as well as increase with time. The most commonly used method for estimating the weights of these two components involves taking four skinfold measurements with calipers at four recognized sites, namely the triceps, biceps, subscapular, and supra-iliac. Body density can then be estimated by a regression equation of the form

$$\text{density} = a + b \log_{10} S,$$

where S is the sum of the four skinfolds in millimeters and a and b are constants that depend on the sex and age of the subject. Body fat percentage can next be estimated by Siri's formula,

$$\text{body fat percentage of total weight} = 100\left(\frac{4.95}{\text{density}} - 4.5\right),$$

which is based on the assumption that the density of fat is 0.9 kg/l and of fat-free mass 1.1 kg/l.

Finally, body fat weight and, by subtraction from total body weight, the weight of lean body mass, can be calculated. Values of the regression coefficients for adults can be found in Durnin & Wormersley [9].

The situation with children is, however, more complicated, for a number of reasons, including the change in the density of fat-free mass with age. In a **validation study** of several suggested formulas, Reilly et al. [18] consider them all sufficiently unreliable as to state, "For the time being skinfolds might best be regarded as indices (rather than measures) of body fatness in individuals, or means of estimating body fatness of groups."

In hospitals and laboratories with suitable equipment, body density can be evaluated more directly by measuring the weight in air followed by the weight in water to estimate the volume; or the volume may be estimated from the amount of water displaced. In either case, since the aim is to measure the volume of body tissues alone, a correction needs to be made to remove residual lung volume from the body volume.

More direct methods of measuring lean body mass, such as potassium emission counting and dual energy X-ray absorptiometry (DXA), are available and have good reproducibility. See Jebb & Elia [16] for a review of methods.

Other Dimensions

Head circumference is measured in the neonatal period to detect diseases associated with a large head, such as hydrocephalus, or a small head. It is measured with a plastic or metal tape along a line midway between the eyebrows and the hairline at the front of the head and the occipital prominence at the back. The main source of error lies therefore in determining this line. Height (length), weight, and head circumference are the only dimensions measured in every child in the UK, and Hall [12] recommends that this last should be measured before discharge from hospital following birth and again at approximately 6–8 weeks of age. Charts of population standards are usually available for the early years of life only; the charts for the UK, published by the CGF, cover just the first year while those for the US, given in [14], cover the first three years.

The *sitting height* (SH) of a subject is measured on a table with a stadiometer attached, the height being the distance from the crown of the head to the table. Unpublished research suggests that the measurement error involved is larger than that for height in view of the added difficulty in placing the subject correctly. Sitting height subtracted from standing height leads to the *subischial leg length* (SLL).

A comparison of SH with SLL can aid the diagnosis of skeletal dysplasias. It is also known that SH may be disproportionately long relative to SLL in precocious puberty. UK charts date from 1978 and are available. They are, however, based on small numbers of children from several years ago and so should be treated with caution when used today.

In view of the inherent variability of a height measurement, clinical practitioners have sought other, less variable, dimensions that might prove useful in monitoring growth, particularly over a very short time period. These include the lengths of individual bones made from radiographs and the *lower leg length* measured on a knemometer, an instrument not unlike a stadiometer but with the headboard placed on the knee with the subject in the sitting position. Since this variable is essentially the sum of a few bone dimensions, it does indeed display a small variance. Insufficient correlation with height makes it unsuitable for making judgments about height. However, it can be used as an early indicator that growth hormone is being successful in the treatment of short stature [25].

Standards and charts have been compiled for a large number of other measures that are useful in diagnosing various syndromes. Many of these can be found in Hall et al. [13].

Derived Measures

Surface Area

Although some earlier attempts at measuring the surface area (SA) of the human body are recorded, the main work began in about 1850. Several methods were devised, including coating the body with paper or adhesive type, surface integration using inked discs, and triangulation. Interest lay initially in determining the number of pores on the skin or the total force exerted on the body by the atmosphere. Over 1000 cases were reported, and these are comprehensively discussed in [3].

The need for such estimation today arises from the fact that both renal function and dosage of cancer chemotherapy are expressed in relation to surface area rather than weight. Clearly the measurement of

SA by any direct method is impossible in routine clinical work. However, even from an early period, estimating formulas were devised based on height H, and weight W. Many of these take the form

$$\mathrm{SA} = cH^{a_1}W^{a_2},$$

where a_1, a_2, and c are constants. One of the first examples is due to DuBois & DuBois [8] and sets $a_1 = 0.725$ and $a_2 = 0.425$ if H is measured in centimeters, W in kilograms, and SA in square meters. This was based on a sample of only nine subjects, including a male cretin and a female cadaver, and is still in common use today!

Gehan & George [11] carried out a bivariate regression analysis on the log of the above model using as data the 401 postnatal cases given in [3] for which measured values are listed for all of H, W, and SA. This finds $a_1 = 0.422, a_2 = 0.515$, and $c = 0.0235$, values recommended by Bailey & Briars [2], who extend their analysis to provide **standard errors** and explain the equivalence of a number of suggested models of the above form.

Body Mass Index

A number of weight for height indices have been suggested for measuring the fatness of an individual, but the one that has established itself as the standard in adults is Quetelet's *body mass index* (BMI) defined by W/H^2, where weight W is measured in kilograms and height H in metres. An individual with a value less than 20 is generally regarded as underweight, while one with a value over 25 is overweight. This latter range is sometimes subdivided into three (25–30, 30–40, and >40) that define three grades of obesity.

Despite its routine clinical use in adults, the application of BMI to children has always been suspect since its distribution in the population changes quickly with age up to, and even beyond, adolescence and maturity. To overcome this problem, Rosenthal et al. [19] have shown that, for healthy London school children between the ages of about $4\frac{1}{2}$ years and 19, the index $W/H^{2.88}$ is independent of height or age, and they have provided centile charts and nomograms for its use. On the other hand, Cole et al. [6] have given centile charts of BMI for UK children from birth to age 23 years on the basis of data used in updating standards for height and weight. Centile charts for white US children aged 1–19 years are to be found in Hammer et al. [15].

Anticipation

Anticipation denotes a phenomenon characterized by increasing severity and/or earlier onset of a disease in successive generations; some definitions also include greater recurrence risk (*see* **Genetic Counseling**) among the possible factors delineating a progressive degeneration from parent to child across the generations. Observations of apparent anticipation in myotonic dystrophy date from the early twentieth century, and there are indications that the first observations of the phenomenon may be traceable to the nineteenth century [4].

In 1948, Penrose [6] noted that the clinical impression of anticipation could be an artifact induced by **ascertainment** bias, and cited ways in which preferential ascertainment of certain types of pedigrees could result in the appearance of anticipation in hereditary diseases. These included preferential ascertainment of late onset parents, who may have had an enhanced likelihood of reproduction relative to persons with earlier onset, and of children with very early onset, who might be more likely to attract medical attention. Both would tend to create the appearance of earlier onset in the offspring generation. Another possible source of **bias** is the simultaneous identification of parent–offspring affected pairs, in which the parent would have had a notably longer time of exposure to risk of onset, resulting again in a tendency toward the observation of later onset ages in the parental generation. Such rationales cast serious doubt on the reality of anticipation as a biologically based phenomenon in the minds of many geneticists.

However, in the late twentieth century a new type of dynamic mutation was linked to the clinical observation of anticipation in at least some disorders. In this type of mutation, called trinucleotide repeat expansion, the number of triplet repeats can increase with the transmission of genetic material from one generation to the next (*see* **DNA Sequences**; **Genetic Markers**). An increased number of such repeats at a particular genomic site within an individual is associated with disease for a set of disorders including myotonic dystrophy, Friedrich's ataxia, Huntington disease, and Fragile X syndrome. Moreover, the number of repeats has been found to correlate with severity and onset age, providing a molecular mechanism explaining the phenomenon of anticipation in these and other hereditary diseases [7, 8]. A variety of models have been put forward to explain how such expansions disrupt gene expression, and there is evidence that the specific mechanism may vary with the particular syndrome [4]. Because the likelihood of such expansion can differ with parental gender, this type of dynamic mutation also provides an explanation for the phenomenon of parent-of-origin effect often associated with disorders displaying anticipation (*see* **Parental Effects**).

Anticipation has been reported for a growing number of disorders not found to be associated with trinucleotide repeat expansion, and certainly the existence of unstable deoxyribonucleic acid (DNA) disorders does not preclude the possibility of other mechanisms leading to anticipation [5, 7]. Furthermore, the potential for ascertainment-related artifact should not be discounted. Since large, population-based prospective studies are rare, there is persistent interest in statistical methods for the detection of anticipation that are able to appropriately adjust for ascertainment bias. A number of such approaches have focused on correction for bias induced by differential age at interview for pedigree members of different generations. Such circumstances result in a tendency for parents to have longer periods of exposure to risk than their offspring [1, 3, 9]. However, even methods that successfully adjust for such truncation effects may be adversely affected by other commonly encountered sources of ascertainment bias, including problems arising from decreased fertility among affected persons and preferential selection of pedigrees with multiple affected individuals [3, 9]. **Simulation** studies have identified difficulties associated with a number of available methods, including inflation of type I error rates, and deficiencies of power [1, 3, 9], but also point toward promising new designs, such as those utilizing collateral relatives [2], for the statistical evaluation of anticipation.

DEBORAH V. DAWSON

Antidependence Models

One important approach to the analysis of continuous repeated measurements data uses a *linear regression model* to relate the *expected value*, or mean, of each subject's sequence of response measurements to covariates such as treatment group and time of measurement. The sequence of observations from a subject will deviate in some random way from the postulated regression model. With repeated measurements it cannot typically be assumed that these deviations, or residuals, are independent and equally variable – the assumptions that underly conventional multiple regression analysis. The pattern of variances and correlations among the residuals from a subject is called the *covariance structure* of the repeated measurements and a full analysis requires this to be specified as part of the model. The ante-dependence model defines a family of covariance structures for repeated measurements.

We assume that we have a repeated measurements trial or experiment in which all subjects are observed at the same times relative to the start. There may be missing values. Many models of covariance structure have been proposed for this setting, some, such as the *compound-symmetry* (or uniform) and *stationary first-order autoregressive* models, depending on a small number of parameters (*see* **Analysis of Variance for Longitudinal Data**; **ARMA and ARIMA Models**; **Time Series**). Such simple models, particularly those with variances that are constant across time, are often too restrictive to provide an adequate representation of the variances and correlations observed in practice with repeated measurements. At the other extreme we have the most general model: the so-called *unstructured* covariance matrix. This allows a different variance for each time of measurement and a different correlation for every pair of time points. With T times of measurement, the unstructured matrix has $T(T+1)/2$ parameters and this figure grows at the rate of the *square* of the number of times. While, by definition, the unstructured covariance matrix must provide an adequate model for the observed structure, the large number of parameters means that, when sample sizes are not large, the subsequent analysis can be inefficient. The class of ante-dependence models provides structures that are intermediate in complexity between the very simple models with a fixed number of parameters and the unstructured model. Typically, the number of parameters in an ante-dependence model grows at the same rate as the number of time points. The class includes the unstructured matrix as a least efficient special case.

The class of ante-dependence covariance structures can be defined in several ways. The definition, in terms of *conditional independence*, illustrates well the rationale behind the structure and provides a clear link with the important topic of graphical models [7]. Following Gabriel [1, 2] and Kenward [4] we say that the sequence of random variables $Y_1, \ldots, Y_T$ has an ante-dependence structure of order r (AD(r)) if, for every $t > r$,

$$Y_t | Y_{t-1}, Y_{t-2}, \ldots, Y_{t-r}$$

is conditionally independent of $Y_{t-r-1}, \ldots, Y_1$. In other words, once we have taken account of the r observations preceding Y_t, the remaining preceding observations carry no additional information about Y_t. Typically, we would expect r to be small. This is plausible in many settings, but there are important exceptions; for example, where changes over time are nonlinear and times of rapid change vary at random among subjects.

If the $\{Y_t\}$ follow a Gaussian distribution, then the assumption of an AD(r) structure is equivalent to the assumption that the *inverse* of the covariance matrix has a band form of order $r+1$; that is, all elements of the inverse are zero except for the leading diagonal and the r diagonals immediately above and below it. This establishes an important distinction between the ante-dependence structure and the majority of models for repeated measurements covariances structures: the latter typically impose structure on the covariance matrix itself rather than the inverse. An important special case is the AD(1) structure which corresponds to a tri-diagonal inverse: this is a well-known property of processes with a first-order *Markov* structure, to which the AD(1) structure corresponds.

The AD(r) structure imposes no constraints on the constancy of variance or covariance with respect to time; that is, in terms of second-order moments, it is not *stationary*. The familiar stationary autoregressive [AR(r)] covariance structures can be expressed as special cases of the AD(r) structures. This lack of stationarity means that the structure is particularly well suited to situations where the variability fluctuates during the course of a trial and where intervals between times of measurement are not

equal. Additional smoothness can be introduced by imposing a polynomial form on the variances and auto-regressions as in the so-called "structed antedependence" models [5].

The AD(r) structure can be combined with any appropriate linear model for the mean profiles and fitted to data using conventional likelihood and restricted likelihood methods as described, for example, in [3]. The resulting inferences are based on asymptotic results.

The AD structures have an additional advantage when used in the special (and restricted) setting in which the saturated means model is used; that is, in which a different parameter is used for each combination of between-subject covariate and time of measurement. Such models are implicit in repeated measurements analysis of variance. Under the AD structure, pivotal **likelihood ratio test** statistics can be constructed for overall profile comparisons for any between-subject comparison and, when applied to successive differences among the repeated measurements, for interactions of such comparisons with time. The test statistics can be calculated in a simple way from univariate analyses of covariance and have known finite sample distributions. They can be regarded as generalizations of Wilks' lambda statistic from repeated measurements **multivariate analysis of variance**. Further, the same construction produces pivotal likelihood ratio statistics with known distributions even when there are drop-outs; that is, when some sequences terminate early. Full details are given in [4]. In this way, the AD structure leads to analyses that provide a practical likelihood-based alternative to simple analysis-of-variance-based methods for analyzing repeated measurements with drop-out. The validity of the AD-based analyses rests on the assumption that the drop-out process is random [6], while *ad hoc* methods such as modified repeated measurements analysis of variance require the stricter assumption of completely random drop-out.

M.G. KENWARD

Antithetic Variable

The efficiency of a **simulation** can be increased by the judicious use of variance-reduction methods, of which antithetic variables (or variates) is one example, due originally to Hammersley & Morton [2].

The basic idea is simply illustrated in the context of integral estimation (*see* **Numerical Integration**). Consider the following example, taken from Morgan [4].

The integral,

$$I = \int_0^1 (1 - x^2)^{1/2} \, \mathrm{d}x, \tag{1}$$

is known to take the value $\pi/4$.

If a random sample, $U_1, \ldots, U_n$, is taken from a **uniform distribution** on (0,1), then a crude **Monte Carlo** approach estimates I by

$$I_c = \frac{1}{n} \sum_{i=1}^{n} (1 - U_i^2)^{1/2}. \tag{2}$$

This is because the integral in (1) can be interpreted as the expectation, $\mathrm{E}[(1 - U^2)^{1/2}]$, where U has the uniform, U(0, 1) distribution. The estimate, I_c, is then seen as the sample average, providing an unbiased estimate of I. It is straightforward to show that

$$\mathrm{var}(I_c) \approx \frac{0.0498}{n}.$$

The method of antithetic variates estimates I by

$$I_A = \frac{1}{2n} \sum_{i=1}^{n} \left\{ (1 - U_i^2)^{1/2} + [1 - (1 - U_i)^2]^{1/2} \right\}. \tag{3}$$

Clearly, since $1 - U$ also has a U(0, 1) distribution, $\mathrm{E}[I_A] = I$, but the negative correlation between U and $1 - U$ has a variance-reducing effect. If we are trying to estimate π by these approaches, then the method of crude Monte Carlo requires a random sample from the U(0, 1) distribution that is slightly more than nine times larger than that required by the approach based on (3) to achieve the same variance.

An attractive practical demonstration of the value of using antithetic variates is again in terms of estimation π, but through Buffon's cross replacing Buffon's needle (*see* **Stereology**); see Hammersley & Morton [2] and Morgan [4]. In simple computer simulations, antithetic variates can be readily obtained if the inversion method is employed to transform **pseudo-random** U(0, 1) variates to provide realizations of random variables from other desired distributions; see Ripley [6]. For examples and variations on this approach in the context of simulating queueing systems, see Page [5] and Mitchell [3]. The paper by Schruben & Margolin [7] provides an application in a medical context, in which patients with heart problems queue for beds in a hospital unit. The antithetic variate approach has wide application; see, for example, Green & Han [1].

BYRON J.T. MORGAN

ARMA and ARIMA Models

Public health institutions frequently collect notifications of diseases, entries into a hospital, injuries due to accidents, etc. at weekly or monthly intervals. Consecutive observations of such "time series data" are likely to be dependent. In environmental medicine, where series such as daily concentrations of pollutants are analyzed, it is evident that stochastic dependence of consecutive measurements may be important: a high concentration of a pollutant today, for example, has a certain inertia, that is, a tendency to be high tomorrow as well (positive autocorrelation). Dependence of consecutive observations may be equally important when data such as blood glucose are recorded within an single patient.

An important class of models having the flexibility to represent the stochastic dependence of consecutive data are autoregressive integrated moving average (ARIMA) models. Box & Jenkins [3] presented a detailed and influential account of these models and "ARIMA modeling" has become well established in such fields as economics and industry. The method of model identification, estimation, and checking is now often referred to as "the Box–Jenkins approach" and ARIMA models are also often called *Box–Jenkins models*.

ARIMA models may be particularly useful for **forecasting**. Forecasts of epidemiologic time series, for example, are often needed by public health organizations, since it is clearly of interest to know what frequencies of diseases might be expected in the future in order to better plan the distribution of resources. It may also be of interest to assess relations between two ARIMA time series, a "response" or "output" series, such as the daily number of patients coming to a clinic, and "explanatory" or "input" series, such as daily concentrations of a pollutant, daily mean temperature or other climatic series. Such situations may be represented adequately by the so-called **transfer function models**. Analogous questions arise when studying time series data recorded in an individual subject. Studies on individual subjects may have great potential for the investigation of biological mechanisms. Other questions are concerned with "changes" of time series: how efficient was a preventive program to decrease the monthly number of accidents? How did the pattern of morbidity in a population change after an environmental accident? These and other related questions may be investigated by an extension of ARIMA modeling [4] called *intervention analysis*.

The ARMA Model

Denote the observations at equally spaced times $t, t-1, t-2, \ldots$ by $z_t, z_{t-1}, z_{t-2}, \ldots$. For simplicity assume that $\mathrm{E}(z_t) = 0$ (otherwise the z_t may be considered as deviations from their mean). Let a_t, $a_{t-1}, a_{t-2}, \ldots$ be a white noise (*see* **Noise and White Noise**) series consisting of independent identically distributed random variables whose distribution is normal with mean zero and variance σ_a^2. It is helpful to think of the a_t as a series of "random shocks".

To begin, assume that the present observation, z_t, is linearly dependent on the previous observation, z_{t-1}, and on the random shock, a_t:

$$z_t = \phi z_{t-1} + a_t, \quad \text{where } \phi \text{ is a parameter.} \qquad (1)$$

Since z_t is regressed on z_{t-1} it is called an autoregressive model of first order [abbreviated AR(1)] model.

Alternatively, one may express z_t as a linear combination of the present and the previous random shock:

$$z_t = a_t - \theta a_{t-1}, \quad \text{where } \theta \text{ is a parameter.} \qquad (2)$$

This expression is called a moving average model of first order [abbreviated MA(1)] model.

The above two basic models are special cases of two more general models:

$$z_t = \phi_1 z_{t-1} + \cdots + \phi_p z_{t-p} + a_t, \qquad (3)$$

called an autoregressive model of order p [AR(p) model] and

$$z_t = a_t - \theta_1 a_{t-1} - \cdots - \theta_q a_{t-q}, \qquad (4)$$

called a moving average model of order q [MA(q) model].

By combining these two equations one obtains what is called the autoregressive moving average model of order p and q [ARMA(p, q) model]:

$$z_t = \phi_1 z_{t-1} + \cdots + \phi_p z_{t-p} + a_t - \theta_1 a_{t-1} - \cdots - \theta_q a_{t-q}. \qquad (5)$$

This representation is relatively cumbersome to read and the situation becomes worse when considering generalizations, for example seasonality. The use of the backshift operator notation considerably improves the situation. The *backward shift operator* B is such that

$$Bz_t = z_{t-1}, \qquad B^k z_t = z_{t-k}. \tag{6}$$

The AR(1) model may then be written:

$$\begin{aligned} z_t &= \phi z_{t-1} + a_t, \\ z_t - \phi B z_t &= a_t, \\ (1 - \phi B) z_t &= a_t. \end{aligned} \tag{7}$$

Analogously, the AR(p) model may be written:

$$(1 - \phi_1 B - \cdots - \phi_p B^p) z_t = a_t, \tag{8}$$

and the MA(q) model may be written:

$$z_t = (1 - \theta_1 B - \cdots - \theta_q B^q) a_t. \tag{9}$$

Combining the AR(p) model and the MA(q) model, we obtain the ARMA(p, q) model:

$$\begin{aligned} &(1 - \phi_1 B - \cdots - \phi_p B^p) z_t \\ &\quad = (1 - \theta_1 B - \cdots - \theta_q B^q) a_t \end{aligned}$$

or

$$\phi(B) z_t = \theta(B) a_t, \tag{10}$$

where $\phi(B) = 1 - \phi_1 B - \cdots - \phi_p B^p$ and $\theta(B) = 1 - \theta_1 B - \cdots - \theta_q B^q$.

The two polynomials in B, $\phi(B)$ and $\theta(B)$, are called the autoregressive and moving average operators, respectively. If the polynomial $\phi(B)$ has complex roots corresponding to $\phi(B) = 0$ (where B is viewed as a complex variable), then this indicates that the series contains random or quasi-periodic components [3].

To obtain more insight into the structure of the models, we use the backshift operator notation and write the AR(1) model in a different form:

$$\begin{aligned} (1 - \phi B) z_t &= a_t, \\ z_t &= (1 - \phi B)^{-1} a_t, \end{aligned}$$

or

$$z_t = (1 + \phi B + \phi^2 B^2 + \cdots) a_t,$$

or

$$z_t = a_t + \phi a_{t-1} + \phi^2 a_{t-2} + \cdots. \tag{11}$$

Thus, the current observation, z_t, is given by an (exponentially) weighted sum of random shocks. The relation shows that the AR(1) model can also be represented by a MA(∞) model. This duality holds, in general, between AR and MA models. In particular, the AR(1) and the MA(1) models are both generated by the white noise series, but they differ strongly in absorbing the random shocks. This difference is reflected in the different dependence structure and in the different forecasting properties of the models.

It has been shown that ARMA(p, q) models may be represented by a weighted sum of random shocks:

$$z_t = a_t + \psi_1 a_{t-1} + \psi_2 a_{t-2} + \cdots \tag{12}$$

or

$$z_t = \psi(B) a_t,$$

where $\psi(B) = 1 + \psi_1 B + \psi_2 B^2 + \cdots$. Comparing with (10) we see that $\psi(B) = \theta(B)/\phi(B)$. z_t is the output from a "linear filter" whose input is white noise and the "transfer function" $\psi(B)$ is a rational function of B. Representation (12) is not used for estimation since, in general, it contains an infinite number of parameters. However, the ARMA representation $\phi(B) z_t = \theta(B) a_t$ contains only $p + q$ parameters. Often, it is possible to find a parsimonious and adequate ARMA(p, q) representation with $p \leq 2$ and $q \leq 2$.

The Nonseasonal ARIMA Model

If the roots of the polynomial $\phi(B)$ lie outside the unit circle, it may be shown than an ARMA(p, q) process is stationary. Stationarity signifies that the probability structure of the series does not change with time. In particular, a stationary series has a constant mean and variance and a covariance structure that depends only on the difference between two time points.

Experience in industry, economics and, more recently, in medicine have shown that many time series are not stationary. However, it has been found that the series of first differences,

$$w_t = z_t - z_{t-1} = \nabla z_t, \tag{13}$$

is often stationary. The symbol $\nabla = 1 - B$ is called the (ordinary) differencing operator. If a series has to be differenced one time to obtain stationarity, then the model corresponding to the original series

is called an integrated ARMA model of order $p, 1, q$ or an ARIMA$(p, 1, q)$ model. If differencing has to be performed d times to obtain stationarity the model is written

$$\phi(B)\nabla^d z_t = \theta(B)a_t \tag{14}$$

and called an ARIMA(p, d, q) model.

To stabilize the variance it may be useful to consider transformations of the raw data; in particular, the logarithmic or the square root transformation [3, 11] (*see* **Power Transformations**).

The Seasonal ARIMA Model

Box & Jenkins have extended the above concepts to cope with **seasonal time series**. The model is obtained in two steps. Consider the case of monthly data.

1. An observation for a particular month is related to the observation for 12 months, 24 months, etc. previously by

$$z_t - \Phi_1 z_{t-12} - \Phi_2 z_{t-24} - \cdots - \Phi_P z_{t-12P} = \alpha_t - \Theta_1 \alpha_{t-12} - \Theta_2 \alpha_{t-24} - \cdots - \Theta_Q \alpha_{t-12Q},$$

or

$$\Phi(B^{12})z_t = \Theta(B^{12})\alpha_t, \tag{15}$$

where the AR and MA operators are now polynomials in B^{12},

$$\Phi(B^{12}) = 1 - \Phi_1 B^{12} - \Phi_2 B^{24} - \cdots - \Phi_P B^{12P},$$
$$\Theta(B^{12}) = 1 - \Theta_1 B^{12} - \Theta_2 B^{24} - \cdots - \Theta_Q B^{12Q},$$

and

$$B^{12}\alpha_t = \alpha_{t-12}.$$

Capital letters are used to distinguish this from the nonseasonal ARIMA model (14).

2. The error component, α_t, for a particular month is related to that for previous months by the usual ARMA model:

$$\phi(B)\alpha_t = \theta(B)a_t. \tag{16}$$

Joining the seasonal and the nonseasonal parts gives

$$\phi(B)\Phi(B^{12})z_t = \theta(B)\Theta(B^{12})a_t. \tag{17}$$

Extending the concept of ordinary differencing to seasonal differencing by forming seasonal differences,

$$w_t = z_t - z_{t-s} = \nabla_s z_t, \tag{18}$$

where $\nabla_s = 1 - B^s$ is the seasonal differencing operator and $s = 12$, for, for example, monthly data, one obtains the seasonal ARIMA model:

$$\phi(B)\Phi(B^s)\nabla^d \nabla_s^D z_t = \theta(B)\Theta(B^s)a_t, \tag{19}$$

abbreviated to the ARIMA$(p, d, q)(P, D, Q)_s$ model.

The Autocorrelation Function and Model Identification

The dependence structure of a stationary time series is characterized by the **autocorrelation function** (ACF). The ACF is defined as the correlation between z_t and z_{t+k}:$\rho_k = \text{cor}(z_t, z_{t+k})$. k is called the time lag.

The ACF is estimated by the empirical ACF:

$$r_k = \frac{c_k}{c_0}, \quad k = 0, 1, 2, \ldots,$$

where

$$c_k = \frac{1}{n}\sum_{t=1}^{n-k}(z_t - \bar{z})(z_{t+k} - \bar{z}) \quad \text{and} \quad \bar{z} = \frac{1}{n}\sum_{t=1}^{n} z_t. \tag{20}$$

c_k are the empirical autocovariances.

The empirical ACF is the main tool for the identification of the ARIMA model. ACFs of the basic processes have a typical shape. The ACF of the AR(1) process decays exponentially. The ACF of the MA(1) process has only ρ_1 nonzero and of the MA(2) process only ρ_1 and ρ_2 nonzero. Valuable complementary tools for model identification are the partial autocorrelation function [3] and the inverse autocorrelation function [5].

To obtain an adequate ARIMA model, Box & Jenkins have suggested the following procedure (the "Box–Jenkins method"):

0. "Make the series stationary", that is, consider transformations to stabilize the variance, consider ordinary and seasonal differencing.
1. Choose a provisional model; in particular, by looking at the empirical ACF.

2. Estimate the model parameters (standard software such as SAS or BMDP allow maximum likelihood estimation of Box–Jenkins models).
3. Check the adequacy of the model. In particular, check the ACF of the residuals for white noise.

If the model does not fit the data adequately, then go back to point 1 and choose an improved model. Among different models that represent the data equally well choose the simplest one, that is, the model with the fewest parameters. If this concept of parsimony is ignored, poor forecasts may result.

Forecasting

To obtain forecasts $\hat{z}_{t+h}$ for h time units (days, months, etc.) ahead from an ARIMA model, one writes the corresponding model equation by replacing (i) future values of the random shocks a by zero and past values by observed residuals; (ii) future values of z by the corresponding forecasts; (iii) past values of z by their observed values.

The following example illustrates how to obtain forecasts for an AR(1) model:

$$\begin{aligned} h=1:\quad & z_{t+1} = \phi z_t + a_{t+1}, \\ & \hat{z}_{t+1} = \phi z_t, \\ h=2:\quad & z_{t+2} = \phi z_{t+1} + a_{t+2}, \\ & \hat{z}_{t+2} = \phi \hat{z}_{t+1} = \phi(\phi z_t) \\ & \qquad = \phi^2 z_t, \text{ etc.} \end{aligned} \tag{21}$$

By continuing this procedure one may see that the forecasts corresponding to the AR(1) model follow an exponential curve.

The Transfer Function Model

Box & Jenkins [3] have developed an important extension allowing us to analyze relations between an "output" series (e.g. the daily number of patients with a specified disease coming to a clinic) and one or several "input" series (e.g. the daily concentrations of pollutants, daily mean temperature, etc.). In the **transfer function models** the output series, y_t, is considered to be composed of two parts:

$$y_t = u_t + n_t. \tag{22}$$

u_t is the part that may be explained in terms of one (or several) input series x_t (concentration of a pollutant, etc.). n_t is an ARIMA process as described above. It represents the unexplained part of y_t (noise process).

It is assumed that the explained part, u_t, is given by a weighted sum of the present and past values of the input, x_t:

$$u_t = v_0 x_t + v_1 x_{t-1} + \cdots \tag{23}$$

or

$$u_t = v(B) x_t,$$

where

$$v(B) = v_0 + v_1 B^1 + v_2 B^2 + \cdots.$$

$v(B)$ is called the transfer function or the impulse response function; $v_0, v_1, \ldots$ are called transfer function weights. Eq. (23) is not a parsimonious representation of the transfer function model, but it is useful for model identification via the "prewhitened cross-correlation function" (see below).

A parsimonious "rational lag representation" of u_t can be obtained by writing $v(B)$ as the quotient of two polynomials in B, $v(B) = \omega(B)/\delta(B)$ [3]. Thus, $\omega(B)u_t = \delta(B)x_t$ and the transfer function model is given by

$$y_t = \left[\frac{\omega(B)}{\delta(B)}\right] x_t + \left[\frac{\phi(B)}{\theta(B)}\right] a_t. \tag{24}$$

Identification of a Transfer Function Model

Identification of Univariate Models for Input and Output Series

The univariate models of the *input* series are necessary in order to obtain a guess of the transfer function (via the prewhitened cross-correlation function).

The univariate model of the *output* series has two purposes:

1. It provides an initial guess of the noise process, n_t.
2. The residual variance of the univariate model may be used as a "yardstick" when comparing different transfer function models.

The Cross-correlation Function and Prewhitening

The relation between two time series, x_t and y_t, is determined by the cross-correlation function (CCF): $\rho_{xy}(k) = \text{cor}(x_t, y_{t+k}), k = 0, \pm 1, \pm 2, \ldots$. This function determines the correlation between the two series as a function of the time lag, k.

The main tool to identify a transfer function model is the empirical CCF $r_{xy}(k)$. However, a basic difficulty arises in the interpretation of the empirical CCF. As discussed by Box & Jenkins [3] the empirical CCF between two completely unrelated time series, which are themselves autocorrelated, can be very large due to chance alone. In addition, the cross-correlation estimates at different lags may be correlated. This is due to the autocorrelation within each individual series.

Box & Jenkins [3] proposed a way out of this difficulty called "prewhitening": the ARIMA model for the input series converts the correlated series x_t into an approximately independent series α_t. Applying the identical operation to the output series, y_t, produces a new series, β_t. It may be shown that the CCF between α_t and β_t (called the prewhitened CCF) is proportional to the transfer function. Thus, the empirical prewhitened CCF allows one to obtain a guess of the transfer function. An analogous iterative procedure as described above for ordinary ARIMA models leads to an adequate parsimonious transfer function model.

Example

The purpose of this study was the assessment of the relation between environmental time series and respiratory symptoms in preschool children. During about one year daily concentrations of SO_2, NO_2 and other environmental time series were collected in Basle. Simultaneously, the daily number of respiratory symptoms per child in a randomly selected group of preschool children was recorded. This series is termed "SYMPTOMS". Since January and February are the months with the strongest winter heating (SO_2), a separate model was identified for this "winter period". In a first step, ARIMA models for the individual series SO_2, NO_2, and SYMPTOMS had to be identified.

For the input series, SO_2, the Box–Jenkins method of model identification was straightforward. The mean-range plot [11] of SO_2 showed a tendency for the range to increase with the mean, whereas for $\ln(SO_2)$ the range was approximately independent of the mean, indicating that the logarithmic transformation stabilizes the variance. Figure 1 (lower curve) shows the plot of $\ln(SO_2)$. Figure 2 shows the corresponding ACF and PACF. The observed pattern (slow

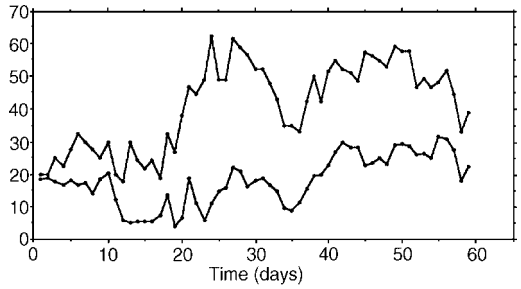

Figure 1 Upper curve: series SYMPTOMS × 100. Lower curve: rescaled series of $\ln(SO_2)$; Day 1 corresponds to 1 January 1986

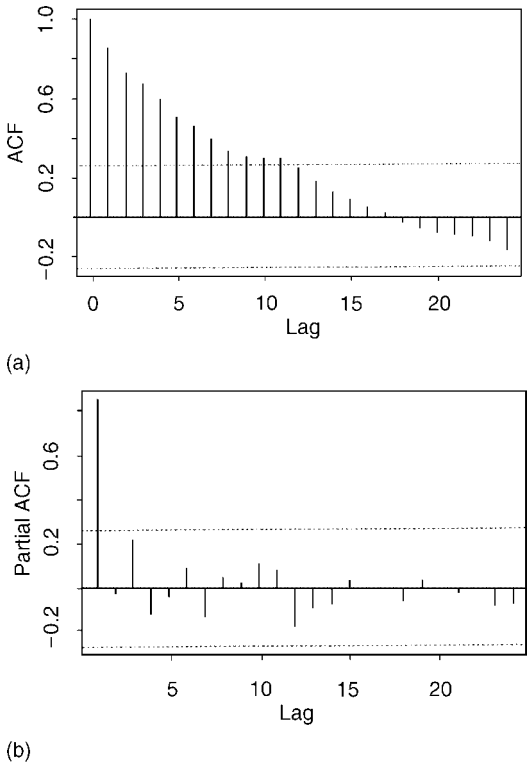

Figure 2 (a) Autocorrelation function (ACF) of series $\ln(SO_2)$; (b) partial autocorrelation function of series $\ln(SO_2)$

decay of ACF and marked peak at lag 1 in the PACF) suggests tentative fitting of an AR(1) model. The ACF and PACF of the residuals showed no marked peaks. The goodness-of-fit test [1] showed no sign of model inadequacy. A similar AR(1) model was found for the input series NO_2.

The output series SYMPTOMS is plotted in Figure 1 (upper curve). The ACF of this series showed a similar pattern. Tentative fitting of an AR(1) model gave an acceptable fit. However, the estimated autoregressive coefficient was close to one ($\phi = 0.96$), indicating possible nonstationarity. Thus, for the series SYMPTOMS one had to choose between two competing ARIMA models. Fitting a MA(1) model to the series of differences, that is, fitting an ARIMA (0,1,1) model, showed no sign of model inadequacy. Akaike's information criterion (AIC) was 388 for the AR(1) model and 379 for the ARIMA (0,1,1) model. In addition, the residual variance was somewhat smaller in the latter model. Both signs indicated superiority of the (nonstationary) ARIMA (0,1,1) model over the (stationary) AR(1) model. The corresponding estimated univariate model is shown in the first line of Table 1.

The CCF between the series $\ln(SO_2)$ and the series SYMPTOMS before prewhitening was not interpretable: "significant" coefficients are "smeared" over a large range of positive and negative time lags and there are typical nonsense coefficients suggesting that a high number of respiratory symptoms today are expected to be followed by high pollution during the next 10 days! After prewhitening, one marked positive peak is found at time lag zero, while all other coefficients are not significantly different from zero.

These results suggested the following transfer function model for y_t (SYMPTOMS) and $x_t(\ln(SO_2))$:

$$y_t = v_0 x_t + n_t, \quad \text{where } \nabla n_t = (1 - \theta B)a_t, \quad (25)$$

or, written compactly in standard notation,

$$\nabla y_t = v_0 \nabla x_t + (1 - \theta B)a_t. \quad (26)$$

The diagnostic checks of the residuals of the transfer function models showed no sign of model inadequacy. The same type of model was identified for SYMPTOMS and $\ln(NO_2)$ as the input series. In addition, a two-input model was fitted with $\ln(SO_2)$ and $\ln(NO_2)$ as the input series.

The summary of the models is presented in Table 1. One sees from the residual variances of the corresponding one-input models that the series SO_2 contributes more to the explanation of the series SYMPTOMS than the series NO_2. The two-input model shows no stronger reduction of the residual variance of SYMPTOMS than the one-input model with SO_2. Thus, the transfer function model revealed that input is related "instantaneously" with output; in particular, there is no "delayed" effect of the pollutant (no transfer function weight different from zero at nonzero time lags). A more detailed discussion of this example can be found in [10].

Literature

The following suggestions for further reading may be helpful. A thorough introduction to ARIMA models and transfer function models may be found in [1].

Table 1 Comparison of univariate and transfer function models fitted for output series y_t (SYMPTOMS) and input series x_{1t} [$\ln(SO_2)$] and x_{2t} [$\ln(NO_2)$]

Model type	Estimated model	Residual variance ($\times 10^4$)
Univariate:	$\nabla y_t = (1 - 0.24B)a_t$ ± 0.13	0.00387
One-input:		
x_{1t} : $\ln(SO_2)$	$\nabla y_t = 0.078\nabla x_{1t} + (1 - 0.26B)a_t$ $\pm 0.17 \qquad \pm 0.13$	0.00288
x_{2t} : $\ln(NO_2)$	$\nabla y_t = 0.068\nabla x_{2t} + (1 - 0.19B)a_t$ $\pm 0.022 \qquad + 0.13$	0.00339
Two-input:		
x_{1t} : $\ln(SO_2)$, x_{2t} : $\ln(NO_2)$	$\nabla y_t = 0.067\nabla x_{1t} + 0.025\nabla x_{2t} + (1 - 0.26B)a_t$ $\pm 0.20 \qquad \pm 0.24 \qquad \pm 0.13$	0.00288

An introduction to ARIMA models using biological and medical datasets is given by Diggle [7]. The classical reference to ARIMA models is Box & Jenkins [3]. Jenkins [11] provides instructive case studies in the fields of business, industry and economics. For studying specific medical time series problems the following articles are thought to be of interest. Examples of pitfalls in the analysis of relations between seasonal series in epidemiology are presented in [2]. Identification of seasonal ARIMA models representing infectious diseases is presented in some detail in [8]. A review, examples and references of studies concerned with ARIMA modeling in medicine are given in [9]. Applications and references of studies concerned with ARIMA modeling of single patient data may be found in [6].

ULRICH HELFENSTEIN

Artificial Intelligence

Artificial intelligence (AI) has been defined as the study of artificial systems which exhibit intelligent behavior. This definition neatly sidesteps the need to define precisely what "intelligence" itself is!

Research in artificial intelligence splits broadly into two camps. The first seeks to yield greater understanding of how naturally intelligent systems (human brains, for example) function. This area has developed according to the principle that we can only be sure we understand the natural system being investigated if we can build a model which behaves in the same way as that system. This perspective views artificial intelligence research as a subdomain of cognitive psychology. The second camp seeks to build systems (computer programs, robots, etc.) which behave in apparently intelligent ways, regardless of whether the way in which this behavior is achieved emulates naturally intelligent systems. An analogy for the motivation underlying the second camp is with flight: we could fly by building ornithopters, emulating the flapping wings of birds; but we need not – we could, instead, build a helicopter or a fixed wing aeroplane. Instead of a subdomain of psychology, then, the second camp might be viewed as a subdomain of engineering.

Examples of systems of the second kind that can already be encountered in regular use are expert systems, natural language understanding systems, software verification systems, symbolic algebra systems (*see* **Computer Algebra**), and game-playing machines. The last example here provides a nice illustration of how apparently intelligent behavior can be achieved without necessarily emulating humans: chess-playing programs have now been developed which can compete at grand master level. However, they achieve their successes through strategies quite different from those of human grand masters. In particular, they adopt massive searches of the state–space of the chess game, whereas humans conduct focused searches of a much smaller space.

Artificial intelligence research is fundamentally interdisciplinary. It overlaps with computer science, cognitive psychology, statistics, mathematics, engineering, biology, linguistics, and other disciplines, and has developed through several stages. Early work was characterized by inflated claims of imminent achievement. In the context of the time, these were quite understandable. Such early work picked, as its problem domains, areas such as logical problems, puzzles, and the kind of matching problems found in IQ tests. From a human perspective, problems such as these clearly require intelligence. The early success of computer programs on such problems was taken to imply that mere scaling up would enable domains such as natural language understanding and visual object recognition to be readily tackled. However, this turned out not to be the case. More than a question of scale was involved. In retrospect, it can be seen that the early problem domains were defined in terms of a small and precise dictionary of concepts. (The extreme example is arithmetic, with a dictionary of 14 symbols – the digits and four arithmetic operators. Computers can perform arithmetic effectively instantaneously, making a human feel rather stupid by comparison.) This is in contrast to the huge ill-defined dictionaries of concepts of more "realistic" domains. (However, there are real practical problems which involve well-defined concept dictionaries, and where modern AI systems, notably expert systems, have been effectively applied.) As a consequence, the early expectations of rapid practical applications were not fulfilled. Instead, a long hard haul has been required, in which developments in the theory and methods of AI have been matched and supported by dramatic developments in computer hardware. The progress that has been made in AI technology over the past two decades owes a great deal to the latter.

The bulk of the early work in AI was based on the *symbol manipulation* paradigm, mentioned in the preceding paragraph. In this, a basic dictionary of symbols is defined, along with relationships between them. These symbols are combined into more complex structures, with relationships between these structures; and this is repeated, each time moving up a level of complexity until extremely complex structures are created. Achieving structural complexity in this way, by means of series of levels, emulates the situation in other domains. Examples are using letters to build words, words to build sentences, sentences to build paragraphs, and paragraphs to build books, or the natural example of atoms, molecules, cells, and multicellular organisms. Special purpose languages (*see* **Computer Languages and Programs**) were developed for AI programming, notably LISP, which followed this paradigm.

The symbol manipulation approach toward constructing intelligent machines has continued, but

over the past decade a new paradigm has also attracted considerable interest. This is the *connectionist* paradigm. Digital computers are essentially *serial* machines. They read a command, act on it as appropriate, and then move on to the next one. Biological brains, however, are anything but serial. They are *parallel*. They consist of huge numbers of cells (neurons), each connected to vast numbers of other cells, not merely connected to a "preceding" and "following" cell. Thus, the fact that the processing speed of a single neuron is tiny compared to that of a single electronic switch becomes irrelevant. With 1000 electronic switches connected in a line, switching at a rate of one on/off per millisecond, serial computation means that a second will elapse before a signal can propagate from one end to the other and switch them all on. In contrast, if the switches are in parallel, they can all switch on simultaneously. This parallelism explains how the brain can carry out certain kinds of operations much faster than can a digital computer. Recognition of this fact was an early stimulus behind connectionist or parallel approaches to artificial intelligence.

In the sections that follow we examine some important subdomains of AI research.

Knowledge Representation

One key to effective problem solving is finding a good way to think about the problem. In general, the key to effective knowledge manipulation is finding a way to represent the knowledge which permits ready search and restructuring to match the objectives. Several representations are particularly important in AI.

Semantic networks have nodes representing objects, with labeled links connecting these nodes. The links represent relationships between the objects and the labels on the links specify attributes and types of relationships. This is a powerful general knowledge representation. For example, geometric diagrams or visual scenes can be represented: objects might be tables, plates, and cutlery, with relationships such as "on top of" and "beside" being represented by links. Perhaps at the other extreme, stories and verbal discourse can be represented: nodes might represent individuals and objects within the story, while changes in the way individuals feel about each other can be represented by changing values of labels on links of the net.

Production systems represent knowledge in terms of *antecedent–consequent rules*. The left-hand sides, or antecedents, of such rules consist of a set of conditions which must be satisfied by the items in a database. When they are satisfied the rule is said to *fire* – it carries out some operation (the consequent), such as altering the database. The system cycles through a set of such rules: each time a rule fires the database is changed, until some terminating state is reached. This is the basic representation underlying *expert systems* (see, for example, the summary of the MYCIN project described in [2]). In the case of medical diagnosis, for example, an initial set of signs and symptoms is fed into the database and the system cycles through its rule base, updating and modifying the database until a diagnosis is reached (*see* **Computer-aided Diagnosis**; **Decision Analysis in Diagnosis and Treatment Choice**).

Logic has the advantages that it is well-understood, rigorous, and (by definition) completely formalized. Different kinds of logic – propositional calculus, first-order predicate calculus, second-order predicate calculus – permit increasingly complex situations to be represented. Logical structures involve predicates, variables, constants, logical connectives, and quantifiers. In particular, *predicates* are building blocks which can take particular values. Thus *blue(book_6)* might be used to indicate that the colour of "book_6" is blue and *lift(John, book_6)* might indicate that John lifted book_6. Considerable effort has gone into developing automatic proof procedures in logic, so that powerful systems can be developed. The important AI language Prolog is based on a subset of predicate calculus.

Search

If knowledge representation is one key to problem solving, then effective search strategies are the other. Many problems reduce to finding the best, or at least a good, solution to a particular question in a space consisting of a large number of potential solutions. "Large" here can often mean astronomically vast, so that no exhaustive search will ever be conceivably feasible, even by the fastest of imaginable computers ever. (In chess for example, there are around 10^{120} possible games. Put this in the context of there being around 3×10^7 seconds in a year.) Examples of problems requiring efficient searches are graph

matching problems (such as matching a parsed input spoken sentence to a dictionary of sentences, or matching a segment of a semantic network to the right part of a larger net), identifying eligible production rules in a rule base, or finding a proof of a theorem (in logic, perhaps). This last example requires finding a path from the premises of the theorem to the conclusion of the theorem.

Sophisticated search methods, such as branch and bound or mathematical programming, guarantee finding the global optimum (*see* **Optimization and Nonlinear Equations**), and extend the range of problems from those that can be tackled by exhaustive search, but even they fail in the face of really large search spaces.

Of course, efficient search strategies will be familiar to statisticians, in the form of forward and backward stepwise methods in regression (*see* **Variable Selection**), discriminant analysis (*see* **Discriminant Analysis, Linear**), and other model building situations. Such methods achieve their aim of making the search feasible by restricting the search to a subspace of the complete space – and so risk missing the global optimum. Classical search methods, such as steepest descent and other mathematical *optimization* methods, may be stymied by the nature of the search space: it often involves categorical variables, so that the function for which an optimum is sought is not differentiable (or even continuous). Another general strategy which can facilitate efficient search is that of breaking the problem down into components. For some situations, we might be able to show that "if A is true" and "if B is true" then the original problem is solved. If we are lucky, A and B separately may be much easier to prove than the original problem.

Often progress can be made by utilizing problem specific general guidelines about what might assist in finding a good solution. Such guidelines are known as *heuristics* [7]. Examples of heuristics are summary values of the estimated strengths of positions in chess games and the use of samples to infer (with the risk of error) some general property of a population. We see from the latter that statisticians are masters at certain kinds of heuristic reasoning!

Constraints on solutions can be extremely effective in narrowing down the potential search space. In vision and speech recognition, for example, we can utilize information about possible global structures to restrict the possible components (parts of an image, words or phonemes in speech) which need to be tested.

Search strategies can often be described as *tree structures*. Suppose, for example, the problem involves matching the description (of a semantic net or a logical structure, say) of one structure (A) to that of another (B). The nodes of a tree might represent different descriptions of B, with higher level nodes being general descriptions and lower level nodes being more specific (filling in the values or restricting the ranges of variables, for example). We start at the highest (most general) level – which A necessarily matches – and work our way down, looking at more specific descriptions. Our aim is to find that completely specified description – that leaf node – of the B tree which matches A. We can undertake this search *depth first* or *breadth first*. The former involves running right down one branch until the end is reached and (assuming a perfect match is not obtained) backing up and following a neighbouring branch. The latter involves looking a little bit down all the branches, hoping that some will be eliminated early on.

Connectionist Approaches

The earliest parallel system explored in depth was the *perceptron*. In statistical terms this is a simple linear model used to predict class membership – as in linear discriminant analysis. It takes as inputs the values of several variables and forms their weighted sum, which is then compared with a threshold to determine predicted class membership. The variables thus contribute in a parallel way to the decision. The difference between discriminant analysis and the perceptron involves mainly the parameter estimation methods and the criterion being optimized. The parameter estimation methods of the perceptron involve sequential presentation of the data points, with iterative updating, rather than the algebraic solution of linear discriminant analysis; and the perceptron minimizes misclassification rate rather than the ratio of between-to-within-group distances to determine the best set of weights.

Unfortunately, as was shown by Minsky & Papert [5] in an influential book, the capabilities of the perceptron are severely limited. Minsky & Papert did describe how to overcome this problem – by using extra stages of linear combinations and

applying nonlinear transformations prior to the combination – but the parameter estimation problems seemed intractable at the time. It was not until several years later, with progress in hardware capabilities, and after several authors had presented estimation techniques, that interest again picked up. Since then, the interest that the idea of the **neural network** or *connectionist* approaches have attracted has been remarkable – especially from a statistical perspective, since from that perspective such models can be seen to be mere generalizations of **logistic regression** models (and, indeed, alternative, similarly flexible, statistical models, have also been developed).

One way of looking at neural networks is to regard them as searching the space of possible transformations of the vector of input variables, so as to find a set which permits a highly discriminatory linear combination. This lies in sharp contrast to earlier methods of **pattern recognition** (and, indeed, discriminant analysis), which required the system developer to identify good transformations of the input vectors. It means that little expert knowledge of the problem domain is required. This is obviously attractive to many potential users, since it implies a saving of time and effort.

Conclusions

Although the early promise of quick solutions did not materialize, steady development, coupled with the huge advances in computing hardware (*see* **Computer Architecture and Organization**), has led to significant progress in AI. The widespread use of computers (often concealed within devices and machines) means that the impact of this progress is likely to be substantial over the next few years.

An illustration of one area of development in which this is likely to be the case is language processing. It was realized, some time ago, that perfect translation between natural languages needed a deep representation of the ideas being expressed. It is insufficient, for example, merely to use a huge dictionary of words and expressions. However, effective language processing systems can be produced if the aims are less grandiose; in particular, if a restricted set of expressions are involved or if the system drives the interaction, as in computer interviewing to collect data for medical diagnosis (*see* **Computer-assisted Interviewing**). Sophisticated versions of such systems develop internal models of the patient as they proceed with the interview. Similar systems are being developed for computer-aided instruction, where more focused teaching is possible if the system refines a model of the student's abilities and likely responses as the instruction session proceeds.

One of the difficulties with which AI research has to cope is the perception that once a problem has been analyzed and a system built to tackle it, then "intelligence" is no longer required. In this sense, AI research is a doomed enterprise. In spite of that, the results of AI research are beginning to be felt in everyday life, as computers become more and more ubiquitous. In many areas, the problems tackled by AI are identical to those tackled by statisticians. Each of the two disciplines brings their own strengths to tackling the problems, and a rich synergistic interaction can result.

Recommended books in the area include [6] and [10]. Some medical applications are described in [9], and its potential role in psychiatry is outlined in [3]. Neural networks and their relationship to statistical methods for tackling the same problems are described in [1, 4], and [8].

Ascertainment

What is the ascertainment problem? In brief, this problem arises from the fact that for most genetic disorders of interest, families are not selected for study at random, but come to the attention of investigators (i.e. are "ascertained") via some process which may or may not be well understood. These deviations from random sampling can introduce **bias** into genetic analysis if they are not correctly understood and allowed for.

In particular, for a **segregation analysis** one needs to incorporate the ascertainment model into the analysis (for example, by including the probability model for ascertainment in the likelihood of the genetic model); otherwise, serious distortion may result. Ascertainment has been believed not to be an issue for **linkage analysis** as long as individuals were ascertained based only on a single trait (e.g. [4] and [13]), i.e. based on either the trait of interest or the marker, but not both. However, see also the section "Sequential Sampling" below.

A very simple example will illustrate the general principles. Imagine we are studying a genetic disease, thought to be inherited as a rare recessive (*see* **Genotype**), and we wish to determine whether the **segregation ratio** within nuclear families is $\approx 25\%$ (as predicted for a rare recessive disease). Imagine further that we are able to locate every family in our catchment area with at least one affected child, and that every such family is willing and able to participate in our study. The actual proportion of affected children that we will observe in this hypothetical example will be not 25%, but rather a higher proportion. The apparent distortion arises because those families which, by chance alone, failed to produce any affected children will not enter the sample. For example, say we had an ideal population of 10 000 two-child families who were at risk to have an affected child (i.e. both parents are carriers). With each birth, such a mating type (pair of parents) has a probability of 3/4 of having an *un*affected child. Thus, on average, $(0.75)^2$ of these two-child families, i.e. 5625 families, would have *no* affected children and would be unable, a priori, to enter our sample. Of the remaining 4375 families that would enter our sample, 3750 would have one affected and one unaffected child, and 625 would have both children affected. If we naively counted up the total number of affected children ($3750 + [625 \times 2] = 5000$) and divided by the total number of children in our sample ($4375 \times 2 = 8750$ children), without awareness of the 5625 families that we did not "see", we would estimate the segregation ratio as 57.1%, which is seriously distorted from the expected segregation ratio of 25%.

Moreover, there is no guarantee that we will even find every family with at least one affected child. In many situations families with more affected children are more likely to come to the attention of an investigator than those with fewer affected children, and this fact can introduce additional distortion into segregation analysis.

If all details of the ascertainment model are known and can be modeled probabilistically, then they can in most cases (except sequential sampling; see below) be incorporated into the likelihood required for any type of statistical–genetic analysis. The difficulty arises when the ascertainment model is not known, or is not known accurately.

In the next section we explore in some detail the "classical" ascertainment model of Weinberg [34] and Morton [23], based on the concept of "probands". In the third section we consider some alternative models, along with their criticisms of the proband concept. The fourth section considers some other methods of dealing with ascertainment, other than incorporating the ascertainment model into the likelihood. The fifth section examines two additional complications: sequential sampling and stoppage. The final section summarizes the conclusions of this article.

"Classical" Ascertainment Model

The classical model, also called the π-model, was formulated by Weinberg [34] and specifically applied to genetics by Morton [23]. This model requires the concept of a "proband", defined by Morton as "an affected person who at any time was detected independently of the other members of the family, and who would therefore be sufficient to assure selection of the family in the absence of other probands" [23]. Then the "ascertainment probability" π for an individual is defined as the probability that any affected individual becomes a proband, i.e. is ascertained. The ascertainment probability for a *family* is defined to be the probability that a family has at least one

"proband". A family that has at least one proband is then assumed to be ascertained. Note that the event "to be ascertained" is defined differently for an individual and a family. An individual is ascertained if s/he becomes a proband, whereas a family is ascertained if it contains at least one proband.

The fundamental quantity that we need to formulate is the probability distribution of r affected children within s-child families, *within our ascertained dataset*, i.e.

$$\Pr_s(r \text{ affected children}|\text{sibship is ascertained}). \quad (1)$$

We will refer to the quantity in (1) as the "fundamental ascertainment probability", i.e. the fundamental segregation probability in the presence of ascertainment.

These probabilities were originally developed for nuclear families, i.e. families consisting of two parents and their children, under the assumption that only children could be probands; however, the formulas can also be applied to extended pedigrees, in which any class of members may potentially be probands.

The ascertainment probability π can assume values in the interval $0 < \pi \leq 1$. We consider first two special cases, (a) and (b), then the general formulation, (c).

(a) If every affected individual is sure to become a proband, then $\pi = 1$. This is called "truncate selection" by Morton [23], or "complete ascertainment" by many other authors. It follows that every family with at least one affected member will be ascertained; thus families with at least one affected member appear in the dataset in the same relative proportions as they appear in the general population. Let p represent the segregation probability (e.g. 0.25 in the example above). When $\pi = 1$, the segregation analysis likelihood for a sibship of s children takes on the following relatively simple form, since the fundamental ascertainment probability in (1) can be rewritten:

$$\begin{aligned}
&\Pr_s(r \text{ affected children}|\text{sibship is ascertained}) \\
&\quad = \Pr(r \text{ affected children}|\geq 1 \text{ child is affected}) \\
&\quad = \frac{\Pr(r \text{ affected children})}{\Pr(\geq 1 \text{ child is affected})} \\
&\quad = \frac{\Pr(r \text{ affected children})}{1 - \Pr(0 \text{ children are affected})} \qquad (2)
\end{aligned}$$

for $r \geq 1$. Therefore

$$\begin{aligned}
&\Pr_s(r \text{ affected children}|\text{sibship ascertained}) \\
&\quad = \frac{\binom{s}{r} p^r (1-p)^{s-r}}{1 - (1-p)^s}. \qquad (3)
\end{aligned}$$

The numerator of (3) is a standard binomial probability, for an s-child family with r affected children, and the denominator gives the probability of at least one affected child, as in the denominator of (2). The complete formula in (3) represents a "truncate binomial" probability distribution.

Complete ascertainment can arise when one is able to ascertain every affected person in the population under study – for example, if all population members belong to a centralized health care system or a national health registry. Complete ascertainment may also occur if a disease is severe and rare, and there exists just one medical center in a certain geographic area that specializes in that disease. In such a situation it may be reasonable to assume that every family in that area with at least one affected child will come to that center and will be studied.

Table 1 (right column) summarizes the properties of truncate selection. Note that the segregation ratio is distorted because of the at-risk families who happen not to have an affected child, but that there is no *additional* distortion to that.

(b) A completely different kind of scenario occurs when the probability for any one affected child to become a proband is very small, and, concomitantly, the probability that any given family will have *more than one* proband is essentially zero. This can happen, for example, if the investigator ascertains only children attending second grade within one's geographic area of study: the probability that any given affected child will happen to be in second grade at this time is small; and essentially no families will have *two* affected children in second grade at the same time. Scenarios such as this correspond to letting π approach zero. This ascertainment model is known as "single selection" or "single ascertainment" and represents our second special case. It can be shown that under single ascertainment, the likelihood in (1) is

Table 1 Features of the classical π-model, applied to s-child sibships, ascertained through the children

$\pi \to 0$	π in between	$\pi = 1$
Name		
"Single selection" (single ascertainment)	"Multiple incomplete selection" (multiple ascertainment)	"Truncate selection" (complete ascertainment)
Number of probands		
One proband/sibship	>1 proband/sibship, but not every affected child is a proband	Every affected child is a proband
"Distortion" in the segregation ratio occurs because not every at-risk sibship actually has an affected child		
Additional distortion		
Sibships with r affected children occur r times more often than in their population proportions	In-between additional distortion	No additional distortion; sibships with $\geq$1 affected child occur in their population proportions
Probability distribution		
Binomial with $s-1$, $r-1$. (Exact analytic maximum likelihood estimate (MLE) of p)	No special probability distribution. (No exact analytic MLE of p)	Truncate binomial probability distribution (No exact analytic MLE of p)
Application		
"Every second-grader..." (see text)	"Real life..." (other ascertainment schemes)	"National Health Registry" (see text)
Equation in text:		
(4)	(7)	(3)

given by

$$\Pr_s(r \text{ affected children} | \text{sibship ascertained}) = \binom{s-1}{r-1} p^{r-1}(1-p)^{s-r}. \quad (4)$$

This represents a simple binomial probability in p, but applied to a sibship of $s-1$ children, of whom $r-1$ are affected.

Since (4) corresponds to simply removing the proband from the family, the correction for single ascertainment is sometimes referred to as "discarding the proband". However, the reader should note that "discarding the proband" works only for single ascertainment of nuclear families with a single mating type. More generally, one can think of "conditioning on the proband" to allow for single ascertainment [20].

It can also be shown that the probability that a sibship will be ascertained is then *proportional* to the number of affected sibs. For example, a family with two affected children is twice as likely to be ascertained as a family with one affected child. Thus, sibships with multiple affected children will be *over*-represented in the sample, compared with their proportions in the general population. See Table 1, left column.

This proportionality property is a powerful result and can be taken as the fundamental *defining* characteristic of single ascertainment [31]. It can be shown that in a number of circumstances single ascertainment is "special" in ways that do not hold for other ascertainment schemes [20]. For example, if extended pedigrees have been selected under single ascertainment, segregation analysis can be performed on them without bias simply by "conditioning on the proband", whereas under other ascertainment schemes, correcting for ascertainment becomes difficult or even impossible. This remarkable result holds even if the pedigrees were collected "sequentially"; see below. In addition, Haghighi & Hodge [18] have shown that in a simple model of differential parent-of-origin effects, single ascertainment is the only situation in which the parent-of-origin effect can be ignored. However, note that in the case of "stoppage" (see below), even single ascertainment does not allow for simple solutions.

(c) If the probability that an affected individual will become a proband is neither vanishingly small nor equal to unity, then some but not all affected individuals will be probands, and some but not all families will have multiple probands. This is known as "(incomplete) multiple selection" or "multiple ascertainment", and represents the most complicated situation under the classical model. The full likelihood is derived as follows:

$$\Pr(r \text{ affected children}|\text{sibship ascertained}) = \frac{\Pr(\text{sibship asc'd}|r \text{ aff. ch.})\Pr(r \text{ aff. ch.})}{\Pr(\text{sibship asc'd})}. \quad (5)$$

The first factor in the numerator of (5), Pr(sibship ascertained|r affected children), is derived by recognizing that under the assumptions of the proband model, the probability of an affected child becoming a proband is binomial. Thus, among r affected children, the probability of at least one proband equals one minus the binomial probability of *no* probands, i.e. $1-(1-\pi)^r$. The second factor in the numerator, Pr(r affected children), is the binomial probability for r affected children in an s-child family, $\binom{s}{r}p^r(1-p)^{s-r}$. The denominator of (5) represents the sum of possible numerator terms, summed over $r = 1$ to s, i.e.

$$\sum_{r=1}^{s}[1-(1-\pi)^r]\binom{s}{r}p^r(1-p)^{s-r} = 1-(1-p\pi)^s. \quad (6)$$

Putting together the numerator and denominator of (5) yields the general likelihood for the π-model of ascertainment for a nuclear family, with a single mating type:

$$\Pr_s(r \text{ affected children}|\text{sibship ascertained}) = \frac{\binom{s}{r}p^r(1-p)^{s-r}[1-(1-\pi)^r]}{1-(1-p\pi)^s}. \quad (7)$$

Equations (3) and (4) are special cases of (7). The reader can confirm that setting $\pi = 1$ in (7) will yield (3), whereas letting $\pi \to 0$ in (7) yields (4). The middle column of Table 1 summarizes the features of this more general case.

Equations (3), (4) and (7) give the probabilities for a single s-child family. However, typically a dataset consists of a number of sibships of different sizes, so the likelihoods of the individual families are multiplied across all families. Let R represent the total number of affected children in all the sibships, and let C represent the total number of unaffected children; also, let n_s denote the number of s-child families in the dataset. Then the total log-likelihood over the whole dataset can be written:

$$\log L(p) = R\log p + C\log(1-p) - \sum_s n_s \log[1-(1-p\pi)^s]. \quad (8)$$

The quantity in (8) is then maximized with respect to p to yield the desired maximum likelihood estimates (MLEs).

The π-model can be incorporated into the likelihood for any kind of genetic analysis. Equations (3), (4), and (7) show the likelihoods for the relatively simple situation of nuclear families and a single mating type. Beyond that, numerous extensions are possible. One we mention briefly is simultaneous estimation of p and π. So far we have assumed that the ascertainment probability π has a known value, but in other situations one might need to incorporate π as an unknown parameter (either as another parameter of interest to be estimated, or as a "nuisance parameter"). One approach is to record the actual number of probands a in each family. In (7), replace $[1-(1-\pi^r)]$, i.e. the binomial probability of "at least one proband", with the binomial probability of "exactly a probands": $\binom{r}{a}\pi^a(1-\pi)^{r-a}$. Thus, the appropriate probability is now:

$$\Pr_s(r \text{ affected children}, a \text{ probands}|\text{sibship asc'd}) = \frac{\binom{s}{r}p^r(1-p)^{s-r}\binom{r}{a}\pi^a(1-\pi)^{r-a}}{1-(1-p\pi)^s}. \quad (9)$$

The likelihood is now $L(p,\pi)$ and can be maximized to estimate p and π.

For further details, as well as other extensions, such as multiple parental mating types, multiple loci, complex pedigrees, etc. the interested reader is referred to, for example, [5, 6, 9, 12, 17, 23, 27], and [30].

All these situations involve ascertainment through the children, or what Morton [23] denoted "incomplete selection". If nuclear families are ascertained

through the parents ("complete selection"), then the situation is simpler, and no ascertainment correction is needed. There is no longer any bias, and the segregation ratio can simply be estimated from the standard binomial distribution. For example, if there were 25 families, of 3 children each, and of those 75 children, 35 were affected, then the MLE of segregation ratio p would be simply $\hat{p} = 35/75 = 0.47$. An approximate 95% confidence interval about this estimate, 0.47 ± 1.96 (SEP), where SEP = standard error of the proportion $\approx \sqrt{[(0.47)(0.53)/75]} \approx 0.058$, would not rule out a fully penetrant autosomal dominant disease, for which $p = 0.50$.

Alternative Ascertainment Models

It has been recognized from the beginning (e.g. [23]) that the concept of "proband" is not always applicable in real-life situations and that therefore the π-model does not necessarily hold. Greenberg [15] described realistic ascertainment scenarios in which whole families are ascertained by processes that do not permit one to define "probands" meaningfully. For example, consider the following "screening" scenario. A certain proportion of pregnant women come to a certain clinic to have the fetus screened for a genetic condition. But once a woman has had an affected fetus identified, she is much more likely to return for screening of her subsequent pregnancies. Which affected fetuses are the "probands"? Whether one labels only the first identified one as a proband, or all affected fetuses as probands, one violates the assumption of independence, which is critical to the definition of a proband. Greenberg [15] documented the magnitude of bias and the probability of wrong conclusions that can be introduced into a segregation analysis if the investigator mistakenly models ascertainment as a proband-based process when it is not.

Note also that it is not legitimate simply to designate the *first* member of the family to come to one's attention (that is, the index case) as the "proband". Index cases do not necessarily satisfy the independence requirement. One common and dangerous error is to designate the index case as the proband and then reason that since one has only one index case per family, therefore one has satisfied the conditions of single ascertainment. This is false reasoning [22]. One's ascertainment scheme represents single ascertainment only if the proportionality property described above is satisfied, i.e. only if families with two affected children are twice as likely to be ascertained as those with one affected child, families with three affected children are three times as likely to be ascertained as those with one affected child, etc.

Stene [31] and Ewens & Shute [10] discussed models of family-based ascertainment, for example such that Pr(family is ascertained|r affected members) $\propto r^k$, where k can be any real number. Thus, $k = 0$ corresponds to "complete ascertainment" and $k = 1$ to "single ascertainment" above. However, other values of k, such as $k = 2$ ("quadratic ascertainment"), do not correspond to any values of π in the π-model. This implies that the cases $\pi \to 0$ and $\pi = 1$ do *not* provide "limits" on ascertainment models; rather, there exist numerous possible ascertainment models that do not fit into the "π" framework at all. These family-based models do not designate any individuals as probands, and thus they circumvent the difficulties in the proband concept.

Let us examine the "quadratic ascertainment" model more closely, as an example. In this model a family with, for example, two affected children is four times more likely to be ascertained than one with one affected child (as opposed to being twice as likely, as under single ascertainment). To derive the fundamental ascertainment probability we return to (5). In the numerator, the probability Pr(sibship ascertained|r affected children), which formerly equaled $1 - (1 - \pi)^r$, now equals βr^2, where β is the constant of proportionality. Thus, the desired probability becomes

$$\Pr(r \text{ affected children}|\text{sibship ascertained}) = \frac{\binom{s}{r} p^r (1-p)^{s-r} \beta r^2}{\sum_{r=1}^{s} \binom{s}{r} p^r (1-p)^{s-r} \beta r^2}, \tag{10}$$

instead of (7). Simplifying the denominator and canceling β yields

$$\Pr(r \text{ affected children}|\text{sibship ascertained}) = \frac{\binom{s}{r} p^r (1-p)^{s-r} r^2}{sp[1 + (s-1)p]}. \tag{11}$$

Equation (11) provides an example of how ascertainment models other than the "classical" one can still

be formulated precisely and mathematically. It also illustrates the fact that this "quadratic" model cannot be viewed as a special case of (7), nor can any child in these families be identified as the "proband".

Ginsburg & Axenovich [14] suggested a "cooperative binomial ascertainment" model which allows the ascertainment probability for an individual to depend on the number of potential probands per pedigree.

Even though these alternative ascertainment models do not fit the mold of the classical π-model, they can be incorporated into the likelihood if they are known, as we have seen with quadratic ascertainment above.

Other Methods of Dealing with Ascertainment

As mentioned, if one knows the true ascertainment model, then in theory one can incorporate that probability model into genetic analyses (except in some cases of sequential sampling; see below). The major problem in genetic epidemiology arises when the ascertainment model is not known. Often human families come to the attention of investigators via pathways that are haphazard, ill-defined, or completely unknown. Thus, it is worthwhile to consider alternative ways to deal with ascertainment when the mode of ascertainment is not known or is known only vaguely.

One way to circumvent the whole problem of ascertainment is to condition the likelihood on all information that could possibly have influenced the ascertainment of the family. For example, if one is studying nuclear families and does not know how these families were ascertained, but does know that ascertainment occurred only via the *children*, then one can condition the likelihood on the children's phenotypic information [11]. One then has a *conditional* likelihood, which yields valid maximum likelihood estimators of genetic parameters. Ewens & Shute [11] call this an "ascertainment assumption free" (AAF) approach.

The disadvantage of the AAF approach is that the resultant estimates of genetic parameters may have very large variances. In the above example, once one has conditioned the likelihood on the phenotypes of the children, there is usually little genetic information "left" in the parents. In the extreme, if one could not even be sure through whom ascertainment may have occurred, one would have to condition on the phenotypes of *all* family members, and the variances of the estimators would be infinite.

Thus, in practice this method is not recommended for pure segregation analysis. Where this approach does become practical is when the investigator also has a **marker** locus (*see* **Linkage Analysis, Model-based**) that is reasonably tightly linked to the disease. The resultant analysis can be viewed as a form of combined segregation-and-linkage analysis. If one has a linked marker locus, then even though one has "conditioned out" much of the pure trait information, the information remaining from the *cosegregation* of the marker and the disease can help to determine the mode of inheritance of the disease. It has been shown that conditioning on all trait data in a combined segregation–linkage analysis in this way is equivalent to maximizing the maximum lod score (*see* **Linkage Analysis, Model-based**) over genetic models. For more details, see [3, 7, 16, 19], and [25].

Another way to deal with the ascertainment problem would be to develop good approximations. For example, Sawyer [26] has suggested that treating ascertainment as if it is single, even when it is not single, may provide a reasonable approximation over a broad range of ascertainment schemes. In another approach, Rabinowitz [24] proposes using a pseudo-likelihood, which yields asymptotically unbiased estimates (although variance is inflated) of genetic parameters under a class of ascertainment models broader than those allowed by the classical π-model. More work needs to be done on these and other approximation-based approaches.

Additional Complications

We conclude with two additional complications, whose effects are not yet fully understood: sequential sampling of pedigrees, and stoppage.

Sequential Sampling

We call it sequential sampling when, after a pedigree is ascertained, decisions about who within the pedigree will be included in the study are made in a "proband-dependent" or sequential manner. For example, one possible sequential-sampling rule is: "Include all available first-degree relatives of the

proband. For any of these relatives who are affected, include all *their* available first-degree relatives. Continue until no new person included in this way is affected, i.e. continue until no sampled pedigree member has any additional affected first-degree relatives". In an influential paper, Cannings & Thompson [2] considered pedigrees sampled following this kind of sequential scheme. They showed that under single ascertainment, conditioning the likelihood on observed pedigree structure, and dividing by the population probability of a proband, would yield the correct likelihood (as long as the sequential sampling rules follow certain reasonable commonsense restrictions). Subsequently, Vieland & Hodge [32] demonstrated that the result in [2] holds *only* for single ascertainment and, moreover, that under other modes of ascertainment, the correct likelihood for these kinds of sampling situations inherently cannot be formulated – even when the ascertainment model is known [32]; see also [8]. Rabinowitz's pseudo-likelihood [24] still yields asymptotically unbiased estimates in this situation, but the variance is inflated and must be approximated (see above).

Later, Vieland & Hodge [33] showed that *linkage analysis* is also affected by ascertainment issues when pedigrees are sampled sequentially, though it is not clear whether the effect is ever large enough to be of practical concern [28]. This finding violates the commonly accepted wisdom that linkage analysis is immune to ascertainment issues.

Stoppage

Standard segregation analysis assumes that the observed distribution of sibship sizes in the dataset (FSD = family-size distribution) is independent of the segregation ratio p. However, for certain serious diseases with early onset and diagnosis, e.g. autism, parents may *change* their original desired family size after having one or more affected children, thus violating that assumption. If parents reduce their family size, then the phenomenon is called "stoppage". Thus, stoppage also represents a type of biased ascertainment, in that families will display a smaller number of affected children than they "should", based on the value of the genetic parameter p. This situation has been investigated by Jones & Szatmari [21] and Brookfield et al. [1]. More recently, Slager et al. [29] showed that stoppage can be considered as a special case of sequential within-family sampling [2]. They demonstrated that if families are ascertained completely at "random",[1] the presence of stoppage does not bias estimates of p, but under any other ascertainment schemes, including those in (3), (4), and (7) above, stoppage introduces an additional bias, which can be quite large. Slager et al. [29] derived the full correct likelihood for a stoppage model in which after the birth of each affected child, there is a stoppage probability d that the parents will have no more children, even if they had originally intended a larger family. They showed that unless one already knows the FSD of the population from which the data are drawn, correcting for stoppage is difficult. Even when there is single ascertainment, the likelihood does not simplify, unlike in so many other situations involving single ascertainment.

Conclusions

In this article we have defined the ascertainment problem and tried to convey some idea of its nature and importance. We have shown how, starting with basic probability principles, one can incorporate ascertainment assumptions into genetic analysis, starting with simple ascertainment models and proceeding to more complex ones. However, some situations remain difficult or even intractable, and research still remains to be done in this area.

Aspin–Welch Test

The assumptions used in deriving the independent samples (or two-sample) t test are: (i) within each of two groups the observations are independently, identically, and normally distributed; (ii) observations are independently distributed across groups, and (iii) the populations from which the observations in the two groups are drawn have equal variances (*see* **Student's *t* Distribution**; **Behrens–Fisher Problem**). If (iii) is violated, then the actual type I error rate, τ, is near the nominal type I error rate, α, provided the group sizes are equal and sufficiently large (*see* **Hypothesis Testing**). Results in [8] suggest that the required sample size is between 8 and 15, depending on how large a discrepancy between τ and α one will tolerate. If (iii) is violated and the group sizes are unequal, then $\tau < \alpha$ if the larger sample comes from the population with the larger variance and $\tau > \alpha$ if the smaller sample comes from this population.

An alternative to the test statistic used in the independent samples t test is

$$t' = \frac{\overline{x}_1 - \overline{x}_2}{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^{1/2}}.$$

Welch [9] proposed using t' with the approximate **degrees of freedom** (APDF) critical value $t_{1-\alpha}(\nu)$, where

$$\nu = \frac{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)^2}{\frac{\sigma_1^4}{n_1^2(n_1-1)} + \frac{\sigma_2^4}{n_2^2(n_2-1)}}.$$

In practice ν is estimated by substituting sample variances for population variances.

Welch [10] proposed a method for approximating the critical value for t' by a power series in $1/f_i = 1/(n_i - 1)$ and presented the solution to order $(1/f_i)^2$:

$$z\left[1 + \frac{(1+z^2)V_{21}}{4} - \frac{(1+z^2)V_{22}}{2} + \frac{(3+5z^2+z^4)V_{32}}{3} - \frac{(15+32z^2+9z^4)V_{21}^2}{32}\right],$$

where

$$V_{ru} = \frac{\left(\sum_{i=1}^{2} \frac{(s_i^2/n_i)^r}{f_i^u}\right)}{\left(\sum_{i=1}^{2} s_i^2/n_i\right)^r}$$

and $z = z_{1-\alpha}$. Aspin [2] presented the solution to order $(1/f_i)^4$ and Aspin [3] presented an abbreviated table of fourth-order critical values.

Results in Lee & Gurland [7] indicate that with small sample sizes (≤ 9) τ is nearer to α when the fourth-order critical value is used than it is when the second-order or the APDF critical values are used. However, all three critical values controlled τ fairly well. Algina et al. [1] investigated larger group sizes and reported that the APDF critical value and the second-order critical value result in estimates of τ that typically agree to the third or fourth decimal place.

Using t' to test equality of means has two shortcomings. Yuen [14] demonstrated lower **power** for t' when the data are long tailed. Both Yuen's tests on trimmed means and Wilcox's [13] test on one-step M-estimates of location (*see* **Robustness**) can be used to address this problem. Wilcox [12] demonstrated that when the data in either or both groups are drawn from skewed populations, the numerator and denominator of t' are not independent. The **simulation** in Algina et al.indicates that as a result of the lack of independence large discrepancies can occur between τ and α. When the larger group is drawn from the population with the smaller variance, τ can be much larger than α. If one is willing to use trimmed means or one-step M-estimates when the data are skewed, then the second problem can be addressed by using Yuen's and Wilcox's tests, respectively.

Welch [11] generalized the APDF approach to the one-way layout with $G \geq 3$ groups and Johansen [6] further generalized the approach to multi-way layouts and to test multivariate hypotheses. James [4] generalized the series approach to the one-way layout and James [5] generalized the approach to test multivariate hypotheses for the one-way layout.

Association, Measures of

For **categorical data**, measures of **association** are used to quantify the degree of relationship between variables. In particular, a high degree of association between two variables indicates that knowledge about the level of one variable increases the ability to predict accurately the level of the other variable; a low level of association would indicate that the two variables tend to be independent of one another.

Interest in measures of association arose as early as the late 1800s, instigated by the study of meteorological phenomena, smallpox vaccinations, and anthropology. Discussion of such measures began in earnest in the early 1900s. Pearson [28, 30] believed that the measure of association should be based on the correlation for a presumed bivariate continuous distribution that underlies the contingency table; his *tetrachoric correlation* for **two-by-two contingency tables** and *contingency coefficient* for $I \times J$ tables are such measures. Relying on the inherent discreteness of the categorical variables involved, Yule [37, 38] developed measures of association that assumed nothing about underlying continuous distributions, such as Q (now called *Yule's Q*), named in honor of the Belgian statistician **Quetelet**. Goodman & Kruskal [17] wrote a series of four landmark papers on measures of association for cross classifications emphasizing *interpretable* measures, including a thorough history and bibliography on the subject (*see* **Goodman–Kruskal Measures of Association**). We will begin our discussion with 2×2 tables and then cover the more complicated case of $I \times J$ tables.

2 × 2 Tables

Several measures of association for 2×2 tables are based on the value of the Pearson **chi-square** (χ^2) statistic. Note that it is inappropriate to use the value of χ^2 itself as a measure of association for two dichotomous variables because it is a function of the sample size (see [10, Section 21]); Fleiss [11, p. 59] provides an example of this point.

In what follows, n_{ij} represents the frequency for the ith level of the row variable and the jth level of the column variable, $i, j, = 1, 2$, and a "+" in the subscript represents summation over the subscript replaced (e.g. $n_{1+} = n_{11} + n_{12}$). Then, one of the χ^2-based measures of association is the *phi coefficient*:

$$\phi = \left(\frac{\chi^2}{n_{++}}\right)^{1/2},$$

where

$$\chi^2 = \frac{n_{++}(n_{11}n_{22} - n_{12}n_{21})^2}{n_{1+}n_{2+}n_{+1}n_{+2}}.$$

Two additional measures based on ϕ are the *mean square contingency*, ϕ^2 [8, 28], and Pearson's [28] *coefficient of contingency*:

$$C = \left[\frac{\phi^2}{(1+\phi^2)}\right]^{1/2}.$$

Values of ϕ close to zero indicate very little association, while values of ϕ close to one imply close to perfect predictability. The maximum possible value of ϕ is 1 if the marginal distributions are equal, but less than 1 otherwise. Fleiss [11] provides, as a rule of thumb, that any value of ϕ less than 0.30 or 0.35 may be taken to indicate no more than trivial association. There are some disadvantages of the phi coefficient as a measure of association. For instance, the value of ϕ in **case–control studies** is not comparable to the value of ϕ in **cohort studies** [11, Chapter 6]. Also, if one or both of the characteristics being studied is obtained by dichotomizing a continuous random variable, then the value of ϕ is strongly dependent on where the continuous variable is divided [6] (*see* **Categorizing Continuous Variables**). This lack of invariance of the phi coefficient, among other reasons, led Goodman and Kruskal to recommend against the use of χ^2-like statistics as measures of association, except perhaps as they relate to **loss functions** and proportional prediction [17, pp. 10, 26, and 29–30].

A basic measure of association in 2×2 tables is the *cross-product ratio* or **odds ratio** (see [37] and [27]). The odds ratio is defined as

$$\alpha = \frac{p_{11}p_{22}}{p_{12}p_{21}},$$

where p_{ij} represents the probability associated with the ith row and jth column of the contingency table, $i, j = 1, 2$. The odds ratio is useful as a measure of association because (i) it is appropriate for a number of different sampling models, (ii) it serves as the

building block for loglinear model theory, and (iii) it has a number of important properties, as follows:

1. invariance (except perhaps for direction) under interchange of rows and/or columns,
2. invariance (except perhaps for direction) under row and/or column multiplication,
3. clear interpretation: p_{11}/p_{12} is the odds of an item being in the first column given that it is in the first row, and p_{21}/p_{22} is the corresponding odds for the second row; then α is the ratio of these two odds, just as the name implies, and
4. usefulness in $I \times J$ tables by considering several 2×2 tables.

The value of α falls in $[0, \infty)$ and is symmetric in the sense that two odds ratios, α_1 and α_2, with $\log \alpha_1 = -\log \alpha_2$, represent the same degree of association, but in opposite directions. If $\alpha = 1$, then the row variable and column variable are independent; if $\alpha \neq 1$, then they are associated or dependent. The observed odds ratio,

$$a = \frac{n_{11}n_{22}}{n_{12}n_{21}},$$

is the maximum likelihood estimate of α. To construct confidence intervals, note that $\ln a$ is normally distributed with mean $\ln \alpha$ for large samples, and

$$\text{se}(\ln a) = (n_{11}^{-1} + n_{12}^{-1} + n_{21}^{-1} + n_{22}^{-1})^{1/2}.$$

For reviews of alternative ways of obtaining confidence intervals for α, see [13] and [11]. Some authors prefer to add a continuity correction of 0.5 to each of the cell frequencies in the expressions above [11] (*see* **Yates's Continuity Correction**). Other suggested improved estimates are given in [4], [12], and [14].

A large number of the measures of association for 2×2 tables discussed in [17] are monotone functions of the odds ratio. For example, Yule's Q can be written

$$Q = \frac{(a-1)}{(a+1)}.$$

Edwards [9] showed that the odds ratio and functions of it are the only statistics that are invariant to both row/column interchange and to multiplication within rows/columns by a constant, and recommends that they be used to measure association in 2×2 tables. See [3] for related results concerning $I \times J$ tables.

Simple measures, such as the difference of proportions, $(p_{11}/p_{1+}) - (p_{21}/p_{2+})$, and **relative risk**, $(p_{11}/p_{1+})/(p_{21}/p_{2+})$, have a long history of use. Goodman & Kruskal [17] noted that the relative risk was used by Quetelet in 1849. The magnitude of the relative risk is similar to that of the odds ratio whenever the probability of response level one is close to zero for both groups. For further discussion of these measures, see [2] and [11].

While single numbers such as the odds ratio can summarize the association in 2×2 tables, it is difficult to summarize the association in $I \times J$ tables for $I > 2$ and/or $J > 2$ by a single number without some loss of information.

$I \times J$ Tables

The above measures can be generalized to $I \times J$ tables, with $I > 2$ and/or $J > 2$. For instance, the association in an $I \times J$ table can be described with a set of $(I-1)(J-1)$ odds ratios. Such a set is not unique; one basic set is

$$\alpha_{ij} = \frac{p_{ij}p_{IJ}}{p_{Ij}p_{iJ}},$$

$i = 1, 2, \ldots, I-1$ and $j = 1, 2, \ldots, J-1$. Or, the set of *local* odds ratios is

$$\alpha_{ij} = \frac{p_{ij}p_{i+1,j+1}}{p_{i,j+1}p_{i+1,j}},$$

$i = 1, 2, \ldots, I-1$ and $j = 1, 2, \ldots, J-1$. Such sets of odds ratios can be used to describe features of the association in the table.

The usefulness and interpretation of measures of association in $I \times J$ tables depend upon the nature of the variables involved (*see* **Measurement Scale**). Generally, a categorical variable is *ordinal* (*see* **Ordered Categorical Data**), in which case there is a natural order associated with its levels, or **nominal**, in which case there is no natural order associated with the levels. Examples of ordinal variables are *severity of disease* (mild, medium, severe) and *opinion* (strongly disagree, disagree, neutral, agree, strongly agree). For nominal variables, we might have *political party affiliation* or *diagnosis*.

Ordinal Variables

For ordinal variables, measures of association describe the degree to which the relationship is

monotone, i.e. whether Y tends to increase as X does. More specifically, a pair of subjects is *concordant* if the subject ranking higher on variable X also ranks higher on variable Y; they are *discordant* if the subject ranking higher on X ranks lower on Y (*see* **Ranks**; **Rank Correlation**). The pair is *tied* if the subjects have the same classification on X and/or Y. For a pair of observations, the probability of concordance is

$$\Pi_c = 2\sum_i \sum_j p_{ij} \left(\sum_{h>i} \sum_{k>j} p_{hk} \right),$$

and the probability of discordance is

$$\Pi_d = 2\sum_i \sum_j p_{ij} \left(\sum_{h>i} \sum_{k<j} p_{hk} \right).$$

The difference, $\Pi_c - \Pi_d$, is used in several measures of association for ordinal variables; the association is positive if $\Pi_c - \Pi_d > 0$ and negative if $\Pi_c - \Pi_d < 0$.

For those pairs that are untied on both variables, the probability of concordance is $\Pi_c/(\Pi_c + \Pi_d)$ and the probability of discordance is $\Pi_d/(\Pi_c + \Pi_d)$. Then, a measure proposed by Goodman & Kruskal [17] is *gamma*, where

$$\gamma = \frac{(\Pi_c - \Pi_d)}{(\Pi_c + \Pi_d)}.$$

This is simply the difference in the above two probabilities. In fact, γ tells us how much more probable it is to get like than unlike orders in the two classifications when two individuals are chosen at random from the population.

If C is the observed number of concordant pairs and D is the observed number of discordant pairs, then the sample version of gamma is $g = (C-D)/(C+D)$. Note that $-1 \le \gamma \le 1; \gamma = 1$ if $\Pi_d = 0$ and $\gamma = -1$ if $\Pi_c = 0$. That is, $|\gamma| = 1$ under monotonicity. Independence implies $\gamma = 0$; however, the converse is not true except in the 2×2 case. And, γ is invariant (except for sign) to the reversal in the category orderings of one variable. For 2×2 tables, γ is the same as Yule's Q, and hence is related to the odds ratio, α. In fact, γ is a strictly monotone transformation of α from the $[0, \infty)$ scale onto the $[-1, +1]$ scale.

There are a number of other ordinal measures of association that may be useful in a given application, such as Kendall's [19, 20] τ_b and Stuart's [35] τ_c. For a survey of such measures, see [24], [20], [17], and [1, Chapters 9 and 10].

Nominal Variables

For nominal variables, the concepts of positive/negative association and monotonicity are no longer appropriate for measuring the relationship. Instead, the most interpretable indices are those that describe the proportional reduction in variance from the marginal distribution to the conditional distributions of the response. One such measure is *Goodman & Kruskal's tau* [17] (also called the *concentration coefficient*):

$$\tau = \frac{\sum_i \sum_j p_{ij}^2/p_{i+} - \sum_j p_{+j}^2}{1 - \sum_j p_{+j}^2}.$$

Goodman & Kruskal provided the following interpretation: τ is the proportional reduction in the probability of an incorrect guess obtained by making predictions on Y using the classification on X. A large value of τ corresponds to a strong association because it indicates that we can guess Y much better when we know X than when we do not know X.

An alternative index for proportional reduction in variation, called the *uncertainty coefficient*, is proposed by Theil [36]:

$$U = -\frac{\sum_i \sum_j p_{ij} \ln(p_{ij}/p_{i+}p_{+j})}{\sum_j p_{+j} \ln(p_{+j})}.$$

Both τ and U take values on [0, 1], and $\tau = U = 0$ is equivalent to the independence of X and Y. The condition that, for each i, $p_{ij}/p_{i+} = 1$ for some j (no conditional variation) is equivalent to $\tau = U = 1$.

The larger τ or U is, the stronger is the association between the variables. However, note that these measures tend to decrease as the number of categories of the response variable increases.

$I \times J$ Tables, Other Cases

The measures of ordinal association mentioned above are appropriate if one variable is ordinal and the other is nominal with two categories. If one variable is ordinal and the other is nominal with more than two categories, then *ridits* may be used to measure the association; see [5, 11, Section 9.4, 25, 32, and 1, Sections 9.3 and 10.2].

To determine the association between, say, the ith level of A (row variable) and the B (column) polytomy, simply collapse all levels of A other than the ith to form a variable with two levels: the ith level and all other levels. Then the resulting $2 \times J$ table can be analyzed. This suggestion was made by Pearson [29]. This can be generalized to the study of the association between a particular set of A categories and a particular set of B categories; see [17, p. 38].

When two polytomies, X and Y, are nominal and *asymmetric* (i.e. X precedes Y chronologically, causally, or otherwise), Goodman & Kruskal [17] propose as a measure of association,

$$\lambda_y = \frac{\sum_i \max_j(p_{ij}) - \max_j(p_{+j})}{1 - \max_j(p_{+j})}.$$

This measure, first suggested by Guttman [18], gives the proportion of errors that can be eliminated by taking account of knowledge of the X classifications of individuals. Similarly, λ_x may be defined, as well as a measure for the symmetrical case, λ. See [17, pp. 10–15] for further discussion of these. Another measure, Somers' D [34], is an asymmetric modification of Kendall's τ_b (see [17]). Note that the measures τ and U also treat the variables asymmetrically.

Because λ_x, λ_y, and λ depend on marginal frequencies, one may wish to weight columns or rows (**standardization** of marginal distributions); see [38]. For example, it may be reasonable to base the association measure on a table for which all X-levels are equiprobable; an example of this is given in [17, pp. 15–16]. Other forms of standardization are given in [27].

More than Two Factors

When there are more than two polytomies, the *multiple association* between A and all other variables can be assessed by forming a two-way table with rows representing the A-polytomy and columns representing all possible combinations of levels of the remaining polytomies. The *partial association* in this case is the association between two of the variables with the effect of the others averaged out in some sense. Goodman & Kruskal [17, pp. 30–31] and Kendall & Stuart [21, pp. 571–575] discuss such measures.

When combining evidence from several four-fold tables, it is often of interest to know if the degree of association is consistent from one group to another, and if so, what the best estimate of the common value for the measure of association is. Mantel & Haenszel [26] proposed a measure that estimates a common odds ratio for several 2×2 tables (*see* **Mantel–Haenszel Methods**). Fleiss [11, Chapter 10] and Sokal & Rohlf [33] discuss these issues further.

Miscellaneous Topics

The traditional χ^2-like measures of association, unlike the λ and γ measures discussed by Goodman & Kruskal [17], assume the value zero if and only if there is independence in the cross classification. Note that independence is sufficient for $\lambda = 0$ and $\gamma = 0$, but not necessary. Goodman & Kruskal [17, p. 52] argue that λ and γ measure one dimension or aspect of association, and hence may be zero even when there is association along some other dimension.

A **misclassification error** can alter the degree or even direction of an association. A number of researchers have analyzed the effects of misclassification on measures of association; see [31], [22], [23], [15], and [7].

Measures of **agreement** are used in cases where the classes are the same for the two polytomies ($I \times I$ table) but differ in that assignment to level depends on which of two methods of assignment is used. For example, two psychiatrists may independently classify each of n_{++} subjects according to four diagnoses (4×4 table), and a measure of the agreement between their diagnoses is of interest. Measures of *association* differ from measures of *agreement* because there can be strong association without strong agreement in a table.

The asymptotic sampling theory for association measures is based on the sampling scheme used

to generate the contingency table and the sample estimator for the measure. The most common sampling schemes for contingency tables are based on the **multinomial distribution** or the product-multinomial distribution (i.e. independent multinomial distributions for each row or column). The estimator used for a measure of association is simply the sample analogue of the population measure; in almost every instance this is the maximum likelihood estimator. Goodman & Kruskal [17, pp. 76–146] develop formulas for the standard errors of some of their coefficients under various sampling models; also, see [16]. While most of the formulas are complex, major statistical software packages routinely provide standard errors for many of the measures of association (*see* **Software, Biostatistical**).

Association

Two variables may be said to be *mutually dependent* if the distribution of values of one variable depends on the value taken by the other. *Association* is a common form of dependence affecting changes in the mean values, or some other measures of level of response; association thus implies that the general level of one variable changes according to the value of the other variable. In informal usage it often carries the further implication that the relationship is monotone; for instance, in statements such as "Exposure to factor *A* is associated with an increased risk of disease *B*".

A well-known and very important precept is that association does not imply **causation**: two variables may be associated merely because each is in turn associated with one or more other variables, although the two in question are not causally related to each other (*see* **Correlation**). The term "association" is closely related to, and almost synonymous with, "correlation". The distinction is that correlation is a measure of closeness to a linear relationship, between either the original variables or some transformation of them, whereas a close association between quantitative variables may be markedly nonlinear. Association need not be monotone: one variable may tend to rise and then fall as the other increases (*see* **Correlation**, Figure 2).

The term "association" is also used to describe relationships between categorical variables (*see* **Association, Measures of**). With ordinal variables, the interest may lie in the degree of concordance; that is, whether movements along the scale of categories of one variable tend to be accompanied by similar movements in the other variable. When one variable is nominal the order of its categories is undefined, and association here would imply merely that the distribution of the other variable varied with the category of the nominal variable. An example is the association between blood groups (a nominal variable) and a particular disease, where the prevalence or incidence of the disease may vary from one blood group to another.

Association between two or more random variables implies departure from *independence* (*see* **Statistical Dependence and Independence**). For a description of concepts and measures of dependence between random variables, see [2] and [3]. Most measures of dependence, defined over the range (0, 1), are such that nonzero values imply positive or negative association. The term "association" has been used [1] for a specific form of dependence between a set of random variables, requiring that any nondecreasing functions of any pair of variables in the set should be nonnegatively correlated.

PETER ARMITAGE

Assortative Mating

Assortative mating for a characteristic is a process whereby biological parents are more similar (or occasionally more dissimilar) for a phenotypic trait than they would be if mating occurred at random in the population. The two characteristics usually given as examples in human populations are height and intelligence. There are many others; see, for example, [5, 8] and [11]. The phenotypic similarity can induce changes in genotypic relationships. Evaluating these changes is challenging, and usually involves complex mathematical modeling of genetic inheritance and environmental effects (*see* **Gene-environment Interaction**). Furthermore, genetic and environmental factors that affect those characteristics for which there is assortative mating may also affect other characteristics, producing an observed correlation between parents for these other characteristics.

Much of the early literature in **population genetics** theory considered the effects of assortative mating on population characteristics, and can be traced back to Jennings [7] for a phenotypic trait being determined by a single locus, to Fisher's notoriously difficult paper [4] for a continuous characteristic arising from a multifactorial model, and to Wright's [15] formulation of path analysis (which underlies the approach taken today by some behavioral geneticists). References to some of the more extensive literature of the 1960s and 1970s can be found in population genetics texts, such as Crow & Kimura [1] and Ewens [2]. Recent published scientific literature appears to be more concerned with assortative mating in animal populations. For human behavioral traits, assortative mating is still being incorporated in models based essentially on a path analysis approach.

The problem in accommodating assortative mating is that the choice of a mathematical model is not very clear-cut. Certainly, from the geneticist's viewpoint the choice is not as noncontroversial as it would be if, say, the nonrandom process had been the result of **inbreeding**. The essential difficulty in modeling assortative mating is that different social and behavioral patterns in the population can produce different outcomes. There is no agreement concerning these patterns. Furthermore, many assumptions must be made, either implicitly or explicitly. Then, if one takes the traditional, population genetic, approach of following the process to equilibrium, the consequences may lack biological (and perhaps social) relevance or realism. Some of the difficulties will be overviewed briefly in the context of assortative mating for a multifactorial trait, based on Fisher's classical multifactorial model.

First, a general mathematical representation is given that distinguishes between two-sided assortative mating, where each sex is involved in the choice of mates, and one-sided assortative mating, where only one sex selects its mates. Let m and m_{p} represent analogous phenotypic trait values in the male and male-parent populations, and, similarly, f and $f_{\uparrow \mathrm{p}}$ for the female and female-parent values. Then for two-sided assortative mating we can write

$$p(m_{\mathrm{p}}, f_{\uparrow \mathrm{p}}) = q(m)q(f)a(m, f), \tag{1}$$

where p and q represent appropriate probability functions, and a the assortation function. Under the hypothesis of random mating, $a = 1$. Otherwise, a could be quite complex; for instance, it might represent a sum over a proportion of the population mating assortatively with respect to this characteristic and the remainder at random. For one-sided assortative mating, we can write

$$p(m_{\mathrm{p}}, f_{\uparrow \mathrm{p}}) = q(m)Q(f|m), \tag{2}$$

where Q is a conditional probability or density. Such a model is usually not considered particularly realistic for human populations.

Now consider Fisher's multifactor model for the mode of inheritance of a continuous trait [9]. In this model, it is supposed that the measurements x and y of males and females, respectively, are the result of a large number of independently segregating factors, and are thus normally distributed. Taking the means as zero and variances as σ^2, the probability that a measurement lies in the range $(x, x + \mathrm{d}x)$ is given by $(2\pi\sigma^2)^{-1/2} \exp(-x^2/2\sigma^2)\,\mathrm{d}x$ (giving q), and analogously for y. Furthermore, it is supposed that the joint probability distribution of male and female parental values is bivariate normal with correlation ρ, so the joint probability for parents of having values in the ranges $(x, x + \mathrm{d}x)$, $(y, y + \mathrm{d}y)$ is

$$[2\pi\sigma^2(1-\rho^2)^{1/2}]^{-1} \times \exp - \left[\frac{(x^2 - 2\rho xy + y^2)}{2\sigma^2(1-\rho^2)}\right] \mathrm{d}x\,\mathrm{d}y$$

(giving p). Substituting into (1) above and solving we obtain a to be

$$(1-\rho^2)^{-1/2}\exp-\left[\frac{(\rho^2x^2-2\rho xy+\rho^2y^2)}{2\sigma^2(1-\rho^2)}\right].$$

Although this expression was regarded as the "relative probability" of a mating between two individuals with values x and y [4], in theory it can be unbounded. An interpretation can be given as one-sided assortative mating, based on the formulation in (2). To accommodate two-sided assortative mating and maintain the normality assumptions, selection against individuals having extreme values needs to be introduced, and details have been explored by Wilson [12]. For a single characteristic, the consequences of introducing a selection function that maintains the normality assumptions may not be particularly realistic. For example, the model may require too large a proportion of the population to remain biologically celibate. These modeling problems may be overcome by inbedding the assortation process into a more complex (and possibly more realistic) framework [14], so that assortative mating for a single characteristic is regarded as a consequence of mixing, simultaneously, over more than just one variable.

The classical multifactorial model also assumes that the observed measurement of an individual in the population can be split into two independent parts, the genetic value (given by the sum of contributions from many loci which are assumed initially to be independent) and the environmental value. Furthermore, it is assumed that there is no **interaction** between genotype and environment, and no epistatic effects (*see* **Genotype**) between loci. Moreover, Fisher [4] shows that the genetic value of an individual in the general population also can be split into two independent parts, the representative value and the dominance deviation value, where the representative value is the sum taken over all loci of the value of the genotype at each locus fitted by least squares, and the dominance deviation value is the sum over all loci of the deviation of the genotypic value at each locus from this value. If the population is such that initially each locus is in **Hardy–Weinberg equilibrium** and there is linkage equilibrium between loci, then it can be shown that the effect of assortative mating is to lose the Hardy–Weinberg equilibrium, and to produce **linkage disequilibrium** [12, 13]. Of most interest historically is the correlation, ρ, between relatives, and some important examples are

$$\frac{\rho(\text{parent–child}) = \frac{1}{4}c_1c_2\sigma^{-2}(\varepsilon_1^2+2\rho\varepsilon_1\varepsilon_2+\varepsilon_2^2)}{\left[\frac{1}{2}\sigma^{-2}(\varepsilon_1^2+\varepsilon_2^2)^{1/2}\right]=\rho_c},$$

$$\frac{\rho(\text{grandparent–grandchild})=\frac{1}{2}\rho_c(1+\rho c_1c_2\varepsilon_1\varepsilon_2\sigma^{-2})}{\left[\frac{1}{2}\sigma^{-2}(\varepsilon_1^2+\varepsilon_2^2)^{1/2}\right]},$$

$$\rho(\text{sibs}) = \tfrac{1}{4}c_1[1+c_2-2c_1c_2^2 + c_1c_2^2\sigma^{-2}(\varepsilon_1^2+\varepsilon_2^2+2\rho\varepsilon_1\varepsilon_2)], \quad (3)$$

where ε_1^2 and ε_2^2 are the variances in the populations of male parents and female parents, and

$$c_1 = \frac{\text{var(genetic values)}}{\text{var(observed values)}}, \quad (4)$$

and

$$c_2 = \frac{\text{var(representative values)}}{\text{var(genetic values)}}. \quad (5)$$

If $\varepsilon_1^2=\varepsilon_2^2=\sigma^2$, then the correlations simplify to those found by Fisher [4].

These formulas assume no epistasis, no **gene–environment interaction** or covariation, as well as no environmental covariation between relatives. Although these effects can be incorporated into statistical analyses (see [6]), there has been no systematic study of the effects of incorporating all realistic factors and processes. Moreover, whether a set of assumptions is reasonable or not depends on the particular trait being studied, and often will be controversial, especially as many of the assumptions will not be verifiable in practice. The effect of assortative mating on analyses has been investigated in only a few situations. It has been shown that assortative mating can affect the estimation and interpretability of **heritability** [10], and lowers the power of **linkage** studies [3].

SUSAN R. WILSON

Asymptotic Relative Efficiency (ARE)

One of the most important problems of statistical practice is point **estimation** of an unknown parameter, say θ. In most cases, there are many apparently reasonable estimators of θ. For example, if one wants to estimate the **mean** of a normally distributed characteristic, it seems reasonable to estimate it by the mean of the characteristic from a sample. Since for normal random variables, the mean and **median** are the same, it also seems reasonable to use the median of the sample values as an estimate. Indeed, each estimate is a consistent estimate in this case (*see* **Consistent Estimator**); i.e. each estimate $\hat{\theta}$ satisfies $\Pr(|\hat{\theta} - \theta| > \varepsilon) \to 0$ as $n \to \infty$, for any given $\varepsilon > 0$. Asymptotic efficiency is a common method to discriminate between two reasonable estimates when there is nothing to discriminate between them from the viewpoint of consistency.

Typically, two consistent estimates, say $\hat{\theta}_1$ and $\hat{\theta}_2$, will also have limiting normal distributions, i.e. $\sqrt{n}(\hat{\theta}_i - \theta) \to \mathrm{N}(0, \sigma_i^2(\theta))$, $i = 1, 2$. In such a case, it is common to approximate the variance of $\hat{\theta}_i$ by $\sigma_i^2(\theta)/n$. The exact variance of $\hat{\theta}_i$ may be hard to calculate for a fixed sample size n, and thus the approximation really does become important. Since variance is a natural measure of accuracy of an estimate, it seems natural to define the efficiency of $\hat{\theta}_1$ with respect to $\hat{\theta}_2$ as the ratio $\sigma_2^2(\theta)/\sigma_1^2(\theta)$. In principle, the quantities $\sigma_1^2(\theta)$ and $\sigma_2^2(\theta)$ may depend on the unknown parameter θ. However, fortunately, in many important problems of statistics, they are just fixed positive constants not depending on θ, and therefore the asymptotic relative efficiency (ARE) σ_2^2/σ_1^2 has the very appealing interpretation of being one number summarizing the performance of $\hat{\theta}_1$ with respect to $\hat{\theta}_2$. The values of ARE are between 0 and ∞, and ARE > 1 corresponds to $\hat{\theta}_1$ being more efficient than $\hat{\theta}_2$.

Example 1 Suppose $X_1, X_2, \ldots, X_n$ are independent observations from a $\mathrm{N}(\theta, 1)$ population. Then, $\sqrt{n}(\overline{X} - \theta) \to \mathrm{N}(0, 1)$ in distribution, and $\sqrt{n}(M - \theta) \to \mathrm{N}(0, \pi/2)$ in distribution, where M is the median of the sample data $X_1, X_2, \ldots, X_n$. Thus, according to our definition, the asymptotic relative efficiency of the sample median with respect to the sample mean for a normally distributed population is $2/\pi \approx 0.63$.

Interestingly, the situation reverses and the sample median becomes a more efficient estimate if the observations $X_1, X_2, \ldots, X_n$ are instead obtained from a population with a double exponential density, $1/2 \exp(-|x - \theta|)$. In this case, $\sqrt{n}(\overline{X} - \theta) \to \mathrm{N}(0, 2)$ and $\sqrt{n}(M - \theta) \to \mathrm{N}(0, 1)$, and the asymptotic relative efficiency of the sample median with respect to the sample mean is 2.

Example 2 Sir Ronald Fisher, one of the founding fathers of much of statistics as we know it today, once had a communication with A. Eddington, a noted physicist, about how to estimate the standard deviation of a normal distribution. Thus, if $X_1, X_2, \ldots, X_n$ are independent samples from the $\mathrm{N}(\theta, \sigma^2)$ distribution where both parameters are unknown, the specific question was a comparison of the two estimates

$$\hat{\sigma}_1 = \frac{\Gamma\left(\frac{n-1}{2}\right)}{\sqrt{2}\Gamma\left(\frac{n}{2}\right)} \left[\sum_{i=1}^{n} (x_i - \overline{x})^2\right]^{1/2}$$

$$\text{and} \quad \hat{\sigma}_2 = \frac{\sqrt{\pi}}{[2(n-1)n]^{1/2}} \sum_{i=1}^{n} |x_i - \overline{x}|,$$

based on the **mean deviation**, where $\Gamma(\cdot)$ denotes the Euler gamma function. Each estimate is unbiased for estimating σ. It is known that $\hat{\sigma}_1$ is the uniformly **minimum variance unbiased (MVU) estimator** of σ for each fixed sample size. So in fixed samples, $\hat{\sigma}_1$ is more efficient than $\hat{\sigma}_2$. An interesting question would be if, even asymptotically, it has an ARE > 1. Using standard methods of large sample theory, it is seen that $\sqrt{n}(\hat{\sigma}_1 - \sigma) \to \mathrm{N}(0, \sigma^2/2)$ and $\sqrt{n}(\hat{\sigma}_2 - \sigma) \to \mathrm{N}(0, [(\pi - 2)/2]\sigma^2)$ in distribution as $n \to \infty$. Thus, applying the definition of the ARE, the ARE of $\hat{\sigma}_1$ with respect to $\hat{\sigma}_2$ is $\pi - 2$, which is indeed larger than 1.

Efficient Estimates

A question of natural interest is the following: is there such a thing as a "most efficient" estimate (*see* **Efficiency and Efficient Estimators**), and how do we formulate such a concept? It turns out that in parametric estimation problems, it is

indeed possible to easily formulate such a concept. Thus, suppose $X_1, X_2, \ldots, X_n$ are independent observations from a population with density $f(x|\theta)$. The quantity $I(\theta) = -E_\theta[\,\mathrm{d}^2 f(x|\theta)/\,\mathrm{d}\theta^2]$, whenever the definition makes sense, is called the Fisher **information** function. Let $\hat{\theta}$ be any estimate of θ that is consistent and asymptotically normal, i.e. $\sqrt{n}(\hat{\theta} - \theta) \to \mathrm{N}(0, \sigma^2(\theta))$. Then, under some (frequently satisfied) regularity conditions on the density $f(x|\theta)$, it is true that $\sigma^2(\theta) \geq 1/I(\theta)$ (exceptions may occur at a "few" values of θ; this phenomenon is known as superefficiency, but we will not worry about this). Thus, any estimate $\hat{\theta}$ of θ which actually attains the bound $\sigma^2(\theta) \equiv 1/I(\theta)$ can be legitimately called an *efficient* estimate of θ.

In a given problem there are usually many efficient estimates of the unknown parameter θ. Standard methods of estimation typically result in efficient estimates, although in finite samples they may have different variances, biases, etc. This reinforces the fundamental issue that efficiency and ARE are intrinsically asymptotic indices in nature, but one hopes that if one estimate is more efficient than another according to the definition of ARE, in moderate samples it outperforms the other estimate as well. Among the standard methods of point estimation, **maximum likelihood** estimates and Bayes estimates typically are all efficient estimates, although exceptions to these general phenomena can and do occur. For instance, if the number of nuisance parameters grows with an increasing sample size, then maximum likelihood estimates of the most important parameter will usually not be efficient. Also, **method of moments** estimates may not be efficient even in very simple problems.

Other Measures of Efficiency

Besides point estimation, another very important problem of statistics is that of **hypothesis testing**. As in point estimation, there are usually many reasonable tests of a specified hypothesis and it is useful to have a concept of efficiency of one test with respect to another. Various efficiency measures have been proposed here too, primarily among them **Pitman efficiency** and Bahadur efficiency.

The Pitman efficiency is defined in the following way: fix a type I error probability or level α, fix an alternative θ, and specify a desired power $1 - \beta$ at this alternative. Let $n_i(\alpha, \beta, \theta)$ denote the minimum sample size required by the ith test, $i = 1, 2$, to achieve this goal. The Pitman efficiency of the first test with respect to the second is taken as the limit of the ratio $n_2(\alpha, \beta, \theta)/n_1(\alpha, \beta, \theta)$ as the alternative $\theta \to \theta_0$ at a suitable rate, where θ_0 is exactly (the) boundary between the null and the alternative hypothesis.

Of course, there are a number of subtle issues involved here. Dependence of this limit on α and β would make universal interpretation of the efficiency value difficult. Also, the limit itself should exist for the definition to make any sense. Finally, the boundary value θ_0 may not be unique. In almost all problems that commonly occur, fortunately these subtleties do not cause any problems and one has a quite good efficiency measure.

Bahadur efficiency proceeds along the same lines, except that one lets α tend to zero, keeping the alternative θ fixed. Thus the Bahadur efficiency can depend on both θ and the desired particular power $1 - \beta$. Fortunately, again, usually dependence on β does not occur, although dependence on θ does. Thus, in contrast to the Pitman measure of efficiency, which is usually one single number, the Bahadur efficiency measure is a curve or a function – a function of the specified alternative θ. This is actually good in some sense, as one has an efficiency measure that discriminates between two competing tests based on which alternative values are really important in the given context. Bahadur's original approach [3] was to compare the rates at which the P values corresponding to the two tests converge to zero at the specified θ. However, the two descriptions are equivalent.

Example 3 Suppose $X_1, X_2, \ldots, X_n$ are independent observations from the double exponential density (1/2) $\exp(-|x - \theta|)$ and we wish to test H_0: $\theta \leq 0$ vs. H_1: $\theta > 0$. The following two tests appear to be reasonable (*see* **Sign Tests**):

1. Sign test.
   Count N = number of sample values > 0.
   Reject H_0 if N is large.
2. Median test.
   Find the median M of the sample values.
   Reject H_0 if M is large (large positive).

The exact critical values for each test (i.e. what is to be regarded as a "large" value) can be found

by large-sample considerations (or even exactly, although it may involve numerical computing and randomization).

Now, it turns out that the Pitman efficiency of the sign test with respect to the median test is 1. So the Pitman measure does not discriminate between the two tests. Interestingly enough, the Bahadur efficiency does, and indeed, Sievers [27] shows that the Bahadur efficiency of the sign test with respect to the median test equals

$$e_{\mathrm{B}}(\theta) = \log \frac{1}{\{4g(\theta)[1-g(\theta)]\}^{1/2}} \{\log 2 + g(\theta)\log g(\theta) + [1-g(\theta)]\log[1-g(\theta)]\}^{-1},$$

where $g(\theta) = (1/2)\mathrm{e}^{-\theta}$.

$e_B(\theta)$ is seen to be > 1 for any $\theta > 0$, establishing for double exponential data that the sign test could be regarded as a better choice than the median test. Table 1 gives the Bahadur efficiency at selected values of θ.

Relevance for Finite Samples

An important practical question is how closely the ARE approximates the ratio of the variances of two estimators in finite samples. It is difficult to give a very general answer to this, but in many examples the fixed sample relative efficiency seems to converge monotonically to the asymptotic relative efficiency, and the approximation becomes quite close for sample sizes $\geq$ 25. For example, for estimating the mean of a normal distribution, the ARE of the median with respect to the mean differs from the asymptotic value $2/\pi$ by at most 6.8% for sample sizes $\geq$ 20. Trimmed means are also common alternatives to usual sample averages as estimates of population means (*see* **Trimming and Winsorization**). A certain amount of trimming of the smallest and the largest observations causes the effect of potential outliers to be decreased and has other nice advantages. Usually 5 or 10% trimming from each side is recommended; see [6]. For the 10% trimmed mean estimate for estimating a normal mean, the fixed sample relative efficiency with respect to the regular mean differs by at most 2.75% from the asymptotic value 0.975 for sample sizes $\geq$ 20. Thus, there is some empirical evidence that the ARE reasonably approximates the fixed-sample efficiency in moderate sample sizes. Expansions of the fixed sample quantity in which the asymptotic quantity is the leading term have also been attempted, frequently on a case-by-case basis. (See [2, 12, 18], and [22] for such developments.)

Table 1

θ	0	0.1	0.25	0.5	1	2	5
$e_{\mathrm{B}}(\theta)$	1	1.003	1.017	1.057	1.182	1.545	3.214

Sensitivity with Respect to Underlying Distribution

It is entirely possible that one estimate or test is more efficient than another if samples are obtained from one distribution, but loses these advantages, maybe drastically, for a fairly similar distribution. The comparison of the sample median and the sample mean is a good illustration. The mean has an efficiency of 1.57 with respect to the median if samples are known to come from a normal distribution, but this efficiency drops to 0.5 if data instead come from double exponential density, described before. Yet it is not easy to distinguish between the two distributions from moderate samples by using common methods, graphical or otherwise. Bickel & Lehmann [6] provide some concrete results in this direction. For example, they show that if samples are obtained from any density that is symmetric and unimodal about the mean, then the 5% trimmed mean has an ARE of at least 0.83 with respect to the mean for estimating the population mean, and, of course, for many such densities the efficiency is substantially larger than 1. This may be used as an argument for using the 5% trimmed mean if concerns about the exact density from which one is sampling exist. More information on this can be found in [23] and [28].

Concepts of Higher-order Efficiency

As stated before, in parametric estimation problems, it is customary to have many estimates which are fully efficient. It then becomes necessary, at least from a theoretical standpoint, to have a criterion to distinguish among them. The concept of second-order efficiency (now usually referred to as third-order efficiency) was introduced to address this issue.

(See [25, 26, 1, 14], and [16] for later developments.) The idea is to derive an expansion for n times the variance of a statistic, in which the leading term is the Fisher information function and subsequent terms decrease in reciprocals of powers of $1/n$. The second term is used as a comparison among different estimators, or simply for selecting an estimator which is first- as well as second-order efficient. In a peculiar result, Pfanzagl [24] showed that often first-order efficiency automatically implies second-order efficiency as well, making it necessary to consider higher-order efficiencies as a basis for comparison and selection. Bickel et al. [9] and Ghosh [15] expand on these results and ideas.

Complex Models

Parametric models using a given functional form for the density are often convenient choices, and perhaps restrictive. Similarly, the assumption that the sample observations are independent also often does not meet the criteria of realism. Real data often have a positive **serial correlation** or have a **time series** character. Models broader than parametric can be of various types; **nonparametric models** have been the popular alternative. In standard nonparametric modeling, very little is assumed about the density besides some minimal features, mostly to do with shape and symmetry, unimodality, etc. Intermediate between fully parametric and fully nonparametric models are the recent **semiparametric models**. It should be mentioned that complexity may arise not just from more complex models, but also because the quantity to be estimated is more complex than a simple thing like a mean or variance. For example, Bickel & Ritov [8], and Hall & Marron [20] consider estimation of $\int [f'(x)]^2 \, dx$, the integrated squared derivative of a density.

Efficient estimation in complex models has a large literature, of a substantially more difficult nature, as expected. The literature includes [4], [7], [10], [13], [19], [21], and [29]. Efficiency for dependent samples also has a substantial literature, but is more scattered. Grenander & Rosenblatt [17] is a classic reference which established efficiency of the sample mean for estimating the mean of a **stationary** process under quite mild conditions. Brockwell & Davis [11] give more information and discuss more problems. Efficient estimation in a relatively recent class of time series models known as long memory processes appears to be of a totally different qualitative nature. This can be seen in [5].

ANIRBAN DASGUPTA

Attributable Fraction in Exposed

The attributable fraction in the exposed (AF_{E}) is defined as the proportion of disease cases that can be attributed to an exposure factor among the exposed subjects only [2–5]. It can be formally written as

$$AF_{\mathrm{E}} = \frac{[\Pr(D|E) - \Pr(D|\overline{E})]}{\Pr(D|E)}, \qquad (1)$$

where $\Pr(D|E)$ is the probability of disease in the exposed individuals, E, and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same subjects but with all exposure eliminated. It is also called the **attributable risk** among the exposed [1, 3] and can be rewritten as

$$AF_{\mathrm{E}} = \frac{(RR - 1)}{RR}, \qquad (2)$$

a one-to-one increasing function of the **relative risk** (RR). It can be seen to equal the attributable risk in the special case of an exposure present in all subjects in the population (exposure **prevalence** of 1).

When the exposure factor under study is a risk factor ($RR > 1$), it follows from the above definition that AF_{E} lies between 0 and 1, and it is usually expressed as a percentage. AF_{E} increases with the strength of the association between exposure and disease measured by the relative risk and tends to 1 for an infinitely high relative risk. AF_{E} is equal to zero when there is no **association** between exposure and disease ($RR = 1$). Negative values of AF_{E} correspond to a protective exposure ($RR < 1$), in which case AF_{E} is not a meaningful measure.

While AF_{E} has some usefulness in measuring the disease-producing impact of an association between exposure and disease, it is much less useful than the attributable risk and does not share the same public health interpretation. This is because it is only a one-to-one transformation of relative risk. It does not take the prevalence of exposure into account, and, for instance, it can be high even if the prevalence of exposure is low in the population. Moreover, while AR estimates for several risk factors can be compared meaningfully to assess the relative importance of these risk factors at the population level, such is not the case with AF_{E} estimates. Indeed, each AF_{E} estimate refers to a different group which is specific to the risk factor under consideration (subjects exposed to that risk factor). However, one advantage of AF_{E} over attributable risk is that, since it does not depend on the prevalence of exposure, portability from one population to another is less problematic than with attributable risk and depends only on the portability of relative risk.

Issues of estimability and **estimation** of AF_{E} are the same as those for relative risk. AF_{E} can be estimated from the main types of epidemiologic studies (**cohort**, **case–control**, **cross-sectional**, **case–cohort**). Point estimates are obtained from point estimates of relative risk (**odds ratio** in case–control studies). **Variance** estimates can be obtained from variance estimates of relative risk (odds ratio in case–control studies) through the **delta method** [6], which yields:

$$\mathrm{var}(\widehat{AF}_{\mathrm{E}}) = \frac{\mathrm{var}(\widehat{RR})}{RR^4}, \qquad (3)$$

where $\widehat{RR}$ denotes a point estimate of relative risk (odds ratio in case–control studies), and $\widehat{AF}_{\mathrm{E}}$ denotes a point estimate of AF_{E}.

JACQUES BENICHOU

Attributable Risk

The attributable risk (AR), first introduced by Levin [45], is a widely used measure to assess the public health consequences of an association between an exposure factor and a disease. It is defined as the proportion of disease cases that can be attributed to exposure and can be formally written as:

$$AR = \frac{[\Pr(D) - \Pr(D|\overline{E})]}{\Pr(D)}, \qquad (1)$$

where $\Pr(D)$ is the probability of disease in the population, which may have some exposed (E) and some unexposed ($\overline{E}$) individuals, and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same population but with all exposure eliminated.

The AR takes into account both the strength of the association between exposure and disease and the **prevalence** of exposure in the population. This can be seen, for instance, through rewriting AR from (1), using **Bayes' theorem**, as [15, 53]:

$$AR = \frac{[P(E)(RR - 1)]}{[1 + P(E)(RR - 1)]}, \qquad (2)$$

a function of the prevalence of exposure, $P(E)$, and the **relative risk** RR. Therefore, while the relative risk is mainly used to establish an association in etiologic research, AR has a public health interpretation as a measure of preventable disease. A high relative risk can correspond to a low or high AR depending on the prevalence of exposure, which leads to widely different public health consequences. One implication is that, while the relative risk is often portable from one population to another, as the strength of the association between disease and exposure might vary little among populations, portability is not a property of AR, as the prevalence of exposure may vary widely among populations that are separated in time or location.

Range

When the exposure factor under study is a risk factor (relative risk > 1), it follows from the above definition that AR lies between 0 and 1, and is, therefore, very often expressed as a percentage. AR increases both with the strength of the **association** between exposure and disease measured by the relative risk, and with the prevalence of exposure in the population. A prevalence of 1 (or 100%) yields a value of AR equal to $(RR - 1)/RR$, and AR tends to 1 for an infinitely high relative risk provided the prevalence is greater than 0.

AR is equal to zero when either there is no association between exposure and disease ($RR = 1$) or no subject is exposed in the population.

Finally, negative values of AR are obtained for a protective exposure (relative risk < 1). In this case, AR varies between 0 and $-\infty$ and AR is not a meaningful measure. Either one must consider reversing the coding of exposure to go back to the situation of a positive AR or one must consider a different parameter; namely, the prevented fraction (*see* **Preventable Fraction** and the section "Related Quantities" below).

Synonyms

Numerous terms have been used in the literature instead of attributable risk. Attributable risk was the term originally introduced by Levin [45], but it is not a universally accepted term because (i) the word "risk" may be misleading as AR does not represent a risk in the usual sense and (ii) it may not allow a clear enough distinction from the more restrictive concept of attributable risk (or fraction) in the exposed (*see* **Attributable Fraction in Exposed** and the section "Related Quantities" below). Most common alternative terms are population attributable risk [47] and population attributable risk percent [15], etiologic fraction and fraction of etiology [53], and attributable fraction [33, 43, 57]. Up to 16 terms have been used to denote attributable risk in the literature [26].

Interpretation and Usefulness

AR is used to assess the potential impact of prevention programs aimed at eliminating exposure from the population. It is often thought of as the fraction of disease that could be eliminated if exposure could be totally removed from the population.

However, this interpretation can be misleading because, for it to be strictly correct, the three following conditions have to be met. First, estimation

of AR has to be **unbiased** (see the section "Estimation" below). Secondly, the exposure factor has to be causal rather than merely associated with the disease (*see* **Causation**). Thirdly, elimination of the risk factor has to be without having any effect on the distribution of other risk factors. Indeed, as it might be difficult to alter the level of exposure to one factor independently of other risk factors, the resulting change in disease load might be different from the AR estimate [74]. For these reasons, various authors elect to use weaker definitions of AR, such as the proportion of disease that can be related or linked, rather than attributed, to exposure [53].

Despite these limitations, AR can serve as a useful guide in assessing and comparing various prevention strategies. It should be noted that authors have estimated AR in situations where causality was far from being established, and the association between exposure and disease still tentative and controversial. For instance, Alavanja et al. [2] estimated the risk of lung cancer attributable to elevated saturated fat intake in a population of nonsmoking women in the state of Missouri. They interpreted their estimate as quantifying the potential impact of eliminating elevated saturated fat exposure were it later proven to be causally related to lung cancer. This use of AR is somewhat controversial, the more so when the association is not well established, and it needs, therefore, to be presented with proper qualification.

Estimation of AR can usefully be complemented by applying the AR estimate to the **incidence rate** of the disease in the population to see not just what proportion of disease, but how many cases per unit of time are attributable to exposure. Moreover, multiplying an estimate of $1 - AR$ times an estimate of the incidence rate in the population yields an estimate of the incidence rate in the unexposed (baseline incidence rate), which can be useful in a perspective of etiologic research. For instance, Silverman et al. [66], estimated the risk of pancreatic cancer attributable to alcohol in white and black men separately in the United States. They found that the substantial difference in incidence rates between black and white men (16.0 vs. 12.8 per 100 000 person-years, a 25% higher rate in black men) could be explained in part by the higher AR for alcohol among black men, since the race difference among the unexposed (i.e. having removed the contribution of alcohol) was reduced by almost half (14.2 vs. 12.5 per 100 000 person-years, a 14% higher rate in black men). The higher AR estimate among black men was itself related to both a higher relative risk estimate for elevated alcohol consumption and a higher prevalence of that exposure among black men.

Finally, AR can be considered for not just one, but several, risk factors in combination. One can be interested in the potential effect on disease load of removing these risk factors from the population. Alternatively, one might interpret an AR estimate for all known risk factors as a gauge of what is known about the disease etiology, and its complement to 1 as a gauge of what remains unexplained by known risk factors. For instance, Madigan et al. [48] estimated at 41% the AR of breast cancer for well-established risk factors; namely, later age at first birth, nulliparity, family history of breast cancer in a first-degree relative and higher socioeconomic status. They argued in favor of more etiologic research to find new risk factors, whether genetic, hormonal, or biological, to account for the remaining 59% of unexplained breast cancer cases. In fact, most authors in that field have come to similar conclusions and the AR figure of 50% or less is a useful indicator and reminder of the need for new research directions in breast cancer etiology.

Properties

Two basic properties of AR need to be emphasized. First, AR values greatly depend on the definition of the reference level for exposure (unexposed or baseline level). A larger proportion of subjects exposed corresponds to a more stringent definition of the reference level and, as one keeps depleting the reference category from subjects with higher levels of risk, AR values and estimates keep rising. This property has a major impact on AR estimates as was illustrated by Benichou [5] and Wacholder et al. [71]. For instance, Benichou [5] found that the AR estimate of esophageal cancer for an alcohol consumption greater or equal to 80 g/day (reference level of 0–79 g/day) was 38% in the Ille-et-Vilaine part of France [70], and increased dramatically to 70% for an alcohol consumption greater or equal to 40 g/day (more restrictive reference level of 0–39 g/day). This property plays a role whenever studying a continuous exposure with a continuous gradient of risk and when there is no obvious choice of threshold. Therefore, AR estimates must be reported with reference to a

clearly defined baseline level in order to be interpreted validly. In the previous example, one notes that the interpretation in preventive terms would differ for the two AR estimates. One would conclude that 70% (respectively 38%) of all esophageal cancers in Ille-et-Vilaine can be attributed to an alcohol consumption of at least 40 g/day (respectively 80 g/day) and could potentially be prevented by reducing alcohol consumption to less than 40 g/day (respectively 80 g/day).

The second main property is distributivity. If several categories of exposure are considered instead of just one, then the sum of the category-specific ARs (see the section "Special Problems" below) equals the AR calculated from combining those categories into a single exposed category, regardless of the number and the divisions of the categories that are formed [5, 71, 74], provided the reference category remains the same. This property applies strictly to unadjusted AR estimates and to adjusted AR estimates calculated on the basis of a saturated model (see below) [5]. In other situations, it applies approximately [71]. For instance, Wacholder et al. [71] used data on malignant mesothelioma [67], and obtained an unadjusted AR estimate equal to 82% for a nontrivial (moderately low, medium, or high) likelihood of exposure to asbestos, identical to the sum of the respective category-specific AR estimates of 13%, 6%, and 64% for moderately low, medium, and high likelihoods of exposure. Thus, if an overall AR estimate for exposure is the focus of interest, there is no need to break the exposed category into several mutually exclusive categories, even in the presence of a gradient of risk with increasing exposure.

Estimability

AR can be estimated from the main types of epidemiologic studies, namely **cohort**, **case–control**, **cross-sectional**, and **case–cohort studies**. It can be seen immediately that all quantities in (1) are estimable from all four types of studies except case–control studies. For case–control studies, one has to consider (2) and estimate $P(E)$ from the proportion exposed in the controls, making the rare-disease assumption also involved in estimating odds ratios rather than relative risks. Alternatively, one can rewrite (1) using Bayes' theorem in yet another manner as

$$AR = \frac{\Pr(E|D)(RR - 1)}{RR}. \tag{3}$$

In (3), the quantity $\Pr(E|D)$ can be directly estimated from the diseased individuals (cases) and RR can be estimated from the **odds ratio**. Therefore, AR is estimable from case–control studies as well.

Often, cohort studies are based on groups with a different prevalence of exposure than the general population. This renders AR estimates obtained from cohort studies less applicable to the general population and might explain why AR is seldom estimated from cohort studies.

Estimation

Since Levin [45] first introduced AR, there has been a very active research in AR estimation and numerous developments have appeared, particularly in recent years. Case–control studies have been the most explored. The outline given here applies to cohort, case–control and cross-sectional studies, unless stated otherwise. While AR is estimable from case–cohort studies, no study of AR estimation methods seems to have been published, and case–cohort studies will be considered separately (see the section "Special Problems" below).

Unadjusted Estimation

From the three types of studies considered, it is easy to obtain unadjusted (crude) AR estimates, either from (2) or (3). No other factor than the exposure of interest is considered, and the data are limited to exposure and disease state. For instance, one obtains the following estimate both from (2) and (3) in case–control studies:

$$AR = \frac{(n_1 m_0 - m_1 n_0)}{m_0 n}, \tag{4}$$

where n_0 and n_1 respectively denote the numbers of unexposed and exposed cases ($n_0 + n_1 = n$) and m_0 and m_1 the numbers of unexposed and exposed controls ($m_0 + m_1 = m$).

Variance estimates can be obtained from the **delta-method** [60] by considering the following distributions. In case–control studies, the quantities n_1 and m_1 have independent **binomial distributions**

with respective indexes n and m considered as fixed (exposure is random conditional on disease status). In cohort studies, the quantities n_0 and n_1 have binomial distributions with respective fixed indexes $n_0 + m_0$ and $n_1 + m_1$ considered as fixed (disease status is random conditional on exposure). In cross-sectional studies, one has to consider the full (unrestricted) **multinomial** model in which all four quantities n_0, n_1, m_0, and m_1 come from a common multinomial distribution with index $n + m$ considered as fixed (exposure and disease status are random).

Once a variance estimate is obtained, a standard **confidence interval** for AR can be constructed based on the asymptotic **normal distribution** of AR. Alternatively, Walter [73] suggested using the interval based on the log transformed variable $\log(1 - AR)$, and Leung & Kupper [44] based the interval on the logit-transformed variable $\log[AR/(1 - AR)]$ (*see* **Transformations**). Whittemore [77] noted that the log-transformation yields a wider interval than the standard interval for $AR > 0$. Leung & Kupper [44] showed that the interval based on the logit transform is narrower than the standard interval for values of AR strictly between 0.21 and 0.79, whereas the reverse holds outside this range for positive values of AR. While the coverage probabilities of these intervals have been studied in some specific situations and partial comparisons have been made, no general study has been performed to determine their relative merits in terms of coverage probability.

Unadjusted estimates of AR are, in general, biased, because they fail to take into account other risk factors that **confound** the association between exposure and disease. The problem is analogous to estimation of relative risks or odds ratios, and has been studied by several authors [53, 74–78]. It is one of inconsistency rather than small-sample **bias**. Walter [75] showed that, if X_1 and X_2 are two binary exposure factors and if one is interested in estimating an AR for X_1, then the following applies. The crude AR estimate is unbiased if and only if at least one of the following two conditions is true:

1. X_1 and X_2 are independently distributed in the population, that is:

$$\Pr(X_1 = 0, X_2 = 0)\Pr(X_1 = 1, X_2 = 1) = \Pr(X_1 = 0, X_2 = 1)\Pr(X_1 = 1, X_2 = 0),$$

   where level 0 denotes the absence of exposure and 1 the exposed category.

2. Exposure to X_2 alone does not increase disease risk; that is:

$$\Pr(D|X_1 = 0, X_2 = 1) = \Pr(D|X_1 = 0, X_2 = 0).$$

Therefore, if X_2 acts as a true confounder of the association between exposure X_1 and the disease, then the crude estimate of AR is inconsistent, as is a crude estimate of relative risk or odds ratio. When neither condition 1 nor 2 is true, the direction of the bias can be determined. If X_2 alone increases risk, then the bias is positive (AR is overestimated) if X_1 and X_2 are positively correlated, and negative if they are negatively correlated [75]. When considering several factors $X_j (j = 2, \ldots, J)$, conditions 1 and 2 can be extended to a set of $2(J - 1)$ analogous **sufficient** conditions concerning factors X_1 and $X_j (j = 2, \ldots, J)$ as shown by Walter [75].

Adjusted Estimation – Inconsistent Approaches

Let us first note that two simple adjusted estimation approaches discussed in the literature are inconsistent. The first approach ever proposed to obtain adjusted AR estimates, based on decomposing AR into exposure and confounding effects [74], was shown to be inconsistent [27] and, accordingly, bias was exhibited in **simulations** for the **crossover design** [26, 27]. The approach based on using (2) and plugging in an adjusted relative risk estimate (odds ratio estimate in case–control studies), along with an estimate of $P(E)$, has also been advocated [15, 55], but it too has been shown to yield inconsistent estimates [28, 32] of AR, and, accordingly, bias was exhibited in simulations for the crossover design (i.e. under the unrestricted multinomial model) [26, 27].

Two adjusted approaches based on **stratification**, the **Mantel–Haenszel** approach and the weighted-sum approach, yield valid estimates.

Adjusted Estimation – The Mantel–Haenszel Approach

The Mantel–Haenszel (MH) approach has been developed by Greenland [29] and Kuritz & Landis [38, 39]. It allows adjustment for one or more polychotomous factors forming J joint levels or strata. It is based on the formulation of AR as a function of the relative risk (odds ratio in case–control studies) and

the prevalence of exposure in diseased individuals, as given by (3). One plugs in an estimate of $\Pr(E|D)$ (given by the observed proportion of cases exposed) and an estimate of the common adjusted relative risk (odds ratio in case–control studies). The MH estimate of the common odds ratio [49] can be used in case–control studies, while MH-type estimates of the common relative risk [36, 69] can be used in cohort or cross-sectional studies.

Other choices than the MH estimator of odds ratio or MH-type estimators of relative risk are possible, and this approach could be more generally termed the common relative risk (odds ratio in case–control studies) approach. Other choices have been suggested, such as an internally standardized mortality ratio [53] (*see* **Standardization Methods**) or the **maximum likelihood** estimator from **logistic regression** [29]. MH-type estimators combine properties of lack of (or very small) bias even for sparse data (e.g. individually matched case–control data), good efficiency except in extreme circumstances [10–12, 42], and the existence of consistent variance estimators even for sparse data ("dually-consistent" variance estimators) [29, 62].

While point estimation with the MH approach is simple, variance estimation is more complex. Variance estimators can be obtained either through applications of the delta method [38, 39] or by relying on asymptotic properties of first derivatives of log likelihood functions [29]. Finite sample properties were studied by simulations under the assumption of a common odds ratio or relative risk. It was found that bias in estimating AR was negligible in case–control studies with **simple random sampling** [38], **stratified random sampling** [29] and individual **matching** [39], as well as in cross-sectional studies [26, 27]. Variance estimates were also unbiased and coverage probabilities close to nominal for those various designs.

The crucial assumption in the MH approach is that of a common or homogeneous relative risk or odds ratio, which amounts to a lack of **interaction** between the adjustment factor(s) and the exposure factor (no **effect modification**). If interaction is present, the MH estimator of AR is inconsistent, which was illustrated in simulations for the crossover design [26, 27]. Greenland [29] proposed a modification of the MH approach, consisting in defining H levels out of the original J levels formed by adjustment factors. The H levels are defined so that, within each of them, the odds ratio or relative risk can be considered as homogeneous and is estimated separately. This constitutes a possible solution although (i) the definition of the H levels, which is critical to this modified approach, is somewhat arbitrary in view of the low **power** of tests to detect interaction, and (ii) finite sample properties of this modified approach might not be as favorable as the original MH approach and bias might arise as with the weighted-sum approach (see below). Indeed, this modified approach is a hybrid approach, being intermediate between the MH and weighted-sum approaches.

Adjusted Estimation – The Weighted-sum Approach

This approach allows adjustment for one or more polychotomous factors forming J levels or strata. AR is written as a weighted sum of the ARs over strata, namely [74, 77, 78]:

$$AR = \sum_j w_j AR_j, \tag{5}$$

where AR_j and w_j are respectively the AR specific to level j and the corresponding weight. Setting w_j as the proportion of diseased individuals (cases) in level j yields an asymptotically unbiased estimator of AR, which can be seen to be a maximum-likelihood estimator [73, 77]. This choice of weights defines the "case-load method". An alternative choice of weights, called "precision-weighting" is given by setting w_j as the inverse variance of the AR estimate in level j over the sum of inverse variances over all levels [25]. It can be shown to be an inconsistent estimator of AR except in special circumstances [27].

The weighted-sum approach does not require the assumption of a common relative risk or odds ratio. The odds ratios or relative risks are estimated separately for each level j. No restrictions are placed on them, which corresponds to a saturated model (*see* **Generalized Linear Model**). Thus, the weighted-sum approach not only accounts for confounding but also for interaction. It is interesting to note that, under the assumption of a common relative risk or odds ratio, the weighted-sum approach yields the same expression for AR as the MH approach [5].

Point estimates are easy to obtain for the various types of designs. Variance estimates can be obtained from specializing the distributions described above

(see the subsection "Unadjusted Estimation" above) for each level j and applying the delta method [60]. They have been worked out for case–control designs [77], cross-sectional designs [27] and cohort designs [48].

Unlike the MH approach, small-sample bias is an issue with the weighted-sum approach, at least for case–control designs. Negative bias was found in simulations of case–control studies for **frequency matching** and simple random sampling of the controls, under the assumption of a common odds ratio and with case-load weighting [38, 77]. This bias was substantial for sparse data and a high prevalence of exposure in controls. Precision-weighting yielded a positive bias of similar magnitude [38]. The strong negative (or positive) bias renders the approach inappropriate for individual matching [38, 77]. A tendency towards conservative variance estimates and confidence intervals was also observed [38, 77]. For crossover designs, however, the results were much more favorable, as no severe small-sample bias was found in simulations, whether or not a common relative risk was considered [26, 27].

Model-based Adjusted Estimation

The MH approach rests on the assumption of a common relative risk or odds ratio and yields biased estimates in the case of interaction between exposure and adjustment factors. The weighted-sum approach does not impose any structure on the relative risk or odds ratio and its variation with levels of adjustment factors, but is plagued by problems of small sample bias, particularly for case–control designs. A natural alternative has been to develop adjustment procedures based on **regression** models in order to take advantage of their flexible and unified approach to efficient parameter estimation and **hypothesis testing**.

Walter [74] first suggested this route, and others have followed [22, 68]. Greenland [29] proposed a modification of the MH approach for case–control studies, consisting in substituting a maximum-likelihood estimate of the odds ratio from conditional logistic regression rather than the MH estimate of odds ratio in (3), and he worked out the corresponding variance estimate for AR. This modification could be applied to other designs but retains the constraint of a homogeneous odds ratio.

The full generality and flexibility of the regression approach was first exploited by Bruzzi et al. [14] who expressed AR as:

$$AR = 1 - \sum_j \sum_i \frac{\rho_{ij}}{RR_{i|j}}. \tag{6}$$

In this formula, the first sum is taken over all J levels formed by polychotomous adjustment factors, and the second sum is taken over all exposure levels (usually one unexposed level and one exposed level). The quantity ρ_{ij} represents the proportion of diseased individuals (cases) with respective levels i and j of exposure and adjustment factors, while $RR_{i|j}$ represents the relative risk for level i of exposure given level j of adjustment factors. An informal proof of (6) can be found in Bruzzi et al. [14] and a more formal one in Benichou [5].

The model-based approach based on (6) is very general in several respects. First, while it was derived by Bruzzi et al. [14] for case–control studies, it can be used as well for cohort and cross-sectional studies. For all three designs, an estimate is obtained by replacing ρ_{ij} by the observed proportion among diseased individuals, and by replacing $RR_{i|j}$ by a maximum likelihood estimate obtained from a regression model. In case–control studies, an estimate of the odds ratio from unconditional or conditional logistic regression can be used; in cross-sectional studies, an estimate of the relative risk from unconditional logistic regression can be used; in cohort studies, an estimate of the relative risk from unconditional logistic regression or from **Poisson regression** can be used. Models with additive forms have also been proposed [17].

Secondly, since estimates of odds ratio and relative risk are obtained from regression models, this approach provides a unified framework for testing hypotheses and selecting models. In particular, interaction terms can be introduced in the model, tested and retained or not, depending on the result of the test. This approach allows control for confounding and interaction and essentially parallels the estimation of the relative risk or odds ratio. **Parsimony** can be balanced against bias and the "best" model selected. More elaborate models (e.g. models with interaction terms) protect against inconsistency but can lead to small-sample bias and larger **random error**, while more parsimonious models have the reverse properties.

Thirdly, the model-based approach is general in that it includes the crude and other adjusted

approaches as special cases [5]. The unadjusted approach corresponds to models with exposure only. The MH approach corresponds to models with exposure and confounding, but no interaction terms between exposure and confounding factors. The weighted-sum approach corresponds to fully saturated models with all interaction terms. Intermediate models are possible; for instance, models allowing for interaction between exposure and one confounder only, or models in which the main effects of some confounders are not modeled in a saturated way.

While point estimates are easy to obtain, variance estimates are complex because they involve **covariances** between quantities ρ_{ij} and $RR_{i'|j'}$ that are related implicitly (rather than explicitly) through score equations. Benichou & Gail [8] worked out a variance estimator for all types of case–control studies (with simple random sampling, stratified random sampling, frequency-matching and individual matching of the controls), using an extension of the delta method to implicitly related random variables [7]. Basu & Landis [3] used a similar approach for cohort and cross-sectional designs. In case–control studies, simulations showed little or no bias in most situations [8]. However, as the data became sparse, negative bias was observed with the unconditional logistic model [8]. This could be remedied by the use of more parsimonious models when appropriate or the use of conditional logistic regression. Use of the latter approach, however, remains a research issue, as variance estimates have been derived for conditional logistic regression only for the situation of individual matching. Finally, variance estimates were unbiased and coverage probabilities close to nominal for all types of case–control studies in the aforementioned simulations [8].

Greenland & Drescher [31] have made the point that Bruzzi et al.'s estimator of AR is not exactly a maximum likelihood estimator, and have proposed a modified approach in order to obtain a maximum likelihood estimator. The proposed modification consists in using a model-based estimate of quantities ρ_{ij} rather than estimating these quantities from the corresponding observed quantities. They developed point and variance estimators for case–control designs under the unconditional logistic model, and for cohort designs under the unconditional logistic model and the **Poisson** model. In case–control studies, their approach can be seen as a generalization of Drescher & Schill's approach [24]. Variance estimators rely on the delta method [60] rather than on the implicit delta method [7] as for Bruzzi et al.'s estimator.

The two model-based approaches are identical for fully saturated models, in which case they also coincide with the weighted-sum approach. More generally, provided that the model is not misspecified, the two approaches are practically equivalent, as was illustrated by simulations for the case–control design [31]. Point and variance estimators differed only trivially between the two approaches, with mean differences equal to less than 0.001 and correlations in excess of 0.999. In simulations of the cohort design for Greenland & Drescher's modified model-based approach, some downward bias was found, in a similar way to what had been observed for Bruzzi et al.'s model-based approach for case–control designs [8], and variance estimates appeared to be without substantial bias [31].

In practice, the two model-based approaches seem, therefore, to differ very little. The maximum likelihood approach might be more efficient for small samples, although no difference was observed in simulations of the case–control design even for samples of 100 cases and 100 controls. The maximum likelihood approach might be less robust to model **misspecification**, however, as it relies more heavily on the model for the relative risk or odds ratio. In one circumstance, the distinction between the two approaches is unequivocal. The modified approach does not apply to the conditional logistic model, and if that model is to be used (notably, in case–control studies with individual matching), Bruzzi et al.'s original approach is the only possible choice.

Special Problems

Case–Cohort Design

In the case–cohort design, information on exposure is gathered only in a subcohort of subjects randomly selected from the original cohort and among subjects who develop the disease [59]. Case–cohort data contain information on the prevalence of exposure and allow estimation of the relative risk. Therefore, AR is estimable from case–cohort data, and all estimation methods presented above could, in principle, be used to estimate AR. However, the details have not been worked out in the literature and variance estimators may prove complex to derive.

Risk Factor with Multiple Levels of Exposure

It has been seen above that, because of the distributive property (see the section "Properties" above), it is sufficient to consider one overall exposed level to estimate AR. However, several levels of exposure are worth considering when estimates of AR at specified levels are of interest.

The concept of partial or level-specific AR corresponds to the proportion of disease cases that can be attributed to a specified level of exposure, and may have important policy implications for screening groups at highest risk of disease, for instance [21, 53, 74]. All estimation methods described above can be extended to produce such AR estimates. In particular, Denman & Schlesselman [21] have developed unadjusted estimates for case–control designs. The model-based approach lends itself naturally to this problem, as (6) need only be slightly modified (all RR are set equal to 1 in it, except those for the exposure level of interest). Use of the model-based approach is illustrated in Coughlin et al. [16] who considered the esophageal cancer case–control data mentioned above (see the section "Properties" above) and showed that the AR for "moderate" drinkers (40–79 g/day) was higher than that for heavy drinkers (120+ g/day) (27% vs. 22%), suggesting that prevention policies targeting "moderate" drinkers might be potentially more effective than those aimed at heavy drinkers in that population.

Finally, AR estimates have been developed for a continuous exposure [8], but their main interest is not for AR estimation but, rather, for the estimation of a related quantity; namely, the generalized impact fraction (see below).

Multiple Risk Factors

When there are several risk factors at play, it is useful to estimate AR for each risk factor separately as well as an overall AR for all risk factors jointly. Contrary to some investigators' intuition, the sum of AR estimates for each risk factor does not equal the overall AR except in special circumstances. Walter [76] showed that the equality holds for two risk factors if and only if either no subject is exposed to both risk factors or the effect of the two risk factors on disease incidence is additive. This generalizes into a set of J sufficient conditions when more than two factors forming J levels are taken into account [76]. Another important result is that, if the risk factors are statistically independent and their joint effect on disease incidence is **multiplicative** (i.e. no interaction on a multiplicative scale is present), then the complement to 1 of the overall AR is equal to the product of the complements to 1 of the separate ARs [14, 53, 74].

Finally, it has been recommended to consider a single exposed level defined by exposure to at least one risk factor, and a reference level defined by exposure to no risk factor, in order to estimate the overall AR for several risk factors [5, 71]. However, this procedure, while appealingly simple, can lead to a very small reference level and thus a very unstable AR estimate. For this reason, some authors prefer to use the model-based approach (6) and retain one parameter for each exposure factor in an overall relative risk or odds ratio model to obtain a more stable AR estimate [20, 40].

Misclassification of Exposure

The effects of **misclassification** of exposure have been studied by several authors [35, 71, 76]. AR has a "canceling feature" [76] in that misclassification may result in compensatory effects. For example, if misclassification of exposure is **nondifferential**, reduced **specificity** of exposure classification (marked by the presence of **false positive** subjects in terms of exposure) biases the odds ratio or relative risk towards the null (*see* **Bias Toward the Null**), but exposure prevalence increases, so that the net result is an absence of bias. However, still for nondifferential misclassification, reduced **sensitivity** (marked by the presence of **false negative** subjects in terms of exposure) biases AR estimates towards the null. Hsieh & Walter [35] gave a formal proof of this result and Wacholder et al. [71] a heuristic proof based on the distributive property of AR. Moreover, this downward bias increases with the prevalence of exposure.

Thus, in order to minimize bias in estimating AR, a sensitive classification scheme is an appropriate strategy, even when specificity is exceedingly low. In other words, the estimate of AR is unbiased as long as all exposed individuals are classified as exposed, regardless of the proportion of unexposed subjects who are misclassified nondifferentially as exposed. This is illustrated by Wacholder et al. [71]

with case–control data on mesothelioma and asbestos exposure (see the section "Properties" above). As exposure to asbestos is hard to prove, there are categories with "moderately low" or "medium" probability of exposure in their example. They recommend to consider these subjects as exposed in order to obtain a perfectly sensitive classification. However, there is a price to pay when high sensitivity is obtained at the expense of reduced specificity. Precision decreases (the variance of the AR estimate increases) when the definition of exposure encompasses levels of exposure that have the same risk of disease as the unexposed [71]. Therefore, there might be a tradeoff between bias and precision.

If misclassification is differential with diseased subjects (cases) being falsely classified as exposed more often that nondiseased subjects (controls), then the estimate of AR, as well as of relative risk or odds ratio, will be biased upward [71].

Finally, it should be noted that Hsieh studied the effect of disease status misclassification ("outcome misclassification") on AR estimation, and defined conditions under which bias occurs in this less common situation [34].

Use of AR to Determine Sample Size

Browner & Newman [13] derived formulas for **sample size determination** in case–control studies that are based on AR instead of odds ratio. Upon comparing sample size and power estimates based on the detection of a given AR with conventional estimates based on the detection of a given odds ratio, they found the following results. For a rare dichotomous exposure, case–control studies having little power to detect a small odds ratio may still have adequate power to detect a small AR. However, even relatively large case–control studies may have inadequate power to detect a small AR when the exposure is common. Such sample size calculations may be useful when the public health importance of an association is of primary interest, as further discussed by Coughlin et al. [16] and Adams et al. [1].

Ordinal Data

Basu & Landis [4] considered the situation where the disease classification is not dichotomous (diseased, nondiseased) but includes more than two **ordered categories** (e.g. none, mild, moderate, severe) and the exposure factor has at least two ordinal levels (e.g. none, low, medium, high exposure). They extended the concept of AR to that special case in order to quantify the potential extent of disease reduction in the target population relative to each increasing level of the ordinal disease classification, which could be realized if the exposure factor were eliminated. They developed model-based estimates based on a cumulative logit model, assuming a proportional odds structure for cohort, case–control and cross-sectional designs, and obtained corresponding variance estimates based on the delta method for implicitly related random variables [7].

Recurrent Disease Events

Pichlmeier & Gefeller [58] extended the concept of AR to diseases that may recur, such as some skin diseases (e.g. urticaria, psoriasis) or chronic diseases like asthma, epilepsy, or multiple sclerosis. They defined the "recurrent attributable risk" as the proportion of disease events (first occurrence plus recurrences) that can be attributed to an exposure factor. This concept is of interest for risk factors that also act as **prognostic factors** of recurrences. Point estimators were derived for cohort, case–control and cross-sectional designs based on the unadjusted, weighted-sum and MH approaches. Corresponding approximate variance estimators were developed using the delta method [60].

Conceptual Problems

The public health interpretation of AR refers to the proportion of cases that are excess cases, i.e. that would not have occurred if exposure had not occurred. Greenland & Robins [33, 61] identified a different concept. From a biologic or legal perspective, one might refer to cases for which exposure played an etiologic role, i.e. cases for which exposure was a contributory cause of the outcome. They argued for the distinction between "excess fraction" and "etiologic fraction" to refer to the standard and new concept, respectively. While the "excess fraction" can be estimated under the usual conditions for validity of an epidemiologic study (e.g. lack of biases), estimation of the etiologic fraction requires nonidentifiable biologic assumptions about exposure action and interactions [61]. It is true, however, that the interpretation of the excess fraction also depends

on considerations of causality, as discussed in the section "Interpretation and Usefulness" above.

Related Quantities

AR in Exposed

The attributable risk in the exposed or **attributable fraction in the exposed** (AF_E) is defined as the proportion of disease cases that can be attributed to an exposure factor among the exposed subjects only [15, 45, 47, 53]. It can be formally written as:

$$AF_E = \frac{[\Pr(D|E) - \Pr(D|\overline{E})]}{\Pr(D|E)}, \qquad (7)$$

where $\Pr(D|E)$ is the probability of disease in the exposed individuals (E) and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same subjects but with all exposure eliminated.

Excess Incidence

Excess incidence δ is defined as the difference between the incidence rate in the exposed and the incidence rate in the unexposed, or $\delta = \lambda_1 - \lambda_0$ [9, 47, 51]. It takes into account the incidence of the disease in the unexposed and the strength of the association between exposure and disease, as it can be rewritten as $\delta = \lambda_0(RR - 1)$. It can be seen to equal the numerator of the AR in the exposed (7) if the latter is expressed in terms of incidence rates rather than probabilities. Its main interest lies, however, at the individual, rather than the population, level. It quantifies the difference in incidence that can be attributed to exposure for an individual. Other terms have been used to denote this quantity; namely, "**excess risk**" [63], "Berkson's simple difference" [74], "incidence density difference" [54], "excess prevalence" [74], or even "attributable risk" [50, 63], which may have introduced some confusion. Moreover, it should not be confused with the concept of "excess fraction" [33, 61] (see above). Estimation of δ pertains to estimation of incidence rates.

Prevented Fraction

When considering a protective exposure or intervention, an intuitively appealing alternative to attributable risk (AR) is the prevented fraction (PF). The prevented fraction measures the impact of an association between a protective exposure and disease at the population level. It is sometimes called the **preventable fraction**, although this term may have a different meaning. It is defined as the proportion of disease cases averted by a protective exposure or intervention [53]. It can be written formally as:

$$PF = \frac{[\Pr(D|\overline{E}) - \Pr(D)]}{\Pr(D|\overline{E})}, \qquad (8)$$

where $\Pr(D)$ is the probability of disease in the population, which may have some exposed (E) and some unexposed ($\overline{E}$) individuals, and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same population but with all (protective) exposure eliminated. Another formulation of PF is the proportion of cases prevented by the (protective) factor or intervention among the totality of cases that would have developed in the absence of the factor or intervention [53], which is why the denominator in (8) is the hypothetical probability of disease in the population *in the absence of the protective factor*.

Generalized Impact Fraction

The generalized impact fraction (or generalized attributable fraction) was introduced by Walter [75] and Morgenstern & Bursic [56] as a measure that generalizes AR. It is defined as the fractional reduction of disease that would result from changing the current distribution of exposure in the population to some modified distribution; namely, $[\Pr(D) - \Pr^*(D)]/\Pr(D)$, where $\Pr(D)$ and $\Pr^*(D)$, respectively, denote the probability of disease under the current distribution of exposure and under the modified distribution of exposure. AR corresponds to the special case in which the modified distribution puts unit mass on the lowest risk configuration and can be used to assess interventions aimed at eliminating exposure. A level-specific AR corresponds to the special case where the modified distribution of exposure differs from the current distribution in that subjects at the specified level of exposure are brought to the lowest risk configuration and can be used to assess interventions aimed at eliminating exposure in that specified group only. The generalized impact fraction is a general measure that can be used to assess various interventions,

targeting all subjects or subjects at specified levels, and aimed at modifying the exposure distribution (reducing exposure), but not necessarily eliminating exposure.

It has been used, for instance, by Lubin & Boice [46] who considered the impact on lung cancer of a modification in the distribution of radon exposure consisting in truncating the current distribution at various thresholds. Wahrendorf [72] used this concept to examine the impact of various changes in dietary habits on colorectal and stomach cancers.

Methods to estimate the generalized impact fraction are similar to methods for estimating AR. However, unlike for AR, it might be useful to retain the continuous nature of risk factors to define the modification of the distribution considered (for instance, a shift in the distribution), and extensions of methods for estimating AR for continuous factors [8] are useful. Drescher & Becher [23] proposed extending the model-based approaches of Bruzzi et al. [14] and Greenland & Drescher [31] to estimate the generalized impact fraction in case–control studies and considered categorical as well as continuous exposure factors.

Probability of Causation – Assigned Share

Cox [18, 19] proposed a method of partitioning the increase in disease risk among several risk factors for subjects jointly exposed to them. The part corresponding to each factor is called the assigned share or probability of causation [6, 18, 19, 41, 64, 65]. It is useful in a legal context to assign shares of responsibility to risk factors in tort liability cases but does not have a population interpretation, unlike AR [6]. The assigned share enjoys the additive property that the sum of separate assigned shares for two (or more) factors is equal to the joint assigned share for these factors [19].

Prospects and Conclusion

Although most important issues about AR estimation have been settled, research is still needed on specific points, such as the use of resampling methods (*see* **Bootstrap Method**) to estimate variance and confidence intervals [30, 37], the development of model-based estimates based on conditional logistic regression for stratified or frequency-matched, case–control studies [8], improvements of the weighted-sum approach in case–control studies, or the development of AR estimators for case–cohort designs and complex survey designs (e.g. **cluster sampling**). Research is also needed for issues regarding quantities related to AR (see above), special problems (see above), and for software development [52] (*see* **Software, Biostatistical**).

The biggest challenge at this point, however, might be the need to encourage the proper use and interpretation of AR in practice and to make investigators aware of correct estimation techniques.

JACQUES BENICHOU

Autocorrelation Function

An autocorrelation is simply a correlation between two random variables X_t and X_s that are both part of the same **time series** (or other stochastic process, e.g. a spatial random field). From a single realization of the process it is possible to estimate the autocorrelations only if the process may be assumed to be second-order stationary, so that the autocorrelation between X_t and X_s depends only on the difference or *lag* between t and s, $\tau = t - s$. (In a spatial process, the autocorrelation function may also depend on the direction of the displacement between t and s unless the process is isotropic). For second-order stationary processes, the autocorrelation function (ACF), denoted ρ_τ, is defined as the correlation between variables separated by a lag τ.

If the process has been observed at equally spaced points, $t = 1, \ldots, N$, then the autocorrelation function ρ_τ at lag τ may be estimated by

$$r_\tau = \frac{c_\tau}{c_0},$$

where c_τ, the sample autocovariance function, is given by

$$c_\tau = \sum_t^{N-k} \frac{(x_t - \overline{x})(x_{t+\tau} - \overline{x})}{N}. \qquad (1)$$

The sampling properties of this estimator are discussed in [2, Chapter 48] where it is shown that the bias in c_τ is of the order $1/N$. To reduce this bias for small N, an alternative estimator is sometimes used in which the denominator N in (1) is replaced by $N - \tau$. However, Jenkins & Watts [1] show that the alternative estimator generally has a larger mean square error than (1). Also, the advantage of (1) is that it yields positive semidefinite autocovariances, a useful property for estimating the spectrum. For a purely random process with an autocorrelation function equal to zero for $\tau > 0$, the mean and variance of the sample autocorrelations are approximately given by

$$\mathrm{E}(r_\tau) \approx \frac{-1}{N}$$

and

$$\mathrm{var}(r_\tau) \approx \frac{-1}{N},$$

respectively.

A plot of the sample autocorrelation function, called a *correlogram*, may be used to explore the time series. For example, a slowly decreasing correlogram may be due to nonstationarity (i.e. a trend in the time series) and an oscillating correlogram indicates seasonal fluctuations. The correlogram is also helpful in identifying the order q of a moving average process [MA(q)], since the autocorrelations of an MA(q) are nonzero only for lags $\leq q$. Confidence limits of $-1/N \pm 2/\sqrt{N}$ may be drawn on a correlogram to help assess which autocorrelations differ significantly from zero. For autoregressive processes [AR(p)], the autocorrelation function decreases only slowly and the *partial* autocorrelation function is more useful for identifying the order of the process. An example of a time series and its correlogram are given in Figure 1 for the lutenizing hormone levels in blood samples from a healthy woman.

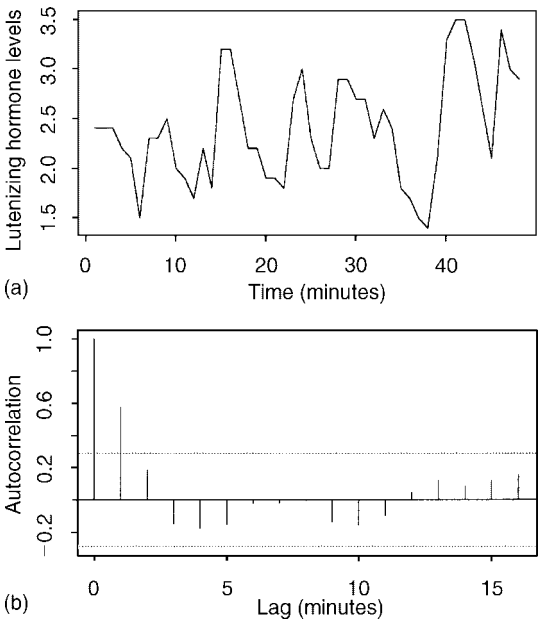

Figure 1 Levels of lutenizing hormone in blood samples taken from a healthy woman every 10 minutes (a) and the autocorrelation function with approximate 95% confidence limit for zero autocorrelation (b)

SOPHIA RABE-HESKETH

Average Age at Death

The fallacy of using average age at death as an "alias" to summarize **life expectancy** and other aspects of mortality plays a prominent role in the history of statistics [1, p. 23]. While its use for this purpose is tempting because of its availability, it is nonetheless incorrect [2]. Proper analysis of mortality involves the determination of age-specific mortality rates, which requires denominator data on the age distribution of the population [2], and failure to account for the age distributions of the underlying populations is the principal determinant of this fallacy (*see* **Denominator Difficulties**). Age-distribution data come from the total population being studied, including those who are still alive as well as those who have died.

Although summarizing mortality using the average age of death may be a convenient measurement, it (alone) is often neither a useful nor helpful measure [2, 3]. Information regarding frequency distributions and variability around the average also should be considered. Whereas, for example, the average age at death from a particular disease may be 55 years, all deaths may have occurred in persons younger than 50 years and older than 60 years – information that is not conveyed by the **mean** age alone.

Furthermore, average age of death can be a misleading statistic for other reasons [2, 3]. For instance, in the comparison of longevity among persons in various occupations (*see* **Occupational Mortality**), the average age at death depends, at least in part, on the age at entry into an occupation as well as age at exit, if exit occurs for reasons other than death. **Death certificates** provide age at death data; age at job entry and exit are less readily available. Also, average age at death may be determined by the intensity of the exposure to risk as well as by the duration of the exposure.

Andersen [1, p. 13] remarked on a study comparing the average length of life for male symphony orchestra conductors and for the entire US male population.

On average, the conductors lived about 4 years longer. The methodological flaw was that because age at entry was birth, those in the US male population who died in infancy and childhood were included in the calculation of the average life span, whereas only men who survived to become conductors could enter the conductor cohort. The apparent difference in longevity disappeared after accounting for **infant and perinatal mortality** in the US male population.

In comparing two groups with respect to mortality experience, both Andersen [1] and Colton [2] emphasized the importance of considering the age distribution of the groups. Arguments about life span based on the average age at death ignore those who are still alive. If among those still living there are more who are elderly in one group compared with the other, then differential mortality experience does not necessarily explain group differences in average age at death. Even if the groups had identical age-specific death rates, the group with the larger number of elderly individuals will have the higher average age of death.

Rather than looking at average age at death, Rothman [4] suggests that we should compare the *risk of death* among orchestra conductors (or whatever group is being looked at) with the risk of death among other people who have attained the same ages as the conductors. Average age at death is only a characteristic of those who die and does not reflect the risk of death.

HOWARD M. KRAVITZ

Axes in Multivariate Analysis

Visual presentation of data is valuable throughout any statistical analysis, right from the preliminary stages (where graphical examination of sample values can often reveal features that are difficult to detect in a table of numbers) through to the conclusion (where graphs and charts often provide the most effective way of presenting the results; *see* **Graphical Displays**). **Multivariate analysis** particularly benefits from pictorial support, as a typical multivariate sample contains too many numbers to be readily assimilable in tabular form. Indeed, many multivariate techniques can be regarded primarily as mechanisms for systematic exploration of multidimensional sample spaces in which sample individuals are represented as points. In this article we highlight just one important aspect of such representations.

Suppose that p variables $X_1, X_2, \ldots, X_p$ have been measured on each of n sample individuals, and write $\mathbf{x}_i' = (x_{i1}, x_{i2}, \ldots, x_{ip})$ for the vector of p values observed on the ith individual, $i = 1, 2, \ldots, n$. Assume for the present that all variables are *quantitative*, i.e. on a numerical scale (*see* **Measurement Scale**). Then the sample can be modeled geometrically as a swarm of n points in p-dimensional space, by associating each variable X_j with an **orthogonal** axis in this space and assigning the observed value $\mathbf{x}_i$ to the point with coordinates $(x_{i1}, x_{i2}, \ldots, x_{ip})$ on these axes. Thus the original variables constitute a fundamental system of axes in multidimensional space. Furthermore, if the data matrix has been mean-centered, then the origin of these axes is at the centroid of the swarm of points.

However, this geometrical model is of little immediate practical utility because we can graphically depict only a few dimensions (usually just two), but multivariate data sets generally involve more than two variables. Some approximation is therefore necessary, and many techniques of multivariate analysis are concerned with identifying either single *directions* in the sample space along which something "interesting" happens, or (low-dimensional) *subspaces* into which the points should be *projected* to highlight some relevant sample features. The two objectives are in essence the same, as any k-dimensional subspace can be defined simply by specifying k mutually orthogonal directions in the original space to act as coordinate axes for the subspace. Also, since most multivariate analyses operate on mean-centered data, any such subspace axes are essentially lines through the origin of the sample space.

Now any line $\mathcal{L}$ through the origin can be specified by a unit vector starting at the origin and having an end point on the line. If the end point of this vector has coordinates $\mathbf{a}' = (a_1, a_2, \ldots, a_p)$, then unit length implies the condition $\sum_i a_i^2 = 1$, so the a_i can be interpreted as direction **cosines** of the vector with each of the original axes. The coordinates of any point $\mathbf{x}' = (x_1, x_2, \ldots, x_p)$ in the sample space can likewise be thought of as a vector from the origin to this point, so by elementary vector theory it follows that the projection of the point $\mathbf{x}$ onto the line $\mathcal{L}$ is a distance $\mathbf{a}'\mathbf{x} = \sum_i a_i x_i$ from the origin. We can therefore view $\mathcal{L}$ as an *axis* in the original space, and the point $\mathbf{x}$ has coordinate value $\mathbf{a}'\mathbf{x}$ on this axis. For convenience, the defining unit vector $\mathbf{a}$ is often referred to as the line $\mathcal{L}$.

We can specify any number of axes $\mathbf{a_1}, \mathbf{a_2}, \mathbf{a_3}, \ldots$ in this way. Two such axes $\mathbf{a}_i, \mathbf{a}_j$ are *orthogonal* (i.e. at right angles to each other) if $\mathbf{a}_i'\mathbf{a}_j = 0$, and if the sample space is of dimension p, then *any* set of p mutually orthogonal lines can be chosen as reference axes for it. A particular set of p mutually orthogonal $\mathbf{a}_i$ constitutes a **rotation** of the original coordinate axes. Taking a subset of k of these axes defines a k-dimensional subspace of the original space into which the data swarm can be projected.

Given the association between the measured variables $X_1, X_2, \ldots, X_p$ and the original axes in the sample space, we thus see that all those multivariate techniques that obtain linear combinations of the X_i are in fact identifying new axes in the sample space. Moreover, if the linear combinations are orthogonal, then so are the corresponding axes, in which case k such linear combinations define a k-dimensional subspace of the sample space. Such is the case, for example, with successive components in **principal component analysis** and with the linear combinations derived in various forms of **projection pursuit**. In these cases, projecting the data points into several such orthogonal dimensions enables us to obtain a low-dimensional approximation to the full data representation; this is the objective, for example, of principal component score plots.

Other multivariate techniques result in linear combinations that are either derived implicitly from a

statistical model, or ones that are nonorthogonal. In the former case, for example in **factor analysis**, we can still view the combinations as defining axes and subspaces of the sample space, but direct projection of points into these subspaces may not necessarily correspond to derived scores. In the latter case, for example in canonical **discriminant analysis**, the axes will be **oblique**, so care must be taken with projection or representation of points.

A final point worth noting about such data representations is that it is often instructive to project the original axes into any k-dimensional subspace generated from orthogonal linear combinations, as these projections show the inclination of the derived subspace to the original axes. Such projections are obtained as biplots in principal component analysis, for example (*see* **Graphical Displays**).

The above ideas are based on the assumption that all the variables are quantitative, allowing the formulation of an underlying model of points in space with coordinates given by variable values. Many multivariate data sets, however, contain **categorical data**, either, **nominal** or ordinal variables (*see* **Ordered Categorical Data**), which do not permit the direct formulation of such a model. It is nevertheless possible to *construct* a model by means of **multidimensional scaling**. This construction requires a matrix of dissimilarities between every pair of sample members to be calculated (*see* **Similarity, Dissimilarity, and Distance Measure**), whereupon the scaling technique will find a k-dimensional configuration of points representing sample individuals in which between-point distances approximate between-individual dissimilarities as closely as possible. New axes and subspaces can be sought in this representation in the same way as above. However, since the multidimensional scaling method does not associate variables with coordinate axes in the constructed representation, there is no longer any association between new axes and linear combinations of variables.

Axioms of Probability

Probability theory, like many other branches of mathematics such as geometry, for example, is a subject whose development arose out of an attempt to provide a rigorous mathematical model for observable real-world phenomena (*see* **Foundations of Probability**). The real-world phenomenon in the case of probability theory is chance or random behavior involving a physical system or a biological process. While some probabilistic ideas date back to India as early as the fifth century B.C. [2, p. 1], the formal study of probability is generally attributed to have its origin in the correspondence between Fermat and Pascal in the 1650s concerning various gambling issues. Today, probability theory has numerous applications in diverse fields such as statistical inference, number theory, the physics of particle movement, economics, the social sciences, the biological sciences, genetics, epidemiology, and demography.

The probability of an event is the abstract counterpart to the real-world notion of the long-run relative frequency of the occurrence of the event through replicating the experiment over and over again. For example, if a medical researcher asserts that the probability that a particular medical procedure results in a cure for those inflicted with a certain disease is (say) 0.85, then the researcher is asserting that in the long run 85% of those inflicted with the disease who receive the medical procedure will be cured. The phrase "in the long run" suggests that the theoretical underpinnings involve the notion of *limit* as the sample size $n \to \infty$. While the long-run relative frequency approach for defining the probability of an event may seem natural and intuitive, it raises serious mathematical questions. Does the limit of the relative frequency always exist as $n \to \infty$ and is the limit always the same irrespective of the experimental outcome? It is easy to see that the answers are in the negative. Indeed, it is within the realm of possibility that in the example above the proportion cured fluctuates repeatedly from near 0 to near 1 as $n \to \infty$. So in what sense can it be asserted that the limit exists and equals 0.85? The answer to this question is provided using the axiomatic (or measure-theoretic) approach.

The problems arising from the relative frequency approach are eliminated by the axiomatic approach which was developed by Kolmogorov in [1]. Kolmogorov's probability model is defined in terms of a triplet $(\Omega, \mathcal{F}, P)$ (called a *probability space*) whose components will now be described via the following four axioms:

Axiom 1. Ω is a nonempty reference set.

Axiom 2. $\mathcal{F}$ is a *σ-algebra* of subsets of Ω, that is, $\mathcal{F}$ is a nonempty collection of subsets of Ω satisfying
- (i) $A \in \mathcal{F} \Rightarrow A^c \in \mathcal{F}$ and
- (ii) $\{A_n, n \geq 1\} \subseteq \mathcal{F} \Rightarrow \bigcup_{n=1}^{\infty} A_n \in \mathcal{F}$.

Axiom 3. P is a *measure* on $\mathcal{F}$, that is, P is a real valued function defined on $\mathcal{F}$ satisfying
- (i) $P(\emptyset) = 0$,
- (ii) $P(A) \geq 0$ for each $A \in \mathcal{F}$, and
- (iii) if $\{A_n, n \geq 1\}$ is a sequence of disjoint sets in $\mathcal{F}$, then $P(\bigcup_{n=1}^{\infty} A_n) = \sum_{n=1}^{\infty} P(A_n)$.

Axiom 4. $P(\Omega) = 1$.

The set Ω is the abstract counterpart of the collection of primitive outcomes of a not completely determined real-world experiment. The objects $\omega \in \Omega$ are called *sample points* and Ω is called the *sample space* of the experiment. A member of $\mathcal{F}$ is referred to as an *event*. For $A \in \mathcal{F}$, its *probability* $P(A)$ is the abstract counterpart to the long-run or limiting relative frequency of the occurrence of A when the experiment is indefinitely repeated.

It is natural to take $\mathcal{F}$ to be the power set of Ω if Ω is countable. (The power set of Ω is the set of all subsets of Ω.) However, if Ω is uncountable, then profound measure-theoretic considerations would force such a choice of $\mathcal{F}$ to preclude the existence of a probability measure P on $\mathcal{F}$. Consequently, $\mathcal{F}$ can be smaller than the power set of Ω but should be large enough so as to contain all subsets of Ω whose probability would be of practical or theoretical interest.

It should be apparent that probability theory as a subject has two sides. On one side is the mathematical use of measure theory, whereas the other side concerns a random experiment arising in connection with a physical system or biological process. The measure-theoretic side gives probability theory its mathematical rigor; the experimental side gives it its application and often its inspiration.

Nothing in the axioms of probability (except Axiom 4) indicates the value of $P(A)$ for a particular event A. The axioms only stipulate that however P is defined on $\mathcal{F}$, it must satisfy Axioms 1–4. The actual experiment under consideration determines the

way in which probabilities should be defined. Various paradoxes in probability theory can arise from different interpretations of the actual experiment, all of which can be reasonable (see [5]). Such paradoxes do not indicate an inconsistency in the axioms of probability.

Moreover, it is interesting to note that there is absolutely nothing in the probability axioms 1–4 which refers to the notion of a limiting relative frequency when an experiment is indefinitely repeated. Shafer [3] advocates actually incorporating in some manner the notions of repetition and long-run relative frequency directly into the axiomatic framework of probability in order to emphasize the unity of the field. The notion of limiting relative frequency is a nontrivial *consequence* of Axioms 1–4 and is made precise by the Borel *strong law of large numbers* (SLLN). The Borel SLLN asserts that if $\{A_n, n \geq 1\}$ is a sequence of independent events all with the same probability p, then

$$P\left(\lim_{n\to\infty} \hat{p}_n = p\right) = 1, \tag{1}$$

where $\hat{p}_n = \sum_{j=1}^{n} I(A_j)/n$ is the proportion of $\{A_1, \ldots, A_n\}$ to occur, $n \geq 1$. [Here, $I(A_j)$ denotes the indicator function of the event A_j.] Hence, with probability 1, the "sample proportion", $\hat{p}_n$, approaches the "population proportion", p, as the "sample size" $n \to \infty$. It is this version of the SLLN which thus provides the theoretical justification for the long-run relative frequency approach to probability theory and so the SLLN lies at the very foundation of statistical science. It should be noted, however, that the convergence in (1) is not pointwise on Ω but, rather, is pointwise on some subset of Ω *having probability 1*. Thus, any practical interpretation of p via (1) would require that one has a priori an intuitive understanding of the notion of an event having probability 1.

The following example of Stout [4, p. 9] illustrates an application of (1) to the field of biostatistics. Consider a new drug for which the proportion p of patients who will be cured by the drug is unknown. A medical researcher continuously estimates p by using the proportion $\hat{p}_n$ of the first n patients treated with the drug who get cured. The medical researcher is interested in knowing if there will ever be a point in the sequence of patients such that, with high probability, $\hat{p}_n$ will be within ε of p *and stay* within ε of p (where $\varepsilon > 0$ is a prescribed tolerance). The answer is affirmative since (1) is equivalent to the assertion that, for given $\varepsilon > 0$ and $\delta > 0$, there exists a positive integer $N = N_{\varepsilon,\delta}$ such that

$$P\left(\bigcap_{n=N}^{\infty} [|\hat{p}_n - p| \leq \varepsilon]\right) \geq 1 - \delta.$$

That is to say, the probability is arbitrarily close to 1 that $\hat{p}_n$ will be arbitrarily close to p simultaneously for all n beyond some point. Consequently, the SLLN (1) is not only of theoretical significance, but also is of practical significance.

Back-calculation

Back-calculation – also called back-projection – estimates past infection rates of an epidemic infectious disease by working backward from observed disease **incidence** using knowledge of the **incubation period** between infection and disease. Although potentially applicable to various diseases, it was first proposed [15, 16] to study the acquired immune deficiency syndrome (**AIDS**) epidemic and has mainly been applied in this area. Performance of back-calculation requires a technical framework for defining and maximizing a likelihood to obtain estimated infection rates, detailed information about key inputs such as incubation and reporting completeness assumptions, and a strategy for assessing uncertainty in the key inputs and resulting uncertainty in back-calculated estimates.

The Basic Method

Suppose that we have n nonoverlapping intervals, (T_{j-1}, T_j), $j = 1, \ldots, n$; let Y_j be the number of persons developing disease in the jth interval, and assume that no infections occurred before time T_0. In practice, these intervals will often be calendar months or quarters. For example, AIDS incidence in the US is reported as the number of new diagnoses each month. Thus, a discrete-time formulation is realistic for practical applications, and we will employ such notation here, assuming a monthly time scale. Back-calculation is based on the following convolution equation:

$$\mathrm{E}(Y_j) = \sum_{i=1}^{j} \theta_i, D_{ij}, \quad j = 1, \ldots, n, \tag{1}$$

where θ_i is the expected number of new infections in month i and D_{ij} is the probability of developing disease in month j given infection in month i; that is, the probability that the incubation time is equal to $j - i$ given infection in month i. Back-calculation is thus a deconvolution method. Given a set of observed values $\mathbf{y} = (y_1, \ldots, y_n)$, it uses known D_{ij} to find a θ likely to have produced $\mathbf{y}$ via (1).

Eq. (1) only specifies the first moment of the Y_j, so implementation of the strategy requires additional specifics. A simple approach is to assume that the Y_j are independent with **Poisson** error structure. This follows from an assumption that infections arise according to a nonhomogeneous **Poisson process**. In our discrete-time framework, this means that the number of infections in month i is Poisson with expectation θ_i and the numbers of infections in different months are independent. This assumption produces a log **likelihood** (up to a constant) of

$$l(\mathbf{y}|\boldsymbol{\theta}) = \sum_{j=1}^{n} \left[y_j \log \left(\sum_{i=1}^{j} \theta_i D_{ij} \right) - \sum_{i=1}^{j} \theta_i D_{ij} \right], \tag{2}$$

which can be maximized to obtain an estimate of $\boldsymbol{\theta}$. To avoid ill-posedness [48], some structure must be imposed on $\boldsymbol{\theta}$. For example, a parametric model might specify that $\theta_i = f_{\boldsymbol{\beta}}(i)$, where $\boldsymbol{\beta}$ is a (small) vector of parameters and f is a family of functions indexed by $\boldsymbol{\beta}$. Projected values of Y_k for $k > n$ (yet to be observed) can be obtained from (1) using estimates $\hat{\theta}_j$, with $\hat{\theta}_j$ obtained by extrapolation for $n < j \leq k$.

Finding parameters that maximize the likelihood (2) may be possible using general numerical approaches such as the Newton–Raphson method, depending on the complexity of the structure imposed on θ (*see* **Optimization and Nonlinear Equations**). Using an expectation-maximization (**EM**) algorithm, however, can greatly simplify the computations. Consider the complete data $\{x_{ij}\}$, where x_{ij} is the number of persons infected in month i and diagnosed in month j. Under the assumptions leading to (2), these counts are independent Poisson with means $\theta_i D_{ij}$. The complete-data log likelihood is therefore (up to a constant)

$$\sum_{i=1}^{n} \left[x_i \log(\theta_i) - \theta_i \sum_{j=i}^{n} D_{ij} \right], \tag{3}$$

where $x_i = \sum_{j=i}^{n} x_{ij}$. This is a linear function of x_i, so its expected value can be calculated using the formula [30]

$$\mathrm{E}(x_i|\mathbf{y}, \boldsymbol{\theta}) = \sum_{j=i}^{n} y_j \frac{\theta_i D_{ij}}{\sum_{k=1}^{j} \theta_k D_{kj}}. \tag{4}$$

The EM algorithm begins with an initial guess for the parameters that determine $\boldsymbol{\theta}$, calculates the expected value of (3) using (4) (the E-step), and finds the

new values of the parameters that maximize (3) (the M-step). The E- and M-steps are iterated until the parameter estimates converge. The simple forms of (3) and (4) make this approach computationally easy.

Inputs

Back-calculation requires a known incubation distribution (the D_{ij}) and accurate data on incidence of disease. In addition, a realistic model for infection patterns must be specified.

Incubation

The estimate of the infection pattern $\boldsymbol{\theta}$ depends crucially on the assumed incubation distribution [6, 8, 58]. Accurate estimates, however, may be difficult to obtain. Estimation of distributions of incubation times from human immunodeficiency virus (HIV) infection to AIDS diagnosis illustrates many potential problems in obtaining accurate D_{ij}. These include inherent limitations in available data, heterogeneity of distributions in different populations, and changes over time (nonstationarity) (*see* **Stationarity**).

Data Sources. Inherent limitations arise because HIV infection is usually not immediately detected, and observed incubation times are therefore only available for special groups whose times of HIV infection can be determined retrospectively. These include persons whose HIV infection can be traced to a particular blood transfusion and those whose time of infection can be bracketed by antibody testing of stored specimens from various times in the past. These special groups may not be representative of the wider population for which back-calculation is to be performed. In addition, the data from these sources may suffer from right-truncation [38, 39, 42] or double-censoring [8, 27]. Such data require specialized statistical analysis and convey less information than fully observed data. An extreme form of double-censoring is present for **prevalent** cases – those already infected at the time that they were recruited into a cohort study and followed for development of AIDS. Such subjects are known to have been infected at some time between the start of the epidemic and their time of recruitment (an interval-censored starting time), and their time of AIDS may be right-censored. An additional difficulty is that persons who had already developed AIDS may have been excluded from recruitment. Thus, methods for left-truncated data must be used. Prevalent cohort participants are much more numerous than those with infection times that are more narrowly bracketed by a positive HIV antibody test preceded by a negative one, so investigators have attempted to utilize data from prevalent subjects by imputing infection times using laboratory markers that change with length of infection [36, 47] and by other methods [5, 41, 59].

Heterogeneity. Back-calculation is usually applied to entire populations defined by region of residence and possibly by risk behaviors, but data on incubation times come from highly selected, small groups of persons with known infection times. This would not be a problem if all populations and all the groups shared the same incubation distribution, or if all differences could be accurately explained and quantified in terms of readily measured characteristics such as age. This, however, does not appear to be the case. Direct comparison of data from different sources has shown statistically significant differences between different groups [12], including groups of gay men of similar ages who differ on other characteristics [7, 8, 60, 65]. This heterogeneity adds considerable uncertainty about what incubation distribution to use for a particular population, especially understudied populations such as women or intravenous drug users.

Nonstationarity. Estimation would be simplified if the D_{ij} all depended only on the elapsed time, $j - i$; that is, if the incubation distribution were stationary. In general, however, the chance of developing disease may be nonstationary and also depend on the time of infection, i, or on the current time, j. For example, diagnosis of AIDS may depend on several factors that change over time, including availability and effectiveness of preventive treatments, changes in the official case definition of AIDS [21, 22, 24], changes in care-seeking patterns, and possible evolution of the virus toward more or less virulence. Such phenomena place even greater demands on limited data. A widely used approach has been to assume that no factor other than treatment has caused nonstationarity, and to use data on effectiveness of treatment and usage rates of treatment over time to modify stationary incubation estimates [13]. This results in models in which persons infected more recently have

longer incubation times. A more direct approach is to examine the special groups discussed above who have approximately known infection dates, and to use standard **survival analysis** methods to estimate the effect of infection date or calendar time (a **time-dependent covariate**) on development of AIDS. This estimates the net effect of all factors that may be changing over time. Several such studies have found that incubation times remained constant or actually shortened in the late 1980s and early 1990s compared with earlier in the epidemic [12, 29, 35, 62]. This suggests that other factors, such as more aggressive care seeking or evolution of the virus, accelerated diagnosis of AIDS more than it was slowed by beneficial treatment effects. A dramatic source of nonstationarity in the US is the expansion in 1993 of conditions officially qualifying as an AIDS diagnosis [24]. This had such a large and sudden impact that accurate estimates of the affected D_{ij} may not be obtainable. In addition, introduction of potent protease inhibitors and increased use of combination antiretroviral therapy starting in the mid-1990s will also influence incubation times.

Incidence

In practice, true disease incidence is not observed exactly because of imperfections in the surveillance system. Incompleteness of the observed incidence arises from reporting delays and from underreporting; that is, cases who are never reported. This incompleteness must be corrected before back-calculation is applied. In addition, the incidence series may contain short-term perturbations, such as seasonal patterns, that can be adjusted out to make long-term trends clearer and to improve the accuracy of back-calculation.

Reporting Delay. Because there is often a lag between diagnosis of disease and the time that it is recorded and tabulated, recent incidence is incomplete. This typically causes a downturn in recent incidence that would severely distort back-calculation results if left uncorrected. The usual strategy is to estimate for each month j a completeness factor, R_j, the proportion of true incidence that has been reported. If y_j^* denotes observed incidence, one can apply back-calculation to corrected counts $y_j = y_j^*/R_j$. (Alternatively, the R_j can be incorporated directly into the back-calculation procedure [6]). A common practice is to exclude counts that are so recent that they are estimated to be less than 50% complete. If surveillance provides both date of disease and date of report, incompleteness due to reporting delay can be estimated if one assumes a maximum possible length of delay [25]. This requires specialized methods [14, 39, 50] because of the severe right-truncation caused by the fact that the only cases available for analysis are those with short enough delays to have been already reported. In addition, dependence of delays on case characteristics and changes in delay patterns over time can be estimated. Estimates of changes over time can be strongly influenced by irrelevant shifts in the patterns of very short delays, so modifications to avoid this lead to better estimates [1]. In the US, the 1993 change in the AIDS case definition apparently had a strong impact on reporting, even of cases meeting the earlier definition [4].

Underreporting. In addition to delays in reporting, there also may be cases that are never reported. Such underreporting of AIDS cases has been investigated to a limited extent by cross matching reported AIDS cases to cases identified by other means, notably **death certificates** that list HIV under cause of death [19, 31]. The proportion of cases found by other means that are not also in the **surveillance** system provides an estimate of the underreporting rate. (More sophisticated **capture–recapture** methods have not been widely used.) Studies of underreporting require use of personal identifiers, and so are usually carried out at a local level. They also usually apply to a specific time period. Consequently, extensive systematic data on underreporting is typically not available for the population under consideration, and assuming constant underreporting of between 10% and 20% is a common practice. Such assumptions must be combined with estimated incompleteness due to reporting delay to obtain R_j that reflect both sources of incompleteness.

Short-term Patterns. Season can influence the incidence of some infectious diseases, notably AIDS, and incidence of AIDS in a particular month is also influenced by how many workdays it includes [2]. The lengths of calendar months also vary by 10%. These short-term influences increase month-to-month variability and can degrade back-calculation results. Performance can be improved by estimating these

effects and adjusting them out of the incidence series to be used [2, 3].

Infection Model

As noted above, some structure must be imposed on $\boldsymbol{\theta}$ to allow stable estimation. Both parametric and nonparametric approaches have been used. Parametric approaches include smooth families indexed by two or three parameters [26, 58, 63], as well as step functions with four or five steps, within which infection rates are assumed to be constant [16, 55]. Although these step models are not plausible, they are flexible, and have been made more so by modifications to allow adaptive selection of cutpoints between steps [56]. Nonparametric approaches do not directly parameterize $\boldsymbol{\theta}$ but obtain smooth estimates by either adding a smoothing step after the M-step of the EM algorithm [11], or by using **penalized maximum likelihood** [6] or **ridge regression** [49]. Some methods combine aspects of the parametric and nonparametric approaches [13, 32].

Sensitivity Analyses

Asymptotic standard errors for estimated infection rates and future incidence projections can be obtained from the observed **information matrix** for $\boldsymbol{\theta}$ or by **bootstrap** methods, but this captures only a small part of the real uncertainty. Possible errors in the inputs to back-calculation cause much greater uncertainty in the results. **Sensitivity analyses** that employ a wide variety of inputs (consistent with available data on incubation and incidence) can serve to more realistically illustrate the plausible range of possibilities. (**Bayesian methods** that incorporate **priors** for the various inputs could offer a more formal assessment of uncertainty [20, 58], but these have not been widely used.) If the range of plausible inputs is large, as in the case of HIV and AIDS, exhaustive exploration of possible uncertainty may be difficult. Sensitivity analyses for back-calculation from AIDS incidence have generally considered from two to five possible incubation distributions [6, 54, 63], and often not considered uncertainty in the incidence series. An additional difficulty when uncertainties in the inputs are wide is that back-calculated results from some inputs may contradict what is known (at least qualitatively) from other sources, such as cross-sectional prevalence surveys or cohort studies. Simply dropping the offending inputs from the sensitivity analyses, however, is not adequate, because the remaining set of possibilities will be too narrow, even if the original set was adequate. This is because there is a continuum of plausible possibilities between the eliminated and retained possibilities, some of which are consistent with the outside information. When inputs that are a priori plausible produce implausible results, formal methods to combine back-calculation with the outside data [17] should be considered, as should the possibility that back-calculation cannot meaningfully improve on what is known directly from the outside data.

Incubation

The assumed incubation distribution strongly influences estimated infection rates. This is apparent from the forms of (1) and (2), where the incubation terms D_{ij} and the θ_i always appear multiplied together. Different plausible AIDS incubation distributions can lead to estimates of cumulative HIV infections in the US that differ by factors of two or more, while providing nearly identical fits to the observed AIDS incidence data [6, 8]. This implies that errors in the D_{ij} will not be detectable in the back-calculation process itself, because their influence will be masked by compensating errors in the estimate of $\boldsymbol{\theta}$ and no lack of fit will be apparent. This and the sources of uncertainty noted above underscore the need for careful sensitivity analysis of incubation assumptions. Nonstationarity in the incubation distribution can also influence back-calculated estimates. For example, a slowdown in incidence will be attributed to an earlier decline in infections if a stationary incubation is assumed, but could also be explained by recent lengthening of incubation times.

Disease Incidence

Assumptions about reporting delay and underreporting can strongly influence projections. Differing reasonable assumptions about underreporting and late reporting of AIDS cases diagnosed through 1991 in the US resulted in two-year projections that differed by 20% or more [1], and additional uncertainty about very late reporting increases this difference to at least 30% [3, 25]. In addition, one can see from (1) that underreporting has a direct impact on the estimate

of $\boldsymbol{\theta}$. For example, assuming constant 80% reporting instead of 90% reporting would increase all of the imputed y_j by about 13% (0.9/0.8), resulting in a corresponding proportional increase in all of the estimated θ_i.

Refinements

A wide variety of technical refinements, extensions, and modifications of back-calculation have been studied. Notable among these are methods for: incorporating results of HIV **prevalence** surveys [17]; allowing for dependence in the HIV infection process [9]; estimating **overdispersion** in a **quasi-likelihood** approach [17, 43]; utilizing data on HIV tests [45, 52]; using age at time of AIDS to back-calculate age-specific HIV incidence [10, 53]; nonparametric modeling of infection rates, including data-driven choices of smoothness parameters [6, 32, 44]; incorporating knowledge of the size of the susceptible population [61]. Because of the considerable uncertainty about crucial inputs, however, these refinements may not be able meaningfully to improve the accuracy of back-calculation.

Limitations

A key limitation of back-calculation is the need for accurate inputs, as noted above. Because uncertainty in the results comes mainly from uncertainty about these inputs, estimates of pure statistical uncertainty are misleading. Two additional limitations of the method are that it provides little information about recent infection rates and that projections can be overly sensitive to recent incidence.

Back-calculation is primarily useful with epidemic infectious diseases for which there is a substantial lag between infection and disease. If a disease is in a steady state or if disease rapidly follows infection, then infection rates can be adequately ascertained directly from disease incidence. Because of this focus, there will be little direct information about recent infection rates and back-calculated estimates of θ_j for j close to n will be determined mainly by implicit extrapolation, from either the parametric model of $\boldsymbol{\theta}$ or the form of the smoothness assumption. For example, because few persons develop AIDS within two years following HIV infection, back-calculation from AIDS incidence provides little information about infection rates in the last two years.

Projections from back-calculation can be overly sensitive to counts near the end of the incidence series. This is particularly true for AIDS if seasonal patterns are not adjusted out of the incidence series [3]. For example, anomalously high AIDS incidence in the US in the first half of 1987 caused projections from back-calculations to be too high, which was interpreted as evidence for a treatment-induced downturn in incidence [28]. The projections would have been more accurate if deseasonalized incidence had been used, and would have been much better if a more robust projection method had been used. Two- or three-year projections based on incidence through the end of 1986 also would have been fairly accurate [3].

Alternatives

A simple alternative for projecting future incidence is empirical **extrapolation** [34, 40, 46, 64]. This can be reasonably accurate [3], but provides no information about infection rates and has no ability to anticipate changes in trajectory. Measurement of infections in cross-sectional surveys and cohorts followed over time provides direct information on prevalence and incidence of infections. Such studies are most useful when performed anonymously on specimens collected for other purposes [33, 51], because this can eliminate the potentially serious problem of **nonresponse bias** [23]. In **cohort studies** of incidence, serious dropout bias can result from the fact that higher-risk subjects may be more likely to fail to return for follow-up testing (*see* **Nonignorable Dropout in Longitudinal Studies**). Markers of recent infection can be used to estimate current incidence without relying on follow-up and to correct dropout bias [18], provided that the initial sample is representative and that the average duration of the marker is known. One can deduce the shape of the infection density from the mix of laboratory markers, such as CD4 counts, in one or more cross-sectional surveys of infected individuals [57]. This requires a representative sample of infected persons and detailed knowledge of how the marker evolves over time since infection, which may be more difficult to obtain than the incubation information required by back-calculation [37]. Mathematical epidemic modeling is used mainly to further qualitative understanding, and typically requires too detailed input to provide useful

quantitative results (*see* **Epidemic Models, Deterministic**; **Epidemic Models, Stochastic**).

Backward and Forward Shift Operators

The backward shift operator B is defined for time series X_t by

$$B^k X_t = X_{t-k}.$$

Similarly, the forward shift operator F is defined by

$$F^k X_t = X_{t+k}.$$

These operators provide a convenient notation for defining times-series models. For example, the first-order autoregressive process can be written as

$$X_t = \alpha B X_t + Z_t.$$

Treating B as if it were a constant, models may be manipulated using simple algebra. For example, the first-order autoregressive model can be rewritten as

$$X_t = \frac{Z_t}{1 - \alpha B} = (1 + \alpha B + \alpha^2 B^2 + \cdots) Z_t.$$

The general ARMA model of order p, q is given by

$$\Phi(B) X_t = \Theta(B) Z_t,$$

where

$$\Phi(B) = 1 - \alpha_1 B - \cdots - \alpha_p B^p$$

and

$$\Theta(B) = 1 + \beta_1 B + \cdots + \beta_q B^q.$$

Another useful aspect of the backward shift operator here is that it allows the conditions for **stationarity** and invertibility to be stated simply. The ARMA process, for example, is stationary if the roots of $\Phi(B) = 0$ lie outside the unit circle and it is invertible if the roots of $\Theta(B) = 0$ lie outside the unit circle.

Bacterial Growth, Division, and Mutation

> The problems of growth and division of cells lie in the very heart of biology [9].

Bacteria normally reproduce asexually, by binary fission. When organisms are introduced to a new environment, for instance by inoculation into a new growth medium, they undergo a *lag phase*, during which no growth takes place. When they have adapted to the new medium, they enter a so-called *logarithmic* phase, during which they reproduce with an approximately constant mean generation time, which may be as short as 20 minutes, leading to approximately exponential growth in the population size. In due course, the population reaches saturation level, with the depletion of nutrients and the accumulation of waste products, and there is an increasing proportion of nondividing and dying cells.

Models of cell growth and division in bacteria were considered more than 60 years ago (see [10] and [12]; reviewed by Harvey [7], Cooper [5], and Koch [16]). The evolution of models of bacterial growth was closely followed by development of models of the cell cycle in budding and fission yeast, cell cultures, and mammalian cells (*see* **Cell Cycle Models**). Many important biological hypotheses concerning the organization of the cell cycle and its effect on cell population dynamics were first tested in bacterial models, and were modified later for description of the eukaryotic cell-cycle. In some of these theoretical models new mechanisms have been hypothesized, which later have been confirmed in experiments on spontaneous and induced mutations, signal transduction pathways, cell cycle regulation, and programmed cell death. Thus, for many years, modeling of the bacterial cell cycle has been a "proving ground" for refinement of theoretical models in cell biology.

The major questions addressed in bacterial growth models have concerned:

1. stochastic and deterministic models of cell population dynamics (see reviews in [6] and [18]);
2. different models of the cell cycle in individual cells, such as growth control (review in [16]), random transition (review in [31]), and mitotic clocks [45];
3. generational dependence models such as continuum [5], supramitotic control [5, 34], multiple transitions [4, 31], and clonal inheritance [6];
4. cell-cycle regulation models [43, 44];
5. unequal cell-division models [13];
6. spontaneous mutation models and fluctuation tests (reviews in [24] and [25]).

Some of these models were derived by generalization of earlier bacterial models, though the majority of the models were designed for description of experiments with cell lineages and colony-forming assays and did not discriminate between bacterial and eukaryotic cells. Some of the bacterial models were later applied to the analysis of cancer cells, on the assumption of uncontrolled division of cancer cells which was widely accepted at the time (*see* **Tumor Growth**).

From the biological viewpoint such a generalization of bacterial models might not be justified, since there are significant evolutionary differences in organization of the cell cycle in prokaryotes and eukaryotes. However, as Nurse noted [27], many experiments suggest that cell-cycle control may be qualitatively similar in microbial cells and eukaryotic cells, and that a quantitative difference is due to a difference in the rates of cell progression through the deterministic and stochastic stages of the cell cycle.

Over five decades, bacterial models have evolved in diverse directions. We briefly review major directions of modeling which have provided important progress in the understanding of biological and mathematical aspects of cell growth, division and mutations.

Cell-Cycle Control Models

Several classes of empirical models of cycle control in individual cells have provided different answers to the problem of estimation of the generational time distributions (τ-distributions) in populations of dividing cells.

Early observations on cultured bacterial cell pedigrees [10] demonstrated significant variability of many observable parameters such as interdivisional times of individual cells, and growth rates of individual cells and clones. However, many models of exponentially growing bacterial colonies approximated this process in deterministic fashion. These models postulated that for large numbers of cells growing

with stable constant supply of nutrients, the variability of growth rates is not significant.

The *growth control model* (also referred to as a *size control model*) postulates that bacterial cells divide after a permissible size is reached [17]. Thus, the rate of cell division in this model is determined by the rate of cell growth. Variation of interdivisional times was assumed to be due to normally distributed fluctuations of duration of actual division. Direct implications of such postulates were that the size of bacteria at division should be constant, mother–daughter **correlation** of size and generation time should be equal to -0.5, and the correlation of sizes and generation times between sisters should be positive.

Deterministic models of growth control failed to reproduce many observations on exponentially growing cell cultures with constant concentration of substrate: namely, high variation of growth rates and colony sizes, and positive mother–daughter correlations. Later modifications of growth control models incorporated stochastic components, assuming variation of cell sizes as a result of unequal division. Such models were in better agreement with the observations [16].

Transition probability models were developed in the 1970s and 1980s as a result of pulse-labeling experiments in cell cultures [3, 4, 36]. Later modifications of the transition probability model included multiple random transitions and were also applied to bacterial and other cell cultures (see reviews by Rigney [31] and Staudte et al. [37]).

The transition probability model, originally proposed by Smith & Martin [36], postulates that the cell cycle is composed of two stages: A state and B phase. In the A state a cell does not progress to cell division, and it can transit to the B phase with constant probability. In the B phase a cell requires a constant time to complete division. The rate of division is determined by the random time period a cell spent in the A state and the constant time period in the B phase. The experimental support of this model came from findings of an exponential component in the distribution of cell-cycle times for many types of cells. The model accommodated a genetically predetermined constant duration of cell cycle, and variation of cell-cycle time as an effect of changes in the environment.

The mitotic oscillator model (also referred to as *internal clock* or *spontaneous oscillator*) was introduced in 1990 (reviews in [28] and [42]). It reflects new experimental data on the interaction of newly discovered protein complexes, MPF and cyclin [8]. Interactions between these complexes and associated protein kinase cdc2 drive cell-cycle progression by periodic changes of their enzymatic activity, operating as a spontaneous minimum oscillator [45]. The mitotic oscillator model incorporated these new data and reproduced oscillations which effectively defined duration of the cell cycle. This model demonstrated that experimentally identifiable molecular mechanisms can provide control of division in a deterministic fashion. This result was in support of the classical growth control model.

During recent years, more members of the cyclin protein family have been identified in yeast and mammalian cells [29], thus providing solid biological evidence in support of Nurse's idea of quantitative but not qualitative differences in cell-cycle organization of bacteria and eukaryotes [27]. These newly discovered cyclins are activated only during specific cell-cycle phases, and are deactivated at (or near) restriction points previously identified in transition probability models. This new biological evidence provides a solid ground for reconciliation of two major views, deterministic and stochastic, of the cell-division cycle in bacteria and mammalian cells [23, 26].

Spontaneous Mutation Models and Fluctuation Tests

Bacteria experience mutations of various types, which occur apparently randomly, with constant probability per cell division. For instance, a population growing from a single organism sensitive to a drug may, on reaching a population size of, say, 10^8, contain a number of resistant organisms, having descended from one or more cells that mutated during growth. In some instances, back-mutation may occur, from resistant to sensitive type. Mutation is, thus, a more random phenomenon than growth. Deterministic theories of mutating populations may be useful as broad descriptions of population dynamics, especially when population sizes are large. Many situations, though, are dominated by random variation, and stochastic theories are needed.

Deterministic Population Dynamics

Consider a mixed population of two forms of intermutating organisms, with x members of the wild-type X, and y members of the mutant type Y. Suppose the two strains have exponential growth rates a and b, respectively, and that the mutation rates (expressed as the proportion of new organisms which differ in type from the parent) are λ from X to Y, and ν from Y to X. The differential equations are easily solved. If the two growth rates are equal, the proportion of mutants in the population will approach asymptotically the value $\lambda/(\lambda + \nu)$.

Experiments to study the long-term development of a mixed population are hampered by the restrictions on the duration of the logarithmic phase of growth. These restrictions are overcome by experiments in continuous cultures, in which a liquid medium is continuously changed so as to provide the conditions for constant growth [41]. Long-term experiments, interpreted by the deterministic theory, provide rough estimates of the growth rate (and a check on the near-equality of growth rates for the two types), and of the two mutation rates [2, 35].

Stochastic Models

As noted earlier, the case for a stochastic treatment arises mainly because of the effects of random mutation, rather than to improve the description of bacterial growth. These effects are especially important in short-term experiments, such as *fluctuation tests* in which replicate cultures are grown from small inocula. In such an experiment, with replicate cultures grown to the same final population size, n, the proportion of mutant organisms is likely to be relatively small, and back-mutation can be ignored. The expected number of *mutations* (as distinct from *mutant organisms*) will be approximately $\mu = \lambda n$, and the numbers in different cultures should follow a **Poisson distribution** with mean μ. These numbers are not directly observable, because of the reproduction of mutant progeny, but what can be observed is the proportion of cultures with no mutants (and, hence, no mutations). This should be the zero term of the Poisson distribution, $e^{-\mu}$. This provides a simple way of estimating the mutation rate λ, since the total population size, n, can be estimated by standard methods.

Further information is provided by the distribution, between replicate cultures, of the number of mutant organisms per culture. This will clearly be extremely variable and highly skewed. A culture in which, by a rare chance, an early mutation occurred, will accumulate a large number of progeny descended from the first mutant. Most cultures will experience their first mutation much later, and the mutant progeny will be relatively few. Some features of the distribution were described by Luria & Delbrück [20], who conducted experiments on the resistance of *Escherichia coli*, strain B, to bacteriophage. They found highly skew distributions, of the type expected on mutation theory, and considered that their findings strongly supported the view that resistance was caused by mutation, rather than by some form of Lamarckian-like adaptation.

Luria & Delbrück assumed deterministic growth, at the same rate a for both strains, and obtained asymptotic expressions for the mean and variance of the number of mutants, Y, at time t, in replicates with initial size x_0:

$$\mathrm{E}(Y) = x_0 \lambda\, at \exp(at) = \lambda n \ln\left(\frac{n}{x_0}\right) \qquad (1)$$

and

$$\begin{aligned}\mathrm{var}(Y) &= x_0 \lambda \left[\exp(2at) - \exp(at)\right] \\ &= \frac{\lambda n (n - x_0)}{x_0}. \end{aligned} \qquad (2)$$

The dependence of (1) and (2) on x_0 is due to its effect only on the extreme upper tail of the distribution: the general shape of the distribution is unaffected. The **method of moments** is therefore a poor basis for inference about λ from the distribution of Y.

Lea & Coulson [19] derived a probability **generating function** for Y, now regarded as a discrete random variable:

$$G(\mu, z) = (1 - z)^{\mu(1-z)/z}. \qquad (3)$$

Eq. (3) can be derived under various assumptions, asymptotically for large n and small λ, and independently of x_0 [1].

Expansion of (3) gives the individual probabilities. For instance, the probabilities of 0 and 1 mutant are, respectively, $p_0 = e^{-\mu}$ (in agreement with the Poisson derivation), and $p_1 = (1/2)\mu e^{-\mu}$. Lea & Coulson provided tables of the distribution for selected values of μ up to 15. They also showed that a transformed

variable,

$$\chi = \frac{11.6}{y/\mu - \ln \mu + 4.5} - 2.02,$$

is approximately normally distributed with zero mean and unit variance.

Various methods of estimation from Lea & Coulson's distribution are described and illustrated by the authors and Armitage [2]. The use of the distribution is complicated by various possible deviations from the model.

Other models of mutations and several alternative methods of mutation rate estimation were introduced by Armitage [1], Mandelbrot [22], and Koch [15]. These models generalized the Luria & Delbrück model and the results of Lea & Coulson, and included the effects of phenotypic lag (that is, delay in detection of a mutant phenotype in clones), and differential fitness (difference in growth rates of mutant and wild-type cells) [1, 15].

Fluctuation analysis, as introduced by Luria & Delbrück, has been used in biological laboratories worldwide, and was adopted for the analysis of experiments with bacteria, yeast, and mammalian cells. Once again, bacterial models were applied to experimental conditions drastically different from the originally specified postulates of the Luria & Delbrück model (as had happened before with models of bacterial growth).

During the last decade a number of publications have provided a thorough revaluation of earlier mutation models and methods of mutational rate estimation [11, 30, 32, 33, 38, 40]. New models of mutation have taken into account reversible mutations and two-stage mutations. Several new computational methods were introduced for mutation rate estimation in mammalian cells [14, 32, 33, 39].

Mathematically interesting discussions of the Luria & Delbrück model have been published recently by Pakes [30], Stewart [39], and Nadas et al. [24, 25]. Many recent publications have pointed out that "certain mathematical artifacts had been appended by others to the Luria–Delbrück model" [24, 25], thus providing a source of confusion to the measurement of spontaneous mutation rates. Specifically Ma et al. [21] have pointed out, as noted by Armitage [1], that the Lea & Coulson approximation (3) has infinite mean and variance. As a mathematically sensible alternative several models have been proposed that avoid the infinite mean [33]. Some of them have adopted the **Galton–Watson** branching process [32]. A modification of fluctuation tests described by Nadas et al. [24, 25] allows one to estimate mutation rates using sufficiently large initial cell populations.

Bagging and Boosting

Introduction

The past decade has witnessed an explosion of machine learning papers and research. Given the large number of **algorithms** proposed and explored for classification and regression problems (*see* **Tree-structured Statistical Methods**), it is not surprising that methods that combine these algorithms have been proposed as well. Statisticians have employed prediction averaging in many settings. In **forecasting**, averaging different models is a common way to reduce the **variance** and the **bias** inherent in choosing a single model form. In the machine learning context, two ensemble methods called *bagging and boosting* have become popular for combining models.

Bagging

Bagging is an acronym for "*bootstrap aggregating*". First introduced by Leo Breiman in 1996 [2], bagging is simple to describe and to implement. Given a certain model form (like a classification tree, or a **linear regression**), take repeated **bootstrap** samples of the original data set, refitting the model each time. Each of these models will be slightly different, and the predictions at each point will vary from model to model. The "bagged" prediction for each point is an "average" over the predictions of all the models for that point.

More precisely, let the data set on which we will build the model be described by $\{(y_i, x_i), i = 1, \ldots, N\}$. This is the so-called *training set*. Now, suppose we have a model, f, whose prediction for the ith point is $f(x_i) = \hat{y}_i$. Call the set of predictions of all the data points $\{\mathcal{L}\}$. Take repeated bootstrap samples from the training set, each consisting of N cases as well, drawn with replacement from the original $\{(y_i, x_i)\}$. For each of these, refit the model $f^{(\mathrm{B})}$ and get a new set of predictions $\{\mathcal{L}^{(\mathrm{B})}\}$. Repeat this many times.

For a **classification** problem, we may want to predict the class of x_i. If there are j classes, each prediction will be a class $j \in \{1, \ldots, J\}$. For each case x_i, we will have many different predictions given by the successive bootstrapped data sets. The usual method for obtaining the "bagged" prediction is to let these different models "vote". Take the most frequent **modal** predicted class as the bagged prediction. For a regression problem, where the output of f is numeric, we use the same procedure, but take an average (or **median** or other averaging procedure) of the predictions.

The most common class of models used for bagging are decision trees (using classification or regression trees, depending on the form of the response). Leo Breiman's implementation of bagged trees are called "Random Forests" [3].

Because of the fact that it averages predictions across many bootstrapped samples, it seems logical that the bagged prediction reduces the prediction variance. This fact is demonstrated by Breiman [2]. Bagging works best on models that have inherently high variance. Of course, the amount of variance reduction and the resulting improvement in error rate are dependent on the data set and the model employed, but empirical studies have shown that variance reductions of 10 or even 20% are not uncommon (see [1]). Unfortunately, bagging appears to do little to reduce the bias, which is often a problem with small decision trees and other so-called weak learners.

Boosting

Boosting is also a method for combining an ensemble of predictions, but it does so in quite a different way from bagging. Again we start with a model f from which we get a prediction on the training data $\{(y_i, x_i), i = 1, \ldots, N\}$. In boosting, however, we reweight the data set depending on the performance of the model. The observations that are misclassified are given *higher* weights and the model is refit. This process is repeated many times. At the end, we have a succession of predictions from these various reweighted fits. The boosted prediction is a weighted "vote" of the outputs from these models, this time reweighted by the performance of the model. Boosting puts successively more importance on the misclassified data by increasing their weights, thus making the problems harder as the number of models increases.

Boosting has received a lot of attention, especially in the machine learning literature where it first appeared [4, 5, 10]. In its simplest form, it is used on classification problems, as originally described by Freund and Shapire [5]. To make things even simpler, we will describe the case of only two classes:

-1 or $+1$. Here is the original "Adaboost" algorithm from [5] as described by Friedman, Hastie, and Tibshirani in [8]:

1. Initialize training set using weights $w_i = 1/N$ for all i.
2. Repeat a, b, c for $m = 1, 2, \ldots .M$:
   a. Fit the model $f_m(x)$ using weights w_i. The output for each point is either -1 or $+1$.
   b. Compute the overall weighted error rate $e_m = \left(\sum w_i (f_m(x_i) \neq y_i)\right)/\sum w_i$ and the adjusted overall weighted error rate $c_m = \log((1 - e_m)/e_m)$
   c. Set $w_i = w_i \exp(c_m \times 1_{y_i \neq f_m(x_i)})$ and renormalize so that $\sum w_i = 1$.
3. The resulting output $f_b(x_i)$ for each point is a weighted average of the predictions of the each $f_m : f_b(x_i) = \text{sign}\left(\sum_m c_m f_m(x_i)\right)$.

(The function $1_{\{A\}}$ gives the value 1 if A is true; 0 otherwise.) The sign function is used at the final stage because each prediction is either -1 or $+1$. Thus, if the (weighted) majority of votes is positive, the boosted prediction is $+1$; otherwise it is -1. Other schemes can be used to combine the models when the number of classes is greater than 2, or the output is continuous. Notice that boosting used weighting twice. The model is refit each time with cases by whether they were correctly predicted or not, with misclassified cases receiving *higher* weights. For the final predictions, the results of all the models are averaged, but models with lower error rates are given higher weight.

In spite of the simplicity of the algorithm, the reason for its success in reducing both the bias and variance of the individual models remained mysterious for some time. A great deal of light was shed by Friedman, Hastie, and Tibshirani [8, 9] who showed that the Adaboost algorithm fits an additive model using a loss function that is well suited for classification. Armed with this insight, they suggest several variants of boosting for both classification and regression. A version using boosted decision trees called TreeBoost (and later Multiple Additive Regression Trees or MART) was proposed by Friedman [6, 7].

The reason why boosting reduces both the bias and variance of simple learning algorithms is still not completely understood. Nor is it clear exactly why boosting seems to avoid the problem of overfitting even though hundreds, or even thousands of successive models are fit. However, the empirical evidence is strong that in a great many data sets, boosting can substantially lower the overall error rate (e.g. see [1]). Like bagging, the final "model" obtained by boosting is not interpretable, because the predictions are obtained by averaging over many different models. However, in the case of boosted trees, some progress has been made for help in interpreting variable importance and the influence of the individual predictors [6].

Further Comments

Bagging and boosting share several properties. Both are used to improve the prediction accuracy of a class of models by creating a "committee" of models that then vote to combine their predictions. Bagging does so by resampling from the original data set while boosting successively focuses on the part of the data set that was not fit well. Because they combine predictions, both are useful for reducing variance of predictions when compared with individual model fits. Both appear to be resistant to overfitting in spite of the number of models that are created. Boosting appears to be able to reduce bias as well. They also share a disadvantage in that the final combined model is not interpretable. While an individual tree is rule-based and "explains" why it makes the predictions it does, the combined model simply takes a majority vote of a committee.

RICHARD DE VEAUX

Balanced Incomplete Block Designs

When evaluating treatment effects, it is often desirable to assign treatments randomly within homogeneous blocks of experimental units, thus eliminating the effect of differences between blocks when evaluating the differences between treatments (*see* **Blocking**). A **randomized complete blocks design** includes all treatments of interest within each block. In some circumstances, however, there are more treatments of interest than units available per block, so such a design is not possible. There are many naturally occurring blocks that contain limited numbers of experimental units. In some studies of the effect of innoculation on lesions in plants, each leaf may be a block and the two halves of each leaf are experimental units. Studies using twin pairs in humans as blocks are obviously limited to two units per block (*see* **Twin Analysis**). Studies of growth rates in animals often use litters as blocks, and there is a limited number of animals per litter. If two or more factors are crossed to form many blocks, there may be inadequate resources for measuring enough units for each block or combination of factors. A randomized block design with less than the full number of treatments in each block is an **incomplete block design**. If all pairs of treatments occur equally often, it is said to be a balanced incomplete block design (bibd).

The data from a bibd can be analyzed using standard **analysis of variance**. In a bibd, all pairwise treatment contrasts have equal efficiency, so this design is ideal when all pairwise contrasts are of equal interest. The effect of blocks, or interblock information, can also be analyzed from a bibd, although this is usually not of interest.

The concept of the bibd was originally proposed by **Yates** [18]. If there are a total of t treatments to be tested, then the total number of pairs of treatments is $\frac{1}{2}t(t-1)$. If only two units per block are available, then a bibd would assign each pair of treatments to an equal number of blocks; the number of blocks must then be some multiple of $\frac{1}{2}t(t-1)$. If there are $t-2$ units available in each block, then a complementary bibd arrangement is to delete each pair of treatments one at a time and assign the remaining $t-2$ treatments to each block; again, this would require the number of blocks to be some multiple of $\frac{1}{2}t(t-1)$. Yates provides bibd arrangements for different numbers of treatments, up to 10, and different numbers of units per block. He also outlines the standard **least squares** analysis and addresses issues of efficiency.

The standard notation for the parameters of a bibd design is (t, b, r, k, λ), where t is the number of treatments, b is the number of blocks, r is the number of replications of each pair of treatments, k is the number of experimental units per block, and λ is the number of replications of each pair of treatments. In order for the design to be balanced, the relationship $\lambda = r(k-1)/(t-1)$ must hold. A bibd is not possible, then, unless $r(k-1)/(t-1)$ is an integer. Following the initial work by Yates, there has been much attention to constructing more bibds. The problem is to find a set of parameters that satisfy the above condition, and to specify an appropriate arrangement of treatments within blocks given a set of values for the parameters. In the study of combinatorics, this problem is a special case of construction of tactical configurations. Bose [3] originally proposed the method of symmetric differences, which is an application of combinatoric methods to the construction of bibds. Further work on construction of bibds includes tables of specific arrangements or methods of constructing arrangements for different feasible combinations of parameter values [1, 5–11].

A nested balanced incomplete block design is a bibd with two systems of blocks, one nested within the other, such that ignoring either system of blocks leaves a bibd based on the remaining system of blocks. Nested bibds were originally proposed by Preece [12]. Preece provides several arrangements for such designs and gives the least squares equations for analysis. Singh & Dey [13] introduced the balanced incomplete block design with nested rows and columns, which adds yet another dimension to the blocking scheme, organized as rows and columns nested within the initial blocking system. Singh & Dey describe analysis of such designs and propose several arrangements. Further work has been done on construction of bibds with nested rows and columns [2, 4, 14–17].

SALLY FREELS

Ban Estimates

The BAN (best asymptotically normal) estimator is optimal in large samples in a similar way that the **Minimum Variance Unbiased (MVU) estimator** is in small samples. The concept was originally developed by Neyman [8] for parameter **estimation** in models involving the **multinomial distribution**. Suppose each of n randomly selected individuals can be assigned to $s+1$ mutually exclusive categories $C_0, C_1, \ldots, C_s$ with probabilities $\mu_0, \mu_1, \ldots, \mu_s$, where $\mu_0 + \mu_1 + \cdots + \mu_s = 1$. Let $\boldsymbol{\mu} = [\mu_1, \mu_2, \ldots, \mu_s]'$ denote the s-dimensional vector of parameters where μ_0 is determined by the constraint to sum to 1. Let $n_0, n_1, \ldots, n_s$ be the random variables representing the counts of individuals in the $s+1$ categories where $n_0 + n_1 + \cdots + n_s = n$. Let $\mathbf{y}_n = [y_1, y_2, \ldots, y_s]' = [(n_1/n), (n_2/n), \ldots, (n_s/n)]'$ denote the s-dimensional vector of sample proportions where $y_0 = n_0/n$ is determined by the constraint to sum to 1. The crucial feature for asymptotic results is the following:

$$\sqrt{n}(\mathbf{y}_n - \boldsymbol{\mu}) \to N_s[\mathbf{0}, \boldsymbol{\Sigma}(\boldsymbol{\mu})], \tag{1}$$

where $\text{var}(\mathbf{y}_n) = \boldsymbol{\Sigma}(\boldsymbol{\mu})/n$. These count data can be arranged in two-way, $\ldots$, k-way tables and are the subject of **categorical data analysis**. The arrangement of the counts into tables suggests various hypotheses, e.g. independence of row and column effects in a two-way **contingency table**. A hypothesis H can often be described by a set of *constraint equations*

$$\text{H: } \mathbf{f}(\boldsymbol{\mu}) = 0, \tag{2}$$

where f is a vector-valued function of dimension $r < s$ having differential $\mathbf{F}(\boldsymbol{\mu}) = \partial \mathbf{f}(\boldsymbol{\mu})/\partial \boldsymbol{\mu}$ satisfying certain regularity conditions.

From this point on we assume sufficient regularity conditions for the different mathematical operations to be defined and convergence results to hold. Except where noted, all results, regularity conditions, and technical details may be found in [1–3]. A standard approach of estimating μ given H is by **maximum likelihood**. Let $\boldsymbol{\mu}_{\text{E}} = \boldsymbol{\mu}_{\text{E}}(\mathbf{y}_n)$ denote the maximum likelihood estimator of $\boldsymbol{\mu}$ given H. Then $\boldsymbol{\mu}_{\text{E}}$ has the property of being consistent asymptotically normal (CAN)

$$\sqrt{n}(\boldsymbol{\mu}_{\text{E}} - \boldsymbol{\mu}) \to N_s(\mathbf{0}, \boldsymbol{\Sigma} - \boldsymbol{\Sigma}\mathbf{F}'(\mathbf{F}\boldsymbol{\Sigma}\mathbf{F}')^{-1}\mathbf{F}\boldsymbol{\Sigma}), \tag{3}$$

with *minimal* asymptotic covariance matrix:

$$\boldsymbol{\Sigma} - \boldsymbol{\Sigma}\mathbf{F}'(\mathbf{F}\boldsymbol{\Sigma}\mathbf{F}')^{-1}\mathbf{F}\boldsymbol{\Sigma}, \tag{4}$$

where $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\mu})$ and $\mathbf{F} = \mathbf{F}(\boldsymbol{\mu})$.

A CAN estimator with minimal asymptotic covariance matrix is *best*, and is referred to as BAN. The notion of *minimal* is based on the following order relationship among symmetric matrices: $A \leq B$ if $B - A$ is nonnegative definite. In practice, BAN estimators only exist subject to *regularity* conditions and are denoted RBAN. Therefore RBAN estimators are *regular* CAN estimators with *minimal* asymptotic covariance matrix. Maximum likelihood estimators are often difficult to compute and Neyman [8] showed that minimum Pearson χ^2, Neyman χ^2, and linearized Neyman χ^2 estimators are also RBAN [6]. RBAN estimators can also be obtained as the roots of certain linear forms [5].

General Multivariate Distributions

We now drop the assumption of the multinomial distribution. Let $x_1, x_2, \ldots, x_n$ be a random sample from an arbitrary s-dimensional multivariate distribution where $\text{E}(\mathbf{x}_i) = \boldsymbol{\mu}$ and $\text{var}(\mathbf{x}_i) = \boldsymbol{\Sigma}(\boldsymbol{\mu})$. Let $\mathbf{y}_n = (\mathbf{x}_1 + \mathbf{x}_2 + \cdots + \mathbf{x}_n)/n$ be the s-dimensional average of the random sample. Then $\mathbf{y}_n$ satisfies (1) and any estimator $\boldsymbol{\mu}_{\text{E}} = \boldsymbol{\mu}_{\text{E}}(\mathbf{y}_n)$ of $\boldsymbol{\mu}$ given (2) is RBAN if it satisfies (3). If $\boldsymbol{\mu}_{\text{E}}$ is any estimator of $\boldsymbol{\mu}$ and $\mathbf{f}(\boldsymbol{\mu}_{\text{E}}) = 0$, then $\boldsymbol{\mu}_{\text{E}}$ is said to be *admissible* (this is a term in the BAN literature not to be confused with the decision-theoretic meaning; *see* **Decision Theory**). An *admissible* RBAN estimator $\boldsymbol{\mu}_{\text{P}}$ may be obtained as the solution to the following equation:

$$\boldsymbol{\mu} = \mathbf{y}_n - \boldsymbol{\Sigma}\mathbf{F}'(\mathbf{F}\boldsymbol{\Sigma}\mathbf{F}')^{-1}\mathbf{F}(\mathbf{y}_n - \boldsymbol{\mu}), \tag{5}$$

where $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\mu})$ and $\mathbf{F} = \mathbf{F}(\boldsymbol{\mu})$.

Another *admissible* RBAN estimator that may be easier to compute is μ_{N}, the solution to the following equation:

$$\boldsymbol{\mu} = \mathbf{y}_n - \boldsymbol{\Sigma}_n\mathbf{F}'(\mathbf{F}\boldsymbol{\Sigma}_n\mathbf{F}')^{-1}\mathbf{F}(\mathbf{y}_n - \boldsymbol{\mu}), \tag{6}$$

where $\boldsymbol{\Sigma}_n = \boldsymbol{\Sigma}(\mathbf{y}_n)$ and $\mathbf{F} = \mathbf{F}(\boldsymbol{\mu})$.

If one is willing to sacrifice admissibility, then the following *closed-form solution* is RBAN (but not guaranteed to be admissible):

$$\boldsymbol{\mu}_{\text{N}^*} = \mathbf{y}_n - \boldsymbol{\Sigma}_n\mathbf{F}_n'(\mathbf{F}_n\boldsymbol{\Sigma}_n\mathbf{F}_n')^{-1}\mathbf{f}(\mathbf{y}_n), \tag{7}$$

where $\boldsymbol{\Sigma}_n = \boldsymbol{\Sigma}(\mathbf{y}_n)$ and $\mathbf{F}_n = \mathbf{F}(\mathbf{y}_n)$.

Eqs. (5) and (6) are in the form

$$\boldsymbol{\mu} = h(\boldsymbol{\mu}), \tag{8}$$

which together with (7) suggest an iterative solution for $\boldsymbol{\mu}_{\mathrm{P}}$ and $\boldsymbol{\mu}_{\mathrm{N}}$:

$$\boldsymbol{\mu}_{\mathrm{P}(i+1)} = h(\boldsymbol{\mu}_{\mathrm{P}(i)}), \tag{9}$$

with $\boldsymbol{\mu}_{\mathrm{P}(0)} = \boldsymbol{\mu}_{\mathrm{N}^*}$, where $\boldsymbol{\mu}_{\mathrm{P}(i)} \to \boldsymbol{\mu}_{\mathrm{P}}$, and

$$\boldsymbol{\mu}_{\mathrm{N}(i+1)} = h(\boldsymbol{\mu}_{\mathrm{N}(i)}), \tag{10}$$

with $\boldsymbol{\mu}_{\mathrm{N}(0)} = \boldsymbol{\mu}_{\mathrm{N}^*}$, where $\boldsymbol{\mu}_{\mathrm{N}(i)} \to \boldsymbol{\mu}_{\mathrm{N}}$.

RBAN estimators usually have associated χ^2 test statistics for the hypothesis H. With this in mind, define the following Pearson and Neyman χ^2 functions:

$$\chi^2_{\mathrm{P}}(\boldsymbol{\mu}) = n(\mathbf{y}_n - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{y}_n - \boldsymbol{\mu}), \tag{11}$$

where $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\mu})$,

$$\chi^2_{\mathrm{N}}(\boldsymbol{\mu}) = n(\mathbf{y}_n - \boldsymbol{\mu})'\boldsymbol{\Sigma}_n^{-1}(\mathbf{y}_n - \boldsymbol{\mu}), \tag{12}$$

where $\boldsymbol{\Sigma}_n = \boldsymbol{\Sigma}(\mathbf{y}_n)$.

If $\boldsymbol{\mu}_B$ is any RBAN estimator, then the following hold:

$$\chi^2_{\mathrm{P}}(\boldsymbol{\mu}_B) \to \chi^2(r) \tag{13}$$

and

$$\chi^2_{\mathrm{N}}(\boldsymbol{\mu}_{\mathrm{B}}) \to \chi^2(r), \tag{14}$$

where r is the dimension of $\mathbf{f}$.

Multivariate Exponential Family Distributions

Let $x_1, x_2, \ldots, x_n$ be a random sample from the s-dimensional multivariate **exponential family** [4] with probability density function (pdf) of the form:

$$p(\mathbf{x}|\boldsymbol{\theta}) = h(\mathbf{x}) \exp[\mathbf{x}'\boldsymbol{\theta} - q(\boldsymbol{\theta})]. \tag{15}$$

This family includes the s-variate multinomial, s-variate negative multinomial, s-variate Poisson, and s-variate logarithmic series among others. Let $\mathbf{y}_n = (\mathbf{x}_1 + \mathbf{x}_2 + \cdots + \mathbf{x}_n)/n$ be the s-dimensional average of the random sample. Then $\mathbf{y}_n$ satisfies (1), where $\mathrm{E}(\mathbf{x}_i) = \boldsymbol{\mu}$ and $\mathrm{var}(\mathbf{x}_i) = \boldsymbol{\Sigma}(\boldsymbol{\mu})$. Therefore all the results of the previous section apply. In addition, we have the following equivalence:

$$\boldsymbol{\mu}_{\mathrm{P}} = \text{maximum likelihood estimator}, \tag{16}$$

$$\chi^2_{\mathrm{P}}(\boldsymbol{\mu}_{\mathrm{P}}) = \text{Rao's efficient score statistic}, \tag{17}$$

$$\chi^2_{\mathrm{N}}(\boldsymbol{\mu}_{\mathrm{N}^*}) = \text{Wald statistic} \tag{18}$$

(*see* **Likelihood**). The above RBAN estimation and test criteria therefore reduce to familiar methods for the multivariate exponential family.

Sum Symmetric Power Series (SSPS) Distributions

A special case of the s-variate exponential family is the SSPS family of distributions [7] for count data which include the s-variate multinomial, s-variate negative multinomial, and s-variate Poisson. For this family the s-variate vector $\mathbf{x}$ from (15) has the structure $\mathbf{x} = [n_1, n_2, \ldots, n_s]'$, where the n_i represent count data (i.e. nonnegative integers). For the SSPS family the functions (11) and (12) have the familiar form of the Pearson χ^2 and Neyman χ^2 for multinomial data:

$$\begin{aligned}\chi^2_{\mathrm{P}}(\boldsymbol{\mu}) &= n(\mathbf{y}_n - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{y}_n - \boldsymbol{\mu}) \\ &= \sum_i \frac{(n_i - n\mu_i)^2}{(n\mu_i)},\end{aligned} \tag{19}$$

$$\begin{aligned}\chi^2_{\mathrm{N}}(\boldsymbol{\mu}) &= n(\mathbf{y}_n - \boldsymbol{\mu})'\boldsymbol{\Sigma}_n^{-1}(\mathbf{y}_n - \boldsymbol{\mu}) \\ &= \sum_i \frac{(n_i - n\mu_i)^2}{(n_i)},\end{aligned} \tag{20}$$

where $\sum_i$ represents the summation for $i = 0, 1, \ldots, s$, and μ_0 and n_0 have special definitions based on constraints. The constraints for the multinomial were $\mu_0 + \mu_1 + \cdots + \mu_s = 1$ and $n_0 + n_1 + \cdots + n_s = n$. Constraints in the other cases are described in [1].

Return to the Multinomial Distribution

Because the multinomial distribution is a special case of the SSPS family, the general RBAN estimation and test criteria that we developed reduce to familiar

forms for the multinomial distribution:

$$\boldsymbol{\mu}_{\mathrm{P}} = \text{maximum likelihood estimator}, \quad (21)$$

$$\boldsymbol{\mu}_{\mathrm{N}} = \text{minimum Neyman } \chi^2 \text{ estimator}, \quad (22)$$

$$\boldsymbol{\mu}_{\mathrm{N}^*} = \text{linearized minimum Neyman } \chi^2 \text{ estimator}, \quad (23)$$

$$\chi^2_{\mathrm{P}}(\boldsymbol{\mu}_{\mathrm{P}}) = \text{Pearson } \chi^2 \text{ test statistic}, \quad (24)$$

$$\chi^2_{\mathrm{N}}(\boldsymbol{\mu}_{\mathrm{N}}) = \text{Neyman } \chi^2 \text{ test statistic}, \quad (25)$$

$$\chi^2_{\mathrm{N}}(\boldsymbol{\mu}_{\mathrm{N}^*}) = \text{linearized Neyman } \chi^2 \text{ test statistic}. \quad (26)$$

Other Directions

The results in the section on general multivariate distributions hold if $\mathbf{y}_n$ is composed of averages of multiple independent random samples. They also hold if $\mathbf{y}_n$ is an arbitrary random vector (not necessarily an average) that satisfies (1). Similar results hold if the hypothesis H in (2) is expressed in other ways. *Constraint equations* are the most general form, but it may be more natural to express H in the form of *freedom equations* $\boldsymbol{\mu} = g(\boldsymbol{\beta})$, where $\boldsymbol{\beta}$ is of dimension r. Another way to model H is $d(\boldsymbol{\mu}) = e(\boldsymbol{\lambda})$ or as a special case the **general linear model** $d(\boldsymbol{\mu}) = X\lambda$ for design matrix X. These situations and their RBAN estimates and test criteria are covered in [2].

KERRY G. BEMIS

Barahona–Poon Test

The Barahona–Poon test is used to detect nonlinear dynamics in time series (*see* **Nonlinear Time Series Analysis**). Nonlinear dynamical systems may generate deterministic signals, which can be easily mistaken for random noise. Distinguishing nonlinear deterministic dynamics, or "**chaos**", from random noise helps understand the physical process generating the data, and may improve short-term prediction (*see* **Forecasting**). In practice, however, identifying nonlinear dynamics is difficult because methods to detect chaos are often degraded by measurement noise, and need long data sets. The test proposed by C. S. Poon and M. Barahona is particularly suitable to detect chaos in short and noisy time series [1], typical of biological studies where nonstationarities limit the length of the observations [3]. The method compares linear and nonlinear models fitted to the data, and rejects the **null hypothesis** (i.e. that the time series is stochastic with linear dynamics) if at least one nonlinear model is significantly more predictive than all the linear models considered.

The technique is based on modeling the time series $y(n)$ $(n = 1, \ldots, N)$ as the output of a discrete Volterra series of nonlinear degree d and memory k. The predicted value of the series at time n, $y_{d,k}(n)$, is calculated as:

$$\begin{aligned} y_{d,k}(n) = {} & a_0 + a_1 y(n-1) + a_2 y(n-2) \\ & + \cdots + a_k y(n-k) + a_{k+1} y(n-1)^2 \\ & + a_{k+2} y(n-1) y(n-2) \\ & + \cdots + a_{M-1} y(n-k)^d \end{aligned} \tag{1}$$

When $d = 1$, $y(n)$ is simply modeled by an autoregressive linear equation of order k (*see* **ARMA and ARIMA Models**). The $M = (k+d)!/(k!d!)$ coefficients a_m, corresponding to all the combinations of $y(n-i)$ $(i = 1, \ldots, k)$ up to degree d, can be estimated from the data by a fast **algorithm** [2]. The one-step prediction power of each model, $\varepsilon^2_{d,k}$, is:

$$\varepsilon^2_{d,k} = \frac{\displaystyle\sum_{n=1}^{N} (y_{d,k}(n) - y(n))^2}{\displaystyle\sum_{n=1}^{N} (y(n) - \overline{y})^2} \tag{2}$$

where $\overline{y} = \sum_{n=1}^{N} y(n)/N$. Thus $\varepsilon^2_{d,k}$ is the variance of the prediction errors normalized by the variance of the time series.

First, one fixes the total dimension M. Then the best linear model is found by setting $d = 1$ in (1), and by iteratively increasing k from 1 to M. At each step k, a cost function is defined as

$$\mathrm{C}(r) = \log(\varepsilon_{d,k}) + \frac{r}{\mathrm{N}} \tag{3}$$

where r is the number of polynomials in the truncated Volterra series. The best linear model is the one minimizing $\mathrm{C}(r)$. To find the best nonlinear model, $\mathrm{C}(r)$ is computed again for $d > 1$ and for increasing values of k up to $r = M$. Similarly, the best nonlinear model is the one with the lowest $\mathrm{C}(r)$. The presence of "chaos" is indicated by a cost function lower for the best nonlinear model than for the best linear one. In this case, an objective statistical criteria is applied to reject the null hypothesis that nonlinear models are no better than linear models. For Gaussian prediction errors, the F-test is used to reject, with a certain level of confidence, the hypothesis that ε^2 is the same for the best linear and nonlinear model. Alternatively, the nonparametric **Wilcoxon–Mann–Whitney** rank-sum statistic is used.

PAOLO CASTIGLIONI

Barnard, George Alfred

Born: Walthamstow, UK; 23 September, 1915
Died: Brightlingsea, UK; 30 July, 2002

Barnard was born of working-class parents in suburban London and from the local school gained a scholarship to St. John's College, Cambridge, graduating in mathematics. From 1937 to 1939, he held a postgraduate award at Princeton University, USA, mainly studying mathematical logic. The war saw a return to England and a post with an engineering firm, displaying in the move a versatility that embraced theory and practice, a feature that remained with him throughout his life. In 1942, he joined the Ministry of Supply in a group dealing with production problems. There his serious interest in statistics began, to be continued at Imperial College London from 1945 until 1966, when he moved to the University of Essex, retiring in 1975. His retirement years were partly spent at other universities, especially that at Waterloo, Canada, but he kept up a lively correspondence with colleagues throughout the world. His political activities at Princeton resulted in his being refused a US visa for many years. He had the most engaging personality, perhaps shown at its best in debate where the author had the feeling that Barnard wanted to get at the truth, not just to defend his own position.

Barnard made major contributions to the basic ideas of statistics. He supported the **Bayesian** position in **inference**, restricting its use to cases where there existed prior knowledge that could be expressed in terms of probability, and in decision making where losses could be quantified (*see* **Decision Theory**), for example, in **quality control**. In cases where prior knowledge of this type was not available, he advocated methods based on **likelihood**; but he also felt there were cases where even a likelihood was not available and he would use tail-area significance tests (*see* **Hypothesis Testing**). He was an eclectic, but one whose reasons for using a tool were always clear. He was a great admirer of **R.A. Fisher** and was one of the very few people who could dispute with the great man without a touch of sycophancy.

He may have been the first to introduce the concept of conjugate distributions into the Bayesian canon, referring to them as distributions closed under sampling (*see* **Exponential Family**). In the field of likelihood, he was a pioneer, being the first to recognize the **likelihood principle**, this in 1947. He put likelihood inference onto an axiomatic basis [1] and produced, with Jenkins and Winsten, a seminal paper [2], which provided further support for the likelihood concept, applying it to many important statistical models. Both papers are still worth reading. As a consequence of understanding gained there, he was an advocate of the idea that, in most circumstances, the stopping rule was irrelevant to inference; an idea that has still not found general acceptance (*see* **Sequential Analysis**). He also advocated the method of pivots, where a function of parameter and data can be found having a known distribution, so that the data density can be transferred to provide one for the parameter.

It was not just the foundations that interested him: he was also concerned with the practical uses of statistics, for example, the British standard for condoms was largely written by him. A conversation with him could extend from the relevance of Gödel's theorem in inference to the design of schemes for industrial inspection, where he introduced the cumulative-sum (or cusum) chart (*see* **Quality Control in Laboratory Medicine**). He wrote on a great variety of practical problems acting, in his own words, as a midwife between the data and the decision. He was awarded the Deming medal of the American Association of Quality Control in 1991.

He was president of three societies, Operations Research, Institute of Mathematics and its Applications, and the **Royal Statistical Society**. Each of the presidential addresses is marked by the great breadth of subject matter, coming both from his mathematical interests and his experiences in serving on committees. He was a member of the University Grants Committee from 1967 to 1972, concerned with government funds for British universities and with the problem of allocating students to universities, taking into account the preferences of both applicant and faculty. He chaired the Computer Board and was, in 1970, an early advocate of extensive computer facilities in universities for which he was criticized by both academics and the press. He had the satisfaction of living to see his ideas accepted.

Barnard had a delightful personality and was very popular. His politics were to the left and he had a reasoned dislike of religions, so that he was never an establishment type of person. The book edited

by S. Geisser et al. [3] is a collection of essays in his honor and contains a complete bibliography of his works up to then. Unfortunately, he never wrote a book.

DENNIS V. LINDLEY

Bartlett, Maurice Stevenson

Born: June 18, 1910, in London, UK.
Died: January 8, 2002, in Exmouth, UK.

Maurice Bartlett was the leading figure amongst British statisticians starting their careers in the 1930s. He published important work at an early age and remained active throughout his life. He made important contributions to statistical inference and methodology and was a pioneer in the development of the theory of stochastic processes. His interest in biological and medical applications led to important work in factor analysis, mathematical epidemiology, and the spatial analysis of field experiments.

Maurice Stevenson Bartlett was born in Chiswick, London. He said that his lifelong interest in probability began in school with the chapter in Hall and Knight's *Algebra*. In 1929, he was awarded a scholarship to Queens' College, Cambridge where he read mathematics. Whilst an undergraduate, he published a paper with John Wishart on **moment** statistics, and he went on to achieve first-class honors with distinction. He enrolled as a graduate student under Wishart, publishing with him a second paper, and received the Rayleigh Prize in 1933. As an aside from statistics, he attended lectures on physics by Eddington and Dirac, thus starting a lifelong interest in theoretical physics.

In 1933, he was appointed Assistant Lecturer in statistics at University College London, under **E.S. Pearson**. This was the center of academic statistics in England at the time: also at University College were **R.A. Fisher**, J.B.S. Haldane, and **J. Neyman**, with all of whom Bartlett would have made contact. But he stayed there only one year, for in 1934, he was appointed to the post of statistician at an agricultural research station of the Imperial Chemical Industries (ICI). This brought him more forcibly into the world of applied statistics, which he relished. His publications during the next four years ranged widely over areas of science well beyond the confines of agriculture and chemistry: the theory of inbreeding, the estimation of intelligence, **factor analysis**, field and laboratory sampling errors, cotton production, and nutrition. Methodological topics included the effect of nonnormality on **Student's *t* distribution**, important results on **sufficiency**, **marginal** and **partial likelihood**, the eponymous **Bartlett's Test** for homogeneity of variance, multiple regression, and **interactions** in **contingency tables**.

In 1938, Bartlett was appointed to a lectureship at Cambridge, in the Faculty of Mathematics rather than that of Agriculture to which statistics had hitherto been attached. In 1940, after the onset of war, he was assigned to an establishment of the Ministry of Supply concerned with the development of rocket batteries, and he divided his time between London and a testing station in Wales. During this period, he worked with other statisticians including F.J. Anscombe, D.G. Kendall, and P.A.P. Moran, and a later meeting with J. Moyal helped to stimulate his growing interest (shared with Kendall) in **stochastic processes**.

Bartlett returned to Cambridge in 1946, concentrating his research on **time series**, **Brownian motion, and diffusion processes**. An important by-product of the latter topic was a 1946 paper on the large-sample theory of **sequential** tests, reproducing many of Wald's results by a different route. He was invited to visit the University of North Carolina at Chapel Hill for four months, where he lectured

on stochastic processes, producing a set of notes, which he used for a repeat of the course on his return to Cambridge and as the basis for his later book. He joined D.G. Kendall and Moyal in a historic three-paper symposium on stochastic processes at the **Royal Statistical Society** in 1949, and in 1955, he published his important book *An Introduction to Stochastic Processes.* This was highly influential in expounding the subject to a wider audience and in making available operational methods for pursuing further research in stochastic processes.

In 1947, Bartlett moved to Manchester to occupy the Chair in Mathematical Statistics, where he enjoyed the company of an outstanding group of mathematicians and developed new courses in the undergraduate and graduate statistics programmes. He became interested in the mathematical modeling of epidemics, especially in the study of measles where the periodicity of measles epidemics could be explained in part by a stochastic model, whereas the corresponding deterministic model predicted a steady endemic state (*see* **Epidemic Models, Deterministic**; **Epidemic Models, Stochastic**). His book *Stochastic Population Models in Ecology and Epidemiology* appeared in 1960.

In 1960, Bartlett was appointed to the Chair in Statistics at University College London in succession to Egon Pearson. He continued to publish widely on topics including stochastic processes, time series, **multivariate analysis**, spatial analysis, and statistical physics. A book of *Essays in Probability and Statistics* appeared in 1962.

Bartlett's final academic move, in 1967, was to Oxford, where a new Chair of Biomathematics, with a Fellowship at St. Peter's College, had been created as a successor to posts previously held by D.J. Finney and N.T.J. Bailey. Bartlett regarded this somewhat surprising move as a challenge, hoping to stimulate and contribute to the development of mathematical and statistical modeling in biology and medicine. Although the department was in the Biology faculty, Bartlett found the biologists less enthusiastic about his plans than the mathematicians. Nevertheless, he continued his researches in population biology and revived an interest in the spatial models for field experiments studied by Papadakis in 1937. He published *Probability, Statistics and Time* in 1975 and *The Statistical Analysis of Spatial Pattern* in 1976.

During the academic year 1973–1974, and on two occasions after retirement, he visited the Australian National University. Retirement in no way diminished his interest and productivity in a wide range of topics, now including new ones such as **chaos theory**. The volume of selected papers [1] lists 167 papers and 12 letters to *Nature* published by 1989.

As Peter Whittle remarked in an obituary in the *Independent* newspaper, "Bartlett was no self-publicist; both his written and his spoken exposition verged on the terse." Nevertheless, the authority with which he wrote and spoke was self-evident, as was his generosity and goodwill. His younger colleagues and research students received many acts of kindness, and regarded him with great affection.

Bartlett became a Fellow of the Royal Society in 1961 and an Honorary Member of the **International Statistical Institute** in 1980. He served as President of the Manchester Statistical Society (1959–1960), the British Region of the **International Biometric Society** (1964–1966), the Association of Statistics in the Physical Sciences (1965–1967) and the **Royal Statistical Society** (RSS) (1966–1967), and was a Silver and Gold **Guy** Medallist of the RSS. He received the Weldon Prize and Medal of the University of Oxford in 1971 and was elected a Foreign Associate of the US National Academy of Sciences in 1993.

A fuller account of Bartlett's career and a sensitive appreciation of his personality are contained in the obituary notice by Joe Gani [2], who summarizes as follows: "He was profoundly dedicated to research and scholarship, achieving his life's work with exemplary modesty, integrity and humanity."

PETER ARMITAGE

Bartlett's Test

For testing the equality of **variances** of k **normal** populations, Bartlett's modified **likelihood ratio test** statistic is given by T/C, where

$$T = \sum_{i=1}^{k} (n_i - 1) \ln \left[\frac{s_{\mathrm{p}}^2}{s_i^2} \right],$$

$$C = 1 + \frac{1}{3(k-1)} \left\{ \left[\sum_{i=1}^{k} \left(\frac{1}{n_i - 1} \right) \right] - \frac{1}{N-k} \right\},$$

$n_1, \ldots, n_k$ are the sample sizes of the k independent samples, $N = \sum n_i, s_1^2, \ldots, s_k^2$ are the respective unbiased sample variances with denominators $n_i - 1$, and $s_{\mathrm{p}}^2 = (N-k)^{-1} \sum_{i=1}^{k} (n_i - 1) s_i^2$ is the pooled sample variance.

For normal data and even quite small sample sizes (say, $n_i \geq 5$), T/C may be compared with critical values of χ_{k-1}^2, the **chi-square distribution** with $k-1$ **degrees of freedom**. If desired, exact critical values for T/C are available for certain sample sizes (e.g. [7]), or they may be obtained simply by **Monte Carlo** methods. It hardly seems worth the effort, though, since even a slight departure from the normal data assumption will make type I error probabilities (*see* **Level of a Test**) deviate from the nominal level by much more than that caused by using the asymptotic χ_{k-1}^2 critical values in place of exact ones.

Bartlett [1] proposes T/C as a modification of the usual asymptotic form of the normal likelihood ratio statistic $T^* = -2 \ln L$. First he replaces n_i by $n_i - 1$ and puts the **unbiased** s_i^2 in place of the biased form of the sample variances (which arise naturally in normal maximum likelihood estimation). This modification converts T^* to T. Equipped with exact critical values, the resulting test based on T for normal data is unbiased, whereas the test based on T^* is biased. Bartlett then notes that, under the null hypothesis of equal variances, $\mathrm{E}(T) = (k-1)C$ to order $O(n_i^{-3})$ and thus that T/C converges more rapidly to a χ_{k-1}^2 random variable than does T by itself. This type of correction is generally called "Bartlett's correction" and has been the focus of much research.

Bartlett's test has been extended to the multivariate case (see [10, Chapter 8] and [11, Chapter 7]) and to designed experiments [12].

Unfortunately, Bartlett's test is very sensitive to nonnormality. This can be seen by noting that under the null hypothesis of equal variances T/C converges to $(1/2)(\beta_2 - 1)$ times a χ_{k-1}^2 random variable as sample sizes grow large, where β_2 is the fourth moment **kurtosis** coefficient which is equal to 3 for the normal distribution. For example, in [3, Table 1] we find that if $\beta_2 = 5$ and $k = 2$, then the approximate level of a nominal $\alpha = 0.05$ test is $\Pr(2\chi_1^2 > 3.84) = 0.166$. If $k = 5$, then the level jumps to $\Pr(2\chi_4^2 > 9.49) = 0.315$ and gets worse as k increases.

Many investigators feel that this extreme sensitivity to nonnormality is unacceptable. Thus, more robust methods have been proposed including adjustment of critical values for T/C by estimating β_2 [4, 8], **analysis of variance** (ANOVA) on absolute deviations from means [9] and from medians [5], and **bootstrap** estimation of critical values for T/C [2]. Monte Carlo comparisons of procedures are given in Conover et al. [6] and Boos & Brownie [2]. In terms of simplicity and robustness, the ANOVA on absolute deviations from medians is a good alternative to Bartlett's test when normality is in doubt.

Baseline Adjustment in Longitudinal Studies

The word *baselines*, as used in connection with longitudinal studies, may mean one of three things. First, it can be applied to *demographic characteristics* of the patient, which are either unchanging (such as sex), or which change slowly (such as height) or at the same rate (such as age), for all subjects during the course of the study. Secondly, it can mean *true baselines*: measurements taken at some earlier moment (perhaps prior to treatment) of the same variable which is to be used as a measure of outcome. Thirdly, it can indicate *baseline correlates*: measurements taken at an earlier moment than that which will be used to judge the outcome of the study, but not on the same variable (although correlated with it), but which may vary strongly during the course of the study.

At first sight, these three types of baseline seem to be quite different, but from the point of view of many powerful approaches to analyzing data (for example **analysis of covariance**), there is no essential distinction between them, and the common tendency to regard the second sort as being capable of a special use for which the others are not available, i.e. to judge the ability of treatment to effect a change, is false [17]. Nevertheless, except where otherwise specified, it will be implicitly assumed below that the second sort of baseline is being referred to.

The Randomized Trial

Analysis of Covariance

Consider the case of a randomized parallel group **clinical trial** in which outcome measures at the end of the trial are available for both treatment and control groups and baseline measurements prior to treatment have been taken also. Suppose that measurements on patients in the treatment group are X_{ti} (baselines) and Y_{ti} (outcomes), $i = 1$ to n_t. Similarly, let the corresponding measurements in the control group be X_{ci} and Y_{ci}, $i = 1$ to n_c, and define

$$q = \left(\frac{1}{n_t} + \frac{1}{n_c}\right).$$

Suppose that the variance–**covariance matrix** in the two groups is identical and equal to

$$\mathbf{\Sigma}_{x,y} = \begin{bmatrix} \sigma_x^2 & \rho\sigma_x\sigma_y \\ \rho\sigma_x\sigma_y & \sigma_y^2 \end{bmatrix}.$$

Sometimes the further assumption is made that $\sigma_x = \sigma_y$. Although this may frequently be approximately true, there is no particular reason why this assumption should be valid in general, especially since patients are often selected for entry into clinical trials on the basis of baseline measurements.

If the baselines are ignored altogether, then the effect of treatment may be estimated using raw outcomes only as $\hat{\tau}_{raw} = \overline{Y}_t - \overline{Y}_c$ with variance $\text{var}(\hat{\tau}_{raw}) = q\sigma_y^2$. A popular alternative way to analyze such a trial is to construct so-called *change scores*, $Z_{ti} = Y_{ti} - X_{ti}$ and $Z_{ci} = Y_{ci} - X_{ci}$ and define the treatment estimator $\hat{\tau}_{change} = \overline{Z}_t - \overline{Z}_c$ with $\text{var}(\hat{\tau}_{change}) = q\sigma_z^2 = q(\sigma_y^2 + \sigma_x^2 - 2\rho\sigma_x\sigma_y)$. An alternative, but equivalent representation of the change score estimator is as $\hat{\tau}_{change} = (\overline{Y}_t - \overline{Y}_c) - (\overline{X}_t - \overline{X}_c)$. A more general estimator of the treatment effect is given by $\hat{\tau}_\beta = (\overline{Y}_t - \overline{Y}_c) - \beta(\overline{X}_t - \overline{X}_c)$, with variance which may be written as

$$\text{var}(\hat{\tau}_\beta) = q[(\beta\sigma_x - \rho\sigma_y)^2 + (1 - \rho^2)\sigma_y^2]. \qquad (1)$$

The covariance of this estimator with the difference at baseline is

$$\text{cov}_{\hat{\tau},\text{base}} = q(\rho\sigma_x\sigma_y - \beta\sigma_x^2). \qquad (2)$$

The raw outcomes and change-score estimator can be regarded as special forms of the general estimator with β equal to 0 and 1, respectively.

Thus, these three treatment estimators can be seen merely as ways of adjusting the observed difference at outcome using the baseline difference. The first simply relies on the fact that in a randomized trial, in the absence of a difference between treatments, the expected value of the mean difference at outcome is zero. Hence, the factor by which the observed outcome needs correcting, in order to judge the treatment effect, is also zero. The second corresponds to the assumption that the difference at outcome, in the absence of a treatment effect, is expected to be the difference in the means of the baselines. This naive assumption is, in fact, false [2, 6, 15, 18]. The third allows for a more general system of predicting what the outcome difference would have been in the

absence of any treatment effect as a function of the mean difference at baseline.

Analysis of covariance corresponds to choosing a suitable value for β. There are two standard motivations that lead to an equivalent result. The first finds the value of β that minimizes (1) and the second finds the value of β that sets (2) to zero. By inspection of (1) and (2), it is obvious that the value of β that does this is $\beta' = \rho\sigma_y/\sigma_x$ and that the resulting variance is then

$$(1 - \rho^2)\sigma_y^2. \tag{3}$$

β' is the regression of Y on X and this adjustment is known as *analysis of covariance*. It is quite general and can be used for baseline variables of the first and third type discussed above and not just of the second. In practice the **nuisance parameters** ρ, σ_x, and σ_y are unknown and the regression coefficient, β', has to be estimated and the (slight) nonorthogonality observed in nearly all trials means that the expected variance of the treatment estimate is slightly higher than given by (3).

These considerations generalize readily to the case where we have multiple outcomes and baselines. A simple and attractive computational solution is to use appropriate summary measures based on the outcomes (*see* **Summary Measures Analysis of Longitudinal Data**) and adjust these using either multiple baselines or some summary of them in an analysis of covariance. Some good practical advice has been given in [10] and also in [8].

Red Herrings

It is important to note that since analysis of covariance produces both the minimum variance estimator and the estimator which is uncorrelated with the baseline difference, other approaches are deficient in this respect. For example, using the change score alone does not, in fact, deal with the problem of chance imbalance in the baselines, since the change score is correlated with the baselines. Indeed, if the correlation is very low, then it may even produce a higher variance than using the raw outcomes alone.

It is also sometimes argued that clinical relevance may decide the toss between these approaches, but this is just nonsense. All these approaches measure the same thing, and indeed, for a trial in which baseline values are perfectly balanced, give exactly the same answer. Furthermore, because it has the smaller variance, a covariance adjusted estimator from a given trial would actually be expected to predict the change score estimator in a subsequent trial better than the change score estimator itself! Note also, as has been nicely shown by Laird, that adjusting the change scores using analysis of covariance gives exactly the same answer as adjusting the raw scores [9].

Errors in variables [4] also do not affect the validity of analysis of covariance, which can simply be seen as a means of incorporating what is known into the analysis [14, 15]. For example, where no baselines have been measured, using raw outcomes is valid because there is no baseline information to condition on, a fact which will then properly be reflected in the high variance of the treatment estimate. Where baselines have been observed, these observations can be used to decrease the variance of the treatment estimate and to adjust for any chance imbalance. But any chance imbalance observed is a chance imbalance in the observations, and this is what must be adjusted for.

A final point of some confusion is whether one should be interested in estimating a trend or an average. Where there is a single outcome measure, there is essentially no distinction, because, as has already been explained, adjusting the trend measure $Y - X$ for X gives exactly the same result as adjusting the outcome measure Y for X [9]. Where a series of outcome measures is made at different time points, however, a different treatment estimate is possible at each of these time points. To the extent that such separate estimates are made, there is again no distinction between the two approaches. However, a series of such independent estimates may miss the opportunity to make a powerful summary, and if it is decided therefore to do this, inevitably the choice of a suitable summary arises. Appropriate choice depends on the way in which the treatment effect grows over time. For example, regular therapy with a beta-agonist in asthma is likely to produce a near constant bronchodilation over time and hence a mean outcome measure is suitable. However, hormone replacement therapy in osteoporosis may have an effect on bone mineral density which increases with time so that some sort of slope estimate is appropriate. If the choice can be made on the basis of suitable prior information, then it avoids the difficulties to which data-dependent choices are liable. Contrary to what

is sometimes claimed, however, the choice does not depend directly on the way in which outcomes change for individual subjects, since these may be affected by strong (but irrelevant for causal purposes) secular trends.

Testing for Baseline Balance

A rather foolish but common use which is made of baselines is to check that the groups in a randomized clinical trial are "balanced" [1, 3, 13, 16]. A significant result, however, can only mean either that a type I error has been committed or that the **randomization** mechanism itself is flawed. However, where a significant result is found, trialists are generally most reluctant to impugn the conduct of the trial itself and instead treat the result as being the result of a randomly bad allocation. However, **hypothesis tests**, if they are to be used at all, should be used to test hypotheses, not to describe samples. For these and other reasons, whereas such tests of baseline balance might form a legitimate part of data monitoring and quality control, they should not form part of a general strategy of analyzing clinical trials and, in particular, should not be used to decide whether or not to use analysis of covariance [16].

Adjusting for Baselines Taken After the Start of Treatment

Adjusting for late baselines, whether by analysis of covariance or by simple change scores, can be extremely misleading since the treatment effect will be adjusted by a "baseline" difference which may itself reflect the effect of treatment, thus attenuating the final estimate. In the context of survival analysis this controversial topic goes by the name of **time-dependent covariates**. Wherever such adjustments are made, one should be extremely careful in interpreting the result.

Cut-off Designs

There has been some interest in designs that use observed baseline measurements to allocate patients to treatment [7, 19]. For example, the more severely ill get the experimental treatment, whereas those who are less ill get the standard treatment. In such trials some form of adjustment for the baselines is then mandatory. Quite apart from the stronger assumptions required to analyze such trials, the strong degree of imbalance leads to a considerable inflation of variance compared with the randomized design. Such trials have been described in [19] and [7] and some criticisms are given in [17]. The fact that the baselines used for assignment may be measured with error is also not a problem for such trials [11].

Cohort Studies

Baseline measurements can be extremely important in the context of epidemiological cohort studies which, however, have several problems not shared by the controlled clinical trial. From one point of view it may be supposed that analysis of covariance is even more important, since the simple comparison of mean outcome scores between an exposure and a control group is not likely to have an expected value equal to the exposure effect of interest. Therefore some sort of baseline adjustment is required. However, this can cause problems.

First, the errors in variable problem is potentially serious here in the sense that the assignment mechanism of subjects to exposure is not ignorable in Rubin's sense [12, 4] (*see* **Nonignorable Dropout in Longitudinal Studies**). However, if assignment probabilities are related to true covariate values, then adjusting for observed covariate values will not deal with the problem adequately. (This is not to say that it may not be preferable to some of the alternative forms of adjustment used. However, the point remains controversial [5, 14].) Secondly, the definition of exposure itself may be unclear in a way that makes adjustment for baselines problematic. Consider the case of salt and hypertension and a cohort study that measures salt consumption (presumably with some difficulty) and blood pressure in a cohort of individuals from a given time point. Whether and how we should adjust for baseline blood pressure is at least partly bound up with what we are trying to measure: lifetime exposure in terms of salt consumption, which will already have had an effect on the baseline measurements, or "downstream" consumption. Perhaps for these reasons, but no doubt also because computational progress has made this a much more feasible option, there is an increasing interest in complex modeling in this field.

Uncontrolled Studies

Simply comparing outcome with baseline by forming the mean difference for a single treatment group in an uncontrolled study is an inadequate way to assess the effect of treatment. Quite apart from the usual trend biases to which such studies are liable, if the subjects have been selected on the basis of extreme baseline measurements, then the study will be subject to **regression to the mean** [2, 6]. The price one then has to pay to get a reasonable estimate of the effect of treatment is complex statistical modeling with attendant doubt and skepticism as to the result [18].

STEPHEN SENN

Battery Reduction

Often a researcher is in the position where he has n variables of interest under investigation, but desires to reduce the number for analysis or later data collection. Specifically, a researcher may desire to select a subset of m variables from the original n variables that reproduce as much as possible of the information contained in the original n variables. In other words, he may desire to find the subset of m variables which accounts for a large proportion of the variance of the original n variables. For example, if he has a long **questionnaire** measuring the effect of a given treatment on the day-to-day activities of a certain population of patients, there may be concern about the burden such a questionnaire places upon the patient. So there is a need to try to reduce the size of the questionnaire (or reduce the battery of questions) without substantially reducing the information obtained from the full questionnaire. To accomplish this he can perform battery reduction using the data collected from patients who completed the full battery of questions at some time in the past.

There are a number of procedures for performing battery reduction. In the following, we illustrate the concept using **Gram–Schmidt** transformations. Cureton & D'Agostino [1, Chapter 12] contains complete details of this procedure. Also, D'Agostino et al. [2] have developed a macro in SAS (*see* **Software, Biostatistical**) which carries out this procedure which is available from `ralph@math.bu.edu`.

Assume that the n variables on which we would like to perform battery reduction are denoted $X_1, \ldots, X_n$. Assume also that these n variables are standardized with mean zero and variance unity. Then the total variance explained by $X_1, \ldots, X_n$, is n, the number of variables. To find the subset of m variables which will explain as much as possible the variance of $X_1, \ldots, X_n$, we first perform a **principal components analysis** and decide upon the m components to be retained. These are the components that account for the salient variance in the original data set. The SAS [3] procedure PRINCOMP can be used to perform principal components analysis. The SAS [3] procedure FACTOR can also be employed. Both procedures automatically standardize the variables before employing principal components. Note also that the above-mentioned battery reduction macro created by D'Agostino et al. [2] automatically standardizes the variables and creates these components as part of its battery reduction.

Once m is determined, let $\mathbf{A}$ denote the $n \times m$ matrix in which the columns contain the **correlations** of $X_i, i = 1, \ldots, n$, to the m principal components. Symbolically $\mathbf{A}$ is

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \ldots & a_{1m} \\ a_{21} & a_{22} & \ldots & a_{2m} \\ \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & \ldots & a_{nm} \end{bmatrix}.$$

The jth column contains the correlations of the original variables X_i to the jth component, and the sum of the squares of all the a_{ij}, $i = 1, \ldots, n$, $j = 1, \ldots, m$, of $\mathbf{A}$ equals the amount of the total variance of the original n variables that is explained by the m retained components. We refer to this as *salient variance*. In principal components analysis, $\mathbf{A}$ is referred to as the *initial component matrix*. It is also often referred to as the *initial factor matrix*. The elements of $\mathbf{A}$ are called the *loadings*. The sum of the squares of the loadings of the ith row of $\mathbf{A}$ equals the proportion of variance of $X_i, i = 1, \ldots, n$, explained by the m principal components. This is called the **communality** of X_i, symbolized as h_i^2.

Now, to find the subset of m variables which explains, as much as possible, the salient variance of the original n variables, we can employ the Gram–Schmidt **orthogonal rotations** to the $n \times m$ initial component matrix $\mathbf{A}$. The goal of the Gram–Schmidt rotation in battery reduction is to rotate $\mathbf{A}$ into a new $n \times m$ component matrix, where the variable accounting for the largest proportion of the salient variance (call this "variable 1") has a nonzero loading on the first component, but zero loadings on the remaining $m - 1$ components; the variable accounting for the largest proportion of residual variance ("variable 2"), where residual variance is the portion of the salient variance which is not accounted for by the variable 1, has a nonzero loading on the first two components, but zero loadings on the remaining $m - 2$ components; the variable accounting for the largest proportion of second-residual variance ("variable 3") has a nonzero loading on the first three components, but zero loadings on the remaining $m - 3$ components, etc. until the variable accounting for the largest proportion of the $(m - 1)$th residual

variance ("variable m") is found. Variables 1 through m are then the variables which reproduce, as much as possible, the variance retained by the m principal components, and so also the salient variance contained in the original n variables. In the vocabulary of principal components analysis, variable 1 is the first *transformed component*, variable 2 is the second, etc. To determine how much of the original variance of all n variables is explained by the m transformed components, we simply compute the sum of squares of all the loadings in the final $n \times m$ Gram–Schmidt rotated matrix (this should be close to the sum of squares of the elements of the $n \times m$ initial component matrix **A**). The following example will illustrate the use of the Gram–Schmidt process in battery reduction.

In the **Framingham** Heart Study, a 10-question depression scale was administered (so $n = 10$), where the responses were No or Yes to the following (the corresponding name to which each question will hereafter be referred is enclosed in parentheses):

1. I felt everything I did was an effort (EFFORT).
2. My sleep was restless (RESTLESS).
3. I felt depressed (DEPRESS).
4. I was happy (HAPPY).
5. I felt lonely (LONELY).
6. People were unfriendly (UNFRIEND).
7. I enjoyed life (ENJOYLIF).
8. I felt sad (FELTSAD).
9. I felt that people disliked me (DISLIKED).
10. I could not get going (GETGOING).

A Yes was scored as 1 and No as 0 except for questions 4 and 7, where this scoring was reversed so that a score of 1 would indicate depression for all questions.

After performing a principal components analysis on this data, there were three components with variances greater than unity. The variances of these three components were 3.357, 1.290, and 1.022 for a percentage variance explained equal to $100 \times (3.357 + 1.290 + 1.022)/10 = 56.69\%$. Thus, using the Kaiser rule for selecting the number of retained components [1], we set m equal to 3 for this example. The 10×3 initial component matrix **A** is in Table 1.

Now, to use Gram–Schmidt transformations to determine the three *variables* which explain the largest portion of the salient variance from the original 10 variables, we do the following:

Table 1 Initial component matrix **A** for Framingham Heart Study depression questionnaire

	a_1	a_2	a_3	h^2
EFFORT	0.60	0.15	0.41	0.55
RESTLESS	0.39	0.07	0.55	0.46
DEPRESS	0.77	−0.13	−0.10	0.62
HAPPY	0.70	−0.23	−0.06	0.55
LONELY	0.64	−0.23	−0.21	0.51
UNFRIEND	0.35	0.68	−0.33	0.69
ENJOYLIF	0.52	−0.27	−0.27	0.42
FELTSAD	0.71	−0.22	−0.20	0.59
DISLIKED	0.34	0.72	−0.22	0.68
GETGOING	0.58	0.20	0.47	0.60

Note: $h^2 = a_1^2 + a_2^2 + a_3^2$ is the communality.

1. Find, from **A** in Table 1, the variable which explains the largest proportion of salient variance from the original 10 variables. This is the variable UNFRIEND, with a sum of squares of loadings (communality) across the three components equal to $0.35^2 + 0.68^2 + (-0.33)^2 = 0.69$.
2. Take the loadings of UNFRIEND from Table 1 (0.35, 0.68, −0.33) and normalize them (i.e. divide each element by the square root of the sum of the squares of all three elements). This yields the normalized loadings: 0.42, 0.82, −0.40.
3. Create a 3×3 ($m \times m$) matrix $\mathbf{Y}_1$, which, in the Gram–Schmidt process, is given by

$$\mathbf{Y}_1 = \begin{bmatrix} a & b & c \\ k_2 & -ab/k_2 & -ac/k_2 \\ 0 & c/k_2 & -b/k_2 \end{bmatrix},$$

where $a = 0.42$, $b = 0.82$, $c = -0.40$ (the normalized row of UNFRIEND from **A**), and $k_2 = (1 - a^2)^{1/2}$. Thus,

$$\mathbf{Y}_1 = \begin{bmatrix} 0.42 & 0.82 & -0.40 \\ 0.91 & -0.38 & 0.18 \\ 0 & -0.44 & -0.90 \end{bmatrix}.$$

4. Calculate $\mathbf{A}\mathbf{Y}_1'$, which is shown in Table 2. Note that, for UNFRIEND, the only nonzero loading is on the first component (or first column). This loading is equal to the square root of the sum of squares of the original loadings of UNFRIEND in matrix **A** (thus, no

Note: $h^2 = c_1^2 + c_2^2 + c_3^2$ is the final communality.

"information" explained by UNFRIEND is lost during the rotation process). For each of the remaining variables in Table 2, we have the following: (i) the squares of the elements in the first column are the portions of the variances of these variables which are accounted for by UNFRIEND; and (ii) the sum of the squares of the elements in the second and third columns is the residual variance (i.e. the variance of the variables not accounted for by UNFRIEND).

5. Find the variable which explains the largest proportion of residual variance (i.e. has the largest residual communality). This is the variable DEPRESS, with a sum of squares of loadings across the last two columns of Table 2 which is equal to $0.73^2 + 0.15^2 = 0.56$.
6. Take the loadings of DEPRESS from Table 2 (0.73, 0.15) and normalize them. This yields the normalized loadings: 0.98, 0.20.
7. Create a 2×2 matrix $\mathbf{Y}_2$, which, in the Gram–Schmidt process, is given by

$$\mathbf{Y}_2 = \begin{bmatrix} b & c \\ c & -b \end{bmatrix},$$

where $b = 0.98$, $c = 0.20$ (the normalized row of DEPRESS from the last two columns of Table 2). Thus,

$$\mathbf{Y}_2 = \begin{bmatrix} 0.98 & 0.20 \\ 0.20 & -0.98 \end{bmatrix}.$$

8. Postmultiply the last two columns of $\mathbf{A}\mathbf{Y}_1'$ by $\mathbf{Y}_2'$; the result is shown in the last two columns of Table 3. The first column of Table 3 is the first column of $\mathbf{A}\mathbf{Y}_1'$. Together, the three columns are called the rotated reduced component matrix (matrix **C** of Table 3).
   Note that, for DEPRESS, the loading on the last component (or last column) is zero. The sum of squares of the loadings (the final communality) of DEPRESS in Table 3 is, within rounding error, equal to the square root of the sum of squares of the loadings of DEPRESS in the initial component matrix **A** (0.63 vs. 0.62; thus, no "information" explained by DEPRESS is lost during the rotation process). For the remaining variables in the second column of Table 3, the elements are the portions of the variances of these variables which are accounted for by DEPRESS.
9. The last of the three variables which explains the largest portion of variance in the original 10 variables is GETGOING, since its loading is largest in the last column of Table 3.
10. The sum of squares of all the loadings in Table 3 is approximately equal, within rounding error, to the sum of squares of loadings in **A**.

Thus the three variables UNFRIEND, DEPRESS, and GETGOING alone retain approximately the same variance that was retained by the first three principal components (which involved all 10 original variables). We have reduced the original battery of ten questions to three.

The above is presented only as an illustration. It is unlikely that a researcher would need to perform a battery reduction on 10 simple items such as in the example. However, there could be a tremendous gain if the original n was, say, 100 and the number of retained components m was only 10.

Also, the above example focused on finding the m variables that reproduce the variance retained by the principal components. There may be variables with low communalities (thus not related to the other variables). The researcher may want to retain these also. For a discussion of this and presentations of other battery reduction methods, see Cureton & D'Agostino [1, Chapter 12].

Bayes Factors

The Bayes factor provides a number for quantifying the evidence in favor of a scientific theory, and hence provides a **Bayesian** approach to **hypothesis testing** or ascertainment. Its terminology is apparently due to Good [12], but the underlying philosophy and proposed usage has been described by Jeffreys [13, 14]. For the comparison of two competing hypotheses, the Bayes factor is the posterior **odds** in favor of one of the hypotheses when the prior odds of the hypotheses are equal. The Bayes factor is more precisely defined as follows.

Definition

Let H_0 and H_1 denote two competing hypotheses under which data D are thought to have arisen. The **prior** probabilities for H_0 and H_1 are given by $P(H_0)$ and $P(H_1) = 1 - P(H_0)$, and the posterior probabilities by $P(H_0|D)$ and $P(H_1|D) = 1 - P(H_0|D)$, respectively. By **Bayes's theorem**, the latter probabilities can be expressed as

$$P(H_k|D) = \frac{P(D|H_k)P(H_k)}{P(D|H_0)P(H_0) + P(D|H_1)P(H_1)}, \tag{1}$$

for $k = 0, 1$. Using (1), the posterior odds ratio in favor of H_0 can be expressed as

$$\frac{P(H_0|D)}{P(H_1|D)} = \frac{P(D|H_0)}{P(D|H_1)} \times \frac{P(H_0)}{P(H_1)}. \tag{2}$$

From (2), one can see that the prior odds get transformed into the posterior odds via multiplication by the factor

$$BF_{01} = \frac{P(D|H_0)}{P(D|H_1)}, \tag{3}$$

which is termed the Bayes factor of H_0 to H_1. Note that by (2), the Bayes factor is the ratio of posterior to prior odds, regardless of the value of prior odds, and also the posterior odds when the prior odds of H_0 and H_1 are equal. Kass and Raftery [15] summarize Jeffreys' guidelines for interpreting the Bayes factor, which suggest interpretation based on half-units on the log base 10 scale [14]. On this scale, a log base 10 BF_{01} value greater than 2, or raw BF_{01} value greater than 100, represents decisive evidence in favor of H_0, a value between 1 and 2, strong evidence, a value between 1/2 and 1, substantial evidence, and a value between 0 and 1/2, evidence not worth more than a bare mention.

In the simple case, H_0 and H_1 entail no free parameters to be estimated, and B_{01} is the **likelihood ratio** statistic. In the more common scenario, H_0 and H_1 hypothesize a model $p(D|\theta_k, H_k)$ for the data D with unknown parameters θ_k, and prior distributions $\pi(\theta_k|H_k)$ for θ_k, for $k = 0, 1$, respectively. In this case, the densities $P(D|H_k)$ appearing in the numerator and denominator of BF_{01} are the integrated **likelihoods** against the prior densities:

$$P(D|H_k) = \int_{\theta_k} p(D|\theta_k, H_k)\pi(\theta_k|H_k)\,\mathrm{d}\theta_k, \tag{4}$$

for $k = 0, 1$. As seen by (4) two challenges for implementation of Bayes factors are the calculation of the integrals, which may involve highly peaked integrands over high dimensional spaces, and the specification of prior distributions, for which the Bayes factor may be sensitive.

Calculation

There has been considerable research in the calculation of integrals (4) of the type required by the Bayes factor. Exact analytic evaluation of the integrals is possible for a restricted set of scenarios, including **exponential family** distributions with conjugate priors; see for example, [6, Chapter 9]. Otherwise, some type of numerical approximation is needed. Many standard numerical methods, such as numerical quadrature (*see* **Numerical Integration**), however, can be very inefficient for these types of integrals since the dimension may be high and/or the integrand highly peaked near the **maximum likelihood** estimate. Evans and Swartz [8, 9] provide a review of numerical **algorithms** for integrals appearing in the Bayes factor.

Laplace's asymptotic method provides a surprisingly accurate approximation to integrals of the form (4) [16, 22, 23]. One version of the approximation, termed fully exponential, is obtained by assuming that the posterior density, which is proportional to the integrand in (4), becomes highly peaked at the posterior mode $\tilde{\theta}$ as the sample size n increases. Here the subscript k has been dropped for brevity. Denote by $\tilde{\ell}(\theta)$, the log of the integrand in (4).

Laplace's approximation works by expanding $\tilde{\ell}(\theta)$ in a Taylor series about $\tilde{\theta}$. Exponentiating this Taylor series expansion and ignoring some of the latter terms yields an integrand that resembles a **multivariate normal distribution** with mean $\tilde{\theta}$ and variance–**covariance matrix** $\tilde{\Sigma} = [-D^2\tilde{\ell}(\tilde{\theta})]^{-1}$, where $D^2\tilde{\ell}(\theta)$ denotes the Hessian matrix of second derivatives of $\tilde{\ell}(\theta)$. Integrating this integrand yields the following approximation:

$$P(\hat{D}|H) = (2\pi)^{d/2}|\tilde{\Sigma}|^{1/2}P(D|\tilde{\theta}, H)\pi(\tilde{\theta}|H), \quad (5)$$

where d is the dimension of θ. Under the Fisher regularity conditions, given in Kass et al. [16], the relative error of the approximation is $O(n^{-1})$. Thus, when the approximation is applied to both the numerator and denominator of BF_{01}, the relative error of the resulting approximation is also $O(n^{-1})$. A variation of the approximation replaces $\tilde{\theta}$ with the maximum likelihood estimator $\hat{\theta}$ of $P(D|\theta, H)$, and obtains relative error of order $O(n^{-1/2})$. Using the latter approximation, Schwarz [21] derived a rough approximation to the Bayes factor, with error term on the log scale of order $O(1)$, as

$$S = \log P(D|\hat{\theta}_0, H_0) - \log P(D|\hat{\theta}_1, H_1) - \tfrac{1}{2}(d_0 - d_1)\log(n), \quad (6)$$

where d_0 and d_1 are the dimensions of the parameter spaces under H_0 and H_1, respectively. The expression in (6) is a modified log likelihood ratio statistic, which is interpretable even for nonnested models (*see* **Separate Families of Hypotheses**). Kass and Wasserman [17] show that for the case where H_0 is nested in H_1 and with an interesting choice of unit-information prior for the parameters tested, S is an approximation to the log of the Bayes factor to order $O(n^{-1/2})$. Minus twice the Schwarz criterion is often called the Bayesian Information Criterion (BIC), which is similar to **Akaike's Information Criterion** (AIC) [1]. When applied to each model separately, the BIC penalizes models of higher dimensionality more than the AIC; the penalty factor subtracted from the maximized log likelihood for the AIC is proportional to the number of parameters d, whereas for the BIC, it is proportional to $d \log n$.

The increased feasibility of **Markov Chain Monte Carlo** (MCMC) methods [11] for simulating samples from the posterior distribution of parameters has spawned a large variety of new **simulation** and simulation/asymptotic approximation hybrid approaches for calculating the Bayes factor; see, for example, [4, 5, 7, 10, 18, 20, 24]. The choice of method that obtains the highest accuracy depends on features of the individual problem.

Prior Distributions

Prior distributions play a key role in the Bayes factor. First, unlike in Bayesian estimation problems, where as the sample size approaches infinity, the influence of the prior distribution diminishes, the Bayes factor remains sensitive to the choice of prior, even asymptotically. This can be inferred somewhat from approximation (5). Therefore, careful consideration must be given to the selection of the prior distribution and **sensitivity analyses** to assess robustness of conclusions to a range of plausible priors must be performed. In the case of testing nested hypotheses, say where a parameter θ_0 is fixed under H_0 but unknown under H_1, the Bayes factor in favor of H_0 often increases as the prior variance for θ_0 under H_1 increases. This phenomenon, called *Bartlett's paradox* [2], emphasizes that proper informative priors should be used for the parameters under test.

Improper priors pose problems for Bayes factors in that either the integrals comprising the numerator and denominator may not converge, or that the arbitrary proportionality constant of improper priors leads to arbitrariness in definition of the Bayes factor. In the case of testing nested hypotheses, however, many authors are not bothered by the use of improper reference priors for the **nuisance parameters** [14, 17]. The intrinsic Bayes factor of Berger and Pericchi [3] and the fractional Bayes factor of O'Hagan [19] are two proposals for modifying Bayes factors to accept reference, possibly improper, prior distributions, by utilizing part of the data as a training sample for the prior.

DONNA K. PAULER

Bayes' Theorem

The uncertainty, expressed through probability, that you feel about something will depend on your knowledge at the time you state that probability and could change as additional information becomes available. For example, the probability that a woman has breast cancer will depend on your knowing that she is an apparently healthy woman of 40 years of age with three children and no family history of breast cancer. It would change if she tested positive on a screening test for the condition. Bayes' theorem describes how this change, as a result of extra information, should be evaluated.

Let C be the uncertain event under consideration – in the example, the event that the woman has breast cancer. Let $\Pr(C)$ be the probability that C obtains, based on your knowledge at the time the probability is evaluated. Let $+$ denote the additional knowledge – in the example, the positive test result. The revised probability is written $\Pr(C|+)$, which reads "the probability of C given (expressed by the vertical line) the result $+$". Bayes' theorem relates $\Pr(C|+)$ to $\Pr(C)$. It is most easily understood if probability is replaced by **odds**. The odds on C is $\Pr(C)/\Pr(\sim C)$, written $\mathrm{O}(C)$, where $\sim C$ denotes the complementary event – in the example, not having breast cancer. So $\Pr(\sim C)$ is the probability that C does not obtain, namely $1 - \Pr(C)$. In this notation, Bayes' Theorem says

$$\mathrm{O}(C|+) = \frac{\Pr(+|C)}{\Pr(+|\sim C)} \times \mathrm{O}(C).$$

In words, to change the odds as a result of the extra information $+$, the original odds are multiplied by $\Pr(+|C)/\Pr(+|\sim C)$. The multiplier is called the **likelihood ratio** for C, on evidence $+$. In the example, $\Pr(+|C)$ is the probability that a woman with breast cancer will test positive – a true positive; $\Pr(+|\sim C)$ is the similar probability for a woman without breast cancer – a false positive.

Note the distinction between $\Pr(C|+)$ occurring in the odds and $\Pr(+|C)$ occurring in the likelihood ratio. The first expresses your uncertainty about the cancer when a positive result is available; the second concerns your uncertainty about whether a woman with breast cancer will test positive. The reversal of C and $+$ is very important. Bayes' theorem shows how this reversal occurs. The confusion between the two probabilities is called the "prosecutor's fallacy", perhaps because of its frequent appearance in legal cases (*see* **Medico–Legal Cases and Statistics**).

An alternative expression of the theorem is

$$\Pr(C|+) = \frac{\Pr(+|C)\Pr(C)}{\Pr(+)},$$

passing from $\Pr(C)$ to $\Pr(C|+)$. Here a new probability appears,

$$\Pr(+) = \Pr(+|C)\Pr(C) + \Pr(+|\sim C)\Pr(\sim C).$$

This is the probability of a positive result when the breast cancer state is unknown: in the example, for a healthy 40-year-old woman with three children and no family history of breast cancer.

The theorem is usually ascribed to the Rev Thomas Bayes in 1763 (*see* **Bayes, Thomas**). A convenient, modern reprint is [1]. It plays a fundamental role in one approach to statistical **inference** called *Bayesian* statistics. No one disputes the mathematics; the interpretation of $\Pr(C|+)$ is, however, controversial.

Bayes, Thomas

Born: 1701 (?) in Hertfordshire, UK.
Died: April 7, 1761, in Tunbridge Wells, UK.

Thomas Bayes, son of a nonconformist minister, spent most of his adult life in a similar position in Tunbridge Wells, England. He was educated at Edinburgh University and was a fellow of the Royal Society. He is today remembered for a paper that his friend Richard Price claimed to have found amongst his possessions after death. It appeared in the Society's Proceedings in 1763 and has often been republished [1].

By the middle of the eighteenth century it was well understood that if, to use modern terminology, in each of n independent trials the chance of success had the same value, θ say, then the probability of exactly r successes was given by the **binomial distribution**

$$\Pr(r|\theta, n) = {}^{n}C_{r}\theta^{r}(1-\theta)^{n-r}.$$

James **Bernoulli** had established the weak **law of large numbers** and **de Moivre** had found the normal approximation (*see* **Normal Distribution**) to the binomial. The passage from a known value of θ to the empirical observation of r was therefore extensively appreciated. Bayes studied the inverse problem: What did the data (r, n) say about the chance θ? There already existed partial answers in the form of significance tests (*see* **Hypothesis Testing**).

Bayes proceeded differently using the theorem that nowadays always bears his name, though it does not appear explicitly in the 1763 paper,

$$\Pr(A|B) = \frac{\Pr(B|A)\Pr(A)}{\Pr(B)}$$

for events A and B with $\Pr(B) \neq 0$ (*see* **Bayes' Theorem**). The theorem permits the inversion of the events in $\Pr(B|A)$ into $\Pr(A|B)$. Applied when A refers to θ and B to the empirical r, we have

$$\Pr(\theta|r, n) \propto \Pr(r|\theta, n)\Pr(\theta|n).$$

The result effects the passage from the binomial, on the right, to a probability statement about the chance, on the left. It therefore becomes possible to pass from the data to a statement about what are probable, and what are improbable, values of the chance. This elegantly and simply solves the problem, except for one difficulty. It requires a value for $\Pr(\theta|n)$, a probability distribution for the chance before the result of the trials has been observed. It is usual to describe this as the **prior distribution** (prior, that is, to r) and the final result as the posterior distribution. Thus, the theorem describes how your views of θ change, from prior to posterior, as a result of data r. Bayes discussed the choice of prior but his approach is ambiguous. He is usually supposed to have taken $\Pr(\theta|n)$ **uniform** in (0,1) – the so-called Bayes' postulate – but an alternative reading suggests he took $\Pr(r|n)$ to be uniform. Mathematically these lead to the same result.

The theorem is of basic importance because it provides a solution to the general problem of **inference** or induction. Let H be a universal hypothesis and E empirical evidence bearing on H. Bayes' theorem says

$$\Pr(H|E) \propto \Pr(E|H)\Pr(H),$$

expressing a view about the hypothesis, given the evidence, in terms of the known probability of the evidence, given the hypothesis, and the prior view about H. As more evidence supporting H accrues, having large probability on H, so even the skeptic, with low $\Pr(H)$, will become convinced, $\Pr(H|E)$ will approach one and the hypothesis accepted. Many people, following **Jeffreys**, who extensively developed these ideas into a practicable scientific tool, hold that this provides a description of the scientific method.

These ideas have been extensively developed into a systematic treatment of statistics and decision making, termed *Bayesian*. The ideas therein differ from those adopted in the classical school of statistics. All this is a long way from Bayes' original problem and its resolution. He would doubtless be astonished were he to realize how his wonderful idea has been extended and his name used (*see* **Bayesian Methods**).

Bayesian Approaches to Cure Rate Models

Introduction

Survival models incorporating a cure fraction, often referred to as **cure rate models**, are becoming increasingly popular in analyzing data from cancer **clinical trials** (*see* **Clinical Trials, Early Cancer and Heart Disease**). The cure rate model has been used for modeling time-to-event data for various types of cancers, including breast cancer, non-Hodgkin's lymphoma, leukemia, prostate cancer, melanoma, and head and neck cancer, where for these diseases, a significant proportion of patients are "cured". Perhaps the most popular type of cure rate model is the mixture model discussed by Berkson and Gage [2]. In this model, we assume a certain fraction π of the population is "cured", and the remaining $1-\pi$ are not cured. The survivor function for the entire population, denoted by $S_1(y)$, for this model is given by

$$S_1(y) = \pi + (1-\pi)S^*(y), \tag{1}$$

where $S^*(y)$ denotes the survivor function for the noncured group in the population. Common choices for $S^*(y)$ are the exponential and Weibull distributions. We shall refer to the model in (1) as the *standard cure rate model*. The standard cure rate model has been extensively discussed in the statistical literature by several authors, including Farewell [13, 14], Goldman [15], Greenhouse and Wolfe [17], Halpern and Brown [18, 19], Gray and Tsiatis [16], Sposto, Sather, and Baker [31], Laska and Meisner [25], Kuk and Chen [24], Yamaguchi [39], Taylor [34], Ewell and Ibrahim [12], Stangl and Greenhouse [32], and Sy and Taylor [33]. The book by Maller and Zhou [28] gives an extensive discussion of frequentist methods of **inference** for the standard cure rate model. Although the standard cure rate model is attractive and widely used, it has some drawbacks. In the presence of **covariates**, it cannot have a **proportional hazards** structure if the covariates are modeled through π via a binomial regression model (*see* **Generalized Linear Model**). Proportional hazards are a desirable property in survival models when doing covariate analyses. Also, when including covariates through the parameter π via a standard binomial regression model, (1) yields improper posterior distributions for many types of noninformative improper **priors**, including an improper **uniform** prior for the regression coefficients. (see Chen, Ibrahim & Sinha [7]) This is a crucial drawback of (1), since it implies that **Bayesian** inference with (1) essentially requires a proper prior. These drawbacks can be overcome with an alternative definition of a cure rate model, which we discuss in the next section.

Univariate Cure Rate Models

We present a formulation of the parametric cure rate model discussed by Yakovlev et al. [37], Yakovlev [36], and Yakovlev and Tsodikov [38]. A Bayesian formulation of this model is given in [7]. The alternative model can be derived as follows. Suppose that for an individual in the population, let N denote the number of *metastasis-competent* tumor cells for that individual left active after the initial treatment. A metastasis-competent tumor cell is a tumor cell that has the potential of metastasizing. Further, assume that N has a **Poisson distribution** with mean θ. Let Z_i denote the random time for the ith metastasis-competent tumor cell to produce detectable metastatic disease. That is, Z_i can be viewed as a promotion time for the ith tumor cell. Given N, the random variables Z_i, $i = 1, 2, \ldots$, are assumed to be independent and identically distributed with a common distribution function $F(y) = 1 - S(y)$ that does not depend on N. The time to relapse of cancer can be defined by the random variable $Y = \min\{Z_i, 0 \le i \le N\}$, where $P(Z_0 = \infty) = 1$. The survival function for Y, and hence the survival function for the population, is given by

$$\begin{aligned} S_{\text{pop}}(y) &= P(\text{no metastatic cancer by time } y) \\ &= P(N=0) + P(Z_1 > y, \ldots, Z_N > y, \\ &\qquad N \ge 1). \end{aligned} \tag{2}$$

After some algebra, we obtain

$$\begin{aligned} S_{\text{pop}}(y) &= \exp(-\theta) + \sum_{k=1}^{\infty} S(y)^k \frac{\theta^k}{k!} \exp(-\theta) \\ &= \exp(-\theta + \theta S(y)) = \exp(-\theta F(y)). \end{aligned} \tag{3}$$

Since $S_{\text{pop}}(\infty) = \exp(-\theta) > 0$, (3) is not a proper survival function. As Yakovlev and Tsodikov [38]

point out, (3) shows explicitly the contribution to the failure time of two distinct characteristics of tumor growth: the initial number of metastasis-competent tumor cells and the rate of their progression. Thus, the model incorporates parameters bearing clear biological meaning. Aside from the biological motivation, the model in (3) is suitable for ' any type of survival data that has a surviving fraction. Thus, survival data which do not "fit" the biological definition given above can still certainly be modeled by (3) as long as the data has a surviving fraction and can be thought of as being generated by an unknown number N of latent competing risks (Z_i's). Thus, the model can be useful for modeling various types of survival data, including time to relapse, time to death, time to first infection, and so forth.

We also see from (3) that the cure fraction (i.e. cure rate) is given by

$$S_{\text{pop}}(\infty) \equiv P(N = 0) = \exp(-\theta). \tag{4}$$

As $\theta \to \infty$, the cure fraction tends to 0, whereas as $\theta \to 0$, the cure fraction tends to 1. The subdensity corresponding to (3) is given by

$$f_{\text{pop}}(y) = \theta f(y) \exp(-\theta F(y)), \tag{5}$$

where $f(y) = \mathrm{d}/\,\mathrm{d}yF(y)$. We note here that $f_{\text{pop}}(y)$ is not a proper probability density since $S_{\text{pop}}(y)$ is not a proper survival function. However, $f(y)$ appearing on the right side of (5) is a proper probability density function. The **hazard** function is given by

$$h_{\text{pop}}(y) = \theta f(y). \tag{6}$$

Following Chen, Ibrahim, and Sinha [7], we can now construct the **likelihood** function as follows. Suppose we have n subjects, and let N_i denote the number of metastasis-competent tumor cells for the ith subject. Further, we assume that the N_i's are independently and identically distributed (i.i.d.) Poisson random variables with mean θ, $i = 1, 2, \ldots, n$. We emphasize here that the N_i's are not observed, and can be viewed as latent variables in the model formulation. Further, suppose Z_{i1}, Z_{i2}, …, Z_{i,N_i} are the i.i.d. promotion times for the N_i metastasis-competent cells for the ith subject, which are unobserved, and all have proper cumulative distribution function $F(.)$, $i = 1, 2, \ldots, n$. In this subsection, we will specify a **parametric** form for $F(.)$, such as a **Weibull** or **gamma** distribution. We denote the indexing parameter (possibly vector valued) by $\boldsymbol{\psi}$, and thus write $F(.|\boldsymbol{\psi})$ and $S(.|\boldsymbol{\psi})$. For example, if $F(.|\boldsymbol{\psi})$ corresponds to a Weibull distribution, then $\boldsymbol{\psi} = (\alpha, \lambda)'$, where α is the shape parameter and λ is the scale parameter. Let y_i denote the survival time for subject i, which may be right censored, and let ν_i denote the censoring indicator, which equals 1 if y_i is a failure time and 0 if it is right censored. The observed data is $D_{\text{obs}} = (n, \boldsymbol{y}, \boldsymbol{\nu})$, where $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$, and $\boldsymbol{\nu} = (\nu_1, \nu_2, \ldots, \nu_n)'$. Also, let $\boldsymbol{N} = (N_1, N_2, \ldots, N_n)'$. The complete data is given by $D = (n, \boldsymbol{y}, \boldsymbol{\nu}, \boldsymbol{N})$, where $\boldsymbol{N}$ is an unobserved vector of latent variables. The complete data likelihood function of the parameters $(\boldsymbol{\psi}, \theta)$ can then be written as

$$L(\theta, \boldsymbol{\psi}|D) = \left(\prod_{i=1}^{n} S(y_i|\boldsymbol{\psi})^{N_i - \nu_i} \left(N_i f(y_i|\boldsymbol{\psi})\right)^{\nu_i}\right) \times \exp\left\{\sum_{i=1}^{n}(N_i \log(\theta) - \log(N_i!)) - n\theta\right\}. \tag{7}$$

Throughout the remainder of this section, we will assume a Weibull density for $f(y_i|\boldsymbol{\psi})$, so that

$$f(y|\boldsymbol{\psi}) = \alpha y^{\alpha-1} \exp\{\lambda - y^{\alpha} \exp(\lambda)\}. \tag{8}$$

We incorporate covariates for the parametric cure rate model (3) through the cure rate parameter θ. When covariates are included, we have a different cure rate parameter, θ_i, for each subject, $i = 1, 2, \ldots, n$. Let $\boldsymbol{x}_i' = (x_{i1}, \ldots, x_{ip})$ denote the $p \times 1$ vector of covariates for the ith subject, and let $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ denote the corresponding vector of regression coefficients. We relate θ to the covariates by $\theta_i \equiv \theta(\boldsymbol{x}_i'\boldsymbol{\beta}) = \exp(\boldsymbol{x}_i'\boldsymbol{\beta})$, so that the cure rate for subject i is $\exp(-\theta_i) = \exp(-\exp(\boldsymbol{x}_i'\boldsymbol{\beta}))$, $i = 1, 2, \ldots, n$ This relationship between θ_i and $\boldsymbol{\beta}$ is equivalent to a canonical link for θ_i in the setting of generalized linear models. With this relation, we can write the complete data likelihood of $(\boldsymbol{\beta}, \boldsymbol{\psi})$ as

$$L(\boldsymbol{\beta}, \boldsymbol{\psi}|D) = \left(\prod_{i=1}^{n} S(y_i|\boldsymbol{\psi})^{N_i - \nu_i} \left(N_i f(y_i|\boldsymbol{\psi})\right)^{\nu_i}\right) \times \exp\left\{\sum_{i=1}^{n}\left[N_i \boldsymbol{x}_i'\boldsymbol{\beta} - \log(N_i!) - \exp(\boldsymbol{x}_i'\boldsymbol{\beta})\right]\right\}, \tag{9}$$

where $D = (n, \boldsymbol{y}, X, \boldsymbol{v}, \boldsymbol{N})$, X is the $n \times p$ matrix of covariates, $f(y_i|\boldsymbol{\psi})$ is the Weibull density given above, and $S(y_i|\boldsymbol{\psi}) = \exp(-y_i^{\alpha}\exp(\lambda))$. If we assume independent priors for $(\boldsymbol{\beta}, \boldsymbol{\psi})$, then the posterior distributions of $(\boldsymbol{\beta}, \boldsymbol{\psi})$ are conditionally independent given $\boldsymbol{N}$. We mention that the part of the complete data likelihood in (9) involving $\boldsymbol{\beta}$ looks exactly like a Poisson generalized linear model with a canonical link, with the N_i's being the observables.

Various **semiparametric** alternatives to (9) have been proposed. Ibrahim, Chen, and Sinha [22, 23] specify a special type of prior process for $F(y)$, and Chen, Harrington, and Ibrahim [4] assume a piecewise **exponential** distribution for $F(y)$ (*see* **Grouped Survival Times**). Chen and Ibrahim [5] and Chen, Ibrahim, and Lipsitz [6] consider semiparametric cure rate models with missing covariate data, and Chen, Ibrahim, and Sinha [8] present multivariate extensions to (9), allowing for multivariate cure rate models. A recent review paper on cure rate models is given by Tsodikov, Ibrahim and Yakovlev [35]. **Joint** cure rate models for longitudinal and survival data have been considered by Law, Taylor, and Sandler [26], Brown and Ibrahim [3], and Chen, Ibrahim, and Sinha [9].

Multivariate Cure Rate Models

There does not appear to be a natural multivariate extension of the standard cure rate model in (1) (*see* **Multivariate Survival Analysis**). Even if such an extension were available, it appears that a multivariate mixture model would be extremely cumbersome to work with from a theoretical and computational perspective. As an alternative to a direct multivariate extension of (1), we examine the model discussed in Chen, Ibrahim, and Sinha [8], called the *multivariate cure rate model*. This model proves to be quite useful for modeling multivariate data in which the joint failure time random variables have a surviving fraction and each marginal failure time random variable also has a surviving fraction. The model is related to the univariate cure rate model discussed by Yakovlev et al. [37] and Asselain et al. [1]. To induce the correlation structure between the failure times, we introduce a **frailty** term [10, 20, 29], which is assumed to have a positive stable distribution. A positive frailty assumes that we have Cox's [11] proportional hazards structure conditionally (i.e. given the unobserved frailty). Thus, the marginal and conditional hazards of each component have a proportional hazards structure, and thus remain in the same class of univariate cure rate models.

For clarity and ease of exposition, we will focus our discussion on the bivariate cure rate model, as extensions to the general multivariate case are quite straightforward. The bivariate cure rate model of Chen, Ibrahim, and Sinha [8] can be derived as follows. Let $\boldsymbol{Y} = (Y_1, Y_2)'$ be a bivariate failure time, such as Y_1 = time to cancer relapse and Y_2 = time to death, or Y_1 = time to first infection, and Y_2 = time to second infection, and so forth. We assume that (Y_1, Y_2) are not ordered and have support on the upper orthant of the plane. For an arbitrary patient in the population, let $\boldsymbol{N} = (N_1, N_2)'$ denote latent (unobserved) variables for (Y_1, Y_2), respectively. We assume throughout that N_k has a Poisson distribution with mean $\theta_k w$, $k = 1, 2$, and (N_1, N_2) are independent. The quantity w is a frailty component in the model, which induces a correlation between the latent variables (N_1, N_2). Here we take w to have a positive stable distribution indexed by the parameter α, denoted by $w \sim S_{\alpha}(1, 1, 0)$, where $0 < \alpha < 1$. Although several choices can be made for the distribution of w, the positive stable distribution is quite attractive, common, and flexible in the multivariate survival setting.

Let $\boldsymbol{Z}_i = (Z_{1i}, Z_{2i})'$ denote the bivariate promotion time for the ith metastasis-competent tumor cell. The random vectors $\boldsymbol{Z}_i$, $i = 1, 2, \ldots$ are assumed to be independent and identically distributed. The cumulative distribution function of Z_{ki} is denoted by $F_k(t) = 1 - S_k(t)$, $k = 1, 2$, and F_k is independent of (N_1, N_2). The observed survival time can be defined by the random variable $Y_k = \min\{Z_{ki}, 0 \le i \le N_k\}$, where $P(Z_{k0} = \infty) = 1$ and N_k is independent of the sequence $Z_{k1}, Z_{k2}, \ldots$, for $k = 1, 2$. The survival function for $\boldsymbol{Y} = (Y_1, Y_2)'$ given w, and hence the survival function for the population given w, is given by

$$
\begin{aligned}
S_{\text{pop}}(y_1, y_2|w) &= \prod_{k=1}^{2} [P(N_k = 0) \\
&\quad + P(Z_{k1} > t_k, \ldots, Z_{kN_k} > t_k, N_k \ge 1)] \\
&= \prod_{k=1}^{2} \left[\exp(-w\theta_k) + \left(\sum_{r=1}^{\infty} S_k(y_k)^r \right.\right. \\
&\quad \left.\left. \times \frac{(w\theta_k)^r}{r!} \exp(-w\theta_k) \right) \right]
\end{aligned}
$$

$$= \prod_{k=1}^{2} \exp\{-w\theta_k + \theta_k w S_k(y_k)\}$$

$$= \exp\left\{-w\left[\theta_1 F_1(y_1) + \theta_2 F_2(y_2)\right]\right\}, \quad (10)$$

where $P(N_k = 0) = P(Y_k = \infty) = \exp(-\theta_k)$, $k = 1, 2$. We emphasize here that the primary roles of $\mathbf{N_k}$ and $\boldsymbol{Z}_i$ are that they only facilitate the construction of the model and need not have any physical or biological interpretation at all for the model to be valid. They are quite useful for the computational implementation of the model via the Gibbs sampler as discussed below and thus are defined primarily for this purpose. The model in (10) is valid for *any* time-to-event data with a cure rate structure as implied by (10) and the subsequent development. Thus, the model can be useful for modeling various types of failure time data, including time to relapse, time to death, time to infection, time to complication, time to rejection, and so forth. In addition, the frailty variable w serves a dual purpose in the model – it induces the correlation between Y_1 and Y_2 and at the same time relaxes the Poisson assumption of N_1 and N_2 by adding the same extra Poisson variation through their respective means $\theta_1 w$ and $\theta_2 w$.

Following Ibragimov and Chernin [21], the $S_\alpha(1, 1, 0)$ density for w $(0 < \alpha < 1)$ can be expressed in the form

$$f_s(w|\alpha) = a w^{-(a+1)} \int_0^1 s(u) \times \exp\left\{-\frac{s(u)}{w^a}\right\} du, \quad w > 0, \quad (11)$$

where

$$a = \frac{\alpha}{1-\alpha} \text{ and } s(u) = \left(\frac{\sin(\alpha\pi u)}{\sin(\pi u)}\right)^a \times \left(\frac{\sin[(1-\alpha)\pi u]}{\sin(\pi u)}\right),$$

and the Laplace transform of w is given by $E(\exp(-sw)) = \exp(-s^\alpha)$. A useful reference on stable distributions is Samorodnitsky & Taqqu [30]. Using the Laplace transform of w, a straightforward derivation yields the unconditional survival function

$$S_{\text{pop}}(y_1, y_2) = \exp\{-[\theta_1 F_1(y_1) + \theta_2 F_2(y_2)]^\alpha\}. \quad (12)$$

The joint cure fraction implied by (12) is $S_{\text{pop}}(\infty, \infty) = \exp(-[\theta_1 + \theta_2]^\alpha)$. From (12), the marginal survival functions are

$$S_k(y) = \exp(-\theta_k^\alpha (F_k(y))^\alpha), \quad k = 1, 2. \quad (13)$$

Equation (13) indicates that the marginal survival functions have a cure rate structure with probability of cure $\exp(-\theta_k^\alpha)$ for Y_k, $k = 1, 2$. It is important to note in (13) that each marginal survival function has a proportional hazards structure as long as the covariates, $\boldsymbol{x}$, only enter through θ_k. The marginal hazard function is given by $\alpha\theta_k^\alpha f_k(y)(F_k(y))^{\alpha-1}$, with attenuated covariate effect $(\theta_k(x))^\alpha$, and $f_k(y)$ is the survival density corresponding to $F_k(y)$. This property is similar to the earlier observations made by Oakes [29] for the ordinary bivariate stable frailty survival model.

In addition, we can express the marginal survival functions in (13) in terms of standard cure rate models. We can write

$$\begin{aligned} S_k(y) &= \exp(-\theta_k^\alpha (F_k(y))^\alpha) \\ &= \exp(-\theta_k^\alpha) + (1 - \exp(-\theta_k^\alpha)) \\ &\quad \times \left(\frac{\exp(-\theta_k^\alpha (F_k(y))^\alpha) - \exp(-\theta_k^\alpha)}{1 - \exp(-\theta_k^\alpha)}\right) \\ &= \exp(-\theta_k^\alpha) + (1 - \exp(-\theta_k^\alpha)) S_k^*(y), \quad (14) \end{aligned}$$

where

$$S_k^*(y) = \frac{\exp(-\theta_k^\alpha (F_k(y))^\alpha) - \exp(-\theta_k^\alpha)}{1 - \exp(-\theta_k^\alpha)}, \quad k = 1, 2.$$

It is easily shown that $S_k^*(y)$ defines a proper survivor function. Thus, (14) is a standard cure rate model with cure rate given by $\pi_k = \exp(-\theta_k^\alpha)$ and survivor function for the noncured population given by $S_k^*(y)$ for $k = 1, 2$.

The parameter α $(0 < \alpha < 1)$ is a scalar parameter that is a measure of association between (Y_1, Y_2). Small values of α indicate high association between (Y_1, Y_2). As $\alpha \to 1$, this implies less association between (Y_1, Y_2), which can be seen from (12). Following Clayton [10] and Oakes [29], we can compute a local measure of dependence, denoted by $\theta^*(y_1, y_2)$, as a function of α. For the multivariate cure rate model in (12), $\theta^*(y_1, y_2)$ is well defined, and is given by

$$\theta^*(y_1, y_2) = \alpha^{-1}(1-\alpha)(\theta_1 F_1(y_1) + \theta_2 F_2(y_2))^{-\alpha} + 1. \quad (15)$$

We see that $\theta^*(y_1, y_2)$ in (15) decreases in (y_1, y_2). That is, the association between (Y_1, Y_2) is greater when (Y_1, Y_2) are small and the association decreases over time. Such a property is desirable, for example, when Y_1 denotes time to relapse and Y_2 denotes time to death. Finally, we mention that a global measure of dependence such as Kendall's τ (*see* **Rank Correlation**) or the Pearson **correlation** coefficient is not well defined for the multivariate cure rate model (12), since no moments for cure rate models exist due to the improper survival function.

The multivariate cure rate model presented here is attractive in several respects. First, the model has a proportional hazards structure for the population hazard, conditionally as well as marginally, when covariates are entered through the cure rate parameter, and thus has an appealing interpretation. Also, the model is computationally feasible. In particular, by introducing latent variables, efficient **Markov chain Monte Carlo algorithms** can be developed that enable us to sample from the joint posterior distribution of the parameters. Chen, Ibrahim, and Sinha [8] discuss a modified version of the collapsed Gibbs technique of Liu [27] for efficient Gibbs sampling from the posterior distribution.

The likelihood function for this model can be obtained as follows. Suppose we have n subjects, and let N_{ki} denote the number of latent risks for the ith subject, $i = 1, 2, \ldots, n$, $k = 1, 2$. Further, we assume that the N_{ki}'s are independent Poisson random variables with mean $w_i\theta_k$, $i = 1, 2, \ldots, n$ for $k = 1, 2$. We also assume the $w_i \sim S_\alpha(1, 1, 0)$, and the w_i's are i.i.d. We emphasize here that the N_{ki}'s are not observed, and can be viewed as latent variables in the model formulation. Further, suppose $Z_{ki1}, Z_{ki2}, \ldots, Z_{ki,N_{ki}}$ are the independent latent times for the N_{ki} latent risks for the ith subject, which are unobserved, and all have cumulative distribution function $F_k(.)$, $i = 1, 2, \ldots, n$, $k = 1, 2$. Chen, Ibrahim, and Sinha [8] specify a parametric form for $F_k(.)$, such as a Weibull or gamma distribution. We denote the indexing parameter (possibly vector valued) by $\boldsymbol{\psi}_k$, and thus write $F_k(.|\boldsymbol{\psi}_k)$ and $S_k(.|\boldsymbol{\psi}_k)$. For example, if $F_k(.|\boldsymbol{\psi}_k)$ corresponds to a Weibull distribution, then $\boldsymbol{\psi}_k = (\xi_k, \lambda_k)'$, where ξ_k is the shape parameter and λ_k is the scale parameter. Let y_{ki} denote the failure time or censoring time for subject i for the kth component, and let indicator $\nu_{ki} = 1$, if y_{ki} is an observed failure time and 0 if it is a censoring time. Let $\boldsymbol{y}_k = (y_{k1}, y_{k2}, \ldots, y_{kn})$, $\boldsymbol{\nu}_k = (\nu_{k1}, \nu_{k2}, \ldots, \nu_{kn})$, $\boldsymbol{N}_k = (N_{k1}, N_{k2}, \ldots N_{kn})$, $k = 1, 2$, and $\boldsymbol{w} = (w_1, w_2, \ldots, w_n)'$. The complete data is given by $D = (n, \boldsymbol{y}_1, \boldsymbol{y}_2, \boldsymbol{\nu}_1, \boldsymbol{\nu}_2, \boldsymbol{N}_1, \boldsymbol{N}_2, \boldsymbol{w})$, where $\boldsymbol{N}_1$, $\boldsymbol{N}_2$, and $\boldsymbol{w}$ are unobserved random vectors, and the observed data is given by $D_{\text{obs}} = (n, \boldsymbol{y}_1, \boldsymbol{y}_2, \boldsymbol{\nu}_1, \boldsymbol{\nu}_2)$. Further, let $\boldsymbol{\theta} = (\theta_1, \theta_2)'$ and $\boldsymbol{\psi} = (\boldsymbol{\psi}_1', \boldsymbol{\psi}_2')'$. The likelihood function of $(\boldsymbol{\theta}, \boldsymbol{\psi})$ based on the complete data D is given by

$$
\begin{aligned}
L(\boldsymbol{\theta}, \boldsymbol{\psi}|D) &= \left(\prod_{k=1}^{2} \prod_{i=1}^{n} S_k(y_{ki}|\boldsymbol{\psi}_k)^{N_{ki}-\nu_{ki}} \right. \\
&\quad \left. \times \left(N_{ki} f_k(y_{ki}|\boldsymbol{\psi}_k) \right)^{\nu_{ki}} \right) \\
&\quad \times \exp\left\{ \sum_{i=1}^{n} (N_{ki} \log(w_i\theta_k) - \log(N_{ki}!) - w_i\theta_k) \right\},
\end{aligned} \tag{16}
$$

where $f_k(y_{ki}|\boldsymbol{\psi}_k)$ is the density corresponding to $F_k(y_{ki}|\boldsymbol{\psi}_k)$. We assume a Weibull density for $f_k(y_{ki}|\boldsymbol{\psi}_k)$, so that

$$
f_k(y|\boldsymbol{\psi}_k) = \xi_k y^{\xi_k - 1} \exp\left\{ \lambda_k - y^{\xi_k} \exp(\lambda_k) \right\}. \tag{17}
$$

To construct the likelihood function of the observed data, $L(\boldsymbol{\theta}, \boldsymbol{\psi}, \alpha|D_{\text{obs}})$, we integrate (16) with respect to $(\mathbf{N}, \boldsymbol{w})$ assuming a $S_\alpha(1, 1, 0)$ density for each w_i, denoted by $f_s(w_i|\alpha)$, leading to

$$
\begin{aligned}
&L(\boldsymbol{\theta}, \boldsymbol{\psi}, \alpha|D_{\text{obs}}) \\
&\quad \equiv \int_{R^{+n}} \sum_{(\mathbf{N_1}, \mathbf{N_2})} L(\boldsymbol{\theta}, \boldsymbol{\psi}|D) \times \left[\prod_{i=1}^{n} f_s(w_i|\alpha) \right] \mathrm{d}\boldsymbol{w} \\
&\quad = \theta_1^{d_1} \theta_2^{d_2} \alpha^{d_1+d_2} \left[\prod_{k=1}^{2} \prod_{i=1}^{n} f_k(y_{ki}|\boldsymbol{\psi}_k)^{\nu_{ki}} \right] \\
&\quad \times \prod_{i=1}^{n} \left\{ [\theta_1 F_1(y_{1i}|\boldsymbol{\psi}_1) + \theta_2 F_2(y_{2i}|\boldsymbol{\psi}_2)]^{(\alpha-1)(\nu_{1i}+\nu_{2i})} \right\} \\
&\quad \times \prod_{i=1}^{n} \left[\alpha^{-1}(1-\alpha)(\theta_1 F_1(y_{1i}|\boldsymbol{\psi}_1) \right. \\
&\quad \left. + \theta_2 F_2(y_{2i}|\boldsymbol{\psi}_2))^{-\alpha} + 1 \right]^{\nu_{1i}\nu_{2i}} \\
&\quad \times \prod_{i=1}^{n} \exp\left\{ -(\theta_1 F_1(y_{1i}|\boldsymbol{\psi}_1) + \theta_2 F_2(y_{2i}|\boldsymbol{\psi}_2))^{\alpha} \right\},
\end{aligned} \tag{18}
$$

where $f_s(w_i|\alpha)$ denotes the probability density function of w_i defined by (11), $d_k = \sum_{i=1}^{n} \nu_{ki}$ for $k = 1, 2$, $R^{+n} = R^+ \times R^+ \times \ldots \times R^+$, and $R^+ = (0, \infty)$. As before, we incorporate covariates for the cure rate model (12) through the cure rate parameter $\boldsymbol{\theta}$. Let $\boldsymbol{x}_i' = (x_{i1}, x_{i2}, \ldots, x_{ip})$ denote the $p \times 1$ vector of covariates for the ith subject, and let $\boldsymbol{\beta}_k = (\beta_{k1}, \beta_{k2}, \ldots, \beta_{kp})'$ denote the corresponding vector of regression coefficients for failure time random variable Y_k, $k = 1, 2$. We relate $\boldsymbol{\theta}$ to the covariates by

$$\theta_{ki} \equiv \theta(\boldsymbol{x}_i'\boldsymbol{\beta}_k) = \exp(\boldsymbol{x}_i'\boldsymbol{\beta}_k), \tag{19}$$

so that the cure rate for subject i is

$$\exp(-\theta_{ki}) = \exp(-\exp(\boldsymbol{x}_i'\boldsymbol{\beta}_k)), \tag{20}$$

for $i = 1, 2, \ldots, n$ and $k = 1, 2$. Letting $\boldsymbol{\beta} = (\boldsymbol{\beta}_1', \boldsymbol{\beta}_2')'$, we can write the observed data likelihood of $(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha)$ as

$$\begin{aligned}
&L(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha|D_{\text{obs}}) \\
&= \left(\alpha^{d_1+d_2} \prod_{k=1}^{2} \prod_{i \in \mathcal{D}_k} \exp(\boldsymbol{x}_i'\boldsymbol{\beta}_k)\right) \\
&\times \left[\prod_{k=1}^{2} \prod_{i=1}^{n} f_k(y_{ki}|\boldsymbol{\psi}_k)^{\nu_{ki}}\right] \\
&\times \prod_{i=1}^{n} \left\{[\exp(\boldsymbol{x}_i'\boldsymbol{\beta}_1) F_1(y_{1i}|\boldsymbol{\psi}_1) \right. \\
&\left. + \exp(\boldsymbol{x}_i'\boldsymbol{\beta}_2) F_2(y_{2i}|\boldsymbol{\psi}_2)]^{(\alpha-1)(\nu_{1i}+\nu_{2i})}\right\} \\
&\times \prod_{i=1}^{n} \left\{\frac{1-\alpha}{\alpha}[\exp(\boldsymbol{x}_i'\boldsymbol{\beta}_1) F_1(y_{1i}|\boldsymbol{\psi}_1) \right. \\
&\left. + \exp(\boldsymbol{x}_i'\boldsymbol{\beta}_2) F_2(y_{2i}|\boldsymbol{\psi}_2)]^{-\alpha} + 1\right\}^{\nu_{1i}\nu_{2i}} \\
&\times \prod_{i=1}^{n} \exp\left\{-(\exp(\boldsymbol{x}_i'\boldsymbol{\beta}_1) F_1(y_{1i}|\boldsymbol{\psi}_1) \right. \\
&\left. + \exp(\boldsymbol{x}_i'\boldsymbol{\beta}_2) F_2(y_{2i}|\boldsymbol{\psi}_2))^{\alpha}\right\},
\end{aligned} \tag{21}$$

where $\mathcal{D}_k$ consists of those patients who failed according to Y_k, $k = 1, 2$, $D_{\text{obs}} = (n, \boldsymbol{y}_1, \boldsymbol{y}_2, X, \boldsymbol{\nu}_1, \boldsymbol{\nu}_2)$, X is the $n \times p$ matrix of covariates, $f_k(y_{ki}|\boldsymbol{\psi}_k)$ is given by (17), and

$$f_k(y_{ki}|\boldsymbol{\psi}_k) = 1 - \exp\{-y_{ki}^{\xi_k} \exp(\lambda_k)\}. \tag{22}$$

Chen, Ibrahim, and Sinha [8] consider a joint improper prior for $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \alpha)$ of the form

$$\begin{aligned}
\pi(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha) &= \pi(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \alpha) \\
&\propto \pi(\boldsymbol{\psi}_1)\pi(\boldsymbol{\psi}_2) I(0 < \alpha < 1) \\
&= \prod_{k=1}^{2} \pi(\xi_k, \lambda_k) I(0 < \alpha < 1),
\end{aligned} \tag{23}$$

where $I(0 < \alpha < 1) = 1$ if $0 < \alpha < 1$, and 0 otherwise. Thus, (23) implies that $\boldsymbol{\beta}$, $\boldsymbol{\psi}$, and α are independent *a* priori, $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$ are independent *a* priori with an improper uniform prior, α has a proper uniform prior over the interval $(0, 1)$, and $(\boldsymbol{\psi}_1, \boldsymbol{\psi}_2)$ are independent and identically distributed as $\pi(\boldsymbol{\psi}_k)$ *a* priori. They also assume that

$$\pi(\xi_k, \lambda_k) = \pi(\xi_k|\nu_0, \tau_0)\pi(\lambda_k), \tag{24}$$

where

$$\pi(\xi_k|\delta_0, \tau_0) \propto \xi_k^{\delta_0 - 1} \exp\{-\tau_0 \xi_k\}, \text{ and}$$
$$\pi(\lambda_k) \propto \exp\{-c_0 \lambda_k^2\},$$

and δ_0, τ_0, and c_0 are specified hyperparameters. With these specifications, the posterior distribution of $(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha)$ based on the observed data $D_{\text{obs}} = (n, \boldsymbol{y}_1, \boldsymbol{y}_2, X, \boldsymbol{\nu}_1, \boldsymbol{\nu}_2)$ is given by

$$\begin{aligned}
\pi(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha|D_{\text{obs}}) &\propto L(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha|D_{\text{obs}}) \\
&\times \prod_{k=1}^{2} \pi(\xi_k|\delta_0, \tau_0)\pi(\lambda_k),
\end{aligned} \tag{25}$$

where $L(\boldsymbol{\beta}, \boldsymbol{\psi}, \alpha|D_{\text{obs}})$ is given by (21). Chen, Ibrahim, and Sinha [8] show that the posterior distribution in (25) using the noninformative improper prior (23) is proper under some very general conditions.

Bayesian Decision Models in Health Care

In many situations, analysts are required to assess the probability of a unique event, where there are no relevant historical patterns. Sometimes, the environment has changed so radically that the past trends for a familiar event are no longer relevant. Still other times, it is theoretically possible to gather historical data, but time or money limitations prevent data collection. In these circumstances, a "Bayesian subjective probability" model is appropriate (*see* **Bayesian Methods**). The process for creating a Bayesian probability model is explained elsewhere [4].

Bayesian probability models have been used to model complex health care issues such as predicting who will sue a hospital [2], assessing probability of mortality from myocardial infarctions [3], and predicting which health planning project is most likely to succeed [5]. Here, we give an example of the way the model was applied to create an index for predicting preventable hospitalization [1].

A health insurance company wished to adjust premiums on the basis of the preventable and modifiable health risks of individual members. Although many risk factors for hospitalization had been identified (e.g. smoking), no studies had been done that combined the various risks into one aggregate scale. To accomplish this task, leading researchers met in a consensus panel. During this meeting a model was constructed that summarized their opinions about the overall risk of an individual engaged in different lifestyles.

The goal of the exercise was to predict the probability of a major hospitalization during the next three years. The **explanatory variables** of interest were alcohol and tobacco use, weight, blood pressure, dyslipidemia, risk of trauma, and depression. For each factor and its potential levels, experts were asked to estimate two probabilities. For example, the experts individually and then as a group answered the following two questions related to smoking:

1. Of 100 people who *have* been hospitalized, how many smoked a pack a day in the last three years?
2. Of 100 people who *have not* been hospitalized, how many smoked a pack a day in the last three years?

The ratio of the answers to these two questions provided the **likelihood ratio** associated with smoking more than two packs a day. Experts also estimated the prior odds for different population groups, and a predictive model was created [5]. Finally, experts rated 64 hypothetical cases and the average of these ratings was compared with the Bayesian model predictions. The model, which was found to agree with the expert judgments, took only two days to construct, which is considerably less time than would have been required to collect and analyze a large data set. Not only are subjective models quick to construct, but they may also be more valid and generalizable than models based on a specific data set that may have significant biases.

Bayesian Measures of Goodness of Fit

Introduction

With the relatively recent advent of **Markov Chain Monte Carlo** techniques, and their flexibility and ease of application, we might be tempted to believe that we can now fit almost any practical **Bayesian** model, and report inference based on the MCMC's sampled approximation of the posterior **likelihood**. However, this suggested analysis does not at any stage involve checking that the model is indeed "sensible" and, following the model construction and criticism **algorithm** laid down by Carota et al. [6], simply concluding the analysis after completion of the MCMC computation may be unwise and potentially misleading. Exactly as with classical analyses, we should pursue some indication that the fitted model actually fits well. That is, we should critically assess whether the data appears to violate some or all of the model assumptions.

In classical approaches, **goodness of fit** statistics measure the fit, "distance", or "discrepancy" between the specified model and the data. Under a Bayesian approach, this description still holds, but the definition of the "model" now includes a **prior distribution**, which to some extent complicates this assessment.

In the summary that follows, we shall describe Bayesian methods for assessing goodness of fit, which use only the model (and prior) *specified*, and do not refer to any particular alternative formulations. From a strict Bayesian point of view, the reader should note that we may be on thin ice here; as for the prior, if we truly believe the model, then we have no reason to question it, and if there are alternative models, then these should be described and the models compared via their posterior probabilities, as one might when using **Bayes Factors**, or when conducting Bayesian model averaging (*see* **Bayesian Methods for Model Comparison**). This is not the same as the common situation considered here, where we have no specific alternative models, but do have some measures that (we believe) realistically reflect how well the specified model is performing. In summary then, this article will deal with discrepancies between model and data of types, which are somehow prespecified by the user, and therefore a more rigorous title might cite "measures of *practical* goodness of fit".

In this review, we deal first with the general ideas used and their application to relatively simple nonhierarchical models, and then cover the more complicated issues that **hierarchical** structures bring. The field is relatively new, and builds on the classical goodness-of-fit theory with which the reader should compare these methods.

There are a number of related issues of which the reader should be aware but which we will not cover here. *Overfitting* occurs when the model has too many parameters for the size of dataset considered, and it will generally fit suspiciously well. The methods described here are generally derived for testing the opposite problem of poor fit, but most methods could be adapted to look for data at the other extreme.

If we are not seeking an overall measure of fit, but rather methods for choosing the best of a selection of well-defined models, then this is *model comparison* (*see* **Model, Choice of**). A number of authors have considered Bayesian approaches to this issue; for a general review and new contributions, *see* **Bayesian Methods for Model Comparison**.

Finally, if our measure of goodness of fit is not only part of an inferential analysis as considered here, but forms some section of a decision-making process with associated costs, decisions to reject any model because of poor fit must be driven by the processes that determine how poor fit will be ascertained (*see* **Decision Theory**). We must specify the purpose for which the model is unacceptable, and hence a **utility** function. For a short discussion and references, see Draper's comment in [13].

Methods for Assessing Goodness of fit in Nonhierarchical Bayesian Models

***P* values.** Define $T(X)$ to be some measure of discrepancy between the data x, and the model, where T is chosen by the practitioner. Evidence against the model is indicated by large values of T, and we wish to examine what the chances are of seeing a value of T worse than the one we get from our observed data x_{obs}. The probability of observing any of these worse values is given by the ***P* value**

$$p = \mathbb{P}_H(T(X) \geq T(x_{\text{obs}})). \tag{1}$$

To obtain P values, the practitioner therefore has to choose both an appropriate discrepancy measure T

and the distribution H (or density h) for X under the assumed model, which automatically define the distribution of T.

The "natural" [3] Bayesian choice for h is the *prior predictive distribution*, so that

$$h_{\text{prior pred}} = \int f(x|\theta)\pi(\theta)\,\mathrm{d}\theta. \tag{2}$$

However, this cannot be used if our prior π is improper, which precludes the use of some reference distributions, and is therefore rather unsatisfactory. A suggested alternative is to use the *posterior predictive distribution*;

$$h_{\text{post pred}} = \int f(x|\theta)\pi(\theta|x_{\text{obs}})\,\mathrm{d}\theta, \tag{3}$$

where $\pi(\theta|x_{\text{obs}})$ of course is proportional to $f(x|\theta)\pi(\theta)$ by **Bayes' Theorem**.

Defined as the P value obtained using $H_{\text{post pred}}$ from (3) in (1), $p_{\text{post pred}}$ is asymptotically distributed as $U(0, 1)$, and so is interpretable in the same way as a classical P value [9, 10]. However, examining (3), we see that this approach leads to us comparing our observed statistic $T(X_{\text{obs}})$ with a distribution derived using x_{obs}. This uses the data twice, and can lead to overly conservative inferences [1].

Bayarri and Berger [2, 1], have proposed two alternatives, using principles similar to those used in (frequentist) **conditional** and **partial likelihood** arguments. To define these, we denote the density of $T(X)$ by $f(t|\theta)$, its observed value by $t_{\text{obs}} = T(x_{\text{obs}})$, and similarly for other functions of the data.

The *conditional predictive P value*, for some discrepancy function T, requires the user to choose another function U, which is preferably approximately independent of T, does not include T, and contains as much information as possible about θ. (The reader may be interested to compare this with the problem of choosing statistics to condition on for conditional inference.) A simple example, splitting the data into $T = x_1, \ldots, x_k$ and $U = x_{k+1}, \ldots, x_n$ was put forward by Evans [11]. In general, using

$$h_{\text{cond}}(t|u) = \int f(t|u, \theta)\pi(\theta|u)\,\mathrm{d}\theta, \tag{4}$$

where $\pi(\theta|u) \propto f(u|\theta)\pi(\theta)$, we get

$$p_{\text{cond pred}}(t) = \mathbb{P}_{H_{\text{cond}}(\cdot|u_{\text{obs}})}(T \geq t_{\text{obs}}). \tag{5}$$

This P value effectively conditions out almost all of the information about θ, leaving a distribution for T, which reflects the fit of the model f rather than the prior θ. Because the data is (preferably) partitioned into U and T, we should not use any of it twice, and improper priors can be used as long as $\pi(\theta|u)$ is proper. However, the choice of U may not be obvious, and even if some U can be found $p_{\text{cond pred}}$ may be hard to compute.

An alternative to finding an appropriate U is to adjust the posterior predictive distribution $h_{\text{post pred}}$ from (3) to remove the contribution from t_{obs}. This is done by conditioning on T, so we get

$$h_{\text{part pred}}(t) = \int f(t|\theta)\pi_{\text{part}}(\theta)\,\mathrm{d}\theta, \tag{6}$$

where

$$\pi_{\text{part}}(\theta) \propto \frac{f(x_{\text{obs}}|\theta)\pi(\theta)}{f(t_{\text{obs}}|\theta)} \tag{7}$$

Using $H_{\text{part pred}}$ in place of H_{cond} in (5) gives the **partial predictive *P* value**; it is easier to compute while, due to its derivation, we can expect it to give similar inferences to $p_{\text{cond pred}}(t)$.

The work of Gelman et al. [12, 13] defines P values similar to those derived from (1) but explicitly includes the idea of *replication*. Here we imagine that we have x^{rep}, a replicated dataset that might be observed if the experiment were run again, using exactly the same model M, parameters θ and, importantly, the same ancillary statistics, written as $A(X)$. We move from considering $f(x|\theta)\pi(\theta)$ to $f(x|\theta)\pi(\theta)f(x^{\text{rep}}|\theta)$. The classical goodness-of-fit statistic can be written as

$$p_{\text{class}}(x, \theta) = \mathbb{P}(T(x^{\text{rep}}) \geq T(x)|A, M, \theta), \tag{8}$$

for some fixed but unknown θ. The difficulty in the classical application of p_{class} lies in finding some pivotal T, which has a distribution at least approximately free of θ. The Bayesian analogue [12, 13] avoids this by averaging p_{class} over the posterior distribution for θ; hence,

$$\begin{aligned} p_{\text{Bayes}}(x) &= \mathbb{P}(T(x^{\text{rep}}) \geq T(x)|A, M) \\ &= \int p_{\text{class}}(x, \theta) f(\theta|A, M, x)\,\mathrm{d}\theta, \end{aligned} \tag{9}$$

and given a prior for θ, we can compute p_{Bayes} for any dataset. This approach is in turn generalizable in two

ways: firstly, we could take a fully Bayesian approach and allow for θ^{rep}, parameters replicated in the same way as for x^{rep}. Second, we can generalize the discrepancy function T to include some dependence on θ, and consider the model as ill-fitting when

$$p'_{\text{Bayes}} = \mathbb{P}(T(X, \theta) \geq T(x_{\text{obs}}, \theta) | x_{\text{obs}}, A(x_{\text{obs}})) \tag{10}$$

is small. This can in turn be generalized if we change from the symmetric use of discrepancy function T in (10) to the more general $D(x, x^{\text{rep}}, \theta, \theta^{\text{rep}})$, where we also allow for parameter replication as mentioned above. Then (9) becomes

$$p''_{\text{Bayes}}(x) = \mathbb{P}(D(x, x^{\text{rep}}, \theta, \theta^{\text{rep}}) > 0). \tag{11}$$

As a special case of (11), putting $D(x) = \min_\theta D(x, \theta)$, we remove the dependence of p_{Bayes} on θ, and for linear models obtain the classical tests of goodness of fit, comparing a sum of standardized **residuals** from the data with the best fit of the model, a **χ^2 test**. For many models, such a construction also gives some idea of which data points are *causing* the poor fit of the data, clearly a useful tool in many situations, for example, the exclusion of outliers. The analysis of residuals in this way forms the basis of much of frequentist testing, even outside of linear models. For a Bayesian version of these case-influence diagnostics, see the work of Chaloner [7], later generalized by Weiss [27–28]. This method of constructing goodness-of-fit measures is explored further in the section on hierarchical models.

The connection with classical residuals is attractive, but not straightforward. The classical residual has several forms, but they are fundamentally a measure of distance between a data point and its fitted value under the model. Summing these gives the classical overall measure of fit mentioned above. The Bayesian approach gives a posterior distribution for parameters, not fitted values, and so each residual also has a distribution, as does the sum of all residuals. We could of course use "plug-in" values like the posterior mean or median, but this contradicts the Bayesian practice of properly allowing for all sources of uncertainty. Calibrating the size of residuals in a meaningful way is also difficult and often sensitive to parameterization changes, unlike the P value techniques discussed here.

Bayes Factors. All the methods of the previous section result in some form of tail probability, a value between 0 and 1, where this scale indicates poor to good measure of goodness of fit. Care should be taken that this value is distributed (at least approximately) as $U(0, 1)$ if we want to interpret these as P values [9, 10]. This potential incoherence is noted by Conigliani et al. [8], who suggest the alternative use of *Bayes factors*. To use these, we *must* exactly specify all the alternative priors, models and associated parameters, giving a series of $f_i(x|\theta_i)$ and $\pi_i(\theta_i)$ for each model M_i.

(To keep to our remit of discussing models where no alternative is readily available, we shall here only mention models where a "general alternative" can be reasonably assumed; typically, these are models for discrete data (*see* **Categorical Data Analysis**), for example, **binomial** or **Poisson**, where the alternative is that the data comes from a **multinomial** distribution where the cell probabilities have a Dirichlet distribution. Strictly speaking, this is model comparison, but as we have no intention of accepting the **alternative hypothesis**, it can be viewed as constructing a diagnostic measure sensitive to deviations from the **null hypothesis**, or a measure of goodness of fit.)

The Bayes factor in favor of model 1 against the alternative model 2 is

$$B(x) = \frac{\int f_1(x|\theta_1)\pi_1(\theta_1)\,\mathrm{d}\theta}{\int f_2(x|\theta_2)\pi_2(\theta_2)\,\mathrm{d}\theta}, \tag{12}$$

which can be interpreted as the ratio of posterior **odds** (of model 2 to model 1) to the prior odds. A large value of B indicates that model 1 fits better than the alternative, and scales exist for converting numerical Bayes factors into strengths of evidence against the model, for example, [16]. However, similarly to the prior predictive P value, the standard Bayes factor cannot be defined when either $\pi_1(\theta_1)$ or $\pi_2(\theta_2)$ is improper [21]. As discussed above, where we use a "general alternative" for π_2, this choice may well be improper. It should at least be rather diffuse, in which case the Bayes factor is sensitive to the degree of flatness in π_2 [8, 13].

Various solutions to these problems have been proposed. O'Hagan [20] developed the *partial Bayes factor*, where part of the data is used to update the prior so that it is proper, and the rest used to calculate the Bayes factor. If we split x into training sample y

and remainder data z, this gives

$$B(z|y) = \frac{\int f_1(z|\theta_1, y)\pi_1(\theta_1|y)\,\mathrm{d}\theta}{\int f_2(z|\theta_2, y)\pi_2(\theta_2|y)\,\mathrm{d}\theta}, \quad (13)$$

$$= \frac{B(x)}{B(y)}. \quad (14)$$

However, the problematic choice remains of which training sample y to use, and therefore how much of $B(x)$ to use. Various options are available, among them, a simple fixed proportion of the data, or Berger and Pericchi's [4] *intrinsic Bayes factor*, which uses all possible training samples, averaging the results. A further refinement is available through the *fractional Bayes factor* [8, 21]. Here, if the training sample y is assumed to be a given proportion b of the data, it is noted that the likelihood associated with *any* training sample is approximately $f(x|\theta)^b$, and so we get

$$B_{\text{frac}}(x) = \frac{q_1(b, x)}{q_2(b, x)}, \quad (15)$$

where

$$q_i(b, x) = \frac{\int f_i(x|\theta_i)\pi_i(\theta_i)\,\mathrm{d}\theta}{\int f_i(x|\theta_i)^b\pi_i(\theta_i)\,\mathrm{d}\theta}. \quad (16)$$

O'Hagan [21] suggests several ways of choosing b under different circumstances.

For continuous data, the problem of choosing a "general alternative" to the model being checked is more difficult, and techniques are less well advanced. Verdinelli and Wasserman [25] use as an alternative, a likelihood made up of a series of Gaussian packets, spread along the whole real line, choosing them appropriately so that the Bayes factor is *consistent*; that is, tends to ∞ or 0 depending on whether the model is true or false. Robert and Rousseau [23] restrict their attention to the interval [0, 1], postulating that if a model F_θ is not true for data X, then $F_\theta(X)$ does not have a **uniform** $U(0, 1)$ distribution, but is instead distributed as a mixture of **beta** likelihoods.

Methods for Assessing Goodness of fit in Hierarchical Bayesian Models

Assessing goodness of fit becomes more difficult where more than one level of random behavior takes place. For example, we might model pupil performance within school performance within county performance – postulating that each stage will contribute its own uncertainty. We can label the pupil performance as level I, the schools as level II, and so on. Such a model is called *hierarchical*, where ultimately, we place priors on all the parameters left unspecified in the hierarchy. (This is very similar to a **multilevel model**.) Hierarchical models have been found to have the desirable property of **robustness** to the choice of prior [14], and so we might expect that they perform well even if the model is slightly **misspecified**.

The difficulty in testing goodness of fit in hierarchical models comes because we have no direct observations beyond the first level; any data about school performance will contain uncertainty due to pupils. We do not have any data that depends only on parameters from levels II and above (known as intermediate parameters, and labelled ϕ). It is therefore difficult to define a discrepancy statistic T, which assesses how well the model fits at these levels.

One approach to this is motivated by a remark in [5]; if the likelihood and prior give conflicting information about intermediate parameters ϕ, this suggests faults in the model, in other words, lack of fit. This idea is developed by O'Hagan [22], who suggests several ways of measuring this conflict.

Another approach that gives measures of fit for individual data points is **cross-validation**, or "leave-one-out" techniques. Here the model is re-analyzed without a particular data point or points, and the fitted value for some (intermediate) parameter compared with the original estimate. Each data point (or group of points) is left out in turn; if fitted values behave erratically when some data is missing, this indicates poor model fit. However, as these methods will require rerunning the MCMC chain every time we leave a point out to assess its impact, they will almost always be too computationally burdensome to be practical. For details on cross-validation, and more tractable approximations to it, see the work of Stern and Cressie (2000) [24] its development by Marshall and Spiegelhalter (2003) [19].

A final approach used for assessing goodness of fit in Bayesian hierarchical or classical multilevel models involves *embedding* the model in some more general framework [17, 15]. If the model can be considered as a special, large case of, for example, a linear model, then goodness-of-fit **diagnostics** appropriate to the larger linear model can be used.

Embedding the model in this way may require the addition of artificial data points to reflect the hierarchical structure or prior distributions used, which is rather unsatisfactory, leading to accusations that we are fitting the problem to the diagnostics, not the diagnostics to the problem.

An early, but very useful and specifically Bayesian embedding procedure is given by Wakefield et al. [26], used to check the assumption of a normal **random effects** distribution. Here, instead of the **normal distribution** assumed to be "correct", an extension to the **multivariate *t* distribution** is used, represented as a scaled mixture of normals. If the scaling parameter corresponding to individual random effects is too small, we have evidence of poor fit of the model for that part of the data.

Bayesian Methods for Contingency Tables

Motivation for Bayesian Methods

There is an extensive literature on the classical analysis of **contingency tables**. Bishop, Fienberg, and Holland [7] and Agresti [1] illustrate the use of **loglinear models** to describe the **association** structure in a multidimensional contingency table. Chi-square statistics are used to examine independence and to compare nested loglinear models (*see* **Chi-square Tests**; **Chi-square Distribution**); ***P* values** are used to assess statistical significance. **Estimation** and **hypothesis testing** procedures rest on asymptotic results for multinomial random variables (*see* **Multinomial Distribution**).

Several problems with classical **categorical data analyses** motivate consideration of **Bayesian methods**. First, there is the problem of estimating cell probabilities and corresponding expected cell counts from a sparse multiway contingency table with some empty cells. It is desirable to obtain positive smoothed estimates of the expected cell counts, reflecting the knowledge that the cell probabilities all exceed zero. Second, in comparing models, there is difficulty in interpreting the evidence communicated by a test statistic's P value, as noted for instance by Diaconis and Efron [11] in the simple case of a P value for detecting association in a two-way table with large counts. This problem motivates a Bayesian approach to measuring evidence. Lastly, there is the potential bias in estimating association measures from models arrived at by classical model selection strategies, for example, for choosing the best loglinear model (*see* **Model, Choice of**). One typically uses a fitted model to estimate both an association parameter and the variability of the estimated parameter, while ignoring uncertainty in the process of arriving at the model on which estimation is based. Bayesian methods allow a user to explicitly model the uncertainty among a class of possible models by means of a **prior distribution** on the class of models, so that the posterior estimates of association parameters explicitly account for uncertainty about the "true" model on which estimates should ideally be based.

Early Bayesian Analyses of Categorical Data

Early Bayesian analyses for categorical data focused on tractable approximations for posterior distributions and measures of evidence for two-way tables. For a multinomial random variable $\{y_{ij}\}$ with cell probabilities $\{\theta_{ij}\}$, Lindley [27] considered the posterior distribution of the log contrast $\lambda = \Sigma\Sigma a_{ij} \log \theta_{ij}$, where $\Sigma\Sigma a_{ij} = 0$. In a **2 × 2 table** with cell probabilities $(\theta_{11}, \theta_{12}, \theta_{21}, \theta_{22})$, one example of a log contrast is the log **odds ratio**

$$\lambda = \log \theta_{11} - \log \theta_{12} - \log \theta_{21} + \log \theta_{22}. \quad (1)$$

If $\{\theta_{ij}\}$ is assumed to have a Dirichlet $(\{\alpha_{ij}\})$ distribution of the form $p(\{\theta_{ij}\}) \propto \prod \theta_{ij}^{\alpha_{ij}-1}$, Lindley showed that the posterior distribution for λ is approximately normal with mean and variance given respectively by

$$\lambda^* = \sum_i \sum_j a_{ij} \log(\alpha_{ij} + y_{ij}),$$

$$v^* = \sum_i \sum_j a_{ij} (\alpha_{ij} + y_{ij})^{-1}. \quad (2)$$

Lindley used this approximation to obtain the posterior density of the log odds ratio and to develop a Bayesian statistic for testing independence in a 2×2 table (*see* **Independence of a Set of Variables, Tests of**).

The formal way of comparing models from a Bayesian perspective is by the use of **Bayes factors**. If y denotes the data and θ denotes a parameter, a Bayesian model is described by a sampling density for the data, $f(y|\theta)$, and a prior density for the parameter, $g(\theta)$. If one has two Bayesian models $M_1 : \{f_1(y|\theta_1), g_1(\theta_1)\}$ and $M_2 : \{f_2(y|\theta_2), g_2(\theta_2)\}$, then the Bayes factor in support of model 1 over model 2 is given by

$$BF_{12} = \frac{m_1(y)}{m_2(y)}, \quad (3)$$

where $m_i(y)$ is the marginal or predictive density of the data for model M_i:

$$m_i(y) = \int f_i(y|\theta_i) g_i(\theta_i) \, d\theta_i. \quad (4)$$

The Bayes factor may also be interpreted as the ratio of posterior odds of model 1 to model 2, given the data, to the corresponding prior odds.

Jeffreys [20] was one of the first to develop Bayes factors in testing for independence in a 2×2 table. Under the independence model H, the cell probabilities can be expressed as $\{\alpha\beta, \alpha(1-\beta), (1-\alpha)\beta, (1-\alpha)(1-\beta)\}$, where α and β are marginal probabilities of the table. Under the dependence hypothesis, Jeffreys expressed the probabilities as $\{\alpha\beta + \gamma, \alpha(1-\beta) - \gamma, (1-\alpha)\beta - \gamma, (1-\alpha)(1-\beta) + \gamma\}$. By assuming independent uniform $(0, 1)$ prior distributions on α, β, and γ, Jeffreys developed an approximate Bayes factor in support of the dependence hypothesis.

Suppose one observes multinomial $\{y_1, \ldots, y_t\}$ with cell probabilities $\{\theta_1, \ldots, \theta_t\}$ and total count $n = \sum_{i=1}^{t} y_i$. Good [14] noted that simple relative frequency estimates of the probabilities θ_i can be poor when data are sparse, and studied the alternative estimates $(y_i + k)/(n + kt)$, where n is the fixed total count and k is a "flattening constant". This estimate is the mean of the posterior density assuming that the $\{\theta_i\}$ have a symmetric Dirichlet distribution of form

$$p(\theta_i) \propto \prod_{i=1}^{t} \theta_i^{k-1}.$$

In practice, it may be difficult for a user to specify the Dirichlet parameter k. Good then advocated use of a prior distribution $g(k)$ for k, resulting in a prior for the $\{\theta_i\}$ of hierarchical form

$$g(\{\theta_i\}) = \int_0^\infty \frac{\Gamma(tk)}{(\Gamma(k))^t} \prod_{i=1}^{t} \theta_i^{k-1} g(k)\, \mathrm{d}k. \qquad (5)$$

As will be seen later, Good also used this form of a mixture of symmetric Dirichlet distributions to develop Bayes factors for testing independence in contingency tables.

Bayesian Smoothing of Contingency Tables

One difficulty with large contingency tables is that observed sampling zeros in some cells may lead to poor estimates of the underlying cell probabilities. One *ad hoc* adjustment is to add 1/2 to each observed count, as in Good's [14] approach with prespecified flattening constant $k = 1/2$. Fienberg and Holland [13] were interested in developing better estimates for cell probabilities in these tables with sparse counts. They first considered the conjugate Dirichlet model $g(\{\theta_i\} \propto \prod \theta_i^{K\lambda_i - 1}$ as a prior for the cell probabilities, where λ_i is the prior mean of θ_i and K is a precision parameter. The use of this conjugate prior results in the posterior mean estimate

$$\hat{\theta}_i = \left(\frac{n}{n+K}\right)\frac{y_i}{n} + \left(\frac{K}{K+n}\right)\lambda_i. \qquad (6)$$

Since the hyperparameter K is unknown, Fienberg and Holland [13] developed an **empirical Bayes** estimator. For fixed $\{\lambda_i\}$, they showed that the risk of $\hat{\theta}_i$, under squared error loss, is equal to

$$R(\hat{\theta}, \theta) = \left(\frac{n}{(n+K)}\right)^2 (1 - ||\theta||^2) + \left(\frac{K}{(n+K)}\right)^2 n||\theta - \lambda||^2. \qquad (7)$$

The value of K that minimizes this risk is $\hat{K} = (1 - ||\theta||^2)/(||\theta - \lambda||^2)$. If one replaces K with the estimate $\hat{K}$ in the expression for $\hat{\theta}_i$, one obtains the empirical Bayes estimate

$$\theta_i^* = \left(\frac{n}{n+\hat{K}}\right)\frac{y_i}{n} + \left(\frac{\hat{K}}{\hat{K}+n}\right)\lambda_i. \qquad (8)$$

Fienberg and Holland [13] showed that the estimates $\{\theta_i^*\}$ had good risk properties relative to the **maximum likelihood** estimates $\{y_i/n\}$. In practice, one can choose the prior means $\{\lambda_i\}$ to reflect one's prior beliefs, or choose data-dependent values for $\{\lambda_i\}$ based on the estimated expected counts from a log-linear model. For example, one might in this way shrink estimates towards the independence model for two-way contingency tables, or towards conditional independence or the no-three-way **interaction model** for three-way tables (*see* **Shrinkage Estimation**).

A number of alternative fully Bayesian methods have been proposed for smoothing contingency table counts. One approach is based on normal prior distributions placed on components of a logit representation of a cell probability (*see* **Binary Data**). For a two-way table with counts $\{y_{ij}\}$ and cell probabilities $\{\theta_{ij}\}$, Leonard [24] defines the multivariate logit

$$\gamma_{ij} = \text{logit}\ \theta_{ij} = \log \theta_{ij} + D(\theta), \qquad (9)$$

where $D(\theta)$ is chosen to ensure that the probabilities sum to one. The logit is decomposed as

$$\gamma_{ij} = \alpha_i + \beta_j + \lambda_{ij}, \qquad (10)$$

where the terms correspond respectively to a row effect, a column effect, and an **interaction** effect in the two-way table. To model the belief that the set of row effects $\{\alpha_i\}$ is **exchangeable**, Leonard [24] uses the two-stage prior

1. $\alpha_1, \ldots, \alpha_I$ are independent $N(\mu_\alpha, \sigma_\alpha^2)$;
2. $\mu_\alpha, \sigma_\alpha^2$ independent, with μ_α having a vague flat prior and $\nu_\alpha \tau_\alpha \sigma_\alpha^{-2}$ distributed chi-squared with ν_α degrees of freedom (*see* **Exchangeability**). The hyperparameter τ_α represents a prior estimate at σ_α^2 and ν_α measures the sureness of this prior guess.

Similar exchangeable prior distributions are placed on the sets of column effects $\{\beta_j\}$ and interaction effects $\{\lambda_{ij}\}$. Leonard [24] used this model to find posterior modal estimates of the probabilities. When the interaction effects are set equal to zero, these Bayesian estimates smooth the table towards an independence structure. Nazaret [29] extended this multivariate logit representation to three-way tables.

Albert and Gupta [5] and Epstein and Fienberg [12] perform similar smoothing using mixtures of conjugate priors. To model the belief that the cell probabilities satisfy an independence structure, Albert and Gupta [5] assign the $\{\theta_{ij}\}$, a Dirichlet distribution with precision parameter K and prior cell means $\{\lambda_{ij}\}$ satisfying the independence structure $\lambda_{ij} = \lambda_{i+}\lambda_{+j}$, with $\lambda_{i+}, \lambda_{+j}$ respectively the prior row and column marginal means: $\lambda_{i+} = \sum_j \lambda_{ij}, \lambda_{+j} = \sum_i \lambda_{ij}$. At the second-stage of the prior, these marginal prior means $\{\lambda_{i+}\}$ and $\{\lambda_{+j}\}$ are assigned vague **uniform distributions**. The posterior mean of the cell probability θ_{ij} can be expressed as

$$\left(\frac{n}{n+K}\right)\frac{y_{ij}}{n} + \left(\frac{K}{K+n}\right)\mathrm{E}(\lambda_{i+}\lambda_{+j}), \qquad (11)$$

where $\mathrm{E}(\cdot)$ denotes the expectation over the posterior distribution of $\{\lambda_{i+}\,\lambda_{+j}\}$. This estimate is a compromise between the usual unconditional maximum likelihood estimate y_{ij}/n and the estimate under an independence model. Epstein and Fienberg [12] generalized this conjugate approach by modeling the prior mean of θ_{ij} by a logit model. Laird [23] and Knuiman and Speed [22] perform Bayesian smoothing by applying a **multivariate normal** prior to the vector of logarithms of expected cell counts. (King and Brooks [21] show that a multivariate normal prior on the loglinear model parameters induces a multivariate lognormal prior on the expected cell counts of the contingency table.)

Bayesian Interaction Analysis

Leonard and Novick [26] describe the use of a Bayesian **hierarchical model** to explore the interaction structure of a two-way contingency table. Given cell counts $\{y_{ij}\}$ from independent **Poisson distributions** with respective means $\{\theta_{ij}\}$ they assume, at the first stage, that the θ_{ij} have independent **Gamma distributions** with respective means ξ_{ij} and precision parameter α. The means ξ_{ij} are presumed to satisfy the independence structure $\log \xi_{ij} = \mu + \lambda_i^A + \lambda_j^B$. At the second stage of the prior, all unknown parameters are given vague distributions. The posterior distribution of the precision parameter α is informative about the **goodness of fit** of the independence model. In addition, Leonard and Novick [26] consider the posterior distributions of the "parametric **residuals**" $\{\log \theta_{ij} - \log \xi_{ij}\}$ to explore the dependence pattern in the table. Leonard, Hsu, and Tsui [25] consider an alternative interaction analysis based on a nonhierarchical prior. They obtain approximations to the joint posterior distribution of $\{\theta_{ij}\}$, and dependence in the table is studied by considering the posterior distribution of the interaction parameters $\{\theta_{ij} - \theta_{i+} - \theta_{+j} + \theta_{++}\}$, with $\theta_{i+} = \sum_j \theta_{ij}$, $\theta_{+j} = \sum_i \theta_{ij}$, and $\theta_{++} = \sum_i \sum_j \theta_{ij}$.

Bayesian Tests of Equiprobability and Independence

I. J. Good, in a large series of papers, developed Bayes tests for contingency tables under a variety of sampling models. We illustrate the general approach by considering Good's construction of a significance test for equiprobability of a multinomial probability vector [15]. As usual, one observes multinomial $\{y_1, \ldots, y_t\}$ with cell probabilities $\{\theta_1, \ldots, \theta_t\}$ and total count $n = \sum_{i=1}^t y_i$. The hypothesis of interest is $H : \theta_i = 1/t, i = 1, \ldots, t$, and the usual classical test statistic is Pearson's chi-square,

$$X^2 = \sum_{i=1}^{t} \frac{(y_i - \mathrm{E}(y_i))^2}{\mathrm{E}(y_i)} = \frac{t}{n}\Sigma\left(y_i - \frac{n}{t}\right)^2, \qquad (12)$$

which is asymptotically distributed as chi-square with $t - 1$ degrees of freedom.

To develop a Bayes factor to test H against the alternative hypothesis $\overline{H}: \theta_i \neq 1/t$ for some $i = 1, \ldots, t$, note that the density of the data $\{y_1, \ldots, y_t\}$ is fully specified under the hypothesis H. Let H_k denote the hypothesis that the $\{\theta_i\}$ have a symmetric Dirichlet (k) distribution with density $g(\theta) \propto \prod \theta_i^{k-1}$. The hyperparameter k, since it is difficult to specify, is given a log Cauchy prior

$$g(k) = \left(\frac{1}{\pi k}\right)\left(\frac{\lambda}{\lambda^2 + \left(\frac{\log k}{\mu}\right)^2}\right) \tag{13}$$

(*see* **Cauchy Distribution**). Then the Bayes factor BF of $\overline{H}$ against H is given by $BF = \mathrm{E}(BF(k)|\lambda, \mu) = \int BF(k)g(k)\,\mathrm{d}k$, where $BF(k)$ is the Bayes factor of H_k against equiprobability,

$$BF(k) = \frac{t^n \Gamma(tk) \prod_{i=1}^{t} \Gamma(y_i + k)}{\Gamma(k)^t \Gamma(n + tk)}. \tag{14}$$

To illustrate and compare Bayesian and classical measures of evidence, we consider 150 voters of whom 61, 53, and 36 expressed preferences for candidates 1, 2, and 3, respectively. The chi-square statistic for equiprobability is $X^2 = 6.52$ with an associated P value of 0.0384. The following table gives values of the Bayes factor of H_k against H for a range of values of the Dirichlet parameter k. A Dirichlet prior with

k	0.1	0.5	1	2	10	100	1000
$BF(k)$	0	0.2	0.5	0.9	2.8	2.0	1.1

a large value of k, say $k = 1000$, concentrates virtually all of its probability very near the equiprobability hypothesis. The marginal density under $\overline{H}$ is then the data density averaged over models very close to H, and hence only slightly exceeds the density under H. Thus, the Bayes factor only slightly exceeds one. In contrast, Dirichlet priors with very small values of k become increasingly vague. The marginal density from such a vague prior gives roughly equal weights to data densities calculated throughout the parameter space, including parameter regions with which the data are much less compatible than with H. For such values of k, the marginal density under H is thus much higher than under H_k, and the resulting Bayes factor is low; equivalently, the odds of H_k relative to H given the data are much reduced. In fact, the Bayes factor is not defined by the use of an improper prior with $k = 0$.

Note that for the observed data the maximum value of $BF(k)$ in the table is 2.8; for a wide range of log Cauchy priors that might be used in practice, BF will be smaller than 1. Consequently, in contrast with the classical result, the Bayesian measures indicate that there is little evidence against equiprobability in these data. Generally, when testing a point **null hypothesis**, a classical P value overstates the evidence against the hypothesis compared to a Bayes factor test statistic. [6].

Good [16], Crook and Good [8], and Good and Crook [17] extended the above methodology in developing Bayes tests for two-way contingency tables. Tests were constructed on the basis of mixtures of conjugate priors for the three sampling models (multinomial, product-multinomial, multivariate hypergeometric) corresponding respectively to fixed overall table total n or to fixed totals along one or both marginal dimensions (*see* **Hypergeometric Distribution**). An objective of this analysis was to assess whether the marginal totals convey any evidence for or against independence of rows and columns. In the multinomial sampling situation (model 1) where only the total count is fixed, the Bayes factor in support of the dependence hypothesis $\overline{H}$ over the independence hypothesis H is given by

$$BF_1 = \frac{P(\{y_{ij}\}|\overline{H})}{P(\{y_{ij}\}|H)}, \tag{15}$$

where $P(\{y_{ij}\}|\overline{H})$ and $P(\{y_{ij}\}|H)$ are the marginal probabilities of the data under the hypotheses $\overline{H}$ and H, respectively. The marginal probability under $\overline{H}$ is computed using a prior on the vector of cell probabilities $\{\theta_{ij}\}$ that is a mixture of symmetric Dirichlet distributions, and the probability under H is computed by placing similar Dirichlet mixtures as priors on the vectors of marginal cell probabilities $\{\theta_i\}$ and $\{\theta_j\}$. Good and Crook also developed Bayes factors against independence in the situations where either the row or column totals were fixed (model 2), and in the situation where both row and column totals were fixed (model 3). The evidence provided by the row and column totals alone is defined to be the ratio $FRACT = BF_1/BF_3$ of the Bayes factors under model 1, in which information about rows and columns is observed, and model 3, in which

row and column margins are arbitrarily fixed. One conclusion from their studies was that $FRACT$ is usually between 0.5 and 2.5, indicating that the row and column totals typically contain a modest amount of evidence against independence. These Bayesian measures have the advantage that they explicitly allow for the sampling model and do not depend on asymptotic theory. In addition, they can be used as classical test statistics against independence, and tests based upon them can be shown to possess good **power**. Gunel and Dickey [19], and Albert [2] also develop Bayes factors for two-way tables based on conjugate priors and mixtures of conjugate priors, respectively.

Bayes Factors for GLM's with Application to Loglinear Models

Raftery [32] presents a general approach for testing within **generalized linear models**, with direct applications to comparisons of loglinear models for multiway contingency tables. Recall that if one observes data D and has two possible models M_1 and M_2, then the evidence in support of the model M_1 is given by the Bayes factor $BF_{12} = (P(D|M_1)/P(D|M_2))$, where $P(D|M_k)$ is the marginal probability

$$P(D|M_k) = \int P(D|\theta_k, M_k)\, p(\theta_k|M_k)\, \mathrm{d}\theta_k. \quad (16)$$

Raftery presents several methods for approximating $P(D|M_k)$. By the Laplace method for integrals, one has the approximation

$$P(D|M_k) \approx (2\pi)^{p_k/2} |\Psi_k|^{1/2} P(D|\tilde{\theta}_k, M_k)\, p(\tilde{\theta}_k|M_k),$$

where $\tilde{\theta}_k$ is the posterior mode, Ψ_k is the inverse of the negative of the Hessian matrix of $\log P(D|\theta_k, M_k)\, p(\theta_k|M_k)$ evaluated at the mode, p_k is the number of parameters of the model, and $|A|$ indicates the determinant of the matrix A (*see* **Matrix Algebra**).

The following approximation was developed as an alternative that capitalizes on quantities available from standard generalized linear model software:

$$2 \log BF_{12} \approx \chi^2 + (E_1^* - E_2^*),$$
$$E_k^* = -\log |I_k| + 2 \log P(\hat{\theta}_k|M_k) + p_k \log(2\pi), \quad (17)$$

where $\hat{\theta}_k$ and I_k are respectively the maximum likelihood estimate and observed **information matrix** from fitting the model M_k, and X^2 is the classical χ^2 "drop in deviance"test statistic for comparing the two models M_1 and M_2. One important issue is the choice of prior on the **regression** coefficients. Raftery [32] discusses suitable "vague" choices of hyperparameters to use in a testing situation.

To illustrate the use of Bayes factors in model choice, Raftery [32] considers the data shown below from a **case–control study** in which oral contraceptive histories were compared between groups of women having suffered myocardial infarction and control women who had not [34]. The table shows a cross-classification of case (Myocardial infarction) or control status (M), Age category (A), and history of oral Contraceptive use (C).

Suppose we wish to compare the two loglinear models M_1 and M_2, where M_1 denotes the no three-way interaction model indicating that the **relative risk** relating disease and oral contraceptive history (estimated in this context by the odds ratio) is constant across age groups, and the more complicated model M_2 indicating that the relative risk is constant from ages 25 to 34 but may shift to a different constant during ages 35 to 49. Using a classical loglinear analysis, the difference in deviances is 4.7 on one degree of freedom and the P value is 0.03, indicating different relative risks for the age groups 25 to 34 and 35 to 49. Computation of a Bayes factor, in contrast, slightly favors the simpler model M_1.

One advantage of this Bayesian approach is that it can explicitly allow for model uncertainty in the

	Age group (A)									
	25–29		30–34		35–39		40–44		45–49	
	Myocardial infarction (M)									
Oral contraceptives (C)	No	Yes	No	Yes	No	Yes	No	Yes	No	Yes
Not used	224	2	390	12	330	33	362	65	301	93
Used	62	4	33	9	26	4	9	6	5	6

estimation of parameters of interest. Where there are many possible models $\{M_1, \ldots, M_K\}$, the posterior distribution of the parameter θ may be expressed as the mixture of posteriors:

$$p(\theta|D) = \sum_{i=1}^{K} p(\theta|M_k, D)p(M_k|D), \qquad (18)$$

where $p(\theta|M_k, D)$ is the posterior of θ under model M_k and $p(M_k|D) \propto P(M_k)P(D|M_k)$ is the posterior probability of model M_k. Using the above example, Raftery [32] illustrates this "model averaging" approach in estimating a relative risk parameter when there are two plausible models; see [33] for additional applications of this method.)

Use of BIC in Sociological Applications

If one ignores terms of order $O(1)$ or smaller, one gets a further approximation to the log marginal density of the data under model M_k:

$$\log P(D|M_k) \approx \log P(D|\hat{\theta}) - \frac{p_k}{2}\log n \qquad (19)$$

where, as above, p_k is the number of parameters in model M_k [31]. Twice the difference between values of this approximation for a reduced versus a saturated model is the BIC (Bayesian Information Criterion) measure for assessing the overall fit of a model M_k:

$$BIC_k = L_k^2 - \mathrm{d}f_k \log n, \qquad (20)$$

where L_k^2 is the usual deviance statistic and df_k is the associated degrees of freedom of this statistic. Two models M_j and M_k can be compared by the difference $BIC_k - BIC_j$. Raftery [31] gives tables helpful for interpreting the significance of a computed BIC value and comparing it with traditional P values. Specifically, a BIC measure gives precise guidelines on how one should adjust a significance level pertaining to model comparisons as the sample size increases, in order to avoid including trivial complexity in a final model.

Bayesian Model Search for Loglinear Models

Recent advances in Bayesian computing have increased interest in using Bayesian models to search for the "best" loglinear model for a multidimensional contingency table. Madigan and Raftery [28] define some general principles that should be expressed in the behavior of any model selection strategy. One principle is that models that predict the data far less well than the best model should be discarded; that is, models M_k such that $(\max_l P(M_l|D))/P(M_k|D) \geq C$ should be removed from consideration. A second principle, "Occam's Razor", states that if two models predict the data equally well, the simpler should be preferred (*see* **Parsimony**). Madigan and Raftery [28] describe how one can search through the space of models by use of Bayesian posterior model probabilities. In this approach, a model is represented by a directed graph with a node for each variable, and the dependence structure is represented by edges connecting pairs of nodes. Hyper-Dirichlet priors are used to represent prior opinion about the model parameters [9].

Albert [3, 4] describes Bayesian model selection based on priors placed directly on terms of the loglinear model. For a three-way table with a saturated loglinear model represented by

$$\log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{13(ik)} + u_{23(jk)} + u_{123(ijk)}, \qquad (21)$$

Albert [3] places a multivariate normal prior directly on the vector $(u, \boldsymbol{u}_1, \boldsymbol{u}_2, \boldsymbol{u}_3, \boldsymbol{u}_{12}, \boldsymbol{u}_{13}, \boldsymbol{u}_{23}, \boldsymbol{u}_{123})'$ formed by stringing out the sets of u-terms, and models are defined by means of priors that constrain sets of u-terms to zero. The Laplace method [35] is used to compute the model probabilities.

To illustrate the use of a Bayesian model selection strategy, we use the table below, which classifies test rats in an experiment with respect to dose of a possible carcinogen (D), time of death (sacrificed at 132 weeks or age, or prematurely) (T), and presence or absence of cancer at necropsy (C) [13].

	Time of death (T)			
	Premature		At sacrifice	
	Dose (D)			
Cancer (C)	Low	High	Low	High
Present	4	7	0	7
Absent	26	16	14	14

A classical stepwise model search leads to the choice of the model [T], [CD], which indicates that cancer and dose are independent of survival to the end of the experiment. In [3], a Bayesian model search is performed over $2^4 = 16$ models consisting of combinations of the presence or absence of each of the four sets of interaction terms $u_{DT}, u_{DC}, u_{CT}, u_{DTC}$. The table below gives the posterior model probabilities for the six models with the largest values. This Bayesian analysis is similar to that of the classical analysis in the sense that the model with the highest posterior probability includes the interaction u_{CD} and no other interactions, but the probability of this model is only 0.39 and the remaining models have relatively small posterior probabilities. Bayesian estimates of the association between dose and cancer in the table will account for the uncertainty of the "best" loglinear model.

Dellaportas and Forster [10]) propose a **simulation**-based approach for finding the best loglinear model. In this approach, they assume that the vector of logarithms of the expected cell counts has a multivariate normal prior distribution. They work with a parameterization under which all parameters are identifiable and linearly independent, and choose vague priors for these parameters. For searching through the model space, they propose a strategy based on the reversible jump **Markov chain Monte Carlo** (MCMC) algorithm [18]. An attractive feature of this algorithm is that one can move between models of different dimension. These authors apply their model selection strategy, and those of [32] and [28], to finding the best model for a three-way contingency table. Although there are differences in the computed posterior model probabilities, all of these approaches select the same loglinear model. In the normal regression context, George and McCulloch [17] propose an alternative Bayesian algorithm, Stochastic Search Variable Selection (SSVS), for searching through the space of all possible models. Ntzoufras et al. [30] extend the SSVS approach to loglinear modeling.

Interactions included	Posterior probability
None	0.05
u_{CD}	0.39
u_{CA}, u_{CD}	0.07
u_{CD}, u_{ACD}	0.09
u_{CD}, u_{AD}	0.18
u_{CA}, u_{CD}, u_{AD}	0.04

Much of the early Bayesian methodology for contingency tables was devoted to issues regarding computation due to the difficulties in computing integrals of several variables. However, by virtue of great advances in computing posterior distributions by simulation, it is now possible to fit sophisticated Bayesian models for high-dimensional contingency tables. Further, Bayesian advances may be expected, especially with respect to criticism of single loglinear models, and model selection among large classes of hierarchical and graphical models (*see* **Hierarchical Models**).

Bayesian Methods for Model Comparison

This article aims to give a brief overview of methods for comparing competing Bayesian models. This is a large topic of ongoing research interest; for a more thorough review see Key, Pericchi, and Smith or Bernardo and Smith [2, Chapter 6]. Pertinent discussion can also be found in the entries on **Bayes Factors**, **Bayesian measures of goodness of fit**, **Lindley's paradox**, and **choice of model**.

Bayes Factors and Problems Associated with Them

The basic tools of Bayesian model comparison are easily derived from a **decision-theoretic** viewpoint. Suppose we have a series of models M_i, to which we assign **prior** probabilities $P(M_i)$. (For the purposes of this article, "model" includes the distribution of the data and all prior structures associated with parameters.) If we assume the simple **utility** function that scores one for a correct choice of model and zero otherwise, then for data x, it follows simply that the optimal decision is to choose the model with highest posterior probability $p(M_i|x)$. When comparing two models, it is therefore natural to consider

$$\frac{p(M_i|x)}{p(M_j|x)} = \frac{p(x|M_i)}{p(x|M_j)} \times \frac{P(M_i)}{P(M_j)}, \qquad (1)$$

and so given our choice of prior P, the Bayes factor $p(x|M_i)/p(x|M_j)$ gives a straightforward measure for model comparison. See the **Bayes Factor** entry for more details on how to calibrate and interpret Bayes factors.

For a prespecified finite collection of competing models and proper priors, Bayes factors are simple to interpret and calculate. They also follow the **Likelihood Principle** (see e.g. Bernardo and Smith [2, p. 454]) and are unaffected by integrating out nuisance levels of a hierarchical model. But they cannot be defined if we use improper priors and are unstable when using diffuse priors; these properties are described and various modifications proposed in the entry on **Bayesian measures of goodness of fit** or Berger and Pericchi [1]. For further discussion, and a review of techniques used for numerical computation of Bayes factors, see Carlin and Louis [3, pp. 206–219] and Han and Carlin [5].

Lindley's Paradox

Lindley's paradox is a problem related to the stability of Bayes factors for diffuse priors [9]. If the observed data are not "close" to the alternative models, the use of Bayes factors may lead us to accept a hypothesis/model that is rejected by classical **hypothesis tests**. The most famous example of this comes when we have a sample of **normal** data $x_1, x_2, \ldots$. We assume that all X_i are independently distributed $N(\mu, \sigma_0^2)$ for some known σ_0 and wish to compare the models

$$H_0\colon\ \mu = \mu_0 \quad vs \quad H_1\colon\ \mu \neq \mu_0, \qquad (2)$$

where μ_0 is known explicitly. Whenever the sample mean $\overline{x}$ is too far from μ_0, the classical framework rejects H_0. Let us now compare a similar pair of Bayesian models, using the same assumptions that $X_i \sim N(\mu, \sigma_0^2)$, with

$$M_0\colon\ \mu = \mu_0 \quad or \quad M_1\colon\ \mu \sim N(\mu_1, \sigma_1^2), \qquad (3)$$

for some known μ_1, σ_1. Lindley [9] showed that if we let σ_1 become sufficiently large, so that our prior information on μ is extremely diffuse, then use of Bayes factors will lead us to accept M_0 *whatever* the value of $\overline{x}$, even if it is far from μ_0, therefore contradicting the classical approach.

The potentially *huge* diffuseness in the prior is the key to unlocking the "paradox" here. The Bayes factor chooses between two models: one centered around μ_0, which may be a poor reflection of the data, and the extremely diffuse alternative that may give *even less* support to the data, owing to its being so thinly spread. This is a different choice to that posed in the classical analysis, and so different conclusions may be expected. The effect should be taken into account whenever sharp, point values for parameters are compared with diffuse alternative formulations.

Avoiding the Lindley Paradox

Several authors have questioned the value of testing "point" models or hypotheses, as reviewed in Kass and Raftery [6]. However, given the vast frequentist literature on this subject, there is a clear

motivation for Bayesians to seek priors, which are "reasonable" for the alternative model M_1 above. We want to specify a diffuse, weakly informative prior without assuming so little information that we run into Lindley's paradox. A neat solution is given by Kass and Wasserman [10], who advocate setting $\sigma_1 = \sigma_0$ above; this gives a prior that contains the same amount of information as we get from a single observation. They generalize this for multivariate parameters and show that for nested hypotheses (*see* **Hierarchical Models**) the resulting Bayes factors are asymptotically equivalent to the BIC (Bayesian Information Criterion) [11] (or Schwarz Criterion), written as

$$BIC = 2 \log f(x|\hat{\theta}) - 2p \log n \tag{4}$$

for likelihood f, maximum likelihood parameter estimate $\hat{\theta}$, a total of p parameters, and sample size n. This is similar to the work of Smith and Spiegelhalter [12], who derive priors for parameters in nested linear models that are shown to be equivalent to the BIC and the related AIC (Akaike Information Criterion).

The Bayes factor's clear definition makes it desirable to interpret any (sensible) model comparison method as a Bayes Factor for some particular set of prior beliefs, akin to the decision-theoretic results that all admissible decision rules are Bayes rules for some prior. This attractive unifying principle is, however, only helpful for finite numbers of competing models, where we additionally assume that one of the models is correct. Ordinarily, we are only looking for a "best" model, or perhaps just an adequate one, not a strictly "true" one, and this increases the subjectivity in defining prior probabilities for the different models under comparison. See the $\mathcal{M}$-open $\mathcal{M}$-closed discussion by Bernardo and Smith [2, pp. 384–385] for further discussion. In reality, we might additionally expect some models to be motivated by the data itself, further complicating the reasonably simple Bayes factor framework.

Model Averaging, RJMCMC, Utility Discussion

Before exploring Bayesian model comparison techniques beyond the Bayes factor, it is important to ask whether model comparison is to be just one analytical step toward some other ultimate goal, like parameter **estimation** or **prediction** of future behavior. If so, then perhaps the most "fully" Bayesian method for model choice is *not* to choose one model "as if true". Then, following Key et al. [7], we modify all the competing models, and for a decision about some parameter with true value ω, choose the action a that maximizes

$$\int u(a, \omega) \sum_i p_i(\omega|x, M_i)\, p_i(M_i|x)\, \mathrm{d}\omega, \tag{5}$$

where $u(a, \omega)$ is the utility obtained by action a for ω. The summation term here indicates that we are model averaging. In principle, as the amount of data present increases, the choice a should get arbitrarily close to the true parameter value, which is of course equivalent to choosing the correct model. However, this approach neatly produces the analysis we are really interested in without having to make a strict model choice at any stage. An extremely similar approach is used when the choice of model is considered a parameter value, where we subsume all competing models into one large hierarchical model; see the section on Reversible Jump in the **Markov Chain Monte Carlo** entry.

The dependence on utility functions in the model averaging above is clear and essential, and this carries over to other forms of model comparison; if we are to compare models rigorously there must be some specification of the *purpose* for which we are comparing them. For further references, see Draper's discussion of Spiegelhalter et al. [13]. If a utility function can be established, the decision-theoretic framework simply dictates that we use the model that maximizes expected utility. Nonetheless, while clearly desirable in terms of clarifying and simplifying the analysis, deciding on a utility function is difficult and extremely subjective, just like choosing a prior. We therefore consider methods that do not require specific utility functions and instead are based around some measure of comparative goodness of fit to the data.

Some Alternatives to Bayes Factors

Deviance Information Criterion (DIC)

Classical techniques for comparing (nested) models are based around the models' deviances and their numbers of parameters, or degrees of freedom. Bayesian analogues of these quantities are combined in the Deviance Information Criterion (DIC) of

Spiegelhalter et al. [13]. DIC is defined as

$$DIC = 2p_D + D(\overline{\theta}), \tag{6}$$

where

$$p_D = \mathbb{E}_{\theta|y}[-2\log\{p(y|\theta)\}] + 2\log[p\{y|\tilde{\theta}(y)\}] \tag{7}$$

evaluated at $\tilde{\theta}(y) = \mathbb{E}(\theta|y)$ is a measure of the "effective number of parameters" and $D(\overline{\theta})$ is a measure of the "Bayesian Deviance"

$$D(\theta) = -2\log\{p(y|\theta)\} + 2\log\{f(y)\}, \tag{8}$$

again evaluated at the posterior mean $\mathbb{E}(\theta|y)$. We seek **parsimonious** models, which combine low deviance with the minimum number of parameters, and so models that minimize DIC are preferred over alternatives.

DIC has been used in many analyses but further innovation seems possible; negative values of p_D are possible, different parameterizations lead to different values of DIC, and for **multilevel models**, it is not clear which levels of the model should be integrated out (e.g. **random effects**) and which left "in focus". Trevisani and Gelfand [14] show that integrating out different sets of **nuisance parameters** can lead to varying support for the same underlying hierarchical model. However, this applies to other **likelihood**-based criteria, like AIC or BIC, and is not a specifically Bayesian problem.

Although in most practical applications it will be unrealistically optimistic to assume that one of the competing models is "true", in this hypothetical situation, we might prefer methods that, asymptotically, select the correct model. As with AIC, it is possible to find situations in which DIC fails to do this.

Expected Posterior Deviance (EPD)

Another criterion-based approach is the use of Expected Posterior Deviance (EPD), developed initially by Laud and Ibrahim [8] and developed more formally by Gelfand and Ghosh [4]. Here we work with the posterior predictive distribution for new data;

$$f(x_{\text{new}}|x) = \int f(x_{\text{new}}|\theta)\, p(\theta|x)\, \mathrm{d}\theta. \tag{9}$$

The user must choose a discrepancy function $d(x_{\text{new}}, x)$, generally taken to be the (classical) deviance measure, although any reasonable measure of distance between the data sets is acceptable. Then the model that minimizes

$$EPD = \mathbb{E}(d(x_{\text{new}}, x)|x, M_i) \tag{10}$$

is selected. The interpretation of EPD is simple and does not require asymptotic arguments. Furthermore, its calculation, for any particular model, is simple and easily added on to standard MCMC calculations.

Cross-validation

Another alternative to Bayes factors in model comparison is the use of **cross-validation** as an extension of Bayesian measures of goodness of fit. Using the predictive likelihood as a measure of utility, Vehtari and Lampinen [15] suggest comparing models by their expected utility estimates; as with other cross-validation procedures, when data points are removed by more than "one at a time", the computational burden rises quickly and is likely to be unrealistic for large models evaluated using MCMC.

KENNETH RICE

Bayesian Methods in Clinical Trials

A clinical trial is an experiment carried out to gain knowledge about the relative benefits of two or more treatments. Typically, this is part of a gradual accrual of knowledge: a trial to confirm benefits in a large population may follow much careful work on smaller scale studies, or a study may be asking essentially the same question as several other studies. Conventionally, clinical trials are analyzed formally as an individual trial, and their contribution to accruing knowledge then assessed informally. However, increasingly the technique of **meta-analysis** is used to combine the information from similar trials into a formal summary.

More generally, researchers may wish to frame the following questions: "What do we think about the relative benefits of the treatments before knowing the results from this trial?" "What information can be gained from the results of this trial?" "Considering the results of this trial in the light of previous understanding, what do we now think about the relative benefits of the treatments?"

If this seems too subjective, an alternative way of casting this framework is to ask: "What is the previous evidence on the relative benefits of treatment?" "What is the current evidence from this trial?" "What is the updated evidence, once we combine the previous with the new evidence?"

The concept of updating of beliefs or evidence is the essence of Bayesian statistics. This article explains the essential concepts through a simple example, and then discusses some of the issues raised, namely the legitimate sources of previous beliefs or evidence, including the question of subjectivity, and implications for the design of trials and Bayesian reporting of clinical trials. A particular area of application is data monitoring (*see* **Data and Safety Monitoring**).

Most of the discussion is in the context of two-group parallel trials, partly for simplicity of exposition, but mainly because of the preeminence of this design in practice. The framework is, however, completely general, and applies to more complex designs. For the combination of results of several trials, possibly with other evidence, Bayesian meta-analysis is outlined. Clinical trials are often used as part of wider decision-making processes. Bayesian statistics is sometimes set in the context of decision-making, and the implications of this are discussed. Finally, there is a note on computational issues.

An Example

Consider the following example: after a heart attack, thrombolysis is often indicated. There is a tension between whether this is done at home once the ambulance arrives, which confers the advantage of speed, or in hospital, which is a more optimal environment, but necessitates a delay in treatment. The GREAT trial was run to compare these two strategies [8]. When the trial reported, there were 13 deaths out of 163 patients in the home group, and 23 out of 148 in the hospital group. The authors estimated a reduction in mortality of 49%. Some commentators were skeptical that a halving of mortality was really possible. Pocock & Spiegelhalter [14] carried out a Bayesian analysis. They judged, ignoring the trial results, that home treatment probably conferred some benefit, say a 15%–20% reduction, but that a 40% reduction, let alone a halving of mortality, was fairly unlikely. These beliefs are termed the *prior distribution*. The evidence from the trial is described through the *likelihood function*. Combining these two gives the *posterior distribution* of beliefs. This gives an estimate of the reduction of mortality of about 25%, but still says that the extremes of no effect or of a halving of mortality are unlikely.

Differences from classical analyses include the incorporation of prior beliefs, the absence of P values, and the absence of any idea of hypothetical repetitions of such studies. The posterior estimate of effect and its surrounding uncertainty via a *credibility interval* is analogous to a classical point estimate and its associated confidence interval, but has a direct interpretation in terms of belief. As many people interpret a confidence interval as the region in which the effect probably lies, they are essentially acting as Bayesians.

Mathematical Formalization

We can express the preceding analysis formally as

$$P(\theta|\text{data}) \propto P(\text{data}|\theta) \times P(\theta).$$

$P(\theta)$ is the prior distribution expressing initial beliefs about the parameter of interest. In the example, this would be the difference in mortality rates, described using the Normal distribution. $P(\text{data}|\theta)$ is the likelihood function, expressing the statistical model of variability for the data given the parameters. In the example, a Normal distribution is assumed for the difference in binomial proportions. $P(\theta|\text{data})$ is the posterior distribution of beliefs. Its shape depends on the previous two distributions, but where the prior distribution and likelihood are assumed to be Normal, the resulting posterior distribution is Normal.

The equation is usually expressed and worked with in its proportional form: if needed, the constant of proportionality is obtained by integrating the right-hand side with respect to θ, which ensures that the posterior distribution is properly defined, integrating to one.

Clinicians will have views on how different these treatments need to be before it becomes unethical to randomize patients between them. For example, some may think that if the home thrombolysis is no worse than hospital and no more than 20% better than hospital treatment, that **randomization** is acceptable, whereas once there is reasonable evidence that the difference is outside this range, a decision can be reached as to which is preferable. This range is often termed the *region of equivalence*. One end is essentially the same as the "clinically important difference" used conventionally when deciding how large studies should be, and the other end may be the point of no difference. An alternative is to have the range symmetrical about the point of no difference: the range of equivalence in the GREAT trial might be that home is no more than 20% better or worse than hospital. (This is often used in bio-**equivalence studies**.)

Sources of Prior Distributions

The Bayesian approach just outlined gives a framework for updating beliefs or evidence. There are several possible sources of prior distributions. Spiegelhalter et al. [18] recommend that there is no need to select just one, and outline a *community of priors* that can be used for interpretation.

The *reference prior* represents minimal prior information. This is the least subjective, and analyses based on this act as a useful baseline against which to compare analyses using other priors. The *clinical prior* formalizes the opinion of well-informed specific individuals. The *skeptical prior* formalizes the belief that large treatment differences are unlikely. This can be set up, for example, as having a mean of no treatment effect, and only a small probability of the effect achieving a clinically relevant value. By contrast, the *enthusiastic prior* can be specified, for example, with a mean equivalent to a clinically relevant effect, and only a small probability of no effect, or worse.

The reference prior, skeptical prior, and enthusiastic prior are essentially mathematical constructs, calibrated using points such as that of no effect, and the clinically relevant effect. By contrast, a clinical prior is intended to represent the current state of knowledge. Where possible, it should be based on good evidence, such as a meta-analysis of relevant randomized controlled trials. Where this is not possible, evidence from nonrandomized studies may be needed. Alternatively, subjective clinical opinion may form the basis of a prior distribution. Elicitation of opinion can be carried out using techniques such as interviews, questionnaires or interactive computer packages with feedback [5, 13, 21]. These are not mutually exclusive: for example, subjective judgment about relevance or changed circumstances may be needed to modify results from an objective meta-analysis.

For example, in a Bayesian analysis of a cancer clinical trial comparing high-energy neutron therapy versus the standard of photon therapy [18], priors from two sources were used. The first was from a survey of interested clinicians, which showed beliefs favoring neutron therapy; the second was from a meta-analysis of related studies of low-energy neutron therapy, which showed a detrimental effect compared with placebo (*see* **Blinding or Masking**). The data from an interim analysis (*see* **Data and Safety Monitoring**) were against neutron therapy, and, starting from either prior, the posterior belief in a worthwhile benefit was small, with the weight of posterior evidence on a harmful effect. The data monitoring committee (*see* **Data Monitoring Committees**) had actually stopped the trial at that stage (on classical analyses), and the Bayesian analyses express explicitly the wisdom of that decision.

Region of Equivalence

The region of equivalence is the area in which *equipoise* exists: a patient or his/her doctor is indifferent to which of the two treatments is used. Whilst

there is a reasonable probability that the treatments are in equipoise, randomization is ethical.

There are close parallels with the specification of the alternative hypothesis in the design of clinical trials based on the classical statistical paradigm. For a Bayesian analysis of a classically designed trial, an obvious choice for a region of equivalence is to take the points associated with the null and alternative hypotheses. When Bayesian thinking is informing the design, the range of equivalence is often elicited from clinicians using similar techniques to those used for elicitation of prior beliefs. In the neutron therapy trial described above, clinicians had also been asked about how good neutron therapy would need to be before it should be routinely used. They said (on average) that one-year survival of 50% would need to be increased to 61.5%. The range of equivalence was then taken as being between no improvement and an improvement of this magnitude.

The region of equivalence provides a useful benchmark for the design of trials, for reporting of results and for data-monitoring. These are discussed in more detail below. The region of equivalence is often determined in a relatively informal fashion by clinicians. Wider questions, about whose equipoise is really relevant, and what considerations should inform this, point towards a decision-making perspective. These are considered at the end of the article.

Bayesian Power

Classical power calculations for clinical trials are carried out by specifying a null hypothesis that two treatments do not have different effects on the outcome of interest, and an alternative hypothesis that the difference in outcome is equal to some prespecified value. The risks of wrong decisions under these two hypotheses are then fixed at chosen levels, which then determine the necessary sample size. These calculations are essentially conditional on the choice of the alternative hypothesis. There is as yet no consensus on a Bayesian approach to **sample size determination** for clinical trials. Some advocate focusing on a reasonable probability of getting a posterior interval less than a certain width, while others take an explicit decision-making perspective, with utilities either essentially "information", or some trading-off of health benefits and cost. A wide-ranging discussion of Bayesian sample size calculation can be found in a special issue of *The Statistician* [16]. See also [18] and [20].

Data Monitoring

In many trials, results accrue fast relative to patient recruitment. In this situation, data-monitoring committees are often set up to review the data to ensure that equipoise still exists, and it is still ethical to enter patients into the trial. Statistically, the challenge is to guard against stopping a trial too early, as an overreaction to early dramatic results, whilst protecting new trial patients from inappropriate randomization. From a classical statistical perspective, this is often formalized in terms of adjusting significance levels.

One Bayesian approach [18] formalizes it differently. At the start of the trial, a skeptical prior (see above) is used to represent the view that there is not too much difference between treatments. Only when the data dominate this sufficiently would early stopping be considered. The effect of such a prior is to put a brake on early results. For a trial of esophageal cancer comparing surgery with preoperative chemotherapy and surgery, this approach was used [6]. It has been shown that there is a close tie-up between this approach and classical group sequential designs (*see* **Sequential Methods for Clinical Trials**), in that a particular design, say with five interim analyses and a Pocock boundary, corresponds to a Bayesian procedure with a particular choice of prior distribution [7].

An alternative Bayesian approach to monitoring takes a much more decision-theoretic perspective. For a trial of influenza vaccination of Navajo children, monitoring included explicit consideration of future children and their risk of influenza [4].

Complex Trial Designs

The two-group parallel trial described so far is important, but not the only trial design. For more complex designs, the same framework of prior distribution/likelihood/posterior distribution outlined above still holds, although because there are more parameters, careful specification is needed, for example in parameterization. Bayesian methods have been developed for other designs, including **crossover** trials [9] and **factorial** trials [1, 15].

Bayesian Reporting of Clinical Trials

A good report of a trial specifies the question being addressed, describes the design and conduct of the trial, gives results, makes formal statistical inference from these, discusses sensitivity to assumptions, and then interprets the trial in the context of other relevant research. Many of these do not differ from usual good practice, but some aspects can benefit from formalization using Bayesian procedures [11, 19].

The results of the trial should be described clearly, and in enough detail that another reader could carry out alternative analyses if desired. Formal statistical inference follows the prior/likelihood/posterior analysis outlined above. The posterior distribution then represents a summary of beliefs/evidence about the parameters of interest. This is most fully represented graphically, but can be further summarized by giving a *95% credibility interval*. In addition, it is often useful to give the probability that an effect is in a particular region, for example the probability that the parameter lies above the region of equipoise, or, for a bio-equivalence study, the probability that the parameter lies inside it.

The results section of the report should certainly include an analysis that starts from an uninformative prior distribution. If there are other well-specified prior distributions, then an analysis using these can also be presented in full. For example, if Bayesian data-monitoring has been used, then analyses with relevant prior distributions are appropriate. Sensitivity analyses should also be carried out. These may be for sensitivity to the specification of the prior distribution, but also to the specification of other parameters in the model. For example, Grieve [9] presents plots for a bio-equivalence study looking at sensitivity to prior beliefs on the treatment effect. Sensitivity to other choices of the region of equipoise may be needed.

The discussion section of the report often contains more speculative interpretation. This can usefully be formalized through Bayesian analysis. If other opinions can be captured, for example by a skeptical or enthusiastic prior distribution, then the appropriate posterior distributions can be presented here. If there are other similar studies, then a Bayesian meta-analysis (see below) can be used to provide a combined estimate of the effects of interest.

In all Bayesian reporting the separate elements of the prior distributions and likelihood should be clearly specified and appropriately justified, so that the posterior distribution may be clearly interpreted. The likelihood should not be controversial, since it comes from the data, but specification of prior distributions is more difficult. A good rule of thumb is that if the prior distribution is based on belief, then the posterior distribution should be interpreted as an updated statement of belief, but if the prior distribution represents a summary of hard evidence, then the posterior distribution represents an updated summary of hard evidence.

Bayesian Meta-Analyses of Clinical Trials

Bayesian statistics is essentially about the updating of evidence. So far in this article the focus has been on individual trials, but where several trials address essentially the same question, a combined analysis is desirable. Bayesian meta-analysis extends Bayesian ideas used for a single trial to multiple trials. Previous evidence is expressed through *prior distributions* about quantities of interest: in a meta-analysis of binary outcomes, this will include, for example, the log odds ratio. Current data are expressed through the *likelihood*, based on an appropriate model. The *posterior distribution* for quantities of interest can then be obtained. The Bayesian framework also allows calculation of the probability that the odds ratio is at least say 1, or at least 3, which cannot be done in the classical framework.

After a careful search for all relevant trials, it seems strange to combine objective trial data with subjective opinion. In the meta-analysis context, it may be reasonable to use noninformative priors, which give intuitively interpretable results. This is particularly true for the main comparison. However, it may be useful to bring in judgment on some of the other parameters, on which the trials are less helpful, such as the size of the random effects. It is important to carry out sensitivity analyses on assumptions made. Examples of Bayesian meta-analyses include modeling random effects in a meta-analysis of urinary tract infections [17], incorporating external evidence on heterogeneity in a trial of cirrhosis [10] and modeling heterogeneity in relation to underlying risk [22].

Decision-Making with Clinical Trials

The focus in this article has been on the estimation of effects of interest using the accrued evidence. The

purpose of accruing evidence is to make decisions. Bayesian statistics leads naturally towards explicit decision-making.

There is some debate as to whether clinical trials are, in themselves, decision-making contexts. Some (Lindley and others in discussion of [18]) argue they are, whereas Spiegelhalter et al. [19] argue that an individual clinical trial can be put to a variety of purposes, and so it is better not to construe the trial as a decision in itself.

Ashby & Smith [2] argue more generally that evidence-based medicine is about making decisions and the Bayesian approach is a natural one to adopt. When a decision is to be made, the following should be identified: the decision-maker, the possible actions, the uncertain consequences, the possible sources of evidence, and the utility assessments required. For example, a patient is diagnosed with esophageal cancer. He is advised that until recently routine treatment has been surgery, but a new suggestion is to precede the surgery by a course of several weeks of chemotherapy. The *decision-maker* is the patient, who may effectively delegate to his doctor. The *possible actions* are to undergo surgery, or to opt for the combination treatment. The *uncertain consequences* are the length of his survival, the side-effects (such as severe nausea), and the delay in completion of treatment. The possible *sources of evidence* relating to his expected survival come from routine data such as cancer registries, and relating to the additional benefit of combined treatments from clinical trials. The *utility assessment* required is the patient's trade-offs between extra survival, side-effects and time spent undergoing treatment. Within this framework, evidence from clinical trials plays a very important role.

Computation

Some of the simple analyses in this article can be done analytically, using nothing more than a hand calculator. BUGS is a general-purpose package written to facilitate the fitting of complex Bayesian models [21]. It is available from `http://www.mrc-bsu.cam.ac.uk/bugs/`, and can handle the kinds of analyses referred to in this article.

Bayesian Clinical Trials in Practice

For many years the principles of Bayesian statistics have been well understood. Implementation in practical areas such as clinical trials has been hampered, until recently, by computational complexity. However, with the growth in modern computing power, the situation is changing rapidly. Analyses of real complex studies are relatively recent, and their use as the first or primary approach even newer. A Bayesian analysis now offers an intuitive approach, combined with the power to deal with complexity when necessary. Bayesian clinical trials, and integrated summaries of them using Bayesian analyses, are finding their place in practice.

A comprehensive discussion of Bayesian clinical trials with excellent references based on systematic review, can be found in Spiegelhalter et al. [19] and several case studies of Bayesian clinical trials in Berry & Stangl [3] and Kadane [12].

Bayesian Methods

Bayesian formulations appear in various guises in statistics, most fundamentally for assessing and interpreting posterior distributions for unknown quantities, such as population means or predictions of future observations. Considered more broadly, posterior distributions can be used to calculate posterior expectations that can be compared for decision-making purposes. And modern frequentist **decision theorists**, who are mostly anti-Bayesian in outlook, nevertheless value Bayesian procedures because the class of Bayesian decision rules is typically complete in the sense that for every non-Bayesian procedure one can find a Bayesian procedure that is at least as good [33]. This article stresses the original use for computations whose inputs are data and a probability model, and whose outputs are posterior distributions of unknown quantities of interest, a canonical example being uncertain assessment of a population mean from data on a random sample.

The simplest case of sampling a dichotomy was given a non-Bayesian treatment by Jacob Bernoulli [3] in a famous posthumous publication (*see* **Bernoulli Family**). Bernoulli was interested in estimating from data the chance of an individual of known current age surviving to a specified later age, and with this goal in mind he derived the **binomial** sampling distribution and concluded that when samples are large enough one can with high *prior* probability be nearly certain that the sample relative frequency will be close to the population relative frequency. Fifty years later the same estimation problem was reformulated by **Bayes** [1] in another famous posthumous paper showing how to associate a posterior probability distribution with the population relative frequency given the sample relative frequency.

Bayes' method was soon taken up by Laplace [23] as a fundamental principle of inference, and applied both to sampling and measurement error models. Gauss [17] claimed that he proposed the method of **least squares** and applied it to tracking an asteroid, all this in 1795 while still in his teens. Although many years later Gauss also proposed the sampling theory justification that Neyman dubbed the Gauss–Markov theorem, Gauss's original derivation applied Bayesian reasoning to a model that used the normal law of error. By 1800, Bayesian inference was well on its way to becoming the primary technical approach for probabilistic evaluation of statistical estimates. Although not without detractors, it remained in this position for more than a century, the key technique being to use as a point estimate (*see* **Estimation**) the **mode** of a posterior density of an unknown quantity assuming a **uniform** prior density.

The underlying technical concepts of Bayes' paradigm are joint, conditional, and marginal **probabilities**, where joint probability equals **conditional probability** times **marginal probability** or, in symbols,

$$\Pr(A \text{ and } B) = \Pr(A|B) \times \Pr(B).$$

Not only did Bayes [1] explicitly define this relation, he cleverly went on to make twofold use of it, first as written, and then with the roles of A and B interchanged. Thus, if A denotes the information in an observed sample, and B the unknown properties of the population from which the sample is randomly drawn, and if the two factors on the right side of the formula are assumed given, with $\Pr(A|B)$ being what is now called the sampling model, and $\Pr(B)$ what is now called the **prior distribution** of B, then the formula yields on the left-hand side the joint uncertainty of A and B prior to observation of A. Interchanging A and B in the formula, and performing minor algebraic rewriting, one obtains:

$$\Pr(B|A) = \frac{\Pr(A \text{ and } B)}{\Pr(A)},$$

which yields on the left-hand side Bayes' proposed posterior distribution of B given the observation A. In these formulas, $\Pr(A)$ can be calculated from $\Pr(A \text{ and } B)$ by summing over the possible values of B, so that the essential inputs to the computation of $\Pr(B|A)$ are the right-hand-side terms in the first equation, namely the sampling model $\Pr(A|B)$, which in Bayes' example is Bernoulli's binomial distribution, and the prior distribution $\Pr(B)$ of the target quantity B, which Bayes chose with some trepidation to be a uniform prior distribution for the unknown value of the binomial parameter (*see* **Bayes' Theorem**).

From the mid-nineteenth century onward, Bayesian inference has had persistent critics balanced by steadfast defenders. The criticisms are basically twofold. The more fundamental of the pair is a stern objectivist principle denying that probability conceived as subjective degree of belief has any acceptable place in science. The more pragmatic position

is that the logic embodied in Bayes' concept of conditional probability makes sense, but in practice the method is often unusable, or at least compromised, because unlike the sampling probabilities $\Pr(A|B)$ the prior probabilities $\Pr(B)$ are typically hard to specify in a way grounded in scientific experience.

A pragmatic position was presented long ago in a remarkably modern way by Edgeworth [11]. The critics who "heaped ridicule upon Bayes' theorem and the inverse method" were justified only under "the pretence, here deprecated, of eliciting knowledge out of ignorance, something out of nothing". Edgeworth averred that "the so-called intellectual probability is not essentially different from the probability which is founded upon special statistics," and that the change from objective to **subjective probability**, or in critic Boole's terms "material" to "intellectual" probability, "is not from experience into dreamland, but from a particular to a more general sort of experience", and if this is somewhat imprecise it is not unlike other imprecisions routinely encountered in science. Edgeworth refers to Cournot [9, Section 95, p. 69] for the argument that the arbitrariness apparent in the widespread Bayesian use of uniform priors may have little effect a posteriori. Another passage notes Cournot's introduction of the term "subjective probability, as he calls it" and argues that Cournot's suggestion that subjective probabilities only be used "to regulate the conditions of a bet" is too narrow, and should be extended to allow that such probabilities may "afford an hypothesis which may serve as a starting point for further observation".

In the twentieth century, practical statistical inference via sampling distributions has overshadowed Bayesian methods, at least until relatively recently. **R.A. Fisher** was largely responsible for initiating the shift of statistical practice toward Bernoulli's *direct* use of sampling distributions, as contrasted with Bayes' *inverse* use through combination with a prior distribution. Fisher [13] had evidently learned while a student of the criticisms of Boole, Venn, and others, and he consciously sought to construct a theory of **estimation** not dependent on Bayesian prior distributions. Fisher held a pragmatic attitude that understood and approved Bayesian logic, but felt it was limited to situations where a "superpopulation" of parameter values was available to support a choice of prior distribution. **Jerzy Neyman** also developed a theory of estimation based on **sampling distributions** that followed Fisher's attempts by about 10 years, and Neyman likewise recognized the need to break free from the Bayesian formulation [28] before beginning to develop the strongly frequentist and behaviorist theories that went hand in glove with Neyman's strong rejection of subjective probability. Fisher had a different view of probability [15], much more in tune with the pragmatism of Edgeworth than with Neyman's hard line rejection of subjective probability, and this may well have been the underlying cause of Fisher's aggressive and lifelong attacks on Neyman and company [27] for what he saw as excessive preoccupation with mathematical theories insufficiently connected with the practice of making uncertain inferences.

By 1950, despite Fisher's continuing efforts, most mathematical statisticians had adopted Neyman's positions on the use of sampling distributions, specifically, on the importance of evaluating long-run properties of statistical procedures under hypothetical repetitions, to be used in turn for comparing and choosing among procedures. Not only was Fisher's star in decline, but the earlier Bayesian tradition was lost in the shrouds of time, and regarded as a historical relic. It is interesting that when a Bayesian revival began, especially in the US in the mid-1950s, it remained for a considerable time in the behavioral or decision-theoretic mold of the school that Neyman founded. Perhaps the most influential member of the neo-Bayesian resurgence of the 1950s and 1960s was the mathematical statistician **Jimmie Savage**. Savage's axioms [30] were directed at the construction of formal models that simultaneously specified probabilities and utilities, and even his more informal forays into applied statistics [31] emphasized decision-oriented thinking more than direct assessment of uncertainty through subjective probability. The movement also paid tribute to unreconstructed Bayesians such as the mathematician **Bruno de Finetti** [10] and the geophysical scientist **Harold Jeffreys** [22] who were more interested in inferential statistics than in decision making, as was Dennis Lindley (e.g. [25]) who, especially through students, was pivotal in developing the strong contemporary school of Bayesian applied statistics in the UK. In the US, an early supporter was the highly regarded biostatistician **Jerome Cornfield**; see Cornfield [7, 8] and Zelen [34]. It was not until the mid-1980s, however, under the impetus of rapidly developing computer technologies, that Bayesian applied statistics started to exhibit capabilities of handling

complex scientific phenomena (e.g. [5] and [20]) in ways that older sampling theories appear ill-designed to address. Another important feature of modern Bayesian statistics is its straightforward adaptability to **prediction** [18].

Contemporary Bayesian Analysis: The Problem of many Parameters, and Applications in Complex Circumstances

Inference methods based on sampling distributions made big strides in the area of small sample theory in the first half of this century. Many exact **hypothesis testing** and **confidence** procedures became available for practical application to small data sets whose analysis was comfortably within the capability of the limited computers of the time. It turned out, however, that Bayesian analogs of commonplace non-Bayesian small sample procedures were easily derived and were dependent on the same analytically tractable mathematical forms, as illustrated by the conjugate Bayes theory of Raiffa & Schlaifer [29]. Furthermore, there was typically little practical difference in the interpretations associated with competing Bayesian and sampling theory methods, albeit with some interesting exceptions such as the Lindley [24] paradox. The practical congruence is especially evident for sampling models with limited parameter sets and enough data to guarantee quite accurate estimates, since, as can be demonstrated by large-sample theory, estimation errors, whether evaluated through sampling distributions or through posterior distributions, then have variances and covariances approximately given by the inverse of the Fisher **information matrix**.

The approximate similarity of Bayesian and non-Bayesian inferences is a fortuitous mathematical result that hides very different logical arguments, as was already obvious in the original papers of Bernoulli and Bayes. The logical differences are highlighted by the differing treatments of **nuisance parameters**, defined as parameters in a stochastic model whose unknown values confound the uncertainty in a primary estimate. When using sampling theory methods, it is sometimes possible to finesse nuisance parameters through a mathematical trick, as illustrated by the famous device of **Student's *t* distribution** that permits exact small sample theory concerning the mean of a normal population despite the unknown population variance nuisance parameter. Fisher and others were quick to discern mathematically straightforward extensions of **studentization** to **general linear models** with many parameters and to **multivariate normal** models. But in truth, such tricks are mainly limited to relatively few and often unrealistic sampling models, and otherwise the elimination of nuisance parameters can only be achieved approximately through the cruder device of substituting point estimates in place of unknown nuisance parameter values. By contrast, the Bayesian argument has a unified approach to elimination of nuisance parameters, namely, the reduction of a joint posterior distribution to a marginal distribution, technically describable as integrating the full joint posterior density over the nuisance parameters.

Associated with these different methods of dealing with nuisance parameters are different nonuniquenesses of inferences derived Bayesianly and non-Bayesianly from the same parametric sampling model. With samples of moderate size, deviations from the congruent asymptotic theories of **efficient** estimation depend in ways that are complex and varied, involving specific choices of estimators in the sampling theory case, and on choices of prior distributions in the Bayesian case. Thus, estimates depend on more than the data and sampling model under either theory. The Bayesian argument transparently specifies that a joint prior distribution for all the unknowns is both logically and practically necessary when sample sizes are small, a principle that has no analog in Neyman-Pearson theory and is explicitly rejected by frequentists.

Just as the task of estimating a single mean was an important test case for the early development of basic inference methodologies, the more complex task of simultaneously estimating several or many means becomes an important test case for contemporary methods of statistical inference. Biostatistical examples are abundant. For example, experimental treatment effects may vary from center to center in a **multicenter** randomized clinical trial, or vary from study to study as in a **meta-analysis**. The concept of variation between and within groups goes back to R.A. Fisher's contributions to **experimental design** and the **analysis of variance** (ANOVA) [13, 14] examples being variation among and within varieties of a crop, or among blocks and among plots within a block, arising in **randomized block** experimentation. A currently popular term for structures

with variation within and variation among levels of statistical units is hierarchical models (*see* **Multilevel Models**).

A basic question posed by hierarchical structure is whether the mean of a group should be estimated using only sample data from within the group, or whether one can borrow strength from data on other groups. One seminal idea is that of **shrinking** a mean estimated from data within one group part way to a grand mean of the estimated means of several groups, typically by using a weighting of the individual mean and the grand mean with weights summing to unity. Under frequentist theory, it is typical to evaluate such shrinking or smoothing procedures under a hypothesis of random sampling within groups, while group mean parameters are assumed fixed and nonrandom. Under Bayesian theory the distinction between fixed and random becomes nonoperational since parameters are assigned a prior distribution, which might be that the group mean parameters are viewed as independently drawn at random from a superpopulation, as in the models called **random effects** models, or originally the Model II of Eisenhart [12], in the ANOVA literature. The Bayes vs. non-Bayes distinction is further blurred by the use of the term **empirical Bayes** for shrinking methods advocated by the frequentist school, the rationale being that the sources of the methods lie in corresponding Bayesian models, so that it is Bayesian interpretation that is rejected in favor of frequentist evaluation. The natural Bayesian position is of course that a genuine prior distribution should be specified and combined with the likelihood from within groups sampling, so that the Bayesian empirical Bayes methods, as they are confusingly called, are interpreted Bayesianly as well as motivated Bayesianly. As is often the case, totally Bayesian interpretations provide simpler and more direct explanations of inferential issues.

Simultaneous estimation of many means is a convenient vehicle for illustrating several features of the Bayesian paradigm. One such is the remarkable flexibility of the method. Modern computers can be easily programmed to simulate joint posterior distributions, the marginal posterior distribution of any function of the set of means, not only their mean, or their standard deviation, but any complex quantity, such as, perhaps, the subset of means exceeding some threshold. There are competing sampling theory methods, such as **simultaneous confidence region** procedures, but they are more limited and difficult to use and interpret accurately. Another Bayesian advantage is automatic differentiation among parameters such that the data are more and less informative. For example, if some means are accurately estimated because the samples are large, while others are poorly estimated because samples are small, Bayesian procedures will automatically smooth less toward the grand mean for the larger samples and more for the smaller samples, without the need for special and often difficult derivations of estimators and their sampling distributions. Of course, there is a price to pay in terms of specification of believable prior distributions. A characteristic of a fully Bayesian treatment of hierarchical models is the necessity of parametric prior distribution modeling of lower level parameters, the parameters at the second level being called hyperparameters with priors called hyperpriors. In practice, however, these may not be as abstract as they first appear. For example, there is likely to be "more general experience", to repeat a quote above from Edgeworth, about the variation of group means, not much different from empirical knowledge of variation within groups, and sufficiently formalizable to be usable in practice.

A case can be made that Bayesian inference methods have the greatest advantage over competing sampling theoretic procedures when the phenomena are complex. By contrast, many statisticians preach keeping it simple as a fundamental principle of practice, and point to Occam's razor in support of the principle (*see* **Parsimony**). Thus, for example, it is not uncommon that a carefully designed and executed clinical trial producing large volumes of data at high cost comes down to a trivially computable single ***P*-value** from a combination of multicenter **two-by-two tables**. But Occam actually advocates "no complexity without necessity", and one necessity is to extract from complex and expensive data sets information that may exist at different levels of aggregation, at different times, at different locations, exhibiting dependence on many different covariates, and so forth. A variety of statistical technologies ought to be applied in sequence, including exploratory fitting of empirical models, construction of stochastic models, and Bayesian evaluations of associated uncertainties in estimates and predictions from models. All of these analyses contribute to constructing and refining the complex models appropriate for a thorough assessment of real experiments. The simplicity and clarity

of Bayesian principles, together with recently developed computational means of implementing these principles, allows use of Bayesian methods in complex situations that available competing inferential technologies are too cumbersome to deal with.

For biostatistics in particular, applications can already be found in a wide variety of serious investigations. For example, the proceedings volume [16] of a recent conference on case studies featuring Bayesian methods contains ten articles of which seven involve biological or biomedical studies. The titles of these articles include the key phrases, "organ blood flow measurement with colored microspheres", "elicitation, monitoring, and analysis for an AIDS clinical trial", "reconstruction of medical images", "multiple sources in the analysis of a nonequivalent control group design", "optimal design for heart defibrillators", "longitudinal care patterns for disabled elders ... missing data". Zelen [35] makes persuasive arguments for the use of Bayesian methods for case–control studies in medical statistics. Berry & Stangl [4] present further case studies. These analyses support the contention that Bayesian analysis is coming of age as a pillar of applied statistics. The sympathetic review of Breslow [6] is also informative.

Modeling for Bayesian Analysis

A statistical or probabilistic model constructed for use in Bayesian analysis is conventionally represented as having the two parts denoted above by $\Pr(A|B)$ and $\Pr(B)$, or data model and prior distribution. If one accepts the pragmatic view illustrated above by quotes from Edgeworth, so that objective and subjective probability are two sides of the same coin, the first term $\Pr(A|B)$ is indistinguishable in origin and interpretation from stochastic models that applied probabilists and frequentist statisticians develop when analyzing a specific real-world situation.

There are important inputs to stochastic models that precede any consideration of probabilistic uncertainty, and also precede data analysis carried out in support of model choice. First, it is essential to reflect knowledge and understanding of scientific context. Typical realistic models rest on a large system of variables constructed so as to formally represent placeholders for both observable and unobservable facts and quantities, to an extent judged to be appropriate and necessary for the purposes at hand. The necessities include the ability to represent factors and variables that capture causal mechanisms operating in the underlying science, and mechanisms of sample selection and experimental manipulation introduced by the statistician.

Once a framework for knowledge representation is in place, the statistician can typically recognize repeated instances of similar entities such as plots within blocks, and blocks themselves. These are the raw materials from which frequency counts can be made, but before such counts, whether observed sample units or unobserved population units, can be taken as estimating or representing probabilities it is necessary to impose an intellectual judgment of symmetry, usually called **exchangeability** in the Bayesian literature [2], meaning that uncertain expectations of any single unit are defined by an unweighted distribution across all units. Under pragmatism, neither symmetry nor frequency assumptions dominate the construction of probabilities, but instead they work in tandem.

In a specific application, a probability model is hypothesized initially through processes that are partly art and partly science, partly subjective and partly objective, partly reliant on informal recollection of what survived critical analysis in similar situations in the past, and partly on being roughly in accord with regularities and empirical models found through data exploration of old and new studies. Given an initial tentative model choice, including any prior distributions required by Bayesian methods, there begins an open-ended process of model criticism and model revision and refinement. A model selected for purposes of implementing and reporting a Bayesian analysis is inevitably a compromise among competing needs to reflect background knowledge and understanding, to render manageable the amount of detail represented and yet to maintain fidelity to the full implications of the data from the study under analysis.

The statistical research literature and texts such as [19] emphasize the use of data in the revision and ultimate choice of models. Traditional non-Bayesian significance tests of **goodness of fit** are well established tools of statistical practice that many pragmatic Bayesians can accept as helpful for model assessment. The Bayesian literature also has its own approaches to significance testing, such as model comparison through the use of Bayes factors or relative weights of evidence. Significance tests can only be part of the story, however, because what can

be detected from data by these methods depends on how adequate and informative the available data happen to be, so that important model failures can easily be missed by significance testing methods. Consequently, a different strategy for model evaluation called **sensitivity analysis** is also indicated in most applications. Sensitivity analysis means the comparison of Bayesian inferences computed from alternative model choices. If several analyses, each based on models that are judged plausible, yield inferences about the same unknown quantities that are sufficiently different to have substantively significant practical consequences, it may be wise to conclude that the study cannot support the demands made on it.

Computation

Once a two-part probability model has been established, Bayesian analysis of a given data set is automatic in principle. The remaining difficulties are largely computational. Specification of the model needs to be in a form allowing numerical representation of the joint probability density of both observables and unobserved quantities of interest, this is because repeated computation of numerical values of the joint density are needed, where the observed variables are held fixed at their values in the data, while the unknowns of interest are varied across plausible values. The basic task is to pass from the joint posterior density of a generally lengthy vector of unknowns to practically interpretable and useful representations of marginal posterior distributions of singletons or small subsets of the unknowns. These marginal representations are precisely defined in a mathematical sense, and may have subcomponents that can be numerically evaluated from analytically tractable mathematical representations. But for a core set of parameters they are typically amenable only to methods of **numerical integration**. When Bayesian methods were attempted mainly for models with small parameter sets, it was often possible to proceed by approximating intractable densities with analytically integrable forms, sometimes obtained from asymptotic theory. By the mid-1980s the limitations of these algorithms had become a roadblock preventing the widespread use of Bayesian methods. Then it was realized that Monte Carlo approaches, such as the methods of Hastings [21], that had originally been pioneered by physicists, were adaptable to marginalizing the high dimensional densities that were appearing more and more in statistics [5, 20, 32] (*see* **Markov Chain Monte Carlo**).

The method of Monte Carlo integration rests on repeated computation of possible values of a set of unknown quantities, varying these values in a way that mimics their posterior distribution. It follows that restriction of these repeated **simulations** to subset of the unknowns varies in a way that similarly mimics the marginal posterior distribution of the subset. Three technical features are characteristic of the Monte Carlo revolution of Bayesian computation. One is that the successive draws from the posterior are generally done, not to be independent from step to step, but rather each draw is dependent on the preceding draw as in a Markov chain, and hence the label MCMC for these methods. The essential feature that makes the simulations directly interpretable is that, despite the dependence, the marginal distribution associated with each draw properly mimics the desired posterior distribution. The dependence does of course complicate the task of understanding the accuracy of the Monte Carlo integration, which is itself a statistical inference problem (that paradoxically is being studied at present mainly by frequentist methods). A second key idea is that of the Gibbs sampler, being a particular way to define an MCMC algorithm that cycles through the variables sampling small subsets holding the remaining variables fixed, the reason for this being that these small individual simulations are achievable by much simpler and faster algorithms than are available for joint simulation of larger sets of variables. The third feature that goes by the name Metropolis–Hastings involves a mathematical trick that facilitates simulation from densities that are known only up to an unknown scale factor, a situation that is more common than not in Gibbs steps. Textbook expositions of MCMC methods are only recently coming on stream (e.g. [19]).

Arguments For and Against Bayesian Methods

As noted above, hard line opponents of Bayesian inference methods in statistics reject the method because it depends on a concept of subjective probability that has no place in science. Defenders, such as Edgeworth quoted above, in their turn reject this position as extreme, noting that scientific practice

has many soft aspects. Analysis of uncertainty is indeed mostly treated in science using soft informal language, while mathematical models are most prominently used for representing objective real-world phenomena. It can be argued, however, that mathematization can also be beneficial for formal representation of uncertainty, not to replace soft informal descriptions but to underpin and support them, much as formal representations of physical systems and laws bring order and validity to informal explanations of the physical world. If it is accepted that long-run frequency cannot be logically linked to specific uncertainties without an accompanying judgment about equally likely drawing of cases, then it appears that formal subjective probability is a sine qua non of the mathematization of uncertainty.

Proponents of Bayesian statistics, in attempting to overturn the establishment position of hard line objectivists, have sought to legitimize the mathematics of uncertainty through axiomatic systems that formally represent beliefs and actions (e.g. [2]). Such proponents themselves often take an extreme position that, as Edgeworth noted, is easy to ridicule. In their enthusiasm for the beauty and precision of formal systems created by axioms, they argue that the system must always be used in full. But practical use of standard Bayesian logic requires complete specification of both $\Pr(A|B)$ and $\Pr(B)$, which for complicated A and B can be difficult, especially if one is required to convince one's fellow scientists, and through them a skeptical public. Bayesian advocates may have damaged their cause by themselves taking the extreme position of insisting that probabilistic frameworks be supplied, if necessary by questioning nominated experts and forcing them to state positions that they may be unable to support from their bases of expert knowledge and experience. It is not the fact of expert opinion that is in doubt, but only the forcing of it to produce a specific form of mathematized uncertainty, or uncertainty plus **utility** for action-based systems.

Most statisticians understand the concept of conditional probability and recognize its appealing qualities as a mechanism that supports informal judgments of uncertainty given data, and they similarly understand the validity of using conditional probabilities for computation of expectations that legitimately guide actions. For such statisticians, axioms have become superfluous, and the difficulty with Bayesian methods is mainly one of understanding applied circumstances and doing the hard and not always successful work of constructing a judgmentally sound and convincing probability model for Bayesian inference and decision making. To this end, Bayesian theorists have developed useful supporting ideas such as those derived from de Finetti's theory of exchangeability [10] and concepts for checking and rebuilding models. The pragmatic view required in applied statistics needs to avoid both extreme positions and focus on scientific modeling. Bayesian thinking may then reassert in the twenty-first century the prominent role that it had in nineteenth century scientific thinking, not only as an attractive ideal, but also as a central element of practice.

Bayesian Model Selection in Survival Analysis

Introduction

Model comparison is a crucial part of any statistical analysis (*see* **Model, Choice of**). Owing to recent computational advances, sophisticated techniques for **Bayesian** model comparison in **survival analysis** are becoming increasingly popular. There has been a recent surge in the statistical literature on Bayesian methods for model comparison, including articles by George and McCulloch [19], Madigan and Raftery [31], Ibrahim and Laud [27], Laud and Ibrahim [30], Kass and Raftery [28], Chib [9], Raftery, Madigan, and Volinsky [36], George, McCulloch, and Tsay [20], Raftery, Madigan, and Hoeting [35], Gelfand and Ghosh [17], Clyde [11], Chen, Ibrahim, and Yiannoutsos [7], Chib and Jeliazkov [10], and Spiegelhalter et al. [42]. Articles focusing on Bayesian approaches to model comparison in the context of survival analysis include Madigan and Raftery [31], Raftery, Madigan, and Volinsky [36], Sahu, Dey, Aslanidou, and Sinha [37], Ibrahim Chen [21], Aslanidou, Dey, and Sinha [2], Chen, Harrington, and Ibrahim (2002) and [5], Sinha, Chen, and Ghosh [39], Ibrahim, Chen, and MacEachern [23], Chen and Ibrahim [6], Ibrahim, Chen, and Sinha [24], and Ibrahim, Chen, and Sinha [25]).

The scope of Bayesian model comparison is quite broad, and can be investigated via **Bayes factors**, model **diagnostics**, and **goodness-of-fit** measures (*see* **Goodness of Fit in Survival Analysis**; **Bayesian Measures of Goodness of Fit**). In many situations, one may want to compare several models that are not nested. Such comparisons are common in survival analysis, since, for example, we may want to compare a fully **parametric model** versus a **semiparametric** model, or a **cure rate model** versus a **Cox model**, and so forth. In this article, we discuss several methods for Bayesian model comparison, including Bayes factors and posterior model probabilities, the Bayesian Information Criterion (BIC), the Conditional Predictive Ordinate (CPO), and the L measure.

Posterior Model Probabilities

Perhaps the most common method of Bayesian model assessment is the computation of posterior model probabilities. The Bayesian approach to model selection is straightforward in principle. One quantifies the prior uncertainties via probabilities for each model under consideration, specifies a **prior distribution** for each of the parameters in each model, and then uses **Bayes theorem** to calculate posterior model probabilities. Let m denote a specific model in the model space $\mathcal{M}$, and let $\boldsymbol{\theta}^{(m)}$ denote the parameter vector associated with model m. Then, by Bayes theorem, the posterior probability of model m is given by

$$p(m|D) = \frac{p(D|m)p(m)}{\sum_{m \in \mathcal{M}} p(D|m)p(m)}, \qquad (1)$$

where D denotes the data,

$$p(D|m) = \int L(\boldsymbol{\theta}^{(m)}|D)\pi(\boldsymbol{\theta}^{(m)})\,\mathrm{d}\boldsymbol{\theta}^{(m)}, \qquad (2)$$

$L(\boldsymbol{\theta}^{(m)}|D)$ is the likelihood, and $p(m)$ denotes the prior probability of model m.

In Bayesian model selection, specifying meaningful prior distributions for the parameters in each model is a difficult task requiring contextual interpretations of a large number of parameters. A need to look for some useful automated specifications then arises. Reference priors can be used in many situations to address this. In some cases, however, they lead to ambiguous posterior probabilities, and require problem-specific modifications such as those in Smith and Spiegelhalter [41]. Berger and Pericchi [3] have proposed the intrinsic Bayes factor, which provides a generic solution to the ambiguity problem. However, reference priors exclude the use of any real prior information one may have. Even if one overcomes the problem of specifying priors for the parameters in the various models, there remains the question of choosing prior probabilities $p(m)$ for the models themselves. A **uniform** prior on the model space $\mathcal{M}$ may not be desirable in situations where the investigator has prior information on each subset model. To overcome difficulties in prior specification, power priors [22] can be used to specify priors for $\boldsymbol{\theta}^{(m)}$ as well as in specifying $p(m)$ for all $m \in \mathcal{M}$. We now describe this in the context of Bayesian variable subset selection.

Variable Selection in the Cox Model

Variable selection is one of the most frequently encountered problems in statistical data analysis. In

cancer or **AIDS clinical trials**, for example, one often wishes to assess the importance of certain **prognostic factors** such as treatment, age, gender, or race in predicting survival outcome. Most of the existing literature addresses variable selection using criterion-based methods such as the **Akaike Information Criterion** (AIC) [1] or Bayesian Information Criterion (BIC) [38]. As is well known, Bayesian variable selection is often difficult to carry out because of the challenge in

1. specifying prior distributions for the regression parameters for all possible models in $\mathcal{M}$;
2. specifying a prior distribution on the model space; and
3. computations.

Let p denote the number of covariates for the full model and let $\mathcal{M}$ denote the model space. We enumerate the models in $\mathcal{M}$ by $m = 1, 2, \ldots, \mathcal{K}$, where $\mathcal{K}$ is the dimension of $\mathcal{M}$ and model $\mathcal{K}$ denotes the full model. Also, let $\boldsymbol{\beta}^{(\mathcal{K})} = (\beta_0, \beta_1, \ldots, \beta_{p-1})'$ denote the regression coefficients for the full model including an intercept, and let $\boldsymbol{\beta}^{(m)}$ denote a $p_m \times 1$ vector of regression coefficients for model m with an intercept, and a specific choice of $p_m - 1$ covariates. We write $\boldsymbol{\beta}^{(\mathcal{K})} = (\boldsymbol{\beta}^{(m)'}, \boldsymbol{\beta}^{(-m)'})'$, where $\boldsymbol{\beta}^{(-m)}$ is $\boldsymbol{\beta}^{(\mathcal{K})}$ with $\boldsymbol{\beta}^{(m)}$ deleted. We now consider Bayesian variable selection for the Cox model based on a discretized gamma process on the baseline hazard function with independent increments (*see* **Bayesian Survival Analysis**). Let $0 = s_0 < s_1 < \cdots < s_J$ be a finite partition of the time axis and let

$$\delta_j = h_0(s_j) - h_0(s_{j-1}) \tag{3}$$

denote the increment in the baseline hazard in the interval $(s_{j-1}, s_j]$, $j = 1, 2, \ldots, J$, and $\boldsymbol{\delta} = (\delta_1, \delta_2, \ldots, \delta_J)'$. For $j = 1, 2, \ldots, J$, let d_j be the number of failures, $\mathcal{D}_j$ be the set of subjects failing, c_j be the number of right **censored** observations, and $\mathcal{C}_j$ the set of subjects that are censored. Under model m, the **likelihood** can be written as

$$L(\boldsymbol{\beta}^{(m)}, \boldsymbol{\delta} | D^{(m)}) = \prod_{j=1}^{J} \left\{ \exp\{-\delta_j (a_j + b_j)\} \times \prod_{k \in \mathcal{D}_j} [1 - \exp\{-\eta_k^{(m)} T_j\}] \right\}, \tag{4}$$

where $\eta_k^{(m)} = \exp(\boldsymbol{x}_k^{(m)'} \boldsymbol{\beta}^{(m)})$, $x_k^{(m)}$ is a $p_m \times 1$ vector of **covariates** for the ith individual under model m, $X^{(m)}$ denotes the $n \times p_m$ covariate matrix of rank p_m, and $D^{(m)} = (n, \boldsymbol{y}, X^{(m)}, \boldsymbol{v})$ denotes the data under model m. The rest of the terms in (4) are defined as follows:

$$a_j = \sum_{l=j+1}^{J} \sum_{k \in \mathcal{D}_l} \eta_k^{(m)} (s_{l-1} - s_{j-1}),$$

$$b_j = \sum_{l=j}^{J} \sum_{k \in \mathcal{C}_l} \eta_k^{(m)} (s_l - s_{j-1}), \tag{5}$$

and $T_j = (s_j - s_{j-1}) \sum_{l=1}^{j} \delta_l$. We have written the model here assuming that $\boldsymbol{\delta}$ does not depend on m. This is reasonable here, since our primary goal is variable selection, that is, to determine the dimension of $\boldsymbol{\beta}^{(m)}$. In this light, $\boldsymbol{\delta}$ can be viewed as a nuisance parameter in the variable selection problem. A more general version of the model can be constructed by letting $\boldsymbol{\delta}$ depend on m.

To construct a class of informative priors for $\beta^{(m)}$, one can consider the class of power priors, as discussed in [22, 24, 26]. Following Ibrahim, Chen, and Sinha [24], the power prior under model m can be written as

$$\pi(\boldsymbol{\beta}^{(m)}, \boldsymbol{\delta}, a_0 | D_0^{(m)}) \propto L(\boldsymbol{\beta}^{(m)}, \boldsymbol{\delta} | D_0^{(m)})^{a_0} \times \pi_0(\boldsymbol{\beta}^{(m)} | c_0) \pi_0(\boldsymbol{\delta} | \boldsymbol{\theta}_0) \pi(a_0 | \alpha_0, \lambda_0), \tag{6}$$

where $D_0^{(m)} = (n_0, \boldsymbol{y}_0, X_0^{(m)}, \boldsymbol{v}_0)$ is the historical data under model m, $\pi_0(\boldsymbol{\delta} | \boldsymbol{\theta}_0) \propto \prod_{j=1}^{J} \delta_j^{f_{0j}-1} \exp\{-\delta_j g_{0j}\}$, $\pi(a_0 | \alpha_0, \lambda_0) \propto a_0^{\alpha_0 - 1} (1 - a_0)^{\lambda_0 - 1}$, and $\boldsymbol{\theta}_0 = (f_{01}, g_{01}, \ldots, f_{0J}, g_{0J})'$ and (α_0, λ_0) are prespecified hyperparameters.

An attractive feature of the power prior for $\boldsymbol{\beta}^{(m)}$ in variable selection problems is that it is semiautomatic in the sense that one only needs a one-time input of $(D_0^{(m)}, c_0, \boldsymbol{\theta}_0, \alpha_0, \lambda_0)$ to generate the prior distributions for all $m \in \mathcal{M}$.

Choices of prior parameters for $\boldsymbol{\delta}$ can be made in several ways. One may take vague choices of prior parameters for the δ_j's such as $f_{0j} \propto g_{0j}(s_j - s_{j-1})$ and take g_{0j} small. This choice may be suitable if there is little prior information available on the baseline hazard rate. More informative choices for $\boldsymbol{\theta}_0$ can be made by incorporating the historical data $D_0^{(m)}$

into the elicitation process. A suitable choice of f_{0i} would be an increasing estimate of the baseline **hazard rate**. To construct such an estimate under model m, we can fit a **Weibull** model via **maximum likelihood** using $D_0^{(m)} = (n_0, \boldsymbol{y}_0, X_0^{(m)}, \nu_0)$ as the data. Often, the fit will result in a strictly increasing hazard. We denote such a hazard by $h^*(s|D_0^{(m)})$. Thus, we can take $f_{0j} = b_{0j} h^*(s_j|D_0^{(m)})$, where $b_{0j} = s_j - s_{j-1}$. In the event that the fitted Weibull model results in a constant or decreasing hazard, doubt is cast on the appropriateness of the gamma process as a model for the hazard, and we do not recommend this elicitation method. There are numerous other approaches to selecting this baseline hazard. Alternative classes of parametric models may be fit to $D_0^{(m)}$ or a nonparametric method such as that of Padgett and Wei [33] may be used to construct an increasing hazard.

Let the initial prior for the model space be denoted by $p_0(m)$. Given the historical data $D_0^{(m)}$, the prior probability of model m for the current study based on an update of y_0 via Bayes theorem is given by

$$p(m) \equiv p(m|D_0^{(m)}) = \frac{p(D_0^{(m)}|m)\, p_0(m)}{\sum_{m \in \mathcal{M}} p(D_0^{(m)}|m)\, p_0(m)}, \quad (7)$$

where

$$p(D_0|m) = \int L(\boldsymbol{\beta}^{(m)}, \boldsymbol{\delta}|D_0^{(m)}) \pi_0(\boldsymbol{\beta}^{(m)}|\, \mathrm{d}_0) \times \pi_0(\boldsymbol{\delta}|\boldsymbol{\kappa}_0)\, \mathrm{d}\beta^{(m)}\, \mathrm{d}\boldsymbol{\delta}, \quad (8)$$

$L(\boldsymbol{\delta}, \boldsymbol{\beta}^{(m)}|D_0^{(m)})$ is the likelihood function of the parameters based on $D_0^{(m)}$, $\pi_0(\boldsymbol{\beta}^{(m)}|d_0)$ is the initial prior for $\boldsymbol{\beta}^{(m)}$ given in (6) with d_0 replacing c_0, and $\pi_0(\boldsymbol{\delta}|\kappa_0)$ is the initial prior for $\boldsymbol{\delta}$ with $\boldsymbol{\kappa}_0$ replacing $\boldsymbol{\theta}_0$. We take $\pi_0(\boldsymbol{\beta}^{(m)}|d_0)$ to be a $N_{p_m}(0, d_0 W_0^{(m)})$ distribution, where $W_0^{(m)}$ is the submatrix of the diagonal matrix $W_0^{(\mathcal{K})}$ corresponding to model m. Large values of d_0 will tend to increase the prior probability for model m. Thus, the prior probability of model m for the current study is precisely the posterior probability of m given the historical data $D_0^{(m)}$, that is, $p(m) \equiv p(m|D_0^{(m)})$. This choice for $p(m)$ has several additional nice interpretations. First, $p(m)$ corresponds to the usual Bayesian update of $p_0(m)$ using $D_0^{(m)}$ as the data. Second, as $d_0 \to 0$, $p(m)$ reduces to $p_0(m)$. Therefore, as $d_0 \to 0$, the historical data $D_0^{(m)}$ have a minimal impact in determining $p(m)$. However, as $d_0 \to \infty$, $\pi_0(\boldsymbol{\beta}^{(m)}|d_0)$ plays a minimal role in determining $p(m)$, and in this case, the historical data plays a larger role in determining $p(m)$. The parameter d_0 thus serves as a tuning parameter to control the impact of $D_0^{(m)}$ on the prior model probability $p(m)$. It is important to note that we use a scalar parameter c_0 in constructing the power prior $\pi(\boldsymbol{\beta}^{(m)}, \boldsymbol{\delta}, a_0|D_0^{(m)})$ in (6), while we use a *different* scalar parameter d_0 in determining $p(m)$. This development provides us with great flexibility in specifying the prior distribution for $\boldsymbol{\beta}^{(m)}$ as well as the prior model probabilities $p(m)$. Finally, we note that when there is little information about the relative plausibility of the models at the initial stage, taking $p_0(m) = 1/\mathcal{K}$, $m = 1, 2, \ldots, \mathcal{K}$, *a priori* is a reasonable "neutral" choice.

To compute $p(m)$ in (7), we follow the Monte Carlo approach of Ibrahim and Chen [21] to estimate all of the prior model probabilities using a single Gibbs sample from the full model (*see* **Markov Chain Monte Carlo**). In the context of Bayesian **variable selection** for **logistic regression**, Chen, Shao, and Ibrahim [8] use a similar idea to compute the prior model probabilities. This method involves computing the marginal distribution of the data via ratios of normalizing constants and it requires posterior samples *only* from the *full model* for computing the prior probabilities for all possible models. The method is thus very efficient for variable selection. The technical details of this method are given in Ibrahim, Chen, and Sinha [24], Ibrahim, Chen, and MacEachern [23] and Chen, Shao, and Ibrahim [8].

Criterion-based Methods

Bayesian methods for model comparison usually rely on posterior model probabilities or Bayes factors, and it is well known that to use these methods, proper prior distributions are needed when the number of parameters in the two competing models are different. In addition, posterior model probabilities are generally sensitive to the choices of prior parameters, and thus one cannot simply select vague proper priors to get around the elicitation issue. Alternatively, criterion-based methods can be attractive in the sense that they do not require proper prior distributions in general, and thus have an advantage over posterior model probabilities in this sense. However, posterior model probabilities are intrinsically well **calibrated** since probabilities are relatively easy to interpret,

whereas criterion-based methods are generally not easy to calibrate or interpret. Thus, one potential criticism of criterion-based methods for model comparison is that they generally do not have well-defined calibrations.

Recently, Ibrahim, Chen, and Sinha [25] proposed a Bayesian criterion called the *L measure* [27, 30], for model assessment and model comparison, and proposed a calibration for it. The L measure can be used as a general model assessment tool for comparing models and assessing goodness of fit for a particular model, and thus in this sense, the criterion is potentially quite versatile. A recent extension of the L measure, called the weighted L measure, can be found in [4].

Consider an experiment that yields the data $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$. Denote the joint sampling density of the y_i's by $f(\boldsymbol{y}|\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a vector of indexing parameters. We allow the y_i's to be fully observed, right censored, or interval censored. In the right-censored case, y_i may be a failure time or a censoring time. In the interval-censored case, we only observe the interval $[a_{l_i}, a_{r_i}]$ in which y_i occurred. Let $\boldsymbol{z} = (z_1, z_2, \ldots, z_n)'$ denote future values of a replicate experiment. That is, $\boldsymbol{z}$ is a future response vector with the same sampling density as $\boldsymbol{y}|\boldsymbol{\theta}$. The idea of using a future response vector $\boldsymbol{z}$ in developing a criterion for assessing a model or comparing several models has been well motivated in the literature by Geisser [14] and the many references therein [17, 27, 30].

Let $\eta(\cdot)$ be a known function, and let $y_i^* = \eta(y_i)$, $z_i^* = \eta(z_i)$, $\boldsymbol{y}^* = (y_1^*, y_2^*, \ldots, y_n^*)'$, and $\boldsymbol{z}^* = (z_1^*, z_2^*, \ldots, z_n^*)'$. For example, in survival analysis, it is common to take the logarithms of the survival times, and thus in this case $\eta(y_i) = \log(y_i) = y_i^*$. Also, $\eta(y_i) = \log(y_i)$ is a common transformation in **Poisson regression**. It is also common to take $\eta(\cdot)$ to be the identity function (i.e. $\eta(y_i) = y_i$), as in normal **linear regression** or logistic regression, so that in this case, $y_i^* = y_i$ and $z_i^* = z_i$.

For a given model, we first define the statistic

$$L_1(\boldsymbol{y}^*, \boldsymbol{b}) = \mathrm{E}[(\boldsymbol{z}^* - \boldsymbol{b})'(\boldsymbol{z}^* - \boldsymbol{b})] + \delta(\boldsymbol{y}^* - \boldsymbol{b})'(\boldsymbol{y}^* - \boldsymbol{b}), \quad (9)$$

where the **expectation** is taken with respect to the posterior predictive distribution of $\boldsymbol{z}^*|\boldsymbol{y}^*$. The posterior predictive density of $\boldsymbol{z}^*|\boldsymbol{y}^*$ is given by

$$\pi(\boldsymbol{z}^*|\boldsymbol{y}^*) = \int f(\boldsymbol{z}^*|\boldsymbol{\theta})\pi(\boldsymbol{\theta}|\boldsymbol{y}^*)\,\mathrm{d}\boldsymbol{\theta}, \quad (10)$$

where $\boldsymbol{\theta}$ denotes the vector of indexing parameters, $f(\boldsymbol{z}^*|\boldsymbol{\theta})$ is the sampling distribution of the future vector $\boldsymbol{z}^*$, and $\pi(\boldsymbol{\theta}|\boldsymbol{y}^*)$ denotes the posterior distribution of $\boldsymbol{\theta}$. The statistic in (9) takes the form of a weighted discrepancy measure. The vector $\boldsymbol{b} = (b_1, b_2, \ldots, b_n)'$ is an arbitrary location vector to be chosen and δ is a nonnegative scalar that weights the discrepancy based on the future values relative to the observed data. The general criterion in (9) is a special case of a class considered by Gelfand and Ghosh [17], which are motivated from a Bayesian **decision theoretic** viewpoint.

In scalar notation, (9) can be written as

$$L_1(\boldsymbol{y}^*, \boldsymbol{b}) = \sum_{i=1}^{n}\{\mathrm{Var}(z_i^*|\boldsymbol{y}^*) + (\mu_i - b_i)^2 + \delta(y_i^* - b_i)^2\}, \quad (11)$$

where $\mu_i = \mathrm{E}(z_i^*|\boldsymbol{y}^*)$. Thus, we see that (11) has the appealing decomposition as a sum involving the predictive variances plus two squared "bias" terms, $(\mu_i - b_i)^2$ and $\delta(y_i^* - b_i)^2$, where δ is a weight for the second bias component.

The $\boldsymbol{b}$ that minimizes (11) is

$$\hat{\boldsymbol{b}} = (1 - \nu)\boldsymbol{\mu} + \nu\ \boldsymbol{y}^*, \quad (12)$$

where $\boldsymbol{\mu} = (\mu_1, \mu_2, \ldots, \mu_n)'$, $\nu = \delta/(\delta + 1)$, which upon substitution in (11) leads to the criterion

$$L_2(y^*) = \sum_{i=1}^{n}\mathrm{Var}(z_i^*|y_i^*) + \nu\sum_{i=1}^{n}(\mu_i - y_i^*)^2. \quad (13)$$

Clearly, $0 \le \nu < 1$, where $\nu = 0$ if $\delta = 0$, and $\nu \to 1$ as $\delta \to \infty$. The quantity ν plays a major role in (13). It can be interpreted as a weight term in the squared bias component of (13), and appears to have a lot of potential impact on the ordering of the models, as well as characterizing the properties of the L measure and calibration distribution. Ibrahim, Chen, and Sinha [25] theoretically show that certain values of ν yield highly desirable properties of the L measure and the calibration distribution compared to other values of ν. They demonstrate that the choice of ν has much potential influence on the properties

of the L measure, calibration distribution, and model choice in general. On the basis of their theoretical exploration, $\nu = 1/2$ is a desirable and justifiable choice for model selection. When $\nu = 1$, 13 reduces to the criterion of Ibrahim and Laud [27] and Laud and Ibrahim [30].

If $\boldsymbol{y}^*$ is fully observed, then (13) is straightforward to compute. However, if $\boldsymbol{y}^*$ contains right-censored or interval-censored observations, then (13) is computed by taking the expectation of these censored observations with respect to the posterior predictive distribution of the censored observations. Let $\boldsymbol{y}^* = (\boldsymbol{y}^*_{\text{obs}}, \boldsymbol{y}^*_{\text{cens}})$, where $\boldsymbol{y}^*_{\text{obs}}$ denotes the completely observed components of $\boldsymbol{y}^*$, and $\boldsymbol{y}^*_{\text{cens}}$ denotes the censored components. Here, we assume that $\boldsymbol{y}^*_{\text{cens}}$ is a random quantity and $\boldsymbol{a}_l < \boldsymbol{y}^*_{\text{cens}} < \boldsymbol{a}_r$, where $\boldsymbol{a}_l$ and $\boldsymbol{a}_r$ are known. For ease of exposition, we let $D = (n, \boldsymbol{y}^*_{\text{obs}}, \boldsymbol{a}_l, \boldsymbol{a}_r)$ denote the observed data. Then (13) is modified as

$$L(\boldsymbol{y}^*_{\text{obs}}) = \mathrm{E}_{\boldsymbol{y}^*_{\text{cens}}|D}[1\{\boldsymbol{a}_l < \boldsymbol{y}^*_{\text{cens}} < \boldsymbol{a}_r\} L_2(\boldsymbol{y}^*)], \tag{14}$$

where $1\{\boldsymbol{a}_l < \boldsymbol{y}^*_{\text{cens}} < \boldsymbol{a}_r\}$ is a generic indicator function taking the value 1 if $\boldsymbol{a}_l < \boldsymbol{y}^*_{\text{cens}} < \boldsymbol{a}_r$ and 0 otherwise, and the expectation $\mathrm{E}_{\boldsymbol{y}^*_{\text{cens}}|D}$ is taken with respect to the posterior predictive distribution $f(\boldsymbol{y}^*_{\text{cens}}|\boldsymbol{\theta})\pi(\boldsymbol{\theta}|D)$. Note that $\boldsymbol{a}_l < \boldsymbol{y}^*_{\text{cens}} < \boldsymbol{a}_r$ means that the double inequalities hold for each component of these vectors. If, for example, all n observations are censored, then the above notation means $a_{l_i} < y^*_{\text{cens},i} < a_{r_i}, \quad i = 1, \ldots, n$, where $\boldsymbol{a}_l = (a_{l_1}, \ldots, a_{l_n})'$, $\boldsymbol{a}_r = (a_{r_1}, \ldots, a_{r_n})'$, and $\boldsymbol{y}^*_{\text{cens}} = (y^*_{\text{cens},1}, \ldots, y^*_{\text{cens},n})'$. Small values of the L measure imply a good model. Specifically, we can write (14) as

$$L(\boldsymbol{y}^*_{\text{obs}}) = \int\!\!\int_{\boldsymbol{a}_l}^{\boldsymbol{a}_r} L_2(\boldsymbol{y}^*) f(\boldsymbol{y}^*_{\text{cens}}|\boldsymbol{\theta})\pi(\boldsymbol{\theta}|D)\, \mathrm{d}\boldsymbol{y}^*_{\text{cens}}\, \mathrm{d}\boldsymbol{\theta}, \tag{15}$$

where $f(\boldsymbol{y}^*_{\text{cens}}|\boldsymbol{\theta})$ is the sampling density of $\boldsymbol{y}^*_{\text{cens}}$ and $\pi(\boldsymbol{\theta}|D)$ is the posterior density of $\boldsymbol{\theta}$ given the observed data D. If $\boldsymbol{y}^*$ has right-censored observations, then $\boldsymbol{a}_r = \infty$, and $\boldsymbol{a}_l$ is a vector of censoring times. If $\boldsymbol{y}^*$ has interval-censored observations, then $(\boldsymbol{a}_l, \boldsymbol{a}_r)$ is a sequence of finite interval censoring times. If $\boldsymbol{y}^*$ is fully observed, that is, $\boldsymbol{y}^*_{\text{obs}} = \boldsymbol{y}^*$, then (14) reduces to (13), and therefore, $L(\boldsymbol{y}^*_{\text{obs}}) \equiv L_2(\boldsymbol{y}^*)$ in this case.

Conditional Predictive Ordinate

The CPO statistic is a very useful model assessment tool, which has been widely used in the statistical literature under various contexts. For a detailed discussion of the CPO statistic and its applications to model assessment, see [12, 14, 16, 40]. For the ith observation, the CPO statistic is defined as

$$\begin{aligned}\mathrm{CPO}_i &= f(y_i|D^{(-i)}) \\ &= \int f(y_i|\boldsymbol{\beta}, \boldsymbol{\lambda}, \boldsymbol{x}_i)\pi(\boldsymbol{\beta}, \boldsymbol{\lambda}|D^{(-i)})\, \mathrm{d}\boldsymbol{\beta}\, \mathrm{d}\boldsymbol{\lambda}, \end{aligned} \tag{16}$$

where y_i denotes the response variable and $\boldsymbol{x}_i$ is the vector of covariates for case i, $D^{(-i)}$ denotes the data with the ith case deleted, and $\pi(\boldsymbol{\beta}, \boldsymbol{\lambda}|D^{(-i)})$ is the posterior density of $(\boldsymbol{\beta}, \boldsymbol{\lambda})$ based on the data $D^{(-i)}$. From (16), we see that CPO_i is the marginal posterior predictive density of y_i given $D^{(-i)}$, and can be interpreted as the height of this marginal density at y_i. Thus, large values of CPO_i imply a better fit of the model.

For most models for survival data, a closed form of CPO_i is not available. However, a Monte Carlo estimator of CPO_i can be obtained using a single MCMC sample from the posterior distribution $\pi(\boldsymbol{\beta}, \boldsymbol{\lambda}|D)$, where D denotes the data including all cases. The implementational details for computing CPO_i can be found in [8, Chapter 10].

For comparing two competing models, we examine the CPO_i's under both models. The observation with a larger CPO value under one model will support that model over the other. Therefore, a plot of CPO_i's under both models against observation number should reveal that the better model has the majority of its CPO_i's above those of the poorer fitting model. In comparing several competing models, the CPO_i values under all models can be plotted against the observation number in a single graph.

An alternative to CPO plots is the summary statistic called the logarithm of the Pseudo-**marginal likelihood** (LPML) (see [15]), defined as

$$\mathrm{LPML} = \sum_{i=1}^{n} \log(\mathrm{CPO}_i). \tag{17}$$

In the context of survival data, the statistic LPML has been discussed by Gelfand and Mallick [18] and Sinha and Dey [40]. To compare LPML's from two different studies for a given model, we propose to use

a modification of (17), which is the average LPML given by

$$\text{ALPML} = \frac{\text{LPML}}{n}, \tag{18}$$

where n is the sample size. The statistic ALPML can be interpreted as the relative pseudo-marginal likelihood.

We see from (16) that LPML is always well defined as long the posterior predictive density is proper. Thus, LPML is well defined under improper priors, and in addition, it is very computationally stable. Therefore, LPML has a clear advantage over the Bayes factor as a model assessment tool, since it is well known that the Bayes factor is not well defined with improper priors, and is generally quite sensitive to vague proper priors. In addition, the LPML statistic also has clear advantages over other model selection criteria, such as the *L measure*. The L measure is a Bayesian criterion requiring finite second moments of the sampling distribution of y_i, whereas the LPML statistic does not require existence of any moments. Since for example, cure rate models have improper survival functions, no moments of the sampling distribution exist, and therefore the L measure is not well defined for these models (*see* **Bayesian Approaches to Cure Rate Models**).

Bayesian Model Averaging

A popular approach to model selection is Bayesian model averaging (BMA). In this approach, one base's inference on an average of all possible models in the model space $\mathcal{M}$, instead of a single "best" model. Suppose $\mathcal{M} = \{\mathcal{M}_1, \mathcal{M}_2, \ldots, \mathcal{M}_K\}$, and let Δ denote the quantity of interest such as a future observation, a set of regression coefficients, or the utility of a course of action. Then, the posterior distribution of Δ is given by

$$\pi(\Delta|D) = \sum_{k=1}^{K} \pi(\Delta|D, \mathcal{M}_k) p(\mathcal{M}_k|D), \tag{19}$$

where D denotes the data, $\pi(\Delta|D, \mathcal{M}_k)$ is the posterior distribution of Δ under model $\mathcal{M}_k$, and $p(\mathcal{M}_k|D)$ is the posterior model probability. Equation (19), called BMA, consists of an average of the posterior distributions under each model weighted by the corresponding posterior model probabilities. The motivation behind BMA is based on the notion that a single "best" model ignores uncertainty about the model itself, which can result in underestimated uncertainties about quantities of interest, whereas BMA in (19) incorporates model uncertainty.

The implementation of BMA is difficult for two reasons. First, $p(\mathcal{M}_k|D)$ can be difficult to compute. Second, the number of terms in (19) can be enormous. One solution to reduce the number of possible models in (19) involves applying the Occam's window algorithm of Madigan and Raftery [31]. Two basic principles underlie this ad hoc approach. First, if a model predicts the data far less well than the model that provides the best predictions, then it has effectively been discredited and should no longer be considered. Thus, models not belonging to

$$\mathcal{A}' = \left\{ \mathcal{M}_k : \frac{\max_l \{p(\mathcal{M}_l|D)\}}{p(\mathcal{M}_k|D)} \leq C \right\} \tag{20}$$

are excluded from (19), where C is chosen by the data analyst and $\max_l\{p(\mathcal{M}_l|D)\}$ denotes the model with the highest posterior probability. A common choice of C is $C = 20$. The number of models in Occam's window increases as C decreases. Second, appealing to Occam's razor, models that receive less support from the data than any other simpler models are excluded. That is, models from (19) are excluded if they belong to

$$\mathcal{B} = \left\{ \mathcal{M}_k : \exists \mathcal{M}_l \in \mathcal{M}, \mathcal{M}_l \subset \mathcal{M}_k, \frac{p(\mathcal{M}_l|D)}{p(\mathcal{M}_k|D)} > 1 \right\}. \tag{21}$$

Thus, (19) is replaced by

$$\pi(\Delta|D) = \frac{\sum_{\mathcal{M}_k \in \mathcal{A}} \pi(\Delta|D, \mathcal{M}_k) p(D|\mathcal{M}_k) p(\mathcal{M}_k)}{\sum_{\mathcal{M}_k \in \mathcal{A}} p(D|\mathcal{M}_k) p(\mathcal{M}_k)}, \tag{22}$$

where $\mathcal{A} = \mathcal{A}' \backslash \mathcal{B} \in \mathcal{M}$, $p(D|\mathcal{M}_k)$ is the marginal likelihood of the data D under model $\mathcal{M}_k$, and $p(\mathcal{M}_k)$ denotes the prior model probability.

This strategy greatly reduces the number of possible models in (19), and now all that is required is a search strategy to identify the models in $\mathcal{A}$. Two further principles underlie the search strategy. The first principle – Occam's window – concerns interpreting the ratio of posterior model probabilities

$p(\mathcal{M}_1|D)/p(\mathcal{M}_0|D)$, where $\mathcal{M}_0$ is a model with one less predictor than $\mathcal{M}_1$. If there is evidence for $\mathcal{M}_0$, then $\mathcal{M}_1$ is rejected, but to reject $\mathcal{M}_0$, stronger evidence for the larger model $\mathcal{M}_1$ is required. These principles fully define the strategy. Madigan and Raftery [31] provide a detailed description of the algorithm and mention that the number of terms in (19) is often reduced to fewer than 25.

The second approach for reducing the number of terms in (19) is to approximate (19) using an MCMC approach. Madigan and York [32] propose the MCMC model composition (MC^3) methodology, which generates a **stochastic process** that moves through the model space. A **Markov chain** $\{\mathcal{M}(l), l = 1, 2, \ldots\}$ is constructed with state space $\mathcal{M}$ and equilibrium distribution $p(\mathcal{M}_k|D)$. If this Markov chain is simulated for $l = 1, 2, \ldots, L$, then under certain regularity conditions, for any function $g(\mathcal{M}_k)$ defined on $\mathcal{M}$, the average

$$\hat{G} = \frac{1}{L}\sum_{l=1}^{L} g(\mathcal{M}(l)) \tag{23}$$

converges almost surely to $\mathrm{E}(g(\mathcal{M}_k))$ as $L \to \infty$. To compute (19) in this fashion, set $g(\mathcal{M}_k) = \pi(\Delta|D, \mathcal{M}_k)$. To construct the Markov chain, define a neighborhood $\mathrm{nbd}(\mathcal{M}_*)$ for each $\mathcal{M}_* \in \mathcal{M}$ that consists of the model $\mathcal{M}_*$ itself and the set of models with either one variable more or one variable fewer than $\mathcal{M}_*$. Define a transition matrix q by setting $q(\mathcal{M}_* \to \mathcal{M}'_*) = 0$ for all $\mathcal{M}'_* \notin \mathrm{nbd}(\mathcal{M}_*)$ and $q(\mathcal{M}_* \to \mathcal{M}'_*)$ constant for all $\mathcal{M}'_* \in \mathrm{nbd}(\mathcal{M}_*)$. If the chain is currently in state $\mathcal{M}_*$, then we proceed by drawing $\mathcal{M}'_*$ from $q(\mathcal{M}_* \to \mathcal{M}'_*)$. It is then accepted with probability

$$\min\left\{1, \frac{p(\mathcal{M}'_*|D)}{p(\mathcal{M}_*|D)}\right\}. \tag{24}$$

Otherwise, the chain stays in state $\mathcal{M}_*$.

To compute $p(D|\mathcal{M}_k)$, Raftery [34] suggests the use of the Laplace approximation, leading to

$$\log(p(D|\mathcal{M}_k)) = \log(L(\hat{\boldsymbol{\theta}}_k|D, \mathcal{M}_k)) - p_k \log(n) + O(1), \tag{25}$$

where n is the sample size, $L(\hat{\boldsymbol{\theta}}_k|D, \mathcal{M}_k)$ is the likelihood function, $\hat{\boldsymbol{\theta}}_k$ is the maximum likelihood estimate (MLE) of $\boldsymbol{\theta}_k$ under model $\mathcal{M}_k$, and p_k is the number of parameters in model $\mathcal{M}_k$. This is the BIC approximation derived by Schwarz [38]. In fact, (25) is much more accurate for many practical purposes than its $O(1)$ error term suggests. Kass and Wasserman [29] show that when $\mathcal{M}_j$ and $\mathcal{M}_k$ are nested and the amount of information in the prior distribution is equal to that in one observation, then the error in (25) is $O(n^{-1/2})$, under certain assumptions, rather than $O(1)$. Raftery [34] gives further empirical evidence for the accuracy of this approximation.

BMA for Variable Selection in the Cox Model

Volinsky, Madigan, Raftery, and Kronmal [45] discuss how to carry out variable selection in the Cox model using BMA. Equation (19) has three components, each posing its own computational difficulties. The predictive distribution $\pi(\Delta|D, \mathcal{M}_k)$ requires integrating out the model parameter $\boldsymbol{\theta}_k$. The posterior model probabilities $p(\mathcal{M}_k|D)$ similarly involve the calculation of an integrated likelihood. Finally, the models that fall into $\mathcal{A}$ must be located and evaluated efficiently.

In (19), the predictive distribution of Δ, given a particular model $\mathcal{M}_k$, is found by integrating out the model parameter $\boldsymbol{\theta}_k$:

$$\pi(\Delta|D, \mathcal{M}_k) = \int \pi(\Delta|\boldsymbol{\theta}_k, D, \mathcal{M}_k)\pi(\boldsymbol{\theta}_k|D, \mathcal{M}_k)\, \mathrm{d}\boldsymbol{\theta}_k. \tag{26}$$

This integral does not have a closed-form solution for the Cox model. Volinsky, Madigan, Raftery, and Kronmal [45] use the MLE approximation:

$$\pi(\Delta|D, \mathcal{M}_k) \approx \pi(\Delta|\hat{\boldsymbol{\theta}}_k, D, \mathcal{M}_k). \tag{27}$$

In the context of model uncertainty, this approximation was used by Taplin [43] and found it to give an excellent approximation in his **time series regression** problem; it was subsequently used by Taplin and Raftery [44] and Draper [13].

In regression models for survival analysis, analytic evaluation of $p(D|\mathcal{M}_k)$ is not possible in general, and an analytic or computational approximation is needed. In regular statistical models (roughly speaking, those in which the MLE is consistent and asymptotically normal), $p(D|\mathcal{M}_k)$ can be approximated by (25) via the Laplace method [34].

Equation (19) requires the specification of a prior on the model space. When there is little prior information about the relative plausibility of the models considered, taking them all to be equally likely *a priori* is a reasonable "neutral" choice. When prior information about the importance of a variable is available, a prior probability on model $\mathcal{M}_k$ can be specified as

$$p(\mathcal{M}_k) = \prod_{j=1}^{p} \pi_j{}^{\delta_{kj}} \, (1 - \pi_j)^{1-\delta_{kj}}, \qquad (28)$$

where $\pi_j \in [0, 1]$ is the prior probability that $\boldsymbol{\theta}_j \neq 0$, and δ_{kj} is an indicator of whether or not variable j is included in model $\mathcal{M}_k$. Assigning $\pi_j = 0.5$ for all j corresponds to a uniform prior across the model space, while $\pi_j < 0.5$ for all j imposes a penalty for large models. Using $\pi_j = 1$ ensures that variable j is included in all models. Using this framework, elicitation of prior probabilities for models is straightforward and avoids the need to elicit priors for a large number of models. For an alternative approach, when expert information is available, see [32].

Model Selection Using BIC

Model selection criteria such as BIC are often used to select variables in regression problems. Following Volinsky and Raftery [46], we use BIC to determine the best models (where models are variable subsets) in a class of censored survival models.

When censoring is present, it is unclear whether the penalty in BIC should use n, the number of observations, or d, the number of events. When using the partial likelihood, there are only as many terms in the partial likelihood as there are events d. Kass and Wasserman [29] indicate that the term used in the penalty should be the rate at which the Hessian matrix of the log-likelihood function grows, which suggests that d is the correct quantity to use. However, if we are to use a revised version of BIC, it is important that the new criterion continue to have the asymptotic properties that Kass and Wasserman derived. In fact, the revised BIC does have these properties, with a slightly modified outcome. Suppose that

$$-\frac{1}{d} D^2 l(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\psi}}) - I_u(\boldsymbol{\theta}, \boldsymbol{\psi}) = O_p(n^{-1/2}), \qquad (29)$$

where $I_u(\boldsymbol{\theta}, \boldsymbol{\psi})$ is the expected Fisher **information** for one uncensored observation (the *uncensored unit information*) and $D^2 l(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\psi}})$ denotes the second derivative of the log-likelihood evaluated at $(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\psi}})$. If (29) holds, then the new BIC (with d in the penalty) is an $O_p(n^{-1/2})$ approximation to twice the Bayes factor where the prior variance on $\boldsymbol{\theta}$ is now equal to the inverse of the uncensored unit information. By using d in the penalty instead of n, it can be shown that this asymptotic result holds, the only difference being in the implicit prior on the parameter. More details regarding BIC for the Cox model can be found in Volinsky and Raftery [45].

Bayesian Survival Analysis

Introduction

Nonparametric and semiparametric **Bayesian methods** in **survival analysis** have recently become quite popular due to recent advances in computing technology and the development of efficient computational **algorithms** for implementing these methods. Such methods have now become quite common and well accepted in practice, since they offer a more general modeling strategy that contains fewer assumptions. The literature on nonparametric Bayesian methods has been recently surging, and all of the references are far too enormous to list here. In this chapter, we discuss several types of Bayesian survival models, including **parametric models** as well as models involving nonparametric prior processes for the baseline **hazard** or **cumulative hazard**. Specifically, we examine piecewise constant hazard models, the gamma process, the beta process, correlated prior processes, and the Dirichlet process, with much of the focus being on the **Cox model**. In each case, we give a development of the prior process, construct the **likelihood** function, derive the posterior distributions, and discuss **Markov Chain Monte Carlo** (MCMC) sampling techniques for inference. We also give references to other types of Bayesian models, including **frailty** models, **joint models for longitudinal and survival data** flexible classes of **hierarchical models**, **accelerated failure time models**, **multivariate survival** models, **spatial** survival models, and Bayesian model **diagnostics**.

There are two fundamental approaches to **semiparametric** Bayesian survival analysis, one based on continuous time and the other based on discrete time prior processes. The discrete time approach is an approximation to the continuous time approach. The continuous time approach can be viewed as a limiting case of the discrete time approach. In practice, the model development and implementation of the continuous time approach is much more complicated than that of discrete time models. Moreover, there is the general perception that not much is gained in the continuous time approach since its discrete approximation can be made arbitrarily accurate to approximate the continuous time version. Thus, in practice, discrete time models are most often used over their continuous time versions. Following the book by Ibrahim, Chen, and Sinha [57], we primarily focus on discrete time approaches to semiparametric Bayesian survival analysis in this chapter. Some key references for continuous time Bayesian survival analysis include [29, 38, 55, 60, 67, 68, 89, 90]. References discussing computational implementation of continuous time models include [29, 67, 68, 90] and the references therein.

The rest of this chapter is organized as follows. In the section, "Fully Parametric Models", we review Bayesian parametric survival models. In the next section, we discuss semiparametric Bayesian methods for survival analysis and focus on the **proportional hazards** model of Cox [27]. We examine the piecewise constant, gamma, beta, and Dirichlet process models. In the final section, we give several references to other types of models and applications in Bayesian survival analysis.

Fully Parametric Models

Bayesian approaches to fully parametric survival analysis has been considered by many in the literature. The statistical literature in Bayesian parametric survival analysis and life-testing is too enormous to list here, but some references dealing with applications to medicine or public health include [1, 2, 19, 30, 52, 62].

The most common types of parametric models used are the **exponential**, **Weibull**, and **lognormal** models.

The exponential model is the most fundamental parametric model in survival analysis. Suppose we have independent and identically distributed (i.i.d.) survival times $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$, each having an exponential distribution with parameter λ, denoted by $\mathcal{E}(\lambda)$. Denote the **censoring** indicators by $\boldsymbol{\nu} = (\nu_1, \nu_2, \ldots, \nu_n)'$, where $\nu_i = 0$ if y_i is right censored and $\nu_i = 1$ if y_i is a failure time. Let $f(y_i|\lambda) = \lambda \exp(-\lambda y_i)$ denote the density for y_i, $S(y_i|\lambda) = \exp(-\lambda y_i)$ denotes the survival function and $D = (n, \boldsymbol{y}, \boldsymbol{\nu})$ denotes the observed data. We can write the likelihood function of λ as

$$L(\lambda|D) = \prod_{i=1}^{n} f(y_i|\lambda)^{\nu_i} S(y_i|\lambda)^{1-\nu_i}$$
$$= \lambda^d \exp\left(-\lambda \sum_{i=1}^{n} y_i\right), \qquad (1)$$

where $d = \sum_{i=1}^{n} \nu_i$. The conjugate **prior** for λ is the **gamma** prior. Let $\mathcal{G}(\alpha_0, \lambda_0)$ denote the gamma distribution with parameters (α_0, λ_0), with density given by

$$\pi(\lambda|\alpha_0, \lambda_0) \propto \lambda^{\alpha_0 - 1} \exp(-\lambda_0 \lambda).$$

Then, taking a $\mathcal{G}(\alpha_0, \lambda_0)$ prior for λ, the posterior distribution of λ is given by

$$\begin{aligned}
\pi(\lambda|D) &\propto L(\lambda|D)\pi(\lambda|\alpha_0, \lambda_0) \\
&\propto \left(\lambda^{\sum_{i=1}^{n} \nu_i} \exp\left\{-\lambda \sum_{i=1}^{n} y_i\right\}\right)\left(\lambda^{\alpha_0 - 1} \exp(-\lambda_0 \lambda)\right) \\
&= \lambda^{\alpha_0 + d - 1} \exp\left\{-\lambda\left(\lambda_0 + \sum_{i=1}^{n} y_i\right)\right\}. \qquad (2)
\end{aligned}$$

Thus, we recognize the kernel of the posterior distribution in (2) as a $\mathcal{G}(\alpha_0 + d, \lambda_0 + \sum_{i=1}^{n} y_i)$ distribution. The posterior mean and variance of λ are thus given by

$$\begin{aligned}
\mathrm{E}(\lambda|D) &= \frac{\alpha_0 + d}{\lambda_0 + \sum_{i=1}^{n} y_i} \qquad \text{and} \\
\mathrm{Var}(\lambda|D) &= \frac{\alpha_0 + d}{\left(\lambda_0 + \sum_{i=1}^{n} y_i\right)^2}. \qquad (3)
\end{aligned}$$

The posterior predictive distribution of a future failure time y_f is given by

$$\begin{aligned}
\pi(y_f|D) &= \int_0^\infty \pi(y_f|\lambda)\pi(\lambda|D)\,\mathrm{d}\lambda \\
&\propto \int_0^\infty \lambda^{\alpha_0 + d + 1 - 1} \exp\left\{-\lambda(y_f + \lambda_0 + \sum_{i=1}^{n} y_i)\right\} \mathrm{d}\lambda \\
&= \Gamma(\alpha_0 + d + 1)\left(\lambda_0 + \sum_{i=1}^{n} y_i + y_f\right)^{-(d + \alpha_0 + 1)} \\
&\propto \left(\lambda_0 + \sum_{i=1}^{n} y_i + y_f\right)^{-(d + \alpha_0 + 1)}. \qquad (4)
\end{aligned}$$

The normalized posterior predictive distribution is thus given by

$$\begin{aligned}
&\pi(y_f|D) \\
&= \begin{cases} \dfrac{(d + \alpha_0)\left(\lambda_0 + \sum_{i=1}^{n} y_i\right)^{(\alpha_0 + d)}}{\left(\lambda_0 + \sum_{i=1}^{n} y_i + y_f\right)^{(\alpha_0 + d + 1)}} & \text{if } y_f > 0, \\ 0 & \text{otherwise.} \end{cases} \qquad (5)
\end{aligned}$$

In the derivation of (4) above, we need to evaluate a gamma integral, which thus led to the posterior predictive distribution in (5). The predictive distribution in (5) is known as an *inverse beta* distribution and is discussed in detail in [3].

To build a **regression** model, we introduce **covariates** through λ, and write $\lambda_i = \varphi(\boldsymbol{x}_i'\boldsymbol{\beta})$, where $\boldsymbol{x}_i$ is a $p \times 1$ vector of covariates, $\boldsymbol{\beta}$ is a $p \times 1$ vector of regression coefficients, and $\varphi(.)$ is a known function. A common form of φ is to take $\varphi(\boldsymbol{x}_i'\boldsymbol{\beta}) = \exp(\boldsymbol{x}_i'\boldsymbol{\beta})$. Another form of φ is $\varphi(\boldsymbol{x}_i'\boldsymbol{\beta}) = (\boldsymbol{x}_i'\boldsymbol{\beta})^{-1}$. Feigl and Zelen [42] also discuss this regression model. Using $\varphi(\boldsymbol{x}_i'\boldsymbol{\beta}) = \exp(\boldsymbol{x}_i'\boldsymbol{\beta})$, we are led to the likelihood function

$$\begin{aligned}
L(\boldsymbol{\beta}|D) &= \prod_{i=1}^{n} f(y_i|\lambda_i)^{\nu_i} S(y_i|\lambda_i)^{1 - \nu_i} \\
&= \exp\left\{\sum_{i=1}^{n} \nu_i \boldsymbol{x}_i'\boldsymbol{\beta}\right\} \exp\left\{-\sum_{i=1}^{n} y_i \exp(\boldsymbol{x}_i'\boldsymbol{\beta})\right\}, \qquad (6)
\end{aligned}$$

$D = (n, \boldsymbol{y}, X, \boldsymbol{\nu})$ and X is the $n \times p$ matrix of covariates with ith row $\boldsymbol{x}_i'$. Common prior distributions for $\boldsymbol{\beta}$ include an improper **uniform** prior, that is, $\pi(\boldsymbol{\beta}) \propto 1$, and a **normal** prior. In the regression setting, closed forms for the posterior distribution of $\boldsymbol{\beta}$ are generally not available, and therefore one needs to use **numerical integration** or Markov chain Monte Carlo (MCMC) methods. Before the advent of MCMC, numerical integration techniques were employed by Grieve [52]. However, due to the availability of statistical packages such as BUGS, the regression model in (6) can easily be fitted using MCMC techniques. Suppose we specify a p-dimensional normal prior for $\boldsymbol{\beta}$, denoted by

$N_p(\boldsymbol{\mu}_0, \Sigma_0)$, where $\boldsymbol{\mu}_0$ denotes the prior mean and Σ_0 denotes the prior covariance matrix. Then the posterior distribution of $\boldsymbol{\beta}$ is given by

$$\pi(\boldsymbol{\beta}|D) \propto L(\boldsymbol{\beta}|D)\pi(\boldsymbol{\beta}|\boldsymbol{\mu}_0, \Sigma_0), \tag{7}$$

where $\pi(\boldsymbol{\beta}|\boldsymbol{\mu}_0, \Sigma_0)$ is the multivariate normal density with mean $\boldsymbol{\mu}_0$ and covariance matrix Σ_0. The posterior in (7) does not have a closed form in general, and thus MCMC methods are needed to sample from the posterior distribution of $\boldsymbol{\beta}$. The statistical package BUGS can be readily used for this model to do the Gibbs sampling (*see* **Software, Biostatistical**).

The Weibull model is perhaps the most widely used parametric survival model. Suppose we have independent identically distributed survival times $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$, each having a Weibull distribution with shape parameter α and scale parameter γ. It is often more convenient to write the model in terms of the parameterization $\lambda = \log(\gamma)$, leading to

$$f(y|\alpha, \lambda) = \alpha y^{\alpha-1} \exp(\lambda - \exp(\lambda)y^{\alpha}). \tag{8}$$

Let $S(y|\alpha, \lambda) = \exp(-\exp(\lambda)y^{\alpha})$ denote the survival function. We can write the likelihood function of (α, λ) as

$$\begin{aligned} L(\alpha, \lambda|D) &= \prod_{i=1}^{n} f(y_i|\alpha, \lambda)^{v_i} S(y_i|\alpha, \lambda)^{1-v_i} \\ &= \alpha^d \exp\left\{d\lambda + \sum_{i=1}^{n}(v_i(\alpha-1)\log(y_i) - \exp(\lambda)y_i^{\alpha})\right\}. \end{aligned} \tag{9}$$

When α is assumed known, the conjugate prior for $\exp(\lambda)$ is the gamma prior. No joint conjugate prior is available when (α, λ) are both assumed unknown. In this case, a typical joint prior specification is to take α and λ to be independent, where α has a gamma distribution and λ has a normal distribution. Letting $\mathcal{G}(\alpha_0, \kappa_0)$ denote a gamma prior for α, and $N(\mu_0, \sigma_0^2)$ denote the normal prior for λ, the joint posterior distribution of (α, λ) is given by

$$\begin{aligned} \pi(\alpha, \lambda|D) &\propto L(\alpha, \lambda|D)\pi(\alpha|\alpha_0, \kappa_0)\pi(\lambda|\mu_0, \sigma_0^2) \\ &\propto \prod_{i=1}^{n} f(y_i|\alpha, \lambda)^{v_i} S(y_i|\alpha, \lambda)^{(1-v_i)} \\ &\quad \times \pi(\alpha|\alpha_0, \kappa_0)\pi(\lambda|\mu_0, \sigma_0^2) \\ &= \alpha^{\alpha_0+d-1} \exp\left\{d\lambda + \sum_{i=1}^{n}(v_i(\alpha-1)\log(y_i) \right. \\ &\quad \left. - \exp(\lambda)y_i^{\alpha}) - \kappa_0\alpha - \frac{1}{2\sigma_0^2}(\lambda-\mu_0)^2\right\}. \end{aligned} \tag{10}$$

The joint posterior distribution of (α, λ) does not have a closed form, but it can be shown that the conditional posterior distributions $[\alpha|\lambda, D]$ and $[\lambda|\alpha, D]$ are log-concave, and thus Gibbs sampling is straightforward for this model.

To build the Weibull regression model, we introduce covariates through λ, and write $\lambda_i = \boldsymbol{x}_i'\boldsymbol{\beta}$. Common prior distributions for $\boldsymbol{\beta}$ include the uniform improper prior, that is, $\pi(\boldsymbol{\beta}) \propto 1$, and a normal prior. Assuming a $N_p(\boldsymbol{\mu}_0, \Sigma_0)$ prior for $\boldsymbol{\beta}$ and a gamma prior for α, we are led to the joint posterior

$$\begin{aligned} \pi(\boldsymbol{\beta}, \alpha|D) &\propto \alpha^{\alpha_0+d-1} \exp \\ &\quad \times \left\{\sum_{i=1}^{n}\left(v_i\boldsymbol{x}_i'\boldsymbol{\beta} + v_i(\alpha-1)\log(y_i) - y_i^{\alpha}\exp(\boldsymbol{x}_i'\boldsymbol{\beta})\right)\right. \\ &\quad \left. - \kappa_0\alpha - \frac{1}{2}(\boldsymbol{\beta}-\boldsymbol{\mu}_0)\Sigma_0^{-1}(\boldsymbol{\beta}-\boldsymbol{\mu}_0)\right\}. \end{aligned} \tag{11}$$

Closed forms for the posterior distribution of $\boldsymbol{\beta}$ are generally not available, and therefore one needs to use numerical integration or MCMC methods. Owing to the availability of statistical packages such as BUGS, the Weibull regression model can easily be fitted using MCMC techniques. The development for the lognormal model, gamma models, **extreme value** model, an other parametric models is similar to that of the Weibull model. A multivariate extension of the Weibull model (*see* **Multivariate Weibull Distribution**) includes the Poly-Weibull model of Berger and Sun [8].

Semiparametric Models

Piecewise Constant Hazard Model

One of the most convenient and popular discrete time models for semiparametric survival analysis is the piecewise constant hazard model (*see* **Grouped Survival Times**). To construct this model, we first construct a finite partition of the time axis, $0 < s_1 < s_2 < \cdots < s_J$, with $s_J > y_i$ for all $i = 1, 2, \ldots, n$.

Thus, we have the J intervals $(0, s_1]$, $(s_1, s_2]$, ..., $(s_{J-1}, s_J]$. In the jth interval, we assume a constant baseline hazard $h_0(y) = \lambda_j$ for $y \in I_j = (s_{j-1}, s_j]$. Let $D = (n, \boldsymbol{y}, X, \nu)$ denote the observed data, where $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$, $\boldsymbol{\nu} = (\nu_1, \nu_2, \ldots, \nu_n)'$ with $\nu_i = 1$ if the ith subject failed and 0 otherwise, and X is the $n \times p$ matrix of covariates with ith row $\boldsymbol{x}_i'$. Letting $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \ldots, \lambda_J)'$, we can write the likelihood function of $(\boldsymbol{\beta}, \boldsymbol{\lambda})$ for the n subjects as

$$L(\boldsymbol{\beta}, \boldsymbol{\lambda}|D) = \prod_{i=1}^{n}\prod_{j=1}^{J}(\lambda_j \exp(\boldsymbol{x}_i'\boldsymbol{\beta}))^{\delta_{ij}\nu_i} \times \exp\left\{-\delta_{ij}\left[\lambda_j(y_i - s_{j-1}) + \sum_{g=1}^{j-1}\lambda_g(s_g - s_{g-1})\right]\exp(\boldsymbol{x}_i'\boldsymbol{\beta})\right\}, \quad (12)$$

where $\delta_{ij} = 1$ if the ith subject failed or was censored in the jth interval, and 0 otherwise, $\boldsymbol{x}_i' = (x_{i1}, x_{i2}, \ldots, x_{ip})$ denotes the $p \times 1$ vector of covariates for the ith subject, and $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_p)'$ is the corresponding vector of regression coefficients. The indicator δ_{ij} is needed to properly define the likelihood over the J intervals. The semiparametric model in (12), sometimes referred to as a piecewise exponential model is quite general and can accommodate various shapes of the baseline hazard over the intervals. Moreover, we note that if $J = 1$, the model reduces to a parametric exponential model with failure rate parameter $\lambda \equiv \lambda_1$. The piecewise exponential model is a useful and simple model for modeling survival data. It serves as the benchmark for comparisons with other semiparametric or fully parametric models for survival data.

A common prior of the baseline hazard $\boldsymbol{\lambda}$ is the independent gamma prior $\lambda_j \sim \mathcal{G}(\alpha_{0j}, \lambda_{0j})$ for $j = 1, 2, \ldots, J$. Here α_{0j} and λ_{0j} are prior parameters that can be elicited through the prior mean and variance of λ_j. Another approach is to build a prior correlation among the λ_j's [70, 81] using a correlated prior $\boldsymbol{\psi} \sim N(\boldsymbol{\psi}_0, \Sigma_\psi)$, where $\psi_j = \log(\lambda_j)$ for $j = 1, 2, \ldots, J$ (*see* **Multivariate Normal Distribution**).

The likelihood in (12) is based on continuous survival data. The likelihood function based on grouped or discretized survival data is given by

$$L(\boldsymbol{\beta}, \boldsymbol{\lambda}|D) \propto \prod_{j=1}^{J} G_j^*,$$

where

$$G_j^* = \exp\left\{-\lambda_j \Delta_j \sum_{k \in \mathcal{R}_j - \mathcal{D}_j} \exp(\boldsymbol{x}_k'\boldsymbol{\beta})\right\} \times \prod_{l \in \mathcal{D}_j}[1 - \exp\{-\lambda_j \Delta_j \exp(\boldsymbol{x}_l'\boldsymbol{\beta})\}], \quad (13)$$

$\Delta_j = s_j - s_{j-1}$, $\mathcal{R}_j$ is the set of patients at risk, and $\mathcal{D}_j$ is the set of patients having failures in the jth interval.

Models Using a Gamma Process

The gamma process is perhaps the most commonly used nonparametric prior process for the Cox model. The seminal paper by Kalbfleisch [60] describes the gamma process prior for the baseline cumulative hazard function (see also [13]). The gamma process can be described as follows: Let $\mathcal{G}(\alpha, \lambda)$ denote the gamma distribution with shape parameter $\alpha > 0$ and scale parameter $\lambda > 0$. Let $\alpha(t), t \geq 0$, be an increasing left continuous function such that $\alpha(0) = 0$, and let $Z(t), t \geq 0$, be a **stochastic process** with the properties:

(i) $Z(0) = 0$;
(ii) $Z(t)$ has independent increments in disjoint intervals; and
(iii) for $t > s$, $Z(t) - Z(s) \sim \mathcal{G}(c(\alpha(t) - \alpha(s)), c)$.

Then the process $\{Z(t) : t \geq 0\}$ is called a *gamma process* and is denoted by $Z(t) \sim \mathcal{GP}(c\alpha(t), c)$. We note here that $\alpha(t)$ is the mean of the process and c is a weight or confidence parameter about the mean. The sample paths of the gamma process are almost surely increasing functions. It is a special case of a Levy process whose characteristic function is given by

$$\mathrm{E}[\exp\{iy(Z(t) - Z(s)\}] = (\phi(y))^{c(\alpha(t)-\alpha(s))}, \quad (14)$$

where ϕ is the **characteristic function** of an infinitely divisible distribution function with unit mean. The gamma process is the special case $\phi(y) = \{c/(c - iy)\}^c$.

Gamma Process on Cumulative Hazard

Under the Cox model, the joint probability of survival of n subjects given the covariate matrix X is

given by

$$P(\mathbf{Y} > \boldsymbol{y}|\boldsymbol{\beta}, X, H_0) = \exp\left\{-\sum_{j=1}^{n} \exp(\boldsymbol{x}_j'\boldsymbol{\beta}) H_0(y_j)\right\}. \quad (15)$$

The gamma process is often used as a prior for the cumulative baseline hazard function $H_0(y)$. In this case, we take

$$H_0 \sim \mathcal{GP}(c_0 H^*, c_0), \quad (16)$$

where $H^*(y)$ is an increasing function with $H^*(0) = 0$. H^* is often assumed to be a known parametric function with hyperparameter vector $\boldsymbol{\gamma}_0$. For example, if H^* corresponds to the exponential distribution, then $H^*(y) = \gamma_0 y$, where γ_0 is a specified hyperparameter. If $H^*(y)$ is taken as Weibull, then $H^*(y) = \eta_0 y^{\kappa_0}$, where $\boldsymbol{\gamma}_0 = (\eta_0, \kappa_0)'$ is a specified vector of hyperparameters. The marginal survival function is given by

$$P(\mathbf{Y} > \boldsymbol{y}|\boldsymbol{\beta}, X, \boldsymbol{\gamma}_0, c_0) = \prod_{j=1}^{n} [\phi(i V_j)]^{c_0(H^*(y_{(j)}) - H^*(y_{(j-1)}))}, \quad (17)$$

where $V_j = \sum_{l \in \mathcal{R}_j} \exp(x_l'\boldsymbol{\beta})$, $\mathcal{R}_j$ is the risk set at time $y_{(j)}$ and $y_{(1)} < y_{(2)} < \cdots, < y_{(n)}$ are distinct ordered times. For continuous data, when the ordered survival times are all distinct, the likelihood of $(\boldsymbol{\beta}, \gamma_0, c_0)$ can be obtained by differentiating (17). Note that this likelihood, used by Kalbfleisch [60], Clayton [24], and among others, is defined only when the observed survival times are distinct. In the next subsection, we present the likelihood and prior associated with grouped survival data using a gamma process prior for the baseline hazard.

Gamma Process with Grouped-data Likelihood

Again, we construct a finite partition of the time axis, $0 < s_1 < s_2 < \cdots < s_J$, with $s_J > y_i$ for all $i = 1, \ldots, n$. Thus, we have the J disjoint intervals $(0, s_1]$, $(s_1, s_2]$, …, $(s_{J-1}, s_J]$, and let $I_j = (s_{j-1}, s_j]$. The observed data D is assumed to be available as grouped within these intervals, such that $D = (X, \mathcal{R}_j, \mathcal{D}_j : j = 1, 2, \ldots, J)$, where $\mathcal{R}_j$ is the risk set and $\mathcal{D}_j$ is the failure set of the jth interval I_j. Let h_j denote the increment in the cumulative baseline hazard in the jth interval, that is,

$$h_j = H_0(s_j) - H_0(s_{j-1}), \quad j = 1, 2, \ldots, J. \quad (18)$$

The gamma process prior in (16) implies that the h_j's are independent and

$$h_j \sim \mathcal{G}(\alpha_{0j} - \alpha_{0,j-1}, c_0), \quad (19)$$

where $\alpha_{0j} = c_0 H^*(s_j)$, and H^* and c_0 are defined in the previous subsection. Thus, the hyperparameters (H^*, c_0) for h_j consist of a specified parametric cumulative hazard function $H^*(y)$ evaluated at the endpoints of the time intervals, and a positive scalar c_0 quantifying the degree of prior confidence in $H^*(y)$. Now writing $H_0 \sim \mathcal{GP}(c_0 H^*, c_0)$ implies that every disjoint increment in H_0 has the prior given by (19). Thus, the grouped-data representation can be obtained as

$$P(y_i \in I_j|\boldsymbol{h}) = \exp\left\{-\exp(\boldsymbol{x}_i'\boldsymbol{\beta}) \sum_{k=1}^{j-1} h_k\right\} \times [1 - \exp\{-h_j \exp(\boldsymbol{x}_i'\boldsymbol{\beta})\}], \quad (20)$$

where $\boldsymbol{h} = (h_1, h_2, \ldots, h_J)'$. This leads to the grouped-data likelihood function

$$L(\boldsymbol{\beta}, \boldsymbol{h}|D) \propto \prod_{j=1}^{J} G_j, \quad (21)$$

where

$$G_j = \exp\left\{-h_j \sum_{k \in \mathcal{R}_j - \mathcal{D}_j} \exp(\boldsymbol{x}_k'\boldsymbol{\beta})\right\} \times \prod_{l \in \mathcal{D}_j} [1 - \exp\{-h_j \exp(\boldsymbol{x}_l'\boldsymbol{\beta})\}]. \quad (22)$$

Note that the grouped-data likelihood expression in (22) is very general and not limited to the case when the h_j's are realizations of a gamma process on H_0. Since the cumulative baseline hazard function H_0 enters the likelihood in (22) only through the h_j's, our parameters in the likelihood are $(\boldsymbol{\beta}, \boldsymbol{h})$ and thus we only need a joint prior distribution for $(\boldsymbol{\beta}, \boldsymbol{h})$. One important case is that when one considers the piecewise constant baseline hazard of the previous section with $h_j = \Delta_j \lambda_j$ and $\Delta_j = s_j - s_{j-1}$. In this case, we observe a great similarity

between the likelihoods (17) and (22). In the absence of covariates, (22) reduces to

$$G_j = \exp\{-h_j(r_j - d_j)\}\{1 - \exp(-h_j)\}^{d_j}, \quad (23)$$

where r_j and d_j are the numbers of subjects in the sets $\mathcal{R}_j$ and $\mathcal{D}_j$, respectively.

A typical prior for $\boldsymbol{\beta}$ is a $N_p(\boldsymbol{\mu}_0, \Sigma_0)$ distribution. Thus, the joint posterior of $(\boldsymbol{\beta}, \boldsymbol{h})$ can be written as

$$\pi(\boldsymbol{\beta}, \boldsymbol{h}|D) \propto \prod_{j=1}^{J}\left[G_j h_j^{(\alpha_{0j}-\alpha_{0,j-1})-1}\exp(-c_0 h_j)\right] \times \exp\left\{-\frac{1}{2}(\boldsymbol{\beta}-\boldsymbol{\mu}_0)\Sigma_0^{-1}(\boldsymbol{\beta}-\boldsymbol{\mu}_0)\right\}.$$

Relationship to Partial Likelihood

Kalbfleisch [60] and more recently, Sinha, Ibrahim, and Chen [86] show that the **partial likelihood** defined by Cox [28] can be obtained as a limiting case of the marginal posterior of $\boldsymbol{\beta}$ in the Cox model under a gamma process prior for the cumulative baseline hazard. Towards this goal, discretize the time axis as $(0, s_1]$, $(s_1, s_2]$, ..., $(s_{J-1}, s_J]$, and suppose $H_0 \sim \mathcal{GP}(c_0 H^*, c_0)$. Let $y_{(1)} < y_{(2)} < \cdots < y_{(n)}$ denote the ordered failure or censoring times. Therefore, if $h_j = H_0(y_{(j)}) - H_0(y_{(j-1)})$, then

$$h_j \sim \mathcal{G}(c_0 h_{0j}, c_0), \quad (24)$$

where $h_{0j} = H^*(y_{(j)}) - H^*(y_{(j-1)})$. Let $A_j = \sum_{l\in\mathcal{R}_j}\exp(\boldsymbol{x}_l'\boldsymbol{\beta})$ and $\mathrm{E_{GP}}$ denote expectation with respect to the gamma process prior. Then, we have

$$P(\mathbf{Y} > \boldsymbol{y}|X, \boldsymbol{\beta}, H_0) = \exp\left\{-\sum_{j=1}^{n}\exp(\boldsymbol{x}_j'\boldsymbol{\beta})H_0(y_{(j)})\right\} = \exp\left\{-\sum_{j=1}^{n}h_j\sum_{l\in\mathcal{R}_j}\exp(\boldsymbol{x}_l'\boldsymbol{\beta})\right\} \quad (25)$$

and

$$\mathrm{E_{GP}}\left[P(\mathbf{Y} > \boldsymbol{y}|X, \boldsymbol{\beta}, H_0)|H^*\right] = \prod_{j=1}^{n}\left(\frac{c_0}{c_0 + A_j}\right)^{c_0 h_{0j}} = \prod_{j=1}^{n}\exp\left\{c_0 H^*(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)\right\}. \quad (26)$$

Now let $\boldsymbol{\theta} = (\boldsymbol{\beta}', h_0, c_0)'$, where $h_0(y) = (\mathrm{d}/\mathrm{d}y)H^*(y)$. We can write the likelihood function as

$$\begin{aligned} L(\boldsymbol{\theta}|D) &= \prod_{j=1}^{n}\exp\left\{c_0 H^*(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)\right\} \\ &\quad \times\left\{-c_0\frac{\mathrm{d}H^*(y_{(j)})}{\mathrm{d}y_{(j)}}\left(\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)\right)\right\}^{\nu_i} \\ &= \prod_{j=1}^{n}\exp\left\{H^*(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)^{c_0}\right\} \\ &\quad \times\left\{-c_0 h_0(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)\right\}^{\nu_i}. \end{aligned} \quad (27)$$

Let $d = \sum_{i=1}^{n}\nu_i$ and $h^* = \prod_{j=1}^{n}[h_0(y_{(j)})]^{\nu_i}$. Now we have

$$\lim_{c_0\to 0}\exp\left\{H_0^*(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)^{c_0}\right\} = 1$$

for $j = 1, 2, \ldots, n$, and

$$\lim_{c_0\to 0}\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right) = \log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{A_j}\right) \approx -\frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{A_j}$$

for $j = 1, 2, \ldots, n-1$. Thus, we have

$$\lim_{c_0\to 0}\frac{L(\boldsymbol{\theta}|D)}{c_0^d\{-\log(c_0)\}^{\nu_n}h^*} \approx \prod_{j=1}^{n}\left[\frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{A_j}\right]^{\nu_i}. \quad (28)$$

We see that the right-hand side of (28) is precisely Cox's partial likelihood.

Now if we let $c_0 \to \infty$, we get the likelihood function based on $(\boldsymbol{\beta}, h_0)$. To see this, note that

$$\begin{aligned} &\lim_{c_0\to\infty}\left[\exp\left\{H^*(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)^{c_0}\right\}\right. \\ &\quad \left.\times\left\{-c_0 h_0(y_{(j)})\log\left(1 - \frac{\exp(\boldsymbol{x}_j'\boldsymbol{\beta})}{c_0 + A_j}\right)\right\}^{\nu_j}\right] \\ &= \exp\left\{-H^*(y_{(j)})\exp(\boldsymbol{x}_j'\boldsymbol{\beta})\right\}\left\{h_0(y_{(j)})\exp(\boldsymbol{x}_j'\boldsymbol{\beta})\right\}^{\nu_j}, \end{aligned} \quad (29)$$

and therefore,

$$\lim_{c_0\to\infty} L(\boldsymbol{\beta}, c_0, h_0|D) = \prod_{j=1}^{n} \left(\exp\left\{-H^*(y_{(j)})\exp(\boldsymbol{x}'_j\boldsymbol{\beta})\right\}\right) \times \left\{h_0(y_{(j)})\exp(\boldsymbol{x}'_j\boldsymbol{\beta})\right\}^{v_j}. \quad (30)$$

Thus, we see that (30) is the likelihood function of $(\boldsymbol{\beta}, h_0)$ based on the proportional hazards model.

Gamma Process on Baseline Hazard

An alternative specification of the semiparametric Cox model is to specify a gamma process prior on the hazard rate itself. Such a formulation is considered by Dykstra and Laud [38] in their development of the extended gamma process. Here, we consider a discrete approximation of the extended gamma process. Specifically, we construct the likelihood by using a piecewise constant baseline hazard model and use only information about which interval the failure times fall into. Let $0 = s_0 < s_1 < \cdots < s_J$ be a finite partition of the time axis and let

$$\delta_j = h_0(s_j) - h_0(s_{j-1}) \quad (31)$$

denote the increment in the baseline hazard in the interval $(s_{j-1}, s_j]$, $j = 1, 2, \ldots, J$, and $\boldsymbol{\delta} = (\delta_1, \delta_2, \ldots, \delta_J)'$. We follow Ibrahim, Chen, and MacEachern [56] for constructing the approximate likelihood function of $(\boldsymbol{\beta}, \boldsymbol{\delta})$. For an arbitrary individual in the population, the survival function for the Cox model at time y is given by

$$S(y|\boldsymbol{x}) = \exp\left\{-\eta\int_0^y h_0(u)\,\mathrm{d}u\right\} \approx \exp\left\{-\eta\left(\sum_{i=1}^{J}\delta_i(y - s_{i-1})^+\right)\right\}, \quad (32)$$

where $h_0(0) = 0$, $(u)^+ = u$ if $u > 0$, 0 otherwise, and $\eta = \exp(\boldsymbol{x}'\boldsymbol{\beta})$. This first approximation arises since the specification of $\boldsymbol{\delta}$ does not specify the entire hazard rate, but only the δ_j. For purposes of approximation, we take the increment in the hazard rate, δ_j, to occur immediately after s_{j-1}. Let p_j denote the probability of a failure in the interval $(s_{j-1}, s_j]$, $j = 1, 2, \ldots, J$. Using (32), we have

$$p_j = S(s_{j-1}) - S(s_j) \approx \exp\left\{-\eta\sum_{l=1}^{j-1}\delta_l(s_{j-1} - s_{l-1})\right\} \times \left[1 - \exp\left\{-\eta(s_j - s_{j-1})\sum_{l=1}^{j}\delta_l\right\}\right]. \quad (33)$$

Thus, in the jth interval $(s_{j-1}, s_j]$, the contribution to the likelihood function for a failure is p_j, and $S(s_j)$ for a right-censored observation. For $j = 1, 2, \ldots, J$, let d_j be the number of failures, $\mathcal{D}_j$ be the set of subjects failing, c_j be the number of right-censored observations and $\mathcal{C}_j$ is the set of subjects that are censored. Also, let $D = (n, \boldsymbol{y}, X, \boldsymbol{v})$ denote the data. The grouped-data likelihood function is thus given by

$$L(\boldsymbol{\beta}, \boldsymbol{\delta}|D) = \prod_{j=1}^{J}\left\{\exp\{-\delta_j(a_j + b_j)\} \times \prod_{k\in\mathcal{D}_j}[1 - \exp\{-\eta_k T_j\}]\right\}, \quad (34)$$

where $\eta_k = \exp(\boldsymbol{x}'_k\boldsymbol{\beta})$,

$$a_j = \sum_{l=j+1}^{J}\sum_{k\in\mathcal{D}_l}\eta_k(s_{l-1} - s_{j-1}),$$

$$b_j = \sum_{l=j}^{J}\sum_{k\in\mathcal{C}_l}\eta_k(s_l - s_{j-1}), \quad (35)$$

and

$$T_j = (s_j - s_{j-1})\sum_{l=1}^{j}\delta_l. \quad (36)$$

We note that this likelihood involves a second approximation. Instead of conditioning on exact event times, we condition on the set of failures and set of right-censored events in each interval, and thus we approximate continuous right-censored data by grouped data. Prior elicitation and Gibbs sampling for this model has been discussed in [57] in detail.

Beta Process Models

We first discuss time-continuous, right-censored survival data without covariates. Kalbfleisch [60] and Ferguson and Phadia [45] used the definition of the cumulative hazard $H(t)$ as

$$H(t) = -\log(S(t)), \tag{37}$$

where $S(t)$ is the survival function. The gamma process can be defined on $H(t)$ when this definition of the cumulative hazard is appropriate. A more general way of defining the hazard function, which is valid even when the survival time distribution is not continuous, is to use the definition of Hjort [55]. General formulae for the cumulative hazard function $H(t)$ are

$$H(t) = \int_{[0,t]} \frac{\mathrm{d}F(u)}{S(u)}, \tag{38}$$

where

$$F(t) = 1 - S(t) = 1 - \prod_{[0,t]} \{1 - \mathrm{d}H(t)\}. \tag{39}$$

The cumulative hazard function $H(t)$ defined here is equal to (37) when the survival distribution is absolutely continuous. Hjort [55] presents what he calls a beta process with independent increments as a prior for $H(.)$. A beta process generates a proper cdf $F(t)$, as defined in (38), and has independent increments of the form

$$\mathrm{d}H(s) \sim \mathcal{B}(c(s)\,\mathrm{d}H^*(s), c(s)(1 - \mathrm{d}H^*(s))), \tag{40}$$

where $\mathcal{B}(a, b)$ denotes the **beta distribution** with parameters (a, b). Owing to the complicated convolution property of independent beta distributions, the exact distribution of the increment $H(s)$ is only approximately beta over any finite interval, regardless of how small the length of the interval might be. See [55] for formal definitions of the beta process prior and for properties of the posterior with right-censored, time-continuous data. It is possible to deal with the beta process for the baseline cumulative hazard appropriately defined under a Cox model with time-continuous data, but survival data in practice is commonly grouped within some grid intervals, where the grid size is determined by the data and trial design. So for practical purposes, it is more convenient and often sufficient to use a discretized version of the beta process [55, 82] along with grouped survival data. The beta process prior for the cumulative baseline hazard in (40) has been discussed by many authors, including Hjort [55], Damien, Laud, and Smith [29], Laud, Smith, and Damien [68], Sinha [82], and Florens, Mouchart, and Rolin [46]. Here we will focus only on the discretized beta process prior with a grouped-data likelihood.

Within the spirit of the definition of the cumulative hazard function $H(t)$ defined in (38), a discretized version of the Cox model can be defined as

$$S(s_j|\boldsymbol{x}) = P(T > s_j|\boldsymbol{x}) = \prod_{k=1}^{j} (1 - h_k)^{\exp(\boldsymbol{x}'\boldsymbol{\beta})}, \tag{41}$$

where h_k is the discretized baseline hazard rate in the interval $I_k = (s_{k-1}, s_k]$. The likelihood can thus be written as

$$L(\boldsymbol{\beta}, \boldsymbol{h}) = \prod_{j=1}^{J} \left((1 - h_j)^{\sum_{i \in \mathcal{R}_j - \mathcal{D}_j} \exp(\boldsymbol{x}_i'\boldsymbol{\beta})} \right) \times \prod_{l \in D_j} (1 - (1 - h_j)^{\exp(x_l'\boldsymbol{\beta})}), \tag{42}$$

where $\boldsymbol{h} = (h_1, h_2, \ldots, h_J)'$. To complete the discretized beta process model, we specify independent beta priors for the h_k's. Specifically, we take $h_k \sim \mathcal{B}(c_{0k}\alpha_{0k}, c_{0k}(1 - \alpha_{0k}))$, and independent for $k = 1, 2, \ldots, J$. Though it is reasonable to assume that the h_k's are independent from each other *a* priori, the assumption of an exact beta distribution of the h_k's is only due to an approximation to the true time-continuous beta process. Thus, according to the time-continuous beta process, the distribution of the h_k's is not exactly beta, but it can be well approximated by a beta distribution only when the width of I_k is small.

Under the discretized beta process defined here, the joint prior density of $\boldsymbol{h}$ is thus given by

$$\pi(\boldsymbol{h}) \propto \prod_{j=1}^{J} h_j^{c_{0j}\alpha_{0j}-1} (1 - h_j)^{c_{0j}(1-\alpha_{0j})-1}.$$

A typical prior for $\boldsymbol{\beta}$ is a $N_p(\boldsymbol{\mu}_0, \Sigma_0)$ prior, which is independent of $\boldsymbol{h}$. Assuming an arbitrary

prior for $\boldsymbol{\beta}$, the joint posterior of $(\boldsymbol{\beta}, h)$ can be written as

$$\begin{aligned}\pi(\boldsymbol{\beta}, \boldsymbol{h}|D) &\propto L(\boldsymbol{\beta}, \boldsymbol{h}|D)\pi(\boldsymbol{h})\pi(\boldsymbol{\beta}) \\ &= \prod_{j=1}^{J}\left((1-h_j)^{\sum_{i\in\mathcal{R}_j-\mathcal{D}_j}\exp(\boldsymbol{x}_i'\boldsymbol{\beta})}\right) \\ &\quad\times\prod_{l\in\mathcal{D}_j}\left(1-(1-h_j)^{\exp(\boldsymbol{x}_l'\boldsymbol{\beta})}\right) \\ &\quad\times\prod_{j=1}^{J}h_j^{c_{0j}\alpha_{0j}-1}(1-h_j)^{c_{0j}(1-\alpha_{0j})-1}\pi(\boldsymbol{\beta}). \quad (43)\end{aligned}$$

Given the prior structure of (43), with no covariates, the posterior distribution of the h_j's given grouped survival data is also independent beta with

$$h_j|D \sim \mathcal{B}(c_{0j}\alpha_{0j} + \mathrm{d}_j, c_{0j}(1-\alpha_{0j}) + r_j - \mathrm{d}_j), \quad (44)$$

where $D = \{(\mathrm{d}_j, r_j), j = 1, 2, \ldots, J\}$ denotes the complete grouped data. The joint posterior of the h_j's given interval-censored data is not as straightforward as (44), and is discussed in [57].

Correlated Prior Processes

The gamma process prior of Kalbfleisch [60] assumes independent cumulative hazard increments. This is unrealistic in most applied settings, and does not allow for borrowing of strength between adjacent intervals. A correlated gamma process for the cumulative hazard yields a natural smoothing of the survival curve. Although the idea of smoothing is not new [5, 7, 9, 48, 80], its potential has not been totally explored in the presence of covariates. Modeling dependence between hazard increments has been discussed by Gamerman [48] and Arjas and Gasbarra [5]. Gamerman [48] proposes a **Markov** prior process for the $\{\log(\lambda_k)\}$, by modeling

$$\log(\lambda_k) = \log(\lambda_{k-1}) + \varepsilon_k, \qquad \mathrm{E}(\varepsilon_k) = 0, \quad \text{and} \quad \mathrm{Var}(\varepsilon_k) = \sigma_k^2. \quad (45)$$

Arjas and Gasbarra [5] introduced a first-order autoregressive structure on the increment of the hazards by taking

$$\lambda_k|\lambda_{k-1} \sim \mathcal{G}\left(\alpha_k, \frac{\alpha}{\lambda_{k-1}}\right) \quad (46)$$

for $k > 1$ (*see* **ARMA and ARIMA Models**). Nieto-Barajas and Walker [74] propose dependent hazard rates with a Markovian relation, given by

$$\lambda_1 \sim \mathcal{G}(\alpha_1, \gamma_1), \; u_k|\lambda_k, v_k \sim \mathcal{P}(v_k\lambda_k), \quad v_k|\xi_k \sim \mathcal{E}\left(\frac{1}{\xi_k}\right), \quad (47)$$

$$\lambda_{k+1}|u_k, v_k \sim \mathcal{G}(\alpha_{k+1} + u_k, \gamma_{k+1} + v_k), \quad (48)$$

and

$$\boldsymbol{\beta} \sim \pi(\boldsymbol{\beta}),$$

for $k \geq 1$, where $\pi(\boldsymbol{\beta})$ denotes the prior for $\boldsymbol{\beta}$, which can be taken to be a normal distribution, for example, and $\mathcal{P}(v_k\lambda_k)$ denotes the Poisson distribution with mean $v_k\lambda_k$.

Dirichlet Process Models

The Dirichlet process is perhaps the most celebrated and popular prior process in nonparametric Bayesian inference. The introduction of the Dirichlet process by Ferguson [43, 44] initiated modern day Bayesian **nonparametric methods**, and today this prior process is perhaps the most important and widely used nonparametric prior. Notable articles using the Dirichlet process in various applications include [14, 31, 33, 39, 40, 49, 50, 63, 64, 66, 71, 73, 76, 89, 90].

The Dirichlet process provides the Bayesian data analyst with a nonparametric prior specification over the class of possible distribution functions $F(y)$ for a random variable Y, where $F(y) = P(Y \leq y)$. In Bayesian nonparametric inference with the Dirichlet process prior, the typical approach is to specify a prior distribution over the space all possible cumulative distribution functions, $F(t) = 1 - S(t)$. To define the Dirichlet process formally, let the sample space be denoted by Ω, and suppose $\Omega = B_1 \cup B_2 \cup \cdots \cup B_k$, where the B_j's are disjoint. The B_j's, for example, can be disjoint intervals. Then a stochastic process P indexed by elements of a particular partition $B = \{B_1, B_2, \ldots, B_k\}$ is said to be a Dirichlet process on (Ω, B) with parameter vector α, if for any partition of Ω, the random vector $(P(B_1), P(B_2), \ldots, P(B_k))$ has a Dirichlet distribution with parameter $(\alpha(B_1), \alpha(B_2), \ldots, \alpha(B_k))$.

The parameter vector α is a probability measure, that is, a distribution function itself so that we can

write $\alpha = F_0(\cdot)$, where $F_0(\cdot)$ is the prior hyperparameter for $F(\cdot)$, and thus $\alpha(B_j) = F_0(b_{2j}) - F_0(b_{1j})$. The hyperparameter $F_0(.)$ is often called the *base measure* of the Dirichlet process prior.

Finally, we can define a weight parameter c_0 $(c_0 > 0)$ that gives prior weight to $F_0(\cdot)$, so that $(F(B_1), F(B_2), \ldots, F(B_k))$ has a Dirichlet distribution with parameters $(c_0F_0(B_1), c_0F_0(B_2), \ldots, c_0F_0(B_k))$. Finally, we say that F has a Dirichlet process prior with parameter c_0F_0 if $(F(B_1), F(B_2), \ldots, F(B_k))$ has a Dirichlet distribution with parameters $(c_0F_0(B_1), c_0F_0(B_2), \ldots, c_0F_0(B_k))$ for every possible partition of the sample space $\Omega = B_1 \cup B_2 \cup \cdots \cup B_k$. Some of the earliest work on Dirichlet processes in the context of survival analysis is based on the work of Ferguson and Phadia [45] and Susarla and Van Ryzin [89]. Susarla and Van Ryzin derive the Bayes estimator of the survival function under the Dirichlet process prior and also derive the posterior distribution of the cumulative distribution function with right-censored data. In this section, we summarize the fundamental results of Ferguson and Phadia [45] and Susarla and Van Ryzin [89]. Letting $S(t)$ denote the survival function, Susarla and Van Ryzin [89] derive the Bayes estimator of $S(t)$ under the squared error **loss**

$$L(\hat{S}, S) = \int_0^\infty (\hat{S}(t) - S(t))^2 \, \mathrm{d}w(t), \tag{49}$$

where w is a weight function, that is, a nonnegative decreasing function on $(0, \infty)$ and $\hat{S}(t)$ is an estimator of $S(t)$. Susarla and Van Ryzin [89] show that the Bayes estimator $\hat{S}(u)$ under squared error loss is given by

$$\hat{S}(u) = \frac{c_0(1 - F_0(u)) + N^+(u)}{c_0 + n} \times \prod_{j=k+1}^{l} \left(\frac{(c_0(1 - F_0(y_{(j)}) + N(y_{(j)})}{c_0(1 - F_0(y_{(j)}) + N(y_{(j)}) - \lambda_j} \right) \tag{50}$$

in the interval $y_{(j)} \le u \le y_{(l+1)}$, $l = k, k+1, \ldots, m$, with $y_{(k)} = 0$, $y_{(m+1)} = \infty$. The **Kaplan–Meier estimator** of $S(u)$ [61] is a limiting case of (50) and is obtained when $F_0 \to 1$, as shown by Susarla and Van Ryzin [89]. Other work on the Dirichlet process in survival data includes Kuo and Smith [66], where they used the Dirichlet process for doubly censored survival data. Generalizations of the Dirichlet process have also been used in survival analysis. Mixture of Dirichlet Process (MDP) models have been considered by [14, 39, 63, 64, 71]. The MDP model [39, 71] removes the assumption of a parametric prior at the second stage, and replaces it with a general distribution G. The distribution G then in turn has a Dirichlet process prior [43], leading to

$$\begin{aligned} &\text{Stage 1:} \quad [\boldsymbol{y}_i|\theta_i] \sim \Pi_{n_i}(h_1(\boldsymbol{\theta}_i)), \\ &\text{Stage 2:} \quad \boldsymbol{\theta}_i|G \overset{i.i.d.}{\sim} G, \\ &\text{Stage 3:} \quad [G|c_0, \boldsymbol{\psi}_0] \sim \mathcal{DP}(c_0 \cdot G_0(h_2(\boldsymbol{\psi}_0))), \end{aligned} \tag{51}$$

where G_0 is a w-dimensional parametric distribution, often called the *base measure*, and c_0 is a positive scalar. The parameters of a Dirichlet process are $G_0(\cdot)$, a probability measure, and c_0, a positive scalar. The parameter $c_0G_0(\cdot)$ contains a distribution, $G_0(\cdot)$, which approximates the true nonparametric shape of G, and the scalar c_0, which reflects our prior belief about how similar the nonparametric distribution G is to the base measure $G_0(\cdot)$.

There are two special cases in which the MDP model leads to the fully parametric case. As $c_0 \to \infty$, $G \to G_0(\cdot)$, so that the base measure is the prior distribution for $\boldsymbol{\theta}_i$. Also, if $\boldsymbol{\theta}_i \equiv \boldsymbol{\theta}$ for all i, the same is true. For a more hierarchical modeling approach, it is possible to place prior distributions on $(c_0, \boldsymbol{\psi}_0)$. The specification in (52) results in a semiparametric specification in that a fully parametric distribution is given in Stage 1 and a nonparametric distribution is given in Stages 2 and 3. References [31–33], discuss the implementation of MDP priors for $F(t) = 1 - S(t)$ in the presence of right-censored data using the Gibbs sampler. A Bayesian nonparametric approach based on mixtures of Dirichlet priors [4, 43, 44] offers a reasonable compromise between purely parametric and purely nonparametric models. The MDP prior for F can be defined as follows. If ν is some prior distribution for $\boldsymbol{\theta}$, where $\boldsymbol{\theta} \in \Theta$, and $c_0 > 0$ for each $\boldsymbol{\theta}$, then if $F|\boldsymbol{\theta} \sim \mathcal{DP}(c_0F_{0\boldsymbol{\theta}})$, then F, unconditional on $\boldsymbol{\theta}$ is a mixture of Dirichlet's. The weight parameter may depend on $\boldsymbol{\theta}$, but in most applications it does not. For the case where the data are not censored, there is a closed-form expression for the posterior distribution of F. From this result, it can be easily seen that in the uncensored case, estimators based on mixtures of Dirichlet priors continuously interpolate between those based on the purely parametric and nonparametric models. For large values of c_0,

the estimators are close to the Bayes estimator based on the parametric model. On the other hand, for small values of c_0, the estimators are essentially equal to the **nonparametric maximum likelihood** estimator. One therefore expects that the same will be true for the case where the data are censored.

For the censored case, there is no closed-form expression for the posterior distribution of F given the data, and one has to use **Monte Carlo methods**. A Gibbs sampling scheme described by Doss and Huffer [32] and Doss and Narasimhan [33] will enable us to estimate the posterior distributions of interest. Other generalizations of the Cox model have been examined by Sinha, Chen, and Ghosh [83], and problems investigating interval-censored data have been investigated by Sinha [82]. A nice review paper on Bayesian survival analysis is given in [84]. Further details on Bayesian semiparametric methods can be found in [57].

Other Topics

Fully parametric Bayesian approaches to frailty models are examined in [82], where they consider a frailty model with a Weibull baseline hazard. Semiparametric approaches have also been examined. Clayton [24] and Sinha [81, 82] consider a gamma process prior on the cumulative baseline hazard in the proportional hazards frailty model. Gray [51], Sahu, Dey, Aslanidou, and Sinha [82], Sinha and Dey [84], Aslanidou, Dey, and Sinha [80], and Sinha [80] discuss frailty models with piecewise exponential baseline hazards. Qiou, Ravishanker, and Dey [75] examine a positive stable frailty distribution, and Gustafson [53] and Sargent [78] examine frailty models using Cox's partial likelihood [28]. Posterior likelihood methods for frailty models include those of Sinha [80]. Gustafson [53] discusses Bayesian hierarchical frailty models for multivariate survival data, in which the hierarchical model has elements common with the work of Clayton [24], Gray [51], Sinha [81], Stangl [87], and Stangl and Greenhouse [88]. For detailed summaries of these models, see [57].

Bayesian approaches to joint models for longitudinal and survival data have been considered by Faucett and Thomas [41], Wang and Taylor [93], Brown and Ibrahim [10, 11], Law, Taylor, and Sandler [69], Brown, Ibrahim, and DeGruttola [12], and Ibrahim, Chen, and Sinha [58], Other topics in Bayesian methods in survival analysis include proportional hazards models built from monotone functions, [50] and accelerated failure time models [23, 59, 65, 91, 92]. Survival models using Multivariate adaptive regression **splines** (MARS) have been considered by Mallick, Denison, and Smith [72]. Changepoint models have been considered by Sinha, Ibrahim, and Chen [85], and flexible classes of hierarchical survival models have been considered by Gustafson [54] and Carlin and Hodges [16]. Bayesian methods for model diagnostics in survival analysis have been considered in [50, 77, 79], Bayesian latent residual methods given in [7], and the prequential methods of Arjas and Gasbarra in [6]. Bayesian spatial survival models have been considered by Carlin and Banerjee [15]. Bayesian methods for **missing** covariate data in survival analysis include [21, 22]. Other work on Bayesian survival analysis with specific applications in epidemiology and related areas include [18, 35], applications in fertility include [34, 36], and the references therein. Bayesian survival methods in carcinogenicity studies include [37, 47]. Books discussing Bayesian survival analysis include [17, 20, 25, 26, 57].

DEBAJYOTI SINHA

Behrens–Fisher Problem

Consider the problem of testing for a difference between the means of two normal distributions (*see* **Hypothesis Testing**). Let $y_{j1}, \ldots, y_{jn_j}$ denote a random sample of size n_j from a normal distribution with mean μ_j and variance $\sum_j^2$, $j = 1, 2$. Furthermore, let the mean and variance of sample j be $\overline{y}_j = \sum_{i=1}^{n_j} y_{ji}/n_j$ and $s_j^2 = \sum_{i=1}^{n_j}(y_{ji} - \overline{y}_j)^2/(n_j - 1)$, respectively, $j = 1, 2$. Attention is focused on the parameter of interest, $\delta = \mu_2 - \mu_1$. If the two population variances are assumed to be equal, then the usual two-sample t test may be adopted to test $H_0: \delta = 0$ vs. $H_a: \delta \neq 0$, using the standard pooled variance estimate.

When no assumptions about the variances of the two populations are made, this is known as the Behrens–Fisher problem. The standard advice given in introductory textbooks is first to carry out a test of the hypothesis $\sigma_1^2 = \sigma_2^2$ based on the quantity $F = s_2^2/(s_1^2)$. Under the hypothesis of common variances, this statistic has an ***F* distribution** with $(n_2 - 1, n_1 - 1)$ degrees of freedom. If the hypothesis is not rejected, then it is often recommended to test the equality of the means using the usual two-sample t test (*see* **Student's *t* Distribution**). Since a failure to reject the hypothesis of equal variances does not imply that the variances are indeed equal, the validity of this procedure has been questioned.

A well-defined procedure for testing the difference between the means of two normal distributions can, in fact, be defined provided the variance ratio $\sigma_2^2/\sigma_1^2 = \rho^2$ is specified. The relevant distributional results are

$$t(\delta; \rho) = \frac{\overline{y}_2 - \overline{y}_1 - \delta}{\left\{\left(\frac{1}{n_1} + \frac{\rho^2}{n_2}\right)\left[\frac{(n_1-1)s_1^2 + (n_2-1)s_2^2/\rho^2}{n_1+n_2-2}\right]\right\}^{1/2}} \sim t_{n_1+n_2-2} \quad (1)$$

and

$$F(\rho) = \frac{s_2^2}{s_1^2\rho^2} \sim F_{n_2-1, n_1-1}. \quad (2)$$

Calculation of $t(0; \rho)$ leads to a significance level for a test of $\delta = 0$ as a function of ρ. Confidence intervals for δ may be similarly derived for specified ρ [1].

When ρ is not specified most inference procedures are based on the Behrens–Fisher statistic,

$$t(\delta; \hat{\rho}) = \frac{\overline{y}_2 - \overline{y}_1 - \delta}{(s_1^2/n_1 + s_2^2/n_2)^{1/2}}, \quad (3)$$

which may be obtained by replacing ρ^2 with $\hat{\rho}^2 = s_2^2/s_1^2$ in (1). Behrens's solution [2] was shown by Fisher [5] to arise from a **fiducial** probability calculation. This is equivalent to obtaining the distribution of $t(\delta, \hat{\rho})$ by averaging out ρ over its fiducial distribution. The use of a fiducial distribution is controversial and this procedure is not generally accepted. It can also be obtained, however, by a **Bayesian** calculation which involves a uniform **prior** on $\log \rho$.

Similar **hypothesis testing** is that for which, under the null hypothesis, the probability of exceeding a specified critical value is equal to the required size, α, and does not depend on values for parameters other than the one of interest. Welch [10] derived an approximately similar test for the Behrens–Fisher problem which involved the statistic $t(\delta, \hat{\rho})$, but used different critical values than those advocated by Behrens and Fisher (*see* **Aspin–Welch Test**). Although Linnik [7] has shown that no similar tests which use the **sufficient statistics** in a reasonably smooth way exist, it has been shown numerically that Welch's test is very nearly similar [11].

The requirement of similarity is viewed as unnecessary by some and was the basis of Fisher's criticism of Welch's test. In particular, in the case $n_1 = n_2 = 7$ and under the null hypothesis of common means, the probability of the test statistic exceeding Welch's 0.1 level critical value, conditional on $\hat{\rho}^2 = 1$, is greater than or equal to 0.108 [6]. Thus, if $\hat{\rho}^2 = 1$, the probability of a type I error with Welch's test is known to be greater than the nominal value, and hence the test is anticonservative. Standard arguments of **conditional** inference suggest that the fact that the nominal error rate is valid on average, and upon repeated applications, is not relevant for the interpretation of a particular data set for which it is known that $\hat{\rho}^2 = 1$. Robinson [8] has shown that this situation does not arise with Behrens's test, but that the test may be somewhat conservative. In general, the Behrens–Fisher problem continues to provide a focus for discussions on the foundations of statistical inference.

From a practical point of view, the debate surrounding the Behrens–Fisher problem is most relevant for the analysis of very small samples. Indeed, for larger samples the approximate solution based on normal distributions and neglecting the errors in estimating variances should be satisfactory [3, p. 155]. However, in some settings, the relevance of testing for a difference in means when variances differ dramatically warrants serious consideration.

Another consideration from the data analytic point of view is that $t(0, \rho)$ can be calculated, and significance levels determined, for a range of plausible values of ρ. This range could be determined from a **likelihood ratio** based **confidence interval** for ρ through the use of (2) [9]. The alternative of using a posterior density for ρ based on **empirical Bayes** methodology is suggested in [4]. This would also facilitate a summary inference, although if qualitative conclusions vary widely as a function of ρ, a summary significance level may not provide all of the relevant information.

For illustration, consider the examples in [9]. Summary data from the two examples are given in Table 1.

There is negligible evidence against the hypothesis of equal variances in either example. In Example A, the Behrens–Fisher significance level is 0.005 and the value from Welch's test is 0.0015. A 90% confidence interval for ρ is (0.65, 1.91), and significance levels based on $t(0, \rho)$ for ρ values of 0.65, 1.00 (corresponding to the usual two-sample t test), $\hat{\rho} =$ 1.16, and 1.91 are 0.009, 0.002, 0.001, and 0.002, respectively. Thus inferences about δ are not much influenced by the value of ρ and the choice of the summary procedure does not appear to be critical.

Table 1

	Sample 1			Sample 2		
Example	n_1	$\overline{y}_1$	s_1	n_2	$\overline{y}_2$	s_2
A	9	22.20	0.6498	15	21.12	0.7541
B	8	0.8081	0.1369	4	0.4940	0.1629

In Example B, the Behrens–Fisher significance level is 0.037 and the corresponding value from Welch's statistic is 0.021. The 90% confidence interval for ρ is considerably wider at (0.53, 3.30). The significance levels for ρ values of 0.53, 1.00, $\hat{\rho} =$ 1.19, and 3.30 are 0.006, 0.005, 0.008, and 0.145, respectively. In this case, different plausible values for ρ lead to different qualitative conclusions, and this should be considered in interpreting any summary significance level.

Benefit/Risk Assessment in Prevention Trials

Benefit/risk assessment (B/RA) is a mathematical procedure to estimate the probability of detrimental outcomes, beneficial outcomes and the net-effect anticipated from exposure to a given agent (*see* **Multiple Endpoints in Clinical Trials**). B/RAs of health-related outcomes are used for public health planning, decision-making regarding health care financing (*see* **Cost-effectiveness in Clinical Trials**) and therapeutic decision-making in clinical practice [12, 24]. Information obtained from B/RAs based on findings from controlled clinical trials, particularly those with double-masking of treatment (*see* **Cost-effectiveness in Clinical Trials**), are most informative for health care planning and decision-making because such information is less likely to be biased than is information obtained from observational studies [20, 23, 26]. Thus, B/RAs in prevention trials are an excellent source of information to use as the basis for the types of health care planning and decision-making mentioned above. However, in a **prevention trial** a B/RA is primarily performed as a supplement for planning, monitoring and analyzing the trial. It is designed to provide a global assessment of all potential beneficial and harmful effects that may occur as a result of a treatment that is being evaluated as a means to reduce the incidence of some particular disease or condition. The Women's Health Initiative (WHI), the Breast Cancer Prevention Trial (BCPT) and the Study of Tamoxifen and Raloxifene (STAR) are examples of large-scale, multicenter prevention trials (*see* **Multicenter Trials**) which included B/RA as part of the trial methodology [7, 8, 22, 28, 29].

Compared with treatment trials, the need for the type of information provided by a B/RA may be greater in prevention trials. This situation exists because prevention trials usually involve healthy persons among whom only a small proportion may develop the disease of primary interest during the course of the trial [5–7, 13, 22, 29, 30]. As such, all participants are subjected to the risks of therapy during the course of the trial, but relatively few will receive a preventive benefit from the therapy. In this setting, the use of B/RAs provides an additional mechanism to ensure that all participants comprehend the full extent of potential benefits and risks, and that they make a well-informed decision about the interchange of benefits and risks they are willing to accept by participating in the trial (*see* **Ethics of Randomized Trials** and **Medical Ethics and Statistics**). The use of B/RA in prevention trials also provides a method to evaluate the global effect of the therapy as a safeguard against subjecting trial participants to an unforeseen harmful net effect of treatment. Once the results of the trial are known and the true levels of benefits and risks of the therapy have been established, the individualized B/RA employed in the trial can become the basis for the development of a B/RA methodology that could be used in the clinical setting to facilitate the decision-making process for individuals and their health care providers who may be considering the use of preventive therapy. The trial results can also be used to develop a population-based B/RA to identify changes in patient loads for the outcomes affected by the preventive therapy that would be anticipated as health care professionals incorporate the use of the preventive therapy into their clinical practice. This information could in turn be used for decision-making regarding the planning for and use of health care resources.

Types of B/RAs Performed in Prevention Trials

In a prevention trial a B/RA can take one of three forms which can be classified according to the nature of the population that constitutes the basis for the assessment. These include assessments based on the general population, those based on the trial cohort and those based on an individual trial participant. Each of these forms of B/RA is performed for specific purposes, namely to support various aspects of the conduct of the trial.

A B/RA based on the general population is often performed pre-trial as part of the justification for initiating the trial. The purpose of this form of assessment is to demonstrate the potential net health benefit to society that could be obtained if the therapy being evaluated in the trial actually exhibits the efficacy that is anticipated. This type of assessment is the most generalized form. It is usually accomplished by estimating effects on a national basis assuming the therapy is administered to all susceptible individuals or to a subset of high-risk individuals and demonstrating that there is a significant net benefit when

comparing the number of cases prevented with the estimates for the number of additional cases of detrimental outcomes that may be caused as a side-effect of the therapy.

A B/RA based on the trial cohort is performed during the course of trial implementation as part of the safety monitoring effort (*see* **Data and Safety Monitoring**). It can be accomplished in a regimented fashion as part of the formal plan for the interim monitoring of the trial or as an informal tool used by the data monitoring committee (*see* **Data and Safety Monitoring**) to assess the overall safety of the therapy being evaluated. This type of assessment is not usually necessary during a trial if the anticipated effects from the therapy involve only a few outcomes or if the anticipated beneficial effects substantially outweigh the anticipated detrimental effects. However, in complex situations where the anticipated outcomes affected by the therapy involve multiple diseases or conditions and/or the magnitude of the anticipated net benefit may not be large, a B/RA based on the trial cohort can be a very useful supplement for trial surveillance as a method of monitoring the global effect of all beneficial and detrimental outcomes combined (*see* **Multiplicity in Clinical Trials**). A notable difference between a B/RA based on the general population and one based on the study cohort is in the nature of the measures that are provided by these two forms of assessment. A risk assessment based on a general population provides a measure of the theoretical net effect of the therapy from estimates of anticipated beneficial and detrimental outcomes. In contrast, a risk assessment based on the trial cohort determines the observed net effect of therapy based on outcomes actually experienced by the cohort during the course of the trial.

A B/RA based on an individual trial participant is similar to that of the population-based assessment in that it is also a theoretical estimate. In this case the assessment is not made for the general population, but instead for a specific subpopulation of persons who have the same risk factor profile (age, sex, race, medical history, family history, etc.) for the anticipated beneficial and detrimental outcomes as that of a particular individual participating in the trial. Information from this type of assessment is used to facilitate the communication to each potential trial participant of the nature of the benefits and risks that are anticipated for them as a result of taking therapy during trial participation. This type of individualized B/RA is used in prevention trials when the nature of anticipated effects is complex and benefit/risk communication is a more difficult task due to the interplay of multiple beneficial and detrimental outcomes. When it is used in this manner, it becomes an integral part of the process to obtain informed consent for each individual's participation in the trial.

Alternative Structures of the Benefit/Risk Algorithm Used in Prevention Trials

The core components of a B/RA are the measures of the treatment effect for each of the health outcomes (*see* **Outcome Measures in Clinical Trials**) that may be affected by the therapy being assessed. In this instance the treatment effect is defined as the difference between the probability that the outcome will occur among individuals who do not receive the therapy being evaluated (p_0) and the probability that the outcome will occur among those who do receive the therapy (p_1). For outcomes beneficially affected by therapy, the treatment effect ($p_0 - p_1$) will have a positive sign, representing cases prevented by therapy. For outcomes detrimentally affected by therapy, the treatment effect will have a negative sign, representing cases caused by therapy.

In its simplest structure, the benefit/risk analysis is summarized by an index of net effect (Δ) as the summation of treatment effects for all outcomes affected. If there are I number of outcomes affected by therapy, then the basic algorithm for the B/RA is defined as:

$$\Delta_1 = \sum_{i=1}^{I} (p_{0,i} - p_{1,i}). \qquad (1)$$

When the sign of the index of net effect is positive, the therapy exhibits an overall beneficial health effect. When the sign is negative, the therapy has an overall detrimental effect.

When dealing with a B/RA based on the trial cohort, the probabilities of (1) are obtained directly from the observations in the trial. When dealing with assessments based on the general population or the individual trial participant, the probabilities utilized as anticipated values among those who do not receive therapy (p_0) are usually taken from some type of national database or from prospective studies

of large populations that included measurements of the outcomes of interest. The probabilities used in these latter types of assessments as anticipated values among those who receive therapy are determined by multiplying the anticipated probability among those not treated by the relative risk (untreated to treated) anticipated as the treatment effect. For example, if we anticipate that treatment will reduce the incidence of a particular outcome by 35% then the anticipated relative risk would be 0.65 and the value used for p_1 would be 0.65 p_0. If we anticipate that treatment will increase the incidence of an outcome by 30%, then the anticipated relative risk would be 1.30 and the value used for p_1 would be 1.30 p_0. Estimates of the anticipated treatment effects for each outcome are taken from the literature dealing with pharmacokinetics, animal studies (*see* **Preclinical Treatment Evaluation**) and studies in humans undertaken as preliminary investigations of the therapy as an agent to prevent the disease, or from human studies in which the therapy was being used as an agent for the treatment of disease (*see* **Phase I Trials** and **Phase II Trials**).

In the prevention trial setting it is often advantageous to utilize structures of the benefit/risk algorithm other than that defined in (1). Since a B/RA based on the trial cohort is meant to be performed as part of the effort to monitor safety during the trial, an alternative structure of the benefit/risk algorithm can be used to facilitate this effort. This structure incorporates a standardization of the differences between the probabilities among those receiving and not receiving the therapy being evaluated. In this situation the index of net effect is defined as:

$$\Delta_2 = \frac{\sum_{i=1}^{I}(p_{0,i} - p_{1,i})}{\text{s.e.}\left[\sum_{i=1}^{I}(p_{0,i} - p_{1,i})\right]}. \qquad (2)$$

In this structure, the index of net-effect (Δ_2) becomes a standardized value with an N(0,1) distribution. As such, the standardized values are Z-scores. Critical values of this index of net effect in the form of Z and $-Z$ can then be used as cut-points for global monitoring indicating that there is a significant net effect that is beneficial or detrimental, respectively.

In addition to that for the standardized score, there are other structures of the algorithm used in the prevention trial setting. Instead of expressing the differences between those treated and not treated in terms of the probabilities of the anticipated outcomes, an alternative structure of the algorithm is that based on differences between treatment groups in terms of the number of cases of the outcomes. The structure of the algorithm based on the difference in terms of the number of cases is defined as:

$$\Delta_3 = \sum_{i=1}^{I}(n_{0,i} - n_{1,i}), \qquad (3)$$

where n_0 is the number of cases occurring among those who do not receive the therapy being evaluated and n_1 is the number of cases among those who do receive the therapy. This structure of the algorithm is that which is utilized to perform B/RAs based on the general population. This type of assessment is meant to justify the need for a trial by demonstrating the potential health benefit to society. The net effect to society is more effectively communicated to a greater proportion of individuals when it is expressed as the number of cases prevented from (3) than when it is expressed as the probability from (1). This facilitation of risk communication is also the reason that (3) is preferred over (1) for B/RAs based on individual trial participants where the specific goal of the assessment is to enhance the individual's comprehension of benefits and risks that may be experienced as a result of trial participation.

For a population-based assessment, the numbers of cases in (3) are determined by multiplying the anticipated probabilities $p_{0,i}$ and $p_{1,i}$ by the number of persons in the general population, frequently that of the total US, to obtain an estimate of the number of cases that may be prevented or caused by treatment for each outcome on an annual basis. For an individual participant-based assessment, the numbers of cases in (3) are determined by multiplying the anticipated probabilities by a fixed sample size (N) of theoretical individuals who all have a risk factor profile similar to that of the individual being assessed. A fixed period of follow-up time (t) is assumed to obtain the number of cases prevented or caused by treatment in t years among N individuals. In scenarios where the length of follow-up is long and/or the population is of older age, the estimation of $n_{0,i}$ and $n_{1,i}$ should incorporate the competing risk of mortality that would be anticipated. If d is the probability of dying and RR is the relative risk

anticipated for the outcome of interest, the adjusted expected number of cases among those not treated can be calculated as:

$$n_{0,i} = N\left\{\frac{p_{0,i}}{(p_{0,i}+d_i)}\right\}[1-\exp\{-t(p_{0,i}+d_i)\}], \tag{4}$$

and the adjusted expected number of cases among those treated can be calculated as:

$$n_{1,i} = N\left\{\frac{RRp_{0,i}}{(RRp_{0,i}+d_i)}\right\} \times [1-\exp\{-t(RRp_{0,i}+d_i)\}]. \tag{5}$$

In most prevention trials the outcomes that are potentially affected by the therapy being evaluated encompass a wide range of severity. A simple adding together of the risks of beneficial and detrimental effects without including a consideration of the relative severity of the outcomes may not be appropriate or desirable. For example, suppose a therapy is anticipated to prevent breast cancer and hip fractures, but may cause an increase in uterine cancer and cataracts. Is it appropriate to equate one case of breast cancer prevented to one case of cataracts caused or equate one case of hip fracture prevented to one case of uterine cancer caused? In situations where it is important to include a consideration of the relative severity of the outcomes affected by the therapy, the equations described above for determining the index of net effect can be modified to incorporate a weighting of the outcomes. If w_i is used to represent the weight for each of the I outcomes, then the modification to (3) to incorporate weighting of the outcomes is:

$$\Delta_4 = \sum_{i=1}^{I} w_i(n_{0,i} - n_{1,i}). \tag{6}$$

Equations (1) and (2) can be modified in a similar fashion by including w_i as a multiplier of the quantity of difference in the probabilities.

Methodological and Practical Issues with B/RA in Prevention Trials

There are several issues to be faced when performing a B/RA in a prevention trial. These issues concern the variability of the index of net effect, weighting the outcomes by severity, estimating the index of net effect for individuals with specific profiles of risk factors and communicating the findings of a B/RA to individual participants. Some discussion of each of these issues is presented below.

The estimates of $p_{0,i}$ and $p_{1,i}$ used in a B/RA have a variability associated with them in terms of the strength of evidence supporting the treatment effect and in terms of the precision of the treatment effect. If this variability is substantial, then it may be necessary to incorporate consideration of the variability into the B/RA. Freedman et al. [8, 25] have described a Bayesian approach to incorporating a measure of variability into the index of net effect when it is measured in the form of weighted, standardized probabilities. They assume a skeptical prior distribution based on the strength of the preliminary evidence used as the anticipated treatment effect for each outcome potentially affected by therapy. Gail et al. [10] have described a method to incorporate a measure of variability into the estimate of the index of net effect measured in the form of a weighted number of cases. Their method involves bootstrapping, based on the 95% confidence intervals of the anticipated relative risk associated with treatment for each outcome, to determine the probability that the net number of cases is greater than zero.

The values used for weighting the differences between those treated and not treated can be based on a utility function related to the severity of the outcome, preferences in terms of levels of risk acceptability or other considerations. However, the best choice of a utility function is not always obvious. A measure of mortality such as the case-fatality ratio is one possible utility. If this type of weighting is used, then the choice of the one-year, five-year or ten-year case-fatality ratios would be an issue because the relative weighting of the outcomes could likely be very different depending on which time period for case-fatality is used. Also, weights based on case-fatality would eliminate the consideration of any nonfatal outcome, which would not be preferable if there were several nonfatal outcomes of interest or if a nonfatal outcome has a significant impact on morbidity. Issues also arise with the use of rankings based on the impact on quality of life or preferences regarding the acceptability of risk [1, 11]. The issues with these utilities arise because the rankings are often subjective in nature, based on the opinions of a relatively small panel of individuals, and it

is possible that the rankings of outcomes could differ substantially depending on the population from whom the opinions are ascertained [2, 15, 16]. In light of these issues, attempting to identify a basis for weighting a B/RA is a practical problem that can be difficult to resolve. The preferred choice for any particular trial could differ from one group of individuals to another. As such, if a B/RA is planned as part of trial monitoring, it is essential that the data monitoring committee reviews and reaches a consensus regarding the proposed weighting before it initiates review of the outcome data.

To accomplish the individualization desired for B/RAs based on individual trial participants, it is necessary to provide estimates of effect specific to the individual's full spectrum of risk factors for each of the outcomes expected to be affected by the therapy of interest. A problem likely to be faced when performing individualized assessments is the unavailability of probability estimates specific to the individual's full set of risk factors. For outcomes with several relevant risk factors to be considered or for outcomes that have not been studied in diverse populations, estimates of the outcome probabilities for a specific category of risk factor profiles may not exist. In some cases, multivariate regression models are available that can be used to predict probabilities of outcomes for specific risk factor profiles from data based on the general population. Examples of such models include those for heart disease, stroke and for breast cancer [4, 9, 14, 17–19]. However, the models currently available are primarily limited to those for the more common diseases and are not generally applicable to all race and sex populations. Also, relatively few of these models have been well validated. Thus, in practice it is often necessary to use estimates of outcome probabilities for individualized B/RAs that are taken from populations that are more representative of the general population than of the population specific to the risk factor profile of the individual being assessed. When this is the case, the limitations of the methodology need to be recognized and used in this light. Nonetheless, a B/RA that has been individualized to the extent possible is more informative to a trial participant than one based on the general population. Additional discussions of the limitations of individualized B/RAs can be found in presentations concerning individualized B/RAs for the use of tamoxifen to reduce breast cancer risk [3, 4, 27].

Communicating the results of a B/RA to an individual is a skilled task. An effort must be made to provide information in a manner that facilitates the individual's comprehension [21]. Tools are needed to facilitate this effort. These tools must be developed before the initiation of the trial and included as part of the protocol approved by the Institutional Review Board. Relatively little work has been done in the area of developing tools for communicating the benefits and risks of participation in a prevention trial. However, some tools have been developed that serve as examples for future development.

Tools to enhance the communication of B/RA information to women screened for participation were developed for use in the BCPT [7, 22]. Since the conclusion of this trial, the tools were refined for use in the STAR trial [28]. Table 1 provides an example of the type of tool used in the STAR trial to inform potential participants regarding their individualized B/RA. This tool was developed based on the principles put forth by the participants of the National Cancer Institute's workshop convened to develop information to assist in counseling women about the benefits and risks of tamoxifen when used to reduce the risk of breast cancer. This workshop and the specific methodology used for the B/RA are described by Gail et al. [10]. There were several key working premises that guided the development of the STAR trial tool displayed in Table 1. The premises were considerations of form and format to facilitate the participant's comprehension of their individualized B/RA. These working premises were to: (1) avoid the use of probabilities and relative risk as these concepts are not readily understood by the nonstatistician; (2) provide information for each outcome anticipated to be affected by therapy; (3) group the information presented by severity of the outcomes; (4) provide detailed information for the outcomes with more severe consequences and provide an estimate of effects among those not treated so the individual can understand the context in which to place the expected treatment effects; and (5) limit the tool to one page of data presentation to reduce the amount of data overload perceived by the individual. The precise considerations involved in any prevention trial may differ; however, working premises of this nature designed to enhance comprehension should always be employed when developing tools to communicate B/RA information to potential trial participants.

Table 1 Example of data presentation tool for communicating the benefits and risks of tamoxifen therapy

The information below provides the number of certain events that would be expected during the next five years among 10 000 untreated women of your age (age_X), race ($race_Y$) and five-year breast cancer risk ($risk_Z$). To help you understand the potential benefits and risks of treatment, these numbers can be compared with the numbers of expected cases that would be prevented or caused by five years of tamoxifen use

Severity of event	Type of event	Expected number of cases among 10 000 untreated women	Expected effect among 10 000 women if they all take tamoxifen for five years
			Potential benefits
Life-threatening events	Invasive breast cancer	$N_{0,1}$ cases expected	$N_{1,1}$ of these cases may be prevented
	Hip fracture	$N_{0,2}$ cases expected	$N_{1,2}$ of these cases may be prevented
			Potential risks
	Endometrial cancer	$N_{0,3}$ cases expected	$N_{1,3}$ more cases may be caused
	Stroke	$N_{0,4}$ cases expected	$N_{1,4}$ more cases may be caused
	Pulmonary embolism	$N_{0,5}$ cases expected	$N_{1,5}$ more cases may be caused
			Potential benefit
Other severe events	*In situ* breast cancer	$N_{0,6}$ cases expected	$N_{1,6}$ of these cases may be prevented
			Potential risk
	Deep vein thrombosis	$N_{0,7}$ cases expected	$N_{2,7}$ more cases may be caused
Other events	*Potential benefits*:	Tamoxifen use may reduce the risk of a certain type of wrist fracture called Colles' fracture by about 39%, and also reduce the risk from fractures of the spine by about 26%.	
	Potential risk:	Tamoxifen use may increase the occurrence of cataracts by about 14%.

JOSEPH P. COSTANTINO

Benjamin, Bernard

Born: 8 March 1910, London.
Died: 15 May 2002, London.

Bernard Benjamin had a distinguished career as a statistician, actuary, and demographer, achieving distinction and the highest levels of recognition and honor in each of these fields. Among his particular interests were the effective use of routinely collected data and the application of statistical modeling for making decisions. For example, he was one of United Kingdom's pioneers on applications of statistical methods to nonlife insurance (*see* **Actuarial Methods**).

Bernard Benjamin was born in 1910, the youngest of eight children. He went to school in SE London and went on to study physics part-time at Sir John Cass College (then affiliated to the University of London), graduating in 1933. Meanwhile, he had started work in 1928 as an actuarial assistant to the London County Council (LCC) pension fund, and qualified as an actuary in 1941. From 1936, he worked as a statistician in the public health sections of the LCC until 1943, when military service took him to the Royal Air Force, where he continued his work as a statistician. After the war, he returned to the LCC and public health, and undertook his PhD (also on a part-time basis) on the analysis of tuberculosis mortality.

In 1952, Benjamin was appointed Chief Statistician at the General Register Office (GRO), later to be absorbed into the Office of Population Censuses and Surveys and then into the **Office for National Statistics**, marking his move into **demography**, and promotion to management and the leadership of a major public-sector department. After 11 years at the GRO, he was appointed Director of Statistics at the Ministry of Health in 1963, and then in 1966, became the first Director of the Intelligence Unit of the Greater London Council (GLC). The unit was set up as part of local government reorganization in London, and its task was to make sure that the GLC had "economic and other information at the right time in the right way", to quote Benjamin. In this role, he brought together the entire planning and transportation research staff into a cohesive and effective unit. But this reorganization did not survive without Benjamin's leadership skills and foresight after his retirement in 1970.

A strong theme of Benjamin's later working life was a series of retirements followed by new beginnings. Thus, in 1970, he became Director of Statistical Studies at the newly established Civil Service College. Then in 1973, he retired and joined City University as the Foundation Professor of actuarial science, establishing and designing the first BSc programme in actuarial science in the country. Although Benjamin enjoyed teaching undergraduates, he took particular pleasure in the supervision of PhD students and, over the next decade, he taught a steady stream of research students who were working on statistical methods applied to demography and actuarial science.

In his roles at the GRO, GLC, and Civil Service College, Benjamin was concerned with the collection and analysis of statistics and the presentation of results for the solving of practical problems in public health or demography. He was particularly adept at conveying statistical ideas in a clear manner, without recourse to jargon or indeed mathematical notation.

Benjamin retired in 1975 from City University (because of his wife's failing health), but continued as a visiting professor. On his final departure from City University, he was appointed emeritus professor and awarded an honorary DSc for his contributions to education and research in statistics and actuarial science.

Benjamin's scientific work was extensive. He published over 100 papers in leading statistical, actuarial, and demographic journals over almost 40 years. A notable achievement was his 1954 report on the growth of pension rights and their impact on the national economy, which became the actuarial profession's principal evidence to the 'Phillips Committee' on the economic and financial problems for the provision for old age. When the actuarial profession sought to update this landmark report 30 years later (at a time of government questioning of the role of public pension provision), it was to Benjamin that they turned to lead the research team that produced the monograph entitled *Pensions: The Problems of Today and Tomorrow,* in 1987.

Benjamin was able to write concisely and interestingly and his first drafts were almost of final draft quality. This talent contributed to a series of successful textbooks and monographs: *Elements of Vital Statistics* (1959), *Social and Economic Differentials*

in Fertility (1965), *Social and Economic Factors Affecting Mortality* (1965), *Health and Vital Statistics* (1968), *Demographic Analysis* (1968), *Medical Records* (1977) and *Population Statistics* (1989). The textbooks *Analysis of Mortality and other Actuarial Statistics* (1970, with new editions in 1980 and 1993) and *General Insurance* (1977) have become seminal works of international standing in the actuarial field. His last book, *Mortality on the Move* (1993), appeared at a time of accelerating mortality decline in many industrialized countries, and is now widely cited.

Among his honors and achievements, Benjamin was the UK representative on the UN Population Commission from 1955 to 1963, the honorary consultant in Medical Statistics to the Army, a member of the statistics committee of the Social Science Research Council, and secretary-general of the International Union for the Scientific Study of Population from 1962 to 1963. He was vice president (1963–1966) and president of the Institute of Actuaries (1966–1968), honorary secretary (1956–1963) and president of the **Royal Statistical Society** (1970–1972), and was uniquely awarded the highest honors of both bodies – the Gold Medal (1975) and the **Guy** Medal in Gold (1986), respectively.

At a personal level, Benjamin was modest and self-effacing, yet he was a determined and clear-sighted manager and leader who inspired respect and loyalty. As a colleague, he was both encouraging and supportive, qualities that made him both an excellent PhD supervisor and a research collaborator. He had a number of active hobbies before his sight failed, describing himself both as an 'amateur' pianist and painter. The latter activity gave him much pleasure and his watercolors were of a higher standard than he would admit to.

STEVEN HABERMAN

Berkson, Joseph

Born: May 15, 1899, in Brooklyn, New York.
Died: September 12, 1982, in Rochester, Minnesota.

Joseph Berkson, the sixth child of Russian immigrants, Henry and Jennie (Berkman) Berkson, was educated in the New York public schools and Townsend Harris Hall before attending the College of the City of New York from which he received a B.S. degree in 1920. He obtained an M.A. degree (Physics) from Columbia University in 1922 and two doctoral degrees from Johns Hopkins, an M.D. in 1927 and a Dr.Sc. in statistics in 1928.

Upon completion of these degrees, Dr Berkson accepted positions at Johns Hopkins as an assistant in the School of Hygiene and Public Health and as an Associate in the Institute of Biologic Research. He remained at Johns Hopkins for three years before accepting a position as a Macy Foundation Fellow in Physiology at the Mayo Clinic, which he began in September 1931. Berkson remained at Mayo until his retirement in 1964, first as Acting Director of the Statistics Division and then Head of the Division of Biometry and Medical Statistics, a position he held from January 1, 1934, to July 1, 1964. He was Associate Professor and later Professor (1949) of Biometry in the Mayo Graduate School of Medicine.

Subsequent to the completion of his degrees but prior to coming to Mayo, Berkson published ten manuscripts [1–5, 15, 19, 20, 24, 26]. Several merit comment because they are informative about his lifelong interests. Eight of these first papers [2, 3, 5, 15, 19, 20, 24, 26] are reports of physiological studies (two with the famous Louis Flexner [15, 24]) reflecting Berkson's training and an interest which he retained throughout his career. However, there were harbingers of statistical interests which would blossom in later years. His fourth paper [26] (with the famous epidemiologist Lowell Reed), "The Application of the Logistic Function to Experimental Data", provides the first evidence of his interest in the **logistic functions**, an interest that would reemerge much later in his professional life.

His fifth paper [1] involved a probability nomogram (another lifelong interest of Berkson's). It is difficult to imagine today with the plethora of computers that calculational shortcuts, nomograms, tables, special graph paper, etc. were all essential aids to an applied statistician throughout much of Berkson's professional career. In addition to publishing several papers including nomograms which he designed, Berkson also designed graph paper with a variety of different scales which was useful for many data analysis problems.

Berkson's first purely statistical publication [4] in the *Annals of Mathematical Statistics* was simply titled **"Bayes' Theorem"**. Symbolically, one of his last papers [14] – published 47 years later in the *International Statistical Review* – was entitled, "My Encounter with Neo-Bayesianism". He was certainly no Neo-Bayesian.

During World War II he served as a colonel in the office of the Air Surgeon General in Washington, DC, and in 1946 he was awarded the Legion of Merit. The accompanying Presidential citation reads:

> Colonel Joseph Berkson, Medical Corps, as Chief of the Statistics Division, Office of the Surgeon, Headquarters Army Airforces, contributed immeasurably to the advancement of medical statistics in developing new methods of presenting and interpreting statistical data as applied to Army Airforce matters. His display of professional skill and high standards of efficiency in disease control contributed to a great extent to the success of the Army Airforce health programs.

At the Mayo Clinic Dr Berkson was known as a maverick who tolerated fools reluctantly and "marched to the beat of his own drummer". He was probably

best known to the Mayo staff for three contributions, the most significant of which was the introduction of the then relatively new Hollerith card and the development of diagnostic and procedure coding systems that were used for over 40 years at Mayo [7, 8]. Berkson rejected the existing, widely touted, classification scheme with the quote, "There are hundreds of diseases in that book no one can get and an equal number of diagnoses no one can find". His ingenious coding system, using the new punch card capability, combined into a single scheme two related but not identical functions. First, cross-indexing of medical conditions was made possible so that specific groups of patient histories could easily be identified and retrieved for research or patient care and, secondly, the designation of main numbers facilitated administrative tabulations. Thousands of research papers by Mayo physicians, surgeons, epidemiologists, and statisticians were made possible because of this system.

From the perspective of his Mayo colleagues, Berkson's second major contribution came in the area of **survival analysis**. His first manuscript on the topic [6] was published in 1934 and involved the appropriate construction of a **life-table** to describe the survival experience of a group of patients following an operation. Several manuscripts were subsequently published using his methodology [18, 21, 22, 25] and his own work culminated in two papers with Robert Gage [16, 17], the first published in 1950 (*Mayo Clinic Proceedings*) and the second in 1952 (***Journal of the American Statistical Association***) on the estimation of survival rates and the construction of survival curves for cancer patients. Berkson insisted that research by Mayo investigators involving patient survival use his methods, and as late as 1980 there was a rule in place at the editorial office of the *Mayo Clinic Proceedings* that such papers had to have the approval of a statistician. He made perhaps an even more important contribution to the field by introducing **Jerzy Neyman** to the problem and by working with Lila R. Elveback on her dissertation. Thus, when Elveback and William F. Taylor both came to Mayo, a nucleus was formed which produced fruitful research in this area and which established a precedent continued by Mayo statisticians to this day.

Finally, everyone at Mayo knew about Berkson's attitude regarding the studies purporting to have established a relationship between smoking and lung cancer (*see* **Smoking and Health**). Interestingly, long before this controversy, Berkson had published a manuscript on tobacco and coronary disease [23]. Being a well trained physiologist and also a statistician, Berkson found the statistical studies associating smoking and lung cancer less than persuasive of causality (*see* **Causation**). Thus, all who were interested, and many who were not, were aware of Berkson's disdain for the studies upon which the smoking/lung cancer connection were based. Berkson's plea for more direct physiological evidence of causality and his observations that arguments associating tobacco use and lung cancer lacked specificity because they could be applied equally to tobacco use and other diseases may seem a little strained now, but they were legitimate at the time. In one of his major papers on the topic [13] in the *Mayo Clinic Proceedings*, Berkson discusses some of his concerns with the smoking/lung cancer data. Here he calls upon his "Berkson Bias" paper (*see* **Berkson's Fallacy**) [10] published some years earlier to argue that studies of hospitalized patients, whether retrospective or prospective, have a likely **selection bias** which may invalidate results. Then, turning to the question of **specificity**, he argues in his eloquent style that the question raised by the findings in the American Cancer Society study of higher death rates among cigarette smokers is not, "Does cigarette smoking cause cancer of the lungs?" so much as "What disease does cigarette smoking not cause?"

Finally, and also eloquently, he offers his argument for biological considerations,

> A disquieting element in the array of observations which have been assembled pointing the finger of accusation at smoking as a cause of lung cancer is that it is so ample, yet it is so exclusively statistical. There are lacking observations of the pathologic process of which the statistics are only the supposed reflection. Actually the American Cancer Society study does not point specifically to association of smoking and cancer, for all specific diseases for which the number of cases permits examination show association, exhibiting a larger death rate among smokers than among nonsmokers. Therefore, if the association found is not statistically spurious and is to be explained as a biologically causative effect, it is not on these findings specifically a carcinogenic effect but something which influences broadly whatever may increase the susceptibility of the organism to fatal disease. Now, the most important known cause of cancer and some other diseases, notably those of the cardiovascular system, is age. We might say speculatively that smoking

> accelerates the rate of living and advances age and age causes cancer. The supposed effect of smoking, if it exists, may be to stimulate those trophic processes, of which little is known, that constitute the biology of aging. The idea is not entirely implausible or without support in existing literature. It is in keeping with Pearl's idea that duration of life is inversely related to the rate of living and with Pearl's own study of the effect of heavy smoking on longevity.

Although his Mayo medical colleagues were unlikely to be aware of it, Berkson made major contributions to theoretical statistics. Nothing seems to have held Berkson's attention throughout his career as much as the logistic function, providing him with an opportunity to delve into some of the more esoteric aspects of statistical inference. Among the 118 papers in his bibliography at least 28 contain some, usually substantial, references to the logistic function. In three of his first 10 manuscripts he used and discussed at length the logistic function as a model of the rate of a chemical reaction. Then, in 1944, he published what he may have assumed would be a little blip in the statistical literature, a manuscript entitled, "Application of the Logistic Function to Bio-assay" [9]. In the ensuing 13 years he published 14 more papers on this and related topics and embarked on a sometimes humorous, sometimes vitriolic, exchange of views with **Fisher**, Finney, and **Bliss**. This exchange may have begun over the relative merits of the probit and logit (*see* **Quantal Response Models**) (apparently Berkson coined this term) in bioassay problems (*see* **Biological Assay, Overview**), but soon escalated into a crusade on Berkson's part to persuade the mathematical statistical community to pay attention to **estimation** principles other than the **maximum likelihood (ML)** and to acknowledge the advantage of calculational simplicity. In this first paper Berkson pointed out that probit analysis, the bioassay analytic method in vogue, assumed the Gaussian distribution (*see* **Normal Distribution**) for certain relationships of dose and susceptibility. If true, this certainly suggests the use of the integrated normal for such analyses. He goes on to point out, however, that the logistic function may have a better theoretic basis because it applies "to a wide range of physicochemical processes".

In applying the integrated normal approach, parameter estimation based on the principle of ML needed iterative and time-consuming calculations. Berkson applied the principle of weighted **least squares** to the estimation of the logistic parameters, which by a special simplification could be obtained directly without iteration. This simplification involved obtaining the logit corresponding to a given mortality rate, and he provided in the 1944 manuscript [9] a nomogram to do this for mortality rates ranging from 0.7% to 99.3%.

It is difficult today to conceive of a world in which such giants of the statistical profession would engage in the rhetoric that followed this publication based on questions of iterations and calculational simplicity. Berkson concluded this first paper with the simple statement that he believed that the work of fitting the logit to be considerably simpler and less time consuming than using probits, as advocated by Bliss and Fisher. In a later exchange [12], Fisher apparently accused Berkson of saying that the probit calculations took 30 times as along as the logit and indicated that in his (Fisher's) experience the two were about equivalent. To this Berkson responded by describing an experiment in which two sets of bioassay data were presented to a "computer" (presumably an individual using a mechanical calculator) with instructions to apply both methods of estimation to the data and to record faithfully the amount of time necessary to complete each. He reported that for one set the probit method required 295 minutes while the logit method required 12 minutes. Berkson admitted that this was less than a 30-fold difference but suggested that it was still substantial and deserving of attention.

Of course the argument between Fisher and Berkson did not hinge on how much time a calculation took. Berkson's minimum logit chi-square approach did not yield maximum likelihood estimates (MLEs), a point he did not deny, but he railed against the notion that there was something sacred about MLEs which precluded use or discussion of alternatives. He was particularly offended by the constant defense of the probit method as producing MLEs when it depended on choice of starting value and number of iterations actually carried out. In one hilarious passage [11, p. 591] he defined a hierarchy of estimators depending on the number of iterations conducted.

> The procedure of "probit analysis" as widely advanced and practiced, consisting of a single cycle of iteration based on a provisional graphical estimate, actually is not a maximum likelihood estimate, but only a somewhat modified graphical solution. Since

> it is a step in the right direction toward the maximum likelihood estimate, perhaps it is entitled to the designation "likelihood estimate." If one or two more iterations are performed, it could be called a "very likelihood estimate"; if as many as 9 iterations are accomplished, as in the example from Irwin and Cheeseman, an "exceedingly likely likelihood estimate", and so forth. A really mathematical maximum likelihood estimate in the present circumstance is rarely attainable, but this estimate appears to be held so noble an objective that perhaps we should be contented only to aspire to achieve it. However, it must be remembered that it is solely to the actual maximum likelihood estimate that the optimum properties pertain, which Finney insistently claims for "probit analysis". These optimum properties do not refer to a "likelihood estimate," nor even to a "practically good enough" maximum likelihood estimate.

On Christmas Eve 1935 Berkson was married to Susanna G. Cacioli, a Mayo translator (Italian) from 1927 to 1948. Although they had no children, the family of Dr Frank Falsetti – Susanna's son by an earlier marriage – has fond memories of times with the Berksons and the role Joe played in their lives.

In 1978 his colleagues and successors in statistics at the Mayo Clinic honored Berkson by naming the main departmental conference room after him. They presented him with two bound volumes of his published works which included solicited comments from some of his illustrious colleagues in the statistical world. These included **W.G. Cochran, Jerzy Neyman**, John Tukey, and others. They all reminisced with Joe about their interactions during the previous decades of their professional lives. Neyman acknowledged that Berkson had introduced him to some of the intriguing statistical problems found in medical research, mentioning specifically work in survival analysis and **competing risks** that Neyman and Evelyn Fix worked on. Cochran said, "An important reason for honoring Joe is that he was about the best writer in the business. I was never in doubt as to what Joe meant in a sentence. Moreover, he was a delight to read, ... Joe was continually reminding professional statisticians of their responsibility for keeping their heads clear." Tukey recalled that, "In the late 1940s there was a round-robin letter group consisting of (Berkson and Tukey), George Brown, Churchill Eisenhart, and Charlie Windsor." Tukey suggests that the correspondence was lively and enjoyable and apparently often heated as Berkson's wife, Susie, reported to him that Joe, upon coming home to find letters would read them and often shout, "They can't do this to me", and off he would go to his upstairs office to begin typing his reply.

Berkson was an active and aggressive statistician. He was also an active member of several statistical societies and was honored by many of them. One of the original group who founded the Biometric Society (*see* **International Biometric Society (IBS)**), he held two early regional offices. He was a fellow of the American Association for the Advancement of Science, the **American Public Health Association**, the **American Statistical Association**, and the **Royal Statistical Society**. In the twilight of his career, he was elected to the National Academy of Sciences (April 1979).

Although Berkson was obviously a statistician, he liked to play the role of the humble medical doctor simply trying to get along in this harsh mathematical world. This image was a facade, as his work illustrates, but it was a facade he maintained throughout his career. There appear to be no publications or written references, where degrees were quoted, in which any other than his M.D. degree was mentioned. His final paper was published in 1978 and he had remained in active contact with his statistical colleagues at Mayo and throughout the world until the last few years of his life.

At the August 1983 American Statistical Association meeting, a session organized by Joe's colleague, William F. Taylor, was presented in his honor. James Grizzle and Lucien LeCam made presentations and Fredrick Mosteller, Churchill Eisenhart, and John Tukey participated with the others in a panel discussion regarding interactions with their friend and colleague Joseph Berkson. Grizzle said the following:

> He (Berkson) had a serious concern about the fundamental properties of the statistics he was using. He did not feel comfortable with them until he understood their finite sample size properties and he was dismayed when others advocated statistical methods that did not, in his opinion, have a completely coherent philosophical (i.e., mathematical) base. There is no doubt that Berkson was a serious productive scientist. He was absolutely tenacious in his investigations. He persisted in martialing mathematical and empirical evidence for his views over approximately a 40-year period. He related his views to new developments in methodology in interesting and useful ways to the end of his career.

W. MICHAEL O'FALLON

Berkson's Fallacy

Berkson's fallacy, also referred to as Berkson's bias or Berkson's paradox, was first described in 1946 by **Joseph Berkson**, a physician in the Division of Biometry and Medical Statistics at Mayo Clinic. Berkson demonstrated mathematically that an **association** reported from a **hospital-based case–control study** can be distorted if cases and controls experience differential hospital admission rates with respect to the suspected causal factor [1]. His hypothetical example involved the association between two medical conditions – cholecystitis (the suspected causal factor) and diabetes (the outcome of interest). Assuming a hospital-based study, he defined controls as persons with a third condition, refractive errors, not thought to be correlated with cholecystitis. Calculations were based on the following assumptions: (i) the incidence of cholecystitis does not vary between diabetics and persons with refractive errors in the general population (i.e. **relative risk** and **odds ratio** close to 1.0); (ii) hospital admission rates *do* vary between diabetics and persons with refractive errors (5% and 20%, respectively); (iii) persons with cholecystitis experience a 15% probability of hospitalization; and (iv) the probabilities of hospitalization for the three conditions – diabetes, refractive errors, cholecystitis – behave independently and combine together according to the laws of probability. Using these conditions, a hospitalized subset was defined from Berkson's fabricated general population (Tables 1 and 2). Comparison of these two populations reveals that the association between cholecystitis and diabetes apparent in the hospitalized data (odds ratio of 1.89 calculated from data in Table 2) is not indicative of the "true" association (or lack of it) in the general population (odds ratio of 0.90 calculated from data in Table 1).

Berkson's bias remained theoretical and was largely disregarded by epidemiologists [3] until 1978 when Roberts et al. provided the first empirical support using data from household surveys of health care utilization [2]. They examined associations between several medical conditions and documented

Table 1 Cholecystitis and diabetes, hypothetical general population[a]

	Cholecystitis	Not cholecystitis	Total
Diabetes[b]	3 000	97 000	100 000
Refractive errors (not diabetic)	29 700	960 300	990 000
Total	32 700	1 057 300	1 090 000
Cholecystitis in diabetic group			3%
Cholecystitis in control group (refractive errors)			3%
Difference			0%

[a]Adapted from [1].
[b]10 000 of the 100 000 cases of diabetes also have refractive errors (300 cases with cholecystitis and 9700 cases without cholecystitis); the refractive errors control group contains no known cases of diabetes.

Table 2 Cholecystitis and diabetes, hypothetical hospital population[a]

	Cholecystitis	Not cholecystitis	Total
Diabetes	626	6 693	7 319
Refractive errors (not diabetic)	9 504	192 060	201 564
Total	10 130	198 753	208 883
Cholecystitis in diabetic group			8.55%
Cholecystitis in control group (refractive errors)			4.72%
Difference			+3.83%

Hospital admission rates for cholecystitis = 0.15, diabetes = 0.05, refractive error = 0.20.
[a]Adapted from [1].

significant differences between community- and hospital-based risk estimates. These **biases** occurred in both directions.

Berkson's original representation of the admission rate bias was based on a conservative assumption of independence for disease-specific admission rates [1]. In practice, however, a given medical condition may exacerbate a second condition, increasing the probability of differential hospitalization rates. Additionally, other circumstances such as the manifestation and severity of symptoms, treatment regimen of choice, and specialization of certain hospitals (or physicians practicing within certain hospitals) in treating given medical conditions, may further increase the disparity between case and control admission rates.

Berkson's fallacy has been primarily described for a certain subset of analyses in which the association of interest is between two medical conditions. It is conceivable that a similar bias might impact **case–control studies** considering a nonmedical **explanatory variable**, if: (i) the explanatory variable is represented disproportionately in a hospital setting; and (ii) cases and controls experience differential hospital admission rates. Berkson gives a hypothetical example of a study of occupation as an explanatory variable for heart disease in which one occupation group is more likely to present to a hospital for heart disease treatment than another.

Finally, Berkson's bias may have applications beyond the hospital setting. For example, a study of drug use and violent crime in a prison population, using nonviolent criminals as the control group, might result in a different risk estimate than the same study performed in a community-based population.

It is not possible to correct for admission rate bias during analysis. Berkson's bias, like other biases, is a design issue that needs consideration prior to initiating a case–control study drawing participants from a select segment of the general population.

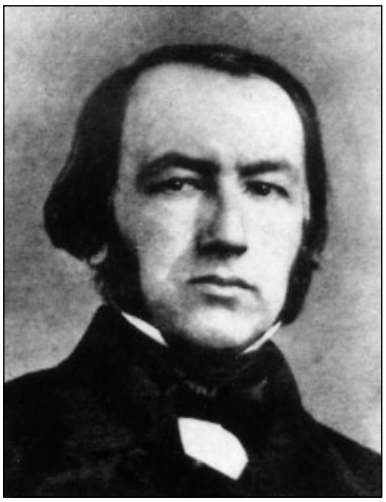
LAURA A. SCHIEVE

Bernard, Claude

Born: July 12, 1813, in St-Julien, France.
Died: February 10, 1878, in Paris, France.



A young man of a very modest extraction (his parents were vineyard workers), Claude Bernard received a pious and humanistic education, and started working as an assistant pharmacist. At 21 he ventured to Paris with the ambition of making a career in literature. He was advised rather to learn a job that would enable him to earn a living. He then turned to medicine, which he studied conscientiously, although clinical work did not much appeal to him. As a resident at the Hotel-Dieu, under François Magendie, he realized what he really wanted to do: experimental work in physiology. For four years he assisted Magendie in his laboratory at the Collège de France, and became an expert at using animal vivisection to trace physiologic facts.

After graduating as an MD with a thesis on gastric juice (1843), he failed to get a teaching position in Paris and reluctantly considered settling as a country doctor in his native province of Beaujolais. In the meantime, he spent his wife's dowry trying to run a private research laboratory of his own, in the latin quarter in Paris. Finally, at the end of 1847, he was appointed as substitute of Magendie at the Collège de France. When in 1852 Magendie retired he was entrusted with his teaching post and his laboratory. He officially became professor of medicine at the Collège after Magendie's death in 1855. The years 1843–1855 were a very creative period, fertile in discoveries: on the nerve control of gastric digestion (1843–1845); on the digestive role of bile and on the functions of cranial nerves (1844–1845); on the mechanism of carbon monoxide intoxication and on the inhibitory action of the vagus nerve on the heart (1846); on the glycogenic function of the liver (1848); on the role of the pancreas and on the metabolism of carbohydrates (1849); on curare poisoning, on vasomotor nerves (1852); and so on. His results on the release of sugar by the liver were presented as a thesis for the doctorate in science (1853). A chair of general physiology was then created for him at the Faculty of Sciences of the University of Paris (1854), and later transferred to the Museum d'Histoire Naturelle (1868), while he went on teaching experimental medicine at the Collège de France. In the later part of his life, Bernard was elected to the Académie des Sciences (1854), to the Académie de Médecine (1861), and to the Académie Française (1869). He was the first French scientist to be honored with a state funeral.

Bernard's teaching at the Collège (ten volumes of *Lessons* were published) attracted large audiences of physicians and physiologists from all over the world. Although not a brilliant lecturer, he communicated a vivid sense of laboratory work in the making: describing techniques such as the experimental section of nerves, showing how experiments are guided by preconceptions (hypotheses), and how preconceptions are dismissed (refuted) by experimental arguments. His teaching at the Sorbonne and at the Museum was more theoretic. It reflects the philosophical turn that Bernard took in his later years, especially when, from 1860, several episodes of illness occasioned prolonged stays for recovery in his native village. He then attempted to conceptualize both his research methodology and his project for the development of the science of general physiology that he had helped to shape.

The *Introduction to the Study of Experimental Medicine* (1865) was meant as a preparatory step toward a comprehensive treatise on the *Principles of Experimental Medicine*, which was never completed (a posthumous putative reconstruction of the *Principles*, based on draft chapters, was published in 1947). The *Lessons on the Properties of Living Tissues* (taught at the Sorbonne), published in 1866, stressed that general physiology aims at identifying traits which are identical in all living animals,

thus revealing the essence of vital phenomena. The *Lessons on the Vital Phenomena Common to Animals and Plants* (taught at the Museum), published in 1878, right after Bernard's death, are an exacting meditation on the unity of living processes and on the intricacy of organic construction and destruction in such processes.

Bernard's views on biostatistics are stated in the *Introduction* (see Part II, Chapter 2, section "De l'emploi du calcul dans l'étude des phénomènes des êtres vivants; des moyennes et de la statistique"), and more explicitly in the draft versions of the *Principles* (especially Chapter VI and VII): "It is easier to statistically count cases pro and con than to conduct proper experimental reasoning" (*Principles*, VII). Bernard wanted to take medicine from the state of "a conjectural science based on statistics" to the state of "an exact science based on experimental determinism". It is not sufficient, he said, to observe (for instance) that inoculation protects against smallpox in 95% of cases. You want to know the exact mechanism by which inoculation is effective, and why it fails to work in particular cases (exceptions do not occur just by chance – they must be explained). Statistical knowledge is descriptive; it has no explanatory power. So-called statistical "laws" are "true in general and false in particular". Should medicine be practiced as an "active science" rather than as an art of guessing, physicians would track physiologic processes in the laboratory up to the point at which there is no uncertainty left.

Bernoulli Family

Of the many distinguished members of the Bernoulli family of Basle, Switzerland, three in particular made important contributions to the development of probability, statistics, and epidemiology: James (1654–1705) and his nephews Nicholas (1687–1759) and Daniel (1700–1782), sons of two of his brothers. The family had originally come to Basle from Antwerp as Protestant refugees, fleeing the government of the Duke of Alba.

James's reputation rests on his posthumous *Ars conjectandi (The Art of Conjecture)* brought out in 1713 by Nicholas. The first of the four parts is a commentary, with text, on Christian Huygens' book *De ratiociniis in aleae ludo (On Reckoning in Games of Chance)*, which had appeared in 1657; part II, on permutations and combinations, is a generally inferior version of **Pascal's** similar *Traité du triangle arithmétique* (published in 1665), with which James was unfamiliar, but it does contain the **binomial distribution** which Pascal had only given for the case of equal chances (hence "Bernoulli trials"); and part III applies the methods discussed earlier to games of chance. Part IV is the seminal part of the work, in which James inaugurates statistical **estimation** theory by stating and proving the first **limit theorem** in probability, the **law of large numbers**.

Nicholas, besides seeing his uncle's book through the press, became interested in 1712 in the biostatistical problem of estimating the probability of a birth being male from some data, and then comparing the distribution of the observations with the binomial model. To do this, he needed an approximation to the binomial distribution, which led him to improve James's limit theorem, sharpening two of the inequalities involved. Nicholas was also the originator, in 1713, of the St Petersburg problem, famous in probability theory as a game with an infinite mathematical **expectation** – so what should be a fair stake?

To Daniel, we owe a novel derivation of the **normal distribution** from the binomial (also in connection with sex-ratio data), the first explicit commendation of the method of **maximum likelihood** for estimation (1778), and a suggested resolution of the St Petersburg paradox (1738). For this, he applied the Pascalian notion of **utility** to the value of money, arguing that the utility of large sums fell away so that the expected utility was not infinite, and that therefore a finite stake was in order. This established him as one of the founders of mathematical economics. He made many contributions to applied mathematics, including the "Bernoulli equation" for fluid flow (in *Hydrodynamica*, 1738).

In 1760, Daniel discussed a model for the mortality from smallpox in various age groups, deriving a differential equation relating the number of survivors and the number of those at age x who had not yet had smallpox. In the same year, he advocated inoculation against smallpox as a means of increasing average survival times (*see* **Life Expectancy**).

Bertillon Family

A dynasty of French natural scientists and physicians interested in vital and social statistics [1].

Louis-Adolphe Bertillon (1821–1883), a physician, was a son-in-law of Achille Guillard (1789–1876), the "founder" of **demography**. Bertillon studied the use of **means** and distributions (e.g. of heights), following **Quetelet**. He was familiar with the work of **William Farr**, and he corrected some of Guillard's methods.

Jacques Bertillon (1851–1922), son of Louis-Adolphe and also a physician, was a demographer and crusaded for a higher French birth rate. In 1893, he chaired a committee of the **International Statistical Institute** to prepare a new classification of causes of death, synthesizing methods used in different countries (*see* **International Classification of Diseases (ICD)**).

Alphonse Bertillon (1853–1914), another son of Louis-Adolphe, produced a system of identification of criminals and other individuals ("bertillonage"), by bodily measurements, photographs, and so on. Fingerprints had been used earlier, and were espoused by **Galton**.

Beta Distribution

The beta distribution is a probability distribution of a continuous random variable taking value in the interval [0, 1]. Its probability density function is

$$f(x; a, b) = B(a, b)^{-1} x^{a-1} (1 - x)^{b-1}, \quad 0 \leq x \leq 1,$$

where a and b are parameters satisfying $a > 0$ and $b > 0$, and where $B(a, b) = \int_0^1 t^{a-1}(1 - t)^{b-1}\, \mathrm{d}t$ is called the beta function. The rth moment of the distribution is

$$\mathrm{E}(X^r) = \prod_{i=0}^{r-1} \frac{a + i}{a + b + i}.$$

The mean and variance are

$$\mathrm{E}(X) = \frac{a}{a + b},$$

$$\mathrm{var}(X) = \frac{ab}{(a + b)^2(a + b + 1)}.$$

The beta density function has a variety of possible shapes, including mound-shaped when a and b exceed 1, **U-shaped** when they are both less than 1, strictly increasing when $a > 1$ and $b = 1$, strictly decreasing when $a = 1$ and $b > 1$, and the **uniform distribution** over [0, 1] when $a = b = 1$. It is symmetric about 1/2 when $a = b$, and otherwise the direction of **skewness** is determined by $a - b$.

If X has a beta distribution with parameters a and b, then $(b/a)X/(1 - X)$ has an ***F* distribution** with $2a$ and $2b$ degrees of freedom. If Y_1 and Y_2 are independent **gamma** random variables with unit scale parameter and shape parameters a and b, then $Y_1/(Y_1 + Y_2)$ has a beta distribution with parameters a and b.

The beta distribution is often used to model proportions. For instance, in **Bayesian** inference it is the conjugate **prior distribution** when the observations have a **binomial distribution**, given the proportion. In that case, the marginal distribution of the observations is the **beta-binomial**. The Dirichlet distribution is a multivariate form of the beta.

For further details about the beta distribution, see [2]. An alternative two-parameter family over the unit interval, called the *logistic-normal* [1], assumes that the logit of the variable has a normal distribution.

Beta-binomial Distribution

It is often the case that an individual provides repeated binary outcomes. For example, in ophthalmology, a subject almost always has information available on the right and left eyes. In obstetrics, one sometimes has outcomes from multiple pregnancies of the same woman. The primary outcome variable is often binary (e.g. reduced visual acuity = visual acuity 20/50 or worse in an individual eye). Such data are referred to as *clustered*. Clusters may be defined not only by replicates for a single individual, but also by outcomes for different related cluster members (e.g. members of a family). The use of standard methods for analyzing categorical data (e.g. the chi-square test for 2×2 tables) which are usually based on either the **binomial distribution** or the **hypergeometric distribution** using the cluster member as the unit of analysis is invalid because the assumption of independence of binary outcomes for different cluster members is often not correct.

An attractive alternative model in this setting is the beta-binomial model.

Definition

Under the beta-binomial model, we assume that there are t_i cluster members in the ith cluster, $i = 1, \ldots, k$. For the ith cluster (or unit) we assume that any cluster member (or subunit) has probability p_i of being affected, where p_i follows a **beta distribution** with parameters a and b. A beta distribution with parameters a and b (both > 0) is a probability distribution over the interval (0,1) with density $\{\Gamma(a+b)/[\Gamma(a)\Gamma(b)]\}p^{a-1}(1-p)^{b-1}, 0 < p < 1$. It has mean $= a/(a+b)$ and variance $= ab/[(a+b)^2(a+b+1)]$. Conditional on p_i, the outcomes for different cluster members are independent. The resulting marginal distribution of $Y_i =$ number of affected cluster members in the ith cluster is referred to as the beta-binomial distribution, which is given by

$$\Pr(Y_i = k) = \binom{t_i}{k} \frac{a_k b_{t_i - k}}{(a+b)_{t_i}}, \quad k = 0, 1, \ldots, t_i, \tag{1}$$

where $a_k =$ the rising factorial $\prod_{j=0}^{k-1}(a+j)$ and b_{t_i-k} and $(a+b)_{t_i}$ are defined similarly.

The expected value of Y_i is $t_i a/(a+b)$ and the variance is $t_i ab/(a+b)^2 + t_i(t_i-1)ab/[(a+b)^2(a+b+1)]$. Standard maximum likelihood methods can be used for parameter estimation [2, 3, 10]. Notice that the variance of the beta-binomial distribution is always greater than the corresponding variance of a binomial distribution with the same expected value, which is given by $t_i ab/(a+b)^2$. This property is referred to as **overdispersion** or extrabinomial variation and provides a rationale for why the beta-binomial distribution can be used more generally to model overdispersed binary data.

Measures of Dependence Among Subunits within a Cluster

The beta-binomial model can be used to quantify dependence between outcomes for two subunits within the same cluster. Two measures that are useful for this purpose are the intraclass **correlation** and the pairwise **odds ratio**. These are given by

$$\begin{aligned} &\text{intraclass correlation} \\ &\quad = \operatorname{corr}(y_{ij_1}, y_{ij_2}) \\ &\quad = 1/(a+b+1), \end{aligned} \tag{2}$$

$$\begin{aligned} &\text{pairwise odds ratio} \\ &\quad = \frac{\Pr(y_{ij_1}=1, y_{ij_2}=1)\Pr(y_{ij_1}=0, y_{ij_2}=0)}{\Pr(y_{ij_1}=1, y_{ij_2}=0)\Pr(y_{ij_1}=0, y_{ij_2}=1)} \\ &\quad = \frac{(a+1)(b+1)}{ab}, \end{aligned} \tag{3}$$

where y_{ij} is the outcome for the jth subunit within the ith cluster. In words, the pairwise odds ratio is a measure of the odds in favor of disease for the j_1th subunit if the j_2th subunit is affected divided by the odds in favor of disease for the j_1th subunit if the j_2th subunit is not affected. For either measure, as $a+b$ decreases, the aggregation between subunits in a cluster increases. If $a+b$ approaches ∞, then the correlation between subunits approaches 0 and the beta-binomial distribution converges to the binomial distribution. If $a+b=0$, then there is perfect correlation between subunits within a cluster. Note that negative correlation is not allowed under the beta-binomial distribution.

The Treatment of Covariates

An important issue is how to use the beta-binomial distribution in the presence of **covariates**. If there is only a single binary covariate (e.g. a treatment indicator variable in a clinical trial), then a simple approach is to fit separate beta-binomial models for a treated and control group and compare the parameters for the two groups. In particular, disease prevalence can be estimated by $a/(a+b)$ and compared between the two groups [11]. More generally, several authors have considered generalizations of the beta-binomial model for correlated binary data in the presence of covariates. Prentice [4] has proposed the following model for the joint distribution of t correlated binary variables in the presence of unit-specific covariates x:

$$\Pr(y_{i+}|x) = \frac{\prod_{j=0}^{y_{i+}-1}[p(x)+\lambda(x)j]\prod_{j=0}^{t-y_{i+}-1}[1-p(x)+\lambda(x)j]}{\prod_{j=0}^{t-1}[1+\lambda(x)j]}, \quad (4)$$

where $p(x)$ is a parametric model relating the marginal probability of disease to x, $\lambda(x) = \delta(x)/[1-\delta(x)]$, and $\delta(x)$ is the intraclass correlation for disease probabilities between cluster members as defined above. This model has the advantage that (i) the marginal probability is explicitly specified as a function of covariate values, and (ii) it reduces to a beta-binomial model if no covariates are present. The disadvantages are (i) only unit-specific covariates are possible, and (ii) the dependence among cluster members is parameterized by a correlation rather than an odds ratio; in general, constraints need to be placed on the correlations so that the probabilities in (4) are ≤ 1.

Rosner [6] proposed a polytomous logistic regression model (*see* **Polytomous Data**) which allows for both unit- and subunit-specific covariates for clustered binary data of the form

$$\Pr(y_i|x_i) = \frac{a_{s_i}b_{t_i-s_i}\exp\left[\sum_{j=1}^{t_i} y_{ij}(\beta x_i^{(0)}+\gamma x_i^{(j)})\right]}{\sum_{z_i} a_{z_{i+}}b_{t_i-z_{i+}}\exp\left[\sum_{j=1}^{t_i} z_{ij}(\beta x_i^{(0)}+\gamma x_i^{(j)})\right]}, \quad (5)$$

where $x_i^{(0)}$ is an $(N_p \times 1)$ vector of unit-specific covariates, $x_i^{(j)}$ is an $(N_e \times 1)$ vector of subunit-specific covariates, $s_i = y_{i+}$, and the summation in the denominator is over all possible permutations $z_i = (z_{i1}, \ldots, z_{it_i})$ of zeros and ones. If no covariates are present, then this model reduces to a beta-binomial distribution with parameters a and b. The measure of dependence in this model is the pairwise odds ratio as defined in (3), which can be shown to be independent of covariate values x. The most natural interpretation of the regression parameters is in conditional form as follows:

$$\ln\left[\frac{p_{ij}}{(1-p_{ij})}\right] = \ln\left[\frac{(a+s_{-j})}{(b+t_i-1-s_{-j})}\right] + \beta x^{(0)} + \gamma x^{(j)}, \quad (6)$$

where s_{-j} is the number of successes among the $t_i - 1$ subunits excluding subunit j. In this context, if $x_p^{(0)}$ is the pth unit-specific variable, then $\beta_p = \ln$ (odds in favor of disease for a 1 unit increase in $x_p^{(0)}$ holding all other variables constant including the disease status of the other cluster members). Thus, β (and likewise γ) has a conditional rather than a marginal interpretation. Qu et al. [5] and Connolly & Liang [1] have considered an extension of (5) of the form

$$\Pr(y_i|x_i) = c(\theta,\beta,\gamma)\exp\left[\sum_{k=0}^{s_i-1} f_t(k,\theta) + \sum_{j=1}^{t_i} y_{ij}(\beta x_i^{(0)}+\gamma x_i^{(j)})\right], \quad (7)$$

where θ is a vector of correlation parameters and $f_t(k,\gamma)$ is an arbitrary function representing the log odds in favor of being affected at a specific visit conditional on there being k successes among the remaining $t_i - 1$ visits and all covariate values being 0. It can be shown that (5) is a special case of (7).

More Complex Patterns of Correlation

An implicit assumption of the beta-binomial model is that subunits are exchangeable within a cluster. A natural generalization is to allow for data structures with multiple levels of nesting. For example, in the ophthalmologic setting one may have data from

several members of the same family where each person provides data on two eyes. In this setting, it would be expected that the correlation between two eyes of the same person is different from the correlation between two eyes from different family members, although both correlations may be greater than zero. To accommodate this data structure [7] let p be the probability that an eye is affected for a person from an average family across all families in the population, let p_i be the probability that an eye is affected for an average person from the ith family, and p_{ij} be the probability that an eye is affected for the jth person in the ith family. We model

$$f_1(p_i|p) \sim \text{beta}\,[\lambda_0 p, \lambda_0(1-p)] \equiv \text{beta}(a, b),$$
$$f_2(p_{ij}|p_i) \sim \text{beta}\,[\lambda_I p_i, \lambda_I(1-p_i)]. \tag{8}$$

The resulting marginal distribution of the p_{ij} is referred to as a *compound beta-binomial distribution* and is a function of p, λ_0 and λ_1. Under this model, the odds ratio between eyes from two different family members is

$$OR_1 = \frac{(a+1)(b+1)}{ab},$$

while the odds ratio between two different eyes of the same person is

$$OR_2 = \frac{(\lambda_1 a + \lambda_1 + \lambda_0 + 1)(\lambda_1 b + \lambda_1 + \lambda_0 + 1)}{(\lambda_1 a)(\lambda_1 b)}.$$

Newton–Raphson methods can be used to obtain **maximum likelihood** estimates of the parameters of this model (*see* **Optimization and Nonlinear Equations**).

Another variant of the beta-binomial model is obtained when one can subdivide a cluster into multiple subclasses, for example when one has both parents and children in the same cluster. In the case of c classes, one wants to generalize the beta-binomial model to allow for $c(c-1)/2$ interclass **correlations** between outcomes for members of different classes, and c intraclass correlation parameters between outcomes for members of the same class. To accomplish this goal, let

$$\lambda_i = \sum_{k=1}^{c} w_{ik}\theta_k, \quad i = 1, \ldots, c, \tag{9}$$

where $\theta_1, \ldots, \theta_c$ are independent beta (a, b) random variables and $\sum_{k=1}^{c} w_{ik} = 1, i = 1, \ldots, c$. It follows that the intraclass correlation between outcomes for subunits in the ith class of the same cluster is given by

$$\rho(y_{ij_1}, y_{ij_2}) = \sum_{k=1}^{c} \frac{w_{ik}^2}{(a+b+1)}, \quad i = 1, \ldots, c, \tag{10}$$

while the interclass correlation between outcomes for pairs of subunits in the i_1th and i_2th class of the same cluster is given by

$$\rho(y_{i_1 j_1}, y_{i_2 j_2}) = \sum_{k=1}^{c} \frac{w_{i_1 k} w_{i_2 k}}{(a+b+1)},$$
$$i_1, i_2 = 1, \ldots, c, i_1 \neq i_2. \tag{11}$$

Note that if $w_{ii} = 1, i = 1, \ldots, c$, then we have c independent subclasses with all intraclass correlations $= 1/(a+b+1)$ and all interclass correlations $= 0$. If $w_{i1} = 1, i = 1, \ldots, c$, then the model in (9) reduces to the ordinary beta-binomial model in (1). Based on (9) one can obtain an explicit function for the joint likelihood of $y = (y_l, \ldots, y_c)$, where y_i is a $1 \times t_i$ vector of outcomes in the ith class. The resulting model is referred to as a beta-binomial mixture model [8, 9].

Bias From Diagnostic Suspicion in Case–Control Studies

Diagnostic suspicion **bias** occurs when there is **systematic error** in case ascertainment. For instance, a knowledge about the subject's prior exposure to a putative cause (family history, being exposed to an epidemic, taking certain drugs, and certain occupational exposure) may increase diagnostic search for the disease, and as a result, exposed subjects are more likely to have the disease diagnosed than the nonexposed [10]. It can occur in both a **case control** and a **cohort study**. In case–control studies, diagnostic suspicion bias is a **selection bias**, whereas in cohort studies, it is considered as a measurement or information bias since it occurs in subjects already included in the study [9].

Diagnostic suspicion bias can result in overestimation of an exposure's effect on the risk of disease [13]. For example, in patients with a suspected risk factor, physicians may perform the diagnosis more carefully. So, they are more likely to make the correct diagnosis in patients with the disease of interest and also more likely to make a **false positive** diagnosis. Conversely, in patients without the suspected risk factors, presence of the disease is less aggressively sought, and consequently, physicians are more likely to make a false negative diagnosis. A false positive diagnosis, however, is unlikely. Figure 1 illustrates the described scenario. Suppose that among the exposed, 90% of subjects who truly have the disease and 20% of subjects who truly do not have the disease are diagnosed to have the disease, while among the nonexposed, 70% who truly have the disease and 0% who truly do not have the disease are diagnosed positive. The unbiased **odds ratio** is AD/BC, while the putative odds ratio becomes $[(0.9A + 0.2B) \times (D + 0.3C)]/[(0.8B + 0.1A) \times 0.7C]$ when diagnostic suspicion bias occurs. Clearly, this odds ratio would in general overestimate the true odds ratio.

Diagnostic suspicion bias is more likely to occur when objective criteria for reliable diagnosis are difficult to establish [12]. For some diseases, such as rheumatoid arthritis, a whole host of symptoms and signs may be present. Different clinicians may interpret these symptoms, signs, and various laboratory test results differently, which may lead to very different diagnoses. Sometimes, diagnoses are classified as "definite", "probable", and "possible". In this situation, with the same borderline symptoms and signs, subjects with the suspected risk factor may be diagnosed "possibly" to have the disease, whereas those without the risk factor may be diagnosed negative.

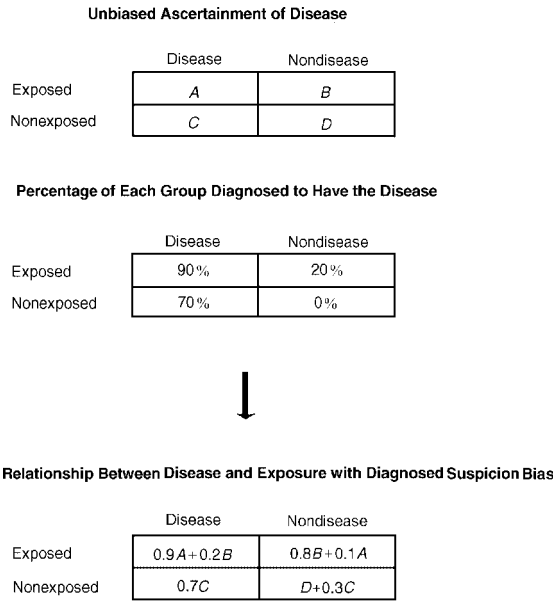

Figure 1 Illustration of diagnostic suspicion bias in case–control studies

Diagnostic suspicion bias is closely related to surveillance bias and **detection bias**. Surveillance bias occurs when individuals under frequent or close surveillance are more likely to have disease diagnosed [11]. For example, postmenopausal women taking estrogen may be more likely to have breast cancer diagnosed because of frequent physician visits. Detection (unmasking) bias occurs when an exposure, rather than causing disease, causes symptoms that precipitate a search for the disease [10]. An early report of postmenopausal estrogens and endometrial cancer was criticized on this ground [5, 6]. It was suggested that subclinical cancers were being diagnosed more frequently in exposed women because estrogen use could cause symptomless patients to bleed, which, in turn, led to more thorough diagnoses. As with diagnostic suspicion bias, surveillance and detection biases can result in a spurious increase in the odds ratios.

Examples of Studies on Checking Diagnostic Suspicion Bias

In a study of oral contraceptives and deep-vein thrombosis and pulmonary thrombosis, Vessey & Doll [14] investigated the possibility that a history of oral contraceptives use might influence doctors' diagnoses. They asked an independent investigator who had no knowledge about the patients' exposure to classify the diagnoses as "possible", "probable", or "certain". It was hypothesized that if the diagnoses were influenced by knowledge of a patient's contraceptive history, the association would be strongest in patients for whom the diagnosis was least certain, because patients in this group were most likely to be diagnosed only because of their oral contraceptives use history. Results indicated, however, that the proportions of subjects using oral contraceptives increased with increasing certainty of diagnosis, suggesting that the clinical diagnoses were not biased by knowledge about the exposure.

Fox & White [3] examined whether diagnostic suspicion bias affected the observed increase in mortality rate of bladder cancer among workers in the rubber industry. The bias might arise from the publicity that followed the initial discovery of excess bladder cancer among these workers. Awareness of the association between work in the rubber industry and bladder cancer among doctors might increase the chance of recording the bladder cancer as the underlying cause on the death certificates of workers in the rubber industry than on the death certificates of other people. The researchers compared death certificates for bladder cancer cases from the rubber industry with those from other groups identified from the National Cancer Registry. They found that proportions of death certificates with mention of bladder cancer as the underlying cause on the certificates were similar between workers in the rubber industry and patients from other occupations, indicating that doctors' awareness did not explain the rise of bladder cancer death among these workers.

Foreman et al. [1] found that intrauterine device (IUD) usage at conception significantly increased septic second-trimester fetal loss. They considered the possibility that, with borderline evidence of infection, patients with an IUD in place might be more frequently diagnosed as septic than those without an IUD in place. To check this bias, they restricted the analyses to only blatant cases (cases with temperature of 39.4°C or higher). The results remained unchanged, indicating diagnosis suspicion bias was not an explanation for the observed association.

Several case–control studies reported a positive association between aspirin use and Reye's syndrome [4, 7, 15]. However, diagnostic suspicion bias may partially explain this association because the diagnosis procedure could be affected by the extensive previous publicity about a relationship between aspirin and Reye's syndrome. Forsyth et al. [2] carried out a further case–control study in which "diagnostic-suspicion" patients (Reye's syndrome was initially suspected but definitely ruled out) were used as an alternative control group. They found that aspirin use in this control group was very low and equal to the rate in the control group identified from communities, suggesting that the diagnosis of Reye's syndrome was not affected by the knowledge of aspirin use and publicity about the association.

Prevention and Minimization

To prevent diagnostic suspicion bias, one must make sure that the disease of interest is sought with equal vigor in exposed and nonexposed subjects [13]. In other words, exposed and nonexposed people should have the same chance to be detected as cases. This may be implausible in circumstances where prevalence cases are selected because diagnoses are made prior to the study. However, multiple data sources can be used to verify diagnoses and minimize **misclassification** [8]. For example, one may review hospital records, death certificates, and pathology reports, in addition to the data from a disease registry, to identify cases.

When cases are gathered prospectively (incidence cases), one important strategy to minimize bias is to ensure that all activities associated with case ascertainment follow the same, standard protocol so that diagnoses are made in the same way in the exposed and nonexposed [8]. In randomized **clinical trials**, outcome assessment is conducted in a blinded manner with regard to treatment conditions. In case-control studies, a blinded assessment requires that neither clinicians nor patients be aware of the study hypothesis. In some cases, independent investigators may be needed to evaluate all available evidence

without having knowledge about the exposure [14] (*see* **Blinding or Masking**).

One way to control diagnostic suspicion bias in data analysis is to stratify cases (*see* **Stratification**) on the basis of certainty of diagnosis or severity of disease [11]. The investigator can also simply restrict the analyses to blatant cases, but this may reduce the **power** of the study. As with other biases in case-control studies, diagnostic suspicion bias should be taken into consideration when a study is conceived.

Bias from Exposure Effects on Controls

In population-based case–control studies, controls are selected at random from the source (or "base") population (*see* **Case–Control Study, Population-based**). In hospital-based case–control studies, cases in the hospital with a disease of interest are compared with controls in the hospital who have other diseases (*see* **Case–Control Study, Hospital-based**). In hospital-based case–control studies, the exposure **odds ratio** comparing cases with controls may be a **biased** estimate of the **relative risk** of disease in the underlying source population if the risks of the control diseases are themselves associated with the exposure under study. For example, in a pioneering hospital-based case–control study of the risk of lung cancer from smoking, Doll & Hill [2] included subjects with bronchitis among the controls. Because the risk of bronchitis is now known to be increased by smoking (*see* **Smoking and Health**), we can infer that estimates of the relative risk of lung cancer from smoking were biased downward by the inclusion of such controls. A quantitative treatment of such bias is given by Breslow & Day [1, pp. 153–154].

MITCHELL H. GAIL

Bias from Exposure Suspicion in Case–Control Studies

Exposure suspicion **bias** is the mirror image of *diagnostic suspicion* bias (*see* **Bias From Diagnostic Suspicion in Case–Control Studies**). It occurs when there is **systematic** error in the ascertainment of exposure. For example, a knowledge of the subject's disease status may increase the intensity of a search for exposure to the putative cause, and as a result, exposure information is gathered more thoroughly in cases than in controls [9]. Exposure suspicion bias is specific to a **case-control studies**, in which exposure is usually ascertained after the outcome event has occurred.

As with diagnostic suspicion bias, exposure suspicion bias can spuriously increase the effect of the exposure on the risk of disease. Consider a study of the presence of a carotid bruit and the occurrence of transient ischemic attack (TIA) [13]. In patients with symptoms of cerebral ischemia, a physician listens very carefully and is able to detect a bruit most of the time if it is truly present. Meanwhile, a **false positive** diagnosis of a bruit is likely to occur owing to awareness of the suspected association. On the contrary, in patients without cerebral ischemia, the presence of a bruit is less aggressively sought, so a **false negative** diagnosis of a bruit is likely to occur. A false positive diagnosis, however, is unlikely. The described scenario is illustrated in Figure 1. Suppose that among the diseased, 90% of subjects who are truly exposed and 20% who are truly nonexposed are detected to have the exposure; while, among the nondiseased, 70% who are truly exposed and 0% who are truly nonexposed are detected to have the exposure. The unbiased **odds ratio** is AD/BC. The putative odds ratio becomes $[(0.9A + 0.2C) \times (D + 0.3B)/(0.7B) \times (0.8C + 0.1A)]$ when exposure suspicion bias occurs. This putative odds ratio would in general overestimate the true odds ratio.

Exposure suspicion bias can arise from several sources. One source relates to clinicians who examine the patients, record the exposure information, and perform histologic assessments and laboratory tests. The second source is the interviewer who inquires about whether or not the patients are exposed to the suspected risk factor. For example, an interviewer

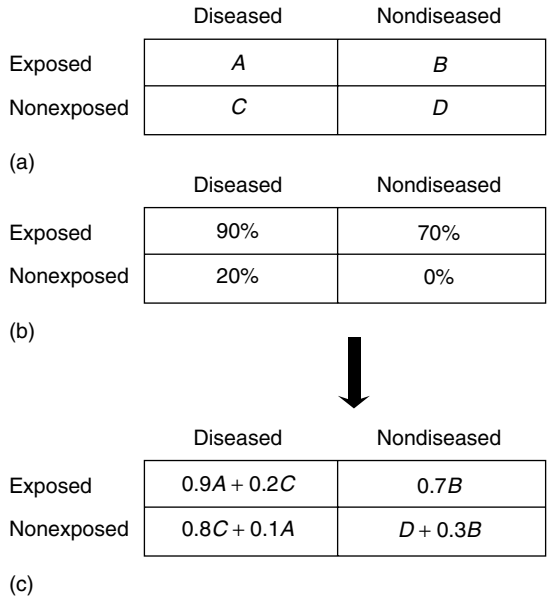

Figure 1 Exposure suspicion bias in case–control studies. (a) Unbiased ascertainment of exposure; (b) the percentage of each group detected to have the exposure; (c) the relationship between exposure and disease with exposure suspicion bias

with knowledge of the study hypothesis may tend to probe the diseased subjects more intensely for histories of exposure and may encourage certain responses among either cases or controls through language, tone, or "body language". A third source is the interviewed subjects or proxies who report or recall exposure information. For example, individuals with specific diseases may be more likely to recall exposures if they suspect that the exposure is related to their disease. Mothers of malformed infants may recall certain exposure more thoroughly than mothers of healthy infants if they believe the exposure to be the cause of the adverse outcome [8]. Differential **recall bias** often tends to overestimate the **risk**, but the opposite may also occur [8].

Examples of Studies on Checking Exposure Suspicion Bias

In Doll & Hill's case–control study of smoking and lung cancer [1], potential bias on reporting of smoking history might arise due to interviewers' knowledge of the diagnosis (*see* **Smoking and Health**).

The researchers checked this possibility by comparing reported smoking habits of patients of confirmed lung cancer with those whose diagnoses were later not confirmed. They found that smoking habits of patients with erroneous diagnoses resembled those of the controls and differed significantly from those of confirmed cases. This indicates that reporting of smoking history was not affected by interviewer's knowledge about the disease status.

Forsyth et al. [4] investigated the possibility of biased recall of medications of the child by the parent or guardian in a case-control study of the association between aspirin use and Reye's syndrome. The bias might arise from physicians' consideration about Reye's syndrome, their repeated questioning about aspirin use, and intensive publicity about the association. It was discounted since the reported aspirin use among those who were suspected initially of having Reye's syndrome, but later were confirmed not to be cases, was found to be as low as in the control group.

MacKenzie & Lippman [7] examined the effect of knowledge about pregnancy outcomes on the reporting of exposure histories by comparing reports from early pregnancy and postdelivery. It was argued that if exposure suspicion bias did occur, cases would add more new information about the exposure and delete less of the previously reported exposure. Results showed that changes in reporting were similar among cases (mothers of died, stillborn, and malformed infants), controls, and mothers whose infants had less serious problems.

Werler et al. [16] compared interview data with exposure information documented during pregnancy in obstetric records and found that serious recall biases existed for many exposure variables. These biases, however, were **nondifferential** in regard to pregnancy outcomes: that is, mothers of severely malformed infants did not recall better or worse than mothers of less severely malformed infants.

Prevention and Minimization

To some extent, the strategies for preventing and minimizing exposure suspicion bias mirror those for preventing and minimizing diagnostic suspicion bias. The key is that the exposure of interest is sought with equal vigor in diseased and nondiseased subjects [13]. In other words, cases and controls should have the same chance to be classified as "exposed" or "nonexposed". This may reduce the degree of differential exposure **misclassification** (*see* **Differential Error**). But nondifferential misclassification caused by the general inability of individuals to report accurately about the histories of exposure may still exist, which often biases the results toward a weak or null association (*see* **Bias Toward the Null**).

In principle, exposure suspicion bias can be diminished by **blinding** the clinicians who perform the physical examinations, histologic assessment, and laboratory tests, the interviewers, and even the subjects themselves to ensure comparability of measurement of the exposure [6]. Blinding implies keeping clinicians, interviewers, and patients ignorant of both the study hypothesis and the classification of the subject as a case or a control. This can be easily achieved for clinicians who perform histologic assessment and laboratory tests. In most actual field operations, blinding interviewers and patients, however, may not be feasible. Nevertheless, **interviewer bias** and differential recall can be reduced by using standardized, uniform data collection procedures and by training the interviewers for unbiased probing [3, 10, 18]. Objective or independent sources of exposure history can also be used.

To address the potential influence of knowledge of disease status on the report of exposure, several authors have advocated the use of "affected", "restricted", or "pseudo" controls [7, 12, 16]. It is argued that if equally sick controls are chosen, interest and/or preoccupation with one's medical state would be similar for the two groups and, as a result, exposure history would be examined or probed in the same way in the two groups. However, use of affected controls may introduce **selection bias** [2, 14] or a subtle **confounder** [5]. To circumvent these problems, one can select controls with a variety of admission diagnoses.

Some authors have suggested that respondents who are aware of the etiologic hypothesis should be excluded from the analyses to control exposure suspicion bias [17]. However, others cautioned that exclusion of "knowledgeable" subjects might introduce selection bias and should not be advocated as general practice [15]. Nevertheless, side-by-side comparison of analyses with and without consideration of subjects' knowledge about the study hypothesis would provide an excellent opportunity to examine whether the knowledge does in fact influence ascertainment of exposure.

Use of biologic markers has received increasing interest in epidemiologic studies [11]. Bio-markers have been developed to assess environmental exposures, nutritional factors, and genetic susceptibility. Although survey methods will continue to play a dominant role in most case-control studies, integration of laboratory methods would in general increase the quality of exposure ascertainment [11].

F.B. HU

Bias from Historical Controls

An historical control trial (HCT) has been defined [8] as a trial that compares the experience of a prospectively treated group with that of either a previously published series or with previously treated patients at the same institution (the historical controls). HCTs are often compared with both randomized **clinical trials** (RCT) and with **observational studies**. In an RCT, treatment assignment is randomly assigned to all subjects (*see* **Randomization**), and **covariate** information and outcomes are collected prospectively. In an **observational study**, treatment assignment is not determined by the investigator. Because RCTs have become the standard by which medical therapies are judged, the focus here will be on the comparison between an HCT and RCT in terms of feasibility, cost, and **bias**.

Advantages of Historical Control Trials

There are both **sample size** considerations and ethical arguments (*see* **Ethics of Randomized Trials**) in support of HCTs. These have been described in [1, 4], and [5].

Sample size considerations center on the reduced number of new patients needed to conduct an HCT with the same **power** as an RCT. As an example, assume that the response, x, in the control group, and, y, in the treatment group, have the same **variance** σ^2 and that there are n_c subjects in the control group and n_T subjects in the treatment group. Then $\text{var}(\overline{x} - \overline{y}) = \sigma^2(1/n_c + 1/n_T)$. A typical clinical trial sets $n_c = n_T = n$. In an HCT in which data for the n_c patients in the control group are already available, only n_T patients – one-half that in the clinical trial – would be needed. If the response in the control group is assumed known with certainty or if n_c is much larger than n_T, only $n_T/2$ – one-quarter that in the clinical trial – would be needed. For rare diseases or for expensive trials the advantage is clear. In addition, a smaller sample size reduces the time required for recruitment and so shortens the trial duration.

Clinical trials are most often undertaken to prove a new treatment superior to standardized ones based on previously accumulated data. As a consequence, a randomized trial allocates to some patients a treatment considered by the investigators to be inferior, while the use of historical controls allows all patients to be given the new, possibly better, treatment. The ethical dilemma of giving a treatment thought to be inferior is avoided. Physicians and patients might then be more willing to participate in a trial when only a single (better) treatment is involved. HCTs are also easier to organize.

Disadvantages

HCTs are actually observational studies, in that the investigator does not prospectively assign a treatment in the control group. In HCTs, the estimated treatment effect may be biased if controls differ systematically from the treatment group in a way that affects prognosis. Differences may occur either in the selection of patients (*see* **Selection Bias**) or in their subsequent evaluation and treatment. The analysis requires either a demonstration that baseline covariates thought to be potentially **confounding** are similarly distributed in the two groups, or a model-based approach to adjust for the baseline differences (see [6] for modeling in the context of **survival analysis**) (*see* **Baseline Adjustment in Longitudinal Studies**).

Sacks et al. [9] note that criteria for inclusion in the treatment group are usually more stringent than for inclusion in the control group (*see* **Eligibility and Exclusion Criteria**). Poor risk patients may not be offered the new treatment, which as a consequence may appear superior. It is also possible that patients with a worse prognosis may be more likely to enter a trial as "last chance" therapy, making the new treatment appear worse. Advances in techniques for cancer staging may also distort comparisons [3]. The less sensitive staging techniques in earlier years make historical controls appear to have less advanced disease, so they will appear to do worse when compared with the treatment group. Ancillary care may also be different for randomized controls, either because of a difference in surveillance or because of medical advancement in other fields.

Several authors have empirically compared HCTs and RCTs designed to answer similar questions. Diehl & Perry [2] matched historical control groups and randomized control groups for six different types of cancers. In 18 of 43 comparisons, survival or relapse-free survival differed by more than 10 percentage points, being worse in the HCT group in

17 of the 18 comparisons. Sacks et al. [9] reached a similar conclusion in a survey of 106 papers on therapeutic questions including cirrhosis with varices, coronary artery disease, acute myocardial infarction, colon cancer, melanoma, and habitual abortion. While only 20% of RCTs found benefit, 79% of HCTs did, despite similar outcomes for the treated patients in the two types of study. The differences were in the outcomes for the control groups, which tended to be poorer in the HCTs. Miller et al. [7] analyzed the results for 221 comparisons from 188 articles in six surgery journals in 1983. For primary outcomes, 79% of 19 HCTs showed the innovation to be better compared with only 50% of 20 randomized controlled trials. For secondary outcomes, 75% of eight HCTs concluded the intervention was better compared with only 57% of 61 randomized controlled trials.

In an RCT, randomization provides a theoretical foundation by which a treatment effect can be estimated and an hypothesis tested without the use of covariate information (*see* **Randomization Tests**). Randomization alone eliminates **bias**. Such is not the case for HCTs, in which the burden is to remove or reduce bias. As a consequence, HCTs may suffer from an inability to convince colleagues who require a RCT for confirmation. Funding for an HCT may then be difficult.

Requirements for a Valid Historical Control Study

Pocock [8] gives four requirements for a valid HCT: (i) the control group has received the precisely defined treatment in a recent previous study; (ii) the criteria for eligibility, workup, and evaluation must be the same (*see* **Outcome Measures in Clinical Trials**); (iii) **prognostic factors** should be completely known and be the same for both treatment groups; (iv) no unexplained indications lead one to expect different results. Gehan [4] adds an additional requirement: (v) if differences in prognostic features exist between the treatment and control groups, these should not be sufficient to explain any observed differences in outcome.

Summary

The potential for bias in historical control trials often requires complex design and analysis. For some therapies, accepted treatments have more commonly come from HCTs than from randomized controlled clinical trials (see Gehan [4] in the context of acute leukemia). In practice, HCTs tend to give results that favor the intervention. HCTs and RCTs are best viewed as complementary techniques. A large-scale randomized trial can be used to confirm the results of HCTs, and HCTs can be used to support the results of RCTs when there is difficulty in repeating trials that have shown a benefit for one of the treatment groups.

Bias from Loss to Follow-up

Loss to follow-up **bias** results when subjects lost from a cohort (*see* **Cohort Study**) have different health response distributions from subjects who remain in follow-up. For example, if sicker patients are lost from a cohort during follow-up, the estimated survival distribution (*see* **Survival Analysis, Overview**) will be biased upward. As another example, if a cohort of subjects with the human immunodeficiency virus (HIV) are being followed in a natural history study to track decreases in T-helper lymphocyte (CD4+ lymphocyte) levels, and if the subjects with low CD4+ lymphocyte levels are dropped from the study in order to begin treatment, then the CD4+ lymphocyte levels in those remaining on study will be upwardly biased. If loss to follow-up bias is greater in an exposed cohort than in an unexposed cohort, the estimates (*see* **Estimation**) of exposure effects will be biased, but if the same degree of loss to follow-up bias operates in both cohorts, **nondifferential error** will result, and estimated exposure effects may be **unbiased** or nearly unbiased.

MITCHELL H. GAIL

Bias from Nonresponse

Nonresponse **bias** results when some members of the intended **study population** fail to provide required data (the nonresponders), and when those who respond are not representative of the entire study population (*see* **Nonresponse**). In comparative studies, such as studies comparing exposed and unexposed **cohorts**, nonresponse bias may severely distort estimates of **exposure effect** if the degree of nonresponse bias differs in the exposed and unexposed groups, resulting in differential nonresponse bias. If the degree of nonresponse bias is the same in the exposed and unexposed groups, then the nonresponse bias is said to be nondifferential, and the bias in the estimate of exposure effect may be minimal, or even zero, depending on which measure of exposure effect is used.

MITCHELL H. GAIL

Bias from Stage Migration in Cancer Survival

> When the Okies left Oklahoma and moved to California, they raised the average intelligence level in both states (attributed to Will Rogers, American humorist, 1879–1935).

Stage, the indicator of a tumor's anatomic dissemination, is a key predictor of cancer survival. In its simplest form, a tumor may be classified as "localized" or "stage I" if there is no evidence of spread of tumor beyond the organ of origin, "regional" or "stage II" if there is evidence of tumor spread to adjacent tissues or lymph nodes, and "distant" or "stage III" if there is evidence that the tumor is disseminated to other organs [1, 7]. "Localized" or "stage I" tumors generally have the best survival **prognosis**, while tumors with distant metastases ("stage III") have the worst. Tumors are "staged" based on morphologic and/or clinical evidence of the tumor's anatomic dissemination. Technological advances in the latter half of the twentieth century have increased the use of and reliance on sophisticated diagnostic imaging procedures for identifying disseminated disease (*see* **Image Analysis and Tomography**).

Feinstein et al. [5] demonstrated that a cancer **cohort** that has undergone use of sophisticated diagnostic imaging will have a different stage distribution than a cohort the members of which were staged with less use of imaging technology. The use of diagnostic imaging uncovers "silent" tumor dissemination to regional and distant sites that previously would have escaped clinical detection. This results in a shift of patients from less advanced to more advanced stages of disease. The effect of this stage migration is to improve cancer survival rates artifactually for both the early stage and late stage patients in the cohort subjected to imaging procedures.

Stage migration and its effect on survival rates were demonstrated in two cohorts of lung cancer patients, one diagnosed between 1953 and 1964 and the other diagnosed in 1977. The latter cohort contained staging data similar to that used in the first cohort; additionally, the latter cohort contained data from diagnostic imaging procedures not available to the first cohort. When six-month survival rates for the two cohorts were compared, the latter cohort had higher survival rates for each stage and for the cohort as a whole (Table 1). When the stage distribution of the two cohorts was compared, the latter cohort had a lower proportion of patients with stage I disease and a higher proportion of patients with stage III disease (Table 2, columns 1 and 2).

Table 1 Six month survival rates for 1953–1964 and 1977 cohorts (data from [4])

	Cohort	
	1953–1964, $n = 1266$	1977, $n = 131$
Stage I	0.75	0.92
Stage II	0.57	0.72
Stage III	0.30	0.42
Total	0.44	0.55

Table 2 Stage distributions of 1953–1964 cohort and 1977 cohort with and without diagnostic imaging data (data from [4])

	1953–1964, $n = 1266$	1977 with imaging data, $n = 131$	1977 without imaging data, $n = 131$
Stage I	0.22	0.18	0.32
Stage II	0.14	0.14	0.19
Stage III	0.64	0.68	0.49
Total	1.00	1.00	1.00

The 1977 cohort was then staged using only those data points available on the first cohort (Table 2, column 3). Without 1977 imaging data, 32% of the 1977 cohort were classified as stage I, compared with 18% when imaging data were used (Table 2, column 2). This reflects a "migration" of cases out of stage I to more advanced stages with the use of diagnostic imaging. While 49% of the 1977 cohort were classified as stage III without imaging data, 68% of the 1977 cohort were classified as stage III when imaging data were used. The stage migration from less to more advanced stages in this cohort with the use of diagnostic imaging data is detailed in Table 3.

The effect of stage migration on cohort survival rates was demonstrated by applying a standardized clinical staging system to both cohorts. There were no clinically or statistically significant differences in survival rates between the two cohorts when members were staged using standardized clinical criteria. The authors concluded that the increase in survival rates (shown in Table 1) between the two cohorts was a

Table 3 Stage migration of 1977 cohort cases when diagnostic imaging data were applied (data from [4])

Number of cases without imaging data		Number of cases with imaging data		
		Stage I	Stage II	Stage III
Stage I	42	24	1	17
Stage II	25	0	17	8
Stage III	64	0	0	64
Total	131	24	18	89

statistical artifact, rather than a real improvement in lung cancer survival [5].

The artifactual increase in survival rates over time is due to the shift of previously undetectable poor-prognosis patients (those with clinically "silent" metastases) from stage I to more advanced stages. When these poorer prognosis patients are removed from the best prognosis group, the survival rate of that group increases. Since their advanced disease is asymptomatic ("silent"), their prognosis is somewhat better than that of the original members of the poorest prognosis group (stage III), whose advanced disease is symptomatic. This raises the survival rate of the poor prognosis group, and of the cohort as a whole, without any changes in individual survival times. To paraphrase the quote attributed to Will Rogers, "When the poor prognosis patients left the best prognosis group and moved to the poorest prognosis group, they raised the survival rates in both groups".

Although the Will Rogers Phenomenon was identified and described in the comparison of cancer cohorts from different eras in time, it can occur at any time when staging methods vary between the cohorts compared. For example, the comparison of survival rates in concurrent cohorts from different geographic regions having diversity in access to imaging technology may be subject to this type of **bias**.

A slightly different form of stage migration may occur with advances in cancer treatment. This was demonstrated by Bosl et al. [2] in patients who received platinum-based chemotherapy for advanced stage germ cell tumors. As the success of this chemotherapy regimen for treating advanced disease became known, clinicians began using it for early stage germ cell tumors. Previously, these localized tumors would have been treated with surgery or radiation alone. This shifted better-prognosis patients into chemotherapy treatment (formerly reserved for poorest prognosis patients), thus improving survival rates for chemotherapy. Additionally, use of diagnostic imaging procedures increased for germ cell tumors, resulting in the classic stage migration bias described above.

Stage migration resulting in artificially inflated cancer survival rates can be avoided by ensuring that reproducible staging methods are used for study cohorts. Standardized clinical staging systems that consider data available from every patient, regardless of access to diagnostic imaging technology, have been advanced for lung and prostate cancer [3, 4, 6].

Bias from Survival in Prevalent Case–Control Studies

In a prevalent case–control study, the exposures of prevalent cases sampled from among living cases are compared with the exposures of living noncases (*see* **Case–Control Study, Prevalent**). Because an exposure that causes disease may also influence the probability that an incident case will survive long enough to be sampled from the population of prevalent cases, exposure **odds ratios** from prevalent case–control studies may yield **biased** estimates of the odds ratio of etiologic interest that relates exposure to the risk of incident disease.

(*See also* **Bias, Overview**; **Biased Sampling of Cohorts**)

MITCHELL H. GAIL

Bias in Case–Control Studies

In recent years, the concept of a *study base* [5, 10, 26, 28] as the source from which any analytical epidemiologic study is derived has gained widespread acceptance [25]. Under this concept, **case–control** and **cohort studies** represent alternative approaches to sampling and information gathering from a definable population/time experience, and the **biases** that arise are a consequence of doing so inappropriately. A common earlier view [11] was that case–control studies are uniquely susceptible to bias because they "look back" from the outcome to the exposure, whereas cohort studies "look forward". For that reason, it has sometimes been claimed that case–control studies are intrinsically more susceptible to bias than cohort studies. Today, it is better recognized that while certain biases occur more commonly when using one or the other approach, others affect them equally, and the problems are not fundamentally different.

The unifying concept of a single study base might be expected in its turn to lead to unified definitions of bias, applicable both to case–control and cohort studies, and attempts to create such definitions have been made [18, 42]. But the matter is complex, and thus far none has gained wide currency. In this article, we use the existing terminology as applied to case–control studies [3, 25].

Bias is present in a case–control study if there is systematic distortion in the data that leads to an **odds ratio** estimate that is different from the true odds ratio in the study base. Because the bias is systematic, large sample sizes do not eliminate it; indeed, the only effect of enlarging sample sizes is to produce biased estimates that are more precise. Bias may arise as a consequence of **systematic errors** in the selection of cases or controls, or errors in the recording of exposure data, or because of **confounding**. When there is **nondifferential** misclassification of exposure data among cases and controls, the usual effect is to bias odds ratio estimates towards unity (*see* **Bias Toward the Null**); if such misclassification is substantial, so may be the bias. Failure to adjust for confounding may distort odds ratio estimates towards or away from unity and, again, the bias may be substantial. The reader interested in a discussion of nondifferential misclassification is referred to the articles **Misclassification Error** and **Measurement Error in Epidemiologic Studies**. Here, we focus on two remaining sources of distortion, **selection bias** and **information** bias. The term information bias is sometimes used to denote both nondifferential and differential misclassification of exposure [36]; here, we use it to denote only differential misclassification (*see* **Differential Error**).

Selection Bias

Selection bias exists when cases or controls are selected in a way that is not representative of the respective exposure distributions in the study base.

Specification of the Study Base

A fundamental step in the avoidance of selection bias is to ensure that the cases and controls are drawn from the same study base. Otherwise, if the **prevalence** of exposure is different in the different bases, bias is unavoidable. A primary study base is one in which the population/time experience, including the cases that occur, can be specified (e.g. new cases of acute myeloid leukemia (AML) occurring in the population of Massachusetts from 1990 to 1994). In a **population-based case–control study**, all cases are identified and selected; alternatively, a representative sample (e.g. a **random sample**) is selected. In either instance, a properly specified **control** series consists of noncases sampled from the same study base. When the base is well defined, and all cases are identifiable, it is possible in principle to sample them using methods that are **unbiased**. In practice, however, problems such as **nonresponse** may nonetheless lead to bias, as discussed below.

Sometimes it may not be possible to specify a primary base, as happens when a series of cases is selected without full insight into the population/time experience from which they are drawn (e.g. new cases of AML diagnosed in one hematology laboratory from 1990 to 1994). The secondary study base may then be conceived of as that population/time experience from which any person would have been selected as a case had he (or she) developed the disease under study. The proper selection of **controls** requires that they be sampled from that hypothetical secondary study base. Operationally, such controls

are often sampled from the same source as the cases (in this example, the control series could perhaps comprise a sample of persons with normal blood counts, recorded in the same laboratory). In other words, certain selection characteristics of the cases determine the secondary study base, which cannot otherwise be specified. Since it is not possible to identify members of a secondary base explicitly, it is necessary to rely on judgment and experience in order to select controls likely to be representative of the exposure in the hypothetical base.

It is worth illustrating how incorrect specification of a secondary study base may give rise to selection bias. Consider a hypothetical study of radon exposure and lung cancer, carried out in one hospital. The hospital has a large thoracic surgery department and selectively admits lung cancer cases from an entire city, in some areas of which household radon levels are high, while in other areas they are low. The hospital admits patients with conditions other than lung cancer only from an immediately adjacent area, in which household radon levels are high. In this example, the cases and controls have not been selected from the same study base, the exposure rates in the different bases are different, and the data are biased. The bias could only be overcome if the case series were to be restricted to those resident in the same area as the controls – in which case the comparison groups are now drawn from the same study base.

Selection Bias due to Nonresponse

Assuming the study base is correctly specified, selection bias may nevertheless arise if there is differential sampling or identification of cases and controls. A common way in which differential sampling may occur is if there are substantial losses in the enrollment of cases or controls originally deemed eligible for inclusion (nonresponse). In a population-based case–control study, all cases, or a representative sample of those that occur in the study base, are included. Alternatively, in a study with a secondary base, the cases should be representative of those occurring in that base (e.g. a single hospital). In each instance, potentially eligible controls should constitute a representative sample of all noncases in the same base. In practice, however, it is virtually inevitable that some of the cases or controls initially specified as eligible will not be enrolled (e.g. because of failure to trace subjects, refusal to participate, severe illness, or death). If, either among the cases or the controls, the exposure rate is systematically different among those who are and are not enrolled, there is selection bias due to nonresponse.

Bias due to nonresponse is negligible if close to 100% of the cases and controls scheduled for sampling are successfully enrolled. Some studies come close to meeting that objective. Other studies do not, and the greater the proportion unenrolled, the greater must be the concern about possible selection bias. Hospital-based case–control studies tend to have higher response rates than population-based studies, especially if it is necessary to collect biological samples.

In the face of high nonresponse rates, some limited reassurance about the absence of material selection bias may be gained when it can be shown that distributions of known characteristics (such as age, sex, or residence) are similar among enrolled and unenrolled subjects. That reassurance may be unjustified, however, if the compared variables are not themselves correlates of the exposure.

Sensitivity analyses are sometimes used in an attempt to cope with high nonresponse rates [15]. Varying assumptions are made about possible exposure rates among unenrolled subjects, and their effects upon the magnitude of any given association are then assessed. Clearly, however, the assumptions may be incorrect, and that possibility limits the interpretability of the data. In general, the more the attrition, the greater is the potential for bias. To limit this source of bias, there is simply no substitute for high enrollment rates.

Selection Bias in the Identification of Study Subjects

Selection bias may also arise if cases or controls are identified in a way that is not independent of the exposure (*see* **Detection Bias**). To illustrate how the biased identification of cases may occur, consider a hypothetical example in which each of two women has a tender and swollen leg due to deep vein thrombosis (DVT); one woman takes oral contraceptives (OCs – a known cause [40]), the other does not. The OC taker is aware that she is at risk of DVT, and so consults her physician, who correctly makes the diagnosis and admits her to a hospital; the nonuser stays home, undiagnosed; both women recover. Even though the diagnosis, when made, is

correct, the case identification is incomplete, and exposure-dependent: a case–control study that enrolls cases of DVT, regardless of whether it is population-based or derived from a secondary study base, would overestimate the association with OC use, because knowledge of the exposure increases the likelihood that exposed cases would be included in the study.

This type of selection bias may take many forms, as can be illustrated further by the following examples. In a study of breast cancer risk in relation to female hormone use, "screening" or "detection" bias may arise if hormone users are more commonly subjected to mammography than nonusers (e.g. because of concern about possible breast cancer risk). As a result, users are more commonly diagnosed than nonusers as having breast cancer that might not otherwise have become clinically apparent for many years [39].

There are instances in which the biases brought about by **screening** may not be at all subtle. It has been estimated, for example, that over 60% of men over the age of 60 years have asymptomatic prostatic cancer [12]. It is now possible to detect cases that would otherwise have remained asymptomatic for many years, and perhaps for life, by means of a new test (the prostate-specific antigen test [41]). Any **association** of prostatic cancer with a correlate of the likelihood of undergoing such a test (e.g. high socioeconomic status) would likely be biased. That bias may be reduced, or perhaps avoided, in a study restricted to cases that must inevitably come to diagnosis, regardless of screening, because of symptoms that oblige them to seek medical care, such as hematuria or bone pain due to metastases. As a general rule, studies that enroll cases (or controls) from screening programs run a substantial risk of selection bias [4, 29].

A similar bias arises when registries that selectively record exposed cases are used as sources for case enrollment (*see* **Disease Registers**). Perhaps the best-known example of this type was the American Registry of Blood Dyscrasias [48], which was initiated in the mid-1950s and maintained for over a decade following reports of an association of aplastic anemia with the use of the antimicrobial drug, chloramphenicol [44]. Exposed cases were far more likely than nonexposed cases to be reported. There is little doubt that chloramphenicol does indeed increase the risk of aplastic anemia, but it is now clear that the association was overestimated [19]. This example illustrates how important it is to ensure that *all* cases within any specified study base, whether primary or secondary, should have the same chance of being identified and included in a case–control study, regardless of exposure status. It also illustrates the limited interpretability of **case series** reported to regulatory agencies, or to medical journals, without reference to the background occurrence of nonexposed cases – or, indeed, without reference to the exposure prevalence among suitably selected controls.

Biased identification of cases may also occur when a cluster of exposed cases gives rise to a hypothesis, and then the same cluster is included in an independent study mounted to confirm the hypothesis. Thus, if a cluster of cases of leukemia occurs in the vicinity of a nuclear power plant [1], it would be inappropriate to include that cluster in an independent study designed to test the hypothesis that leukemia is associated with proximity to a nuclear power plant.

Bias due to the Selection of Nonrepresentative Controls from a Secondary Study Base

Hospitalized patients continue to constitute the most commonly selected controls in case–control research [22, 25, 45–47], and the potential problems posed by their selection serve well to illustrate the biases that may arise when controls are selected from a hypothetical secondary study base.

Particular attention must be paid to ensure that hospitalized patients selected for inclusion as controls have been admitted for diseases that are independent of the exposure under study. An illustration of how bias may occur if this is not done is the classical study by Doll & Hill of smoking and lung cancer [7], in which the control series included patients with chronic bronchitis, a disease not appreciated at the time to be tobacco-related [8, 9]. The magnitude of the association with lung cancer was somewhat underestimated for that reason. The association was nevertheless identified, because most of the control diagnoses were independent of smoking status, and because smoking was more strongly associated with lung cancer than with chronic bronchitis (*see* **Smoking and Health**).

Despite the risk of biases of this type, hospital-based studies have remained a mainstay of case–control research. When well conducted, such studies have continued to document important and valid associations (e.g. OCs and myocardial

infarction [34]). There are several reasons. Interview data are usually less biased among hospital controls (see the section "Information Bias" below), and hospital-based studies are usually easier to conduct than studies that enroll community controls: response rates are usually higher, and when needed, high success rates in obtaining blood or tissue samples can be achieved. Perhaps the most important reason, however, is that there is today a better appreciation of the steps that should be taken to ensure that the selection of hospital controls is unbiased.

In formal terms, the selection of hospital controls is unbiased if the control diagnoses that are selected for inclusion are representative of the exposure distribution in the hypothetical secondary base. In practice, there is usually no reason why such controls cannot be identified if only those persons are selected whose reason for hospital admission (the *primary* diagnosis) is independent of the exposure under study. Those admitted for conditions that are not independent of the exposure should be excluded. When in doubt, one should opt for *exclusion*: what matters is that the selection of those subjects that are *included* should be valid. Clearly, the valid selection of hospital controls calls for experience and judgment. If that judgment is called into question, the interpretation of hospital-based case–control data can sometimes be controversial.

Hospitalized patients, whether cases or controls, commonly have more than one diagnosis, and it is important to note that *secondary* diagnoses are irrelevant to the selection of controls, unless the *secondary* diagnoses have also influenced the selection of the cases (which is unusual). For example, in a study of the risk of myocardial infarction (MI) in relation to OC use [34], cases admitted for a *primary* diagnosis of MI who had a *secondary* diagnosis of diabetes mellitus (a condition that is inversely associated with OC use) were not excluded; correspondingly, controls admitted with *primary* diagnoses unrelated to OC use, such as trauma, but with a *secondary* diagnosis of diabetes, were also not excluded. Instead, potential confounding due to diabetes was controlled in the analysis. If, however, we conceive of a hypothetical study in which patients admitted for MI are excluded if they are also diabetic, then controls admitted for trauma who also happen to be diabetic should also be excluded.

As a general rule, persons whose primary diagnoses are acute conditions for which admission is obligatory (e.g. trauma; appendicitis) meet the requirement of independence, as may persons with other conditions (e.g. elective admission for cataract surgery). However, it is always necessary to consider the particular hypothesis under study, and to use informed judgment. For example, consider a study of the risk of ovarian cancer in relation to OC use [35]: among women hospitalized for trauma, the reason for admission is likely to be independent of the exposure; such women would be eligible as controls. However, if the example is changed to a study of breast cancer risk in relation to alcohol intake [33]), trauma would not be a suitable control diagnosis because its occurrence may not be independent of the exposure.

Reassurance that the identification of hospital controls is unbiased may be gained if the exposure rates among major diagnostic categories (e.g. trauma, acute infections, orthopedic conditions) are uniform: in that circumstance, bias is only possible if the selection of an entire control series is biased, and biased to the same degree for each diagnostic category. However, the confident demonstration of uniformity requires that the categories be large enough to ensure that the rates in each of them are reasonably precise.

As an alternative, it has been suggested [25] that a hospital control series should include as wide a range of diagnoses as possible. If it can be assumed that most of them will be independent of the exposure, then any bias, if present, will be diluted. This latter option is seldom acceptable unless there are good grounds to be reasonably sure that by far the overwhelming majority of the individual diagnoses that led to admission are, indeed, independent of the exposure. This is rarely the case. For this reason, the selection of a random sample of an entire hospital population, without any regard for diagnostic eligibility, can seldom be defended.

Despite the generally distinguished record of hospital-based case–control studies, some epidemiologists have argued that hospital controls are almost always unrepresentative of exposure in the population at large [43, 49]. That argument ignores the premise that when the cases represent a secondary study base (as is usual in hospital-based studies), the only valid control series may be patients admitted to the same hospitals as the cases.

One theoretical drawback to the sampling of hospital controls is that the judgment that the included conditions are independent of the exposure is an assumption, and one that is not needed when selecting

controls in a **population-based study**. In addition, there is evidence to suggest that certain exposures differ for in-hospital and out-of-hospital populations [25, 45–47]. That evidence, however, has been derived from studies that did not take into account the specific eligibility of each control diagnosis in the context of the specific hypothesis under study – an essential step in the proper selection of hospital controls. Nevertheless, there may be circumstances when the exposure under study (e.g. alcohol [33]) influences admission across such a wide range of diagnoses that it may be difficult or impossible to select a valid series of hospital controls.

Bias due to the Nonrepresentative Selection of Controls from a Primary Study Base

Selection bias may arise in analogous ways when population-based controls are chosen [45–47]. For example, if the sampling scheme is based on incomplete coverage of the base population (e.g. a motor vehicle owners' registry, or **random digit dialing**), it may underrepresent people of low socioeconomic status (because they do not have cars or telephones). Similarly, the selection of other controls, such as friends of the cases, or classmates, may give rise to other problems. For example, nonexposed friends of an exposed case may tend selectively to participate in a study because they would like to help. As with hospital controls, it remains important to use judgment in ensuring that population-based controls, however selected, are representative of the study base.

In an idealized example of a **population-based case–control study** with a 100% response rate among the sampled cases and among controls, confidence in the validity of the findings would be greater than for an otherwise identical study in which hospital controls are selected because no unverifiable assumptions about representativeness are required. In practice, however, that theoretical advantage is commonly not achieved because response rates among population controls tend to be considerably lower than among hospital controls, and lower still when it is necessary to obtain biological samples.

Partly in order to circumvent the problem of low response rates in the selection of population controls, random digit dialing [16, 25, 46] has been advocated as one way to obtain high participation rates, at least in societies with almost universal telephone coverage. This method had its origins in market research and opinion polls, and its application in epidemiologic research enjoyed some early success. However, with the passage of time, answering machines, voice mail, call forwarding, and an increasingly hostile attitude in society to what are perceived to be invasions of privacy, have lowered response rates, and sometimes even rendered such rates unmeasurable (because the presence or absence in the household of a potentially eligible control could not be determined) [13]. Despite these difficulties, however, adequate participation rates can sometimes be achieved if the interviewers are carefully trained and care is taken with the wording of invitations to participate (*see* **Interviewing Techniques**).

Selection Bias in Nested Case–Control Studies

In recent years **nested case–control studies** have come to play an increasingly important role in case–control methodology. In a nested case–control study, the cases are members of a cohort who develop a given condition, and the controls are a sample of noncases selected from the same cohort, and followed for the same length of time. There are several advantages to this approach: the cases and controls are unambiguously representative of the same study base; if the follow-up has been successful nonresponse rates are low; and information bias (see below) is avoided, since exposure status is usually determined before the subject qualifies as a case. A further advantage is that it may be easier to obtain biological specimens from people who are already collaborating in a study. All of these advantages were demonstrated in a study [31] that documented an increased risk of stomach cancer in relation to antecedent *Helicobacter pylori* infection, as determined from immunological assays of frozen serum specimens that had been collected and stored an average of 14 years earlier. As a general rule, however, a major disadvantage to the conduct of nested case–control studies is that it may not be possible to assemble sufficient cases, unless the follow-up study is massive.

Information Bias

Information bias exists when cases or controls report their exposures differently, or when the information is solicited differently (as noted above, in this article, bias due to nondifferential misclassification of exposure is excluded from the definition). The likelihood

that information bias will occur is greatest when the study subject, or those responsible for collecting the data, know the hypothesis.

Differential reporting (**recall bias**) may occur if cases aware of the hypothesis tend to report their exposures more fully than controls, with resultant overestimation of the odds ratio. For this bias to occur, it is not necessary to assume that cases may report exposures that did not actually take place (although they may overestimate duration or dosage). Even if the controls share knowledge of the hypothesis with the cases, if they are healthier they may have less reason to probe their memories. For example, one study of breast cancer risk in relation to OC use [24] specifically informed participants of the hypothesis, thus rendering recall bias all but unavoidable (this is also an example of biased solicitation of information – see below). Cases may also be prompted to recall their exposures more completely if their memories (but not those of the controls) have already been "primed" by repeated questioning from their medical attendants about the putative cause before they are interviewed by the study personnel.

A lack of awareness of the hypothesis reduces the likelihood of information bias, but it does not necessarily eliminate it. Hospitalized cases, for example, because of the setting in which the questions are asked, may remember their exposures better than population controls interviewed at home. For this reason, the interviewing of controls in a hospital setting may reduce the likelihood of information bias. Similarly, without any specific hypothesis in mind, patients with cancer, or mothers who have given birth to children with birth defects, may be more inclined than controls to probe their memories for possible "causes", even if such "causes" have not specifically been hypothesized.

These examples illustrate how cases might report their exposures more fully than controls. Sometimes, however, the reverse may occur. In a hypothetical study of trauma in relation to alcohol intake, for example, the cases might understate their consumption relative to controls if they are embarrassed at having contributed to their own illness.

Much the same considerations that apply to recall bias on the part of the study subjects may also apply when those responsible for the data collection are aware of the hypothesis, and it is not uncommon for such awareness to coexist both among the subjects and the study personnel, as in the OC/breast cancer example [24] mentioned above. Or, to give another example, in a further study of the same question [30], women with breast cancer were interviewed face-to-face by a single male physician, while the controls were subjected to telephone interviews, conducted by two female interviewers. The biased solicitation of exposure information may be quite subtle: the inflection of an interviewer's voice, the "body language", the use of open-ended questions, or the way in which they are worded may all influence the respondent's answers.

It is sometimes argued that the presence of **dose–response** or duration–response effects constitutes evidence against information bias. This argument may have merit inasmuch as long-duration exposures, and perhaps high doses, are less likely to be misremembered than short-duration exposures or low doses. The countervailing argument, however, is that cases may tend systematically to overreport, and controls to underreport, duration or dosage. Thus, apparent duration or dosage gradients cannot necessarily be taken as evidence against information bias.

Occasionally, it is possible to avoid or minimize information bias. To give some examples: in a study of breast cancer risk in relation to use of the antihypertensive drug reserpine [20], women were questioned before their breast lumps were biopsied: the cases were those with breast cancer, and the controls were women given a diagnosis of benign breast disease. (But it should be noted that selection bias may have been present if reserpine increased the risk of benign breast disease – an instance in which the control diagnosis would not be independent of the exposure.) In a study of spermicide use at the time of conception in relation to Down's syndrome [23], pregnant women were questioned about exposure before they underwent an amniocentesis: the cases were fetuses with trisomy 21, the controls were fetuses with normal chromosome counts. And in a study of uterine cancer in relation to conjugated estrogen use [50], medical records were examined for prescriptions after all information on case or control status was masked (*see* **Blinding or Masking**): the biased recording of the exposure information was thus avoided.

Information bias can sometimes be assessed by the independent evaluation of exposure, using information from other sources. For example, some interview-based case–control studies have suggested

that induced abortion increases the risk of breast cancer [6]. Information bias could account for the association if women with breast cancer more fully report such a sensitive exposure than do control women [32]. Evidence that this may be so is suggested by the results of a recent Danish cohort study [27] based on national registry data. An increased risk was ruled out, and in that study there was no information bias [17], since the data on abortion status were recorded before the breast cancer outcomes were observed. Indeed, this example serves to illustrate how cohort studies can avoid information bias.

Unfortunately, as illustrated by the abortion/breast cancer example, the circumstances in which information bias can confidently be ruled out in case–control studies tend to be the exception rather than the rule. Usually, even if the investigator judges information bias to be minimal, it may not be possible to demonstrate that this is so. It is necessary to resort to the next best alternative, which is to design studies in which the potential for information bias is reduced as much as possible: for example, by concealment of the hypothesis from the study subjects, and the interviewers – or, if that is not possible, by avoiding mention of the hypothesis; by the use of highly structured and unambiguous questions; memory prompts (e.g. photographs of OCs) to maximize recall; the administration of questionnaires as soon as possible, before there is a substantial opportunity for memory loss; and the rigorous training of interviewers (*see* **Interviewing Techniques**; **Questionnaire Design**).

Even with optimal study design, the question of whether information bias is, or is not, sufficient to invalidate an association is ultimately a matter of judgment. For example, in a study documenting an increased risk of sinonasal cancer among workers exposed to wood dust [21], we may judge that occupational exposure is likely to be equally well remembered by cases and controls. Alternatively, we may judge that information bias is likely, as with the example of breast cancer risk in relation to a history of induced abortion [6, 32].

Conclusions

In this article, we have described two types of systematic bias (confounding, of course, is a third). Yet, in the past, the view has sometimes been taken that there are many more types of bias, each of them sufficiently different to require separate classification, that may affect observational studies: Sackett [37] described more than 35 (*see* **Bias, Overview**). However, all the specific biases that have been reported can readily be classified as instances of selection bias and information bias. For example, **Berkson's fallacy** [2], the proposition that the selection of hospitalized cases may be biased if admission for the condition under study is dependent on the coexistence of another condition, is a form of selection bias.

Systematic bias due to confounding has not been considered in this article. But it is important to mention that selection bias or information bias may affect not only the recording of exposures, but also the recording of confounders. Indeed, both the differential and the nondifferential recording of a confounder can lead to residual confounding, with a bias that can act in either direction [14, 38].

Information bias is sometimes mentioned as the Achilles' heel of case–control methodology. One of the major advantages of follow-up studies, relative to case–control studies, is that exposures are usually measured before the health outcomes occur, thus reducing or eliminating the likelihood of information bias. However, that advantage may be offset by biases that sometimes affect cohort studies, such as high nonresponse rates on follow-up, with differential losses according to exposure status. Another potential disadvantage is that changes in exposure status over time may be missed in cohort studies, unless the recording of the variables at issue is updated frequently (*see* **Bias in Cohort Studies**). And to complete the picture, certain biases (e.g. confounding, selection bias due to knowledge of exposure, or due to selective screening according to exposure status) may affect both approaches. In short, neither the case–control nor the cohort approach can circumvent all sources of bias, and they should, instead, be thought of as complementary strategies, each with certain strengths and certain weaknesses.

Since bias cannot be entirely eliminated in **observational studies**, concern about whether its existence is sufficient to invalidate any given association may be reduced if, in any study, the magnitude of the effect, relative to the magnitude of the plausible biases that may exist, is considerable. By contrast, the possibility of bias limits the interpretability of small associations. Concern about validity may also be reduced when a

variety of well-conducted studies based on different epidemiologic methods, and some of them based on nonepidemiologic methods, converge on the same large and relatively invariant association – an obvious example being lung cancer and smoking (*see* **Smoking and Health**), for which the validity of a causal connection (*see* **Causation**; **Hill's Criteria for Causality**) has long been beyond dispute.

Finally, one strength of the case–control approach can also be considered a major weakness: the ease with which case–control studies can sometimes be done, relative to cohort studies, means that the method can also more easily be abused. Case–control studies should be carried out by experienced investigators who are aware of their limitations, and they should be designed to anticipate and cope with potential sources of bias. When this has been done, there can be no doubt that they have made a major contribution to medical knowledge and to public health.

Bias in Cohort Studies

An epidemiologic **cohort** (or follow-up) study is typically performed by: (i) identifying a group of subjects who are at risk for a disease or condition of interest; (ii) determining the exposure status of each individual; and (iii) observing the subjects over time for the occurrence of the health outcome(s) under investigation. While this approach is advantageous in that it ensures that the temporal relationship between exposure and outcome is unambiguous, cohort studies are susceptible to the same kinds of **bias** (i.e. **selection**, **misclassification**, and **confounding**) as are other types of study design (*see* **Bias in Observational Studies**; **Bias, Overview**).

Selection bias occurs when the study population available for analysis is not representative of the (theoretical) cohort of all eligible participants. This may result from biased sampling of the eligible cohort and/or selective losses from the study population during follow-up (*see* **Biased Sampling of Cohorts**). The common attribute of all sources of selection bias is that the effect estimated from the available study population is meaningfully different from the one that would have been obtained had all subjects theoretically eligible to participate been included in the analysis. A potential source of nonrepresentative sampling is self-selection, whereby subjects who become aware of a study volunteer themselves for participation. If such volunteers have a different probability of developing the outcome of interest compared with the group of all eligible subjects [1, 4], then the result may be a biased estimate of effect. A related concept is the "healthy worker effect," based on the observation that people in the workforce have lower mortality rates than members of the general population [2, 4]. Studies that utilize workers must take this situation into account in order to avoid biased results (*see* **Occupational Epidemiology**).

Other important potential sources of selection bias in cohort studies include losses to follow-up and **nonresponse** during data collection (*see* **Cohort Study**; **Missing Data in Clinical Trials**; **Missing Data in Epidemiologic Studies**). However, bias is created only if data are missing disproportionately from one or more cells of the **2 × 2 table** that relates a dichotomous exposure to a dichotomous outcome. Follow-up on a given subject may be incomplete for a variety of reasons. The subject may choose to withdraw his or her consent and no longer participate in the study. More commonly, the investigator simply loses contact with the subject, and thus cannot know with confidence whether he or she experienced the outcome of interest during the relevant follow-up period. When the outcome of interest is time to an event (e.g. death, diagnosis of disease, relapse, etc.), those individuals who do not experience the event during the study period are said to be **censored**. An assumption that is generally made with regard to such studies is that subjects who are censored at a given time have similar risks compared with those not censored at that time, i.e. that the censoring is "noninformative". If this assumption is violated, then bias results. Biased sampling may also occur if the probability that one is selected into the study sample depends upon whether he or she experiences the event of interest during a prescribed time window.

A final example of selection bias is illustrated by the "prevalent" cohort study. In such a study, subjects who already have a disease or other health condition are enrolled and then followed over time for events such as disease progression, relapse, or death. The goal is to obtain information about the natural history of the disease; however, problems of interpretation arise if the time since disease diagnosis remains unknown and is not uniform across subjects. Such difficulties must be weighed against the effort and costs required to assemble a cohort of newly diagnosed subjects, as would be done with the analogous "incident" cohort study.

Another type of bias to which cohort studies are susceptible is misclassification bias, a distortion in effect estimation that occurs when measurement errors result in incorrect classification of the exposure and/or disease status of study participants (*see* **Measurement Error in Epidemiologic Studies**). Such misclassification errors may be differential or nondifferential. When errors made in classifying subjects along one axis (i.e. exposure or disease) are independent of the subject's status on the other axis, the misclassification is said to be **nondifferential**. If the magnitude of the error along one axis varies according to the category of the other axis (e.g. disease status is misclassified more frequently among the unexposed), then differential misclassification has occurred [4]. This distinction is of value, since, for dichotomous exposure and disease variables, nondifferential misclassification leads consistently to an underestimation of the magnitude of

the association (**bias toward the null**). In contrast, bias from differential misclassification can be in any direction.

Classification errors arise from a variety of sources, including imprecise measurement tools, mistaken or missed diagnoses, and conscious or unconscious inaccuracies in self-reported disease and/or exposure information. An inaccurate diagnostic tool could lead to either over- or underascertainment of cases, causing disease misclassification that may be either differential or nondifferential with respect to exposure status. A potential source of differential disease misclassification is **detection bias**, whereby exposed subjects are followed more closely than their unexposed counterparts and are thus less likely to have unrecognized subclinical disease. The behavior of study personnel can also affect the accuracy of the data being collected. For example, an interviewer who is aware of both the study hypothesis and the exposure status of study participants may be more thorough in his or her questioning of exposed subjects regarding signs and symptoms indicative of the outcome of interest. Such **interviewer bias** is another potential source of differential misclassification and could thus lead to invalid study results.

The final category of bias which may affect cohort studies is **confounding**. Confounding operates similarly in all types of study designs, occurring when the effect of the exposure of interest is mixed up with that of one or more "extraneous" variables. The result can be over- or underestimation of the true effect of the exposure, the magnitude of the bias depending upon the nature of the relationships among the confounder(s), the exposure, and the disease. Confounding can be addressed in the design stage of a study – using **randomization**, restriction or matching – or in the analysis stage by employing stratified analysis (*see* **Stratification**) or applying a mathematical modeling technique [3] (*see* **Matching**; **Matched Analysis**).

Bias in Observational Studies

Bias can be defined as any **systematic error** (in contrast to sampling error) that results in inaccurate **estimation** of the effect of an exposure on an outcome. Such errors may occur in the design and/or analysis phase of an epidemiologic study and may result in either over- or underestimation of the true effect. Since bias is due to systematic rather than **random error**, the magnitude of the bias is not affected by sample size. Studies that produce effect estimates free of bias are said to be internally valid. An estimate which is internally valid may or may not be considered externally valid as well; the contrast between internal and external validity is discussed below. Although many sources of bias have been identified [14, 20, 21, 23], biases can generally be classified into one of three categories: **selection bias**, information bias, and **confounding** [14].

Selection Bias

Selection bias refers to a distortion in the estimate of effect resulting from (i) the manner in which subjects are selected for the study population and/or (ii) selective losses from the study population prior to data analysis. There are many sources of selection bias, and more than one source can contribute to bias in a given study. The common attribute of all sources of selection bias is that the effect estimated from the available study population is meaningfully different from the one that would have been obtained had all subjects theoretically eligible to participate been included in the analysis. Selection bias can occur under any type of study design; however, it is of special concern in the design and conduct of **case–control studies** because the outcome has already occurred prior to selection of study subjects.

Sources of Selection Bias

In **cohort** (follow-up) **studies**, two important potential sources of selection bias include losses to follow-up and **nonresponse** during data collection (*see* **Bias in Cohort Studies**; **Missing Data in Clinical Trials**; **Missing Data in Epidemiologic Studies**). Both situations result in missing exposure and/or outcome information at the time of analysis for some eligible subjects. This creates the potential for selection bias, depending upon whether information is missing disproportionately from one or more cells of the **2 × 2 table** that relates a dichotomous exposure to a dichotomous outcome (Table 1). Because the degree of bias relates to the amount of missing data in a cell relative to each of the other cells, selection bias may occur even with a fairly high overall response rate and/or very little loss to follow-up. For example, a cohort study might be conducted in which 90% of all subjects originally assembled into the cohort remain available for analysis at the end of the study (i.e. 10% of subjects were lost to follow-up). If the losses to follow-up are concentrated among the exposed subjects who ultimately developed the disease, the true **relative risk** could be underestimated by a substantial amount. Conversely, there may be no selection bias despite small response rates and/or large follow-up losses in each exposure category. If only 20% of all eligible subjects choose to participate in a study, but this 20% represents a true **random sample** of all potential participants, the resulting estimate of relative risk will be **unbiased**. In fact, even an assumption this stringent is not required. As long as, within each exposure category, the likelihood of being selected into the study (and available for analysis) is the same for subjects who develop the disease and subjects who do not, the risk for each exposure group (and thus the relative risk) can be estimated without bias.

The validity of any effect estimated from case–control data depends in part upon the appropriate choice of a comparison (**control**) group. The purpose of the controls is to estimate the **prevalence** of the exposure(s) of interest in the population from which the cases emerged. Any control group that yields over- or underestimates of this prevalence produces biased study results, unless there are compensating biases in the case sample. In terms of the 2×2 table (Table 1), selection bias results from an imbalance in the probability of being selected into the study (or remaining for the analysis) across the four

Table 1 2×2 table

	Exposed	Unexposed
Diseased	*a*	*b*
Nondiseased	*c*	*d*

cells. For example, **detection** (also called diagnostic or unmasking) **bias** [12, 21] can result from closer follow-up or more intense scrutiny of exposed vs. unexposed subjects. The detection of a higher proportion of subclinical outcomes among the exposed leads to an overrepresentation of exposed cases in a case–control study. Hospital-based case–control studies are subject to unique types of selection bias as a result of factors associated with admission to the hospital (*see* **Case–Control Study, Hospital-based**). For example, **Berkson's fallacy** (bias) [3] results when an individual with two or more medical conditions is more likely to be hospitalized than someone with only one of the conditions. Thus, in a study utilizing hospital cases, there could be an apparent **association** between two conditions that does not exist in the general population. More generally, exposed cases may have a different chance of entering the hospital than nonexposed cases. Likewise, exposed and unexposed participants with control diseases may have different chances of hospital admission. These selection effects can bias the estimates of exposure effect [23]. Therefore, the choice of an appropriate control group can be difficult in a hospital-based case–control study. If the conditions for which controls have been hospitalized are associated with the exposure under study, then bias will result (*see* **Bias in Case–Control Studies**).

Certain types of selection bias may operate in either cohort or case–control studies. Among these is self-selection (or volunteer) bias, whereby subjects self-refer for participation in a study. Especially if the study hypothesis has been publicized, people who volunteer to become involved may differ in important ways from the group of all potentially eligible participants [5, 20]. Self-selection can also occur prior to the initiation of a study. For example, it has been observed that active workers experience lower mortality than the general population, presumably because one must maintain a certain degree of health in order to remain a part of the workforce [8, 20]. Studies utilizing workers as subjects must therefore account for this "healthy worker effect" by choosing an appropriate comparison group to avoid the risk of drawing invalid conclusions (*see* **Occupational Epidemiology**).

A final illustration of selection bias involves the use of prevalence data to draw conclusions about incidence, for example in a **cross-sectional study** or a case–control study employing prevalent cases (*see* **Case–Control Study, Prevalent**). The problem, commonly referred to as selective survival, arises when persons with the disease of interest are unavailable to participate in a study because they have died prior to the study's initiation. If exposure status happens to be over- or underrepresented in the survivors, then the use of prevalence data to estimate incidence-based effect estimates can lead to biased results (*see* **Bias from Survival in Prevalent Case–Control Studies**).

Addressing Selection Bias

Efforts to avoid or minimize selection bias should be emphasized over attempts to correct for it in the analysis stage. As implied above, one of the most important ways of achieving this goal is through the careful choice of an appropriate comparison group, i.e. the controls should be representative of the population from which the cases emerged. It has been recommended that researchers conducting case–control studies use two or more control groups, as a means of drawing some conclusions about the likelihood of selection bias [16, 17]. If the effect estimate remains the same regardless of which control group is utilized, then this offers some degree of reassurance that selection bias has been avoided (although the possibility remains that all estimates are equally biased). If the estimated effects differ, then one is left with the decision of which control group is the most suitable. Other strategies for minimizing the potential for selection bias include efforts to achieve high response and follow-up rates and to assure equal opportunity for disease detection among exposed and unexposed subjects. Case–control studies using incident cases (including **nested case–control studies**) are preferable to those using prevalent cases or to hospital-based studies.

The degree to which selection bias can be corrected after the collection of data depends on whether reliable estimates of the underlying selection or loss probabilities can be determined [14]. Since these probabilities are rarely known with accuracy, a suggested strategy is to consider a range of values of these parameters to assess the magnitude and direction of the bias that may be operating in a given study.

Information Bias

Information bias refers to a distortion in effect estimation that occurs when measurement of either the exposure or the disease is systematically inaccurate. This presentation focuses on "**misclassification** bias", the term used when such **measurement errors** result in incorrect classification of the exposure and/or disease status of study participants. It is useful to distinguish two types of misclassification – nondifferential and differential – since the distinction has implications for the direction and overall impact of the bias. If the misclassification is **nondifferential**, the errors made in classifying subjects along one axis (i.e. exposure or disease) are independent of their status with regard to the other axis. Differential misclassification occurs when such classification errors along one axis are not independent of the other axis [20]. For example, if a certain proportion of exposed subjects are mistakenly designated as unexposed, but the probability of misclassifying exposure is the same among diseased and nondiseased, then the result is nondifferential misclassification of exposure. If a certain proportion of diseased subjects are mistakenly designated as nondiseased, and the proportion misclassified varies by exposure status, then this represents differential misclassification of disease. In the case of the simple 2×2 table, nondifferential misclassification leads consistently to an underestimation of the magnitude of association between exposure and disease. Since the biased estimate is in the direction of no exposure–disease association, this phenomenon is termed **bias toward the null**. The situation becomes more complex when polytomous rather than dichotomous exposure variables are employed. In this circumstance, it is possible for nondifferential misclassification to result in bias away from the null [6]. Bias from differential misclassification can be in any direction. Therefore, depending upon the situation, differential misclassification can result in an underestimation (bias toward the null) or an overestimation (bias away from the null) of the magnitude of an association. The biased and unbiased effect estimates can even be on opposite sides of the null value ("crossover bias").

It should be borne in mind that misclassification of both exposure and disease can occur in the same study and that errors can be made simultaneously in both directions (e.g. some truly diseased subjects are mistakenly classified as nondiseased while some truly nondiseased are mistakenly classified as diseased). Misclassification probabilities are often expressed in terms of **sensitivity** and **specificity**, terms that are more frequently used in discussions of **screening** or **diagnostic test accuracy** [9, 14].

Sources of Information (Misclassification) Bias

Classification errors can occur in any type of study and may be due to imprecise measurement (of exposure and/or disease), mistaken or missed diagnoses, conscious or unconscious inaccuracies in self-reported information, or any other factor that causes a subject to be placed into the wrong cell of the 2×2 table (Table 1). For example, if subjects are followed over time for the occurrence of a disease, some may develop subclinical disease which goes unrecognized by the investigators. Such subjects would be misclassified as nondiseased. If exposed subjects are under greater scrutiny than the unexposed, then they may be less likely to have undiagnosed subclinical disease. This implies that **detection bias**, described above as a type of selection bias for case–control studies, can lead to differential misclassification in a follow-up study. With an inaccurate diagnostic tool, overascertainment of cases is also possible, and could be either differential or nondifferential with respect to exposure status.

Another potential source of misclassification has to do with the quality of information provided by study subjects. It can probably be assumed that some degree of misclassification is inevitable when subjects are asked to report exposures or to provide other aspects of their medical histories. **Recall bias**, which induces differential misclassification, occurs when the accuracy of self-reported information varies across comparison groups [1]. For example, people who have recently been diagnosed with an illness may be seeking an explanation and therefore could be more motivated to recall past exposures than are those unaffected by the illness. This could lead to an underestimate of exposure prevalence among controls compared to cases, causing the **odds ratio** to be artificially inflated. Recall bias is a potential problem in any case–control study in which subjects are asked to recall previous exposures. Recall bias would be unlikely to affect cohort studies because exposure information is usually based on exposure status at baseline. Misclassification is also

likely if it becomes necessary to gather data from surrogate respondents, depending upon the nature of the information requested and the level of detail required. Another potential source of inaccuracy has been termed "social desirability bias", which results from subjects' natural reluctance to report exposures and/or behaviors that are deemed socially unacceptable [24].

Those who are conducting the study can also have an impact on the degree and type of misclassification that occur during data collection. Knowledge of the study hypothesis and the comparison group to which a subject belongs could influence the behavior of personnel responsible for conducting interviews. For example, in a case–control study of the potential association between oral contraceptive use and development of venous thrombosis, subjects known to have experienced a venous thrombosis might be probed more deeply than controls for a history of oral contraceptive use. A similar situation might arise in a cohort study if an interviewer were more thorough in his or her questioning of exposed vs. unexposed subjects regarding signs and symptoms indicative of the outcome of interest. Such **interviewer bias** is a potential source of differential misclassification and could thus lead to invalid study results.

Addressing Information (Misclassification) Bias

Although there is always likely to be some degree of inaccuracy in measuring both exposures and outcomes, steps can be taken to minimize classification errors and reduce the probability that such errors will be differential (see below). Since nondifferential misclassification is more predictable in its impact and tends to result in underestimation of effects, it has generally been considered to be less of a threat than differential misclassification [20]. It should be noted that if a study finds a significant relationship between an exposure and an outcome, it is illogical to dismiss the study results on the grounds that nondifferential misclassification is present, since the effect estimate obtained in the absence of such misclassification would only be stronger.

One strategy for addressing misclassification bias is to ensure that all study participants are subject to the same follow-up procedures and standardized diagnostic criteria. To the extent possible, both the study personnel responsible for data collection and the study subjects should be blinded as to the main hypothesis under investigation (*see* **Blinding or Masking**). Interviewers must follow standardized protocols and, if practical, should remain unaware of the comparison group (i.e. case/control or exposed/unexposed) to which study participants from whom they gather information belong (*see* **Interviewing Techniques**). Acceptance of surrogate responses may not be appropriate for information that is subjective, highly personal, time-specific, or otherwise difficult to obtain from someone other than the subject him- or herself.

After data collection, correction for misclassification depends on the availability of information on probabilities of misclassification (e.g. sensitivity and specificity estimates) for variables that have been misclassified. Several authors have offered correction procedures: Barron [2] and Copeland et al. [4] provide correction formulae for 2×2 tables that assume nondifferential misclassification. These formulas were extended to allow for differential misclassification by Kleinbaum et al. [14] and to arbitrary multiway cross-classifications (*see* **Contingency Table**) by Korn [15]. Greenland & Kleinbaum [10] provide correction formulae for matched data. Espeland & Hui [7] use **loglinear models** and **maximum likelihood** estimation to incorporate estimates of nondifferential misclassification probabilities gathered either by resampling the study population, sampling a separate population, or a priori assumption. Reade-Christopher & Kupper [19] use **logistic regression** to correct for nondifferential misclassification of exposure with a priori assumptions about misclassification probabilities. Also, recent work by Satten & Kupper [22] provides odds ratio regression methods when we have available only the probability of exposure (POE) for each study subject, and where these POE values are assumed to be known without error.

Correction for misclassification bias often requires information from a **validation study**, which may not be available. If such data are not available, then the best approach to evaluating the results of a study is to assess the probable magnitude and direction of suspected misclassification errors and discuss the likely impact of such errors on the estimated effect. Formulas used for correction for misclassification are useful for this purpose.

Confounding

Confounding is a type of bias that occurs when the effect of the exposure of interest is mixed up with that of one or more "extraneous" variables. This can result in an observed exposure–disease relationship being attributed exclusively to the exposure of interest, when in reality the relationship is due, either wholly or in part, to the effect of another variable or variables (i.e. **confounders**). Confounding can also create the appearance of an exposure–disease relationship when in fact none exists. The amount of bias introduced can be large or small, depending upon the nature of the relationships among the confounder(s), the exposure, and the disease. Confounding can lead to an over- or underestimation of the true effect and can also result in an estimated effect that is on the opposite side of the null from its true value.

Sources of Confounding

There is essentially only one source of confounding – the presence of certain key relationships between an extraneous variable and both the exposure and the disease. The first requirement is that the extraneous variable be a risk factor for the disease, i.e. that it is either causally related to the disease or is a correlate of a causal factor [14, 20] (*see* **Causation**). More specifically, the status of a confounder as a risk factor for the disease must be independent of its association with the exposure of interest; therefore, it must be a risk factor among the unexposed. The second criterion is that the confounder be associated with the exposure of interest. Theoretically, this relationship should hold in the source population that produces the cases of disease [18]. Practically speaking, it is generally assessed among all subjects in a follow-up study and among the controls in a case–control study. A final criterion is that the confounder should not be an "intervening variable" in the causal pathway between exposure and disease. In other words, if an extraneous variable were actually a measure of some type of biological alteration caused by the exposure, which in turn went on to cause the disease, then such a variable would not fulfill the criteria for a confounder but would simply be a mediator between exposure and disease.

In addition to the theoretical considerations described above, there is also a data-based criterion for assessing confounding. The crude measure is considered to be confounded "in the data" if it differs meaningfully in value from the "adjusted" estimate of effect that removes the influence of the extraneous variables being assessed as possible confounders. This "data-based" criterion is also referred to as the "**collapsibility**" criterion [11]. The absence of data-based confounding implies that the strata considered when controlling for a potential confounder can be collapsed (or pooled) without introducing bias.

Addressing Confounding

Although applicable only to experimental rather than observational studies, one technique for decreasing the likelihood of confounding is **randomization**. If the exposure of interest is allocated randomly to study subjects, then the probability that the exposure will be associated with a potential confounder is greatly reduced (*see* **Randomized Treatment Assignment**). Importantly, this benefit is gained for previously unidentified (and unobserved) potential confounders as well as for those suspected potential confounders that are measured. Restriction is another means of avoiding an unwanted relationship between the exposure and an extraneous variable. For example, if gender is a risk factor for the outcome of interest, and there is concern that gender will be unequally distributed between exposure groups, then restricting the study to either males or females will eliminate the possibility of confounding by this variable. However, the advantage of this approach must be weighed against the potential threat to generalizability (external validity, see below) that may result. Another strategy for addressing confounding is the practice of **matching**, whereby the comparison group is selected to be similar to the index group with regard to key variables that are suspected confounders. Although confounding can be controlled in unmatched designs, the primary statistical advantage of matching is that it can make control of confounding more efficient (i.e. increase the precision of an adjusted estimate) [14, 20].

In contrast to the other types of bias, viable options also exist for addressing confounding in the analysis phase of a study. If only one potential confounder is identified, then the simplest approach is to perform a stratified analysis (*see* **Stratification**), calculating a separate effect estimate for subjects in each category of the potential confounder (e.g. separate estimates for males and females, smokers and

nonsmokers, etc.). If the estimates are similar across categories (i.e. there is no **interaction**), then they can be combined into a single adjusted estimate which removes the influence of the potential confounder (*see* **Mantel–Haenszel Methods**; **Matched Analysis**). When several potential confounders are identified, the assessment of confounding is complicated, requiring simultaneous control of several variables as well as determination of which subset of potential confounders is most appropriate for simultaneous control [14]. The "gold standard" (i.e. most valid subset) to which all subsets should be compared contains the entire set of potential confounders. The use of stratified analysis is not a viable option when there is even a moderate number of potential confounders, since the number of strata becomes too large and individual strata may contain few or no subjects. An alternative approach uses a mathematical modeling procedure (e.g. **logistic regression**), and requires determining whether the estimated measure of effect changes meaningfully when potential confounders are deleted from the model [13, 14]. The term "meaningfully" implies a decision that does not involve statistical testing, but rather the consideration of biologic and/or clinical experience about the importance of a change in the effect measure. Variables identified as nonconfounders from this approach may be dropped from the model provided their deletion leads to a gain in precision (i.e. narrower **confidence interval**). In the absence of interaction, the assessment of confounding simplifies to monitoring changes in the estimated coefficient of the exposure variable. However, if there is interaction, then the assessment is more subjective because the collective change in several coefficients must be monitored. Consequently, when interaction is present, we recommend keeping all potential confounders in the model. Note, furthermore, that whether stratified analysis or mathematical modeling is used, misclassification of confounders can lead to incomplete or incorrect control of confounding [9]. Also, the use of regression modeling for control of confounding may yield misleading results if incorrect assumptions are made about the form and characteristics of the model being fit. Important characteristics to consider include the specific variables (e.g. "risk factors") chosen for control, the quantitative form that such variables should take in the model, the interaction effects to be evaluated, and the measurement scale (e.g. **additive** or **multiplicative**) used to assess interaction effects (*see* **Effect Modification**; **Relative Risk Modeling**).

Internal vs. External Validity

The discussion to this point has centered upon the issue of internal validity, or lack of bias. One may also be interested in assessing the external validity of an estimated effect (*see* **Validity and Generalizability in Epidemiologic Studies**). The distinction between internal and external validity has to do with the population about which inferences are to be made [14]. An internally valid effect estimate is one that correctly describes the association between exposure and outcome in the **target population**, i.e. the collection of individuals upon which the study was designed to focus and about whom one is able to draw direct conclusions. This is the group that has been sampled, though not necessarily in a random fashion. By contrast, external validity, or generalizability, refers to the making of inferences to an external population beyond the restricted interest of the particular study from which the effect is estimated. Assessing external validity involves making a judgment regarding whether the results of a study can be extended to apply to individuals who are dissimilar in some aspects (e.g. age, race, occupation) compared with those upon whom the study was focused.

Bias Toward the Null

Bias toward the null usually refers to an effect of **nondifferential errors** in exposure measurements that reduces the apparent effect of the exposure on the dependent variable, which might be a health outcome. For **linear regressions**, bias toward the null is called attenuation (*see* **Measurement Error in Epidemiologic Studies**). Attenuation (or bias toward the null) does not change the sign of the coefficient of exposure in the regression, but it reduces the absolute magnitude toward zero. Similar effects are found for estimates of log relative odds in **logistic regression** and for **odds ratios** in **2 × 2 tables** (*see* **Bias in Observational Studies**; **Misclassification Error**). The odds ratios are biased toward, but not beyond, unity. There are, however, more complex situations in which nondifferential error can induce a bias away from the null and thus exaggerate an apparent exposure effect or induce a bias that reverses the direction of an apparent exposure effect, as mentioned in the articles cited above.

Bias toward the null can also result from other sources of bias, such as **confounding** and **selection bias**.

MITCHELL H. GAIL

Bias, Nondifferential

When comparing exposed with unexposed groups, **unbiased** estimates of **exposure effect** may result if the same (nondifferential) **biases** affect each exposure group. Nondifferential bias is bias that affects each exposure (or treatment) group in such a way that the resulting exposure effect measure remains unbiased. For example, suppose that 10% of the exposed group and 5% of the unexposed group develop cancer in a given time period, corresponding to a true **relative risk** of $10\%/5\% = 2.0$. Suppose, however, that follow-up procedures fail to detect 20% of incident cancers in each group, resulting in apparent cancer risks of 8% and 4%, respectively. Despite the fact that each of these **risks** is biased, the relative risk, $8\%/4\% = 2.0$, is unbiased. Thus, with respect to relative risk, these biases are nondifferential. If, instead, the chosen measure of exposure effect was the risk difference, $10\% - 5\% = 5\%$, these same errors would yield a biased estimate of $8\% - 4\% = 4\%$. Thus, an error process may induce nondifferential bias with respect to one effect measure but differential bias with respect to another measure.

Nondifferential bias results from a **nondifferential error** process. In the previous example, the underestimates, 8% and 4%, depended only on the corresponding true values, 10% and 5%, respectively, and not on the exposure group, because the error process missed 20% of incident cancers, regardless of exposure group. Thus, the error was nondifferential.

(*See also* **Misclassification Error**)

MITCHELL H. GAIL

Bias, Overview

Bias is defined as the "deviation of results or inferences from the truth, or processes leading to such deviation" [12]. In other words, it is the extent to which the expected value of an estimator differs from a population parameter. Bias refers to **systematic errors** that decrease the validity of estimates, and does not refer to **random errors** that decrease the precision of estimates. Unlike random error, bias cannot be eliminated or reduced by an increase in sample size.

Bias can occur as a result of flaws in the following stages of research [17]:

1. literature review,
2. study design,
3. study execution,
4. data collection,
5. analysis,
6. interpretation of results, and
7. publication.

Literature Review Bias

Literature review bias (syn. reading-up bias) refers to errors in reading-up on the field [17]. Examples include:

Foreign language exclusion bias: literature reviews and **meta-analyses** that ignore publications in foreign languages [5].

Literature search bias: caused by lack of a computerized literature search, incomplete search due to poor choice of keywords and search strategies, or failure to include unpublished reports or hard-to-reach journals through interlibrary loans.

One-sided reference bias: investigators may restrict their references to only those studies that support their position [17].

Rhetoric bias: authors may use the art of writing to convince the reader without appealing to scientific fact or reason [17].

Design Bias

Design bias refers to errors occurring as a result of faulty design of a study [12]. This can arise from faulty selection of subjects, noncomparable groups chosen for comparison, or inappropriate sample size.

Selection Bias

Selection bias is a distortion in the estimate of effect resulting from the manner in which subjects are selected for the study population. Bias in selection can arise: (i) if the **sampling frame** is defective, (ii) if the sampling process is nonrandom, or (iii) if some sections of the **target population** are excluded (noncoverage bias) [14].

Sampling frame bias. This type of bias arises when the sampling frame that serves as the basis for selection does not cover the population adequately, completely, or accurately [14]. Examples include:

Ascertainment bias: arising from the kind of patients (e.g. slightly ill, moderately ill, acutely ill) that the individual observer is seeing, or from the diagnostic process which may be determined by the culture, customs, or individual disposition of the health care provider [12]. (See also diagnostic access bias.)

Berkson bias (*see* **Berkson's Fallacy**) (syn. admission rate bias, hospital admission bias): caused by selective factors that lead hospital cases and controls in a case–control study to be systematically different from one another [1, 6].

Centripetal bias: the reputations of certain clinicians and institutions cause individuals with specific disorders or exposures to gravitate toward them [17].

Diagnostic access bias: patients may not be identified because they have no access to diagnostic process due to culture or other reasons. (See also ascertainment bias, hospital access bias.)

Diagnostic purity bias: when "pure" diagnostic groups exclude comorbidity, they may become nonrepresentative [17].

Hospital access bias: patients may not be identified because they are not sick enough to require hospital care, or because they are excluded from hospitals as a result of distance or cost considerations. (See also ascertainment bias, diagnostic access bias, referral filter bias.)

Migrator bias: migrants may differ systematically from those who stay home [17].

Neyman bias (syn. attrition bias, prevalence–incidence bias, selective survival bias; *see* **Bias from Survival in Prevalent Case–Control Studies**):

caused by excluding those who die before the study starts because the exposure increases mortality risk [4, 6].

Telephone sampling bias: if **telephone sampling** is used to select a sample of individuals, then persons living in households without telephones would be systematically excluded from the study population, although they would be included in the target population.

Nonrandom sampling bias. This type of bias arises if the sampling is done by a nonrandom method, so that the selection is consciously or unconsciously influenced by human choice [14]. Examples include:

Autopsy series bias: resulting from the fact that autopsies represent a nonrandom sample of all deaths [12].

Detection bias (syn. selective surveillance bias, verification bias): caused by errors in methods of ascertainment, diagnosis, or verification of cases in an epidemiologic investigation, for example verification of diagnosis by laboratory tests in hospital cases, but not in cases outside the hospital [6, 12]. (See also diagnostic work-up bias, unmasking bias.)

Diagnostic work-up bias (syn. sequential-ordering bias): arises if the results of a diagnostic or screening test affect the decision to order the "**gold standard**" procedure that provides the most definitive result about the disease [16], for example those who have a negative screening test are systematically excluded from the gold standard procedure [3]. (See also detection bias, unmasking bias.)

Door-to-door solicitation bias: subjects obtained by door knocking are more likely to be the elderly, unemployed, and less active individuals who tend to stay at home.

Previous opinion bias: the tactics and results of a previous diagnostic process on a patient, if known, may affect the tactics and results of a subsequent diagnostic process on the same patient [17]. (See also diagnostic work-up bias.)

Referral filter bias: as a group of patients are referred from primary to secondary to tertiary care, the concentration of rare causes, multiple diagnoses, and severe cases may increase [17]. (See also hospital access bias.)

Sampling bias: caused by the use of nonprobability sampling methods that do not ensure that all members of the population have a known chance of selection in the sample [12] (*see* **Quota, Representative, and Other Methods of Purposive Sampling**).

Self-selection bias (syn. self-referral bias): subjects contact the investigators on their own initiative in response to publicity about the investigation.

Unmasking bias (syn. signal detection bias): an innocent exposure may become suspect if, rather than causing a disease, it causes a sign or symptom which leads to a search for the disease [17] (*see* **Bias From Diagnostic Suspicion in Case–Control Studies**). (See also detection bias, diagnostic work-up bias.)

Noncoverage bias. This type of bias arises if some sections of the population are impossible to find or refuse to cooperate [14]. Examples include:

Early-comer bias (syn. latecomer bias): "early-comers" from a specified sample may exhibit exposures or outcomes which differ from those of "latecomers" [6], for example early-comers in a study tend to be healthier, and less likely to smoke [17]. (See also response bias.)

Illegal immigrant bias: when census data are used to calculate death rates, bias is caused by illegal immigrants who appear in the numerator (based on death records) but not in the denominator (based on census data).

Loss to follow-up bias: caused by differences in characteristics between those subjects who remain in a cohort study and those who are lost to follow-up [6] (*see* **Bias from Loss to Follow-up**).

Response bias (syn. nonrespondent bias, volunteer bias): caused by differences in characteristics between those who choose or volunteer to participate in a study and those who do not [7, 12] (*see* **Bias from Nonresponse**). An example is the forecast of the US presidential election in a 1936 survey of 10 million individuals that went wrong because the response rate was only 20%, and the respondents presumably came from a higher social class than the general electorate [14]. (See also early-comer bias.)

Withdrawal bias: caused by differences in the characteristics of those subjects who choose to withdraw and those who choose to remain [6, 12].

Noncomparability Bias

Noncomparability bias occurs if the groups chosen for comparison are not comparable. Examples include:

Ecological bias (syn. **ecologic fallacy**): the associations observed between variables at the group level on the basis of ecological data may not be the same as the associations that exist at the individual level.

Healthy Worker Effect (HWE): an observed decrease in mortality in workers when compared with the general population [4] (*see* **Occupational Epidemiology**). This is a type of membership bias [6].

Lead-time bias (syn. zero time shift bias): occurs when follow-up of two groups does not begin at strictly comparable times, for example when one group has been diagnosed earlier in the natural history of the disease than the other group owing to the use of a screening procedure [12] (*see* **Screening Benefit, Evaluation of**).

Length bias: caused by the selection of a disproportionate number of long-duration cases (cases who survive longest) in one group and not in the other. An example is when prevalent cases, rather than incident cases, are included in a case–control study [12].

Membership bias: membership in a group (e.g. workers, joggers) may imply a degree of health which differs systematically from that of the general population because the general population is composed of both healthy and ill individuals [6, 17].

Mimicry bias: an innocent exposure may become suspect if, rather than causing a disease, it causes a benign disorder which resembles the disease [17].

Nonsimultaneous comparison bias (syn. noncontemporaneous control bias): secular changes in definitions, exposures, diagnoses, diseases, and treatments may render noncontemporaneous controls noncomparable [17], for example use of historical controls [12] (*see* **Bias from Historical Controls**).

Sample Size Bias

Samples that are too small may not show effects even when they are present; samples that are too large may show tiny effects of little or no practical significance [17]. Another name for sample size bias is wrong sample size bias.

Study Execution Bias

Study execution bias refers to errors in executing the experimental maneuver (or exposure) [17]. Examples include:

Bogus control bias: when patients who are allocated to an experimental maneuver die or sicken before or during its administration and are omitted or reallocated to the control group, the experimental maneuver will appear spuriously superior [17].

Contamination bias: when members of the control group in an experiment inadvertently receive the experimental maneuver, the differences in outcomes between experimental and control patients may be systematically reduced [17] (*see* **Bias Toward the Null**).

Compliance bias: in experiments requiring patient adherence to therapy, issues of efficacy become **confounded** with those of compliance, for example when high-risk coronary patients quit exercise programs [17] (*see* **Noncompliance, Adjustment for**).

Data Collection Bias

Data collection bias (syn. information bias, **measurement error**, **misclassification** bias, observational bias) refers to a flaw in measuring exposure or outcome that results in differential quality or accuracy of information between compared groups [12] (*see* **Bias, Nondifferential**). Bias in data collection can arise from (i) defective measuring instruments, (ii) wrong data source, (iii) errors of the observer, (iv) errors of the subjects, and (v) errors during data handling.

Instrument Bias

Instrument bias (syn: instrument error) refers to defects in the measuring instruments [17]. This may be due to faulty calibration, inaccurate measuring instruments, contaminated reagents, incorrect dilution or mixing of reagents, etc. [12]. Examples include:

Case definition bias: definition of cases, for example based on different versions of **International Classification of Diseases** (ICD) codes, or first-ever cases vs. recurrent cases, may change over time or across regions, resulting in inaccurate trends and geographic comparisons [13]. (See also diagnostic vogue bias.)

Diagnostic vogue bias: the same illness may receive different diagnostic labels at different points in space or time, for example the British term "bronchitis" vs. North American "emphysema") [17]. (See also case definition bias.)

Forced choice bias: questions that provide inadequate choices, for example only "yes" and "no", and without other choices like "do not know" or "yes but

do not know type", may force respondents to choose from the limited choices. (See also scale format bias.)

Framing bias: preference depends on the manner in which the choices are presented, for example telling a prospective candidate for surgery that an operation has a 5% mortality, vs. 95% survival rate.

Insensitive measure bias: when **outcome measures** are incapable of detecting clinically significant changes or differences, type II errors occur [17].

Juxtaposed scale bias (syn. questionnaire format bias): juxtaposed scales, a type of self-report response scale which asks respondents to give multiple responses to one item, may elicit different responses than when separate scales are used [10].

Laboratory data bias: data based on laboratory test results are subject to errors of the laboratory test including faulty calibration of the instruments, contaminated or incorrect amounts of reagents, etc.

Questionnaire bias: leading questions or other flaws in the questionnaire may result in a differential quality of information between compared groups [6] (*see* **Questionnaire Design**).

Scale format bias: even vs. odd number of categories in the scale for the respondents to choose from can produce different results, for example (Agree) 1–2–3 (Disagree) tends to obtain neutral answers, i.e. 2, while (Agree) 1–2–3–4 (Disagree) tends to force respondents to take sides. (See also forced choice bias.)

Sensitive question bias: sensitive questions such as personal or household incomes, sexual orientation, or marital status, may induce inaccurate answers.

Stage bias: method for determining stage of disease of patients may vary across the groups being compared, across geographic areas, or through time, leading to spurious comparison of stage-adjusted survival rates (*see* **Bias from Stage Migration in Cancer Survival**) [9].

Unacceptability bias: measurements which hurt, embarrass or invade privacy may be systematically refused or evaded [17].

Underlying/contributing cause of death bias: results of data analysis will be different depending on whether the underlying or the contributing cause of death as recorded on the death certificates is used (*see* **Cause of Death, Underlying and Multiple**; **Death Certification**).

Voluntary reporting bias: voluntary reporting system vs. mandatory reporting system can generate differences in the quality and completeness of routine data.

Data Source Bias

Data source bias refers to wrong, inadequate, or impossible source or type of data. Examples include:

Competing death bias: some causes of death (e.g. cancers) are associated with older age, while others (e.g. infectious diseases) are associated with younger age. Therefore in places where infectious diseases are prevalent, the cancer rates will be underestimated owing to competing causes of death from infectious diseases (*see* **Competing Risks**).

Family history bias: positive family history is not an accurate indicator of familial aggregation of a disease and the influence of genetic factors, because it is a function of the number of relatives and the age distribution of relatives [11].

Hospital discharge bias: hospital discharge data do not reflect hospital admission data since they are affected by length of hospital stay, and therefore do not provide accurate information for disease incidence.

Spatial bias: many environmental data used for health applications, for example geographic information systems (GIS), derive from point measurements at monitoring or survey stations. Unfortunately, many environmental monitoring networks are too sparse spatially and biased towards high pollution sites, generating an inaccurate pollution surface [2].

Observer Bias

Observer bias is due to differences among observers (interobserver variation) or to variations in readings by the same observer on separate occasions (intraobserver variation) [12] (*see* **Observer Reliability and Agreement**). Examples include:

Diagnostic suspicion bias (syn. diagnostic bias): a knowledge of the subject's prior exposure to a putative cause (e.g. ethnicity, drug use, cigarette smoking) may influence both the intensity and the outcome of the diagnostic process [6, 17] (*see* **Bias From Diagnostic Suspicion in Case–Control Studies**).

Exposure suspicion bias: a knowledge of the subject's disease status may influence both the intensity and outcome of a search for exposure to the putative cause [6, 17] (*see* **Bias from Exposure Suspicion in Case–Control Studies**).

Expectation bias: observers may systematically err in measuring and recording observations so that they concur with prior expectations, for example house officers tend to report "normal" fetal heart rates [17].

Interviewer bias: caused by interviewers' subconscious or even conscious gathering of selective data [12], for example questions about specific exposures may be asked several times of cases but only once of controls [17]. Can result from interinterviewer or intrainterviewer errors [6].

Therapeutic personality bias: when treatment is not blind, the therapist's convictions about efficacy may systematically influence both outcomes and their measurement (e.g. desire for positive results) [17] (*see* **Blinding or Masking**).

Subject Bias

Subject bias (syn. "observee" bias) refers to the inaccuracy of the data provided by the subjects (respondents, "observees") at the time of data collection. Examples include:

Apprehension bias: certain measures (e.g. pulse, blood pressure) may alter systematically from their usual levels when the subject is apprehensive (e.g. blood pressure may change during medical interviews) [17].

Attention bias (syn. Hawthorne effect): study subjects may systematically alter their behavior when they know they are being observed [17].

Culture bias: subjects' responses may differ because of culture differences, for example some **ethnic groups**, because of their cultural background, do not want to share publicly their pain or problems such as unemployment, marital troubles, youth crime, and parental difficulties.

End aversion bias: subjects usually avoid end of scales in their answers, try to be conservative, and wish to be in the middle.

Faking bad bias (syn. hello–goodbye effect): subjects try to appear sick in order to qualify for support. Also, subjects try to seem sick before, and very well after, the treatment.

Faking good bias (syn. social desirability bias): socially undesirable answers tend to be underreported. (See also unacceptable disease bias, unacceptable exposure bias.)

Family information bias: the family history and other historical information may vary markedly depending upon whether the individual in the family providing the information is a case or a control, for example different family histories of arthritis may be obtained from affected and unaffected siblings [17].

Interview setting bias: whether interviews are conducted at home, in a hospital, the respondent's workplace, or the researcher's office may affect subjects' responses.

Obsequiousness bias: subjects may systematically alter questionnaire responses in the direction they perceive desired by the investigator [17].

Positive satisfaction bias (syn. positive skew bias): subjects tend to give positive answers, typically when answering satisfaction questions.

Proxy respondent bias (syn. surrogate data bias): for deceased cases or surviving cases (e.g. brain tumors) whose ability to recall details is defective, soliciting information from proxies (e.g. spouse or family members) may result in differential data accuracy.

Recall bias: caused by differences in accuracy or completeness of recall to memory of prior events or experiences [6], for example mothers whose children have had leukemia are more likely than mothers of healthy children to remember details of diagnostic X-ray examinations to which these children were exposed *in utero* [12].

Reporting bias (syn. self-report response bias): selective suppression or revealing of information such as past history of sexually transmitted disease [12]. (See also unacceptable disease bias, unacceptable exposure bias, sensitive question bias.)

Response fatigue bias: questionnaires that are too long can induce fatigue among respondents and result in uniform and inaccurate answers.

Unacceptable disease bias: socially unacceptable disorders (e.g. sexually transmitted diseases, suicide, mental illness) tend to be underreported [12]. (See also reporting bias, faking good bias.)

Unacceptable exposure bias: socially unacceptable exposures (e.g. smoking, drug abuse) tend to be underreported. (See also reporting bias, faking good bias.)

Underlying cause bias (syn. rumination bias): cases may ruminate about possible causes for their illness and thus exhibit different recall or prior exposures than controls [17]. (See also recall bias.)

Yes-saying bias: some subjects tend to say "yes" to all questions.

Data Handling Bias

Data handling bias refers to the manner in which data are handled. Examples include:

Data capture error: errors in the acquisition of the data in digital form, normally by manual encoding (coding error), digitizing (data entry error), scanning, or electronic transfer from pre-existing data bases [2]. (See also data entry bias.)

Data entry bias: difference in data entry practices may cause unreal observed differences in geographic variations in incidence rates [18]. (See also data capture error.)

Data merging error: incorrect merging of data from different databases, for example erroneous merging and failure to merge as a result of illegible handwriting on the routine forms, different dates of service recorded in different databases, etc. (See also record linkage bias.)

Digit preference bias (syn. end-digit preference bias): in converting analog to digital data, observers may record some terminal digits with an unusual frequency [17], for example rounding off may be to the nearest whole number, even number, multiple of 5 or 10, or, when time units like a week are involved, [8, 15], etc. [12].

Record linkage bias: computerized **record linkage** is based on a probabilistic process based on identifiers (*see* **Matching, Probabilistic**). Some identifiers, e.g. some surnames, may have a poor record linkage weight, causing linkage problems, and therefore tend to exclude subjects having those identifiers.

Analysis Bias

Analysis bias results from errors in analyzing the data. It can arise from (i) lack of adequate control of **confounding** factors, (ii) inappropriate analysis strategies, and (iii) *post hoc* analysis of the data set.

Confounding Bias

Confounding bias occurs when the estimate of the effect of the exposure of interest is distorted because it is mixed with the effect of a confounding (extraneous) factor. A confounding factor must be a risk factor for the disease, be associated with the exposure under study, and not be an intermediate step in the causal path between the exposure and the disease [6]. Examples include:

Latency bias: failure to adjust for the **latent period** in the analysis of cancer or other chronic disease data.

Multiple exposure bias: failure to adjust for multiple exposures.

Nonrandom sampling bias: when a study sample is selected by nonrandom (nonprobability) sampling, failure to account for variable sampling fractions in the analysis may introduce a bias, for example weighting by the strata population sizes is needed for a disproportionate stratified sample (*see* **Stratified Sampling**).

Standard population bias: choice of standard population will affect estimation of standardized rates (a weighted average of the category-specific rates) [7] (*see* **Standardization Methods**).

Spectrum bias (syn. case mix bias): heterogeneous groups of patients with different proportions of mild and severe cases can lead to different estimates of **screening** performance indicators [16].

Analysis Strategy Bias

Analysis strategy bias (syn. analysis method bias) refers to problems in the analysis strategies. Examples include:

Distribution assumption bias: wrong assumption of **sampling distribution** in the analysis, for example time variables follow **lognormal distribution** rather than **normal distribution**, and therefore geometric mean time rather than **mean** time should be used [8].

Enquiry unit bias: choice of unit of enquiry may affect analysis results, for example with the school as the unit of enquiry, half the high schools offered no physics, but when the student becomes the unit of enquiry, only 2% of all high school students attended schools that offered no physics, since the small schools do not teach physics (*see* **Unit of Analysis**).

Estimator bias: the difference between the expected value of an estimator of a parameter and the true value of this parameter [12], for example **odds ratio** always overestimates **relative risk**).

Missing data handling bias: how **missing data** are handled, for example treated as a missing case vs. interpreted as a "no" answer, will lead to different results.

Outlier handling bias: arising from a failure to discard an unusual value occurring in a small sample, or due to exclusion of unusual values that should be

included [12]. The latter is also called tidying-up bias (the exclusion of outliers or other untidy results which cannot be justified on statistical grounds) [17].

Overmatching bias: matching on a nonconfounding variable that is associated with the exposure but not the disease can lead to conservative estimates in a matched case–control study [6].

Scale degradation bias: the degradation and collapsing of measurement scales tend to obscure differences between groups under comparison [17].

Post Hoc *Analysis Bias*

Post hoc analysis bias refers to the misleading results caused by *post hoc* questions, data dredging, and subgroup analysis (*see* **Treatment-covariate Interaction**). Examples include:

Data dredging bias: when data are reviewed for all possible associations without prior hypothesis, the results are suitable for hypothesis-generating activities only [17].

Post hoc *significance bias*: when decision levels or "tails" for type I and type II errors are selected after the data have been examined, conclusions may be biased [17].

Repeated peeks bias: repeated peeks at accumulating data in a randomized trial are not independent, and may lead to inappropriate termination [17] (*see* **Sequential Analysis**).

Interpretation Bias

Interpretation bias arises from inference and speculation, for example failure of the investigator to consider every interpretation consistent with the facts and to assess the credentials of each, and mishandling of cases that constitute exceptions to some general conclusion [12]. Examples include:

Assumption bias (syn. conceptual bias): arising from faulty logic or premises or mistaken beliefs on the part of the investigator, for example having correctly deduced the mode of transmission of cholera, John Snow falsely concluded that yellow fever was transmitted by similar means [12].

Cognitive dissonance bias: the belief in a given mechanism may increase rather than decrease in the face of contradictory evidence [17].

Correlation bias: equating **correlation** with causation leads to errors of both kinds [17].

Generalization bias (syn. lack of external validity): generalizing study results to people outside the study population may produce bias, for example generalizing findings in men to women (*see* **Validity and Generalizability in Epidemiologic Studies**).

Magnitude bias: when interpreting a finding, the selection of a scale of measurement may markedly affect the interpretation, for example $1 000 000 may also be 0.0003% of the national budget [17].

Significance bias: the confusion of statistical significance, on the one hand, with biologic or clinical or health care significance, on the other hand, may lead to fruitless studies and useless conclusions [17] (*see* **Clinical Significance Versus Statistical Significance**).

Underexhaustion bias: the failure to exhaust the hypothesis space may lead to erroneous interpretations [17].

Publication Bias

Publication bias refers to an editorial predilection for publishing particular findings, e.g. positive results, which can distort the general belief about what has been demonstrated in a particular situation [12] (*see* **Meta-analysis of Clinical Trials**). Examples include:

All's well literature bias: scientific or professional societies may publish reports or editorials which omit or play down controversies or disparate results [17].

Positive results bias: authors are more likely to submit, and editors accept, positive than null results [17].

Hot topic bias (syn. hot stuff bias): when a topic is hot, investigators and editors are tempted to publish additional results, no matter how preliminary or shaky [17].

Bias, Protopathic

Protopathic (or reverse-causality) **bias** is a consequence of a differential **misclassification** of exposure related to its timing of occurrence. It is observed when a change in exposure taking place in the time period following disease occurrence is incorrectly thought to precede disease occurrence. It can be observed for exposures that may change with time and for diseases for which the date of occurrence is difficult to determine accurately because of an insidious development of symptoms over a prolonged period of time. The term protopathic bias was coined by Horwitz and Feinstein [1]. Suppose that a long delay between early (or protopathic) symptoms and disease suspicion or diagnosis is commonly observed. Suppose also that many patients decrease or stop their exposure to a risk factor as a result of early disease symptoms. This will create a protopathic downward bias upon assessing the association between exposure and disease. For instance, early symptoms of chronic obstructive pulmonary disease (*e.g.*, dyspnea) can start a long time before disease occurrence is suspected or diagnosed. If smoking patients spontaneously reduce their smoking as a result of early disease symptoms, then the magnitude of the association between current smoking and risk of chronic obstructive pulmonary disease will appear smaller than it is (downward bias). Conversely, protopathic bias can correspond to an upward bias if exposure is started or increased during the time period ranging from the start of symptoms to disease diagnosis. For instance, patients may be prescribed a drug to alleviate early disease symptoms before the disease is actually diagnosed. This will yield an apparent association between that drug and disease risk (upward bias). Protopathic bias is a frequent concern in pharmacoepidemiology studies (*see* **Pharmacoepidemiology, Overview**; **Pharmacoepidemiology, Adverse and Beneficial Effects**) because drug prescription and consumption often vary over time and may change in response to early disease-related symptoms. However, it can be observed potentially in all fields of epidemiology. It is a more serious concern **in case-control** studies than in **cohort** studies because timings of exposure and actual disease start need to be ascertained retrospectively, which increases the likelihood of protopathic bias.

JACQUES BENICHOU

Bias

Bias is the expected deviation of an estimate (*see* **Estimation**) from the true quantity to be estimated. If an estimator $\hat{\theta}$ of a parameter θ has **expectation** $\theta + b$, the quantity b is called the bias. If $\hat{\theta}$ converges to $\theta + b$ as the sample size increases, then $\hat{\theta}$ is said to have asymptotic bias b. Some biases result from the small sample properties of the estimator used and vanish asymptotically. Most biases that result from **systematic error**, however, such as **selection biases** or biases in measuring outcomes, persist as the sample size increases. Indeed, increasing the sample size does not eliminate such biases but only leads to more precise biased estimates.

(*See also* **Bias in Case–Control Studies**; **Bias in Cohort Studies**; **Bias in Observational Studies**; **Bias, Overview**)

MITCHELL H. GAIL

Biased Sampling of Cohorts

The epidemiologic **cohort study** involves a sample of individuals followed over time. Individuals are monitored to ascertain the incidence of various endpoints such as the incidence of disease, infection, or death. The goal is to estimate the absolute **incidence rates** of the event or to identify **covariates** called risk factors that modify this risk. Individuals may also be monitored for changes in various markers of health status such as blood pressure measurements in prospective studies of cardiovascular disease, or CD4+ T cell counts or viral load measurements in natural history studies of **AIDS**. Usually cohort studies are prospective because subjects are monitored following establishment of the cohort. In a **historical cohort study**, however, earlier records are used to define membership in the cohort and to determine subsequent changes in health status.

Traditional approaches to the analysis of epidemiologic cohort studies include **person-years** analyses for rare events [1], **survival analyses** for more general time-to-event data [9], and **longitudinal data analysis** for repeated marker data [14]. While classical statistical methodologies routinely address sampling variation, other more systematic sources of error and **bias** that can overwhelm sampling variation are sometimes ignored. For example, **selection bias** resulting from biased sampling of the cohort either at enrollment or during the course of follow-up can seriously distort incidence and **relative risk** estimates. The objective of this article is to review how these different forms of sampling bias arise and how they can affect the results of studies. Other biases that result from **confounding** and measurement errors are discussed in other articles (*see* **Measurement Error in Epidemiologic Studies**; **Bias in Observational Studies**; **Bias in Cohort Studies**).

Self-Selection into the Study

Cohort studies may involve a sample of self-selected volunteers. In some circumstances, the self-selection into cohorts may be an important source of bias. Individuals may be solicited to participate in a cohort study through questionnaires and invitations, and those who respond and choose to participate may differ from those who do not participate with respect to known and unknown disease risk factors. For example, the **Framingham Study**, a long-term cohort study of heart disease initiated about 1950, issued an invitation to every town resident in the age range 20–70 to join the study. A lower death rate was subsequently observed among those individuals who chose to participate compared with nonparticipants [20]. One explanation for the mortality difference was that nonparticipants may be selectively frailer because study participation required a clinic visit. Although one might expect the differences in mortality rates to diminish over time, the Framingham Study found higher mortality rates among nonparticipants at both two and five years after study invitation. In another example involving a cohort study of British physicians, lower mortality rates were observed among physicians who replied to an initial questionnaire compared with those physicians who did not respond [1, 15]. In a population-based **cross-sectional study** of cardiovascular disease (*see* **Cardiology and Cardiovascular Disease**), less cardiovascular disease was found among respondents compared with nonrespondents [10]. In the above examples, less disease was observed among the study participants or responders. However, it is also possible to observe more disease among respondents. For example, the **Centers for Disease Control** investigated leukemia incidence among individuals near the Smoky Atomic Test in Nevada [7, 35]. Among the 18% of subjects who were self-referred and contacted the investigators, because of publicity about the study, there were four leukemia cases. Among the remaining 82% of subjects who were traced by investigators, there were also four leukemia cases. These data suggest that those individuals with disease were more likely to respond voluntarily and to participate in the study.

Self-selection is a potentially important source of bias particularly if the main comparison is with an external **control** group. For example, if the mortality rates of a self-selected group of smokers were compared with general population mortality rates, then the effect of smoking could be masked if the study participants were healthier than the general population. However, if the main comparison is with an internal control group, then self-selection may not be a source of bias. For example, among those who self-selected into the study, the mortality rates of smokers could be compared with those of nonsmokers. If the

assumption is that the effect of self-selection was comparable for both smokers and nonsmokers, then the relative risk of smoking based on the self-selected group may be unbiased. However, the absolute mortality rates of the self-selected groups of smokers and nonsmokers may be a biased estimate of the rates in the general population. There is, however, no guarantee that the relative risks are unbiased because self-selection may act differentially on the exposure groups. Both empirical and theoretical investigations of the impact of self-selection on relative risks have been performed [11, 21, 29].

A related bias is the healthy worker effect (*see* **Occupational Epidemiology**). The healthy worker effect occurs in cohort studies of occupational risks [1, 34]. For example, a cohort study may be conducted to evaluate the health effects associated with working in a particular occupational setting. The mortality rates among those individuals who are employed in the occupation might be compared with an external control group. However, employed individuals may have a lower mortality rate than the general population that is also made up of unemployed. Indeed, individuals may leave employment upon the onset of severe life-threatening diseases. Internal control groups help to correct the bias from the healthy worker effect, where an exposed group of employees is compared with an unexposed group of employees. For example, workers exposed to carbon disulfide were compared with workers in the paper industry as well as with the general Finnish population [23, 28]. Although the exposed workers had the highest coronary heart disease mortality rates, the rates among both exposed and unexposed workers in the paper industry were considerably lower than the rates in the general population.

Follow-Up Bias

Cohort studies typically follow individuals until an event occurs. However, there is often **incomplete follow-up**; that is, an individual may have follow-up data only up to time t and there is no information on the status of the individual beyond t. In that case, all that is known is that the individual did not have an event prior to time t. Such observations are right censored (*see* **Censored Data**). There are different reasons for censoring. One reason may be because the cohort study is ending and the investigators wish to analyze the data. In this case we say the individual is administratively censored. We say the individual is lost to follow-up if the individual is right censored because of all other reasons including the patient has moved away or the individual no longer wishes to participate in the study.

Most statistical methods for the analysis of follow-up data from cohort studies assume that individuals censored at some time t have similar risks as individuals not censored at t. This is noninformative censoring [30]. Generally, the assumption of noninformative censoring is plausible for administrative censoring because the reason for the censoring was external from the individual. If the assumption of noninformative censoring is violated, then we say there is follow-up bias. If the individuals lost to follow-up are at lower risk than those who remain under follow-up, then the event rates will be overestimated. For example, those individuals who are particularly healthy may move away from the study area. Alternatively, if the individuals lost to follow-up are at higher risk of an event than those who remain under follow-up, then the event rates will be underestimated. For example, the frailer individuals may be too weak to attend clinic visits, and are thus the ones lost to follow-up. Of particular concern are studies where the event of interest is a particular cause of death, and individuals who die of other causes are considered censored [17] (*see* **Competing Risks**). The assumption of noninformative censoring may be violated if there is dependence between the cause of death of interest and another cause of death. This can occur if an unknown risk factor is associated with both causes of death. The dependence can be either positive or negative. For example, positive dependence arises between coronary heart disease and some types of cancer if smoking, which is a risk factor for both, is ignored. Alternatively, negative dependence may arise if alcohol consumption is ignored because alcohol may increase risk for some cancers but decrease risk for coronary heart disease [36].

Unfortunately, the assumption that censoring is noninformative cannot usually be verified from observable data [38]. One way to evaluate the sensitivity of the **Kaplan–Meier** estimate to the assumption is to create bounds assuming perfect positive and negative dependence between the censoring and survival times [33]. The lower bound of the estimated survival curve is obtained by assuming that censored observations experience the

event immediately after being censored. The upper bound is obtained by assuming censored observations never experience the event. Dependent censoring cannot only bias survival curve estimation but can also reverse the effect of a true risk factor and make it appear protective [36].

One approach to control the bias introduced by informative censoring is to attempt to identify a variable (covariate) such that in a given level or stratum of the variable, censoring is noninformative. Such a variable would be associated both with the risks of disease and the risk of loss to follow-up. The statistical analysis must then account for this covariate using either **regression** or stratified analyses (*see* **Stratification**). Similar problems arise in longitudinal data analysis where dropouts are informative as opposed to completely random [14]. Some approaches for modeling the dropout process in longitudinal data analysis have been proposed that allow the probability of dropout at time t to depend on the history of measurements up to time t [13].

Truncation

Truncation is a potentially important source of bias in cohort studies with nonstandard sampling. Generally, truncation occurs if the probability that an individual is sampled for follow-up depends on the individual's event time. There are different forms of truncation. Left truncation arises if the individual comes under observation only if the individual's event (survival) time exceeds a known time, which we call the truncation time. Right truncation arises if the individual is included in the cohort only if the individual's event time is less than a known (truncation) time. Left truncation is discussed in more detail in this section, and an example of right truncation is discussed in detail in a later section of this article.

As a simple example of left truncation, consider a study whose objective is to identify **prognostic factors for survival** among patients with a particular disease. Now suppose only individuals with the disease who are *alive* at calendar time C are eligible for sampling into the study. Under this sampling design only individuals with survival times $t_i \geq C - u_i$, where u_i is the calendar time of diagnosis of disease have the opportunity to be included in the cohort. Individuals with shorter survival times are selectively excluded. Unless special adjustments are made for the left truncated data, standard statistical analyses can be seriously biased. For example, suppose the standard **nonparametric** Kaplan–Meier (product–limit) estimate is calculated based on the data (t_i, δ_i), where t_i is the event time for uncensored individuals or the last follow-up time for censored individuals and δ_i is a right censoring indicator that indicates if the individual had an event at time t_i (in which case, $\delta_1 = 1$) or was censored at time t_i (in which case $\delta_i = 0$). The Kaplan–Meier estimate of the survival function, $S(t)$ (probability of surviving beyond time t) is

$$\hat{S}(t) = \prod_{\{t_i \leq t\}} \left(\frac{n_i - d_i}{n_i} \right),$$

where n_i is the number at risk at t_i, i.e. the number of individuals with survival times greater or equal to t_i who have not been previously censored, and d_i are the numbers of (uncensored) events that occurred at t_i. Under usual sampling (i.e. a **random sample** of individuals are chosen for the cohort), the standard Kaplan–Meier estimate is a **consistent estimate** of the survival curve [2]. However, if the data are left truncated, then the standard Kaplan–Meier estimate of the survival curve will overestimate the true survival curve. The intuition for this bias is as follows. If we look at all individuals diagnosed with disease at time u_i, only those with long survival ($t_i \geq C - u_i$) are included in the data set, and this selection results in an overestimation of survival probabilities.

The correct Kaplan–Meier analysis that accounts for left truncation requires a different definition of the risk set. The correct definition of the risk set at time t to account for left truncation includes only those individuals who have neither had an event nor been censored prior to t and *who are under active follow-up at time t*. That is to say we require for an individual to be included in the risk set at time t that (i) the individual has not had an event or been censored prior to time t and (ii) $u_i + t \geq C$. The Kaplan–Meier estimator based on this definition of risk sets has been called the truncation product–limit estimator, and its theoretical properties have been studied by Tsai et al. [37]. Implicit in the truncation product–limit estimator is the assumption that risks (hazards) of the event depend only on follow-up time and depend neither on calendar time of disease diagnosis nor calendar time of study enrollment. These **stationarity** assumptions are discussed in [39].

Parametric estimation of survival curves (*see* **Parametric Models in Survival Analysis**) from left truncated data also requires modification of traditional methods. The key idea is that the contributions from each individual to the **likelihood** function must be *conditional* on the sampling criteria. Specifically, because individuals are required to be alive at calendar time C, we can account for left truncation by conditioning on the event that an individual's survival time is at least $C - u_i$. Then the likelihood function for estimating the parameters in a survival distribution $S(t)$ with density $f(t)$ from data (t_i, δ_i, u_i) for N individuals is

$$\prod_{i=1}^{N} \left[\frac{f(t_i)}{S(C-u_i)} \right]^{\delta_i} \left[\frac{S(t_i)}{S(C-u_i)} \right]^{1-\delta_i}.$$

The usual naive likelihood function that did not account for left truncation would not include the denominator terms $S(C - u_i)$ in the above likelihood function.

Special care is also needed in computing incidence rates when the data are left truncated. The incidence rate is usually calculated as the ratio of the number of events divided by the total person time of follow-up. This estimator of incidence is justified if the hazard of the event is constant over time. A source of confusion in the calculation of total person time is the amount of person time contributed by left truncated individuals. A naive analysis might allocate person time equal to t_i for all individuals, even if left truncated. However, that would lead to an underestimation of event incidence rates because events that occurred before C are not included in the calculation, but person time of the left truncated individuals is included. The correct analysis that accounts for left truncation has individuals contribute person time only during the period that they are actually under observation [1, 3]. Thus, in our example, a left truncated individual contributes person time accrued only after enrollment at calendar time C, that is, the contribution is $t_i - (C - u_i)$.

Special care is also needed in applying the **proportional hazards model** to left truncated data. The model formalizes the relative risk concept for studies of time to response and generalizes it to the regression setting. The model assumes that the time-specific incidence **(hazard) rate** in an exposed population is proportional to the incidence rate in an unexposed population. For a covariate with two levels the model is

$$\lambda_1(t) = \theta \lambda_0(t), \tag{1}$$

where $\lambda_1(t)$ and $\lambda_0(t)$ are the hazard rates at time t among those with and without the risk factor, respectively, and the parameter θ is the hazard ratio (*see* **Hazard Ratio Estimator**) (or relative risk). An important question is: What is the time scale t on which the proportional hazards model (1) is defined? The most appropriate time scale is the one that needs the most careful control to obtain valid comparisons between the treatment groups. Often the time scale is follow-up time, i.e. t is the time the individual has been under active follow-up. Sometimes, however, there is a more natural time scale whose origin is defined by some initiating event [39]. For example, in studies of chronic disease incidence, the most appropriate time scale might be chronological age. In a prognostic factor study for survival among patients with a disease, the origin of the time scale might be the time of disease diagnosis. In this last example, if the time scale refers to time since diagnosis (as opposed to follow-up time) special care is needed in constructing the risk sets of the **partial likelihood** analysis when the data are left truncated. A naive proportional hazards analysis that defined risk sets in the standard way (i.e. all individuals with event times greater or equal to t_i and not previously censored) can yield biased estimates of the relative risk. For example, suppose the cohort study recruits individuals alive with disease at calendar time $C = 1995$. The covariate of interest is disease diagnosed before 1990 ($X = 0$) or after 1990 ($X = 1$). Even if there were no differences in the hazards of death by calendar year of diagnosis ($\theta = 1$), the naive proportional hazards analysis would give $\theta > 1$ (aside from sampling variation). This is because all individuals diagnosed before 1990 ($X = 0$) who have survival times that are less than five years would not have an opportunity to be sampled and included in the cohort. However, among all individuals diagnosed after 1990 ($X = 1$), at least some of the individuals with survival times less than five years could have an opportunity to be sampled. The correct proportional hazards analysis of left truncated data requires an adjusted definition of risk sets similar to the adjustments described previously for Kaplan–Meier estimation. Basically, individuals should be included in risk sets only if they are under active follow-up at that time.

Truncation in Retrospective Studies

Some studies have selected individuals for enrollment based on the occurrence of the primary event of interest, and then studied these cases retrospectively to ascertain their survival time in order to estimate survival curves. The key feature of this type of design is that only individuals who have an event are eligible for inclusion in the study. For example, the first study of the **incubation period** of AIDS involved only a sample of AIDS cases who developed AIDS from a blood transfusion [32]. These patients were identified and selected for study *because they developed AIDS*. These patients were then studied retrospectively to determine the dates of transfusion with infected blood. Thus, the incubation period was determined as the time between blood transfusion and AIDS diagnosis. Another example of a retrospective study with truncation involved the selection of pediatric AIDS patients whose only known risk was maternal transmission; the dates of infection were assumed to be the dates of birth. In this case the incubation period is the time between birth and AIDS diagnosis. These are examples of retrospective studies with *right* truncated data in which individuals with long incubation periods are selectively excluded because they may not yet have had an event at the time of sampling (i.e. the time that individuals are selected for inclusion in the study).

There are also examples of **retrospective studies** with *left* truncated data. For example, a study was conducted to estimate the interval between first exposure to the human immunodeficiency virus (HIV) and the development of detectable HIV antibodies (seroconversion); this interval is called the preantibody phase [41]. This study selected only those individuals who seroconverted late in calendar time (in the late 1980s). Sera samples from these individuals had been stored and were tested by PCR to ascertain the time of first exposure to HIV. However, these individuals are a biased sample and over-represent the longer preantibody durations because individuals with short preantibody duration would have been more likely to seroconvert earlier in calendar time and thus not be included in the study [40, 42].

The remainder of this section considers the analysis of retrospective studies with right truncated data. The methods and issues are illustrated with the study of incubation periods of transfusion associated AIDS described previously. Figure 1 illustrates

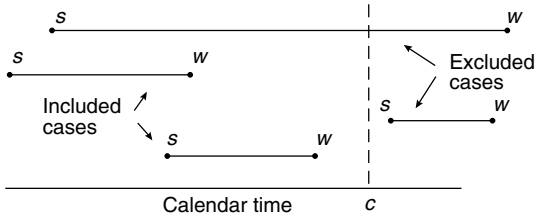

Figure 1 Schematic illustration of a retrospective study of cases (transfusion-associated AIDS) with right truncated data. Only cases diagnosed before calendar time of sampling (C) are included (i.e. $w_i < C$): s = infection date; w = AIDS diagnosis date; c = case ascertainment date

the sampling scheme: all (AIDS) cases diagnosed before some calendar time C are sampled. The figure illustrates the main problems with the analysis and interpretation of this type of data. First, since the data involve only individuals who have experienced events (AIDS diagnoses), without strong parametric assumptions, they can provide no information about the prospective probability that an infected individual eventually develops the disease. Secondly, the sampling scheme tends to over-represent individuals with shorter incubation periods. The data are right truncated because individuals with very long incubation periods are selectively excluded. The data consist of the calendar dates of infection s_i and the calendar dates of diagnosis w_i. The time to event (incubation period) is $u_i = w_i - s_i$. The criterion for inclusion in the data set is that $u_i \leq T_i$, where $T_i = C - s_i$ is called the truncation time. As illustrated in Figure 1, individuals with longer incubation periods tend to be selectively excluded because such individuals are less likely to have developed the endpoint (AIDS) at the time of ascertainment. Failure to account for such **length-biased** sampling will cause the incubation time to be underestimated.

Both nonparametric and parametric statistical procedures have been proposed for estimating the distribution function of the times to event from such data. Nonparametrically, the best that can be done is to estimate the distribution function conditional on the time to event being less than the maximum truncation time. The maximum truncation time T^* refers to the longest event time that could possibly be observed under this sampling procedure. There are simple computational approaches for calculating the nonparametric estimate of $F^*(t)$, which is the cumulative probability that an incubation period is less than t conditional on it being

less than T^*. This is based on expressing F^* as the product of conditional probabilities as follows [26, 31]. Let $t_1, t_2, \ldots, t_n$ be the ordered observed event times. In the AIDS example, these are the incubation times. The nonparametric estimate $\hat{F}^*(t)$ of $F^*(t)$ is

$$\hat{F}^*(t_s) = \prod_{j=s+1}^{n} \left(1 - \frac{d_j}{m_j}\right), \quad s = 1, \ldots, n-1, \tag{2}$$

and $\hat{F}^*(t_n) = 1.0$, where d_j is the number of individuals with event times exactly equal to t_j, and m_j are the numbers of individuals with truncation times greater than or equal to t_j (i.e. $T_i = C - s_i \geq t_i$) and whose event times are less than or equal to t_j. The estimate (2) is a step function with jumps at observed incubation times; $\hat{F}^*$ reaches the value 1.0 at the largest observed event time. The estimate $\hat{F}^*$ accounts for the length-biased sampling that arises from right truncation. A naive estimate that was based simply on the proportion of event times less than t would grossly overestimate the true distribution function $F(t)$ and would suggest that event times are shorter than they really are.

Parametric approaches can also be used to analyze retrospective studies with right truncated data. While some parametric assumptions may permit estimation not only of the conditional distribution F^* but also the unconditional distribution F, the resulting estimates of F are extremely imprecise and depend strongly on parametric assumptions. This is because parametric approaches do not circumvent the main weakness in the data; it is not possible to observe event times greater than the maximum truncation time. Several likelihood functions have been proposed for the parametric analysis of retrospective data on cases with right truncation [5, 26]. The differences in the various likelihood functions that have been proposed arise from using different conditioning events. At a minimum, the likelihood function must condition on having an event prior to the case ascertainment time C. In addition, some of the proposed likelihood functions condition on the time origins (dates of infection s_i).

Prevalent Cohort Studies

Prevalent cohort studies are used to study the **natural history** of disease [6]. The prevalent cohort study consists of a sample of individuals who have a condition or disease at the time of enrollment in the study. These individuals are then followed over time to monitor endpoints such as disease progression or death. In some situations the durations of time the individuals have been prevalent with the disease or condition prior to enrollment are known. For example, Cnaan & Ryan [8] considered survival analysis of a registry of sarcoma patients seen at certain institutions that included some patients who were initially diagnosed elsewhere. These data are left truncated because the patients diagnosed at other institutions must have survived long enough to be included in the sample. The methods for left truncated data outlined in the previous section are required to account adequately for the sampling scheme [8].

A more serious complexity arises in the analysis and interpretation of prevalent cohort studies if the durations of time the individuals have been prevalent with the disease or condition prior to enrollment is unknown. This section is concerned with the issues in the analysis and interpretation of prevalent cohort data when the prior durations are unknown.

An example of a prevalent cohort concerns a study of HIV infected individuals with the objective to estimate rates of progression to AIDS and to identify covariates that modify these rates. In this example, individuals who are alive and previously infected with HIV are eligible for enrollment. These individuals are then followed for the onset of disease progression (AIDS). The main complexity is that the previous calendar times of infection are unknown. Figure 2 gives a schematic illustration of the prevalent cohort study. There are three time scales: calendar time (s), the time from infection (u),

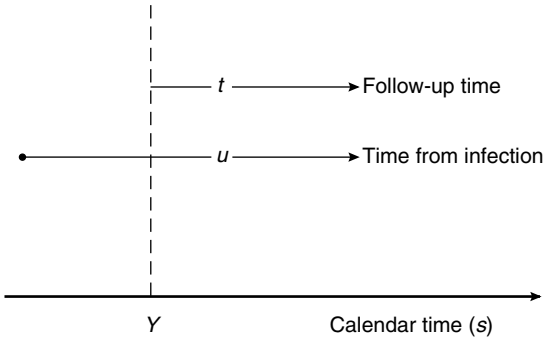

Figure 2 Schematic illustration of the prevalent cohort study

and follow-up time (t). A prevalent sample of individuals who are HIV infected and alive is taken at calendar time Y. The main advantage of the prevalent cohort study is that it can be performed more rapidly than can traditional cohort studies of individuals with incident (new) HIV infection. The traditional cohort study requires a sample of newly infected individuals and there could be considerable expense and effort entailed to identify such a sample. However, a number of important problems arise in the interpretation and analysis of a prevalent cohort that do not arise with a series of newly infected (incident) individuals because the duration of time a person has been infected prior to the beginning of follow-up is not known.

This section outlines the biases and problems of interpretation in prevalent cohorts. Although the prevalent cohort is discussed using the HIV/AIDS example described above, the conclusions, of course, apply to many other settings: for example, a study among prevalent carriers of hepatitis B surface antigen in order to identify modifiers of risk for hepatocellular carcinoma. The unifying feature is that there is an initiating event of a disease (e.g. infection) that defines the natural biological time scale, and individuals who are prevalent with the condition are then enrolled. This results in left truncated data but, unfortunately, one cannot analyze prevalent cohorts using methods for left truncated data because the truncation times are unknown.

Suppose analyses are performed on the time scale of the observed follow-up time (t) instead of the desired, but unobservable, natural time scale (u) such as time from infection. Specifically, how do estimates derived from prevalent cohorts of the probability of an event within t years of follow-up, $F_p(t) = 1 - S_p(t)$, relate to $F(t)$ which is the probability of an event within t years of infection? The proportion of persons in a prevalent cohort who develop disease within t years of follow-up, $F_p(t)$, does not in general approximate $F(t)$. Only if the hazard function on the natural time scale $\lambda(u)$ is constant (an **exponential distribution** for F) do the two coincide. This follows from the lack of memory property of an exponential distribution, which implies that a newly infected individual will progress to the event at the same rate as an individual who has been alive for some time. However, if the hazard $\lambda(u)$ is monotonically increasing, then individuals in the prevalent cohort will be at greater risk of an event than are newly infected individuals. That is to say, the cumulative probability of an event within t years of follow-up of a prevalent cohort is larger than that based on t years of follow-up of an incident (newly infected) cohort [$F_p(t) > F(t)$]. The direction of the bias is reversed for a decreasing hazard. No general statements can be made about the direction of the bias for nonmonotonic hazard functions. Regardless of the shape of the hazard, $F_p(t)$ is a lower bound on the ultimate proportion of individuals who will have an event, $F(\infty)$. Brookmeyer & Gail [4] derived exact expressions for the distribution function on the observed follow-up time scale, $F_p(t)$, in terms of the probability density of infection times among cohort members and the true distribution function F. The magnitude of the biases depend both on the hazard function, $\lambda(t)$, and the density of calendar times of prior infection (the initiating event) among those individuals in the prevalent cohort. For example, the bias would be small if the prevalent cohort is assembled near the beginning of the epidemic, in which case the backward recurrence times (or the times from infection to the onset of follow-up) would be short (*see* **Back-calculation**).

The prevalent cohort study is a rapid and convenient approach to identify cofactors and markers of disease progression. However, because the onset date is unknown, there are biases that result from using follow-up time instead of time from infection. The most important bias associated with identifying cofactors from prevalent cohorts is called *onset confounding* [4, 6]. This occurs when the unknown calendar date of infection is associated both with the risk of disease and the cofactor under study. A subgroup may appear at higher risk of progression to disease simply because they were infected earlier than another subgroup. For example, individuals in one geographic region may exhibit a higher progression rate to disease than other individuals. This finding could be an artifact if individuals in one city were infected earlier in calendar time, and the hazard function $\lambda(t)$ is increasing. The requirement to insure no onset confounding is that the probability densities of infection times among individuals infected before calendar time Y is the same in the two subgroups. Onset confounding can be controlled by stratification on factors such as geographic region. Stratification on a covariate is useful provided we are not interested in determining whether the covariate itself is a cofactor of disease progression.

Unfortunately, even if a covariate has no direct effect on the probability density of infection times among members of the prevalent cohort so that there is no onset confounding, relative risk estimates obtained from prevalent cohorts may still be biased. To see this, assume that a cofactor with two levels obeys the following simple proportional hazards model:

$$\lambda_1(u) = \theta\lambda_0(u),$$

where $\lambda_1(u)$ and $\lambda_0(u)$ are the disease incidence rates at time u among those with and without the factor, respectively, and θ is the ratio of the hazards. In this model, the underlying primary time scale is the natural but unobservable scale u, time since first infection. If this model holds, but a proportional hazards analysis is performed based on follow-up time, then tests of the **null hypothesis** $H_0 : \theta = 1$ will be valid provided there is no confounding. However, estimates of θ based on the incorrect assumption of proportional hazards on the observed follow-up time scale will usually be biased for θ. The term *differential length biased sampling* is used to refer to this bias, which results from differences in the distributions of prior durations of infection (backward recurrence times) between the two prevalent subgroups [4]. Differential length-biased sampling may bias the relative risk from a prevalent cohort, and the direction of the bias depends on whether the hazard function is increasing or decreasing, as discussed below.

If the hazard function is increasing, then relative risk estimates obtained from follow-up on a prevalent cohort will be biased toward unity. A theoretical proof is given in [4] but an intuitive justification is as follows. Infected persons with a risk factor are at higher risk of disease than infected persons without the risk factor. Persons sampled for the prevalent cohort who are in the low-risk group will tend to have longer prior durations of infection than persons in the high-risk group. This is because high-risk persons infected many years earlier are more likely to have developed disease and thus be excluded from the prevalent cohort. Since low-risk persons tend to have been infected for a longer time, their disease is further advanced [with an increasing hazard $\lambda_0(u)$] and therefore the disparity in risk of disease between two groups is reduced, biasing the relative risk toward 1. Analogously, if the hazard function $\lambda_0(u)$ is decreasing, then the relative risk will be biased away from 1. Fortunately, the magnitude of differential length-biased sampling phenomena is never enough to reverse the conclusion, that is to push the relative risk to the other side of 1. Furthermore, there are two situations when the effect of differential length bias could be expected to be negligible: (i) if there is little dispersion in the infection dates (in which case all backward recurrence times are nearly identical) and (ii) if the hazard $\lambda_0(u)$ is small so that only a small proportion of those infected before the initiation of the prevalent cohort study develop disease before the end of follow-up and are selectively excluded (see [4] for a more formal statement of the conditions when the bias from differential length biased sampling is small).

Other types of biases in prevalent cohorts arise in the analysis of the **time-dependent covariate**, that is the variable whose value changes over time u. There are two types of time-dependent covariates, "external" and "internal" [27]. The main distinction is that internal time-dependent covariates reflect the health of the individual (markers) while external time-dependent covariates are applied externally, such as a random assignment to a treatment group. For example, consider an external time-dependent variable which takes effect at some point after the onset of follow-up. An example might be a treatment given to some members of a prevalent cohort. If the treatment is assigned randomly (*see* **Randomization**), then the condition for no onset confounding is satisfied. Unfortunately, even without onset confounding, relative risk estimates of the treatment effects will still be biased [4]. Specifically, assume that the effect of the treatment is to multiply the hazard by θ, that is consider a proportional hazards model with a time-dependent covariate $x(u)$, where $x(u)$ is 0 before initiation of treatment and 1 thereafter:

$$\lambda_1(u) = \theta^{x(u)}\lambda_0(u). \tag{3}$$

Then, the relative risk estimate of θ based on the proportional hazards analysis with a time-dependent covariate on the follow-up time scale t will yield an estimate of θ that is biased toward unity, regardless of whether the hazard function is strictly increasing or decreasing. This bias results because the analysis controls for follow-up time t when in fact the analysis should control for the unknown time from infection u. The result that the risk estimates are biased toward unity is seen intuitively from the following argument. Suppose, without loss of generality, that $\theta > 1$. Then the effect of the variable $x(u)$ is to

accelerate disease, especially among frail individuals. If the hazard is increasing, then the frail individuals are those that have been infected for a longer time. Therefore the individuals with $x(u) = 1$ tend to be selectively depleted from the frail individuals, and the net effect is to decrease the disparity in risk between those with $x(u) = 1$ and those with $x(u) = 0$. This bias has been called *frailty selection*. A similar argument holds if the hazard is decreasing. In either case, the effect of frailty selection is to bias the relative risk toward unity.

Internal time-dependent covariates, also known as *markers*, present different issues. Markers track the progression of disease and change value over the course of follow-up. Markers change in response to disease progression and may convey information about the duration of infection. For example, persons with abnormal marker levels are likely to have been infected longer than persons with normal levels. Suppose the proportional hazards model (3) holds. In model (3) the parameter θ reflects the disease–marker association controlling for duration of infection; that is θ quantifies the prognostic information in the marker over and above the prognostic information in the duration of infection. Unfortunately, in prevalent cohort studies of markers that are performed on the follow-up time scale, estimates of θ in model (3) as well as hypothesis tests of $\theta = 1$ may not be valid and are not comparable with results obtained from an incident cohort. Furthermore, no general statements can be made about the direction of the biases because both frailty selection and onset confounding are operating. For example, a high relative risk associated with an elevated marker may reflect the fact that individuals with the elevated marker have been infected longer.

The various biases associated with prevalent cohorts are summarized in Table 1. Because of these biases, prevalent cohort studies pose serious limitations for studying the disease–marker association of model (3). Prospective studies of an incident cohort are required to disentangle the role of markers and duration of infection on disease risk. Nevertheless, prevalent cohort studies of markers may serve other important purposes. For example, baseline values of markers measured at enrollment ($t = 0$) are useful for prognostic purposes. Survival analyses and proportional hazards analyses on the scale of time since enrollment address the prognostic information in the baseline marker over and above time since enrollment. This is useful for counseling individuals, and for deciding on a course of treatment. These analyses answer the question: "What prognostic information does the baseline marker value provide in addition to *time since enrollment*?" The question "What prognostic information does the baseline marker value provide in addition to *time since infection*?" cannot be answered from such studies and analyses. Nonetheless, such analyses are useful, because the dates of infection are usually unknown in clinical practice; such analyses thus provide important prognostic information for advising patients from similar prevalent cohorts about risk. Such studies may also identify important variables for stratification and adjustment in controlled **clinical trials** of individuals with prevalent infection.

Selection and Regression Towards the Mean

Cohort studies are sometimes performed among the individuals at highest risk of disease. For example, a double blind trial of clofibrate in the primary prevention of ischemic heart disease randomized men who were in the upper third of the distribution of serum cholesterol values [22]. In the Hypertension Detection and Follow-up Program Cooperative Group Study [24], individuals with elevated blood pressure at initial screening were enrolled for follow-up. In these examples, the individuals selected were sampled for inclusion in the study because measurements on a variable at initial screening were extreme. In some instances this selection process can be a source for bias because of **regression toward the mean**.

Regression towards the mean refers to the phenomenon that if a variable is extreme on the first measurement, then later measurements may tend to be closer to the center of the distribution [12]. Regression towards the mean was first described by **Sir Francis Galton** who found that offspring of tall parents tended to be shorter than their parents while offspring of short parents tended to be taller. Galton called this regression toward mediocrity [18].

As a simple example, consider a study to evaluate a treatment to lower blood pressure. Individuals are screened for blood pressure and those in the highest decile are enrolled in the cohort study and given the treatment. Some of those extremely high

Table 1 Bias of relative risk estimate, θ^*, from a prevalent cohort study compared with relative risk estimate, θ, obtained from an incident cohort study[a] (adapted from [6])

		Effect of bias			
		Increasing hazard		Decreasing hazard	
Type of factor	Source of bias	$\theta > 1$[b]	$\theta = 1$	$\theta > 1$[b]	$\theta = 1$
Fixed cofactor affects risk of infection nonmultiplicatively	Onset confounding	No reliable inference from prevalent cohort			
Fixed cofactor unrelated to or acts multiplicatively on risk of infection	Differential length-biased sampling	Biased toward 1 ($1 < \theta^* \leq \theta$)	Unbiased ($\theta^* = 1$)	Biased away from 1 ($\theta^* \geq \theta$)	Unbiased ($\theta^* = 1$)
Time-dependent cofactor which takes effect after enrollment	Frailty selection	Biased toward 1 ($1 \leq \theta^* \leq \theta$)	Unbiased ($\theta^* = 1$)	Biased toward 1 ($1 \leq \theta^* \leq \theta$)	Unbiased ($\theta^* = 1$)
Marker	Onset confounding and frailty selection	No general statements about direction of bias			

[a] θ^* and θ are the large sample expected values of the relative risks obtained from prevalent and incident cohorts, respectively.
[b] Analogous results hold for $\theta < 1$.

measurements at initial screening will decline at the follow-up measurement not because of the efficacy of the treatment but because the initial extreme high measurements were statistical flukes. A naive analysis could lead one to conclude incorrectly that the decline in mean blood pressure is evidence that the treatment is effective. In this example it was especially important to account for regression towards the mean because the study design was a before–after comparison without a control group. Regression towards the mean can lead one to conclude incorrectly that not only are there treatment effects, but there are also **treatment–covariate interactions**. For example, several studies of serum cholesterol lowering diets, such as the National Diet Heart Study, have reported that individuals with initially high serum cholesterol levels experience greater reductions than individuals with initially low cholesterol levels [16].

The effect of regression towards the mean can be formalized [12, 19]. Suppose the only individuals enrolled in a cohort study are those whose initial screening measurement, y_1, are greater than a prespecified value, k. A second measurement, y_2, is taken on follow-up. Suppose y_1 and y_2 are each **normally distributed** with **mean** μ and **variance** σ^2. Then

$$\mathrm{E}(y_1|y_1 > k) - \mathrm{E}(y_2)|y_1 > k) = c\sigma(1-\rho), \quad (4)$$

where c is a positive constant that depends on k, μ and σ, and ρ is the **correlation** coefficient between y_1 and y_2. Thus, even though there is no difference in expected measurements at baseline and follow-up in the entire population $[\mathrm{E}(y_1) = \mathrm{E}(y_2) = \mu]$, there is an expected decline in the two measurements in the *sampled cohort* because of the selection criterion $(y_1 > k)$. The effect of regression towards the mean becomes greater as ρ approaches 0. There is no regression towards the mean if $\rho = 1$.

One approach for accounting for regression towards the mean is to have a suitable control group. For example, if individuals are randomized to either a treated or control group, then both groups could be expected to have the same amount of regression towards the mean, and any significant differences between groups could be attributed to real treatment effects. If a control group is not available, then corrections can be made for the regression towards the mean [12, 25]. The basic idea of these corrections is based on (4) and uses either external or internal estimates of the parameters of the equation.

Various suggestions have been made for improvements in study design to minimize regression towards the mean. For example, the initial selection criteria could be based on the mean $\overline{y}_1$ of n measurements rather than on only a single measurement y_1. Then, only individuals with $\overline{y}_1 > k$ are sampled for inclusion in the cohort. It can be shown that $\mathrm{E}(\overline{y}_1 - y_2|\overline{y}_1 > k)$ goes to 0 as n gets large [12]. Thus, the effect of regression towards the mean can be reduced by using the average of a number of initial measurements as the basis of the selection criteria. Another proposed approach is to use an initial measurement as the basis for selecting individuals into the study. However, then a second initial measurement is taken on the selected sample, and it is this second measurement that is used as the baseline measure to calculate change from the subsequent follow-up measurement. Under this scheme there will be no regression towards the mean if the observations are equicorrelated [12, 16].

Binary Data

Data are said to be binary when the observed value of a response variable falls into one of two possible categories. For example, a patient in a clinical trial to compare alternative therapies may or may not experience relief from symptoms. Similarly, an insect exposed to a particular concentration of an insecticide may either be alive or dead after a certain period of time. The two possible values of the binary response variable for each individual are usually coded as 0 and 1. Expressed in this way, the observations are referred to as *ungrouped* binary data.

In some circumstances, interest centers on a set of individuals that have all been treated in the same manner. The binary responses for each individual in a set are then combined to give a proportion. Thus a batch of insects may be exposed to an insecticide, and the number of insects that respond is expressed as a proportion of the number exposed. Data in this form are referred to as *grouped* binary data.

Usually, grouped binary data will be obtained for a number of sets of individuals. Thus, in the insecticide example we may wish to explore how different batches of insects respond to a range of concentrations of the insecticide. The total number that are killed in each batch is then recorded for each concentration. Interest then centers on how the probability that an insect dies is related to the concentration of the insecticide. Data in this form are commonly encountered in bioassay (*see* **Biological Assay, Overview**).

Probability Models for Binary Data

The random variable associated with the binary response of the ith of n individuals in a study, Y_i, say, will take a value y_i, where y_i is either 0 or 1. These two possible values of the response variable are often referred to as failure and success, respectively. We will write p_i for the probability that the ith individual experiences a success, so that $p_i = \Pr(Y_i = 1)$. The random variable Y_i then has a *Bernoulli distribution*, and

$$\Pr(Y_i = y_i) = p_i^{y_i}(1 - p_i)^{1-y_i},$$
$$y_i = 0, 1; \quad i = 1, 2, \ldots, n.$$

Now suppose that we have a set of m binary observations, $y_1, y_2, \ldots, y_m$, which are mutually independent. If each binary response has the same success probability p, then the total number of successes in the m binary observations is $y = \sum_{i=1}^{m} y_i$, and the corresponding random variable $Y = \sum_{i=1}^{m} Y_i$ has a **binomial distribution** with parameters m and p. We then have that

$$\Pr(Y = y) = \binom{m}{y} p^y (1 - p)^{m-y},$$
$$y = 0, 1, \ldots, m,$$

and this distribution is written as $B(m, p)$. More generally, consider the situation where we have n sets of binary data, such that in the jth set, $j = 1, 2, \ldots, n$, there are y_j successes amongst m_j binary observations. If we write p_j for the true probability of a success for an individual in the jth set, then the values y_j are observations on $B(m_j, p_j)$ random variables. Ungrouped binary data can be regarded as a special case in which $m_j = 1$ for each set, and we would then be back to n binary observations.

Modeling Binary Data

In studies that lead to ungrouped binary data there will usually be other variables recorded for each individual. For example, consider a study to compare two alternative treatments for prostatic cancer, where the response variable concerns whether or not an individual dies within the three-year period following entry to the trial. The age of the patient, and the values of variables such as tumor size, tumor grade, and the level of serum acid phosphatase, may all affect the prognosis of an individual. In analyzing the data from the study we would examine how the three-year survival probability depends on these variables, as well as on the treatment group.

For grouped binary data the values of any explanatory variables will perforce be the same for each of the binary observations in a given set. For example, in the insecticide study, suppose that batches of 20 insects are exposed to one of two chemicals applied at one of four concentrations. The resulting data will be the eight proportions of insects that die, out of the 20 exposed, for each of the eight combinations of chemical and concentration. Of course,

these grouped binary data could be ungrouped to give the $20 \times 8 = 160$ binary observations, but there are advantages in working with the grouped data.

When the structure of a data set is particularly simple, i.e. when there are just one or two explanatory variables recorded for each individual, methods of analysis based on a **contingency table** may be sufficient. However, it is usually much more informative to describe the relationship between the response probabilities and explanatory variables using a statistical model. This approach is now described and illustrated. Full details can be found in [2], [6], [12], and in the research monograph of McCullagh & Nelder [9] on **generalized linear models**.

Example: Incidence of Sore Throat

It will be convenient to illustrate the modeling process using a specific example, and for this we will use data based on a study to compare two devices used in securing the airway in patients undergoing surgery with general anesthesia. The two devices were the laryngeal mask airway (LMA) and the tracheal tube (TT); in the data set the device is denoted by a variable, 0 for LMA and 1 for TT. In addition, information on each patient's age (in years), sex (0 = female, 1 = male), duration of surgery (in minutes) and on whether or not a lubricant was used by the anesthetist (0 = not used, 1 = used) was recorded. The response variable of interest is whether or not a patient experienced a sore throat on waking (0 = no sore throat, 1 = sore throat), and so is binary. Data for 35 patients are given in Table 1.

In analyzing these data we investigate whether the probability of a sore throat depends on the variables age, sex, duration, and lubricant, and the extent of any differences between the two types of airway device.

Table 1 Data on the incidence of sore throat following anesthesia

Patient	Age	Sex	Lubricant use	Duration	Type	Response
1	48	1	0	45	0	0
2	48	1	0	15	0	0
3	39	0	1	40	0	1
4	59	1	0	83	1	1
5	24	1	1	90	1	1
6	55	1	1	25	1	1
7	35	0	1	35	0	1
8	23	1	1	65	0	1
9	57	0	1	95	0	1
10	34	1	1	35	0	1
11	56	0	1	75	0	1
12	35	0	0	45	1	1
13	37	0	1	50	1	0
14	30	1	1	75	1	1
15	45	1	1	30	0	0
16	60	1	0	25	0	1
17	35	1	1	20	1	0
18	41	1	0	60	1	1
19	67	0	1	70	1	1
20	25	0	0	30	0	1
21	63	0	1	60	0	1
22	26	0	1	61	0	0
23	47	0	0	65	0	1

26	64	0	0	45	0	1
27	48	0	0	15	1	0
28	28	1	0	25	0	1
29	54	1	0	15	1	0
30	58	1	1	30	0	1
31	59	1	1	40	0	1
32	67	1	0	15	1	0
33	43	1	1	135	1	1
34	63	1	0	20	1	0
35	41	0	0	40	1	0

Models for Binary Data

Methods used in fitting **multiple regression** models to continuous data, based on ordinary **least squares**, cannot be applied directly to binary or binomial response data. This is because these methods do not take proper account of the fact that the data have a binomial distribution, and second they may well lead to fitted probabilities outside the range (0, 1). Instead, the probability scale is transformed from the range (0, 1) to $(-\infty, \infty)$, and a linear model is adopted for the transformed value of the response probability.

Of the possible transformations, the *logistic transform* is the one most commonly used. The logistic transform or logit of p is $\log\{p/(1-p)\}$, written $\text{logit}(p)$. If $x_{1i}, x_{2i}, \ldots, x_{ki}$ are the values of k explanatory variables $X_1, X_2, \ldots, X_k$ for the ith individual, $i = 1, 2, \ldots, n$, then the **logistic regression** model for p_i, the response probability for that individual, is given by

$$\text{logit}(p_i) = \log\left\{\frac{p_i}{1-p_i}\right\} = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_k x_{ki}.$$

Other transformations of p_i that might be used are the *probit* and *complementary log–log transformations*. The probit of a probability p is that value of ξ for which $\Phi(\xi) = p$, where $\Phi(\cdot)$ is the standard normal distribution function, so that probit $(p) = \Phi^{-1}(p)$. The complementary log–log transform of p is $\log\{-\log(1-p)\}$. For practical purposes the logistic and probit transformations will often give similar results, but the logistic transformation is computationally more convenient and leads directly to **odds ratios**, which help in the interpretation of fitted models. Unlike the logistic and probit transformations, the complementary log–log transformation is not symmetric about $p = 0.5$, but it does arise in particular areas of application, such as a **serial dilution assay** and the analysis of interval-censored survival data.

In what follows the transformation of p is denoted by the function $g(\cdot)$, so that a general model for binary data, or a **quantal response model**, can be expressed as

$$g(p_i) = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_k x_{ki}, \quad i = 1, 2, \ldots, n. \tag{1}$$

This model is, in fact, a member of the class of models known as *generalized linear models*, and the function $g(\cdot)$ is known as the *link function*.

Fitting the Model

The model for a binary response probability can be fitted using the method of **maximum likelihood**. The **likelihood** of n binomial observations is

$$L(\beta) = \prod_{i=1}^{n} \binom{n_i}{y_i} p_i^{y_i} (1 - p_i)^{n_i - y_i}, \tag{2}$$

where the p_i are related to the β coefficients through (1). Note that for ungrouped binary data the n_i in (2) are all equal to unity.

The values of the βs that maximize this likelihood function, denoted $\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k$, can only be obtained numerically, and either the Newton–Raphson method or Fisher scoring are generally used (*see* **Optimization and Nonlinear Equations**). These methods lead to the **information matrix**, from which the standard errors of the $\hat{\beta}$s can be found.

Once estimates of the βs in (1) have been obtained, the corresponding fitted probability for the ith individual, $\hat{p}_i$, is found from

$$g(\hat{p}_i) = \hat{\beta}_0 + \hat{\beta}_1 x_{1i} + \cdots + \hat{\beta}_k x_{ki}, \quad i = 1, 2, \ldots, n. \tag{3}$$

Fortunately, computer software for obtaining the maximum likelihood estimates of the β coefficients in (1) is widely available. The statistical packages MINITAB, GLIM, Genstat, SAS, S-PLUS, SPSS, STATA, and many others all have facilities for modeling binary data (*see* **Software, Biostatistical**). Naturally, there are differences in the numerical methods used to estimate the βs, in the types of variable that can be included in the model (some software does not allow factors to be fitted directly), and in the format of the resulting output.

Goodness of Fit of a Model

Suppose that a model containing certain explanatory variables, known as the *current model*, is fitted to grouped binary data. The agreement between n observed proportions y_i/n_i, $i = 1, 2, \ldots n$, and the corresponding fitted values under the model of interest, $\hat{p}_i$, can be assessed using a quantity known as the *deviance*. This is defined to be $-2\{\log \hat{L}_c - \log \hat{L}_f\}$, where $\hat{L}_c$ is the maximized likelihood under the current model, and $\hat{L}_f$ is the maximized likelihood under the *full* or *saturated model*. The latter model is one that is a perfect fit to the data, and so the fitted probabilities under the full model are simply the observed proportions y_i/n_i. If the current model is satisfactory, then the fit of this model will not be too different from that of the full model. In this case $\hat{L}_c$ will be similar to $\hat{L}_f$, and the deviance will be close to zero. However, if the current model is a poor fit, then $\hat{L}_c$ may be very much smaller than $\hat{L}_f$, and the deviance will be large.

We can calculate a deviance for ungrouped binary data, where $n_i = 1$ for each observation, but then the deviance turns out to be uninformative about the goodness of fit of a model. For example, in the particular case of the linear logistic model, the deviance is a function of $\hat{p}_i$ alone, and so can tell us nothing about the agreement between the binary observations y_i and the corresponding fitted probabilities. Consequently, the deviance for ungrouped binary data cannot be used as a summary measure of goodness of fit. It is

therefore desirable to group binary data when possible, since this leads to an overall measure of the goodness of fit of a model.

Distribution of the Deviance

From results concerning the asymptotic distribution of the maximized likelihood ratio statistic (see, for example, [5]), it follows that the deviance for binomial data has an asymptotic χ^2 distribution on $n - \nu$df, where ν is the number of unknown βs in the current model. Thus a well fitting model should have a deviance that is not significantly large relative to the percentage points of a $\chi^2_{n-\nu}$ distribution. Since $E(\chi^2_{n-\nu}) = n - \nu$, a useful rule of thumb is that the deviance should be close to its corresponding number of degrees of freedom in a satisfactory model. However, caution must be exercised in using such general measures of model adequacy, and the fit of a model should also be assessed critically using the model-checking diagnostics described in a later section.

For binary data the deviance does not have an asymptotic χ^2 distribution, and so even when an appropriate model has been fitted, the deviance will not necessarily be close to its number of degrees of freedom. Nevertheless, we shall see in the next section that this quantity is valuable in comparing models fitted to either grouped or ungrouped binary data.

Comparing Alternative Models

The main use of the deviance is in comparing alternative models for a binary or binomial response variable. Suppose that one model contains terms that are additional to those in another. The difference in deviance between the two models then reflects the extent to which the additional terms improve the fit of the model. For example, suppose that the following two nested models, labeled Model (1) and Model (2), are to be compared:

Model (1):

$$g(p_i) = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_h x_{hi};$$

Model (2):

$$g(p_i) = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_h x_{hi} + \beta_{h+1} x_{h+1,i} + \cdots + \beta_k x_{ki}.$$

Denoting the deviance under each model by D_1 and D_2, so that these deviances have $n - h - 1$ df and $n - k - 1$df, respectively, D_2 will be smaller that D_1, since Model (2) contains more terms than Model (1). The difference in deviances, $D_1 - D_2$, will reflect the additional effect of the corresponding variables $X_{h+1}, X_{h+2}, \ldots, X_k$, after $X_1, X_2, \ldots, X_h$ have been included in the model. This difference in deviance has an approximate χ^2_{k-h} distribution on the hypothesis that the additional $k - h$ variables are not needed in the model. In general, changes in deviance can be compared with appropriate percentage points of a χ^2 distribution to determine whether or not terms need to be included in or excluded from a model. In fact, the difference in deviance between two nested models is asymptotically χ^2 for both binary and binomial data, and so procedures for comparing models apply equally to grouped and ungrouped binary data.

Using the deviance to compare models fitted to binary or binomial response data, the most appropriate combination of variables for describing observed variation in such data can be determined. Methods for identifying subsets of explanatory variables are described in texts on linear regression modeling, e.g. Draper & Smith [7] and Montgomery & Peck [11]. See also [10] and Appendix 2 of [6].

The method for comparing models described above is based on the asymptotic distribution of changes in deviance. For the proper application of this method, the data must not be too sparse, i.e. proportions must not be based on small numbers of individuals, or the number of binary observations needs to be large relative to the number of parameters being fitted. If this is not the case, then there will be difficulties associated with the convergence of the algorithm for fitting the models, and certain parameter estimates may appear to have unusually large standard errors. In such cases one cannot rely on the asymptotic properties of test statistics. Recent computational advances have led to the development of exact methods for analyzing contingency tables and for logistic regression. These techniques are described elsewhere, and are implemented in the software packages StatXact and LogXact.

Example: Incidence of Sore Throat

We first identify which of the variables relating to the age of the patient (A), the sex of the patient (S), the duration of surgery (D) and the use of a lubricant (L)

Table 2 Deviances on fitting logistic regression models

Variables in model	Deviance	df
Constant only	46.18	34
A	45.88	33
S	46.18	33
L	44.08	33
D	33.65	33
T	42.58	33
$D + T$	30.14	32

need to be included in a logistic regression model for the probability of a sore throat before the effect of type of airway (T) is considered. The deviances on fitting certain logistic regression models to the data in Table 1 are given in Table 2. These show that there are no significant reductions in deviance when either A, S, or L are added to the model that contains a constant only. We also find that these variables do not become relevant in the presence of others and so need not be considered further. However, the decrease in deviance on adding D to a model that contains a constant term alone is 12.53 on 1 df, which is highly significant ($P < 0.001$).

The main focus of the study is to compare the two airway devices. When the variable T is added to the model that contains D, the reduction in deviance is 3.51 on 1 df, which is significant at the 10% level ($P = 0.061$). There is therefore evidence of a difference in the two types of airway device, after allowing for the effect of the duration of surgery. Once D and T are included in the model, no further variables lead to a significant reduction in deviance. There is also no need to include interactions between any variables.

The equation of the fitted logistic regression model for the probability of a sore throat is

$$\text{logit}(\hat{p}_i) = -1.417 + 0.069D_i - 1.659T_i, \quad i = 1, 2, \ldots, 35, \tag{4}$$

where D_i and T_i are the values of D and T for the ith individual. This analysis shows that the probability of a sore throat is dependent upon the duration of surgery and the type of airway device used. The positive coefficient of D in the model shows that the probability of a sore throat increases with the duration of surgery, while the negative coefficient of T indicates that there is a higher probability of a sore throat when $T = 0$, i.e. when the laryngeal mask airway is used.

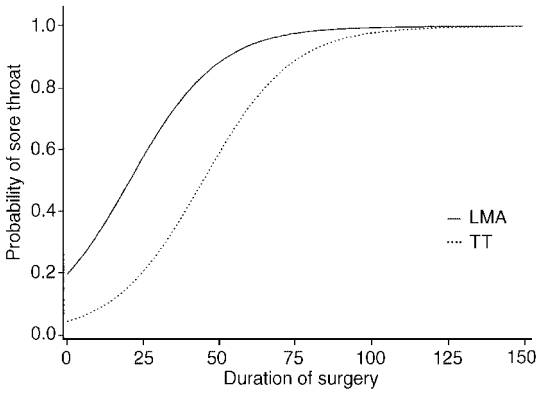

Figure 1 The fitted probability of a sore throat plotted against duration of surgery for laryngeal mask airway (LMA) and tracheal tube (TT)

It is informative to plot the fitted response curves, and such a graph is shown in Figure 1 where we have plotted the observed and fitted probability of a sore throat, $\hat{p}_i$, on the vertical axis. The logistic transform of $\hat{p}_i$ could also have been plotted, in which case the graph would show straight-line relationships between the transformed fitted probability and duration of surgery. This graph shows clearly the relationship between the probability of a sore throat and duration of surgery, and the extent of the difference due to the type of airway.

Model Checking

Once a model has been fitted it is essential to check that the fitted model is appropriate (*see* **Model Checking**). After all, inferences drawn on the basis of an incorrect model will simply be wrong. There are a number of ways in which a model may be unsatisfactory. The linear component of the model may be incorrectly specified in that it may not include explanatory variables that really should be in the model, or variables that are included may need to be transformed. An incorrect choice of link function may have been made, or there may be observations not well fitted by the model, termed outliers. In binary data, outliers may correspond to cases where a failure has been misclassified as a success. There may be values that unduly influence quantities such as parameter estimates. The assumption of a binomial distribution for grouped binary data may also be invalid, possibly

because of the nonindependence of the constituent binary observations.

Techniques for examining the adequacy of a fitted model, known collectively as model-checking diagnostics, are described and illustrated in Chapter 5 of Collett [2]. Some key papers in this area are [13, 8, 14], and [4].

Analysis of Residuals

Much information about model adequacy can be obtained from residuals. Suppose that a model is fitted to n binomial observations of the form y_i/n_i and, as usual, let $\hat{p}_i$ be the fitted probability for the ith observation, $i = 1, 2, \ldots, n$. There are a number of possible residuals for use in binary data analysis, including *Pearson residuals*, given by

$$r_i = \frac{y_i - n_i\hat{p}_i}{[n_i\hat{p}_i(1-\hat{p}_i)]^{1/2}},$$

and the *deviance residuals*

$$d_i = \text{sgn}(y_i - n_i\hat{p}_i) \times (\text{deviance component for } i\text{th observation})^{1/2}.$$

The squares of these residuals sum respectively to Pearson's χ^2 statistic and the deviance for the fitted model. In the particular case of logistic regression, the deviance residuals are

$$\text{sgn}(y_i - n_i\hat{p}_i)\left[2y_i\log\left(\frac{y_i}{n_i\hat{p}_i}\right) + 2(n_i - y_i)\log\left(\frac{n_i - y_i}{n_i - n_i\hat{p}_i}\right)\right]^{1/2}.$$

Both types of residuals can be standardized by division by $(1-h_i)^{1/2}$, where h_i is a quantity known as the *leverage*. This is the ith diagonal element of the matrix $\mathbf{H} = \mathbf{W}^{1/2}\mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}^{1/2}$, known as the hat matrix, in which $\mathbf{X}$ is the matrix of explanatory variables known as the design matrix, and $\mathbf{W}$ is a diagonal matrix of weights with elements $n_i/\{\hat{p}_i(1-\hat{p}_i)[g'(\hat{p}_i)]^2\}$, where $g'(\cdot)$ is the derivative of $g(.)$ with respect to p.

The standardized deviance residuals, $r_{Di} = d_i/(1-h_i)^{1/2}$, are recommended for general use and can be plotted against the observation number or index to give an index plot, explanatory variables in or out of the model, or the linear predictor, $\hat{\eta}_i = \hat{\beta}_0 + \hat{\beta}_1 x_{1i} + \cdots + \hat{\beta}_k x_{ki}$. Observations that are outliers will be shown in an index plot as having unusually large residuals. The pattern in a plot of residuals against explanatory variables in the model may indicate the need for a transformation of that variable, and the pattern in a plot of residuals against the linear predictor may also suggest that the linear component of the model is not correct.

A **half-normal** plot, possibly supplemented by simulation envelopes (Atkinson [1]), can be helpful in revealing model inadequacy. These plots are based on the absolute values of the residuals arranged in ascending order, denoted $|r|_{(j)}$, $j = 1, 2, \ldots, n$. The values $\Phi^{-1}\{(j + n - \frac{1}{8})/(n + \frac{1}{4})\}$ are then plotted against the $|r|_{(j)}$. Outliers will correspond to points in the top right-hand corner of the plot. A simulated envelope indicates the region of the plot where the points should lie, if the model is satisfactory. Consequently, the occurrence of points outside such an envelope indicates that the fitted model is inappropriate.

Most of these plots of residuals are designed for use with grouped binary data, and corresponding plots of residuals obtained from binary response data may not be informative. This is because the plots can have a pattern even when the fitted model is appropriate. For example, plots of residuals obtained from binary data against the linear predictor will show two hyperbolas, corresponding to the observations of 0 and 1. However, index plots and half-normal plots of standardized deviance residuals can be useful in assessing model adequacy.

Influential Observations

An observation is said to be *influential* if its omission from the data set has a substantial effect on model-based inferences. In the assessment of influence, it turns out that the leverage, h_i, is an important quantity. Observations that are distant from the others in terms of the explanatory variables alone have unusually large values of the leverage and so an index plot of the leverage will reveal such observations. They may be influential, but need not necessarily be. The values of the leverage can be obtained directly from some software packages. In situations where a package does not provide the leverage, but gives the variance or standard error of the linear predictor, $\hat{\eta}_i$, the values of h_i can be found using the result $h_i = \text{var}(\hat{\eta}_i)w_i$, where w_i are the weights used

in the model-fitting process, often called the *iterative weights*. For the linear logistic model, $w_i = n_i\hat{p}_i(1-\hat{p}_i)$.

Observations that influence the set of parameter estimates in a model can be detected using the analog of a statistic proposed by Cook [3]. This is an approximation to the change in the maximized log likelihood when the ith observation is omitted from the data base, given by

$$D_i = \frac{h_i r_{Pi}^2}{\nu(1-h_i)}, \quad i = 1, 2, \ldots, n,$$

where $r_{Pi} = r_i/(1-h_i)^{1/2}$ is the standardized Pearson residual, h_i is the leverage and ν is the number of β coefficients in the fitted model. Approximations such as this only involve quantities that can be obtained from fitting the model to the complete data set and so do not require that the model be actually fitted to each reduced data set.

Unusually large values of the D statistic will indicate observations that unduly affect the set of parameter estimates. If such observations were omitted, then the parameter estimates may change quite markedly, and as a result so would conclusions drawn from the fitted model.

It is often of interest to examine the impact of each observation on a particular parameter estimate, $\hat{\beta}_j$, say. For this, we use an approximation to the change in $\hat{\beta}_j$ brought about by excluding each observation in turn from the data base. This is the quantity denoted $\Delta_i\hat{\beta}_j$ and given by

$$\Delta_i\hat{\beta}_j = \frac{(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}_{j+1}\mathbf{x}_i(y_i - n_i\hat{p}_i)}{(1-h_i)\mathrm{se}(\hat{\beta}_j)},$$

where $(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}_{j+1}$ is the $(j+1)$th row of the variance–covariance matrix of the parameter estimates and $\mathbf{x}_i$ is the vector of explanatory variables for the ith observation. This statistic is widely referred to as a delta–beta.

The Binomial Assumption

When an appropriate model is fitted to grouped binary data the deviance is expected to be close to its corresponding number of degrees of freedom. If we find that this deviance is too large, and this cannot be explained by an incorrect model, the presence of outliers and so on, then it may be that there is a positive correlation between the binary responses that form the binomial data. If so, the number of successes will exhibit more variability than the binomial distribution allows. This phenomenon is known as **overdispersion**. It is important to note that the deviance can only indicate overdispersion when the data are grouped. In ungrouped data, the deviance does not necessarily have a χ^2 distribution and so the deviance need not be close to the number of degrees of freedom for a satisfactory model.

Example: Incidence of Sore Throat

On fitting the model for the probability of a sore throat given in (4), index plots of the residuals, leverage, and Cook's D statistic were obtained. These plots are shown in Figures 2–4. The index plot of the residuals shows that the model does not fit particularly well, in that several observations have relatively

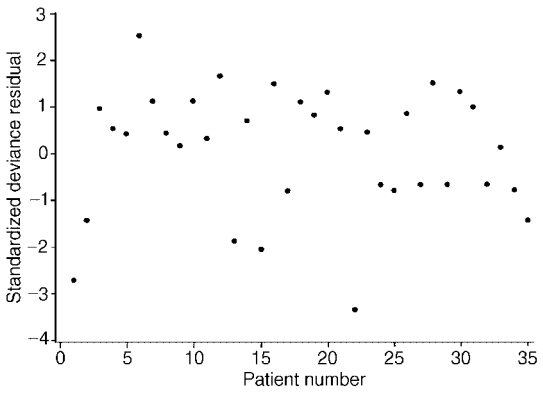

Figure 2 Index plot of the residuals

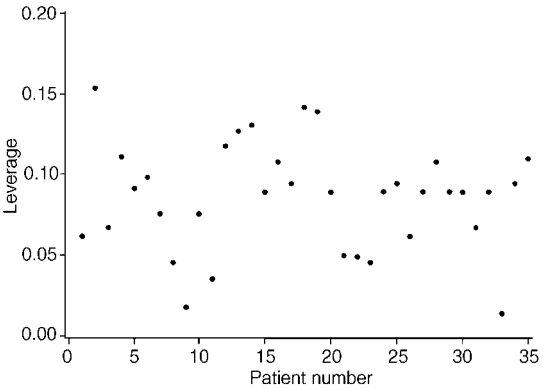

Figure 3 Index plot of leverage

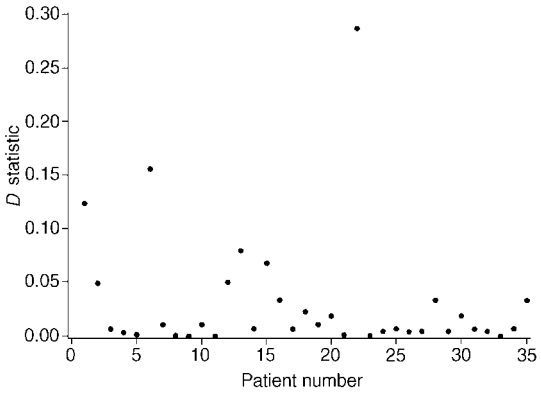

Figure 4 Index plot of the D statistic

large residuals, particularly for patient 22. Under the model, the fitted probability of a sore throat for this individual is 0.94, and yet this patient did not report a sore throat on waking.

The index plot of the leverage shows that there are no patients with an unusual combination of the values of the explanatory variables, but the index plot of the D statistic clearly shows that the observation from patient 22 is influential. The next step would be to investigate whether there have been any errors in recording the data for this particular patient. If not, the actual effect that the data for this patient has on the form of the model will need to be studied.

Binomial Distribution

The binomial distribution is an important discrete distribution arising in many biostatistical applications. To fix ideas, consider a **binary** (or Bernoulli) response from individual subjects, denoted by "success" and "failure". For example, these responses could denote smoking status (smoker vs. nonsmoker), whether or not a patient develops complications following surgery, or other outcomes having two possible states. Assuming a sample of n independent responses or trials, each with a common probability of success, p, the total number of successes, Y, follows a binomial distribution with probability mass function:

$$\Pr(Y=k)=\binom{n}{k}p^k(1-p)^{n-k}, \quad k=0,1,\ldots,n,$$

where

$$\binom{n}{k}=\frac{n!}{k!(n-k)!}$$

and $0 < p < 1$. It is often convenient to denote the probability of failure by $q = 1 - p$. To express that Y follows a binomial distribution with parameters n and p, we write $Y \sim \text{bin}(n, p)$, where "$\sim$" is read as "is distributed as". In practice, the assumptions of independence and common success probability may not be strictly accurate, but the binomial distribution may still give a reasonable representation. Figure 1 provides a histogram of the binomial probabilities for the case where $n = 12$ and $p = 0.4$.

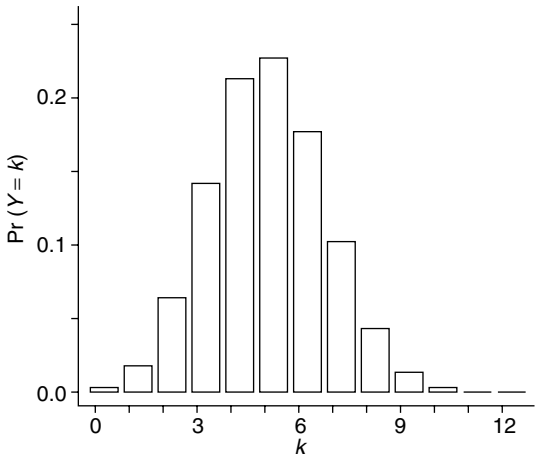

Figure 1 Histogram of the binomial distribution when $n = 12$ and $p = 0.4$

This distribution is one of the oldest to have been studied, dating back to James Bernoulli's *Ars Conjectandi* of 1713 (*see* **Bernoulli Family**). However, binomial coefficients are found in the earlier work of **Pascal**. In fact, the name of the distribution arises from fact that $\Pr(Y = k)$ is the $(k + 1)$st term in the binomial expansion of $(q + p)^n$.

Properties of the Binomial Distribution

The mean and variance are given by

$$\text{E}(Y)=\sum_{k=0}^{n}k\times\Pr(Y=k)=np$$

and

$$\text{var}(Y)=\sum_{k=0}^{n}(k-np)^2\times\Pr(Y=k)=npq.$$

The standard deviation is given by $\text{SD}(Y) = (npq)^{1/2}$. Thus if $Y \sim \text{bin}(12, 0.4)$, then $\text{E}(Y) = 4.8$ and $SD(Y) = 1.70$. The distribution is symmetric if $p = 1/2$, with the **skewness** increasing as p moves away from 1/2 in either direction. The variance and the standard deviation of the binomial distribution decrease as p deviates from 1/2, with the smallest variability near $p = 0$ or 1. As n increases, the binomial distribution gets more symmetric and more closely approximated by a **normal distribution**. Numerical values for $\Pr(Y = k)$ for selected values of n and p are available in published tables (see, for example, Rosner [14] or the references given by Johnson & Kotz [10]). When evaluating many binomial probabilities for the same n and p, it is convenient to use the recursion formula

$$\Pr(Y=k+1)=\left[\frac{n-k}{k+1}\right]\times\frac{p}{q}\times\Pr(Y=k),$$
$$k=0,1,\ldots,n-1.$$

If $Y_1 \sim \text{bin}(n_1, p)$ is independent of $Y_2 \sim \text{bin}(n_2, p)$, then $Y_1 + Y_2 \sim \text{bin}(n_1 + n_2, p)$ and

$$\Pr(Y_1=j|Y_1+Y_2=k)=\frac{\binom{n_1}{j}\binom{n_2}{k-j}}{\binom{n_1+n_2}{k}} \quad (1)$$

for $\max(0, k - n_2) \le j \le \min(n_1, k)$. The **conditional** distribution (1) is a (central) **hypergeometric distribution**.

Calculation of sums of binomial probabilities can be cumbersome, so approximations have been sought. Several approximations to the binomial distribution for large values of n are available. For $Y \sim \text{bin}(n, p)$, application of the **central limit theorem** gives

$$\Pr(Y \le k) \approx \Phi\left[\frac{k - np}{npq}^{1/2}\right], \qquad (2)$$

where $\Phi(\cdot)$ is the standard normal cumulative distribution function (cdf). However, this approximation does not work well in practice and is not recommended. Comparing the histogram of the binomial probability mass function with the approximating normal density having the same mean np and variance npq suggests that a continuity correction of 1/2 may be appropriate, giving

$$\Pr(Y \le k) \approx \Phi\left[\frac{k + \frac{1}{2} - np}{npq}^{1/2}\right]. \qquad (3)$$

This approximation should work well when n is large and p is "central" (not too far from 1/2). For example, as a "rule of thumb" Rosner [14] suggests this approximation can be used when $npq > 5$. Approximating $\Pr(Y \le 8)$ for $n = 24$ and $p = 0.4$ gives 0.252 from (2) and 0.323 from (3), compared with the true value of 0.328. Other more accurate normal approximations, some based on the arc sine square root (or angular) transformation (*see* **Delta Method**), are available [8, 10–12]. Peizer & Pratt [13] developed an extremely accurate, though more complicated, normal approximation.

When n is large and p is small, the binomial distribution can be approximated by a **Poisson distribution**

$$\Pr(Y \le k) \approx \exp(-np) \sum_{j=0}^{k} \frac{(np)^j}{j!},$$

since in this case the mean and variance of the binomial distribution are similar to that of a Poisson distribution with mean np. As a rule of thumb, Rosner [14] suggests that this approximation may be adequate for $n \ge 100$ and $p \le 0.01$. Other more accurate approximations for small p are available [11].

Point Estimation of *p*

In most applications, the number of trials, n, is known but the success probability, p, is not. Then the natural estimate of the success probability, p, is the observed proportion of successes, y/n, which will be denoted by $\hat{p}$. This estimator is **unbiased**, since $\text{E}(\hat{p}) = p$, and is both the **method of moments** and the **maximum likelihood** estimator of p. Application of the **Cramér–Rao inequality** shows that $\hat{p}$ is also the uniformly **minimum variance unbiased estimator** of p.

Since $\text{var}(Y) = npq$ and $\hat{p} = y/n$, it follows that $\text{var}(\hat{p}) = pq/n$, which can be estimated by $\hat{p}\hat{q}/n$. A measure of the precision of $\hat{p}$ is given by its standard error, $(\hat{p}\hat{q}/n)^{1/2}$. Thus the precision increases with sample size.

It can be shown that $\hat{p}$ is admissible under both squared error loss and relative squared error loss (see, for example, [2] and [15]). Thus, there can be no uniformly better estimator than $\hat{p}$ under these loss functions, although other estimators may perform better over wide ranges of p. Santner & Duffy [15] review various **Bayesian** and related methods which incorporate prior knowledge about the unknown p for developing alternative estimators to $\hat{p}$.

When n is unknown, the maximum likelihood and method-of-moments estimators of n can be extremely sensitive to minor fluctuations in the data. Consideration of this problem has been given by Aitkin & Stanisopoulos [1], Casella [5], Hall [9], and the references therein.

Hypothesis Testing

On some occasions, it is of interest to test H_0: $p = p_0$ vs. the alternative H_a: $p \ne p_0$ (a two-sided alternative; *see* **Hypothesis Testing**). Whether or not to reject the null hypothesis, H_0, will depend on how far the sample proportion of successes, $\hat{p}$, is from p_0, as well as on the precision of $\hat{p}$. Using the central limit theorem and assuming that a normal assumption is reasonable (say when $np_0q_0 \ge 5$), under H_0 it follows that

$$\hat{p} \sim \text{N}\left(\frac{p_0,\, p_0q_0}{n}\right). \qquad (4)$$

It is more convenient to standardize $\hat{p}$ by subtracting the expected value under H_0 and dividing by the

standard error under H_0, thus creating the test statistic

$$z = \frac{\hat{p} - p_0}{\left(\frac{p_0 q_0}{n}\right)^{1/2}},$$

which has an approximately unit normal distribution (mean 0, variance 1) under H_0. For a two-sided α level test, we would reject H_0 when either $z < z_{\alpha/2}$ or $z > z_{1-\alpha/2}$, where $\Phi(z_{1-\alpha}) = 1 - \alpha$. Alternatively, the p value for this hypothesis test is given by $2\Phi(z)$ when $\hat{p} < p_0$ or $2[1 - \Phi(z)]$ when $\hat{p} \geq p_0$.
