When n is not large or p is "extreme" (close to 0 or 1), the normal approximation (4) will not perform well, and a more accurate normal approximation needs to be used. Alternatively, we could base the test on the exact binomial probabilities (*see* **Exact Inference for Categorical Data**). In this case, the p value is given by $\min(2\Pr(Y \leq y|p = p_0), 1)$ when $\hat{p} < p_0$ or $\min(2\Pr(Y \geq y|p = p_0), 1)$ when $\hat{p} \geq p_0$, where y is the observed number of successes in the sample.

These hypothesis tests can be modified to accommodate one-sided alternatives. Rosner [14] reviews **power** and **sample size estimation** issues for the one-sample binomial test.

Confidence Interval Estimation of *p*

In most applications it is more informative to calculate a **confidence interval** for p than to perform a hypothesis test. The most commonly used form of confidence interval is based on a normal approximation. Using $\hat{p} \sim N(p, pq/n)$, it follows that

$$\Pr\left(p - z_{1-\alpha/2}\left(\frac{pq}{n}\right)^{1/2} < \hat{p} < p + z_{1-\alpha/2}\left(\frac{pq}{n}\right)^{1/2}\right) = 1 - \alpha.$$

Approximating pq/n by $\hat{p}\hat{q}/n$ and rearranging the inequalities shows that an approximate two-sided $100(1 - \alpha)\%$ confidence interval for p is given by

$$\left(\hat{p} - z_{1-\alpha/2}\left(\frac{\hat{p}\hat{q}}{n}\right)^{1/2}, \hat{p} + z_{1-\alpha/2}\left(\frac{\hat{p}\hat{q}}{n}\right)^{1/2}\right). \quad (5)$$

This method of interval estimation, commonly called the Wald method, should only be used for n large and p "central", e.g. when $n\hat{p}\hat{q} > 5$ (see, for example, [14]). However, Vollset [16] maintains that this rule of thumb does not ensure adequate accuracy. Improved confidence intervals based on more accurate normal approximations are presented and reviewed by Blyth & Still [4] and Vollset [16]. Vollset suggests that score test-based confidence intervals for p, based on inversion of the test without estimating the standard error, have much better (closer to nominal) coverage probabilities than many other methods, particularly the intervals (5), and are only slightly more difficult to calculate.

When use of a normal approximation is not valid, one can resort to the binomial distribution to construct exact confidence intervals. Clopper & Pearson [6] proposed an exact two-sided $100(1 - \alpha)\%$ confidence interval for p of the form (p_L, p_U), where p_L and p_U satisfy $\Pr(Y \geq y|p = p_L) = \alpha/2$ and $\Pr(Y \leq y|p = p_U) = \alpha/2$. These intervals, often called *tail intervals*, have attractive symmetry and monotonicity properties, but require iterative calculations. Using the relationships between binomial, beta, and ***F* distributions** gives an alternative form for these limits, namely

$$p_L = \frac{y}{[y + (n - y + 1) \times F_{1-\alpha/2}(2(n - y + 1), 2y)]}, \quad \text{for } 1 \leq y \leq n$$

(with $p_L = 0$ for $y = 0$) and

$$p_U = \frac{y + 1}{\left\{\frac{y + 1 + (n - y)}{F_{1-\alpha/2}[2(y + 1), 2(n - y)]}\right\}}, \quad \text{for } 0 \leq y \leq n - 1$$

(with $p_U = 1$ for $y = n$). These forms may be attractive if one has access to tables of the F distribution.

Although the tail intervals have intuitive appeal, they are extremely conservative. That is, although the intervals are guaranteed to have at least $100(1 - \alpha)\%$ coverage for all values of p, the actual coverage probabilities are often much greater than the nominal level. Blyth & Still [4] review various exact confidence intervals for p and present tables of less conservative exact 95% and 99% confidence intervals when $n \leq 30$.

Construction of one-sided confidence intervals for p proceeds in a similar fashion as above. Exact one-sided confidence intervals can be derived from the tail intervals. Blyth [3] examines approximate one-sided confidence bounds.

Vollset [16] provides a detailed comparison of the operating characteristics of various two-sided confidence intervals for p, including the Wald intervals, exact intervals, and other approximate confidence intervals. He suggests that only the exact intervals and the score test-based confidence intervals approximately achieve the desired coverage levels. In particular, Vollset recommends the continuity corrected score test-based confidence intervals for p, as they are less conservative and less tedious to calculate than exact intervals, but have coverage close to the nominal levels.

Extensions

In certain applications it is convenient to think in terms of the **odds** of success, $p/(1-p)$, or the log odds, rather than the probability of success, p. Thus, an odds of 2 means that the probability of success is twice the probability of failure, or that $p = 2/3$. The odds are particularly useful when comparing two binomial proportions via the **odds ratio**, or when modeling the log odds of success as a linear function of covariates in **logistic regression**.

The **multinomial distribution** is a generalization of the binomial distribution which allows responses with more than two outcomes. The **negative binomial distribution** arises as the distribution of the number of failures of independent Bernoulli trials until a prespecified number of successes is obtained. Correlated binary responses could be modeled with parametric assumptions, e.g. using the **beta-binomial distribution**, or via methods for **overdispersion**.

The books by Collett [7] and Rosner [14] review basic properties of the binomial distribution. Johnson & Kotz [10] and Santner & Duffy [15] give many more details.

Bioassay

This term is an abbreviation of, and is effectively synonymous with, **biological assay**. In the classical form of biological assay, an experiment is conducted on biological material, to determine the relative potency of test and standard preparations. In recent decades, the term *bioassay* has been used in a more general sense, to denote any experiment in which responses to various doses of externally applied agents are observed in animals or some other biological system. The emphasis here is to measure the effects of various agents on the response variable, and no attempt is made to estimate a relative potency. This usage is common, for instance, in programmes for screening substances for possible carcinogenic effects. Such experiments may include "negative controls" (inert materials) and "positive" controls (known carcinogens), but these controls are used to validate the experimental system rather than as a basis for the estimation of relative potency.

PETER ARMITAGE

Bioavailability and Bioequivalence

The US Code of Federal Regulations (CFR) defines the *bioavailability* of a drug product as the rate and extent to which the active drug ingredient or therapeutic moiety of the drug product is absorbed and becomes available at the site of drug action. Bioavailability studies are usually conducted to assess the pharmacological characteristics of a new drug product during phase I clinical development and to serve as a surrogate for the clinical evaluation of generic drug products. A comparative bioavailability study refers to the comparison of bioavailabilities of different formulations of the same drug (e.g. tablets vs. capsules) or different drug products (e.g. a generic drug vs. a brand-name drug). For the approval of generic drugs, a **bioequivalence** assessment, as a surrogate for the clinical evaluation of the generic drug products, is based on the following *fundamental bioequivalence assumption*. That is, when two formulations of the same drug, or different drug products, are claimed bioequivalent it is assumed that they are therapeutically equivalent [5]. Note that the US Food and Drug Administration (FDA) does not require a complete new drug application (NDA) submission for the approval of a generic drug if the sponsor can provide evidence of bioequivalence in average bioavailability between the generic drug and the brand-name drug through an abbreviated new drug application (ANDA) from bioequivalence studies.

The concepts of bioavailability and bioequivalence did not become public issues until the late 1960s when concern was raised that a generic drug product might not be as bioavailable as that manufactured by the innovator. In 1970, the FDA began to request evidence of biological availability in applications submitted for the approval of certain new drugs. In 1974, a Drug Bioequivalence Study Panel was formed by the US Office of Technology Assessment (OTA) to examine the relationship between the chemical and therapeutic equivalence of drug products. On the basis of the recommendations in the OTA report, the FDA published a set of regulations for the submission of bioavailability data in certain new drug applications. These regulations became effective on July 1, 1977, and are currently codified in 21 CFR Part 320.

In 1984, the FDA was authorized to approve generic drug products under the Drug Price Competition and Patent Term Restoration Act. In recent years, as more generic drug products have become available, there has been concern that generic drug products may not be comparable in identity, strength, quality or purity to the innovator drug product. To address this concern, the FDA conducted a hearing on Bioequivalence of Solid Oral Dosage Forms in Washington, DC in 1986. As a consequence of the hearing, a Bioequivalence Task Force (BTF) was formed to evaluate the current procedures adopted by the FDA for the assessment of bioequivalence between immediate solid oral dosage forms. The BTP report was issued in January 1988. Based on the recommendations of the report by the BTF, guidance on statistical procedures for bioequivalence studies was issued by the FDA Division of Bioequivalence Office of Generic Drugs in 1992 [12].

Pharmacokinetic Parameters

In bioavailability studies, the rate and extent of drug absorption are usually characterized by some **pharmacokinetic** parameters, such as the area under the blood or plasma concentration–time curve (AUC), maximum concentration ($C_{\max}$), time to reach maximum concentration ($t_{\max}$), elimination half-life ($t_{1/2}$), and rate constant (k_e). Gibaldi & Perrier [16] provided a comprehensive overview of these pharmacokinetic parameters. Among these pharmacokinetic parameters, AUC is considered the primary measure for the extent of absorption, which provides information regarding the total amount of the drug absorbed in the body. For comparative bioavailability studies, bioequivalence is usually assessed by bioequivalence measures, such as the difference in means or the ratio of means.

Between 1977 and 1980, the FDA proposed a number of decision rules for assessing bioequivalence in average bioavailability [25]. These decision rules include the 75/75 rule, the 80/20 rule, and the ± 20 rule. The 75/75 rule claims bioequivalence if at least 75% of individual subject ratios (i.e. relative individual bioavailability of the generic (test) product to the innovator (reference) product) are within (75%,

125%) limits. The 80/20 rule concludes bioequivalence if the test average is not statistically significantly different from the reference average and if there is at least 80% power for detection of a 20% difference of the reference average. The BTF does not recommend these two decision rules because of their undesirable statistical properties. The ±20 rule suggests that two drug products are bioequivalent if the average bioavailability of the test product is within ±20% of that of the reference product with a certain assurance (say, 90%). Recently, the FDA guidance recommended an 80/125 rule for log-transformed data. The 80/125 rule claims bioequivalence if the ratio of the averages between the test product and the reference product falls within (80%, 125%) with a 90% assurance.

The ±20 rule and the 80/125 rule are currently acceptable to the FDA for the assessment of bioequivalence in average bioavailability. Current FDA guidance suggests that the 80/125 rule be used for pharmacokinetic parameters such as AUC and $C_{\max}$ after log-transformation. The guidance, however, does not indicate which criterion should be used for other pharmacokinetic parameters. It should be noted that, based on current practice of bioequivalence assessment, either the ±20 rule or the 80/125 rule can be applied to all pharmacokinetic parameters and all drug products across all therapeutic areas.

Designs of Bioavailability Studies

The *Federal Register* [15] indicated that a bioavailability study (single-dose or multiple-dose) should be crossover in design. A **crossover design** is a modified randomized block design in which each block (i.e. subject) receives more than one formulation of a drug at different time periods. The most commonly used study design for the assessment of bioequivalence between reference (R) and test (T) formulations is a two-sequence, two-period crossover design, denoted by (RT, TR), which is also known as the standard crossover design. For the standard crossover design, each subject is randomly assigned to either sequence 1 (R–T) or sequence 2 (T–R). In other words, subjects within sequence R–T (T–R) receive formulation R(T) during the first dosing period and formulation T(R) during the second dosing period. Usually, the dosing periods are separated by a washout period of sufficient length for the drug received in the first period to be completely metabolized and/or excreted by the body.

In practice, when differential carry-over effects are present, the standard crossover design may not be useful because the formulation effect is confounded with the carry-over effect. In addition, the standard crossover design does not provide independent estimates of intrasubject variability for each formulation, because each subject only receives each formulation once. To overcome these drawbacks, Chow & Liu [6] recommend a higher-order crossover design be used. A higher-order design is defined as a crossover design in which either the number of periods or the number of sequences is greater than the number of formulations to be compared. The commonly used higher-order crossover designs include Balaam's design (TT, RR, RT, TR), the two-sequence dual design (TRR, RTT), and the optimal four-sequence design [(TRRT, RTTR) or (TTRR, RRTT, TRRT, RTTR)]. For comparing more than two formulations, Jones & Kenward [19] recommend that a Williams design be used. For example, for comparing three formulations (R, T_1, and T_2), the design (RT_2T_1, T_1RT_2, T_2T_1R, T_1T_2R, T_2RT_1, RT_1T_2) is useful.

For bioequivalence trials, a traditional approach for **sample size determination** is to conduct a **power** analysis based on the 80/20 decision rule. This approach, however, is based on point hypotheses rather than interval hypotheses and, therefore, may not be statistically valid [5]. Phillips [24] provides a table of sample sizes that are based on power calculation of Schuirmann's two one-sided tests procedure using the bivariate **noncentral *t* distribution**. However, no formulas are provided. An approximate formula for sample size calculations is provided in [20].

Statistical Methods

For a standard two-sequence, two-period crossover design, let Y_{ijk} denote the response (e.g. logarithm of AUC) of the ith subject in the kth sequence at the jth period, where $i = 1, \ldots, n_k$, $k = 1, 2$, and $j = 1, 2$. Under the assumption that there are no carry-over effects, Y_{ijk} can be described by the following statistical model:

$$Y_{ijk} = \mu + S_{ik} + F_{(j,k)} + P_j + e_{ijk},$$

where μ is the overall mean; S_{ik} is the random effect of the ith subject in the kth sequence; P_j is the fixed

effect of the jth period; $F_{(j,k)}$ is the direct fixed effect of the formulation in the kth sequence, which is administered at the jth period; and e_{ijk} is the within-subject random error in observing Y_{ijk}.

The commonly used approach for assessing bioequivalence in average bioavailability is the method of the classical (shortest) **confidence interval**. Let μ_T and μ_R be the mean of test and reference formulation, respectively. Then, under a normality assumption, the classical $(1-2\alpha)\times 100\%$ confidence interval for $\mu_T - \mu_R$ can be obtained as follows:

$$L = (\overline{Y}_T - \overline{Y}_R) - t(\alpha, n_1+n_2-2)\hat{\sigma}_d \times \left(\frac{1}{n_1}+\frac{1}{n_2}\right)^{1/2},$$

$$U = (\overline{Y}_T - \overline{Y}_R) + t(\alpha, n_1+n_2-2)\hat{\sigma}_d \times \left(\frac{1}{n_1}+\frac{1}{n_2}\right)^{1/2},$$

where $\overline{Y}_T$ and $\overline{Y}_R$ are least-squares means for the test and reference formulations, $t(\alpha, n_1+n_2-2)$ is the upper αth critical value of a t distribution with n_1+n_2-2 degrees of freedom, and $\hat{\sigma}_d^2$ is given by

$$\hat{\sigma}_d^2 = \frac{1}{n_1+n_2-2}\sum_{k=1}^{2}\sum_{i=1}^{n_k}(d_{ik}-\overline{d}_{\cdot k})^2,$$

where

$$d_{ik} = \tfrac{1}{2}(Y_{i2k}-Y_{i1k}) \quad \text{and} \quad \overline{d}_{\cdot k} = \frac{1}{n_k}\sum_{i=1}^{n_k} d_{ik}.$$

According to the 80/125 rule, if the exponentiations of L and U are within (80%, 125%), then the two formulations are bioequivalent.

On the basis of the interval hypotheses, Schuirmann [27] proposed a procedure consisting of two one-sided tests to evaluate whether the bioavailability of the test formulation is too high (safety) for one side and is too low (efficacy) for the other side. Thus, we conclude that the two formulations are bioequivalent if

$$T_L = \frac{(\overline{Y}_T - \overline{Y}_R) - \theta_L}{\hat{\sigma}_d\left(\frac{1}{n_1}+\frac{1}{n_2}\right)^{1/2}} > t(\alpha, n_1+n_2-2)$$

and

$$T_U = \frac{(\overline{Y}_T - \overline{Y}_R) - \theta_U}{\hat{\sigma}_d\left(\frac{1}{n_1}+\frac{1}{n_2}\right)^{1/2}} < -t(\alpha, n_1+n_2-2),$$

where $\theta_L = \ln(0.8) = -0.2231$ and $\theta_U = \ln(1.25) = 0.2231$ are the limits for bioequivalence. Note that the confidence interval approach is operationally equivalent to Schuirmann's two one-sided tests procedure [5].

Several methods have been proposed for the assessment of average bioequivalence. These methods include the Westlake symmetric confidence interval [29], Chow & Shao's joint confidence region approach [9], Anderson & Hauck's test for interval hypotheses [1], the Bayesian approach for the highest posterior density (HPD) interval, and nonparametric methods [5, 10, 17]. Note that some of these methods are operationally equivalent in the sense that they will reach the same decision on bioequivalence. More details can be found in [5].

Drug Interchangeability

In recent years, as more generic drug products have become available, the efficacy, safety, and quality of generic drug products have become issues of public concern in health care. However, for the approval of a generic drug, regulatory agencies such as the FDA require only that a bioequivalence trial be conducted to provide evidence of bioequivalence in average bioavailability. An approved generic drug can be used as a substitute for the innovator drug product. The regulatory agencies, however, do not require that bioequivalence among generic drugs be provided. Therefore, whether the brand-name drug with its many generic copies can be used interchangeably is an issue of great regulatory and scientific concern.

Basically, drug interchangeability can be classified as drug prescribability or drug switchability. Drug prescribability is referred to as the physician's choice for a new patient, when prescribing an appropriate drug product, between a brand-name drug and a number of generic copies shown to be bioequivalent. Under current regulation for average bioequivalence, Chow & Liu [8] suggest that one should perform a meta-analysis for post-approval bioequivalence review to ensure drug prescribability. The idea is to assess bioequivalence among generic drugs

based on individual bioequivalence submissions. It is suggested that a warning be issued if a significant bioinequivalence is observed between any two generic drug products. To ensure drug prescribability prospectively, many researchers have recommended that, in addition to bioequivalence in average bioavailability, bioequivalence be established in the variability of bioavailability between generic drug products and the brand-name drug product [21, 23]. This concept is known as *population bioequivalence*.

Drug switchability is related to the switch from a drug product (e.g. a brand-name drug) to an alternative product (e.g. a generic copy of the brand-name drug) within the same subject, whose concentration of the drug has been titrated to a steady, efficacious and safe level. To ensure drug switchability, it is necessary to establish bioequivalence within each individual. This concept is known as *individual bioequivalence* [2]. In the past few years, several methods with different criteria for bioequivalence within each subject have been proposed. These methods and criteria can be classified as either probability-based [1, 11] or moment-based [18, 26, 28]. These methods, however, fail to evaluate adequately the equivalence between distributions within the same individual. Recently, although the use of individual bioequivalence as an alternative regulatory requirement for assessment of bioequivalence has attracted much attention [13, 14], many regulatory, scientific, and practical issues remain unresolved [3, 7].

Other Issues

To account for the variability of bioavailability and assess drug interchangeability, it is recommended that a replicated crossover design be used [4, 22]. In addition, the FDA is seeking alternative pharmacokinetic parameters, decision rules and statistical methods for population and individual bioequivalence. Some unresolved scientific issues of particular interest include the impact of add-on subjects for drop-outs, the use of female subjects in bioequivalence trials, *in vitro* dissolution as a surrogate for *in vivo* bioequivalence, post-approval bioequivalence, and international harmonization for bioequivalence requirements among the European Community, Japan, and the US. A comprehensive overview of these issues can be found in [5].

Bioequivalence

Two drug formulations are bioequivalent if their absorption characteristics are closely similar. The most important characteristics are the extent and rate of absorption, which together define the **bioavailability** of a drug formulation. Thus, *bioequivalence* is the comparable bioavailability of drug formulations.

Kinetic Measures of Bioavailability

Measures After a Single Drug Administration

When drugs are not administered directly into the systemic circulation, as in the case of oral intake, at least a fraction of the dose should first be absorbed. As a result, the concentration in blood and plasma initially rises (Figure 1). The drug is then distributed to various tissues and also starts being eliminated from the body. Consequently, after reaching a peak, the concentration declines (Figure 1).

The principal measures (metrics) characterizing bioavailability, and therefore bioequivalence, are the area under the curve (AUC) contrasting concentration with time, and the maximum concentration, $C_{\max}$, which is observed at the time of $T_{\max}$ (Figure 1). AUC is a measure of the extent of absorption. AUC rises as the absorbed fraction of drug dose, i.e. the amount reaching the circulation, increases.

$C_{\max}$ is the most widely used index for the evaluation of absorption rates, especially in comparative studies. $C_{\max}$ actually reflects several processes of drug disposition, including the extent of absorption. However, if, in two drug formulations, all processes except the absorption rate have the same magnitudes (often a good assumption, at least approximately), then differences of $C_{\max}$ values indeed indicate deviations between absorption rates. A higher $C_{\max}$ signals (everything else being equal) a faster absorption rate.

$T_{\max}$ is also determined by various processes of drug disposition. Consequently, contrasts of $T_{\max}$ reflect deviations between absorption rates only if magnitudes characterizing other processes of drug disposition remain the same. Under this condition, a smaller $T_{\max}$ indicates a higher absorption rate.

AUC, $C_{\max}$, and $T_{\max}$ are often referred to as model-free measures of bioavailability because they are determined independently of assumed **pharmacokinetic** models.

Measures After Repeated Drug Administrations

Following repeated administrations of a given drug dose, D, the concentration in plasma and blood eventually reaches a quasi-steady state. In this condition, after each administration of the drug, the concentration first rises, passes through a maximum, $C_{\max}$, and then declines toward a minimum or so-called trough value, $C_{\min}$. The time profile of concentrations is illustrated in Figure 2.

The kinetic measures of bioavailability parallel in the steady state the metrics noted for single administration. AUC is again an index of the extent of absorption. However, it is evaluated after repeated administrations by measuring the area recorded during the time interval between two dosings (the dosing or maintenance interval, T). This AUC is numerically identical to the value obtained following a single drug administration, provided that the drug exhibits first-order kinetics (i.e. the rate of change in the concentration is proportional to the concentration) and that this is identical under the two conditions.

Absorption rates are usually less important when considering repeated drug administrations than after a single drug administration. Nevertheless, $C_{\max}$ is still important, especially as an index of drug safety; unusually high concentrations could indicate a danger of toxicity.

Additional measures of bioavailability are considered later.

Assessment of Bioequivalence

Several statisticians have made distinguished contributions since the early 1970s to developing the methodology for the assessment of bioequivalence. They notably include Carl M. Metzler and Wilfred J. Westlake and also, among others, Sharon Anderson, Walter W. Hauck, Jochen Mau, & Bruce E. Rodda. Chow & Liu [5] reviewed the statistical aspects of the evaluation of bioequivalence.

Procedures will be briefly described which are applied most widely at present. Sauter et al. [10] illustrated examples for detailed calculations evaluating bioequivalence following single drug administrations and in the steady state.

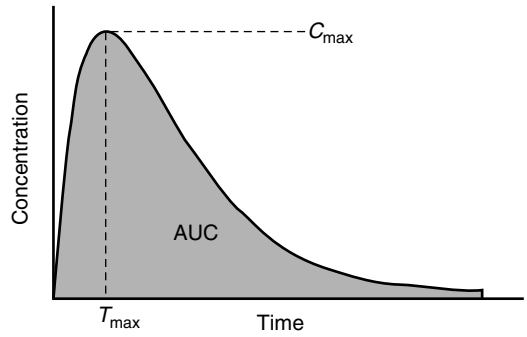

Figure 1 Time course of plasma concentration following a single oral administration of a drug

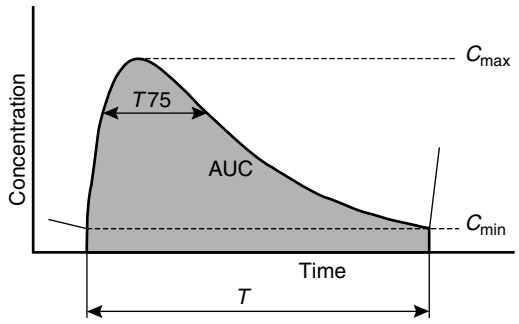

Figure 2 Time course of plasma concentration following repeated oral administrations of a drug

Two One-Sided Tests Procedure

The two one-sided tests (*see* **Alternative Hypothesis**) procedure is nowadays widely applied for the assessment of bioequivalence. Yee [20] presented some features of the approach and Schuirmann [14] elaborated them. The goal is to compare the **mean** kinetic responses of a reference (R) formulation and an investigated test (T) drug product. The **null hypothesis** to be tested is that of bioinequivalence. The test is subdivided into two one-sided problems. They assume bioinequivalence if the difference between the means is either less than or equal to a regulatory criterion θ_1 or (/and) larger than or equal to another regulatory value θ_2:

$$H_{01}: \mu_T - \mu_R \leq \theta_1; \qquad H_{02}: \mu_T - \mu_R \geq \theta_2. \quad (1)$$

The null hypothesis could be rejected in favor of an alternative hypothesis indicating bioequivalence:

$$H_a: \theta_1 < \mu_T - \mu_R < \theta_2. \quad (2)$$

If both null hypotheses are true, their evaluation at the $\alpha/2$ significance level indicates a consumer risk on both sides with this probability.

The two null hypotheses are in practice assessed by the use of **confidence intervals**. Various approaches have been proposed. The application of the shortest interval at the α level [14, 18] has been widely adopted. It yields, at a given significance level (and consumer risk), the highest **power**, i.e. the smallest risk for producers when the two formulations are in fact bioequivalent [16].

Implementation of the Two One-Sided Tests Procedure

Most kinetic quantities are considered to have multiplicative character (their multiplication and division – e.g. whether their magnitudes should be raised or lowered by a factor of 2 or 10 – appear to be relevant). Correspondingly, their errors are also thought to be multiplicative (*see* **Multiplicative Model**) and not additive [16, 19]. Therefore, they are typically evaluated and compared in their logarithmic form. Consequently, μ_T and μ_R are estimated after the logarithmic **transformation** of the investigated quantity, e.g. from log AUC or log C_{max}. The regulatory limits are usually considered to be symmetrical. Consequently, $\theta_2 = -\theta_1$ in the logarithmic scale. Times of the observations are not regarded to have multiplicative character. Moreover, they are recorded only at discrete sampling points. Therefore, T_{max} is generally not transformed and not assessed with regulatory limits. $\alpha = 0.10$ is widely applied.

The bioequivalence of two drug formulations is evaluated generally in two-period, two-sequence **crossover** trials. The kinetic responses (e.g. AUC) estimated for both formulations are contrasted in each subject. From the difference of individual logarithmic responses, their average and its 90% confidence interval are calculated. Bioequivalence is declared if the limits are in the regulatory range, between θ_1 and θ_2. The values of θ_1 and θ_2 are considered below.

Distribution-Free Procedure

Hauschke et al. [8] described a **nonparametric** procedure which, in its implementation of the two-sided hypotheses, took into account the structure of two-period, two-sequence, crossover studies. The kinetic

parameters recorded with the test and reference formulations (X_T and X_R) are contrasted within each individual:

$$X_i = X_{Ti} - X_{Ri}, \quad i = 1, \ldots, n.$$

Let the numbers of subjects in the two sequences of drug administration be n_1 and n_2, with $n_1 + n_2 = n$. A total of $n_1 n_2$ differences in the two sequences,

$$X_{j1} - X_{j^*2}, \quad j = 1, \ldots, n_1, \, j^* = 1, \ldots, n_2,$$

are formed and sorted by magnitude. The median of the pairwide differences is a Hodges–Lehmann point estimator (*see* **Estimation**) of $2(\mu_T - \mu_R)$. Ninety percent confidence limits are also obtained from the ranked differences.

Rapidly Evolving Issues

Various issues remain unresolved about the evaluation of bioequivalence. Two important topics are discussed which have particular relevance in biostatistics. They are developing rapidly and, therefore, their resolution in the near future is anticipated.

Individual Bioequivalence

The criteria discussed so far for the acceptance of bioequivalence involve the comparison of average kinetic parameters. Thus, the resulting similarity of two drug formulations is referred to as *average bioequivalence*. It ensures that the efficacy and safety of the new drug product is, on average, similar to that of the reference formulation. It is recognized that the efficacy and safety of the reference product was thoroughly evaluated during its development.

Average bioequivalence ensures that an individual who had not been exposed to either drug formulation, would have generally similar responses to both products. Thereby the *prescribability* of the test formulation is demonstrated. When, as often happens, patients are already receiving the reference product, then its substitution by the test formulation is contemplated. The issue is therefore the *switchability* from one formulation to another [2]. Thus, the similarity of responses and kinetic parameters *within* individuals, and therefore *individual bioequivalence*, becomes important.

To assess individual bioequivalence, the intrasubject variances of the reference and test products (σ^2_{WR} and σ^2_{WT}) need to be estimated. This can be accomplished if three- or four-period crossover trials are conducted. This design also enables the estimation of the subject × formulation **interaction** (σ^2_{SF}), which can be a major source of lack of individual bioequivalence.

The procedures proposed by several authors for the evaluation of individual bioequivalence can be separated into two principal categories [1, 11]. Probability-based approaches assume that deviations between individual kinetic parameters for the two formulations (X_R and X_T) would remain within a specified range and have a probability $\Pr(|X_T - X_R| \leq r)$, which should be sufficiently high. Moment-based procedures consider the second moment of $X_T - X_R$. A measure would extend that given for average bioequivalence, (2), by including terms for σ^2_{SF}, σ^2_{WR}, and σ^2_{WT}. A one-sided criterion is generally

$$(\mu_T - \mu_R)^2 + \delta\sigma^2_{SF} + \phi\sigma^2_{WR} + \gamma\sigma^2_{WT} < \theta_I. \qquad (3)$$

The regulatory criterion θ_I as well as the coefficients δ, ϕ, and η will have to be determined. For instance, it has been suggested that $\delta = \phi = 1$ and $\gamma = -1$ [13]. Sheiner [15] recommended $\delta = \gamma = 1$ and $\phi = 0$. Also other values have been proposed for the coefficients.

An unscaled measure such as that given above can be divided by a combination of σ^2_{WR} and σ^2_{WT}. The resulting scaled bioequivalence criterion differs intrinsically from its unscaled counterpart. It is anticipated that scaled comparisons will be particularly useful for assessing the bioequivalence of drugs which exhibit high intraindividual variability; the analysis of their equivalence is very difficult and at times even impossible by applying the methodology of average bioequivalence.

Similar conclusions can be drawn for probability-based measures of individual bioequivalence since they have close relationships to the corresponding moment-based measures [9, 12].

Kinetic Measures for the Evaluation of Bioequivalence

There is general agreement that AUCs measure well the extent of absorption, and that the application of

the two one-sided tests procedure to relative AUCs appropriately evaluates the equivalence of extents of absorption of two drug formulations. Consequently, two drug products are considered to be bioequivalent by this criterion if the 90% confidence interval around the geometric average of individual AUC ratios is between 0.80 and 1.25 [3].

A similar consensus has not been reached about metrics evaluating the equivalence of absorption rates. C_{max} is used most frequently. The various regulatory agencies apply differing criteria to indicate equivalence. For example, the **Food and Drug Administration** in the US has requirements for C_{max}s which parallel those for AUCs: the 90% confidence interval around the geometric average of individual C_{max} ratios should be between 0.80 and 1.25. The European Union recognizes that C_{max} is determined generally with larger variation than AUC. Therefore, its condition for the equivalence of C_{max}s is less demanding: the stated 90% confidence limits should be between 0.70 and 1.43. Canadian regulatory requirements do not invoke confidence limits and are, therefore, even less demanding: it is sufficient for the declaration of bioequivalence if the geometric average of individual C_{max} ratios is between 0.80 and 1.25.

In addition to the diversity of regulatory criteria, questions have been raised about the usefulness of C_{max} for determining the equivalence of absorption rates. C_{max} notably reflects various kinetic quantities and processes including the extent of absorption. Moreover, C_{max} responds to changes in absorption rates very insensitively, particularly in the steady state. The statistical properties of the metric are also unfavorable. Interestingly, its variation in the steady state can be higher or lower than that observed after a single drug administration, depending on the contributions of various sources of variation [21].

Therefore, reasonably, alternative measures have been suggested for assessing the equivalence of absorption rates after a single drug administration. They include, following a single drug administration, C_{max}/AUC, AUC measured until the peak of the reference formulation (partial AUC), and the intercept obtained by linear extrapolation from the ratios of concentrations of the two formulations measured in the early stage of a study [4, 6, 7].

After repeated drug administrations, in the steady state, the most frequently applied metric is, in addition to C_{max}, the peak–trough fluctuation, PTF; $\mathrm{PTF} = (C_{max} - C_{min})/C_{ave}$, where C_{ave} and C_{min} are the average and minimum concentrations, respectively, during a dosing interval [17]. Other measures include the Swing $[(C_{max} - C_{min})/(C_{min})]$, the AUC above C_{ave} normalized by the total AUC within a dosing interval (AUCF), and the duration (T75) of the concentration peak at the level of 3/4 of its adjusted height, i.e. at $0.75C_{max} + 0.25C_{min}$ (see Figure 2).

Little is known at present about the properties of these metrics, which are being explored extensively by several investigators.

LASZLO ENDRENYI

Bioinformatics in Functional Genomics

With the sequencing of the human genome (or more accurately, a handful of human genomes), we are now said to be in a post-genomic era (*see* **Human Genome Project**). However, this term is confusing, since it is only now, with the availability of at least a draft outline of the genome of multiple organisms, that we can even begin systematically to deconstruct the relationship of the genetically programmed, physiologic behavior of an organism to the constituent **genes** comprising its individual version of the genome of its species. In this deconstruction, several kinds of biological information are available: **DNA sequences**, physical maps, genetic maps, gene **polymorphisms**, protein structure, gene expression (*see* **Gene Expression Analysis**), and protein interaction effects. The collection of these diverse data in large, internationally curated databases has produced an urgent need for systematic quantitative analysis, which in this domain often goes by the name of *bioinformatics*. The information in Figure 1 provides perhaps the best motivation for applying information sciences to the functional genomics enterprise. Since the invention of deoxyribonucleic acid (DNA) sequencing 25 years ago, the number of gene sequences deposited in international repositories, such as GenBank, has grown exponentially, culminating in the sequencing of the entire human genome in 2001. The *knowledge* about these genes (as measured by the number of papers published in biomedicine, a proxy measurement) has also been growing exponentially but at a much slower rate. As shown, the number of GenBank entries has fast outstripped the growth of MEDLINE entries. This difference serves as a proxy for the large gap between our knowledge of the functioning of the genome and the generation of raw genomic data. Yet GenBank entries represent only a fraction of the various kinds of data (listed above) generated from our investigations of the human genome. This exponentially expanding volume of data must somehow be sifted and linked to the biological phenomena of interest. Accomplishing this exhaustively, reliably, and reproducibly – credibly – is possible only with the application of algorithmic implementations on computers. This has led to an unprecedented demand for investigators who have

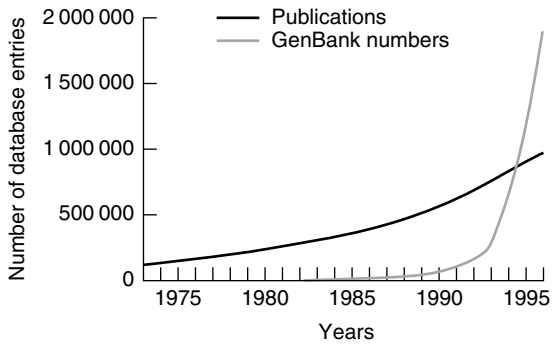

Figure 1 Cumulative growth of molecular biology and genetics literature (black) compared with DNA sequences (grey). Articles in the "G5" (molecular biology and genetics) subset of MEDLINE are plotted alongside DNA sequence records in GenBank over the same time period. The former data wave obtained with the help of R.M. Woodsmall of NCBI and the latter data are available (`ftp://ncbi.nlm.nih.gov/genbank/gbrel.txt`). No attempt has been made to eliminate data redundancy among either the DNA sequence records or information contained in the literature

the required knowledge to manipulate large data sets. These skills may come from investigators in fields as diverse as computational physics, chemical engineering, operations research, and financial modeling. However, once these skills are applied to the domain of functional genomics, they can be collectively described as bioinformatic techniques. Although there is a wide overlap between the methodologies of bioinformatics and those of biostatistics, both the nature of the data and the computer-science orientation of many early practitioners of bioinformatics color much of the current research in and applications of bioinformatics. The breadth of applications of information science to biomedical research and practice far exceeds the scope of a brief article. Consequently, the focus here will be on the bioinformatic efforts that appear to be the most challenging and in the greatest demand: the elucidation of the function of genes – otherwise known as *functional genomics*.

Much of functional genomics has been and will continue to be the hypothesis-driven biological research that has been pursued for the past decades. Addressed here is a computationally intensive branch of functional genomics that has emerged as a result of the practical implementation of technologies for

assessing thousands of genes at a time.[1] The incredible confluence over the past five years of disparate technologies, such as robotics, fluorescence detection, photolithography, and the human genome project, has made it possible for present-day biologists to use ribonucleic acid (RNA) expression microarray detection technologies to greatly increase data about cells in various states. With the commercial tools currently available, a single experiment using RNA expression–detection microarrays can now provide systematic quantitative information on the expression of up to 60 000 unique RNAs within cells in any given physiological state (i.e. all expressed genes can be measured in any cell type under all conditions under which that cell will function).

cDNA and oligonucleotide microarray technology can be used not only to determine various cell functions but also to analyze more complex systems, such as traits with multigenic origins or those linked to the environment [16]. Microarrays can be used in time series to measure how a particular intervention [32, 51] may start a transcriptional program – that is, change the expression of large numbers of genes in a reproducible pattern determined by inherent genetic regulatory networks – and to measure gene expression in the appropriate tissue in groups of patients with and without a particular disease [3] or with two different diseases [28].

The ability to measure such RNA expression affords an opportunity to reduce our dependence on a priori knowledge (or biases) and to allow the biology of organisms to point us in potentially fruitful directions in our investigations. That is, much of the current mission of bioinformatics and functional genomics is a *hypothesis-generating* effort, which, if carefully crafted, can lead to a highly productive set of investigations using more conventional hypothesis-driven research.

Gene expression–detection microarrays are notable not because their ability to measure gene expression is unique, since many technologies have permitted quantitative or semiquantitative measurement of gene expression for well over two decades. What distinguishes gene expression–detection microarrays (and other genome-scale technologies) from these older technologies is the ability to measure tens of thousands of genes at a time, a *quantitative* change of the scale of gene measurement that has led to a *qualitative* change in our ability to understand regulatory processes at the cellular level.

Several approaches have been developed during the past four years to analyze basic RNA expression data sets. The central hypothesis of these techniques is that improved techniques in bioinformatics will enable us to analyze larger data sets of measurements from RNA expression–detection microarrays and thereby to discover the true biological functional pathways in gene regulation.

The related discipline of *clinical informatics* refers to the application of information science to various aspects of clinical care. Although clinical informatics is not addressed here, many of the problems that have dogged clinical informaticians (and, for that matter, biostatisticians) will confront bioinformaticians as they attempt to apply their basic science findings to clinical problems [36].

Why Do We Need New Techniques?

A scientist trained in quantitative techniques or even a biologically trained scientist taking a first look at a typical genomic study might ask the following, quite legitimate, question: Why isn't this field amenable to standard biostatistical techniques? After all, we are trying to understand the relationship between multiple variables and the mechanisms the relationships reveal, and the development of biostatistical techniques to analyze large studies that have large numbers of cases with many variables has a long history.

The following are the types of questions asked by conventional epidemiologic studies: What risk factors are associated with heart disease? Does smoking cause disease? On the surface, these questions seem similar to many of those posed about genetic risk factors for acute and chronic disease. Yet a review of the bioinformatics/functional genomics literature from the past three years reveals that most analyses in this field have used techniques borrowed from the computational sciences and machine-learning communities in particular. There are good reasons for this bias towards the computational sciences that have little to do with disciplinary parochialism.

Figure 2 sketches out a fundamental difference between a typical epidemiologic/clinical study and

[1] Expression microarrays, because they have been the most impressive recent examples of massive parallel acquisition of genomic data, are the canonical example used here. However, this discussion is equally applicable to other genomic technologies.

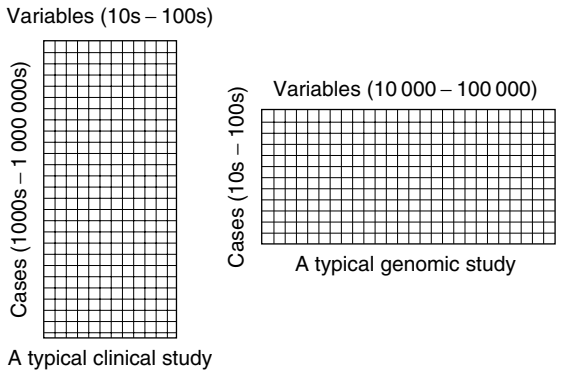

Figure 2 A major difference between classical clinical and epidemiologic studies and microarray analyses

a typical genomic study. A comprehensive epidemiologic study will often involve thousands to tens of thousands of subjects, such as in the Nurses' Health Study [8] or the Framingham Heart Study [19], and the measurement of tens or even hundreds of variables (often longitudinally). In contrast, a typical genomic study involves only tens or, exceptionally, hundreds of cases, each with tens of thousands of measured variables.

Initially the low number of cases in a genomic study may have been due to the high cost of the microarrays (in 1999 on the order of several thousand US dollars per microarray and in 2001 in the low hundreds) but the scarcity of cases in a typical functional genomic study will increasingly relate to the scarcity of appropriate biologic samples. Because these experiments involve measuring gene expression, a particular tissue (e.g. brain, muscle, fat) must be obtained under the right conditions, in contrast to studies using genomic DNA, for which more easily obtained blood samples will suffice. Samples of nonblood tissues may be very difficult to obtain in human populations. Yet although only tens of cases are involved, each case requires the measurement of tens of thousands of variables corresponding to the expression of tens of thousands of genes measurable with microarray technology. The result of the large number of variables as compared with the number of cases is a highly underdetermined system, i.e. these measurements are of very high dimensionality (on the order of tens of thousands) but with the provision of only a small number of cases to explore this high-dimensional space. Stated differently, there are a great many ways the variables being measured could be interrelated mechanistically, which may be difficult to model with the relatively small number of observations. Many of the assumptions underlying standard biostatistical techniques do not hold up well in these systems because of their high dimensionality and underdetermined nature. While statisticians have done quite a lot of research on the analysis of underdetermined systems of high dimensionality, only relatively recently has this work found its way into mainstream functional genomic studies.

The Functional Genomics Dogma

In the first two years of the publication of significant articles regarding the large-scale application of microarray technologies, numerous special-purpose or adapted machine-learning algorithms were described in the literature. Self-organizing maps [53], dendrograms [3, 21, 32, 51], K-means clusters, support vector machines [12], neural networks [13, 40, 55, 58], and several other methodologies (borrowed largely from the machine-learning community of computer science) have been employed. Most of these have worked reasonably well for the purposes described in the papers.

There is a central underlying assumption, or dogma, of all these techniques for expression analysis. Simply put, it is assumed that genes that appear to be expressed in similar patterns are in fact related mechanistically. Furthermore, the corollary to this assumption is that although genes may distantly affect the function of other gene products, they fall into groups of more tightly regulated mechanisms. For instance, the genes that govern chromosome function or meiosis may be more tightly linked to each other than to the genes involved with another function, such as apoptosis. This has been the basis of our collective experience in biologic investigations over the last century: that some groups of proteins have closer interactions than others. Often such groups have been organized into pathways such as glycolysis, the Kreb's cycle, and other metabolic pathways in which the gene products, called enzymes, have to work in concert. Other, more obvious functional clusters are those of structural proteins that have to come together in a conserved and reproducible fashion to serve their purpose, whether they are the components of the ribosomal unit or the histoproteins essential for the maintenance of chromatin structure.

On this basis, it is possible to impute functional clustering of genes whose expression patterns approximate one another, i.e. that they have related functions. Several important caveats are worth noting here. First, it remains unclear just how discrete the functional groupings of gene function is in the cellular apparatus. Individual gene products may have so many different roles under different circumstances that several of them partake in essential roles in significantly different functions.[2] The second caveat is that the term *functionally related* is not in itself well specified. Similar patterns of expression of more than one gene could signify the following possible relationships (the list is not exhaustive):

1. two genes having gene products that physically interact;
2. one gene encoding a transcriptional factor for the other gene;
3. two genes having different functions but similar promoter sequences; or
4. two genes both with promoter sequences bound by repressors that are knocked off when a nuclear receptor is activated even though the two genes have widely disparate functions.

Of course there is a level of abstraction at which *all genes* are functionally related by their roles in keeping the cell alive and producing whatever components are needed for the rest of the organism. But below this level of abstraction are many alternative and, by their nature, "sloppy" definitions of clustering. We should therefore be somewhat wary of the claim that similarity in expression corresponds to similarity in function. Nevertheless, this is a useful starting point for many analyses of a genome whose function remains, by and large, unknown at this time.

The question of what constitutes a similar expression pattern is also poorly defined, or at least has multiple alternative definitions. For example, similarity could mean that patterns of change over time are similar, that absolute levels of expression are similar at any given point in time, or that patterns of expression are perfectly opposite but well choreographed. Just which dissimilarity or similarity measure is chosen for examining patterns of expression will influence the kind of functional clusters that we expect.

[2] One example of this is the transcriptional factor Sonic Hedgehog, which in some tissues at some times is involved in cell proliferation and in others is involved in cell differentiation processes.

Supervised vs. Unsupervised Learning

The preceding sections have motivated the need for computational techniques for the analysis of gene expression that are qualitatively different from those of traditional epidemiologic biostatistics. Because the data sets are of high dimensionality but the number of cases is relatively small, the number of solutions that could explain the observed behavior is quite large. For this reason, the machine-learning community has recognized the potential role for techniques now used to explore high-dimensional spaces (such as those of voice or face recognition) for the exploration of genomic data sets.

Two useful broad categorizations of the techniques used by the machine-learning community are *supervised* learning techniques and *unsupervised* learning techniques, also commonly known as *classification* techniques and *clustering* techniques, respectively. The two techniques are easily distinguished by the presence of external labels of cases. For example, it is necessary to label a tissue as obtained from a patient with acute myelogenous leukemia (AML) or one with acute lymphocytic leukemia (ALL) [28] before applying a supervised learning technique to create a method of learning those labels. In an unsupervised learning technique, such as finding those genes that are co-regulated across all the samples, this type of organization of the data operates independently of any external labels. The kinds of variables (also known as *features* in the language of the machine-learning community) that characterize each *case* in a data set can be quite varied. Each case can include measures of clinical outcome, gene expression, gene sequence, drug exposure, proteomic measurements, or any other discrete or continuous variable believed to be of relevance to the case.

The two types of machine learning are generally used to answer different types of questions. In supervised learning, the goal is typically to obtain a set of variables (e.g. expressed genes as measured on a microarray) that can be used reliably to make a diagnosis, predict future outcome, predict future response to pharmacologic intervention, or categorize that patient or tissue or animal as part of a class of interest. In unsupervised learning, the typical application is to find either a completely novel cluster of genes with putative common (but previously unknown) function or, more commonly, to obtain a

cluster or group of genes that appear to have patterns of expression similar to those of a gene (i.e. that fall into the same cluster) already known to have an important function. The goal of unsupervised learning in this context is to find more details about the mechanism by which the known gene works and to find other genes involved in that same mechanism, either to obtain a more complete view of a particular cellular physiology or, in the case of pharmacologically oriented research, to identify other possible therapeutic targets.

Although the distinct goals of supervised versus unsupervised machine learning techniques may appear rather obvious, it is important to be aware of the implications of these differences for study design. For example, an analyst may be asked to find classifiers between two types of malignancy, as was done in the investigation by Golub et al. of AML and ALL [28]. However, the lists of genes that reliably divide the two malignancies may have little to do with the actual pathophysiologic causes of the two diseases and may not represent any particular close relationship of those genes and function. Why is this? One possibility is that the small amounts of change of some gene products, such as transcriptional activators and genes, e.g. *p53*, cause large downstream changes in gene expression. That is, with only a subtle change, an important upstream gene may cause dramatic changes in the expression in several pathways that are functionally only distantly related but are highly influenced by the same upstream gene. When a classification algorithm is applied directly to the gene expression levels, the algorithm will naturally identify those genes that undergo the most change between the two or more states being classified. A study design geared towards the application of a supervised learning technique may thereby generate a useful artifact for classification, diagnosis, or even prognosis, but will not necessarily lead to valuable insights into the biology underlying the classes obtained. To obtain such insights, unsupervised or clustering methodologies are more likely to be rewarding, as they reveal how genes will affect each other's function. More generally, let us consider the other cases for which gene expression values are not the only data type. A given case may include several thousand gene-expression measurements but also several hundred phenotypic measurements such as blood pressure, laboratory values, or the response to a chemotherapeutic agent. Here again a clustering algorithm can be used to find the features that are most tightly coupled in the observed data. In a generalization of the functional genomics dogma, these tight associations (in space and/or time) can thereby lead to the development of hypotheses that may be tested by standard techniques.

The list of bioinformatic techniques is growing rapidly. Table 1 includes only a brief subset, with references to published biomedic works incorporating each technique and starting with the taxonomy of unsupervised and supervised machine learning. For the experienced biostatistician, many of these techniques will be familiar tools called by a new label or applying a new jargon.

The Immediate Future of Bioinformatics and Functional Genomics

In the last five years of the genomic revolution and the development of concomitant bioinformatic methodologies, the principal weakness of the field has been the poor quality and irreproducibility of many of the measurements made [17, 54]. This is particularly true of microarray-expression experiments[3] that make broad and unsubstantiated claims about gene function on the basis of one, two, or three measurements. As the science and engineering of functional genomics develop (and become more cost-effective), many of the tried and true techniques of biostatistics are being applied to genomic data (often by biostatisticians) [39, 47]. These efforts are still in their infancy but represent the beginnings of the integration of genomic data into the armamentarium of the biostatistician as yet another type of data for clinical trials and basic biologic investigation.

This brief article has only touched on one of the main themes of bioinformatics. Because the bioinformatic and genomic endeavor is so large, much mundane groundwork remains to be covered, and this too is an important component of the enterprise. This includes the development of standardized nomenclatures for describing genes, gene variants, and gene products [6, 37, 41, 57]; the development of standardized data models and databases for storing and sharing genomic data acquired in thousands of laboratories [22, 26, 50];

[3] This is also true of all the massively parallel genomic measurement modalities, whether using proteomic arrays, tissue arrays, or resequencing arrays.

Table 1 Bioinformatic techniques

Unsupervised
Analysis looking for characteristics in the data set, without a priori input on cases or genes
- Feature determination: Determine genes with interesting properties, without specifically looking for a specific pattern to be determined
- Principal component analysis and singular value decomposition: Determine genes explaining the majority of the mathematical **variance** in the data set [5, 23, 31, 46, 56]
- Cluster determination: Determine groups of genes or samples with similar patterns of gene expression
  - Nearest neighbor clustering: The number of clusters is decided first, the boundaries of the clusters are calculated, then each gene is assigned to a single cluster [9]
  - Agglomerative clustering: Bottom-up method, where clusters start as empty, then genes are successively added to the existing clusters
    Dendrogram algorithm: Groups are defined as subtrees in a phylogenetic-type tree, created by comprehensively measuring a pairwise metric, such as the correlation coefficient [56]
    Two-dimensional dendrograms: Both genes and samples are clustered separately
  - Divisive or partitional clustering: Top-down method, where large clusters are successively broken into smaller ones until each subcluster contains only one gene
    Matrix incision tree [35]
    Two-way clustering binary tree [4]
    Coupled two-way clustering [27]
    Cluster affinity search technique [11]
    Gene shaving [30]
- Network determination: Determine networks of gene–gene or gene–phenotype interactions
  Bayesian networks [24]
  Hybrid petri networks [44]
  Boolean regulatory networks [1, 2, 40, 52, 59]
  Relevance networks: Determines associations between features (genes, phenotypic measures, or samples) [14, 15, 17]

Supervised
Analysis to determine ways to accurately split into or predict groups of samples or disease based on external (typically expert-provided) labels
- Single feature or sample determination: Find genes or samples that match a particular a priori pattern
  - Naive Bayes classifier [10, 18]
  - Naive Bayes global relevance [45]
- Multiple-feature determination: Find combinations of genes that match a particular a priori pattern
  - Decision trees: Use the training set of genes or samples to construct a decision tree to help classify test samples or test genes. Typically uses entropy as the classification measure [20]
  - Support vector machines: First take the set of measured genes, then create a richer feature set with combinations of genes, then find a hyperplane that linearly separates groups of samples in this larger multidimensional space [12, 18, 25]
  - Tree harvesting [29]
  - Boosting [9]

distributed annotation efforts – allowing laboratories around the world to contribute in a controlled manner to databases documenting the function of each gene [7, 34, 38, 48, 49]; and leverage of the existing biomedical literature for genomic analysis [33, 42, 43].

Bioinformatics

Bioinformatics is an emerging field that was once considered to be the part of computational biology that explicitly dealt with the management of the increasing number of large **databases**, including methods for data retrieval and analyses, and **algorithms** for sequence similarity searches, structural predictions, functional predictions and comparisons, and so forth. Very recently, the field has been rapidly evolving, not only because of the impact of the various genome projects (*see* **Human Genome Project**) but also because of the development of experimental technologies such as microarrays for gene expression analyses and mass spectrometry for detection of protein–protein interactions. Currently, and increasingly, bioinformatics is being widely viewed as a more fundamental discipline that also encompasses mathematics, statistics, physics, and chemistry. Further, the field is already looking forward to what is currently termed a "systems biology" approach and to simulations of whole cells with incorporation of more levels of complexity; see, for example, [2].

The stated goal for many researchers is for developments in bioinformatics to be focused at finding the fundamental laws that govern biological systems, as in physics. However, if such laws exist, they are a long way from being determined for biological systems. Instead, the current aim is to find insightful ways to model limited components of biological systems and to create tools that biologists can use to analyze data. Examples include tools for statistical assessment of the similarity between two or more DNA sequences or protein sequences (*see* **Sequence Analysis**), for finding genes in genomic DNA (*see* **DNA Sequences**), for quantitative analysis of functional genomics data (*see* **Genetic Markers**), for estimating differences in how genes are expressed in, say, different tissues (*see* **Gene Expression Analysis**), for analysis and comparison of genomes from different species, for phylogenetic analysis (*see* **DNA Sequences**), for DNA sequence alignment and assembly (*see* **Hidden Markov Models**; **EM Algorithm**), and so on. Such tools involve statistical modeling of biological systems; see, for example, [1].

Much biological data arise from mechanisms that have a substantial probabilistic component, the most significant being the many random processes inherent in biological evolution, and also from randomness in the sampling process used to collect the data. Another source of variability or randomness is introduced by the biotechnological procedures and experiments used to generate the data. So, the basic goal is to distinguish the biological "signal" from the "noise". Today, as experimental techniques are being developed for studying genomewide patterns, such as expression arrays, the need to appropriately deal with the inherent variability has multiplied astronomically. For example, we have progressed from studying one or a few genes in comparative isolation to being able to evaluate thousands of genes (or expressed sequence tags) simultaneously. Not only must methodologies be developed that scale up to handle the enormous data sets generated in the postgenomic era but these also need to become more sensitive to the underlying biological knowledge and better understanding of the mechanisms that generate the data. For biostatisticians, research has reached an exciting and challenging stage at the interface of computational statistics and biology. The need for novel approaches to handle the new genomewide data (including that generated by microarrays) has coincided with a period of dramatic change in approaches to statistical methods and thinking. This "quantum" change has been brought about, or even has been driven by, the potential of ever more increasing computing power. What was thought to be intractable in the past is now feasible, and so new methodologies need to be developed and applied.

Unfortunately, too many of the current practices in the biological sciences rely on methods developed when computational resources were very limiting and are often either (a) simple extensions of methods for working with one or a few outcome measures, and do not work well when there can be thousands of outcome measures, or (b) ad hoc methods (that are commonly referred to being "statistical" or "computational") that make many assumptions for which there are no (biological) justifications. The challenge now is to creatively combine the power of the computer with relevant biological and **stochastic process** knowledge to derive novel approaches and models, using minimal assumptions, that can be applied at genomic wide scales. Such techniques comprise the foundation of bioinformatic methods in the future.

Useful web resources are starting to appear. For example, "Functional and Comparative Genomics" has been developed by the US Department of Energy Office of Science, Office of Biological and

Environmental Research, Human Genome Program; see, for example, `http://www.ornl.gov/TechResources/Human_Genome/faq/compgen.html` and links therein.

Federated databases and bioGrids are at the cutting edge of modern biological technology. To date, Grid development has focused on the basic issues of storage, computation, and resource management needed to make a global life-science community's information and tools accessible in a high-performance environment. In the longer term, the purpose of the Grids is to deliver a collaborative and supportive environment that will enable geographically distributed scientists to achieve research goals more effectively, while enabling their results to be used in developments elsewhere. The *in silico* biological experimental process will use efficient tools that allow the e-life scientists to seamlessly link together databases and analytical tools, extract relevant information from free texts, and harness available computational resources for CPU-intensive tasks. Also, there will be an increasing overlap and seamlessness between areas of bioinformatics and Public Health Informatics. For the biostatistician, in the future, both data analysis and simulation will be done increasingly at high speed achieved by parallel processing and heterogeneous distributed processing.

SUSAN R. WILSON

Biological Assay, Overview

This article mainly emphasizes the classical aim of biological assay (or *bioassay*), to estimate *relative potency*, arising out of a need for **biological standardization** of drugs and other products for biological usage. There is a basic difference between biological and chemical endpoints or responses: the former exhibits greater (bio)variability and thereby requires *in vivo* or *in vitro* biological assays wherein a standard preparation (or a reference material) is often used to have a meaningful interpretation of relative potency. However, the term *bioassay*, has also been used in a wider sense, to denote an experiment, with biological units, to detect possible adverse effects such as carcinogenicity or mutagenicity (*see* **Software for Clinical Trials**; **Mutagenicity Study**). In the context of environmental impact on biosystems, *toxicodynamic* and *toxicokinetic* (TDTK) models as well as *physiologically based pharmacokinetic* (PBPK) models have been incorporated to expand the domain of bioassays; *structure–activity relationship information* (SARI) is often used to consolidate the adoption of bioassays in a more general setup; the genesis of dosimetry (or *animal studies*) lies in this complex. The use of *biomarkers* in studying environmental toxic effects on biological systems, as well as in carcinogenicity studies, has enhanced the scope of bioassays to a greater interdisciplinary field; we need to appraise, as well, bioassays in this broader sense. Further, recent advances in **bioinformatics** have added new frontiers to the study of biological systems; bioassay models are gaining more popularity in the developing area of *computational biology*. Our appraisal of bioassay would remain somewhat incomplete without an assessment of the role of *Pharmacogenomics* as well as *Toxicogenomics* in establishing a knowledge base of the chemical effects in biological systems. The developments in genomics during the past eight years, have opened the doors for a far more penetrating level of research focusing on the **gene-environment interaction** in conventional experiments with biological units, and thereby calling for drastically different statistical resolutions for bioassays. We include also a brief synopsis of these recent developments.

Traditionally, in a bioassay, a test (new) and a standard preparation are compared by means of reactions that follow their applications to some biological units (or subjects), such as subhuman primates (or human) living tissues or organs; the general objective being to draw interpretable statistical conclusions on the *relative potency* of the test preparation with respect to the standard one. Usually, when a drug or a *stimulus* is applied to a subject, it induces a change in some measurable characteristic that is designated as the *response* variable. In this setup, the dose may have several chemically or therapeutically different ingredients while the response may also be multivariable. Thus the *stimulus–response* or **dose–response** relationship for the two preparations, both subject to inherent stochastic variability, are to be compared in a sound statistical manner (with adherence to biological standardization) so as to cast light on their relative performance with respect to the set objectives. Naturally, such statistical procedures may depend on the nature of the stimulus and response, as well as on other extraneous experimental (biological or therapeutical) considerations. As may be the case with some competing drugs for the treatment of a common disease or disorder, the two (i.e. test and standard) preparations may not have the same chemical or pharmacological constitution, and hence, statistical modeling may be somewhat different than in common laboratory experimentation. Nevertheless, in many situations, the test preparation may behave (in terms of the response/tolerance distribution) as if it is a dilution or concentration of the standard one. For this reason, often, such bioassays are designated to compare the relative performance of two drugs under the *dilution–concentration* postulation, and are thereby termed *dilution assays*.

Dilution assays are classified into two broad categories: *Direct dilution* and *indirect dilution* assays. In a direct assay, for each preparation, the exact amount of dose needed to produce a specified response is recorded, so that the response is certain while the dose is a nonnegative random variable that defines the *tolerance distribution*. Statistical modeling of these tolerance distributions enables us to interpret the relative potency in a statistically analyzable manner, often in terms of the parameters associated with the tolerance distributions. By contrast, in an indirect assay, the dose is generally administered at some prefixed (usually nonstochastic) levels, and at each level, the response is observed for subjects included in the

study. Thus, the dose is generally nonstochastic and the stochastic response at each level leads to the tolerance distributions that may well depend on the level of the dose as well as the preparation. If the response is a quantitative variable, we have an indirect *quantitative* assay, while if the response is *quantal* in nature (i.e. all or nothing), we have a *quantal* assay (*see* **Binary Data**). Both of these indirect assays are more commonly addressed in statistical formulations.

Within this framework, the nature of the dose–response regression may call for suitable **transformations** on the dose variable (called the *dosage* or *dose-metameter*) and/or the response variable, called the *response-metameter*. The basic objective of such transformations is to achieve a linear dosage-response regression (*see* **Linear Regression, Simple**), which may induce simplifications in statistical modeling and analysis schemes. In view of the original dilution structure, such transformations may lead to different designs for such assays, and the two most popular ones are (i) **parallel-line assays** and (ii) **slope-ratio assays**. Within each class, there is also some variation depending on the (assumed) nature of tolerance distributions, and within this setup, the *probit* (or normit) and *logit* transformations, based on normal and logistic distributions respectively, are quite popular in statistical modeling and analysis of bioassays. Bliss [2] contains an excellent account of the early developments in this area, while the various editions of Finney [6] capture more up-to-date developments, albeit with a predominantly parametric flavor. We refer to these basic sources for extensive bibliography of research articles, particularly in the early phase of developments where biological considerations often dominated statistical perspectives.

In this framework, it is also possible to include bioassays that may be considered for **bioavailability and bioequivalence** studies, though basically there are some differences in the two setups: Bioassays for assessing relative potency relate to *clinical therapeutic* **equivalence trials**, while in **bioequivalence** trials, usually, the relative bioavailability of different formulations of a drug are compared. Thus, in bioequivalence studies, the *pharmacologic* results of administrating essentially a common drug in alternative forms, such as a capsule versus a tablet, or a liquid dose of certain amount, capsules (tablets) or liquid forms of larger dose versus smaller dose with increased frequency of prescription, or even the administration of a drug at different time of the day, such as before breakfast or sometime after a meal, and so on, are to be assessed in a valid statistical manner. In this sense, the active ingredients in the drug in such alternative forms may be essentially the same, and differences in bioavailability reflect the form and manner of administration. We shall see later on that these basic differences in the two setups call for somewhat different statistical formulations and analysis schemes.

Direct Dilution Assays

As an illustrative example, consider two toxic preparations (say, S and T), such that a preparation is continuously injected into the blood stream of an animal (say, cat) until its heart stops beating. Thus, the response (death) is certain, while the exact amount of the dose (X) required to produce the response is stochastic. Let X_S and X_T stand for the dose (variable) for the standard and test preparation, and let $F_S(x)$ and $F_T(x)$, $x \geq 0$, be the two tolerance distributions. The *fundamental assumption* of a direct dilution assay is the following:

$$F_T(x) = F_S(\rho x), \quad \text{for all } x \geq 0, \tag{1}$$

where $\rho(>0)$ is termed the relative potency of the test preparation with respect to the standard one. Standard parametric procedures for drawing statistical conclusions on ρ are discussed fully in the classical text of Finney [6], where other references are also cited in detail. If $F_S(.)$ is assumed to be a **normal distribution** function, then ρ is characterized as the ratio of the two means, as well as the ratio of the two standard deviations. Such simultaneous constraints on means and variances vitiate the simplicity of achieving optimality of parametric procedures (in the sense of **maximum likelihood** estimators and related **likelihood ratio tests**). On the other hand, if we use the log-dose transformation on the two sets of doses, and the resulting dosage distributions, denoted by $F_S^*(.)$ and $F_T^*(,)$ respectively, are taken as normal, then they have the same variance, while the difference of their means define $\log \rho$. Interestingly enough, in the first case, the estimator of ρ is the ratio of the sample arithmetic means, while in the other case, it turns out as the ratio of the sample geometric means. A different estimator emerges when one uses a *power-dosage* (as is common in slope-ratio assays). Thus,

in general, these estimators are not the same, and they depend sensibly on the choice of a dosage. This explains the lack of invariance property of such parametric estimates (as well as associated test statistics) under monotone dosage transformations.

From an operational point of view, an experimenter may not have the knowledge of the precise dosage, and hence, it may not be very prudent to assume the normality, lognormality or some other specific form of the tolerance distribution. Therefore, it may be reasonable to expect that an estimator of the relative potency should not depend on the chosen dosage as long as the latter is strictly monotone. For example, if the true tolerance distribution is *logistic* while we assume it to be (log)normal, the sample estimator may not be **unbiased** and fully **efficient**. Even when the two tolerance distributions are taken as normal, the ratio of the sample means is not unbiased for ρ. In this respect, such parametric procedures for the estimation of the relative potency (or allied tests for the fundamental assumption) are not so **robust**, and any particular choice of a dosage may not remain highly efficient over a class of such chosen tolerance distributions. **Nonparametric** procedures initiated by Sen [17, 18, 19] and followed further by Shorack [26], and Rao and Littell [14], among others, eliminate this arbitrariness of dosage selection and render robustness to a far greater extent. Basically, we may note that **ranks** are invariant under strictly monotone (not necessarily linear) transformations on the sample observations. As such, a test for the fundamental assumption in (1) based on appropriate rank statistic remains invariant under such transformations. Similarly, if an estimator of the relative potency is based on suitable rank statistics, it remains invariant under such strictly monotone dosage transformations. Both the **Wilcoxon–Mann–Whitney** two-sample rank-sum test and the (Brown–Mood) **median** test statistics were incorporated by Sen [17] for deriving nonparametric estimators of relative potency, and they also provide distribution-free **confidence intervals** for the same parameter. If there are m observations $X_{S1}, \ldots, X_{Sm}$ for the standard preparation and n observations $X_{T1}, \ldots, X_{Tn}$, for the test preparation, we define the differences

$$Y_{ij} = X_{Si} - X_{Tj}, \text{ for } i = 1, \ldots, m; \; j = 1, \ldots, n. \tag{2}$$

We arrange the $N(= mn)$ observations Y_{ij} in ascending order of magnitude, and let $\tilde{Y}_N$ be the median of these N observations. If N is even, we take the average of the two central **order statistics**. Then $\tilde{Y}_N$ is the Wilcoxon score estimator of $\log \rho$, and it is a robust and efficient estimator of $\log \rho$. The estimator is invariant under any strictly monotone transformation on the dose. Similarly, the confidence interval for $\log \rho$ can be obtained in terms of two specified order statistics of the Y_{ij}, and this is a distribution-free and robust procedure. A similar procedure works out for the median procedure; for general rank statistics, generally, an iterative procedure is needed to solve for such robust R-estimators (*see* **Robust Regression**). Rao and Littell [14] incorporated the two-sample **Kolmogorov–Smirnov test** statistics in the formulation of their estimator. For computational convenience, because of the invariance property, it is simpler to work with the log-dose dosage, and in that way, the estimators of the log-relative potency correspond to the classical rank estimators in the two-sample location model.

These direct dilution assays require the measurement of the exact doses needed to produce the response; this may not be the case if there are some *latent effects*. For example, the time taken by the toxic preparation to traverse from the point of infusion to the heart multiplied by the infusion rate may account for such a latent effect. In general, the situation may be much more complex. This naturally affects the fundamental assumption in (1), and variations in the modeling and statistical analysis to accommodate such effects have been discussed in [6] and [17] in the parametric and nonparametric cases respectively.

Indirect Dilution Assays

As an example, consider two drugs, A and B, each administered at $k(\geq 2)$ prefixed levels (doses) $d_1, \ldots, d_k$. Let X_{Si} and Y_{Ti} be the response variable for the standard and test preparation respectively. These drugs may not have the same chemical ingredients, and may not have the same dose levels. It is not necessary to have the same doses for both the preparations, but the modifications are rather straightforward, and hence we assume this congruence. We assume first that both X_{Si} and Y_{Ti} are continuous (and possibly nonnegative) **random variables**. Suppose further that there exist some dosage $x_i = \xi(d_i), i =$

$1, \ldots, k$ and response-metameter $X^* = g(X)$, $Y^* = g(Y)$, for some strictly monotone $g(.)$, such that the two dosage–response **regressions** may be taken as linear, namely, that

$$Y^*_{Ti} = \alpha_T + \beta_T x_i + e_{Ti}, \quad X^*_{Si} = \alpha_S + \beta_S x_i + e_{Si}, \tag{3}$$

for $i = 1, \ldots, k$, where for statistical inferential purposes, certain distributional assumptions are needed for the error components e_{Ti} and e_{Si}, $i = 1, \ldots, k$. Generally, in the context of log-dose transformations, we have a parallel-line assay, while slope-ratio assays arise typically for **power transformations**. Thus, in a parallel-line assay, the two dose–response regression lines are taken to be parallel, and further that the errors e_{Ti} and e_{Si} have the same distribution (often taken as normal). In this setup, we have then $\beta_S = \beta_T = \beta$ (unknown), while $\alpha_T = \alpha_S + \beta \log \rho$, where ρ is the relative potency of the test preparation with respect to the standard one. This leads to the basic estimating function

$$\log \rho = \frac{\{\alpha_T - \alpha_S\}}{\beta}, \tag{4}$$

so that if the natural parameters β, α_S and α_T are estimated from the acquired bioassay dataset, statistical inference on $\log \rho$ (and hence ρ) can be drawn in a standard fashion. For normally distributed errors, the whole set of observations pertains to a conventional linear model with a constraint on the two slopes β_S, β_T, so that the classical maximum likelihood estimators and allied likelihood ratio tests can be incorporated for drawing statistical conclusions on the relative potency or the fundamental assumption of parallelism of the two regression lines. However, the estimator of $\log \rho$ involves the ratio of two normally distributed statistics, and hence, it may not be unbiased; moreover, generally, the classical **Fieller's theorem** [6] is incorporated for constructing a confidence interval for $\log \rho$ (and hence, ρ), and it is known that this may result in an inexact coverage probability (*see* **Confidence Intervals and Sets**). Because of this difference in setups (with that of the classical linear model), design aspects for such parallel-line assays need a more careful appraisal. For equispaced (log −)doses, a symmetric $2k$-point design has optimal information contents, and are more popularly used in practice. We refer to [6] for a detailed study of such bioassay designs in a conventional normally distributed errors model. Two main sources of nonrobustness of such conventional inference procedures are the following:

(i) Possible nonlinearity of the two regression lines (they may be parallel but yet curvilinear);
(ii) Possible nonnormality of the error distributions.

On either count, the classical normal theory procedures may perform quite nonrobustly, and their (asymptotic) optimality properties may not hold even for minor departures from either postulation. However, if the two dose–response regressions (linear or not) are not parallel, the fundamental assumption of parallel-line assays is vitiated, and hence, statistical conclusions based on the assumed model may not be very precise.

In a slope-ratio assay, the intercepts α_S and α_T are taken as the same, while the slopes β_S and β_T need not be the same and their ratio provides the specification of the relative potency ρ. In such slope-ratio assays, generally, a power transformation: dosage $=$ (dose)$^\lambda$, for some $\lambda > 0$ is used, and we have

$$\rho = \left\{ \frac{\beta_T}{\beta_S} \right\}^{1/\lambda}, \tag{5}$$

which is typically a nonlinear function of the two slopes β_T and β_S, and presumes the knowledge of λ. In such a case, the two error components may not have the same distribution even if they are normal. This results in a heteroscedastic linear model (unless $\rho = 1$) (*see* **Scedasticity**), where the conventional linear estimators or allied tests may no longer possess validity and efficiency properties. Moreover, as ρ^λ is a ratio of two slopes, its conventional estimator based on usual estimators of the two slopes is of the ratio-type. For such ratio-type estimators, again the well-known Fieller Theorem [6] is usually adopted to attach a confidence set to ρ or to test a suitable null hypothesis. Such statistical procedures may not have the exact properties for small to moderate sample sizes. Even for large sample sizes, they are usually highly nonrobust for departures from the model-based assumptions (i.e. linearity of regression, the fundamental assumption, and normality of the errors). Again the design aspects for such slope-ratio assays need a careful study, and [6] contains a detailed account of this study. Because of the

common intercept, usually a $2k + 1$ point design, for some nonnegative integer k is advocated here.

The articles on **Parallel-line Assay** and **Slope-ratio Assay** should be consulted for further details. The primary emphasis in these articles is on standard parametric methods, and hence we discuss briefly here, the complementary developments of nonparametric and robust procedures for such assays. These were initiated in [21, 22] and also systematically reviewed in [23]. First, we consider a nonparametric test for the validity of the fundamental assumption in a parallel-line assay. This is essentially a test for the equality of slopes of two regression lines, and as in [21], we consider an aligned test based on the Kendall τ statistic (*see* **Rank Correlation**). For each preparation with the set of dosages as independent variate and responses as dependent variable, one can define the Kendall tau statistic in the usual manner. We consider the aligned observations $Y_{Ti} - bx_i$ and x_i, and denote the corresponding Kendall τ (in the summation but not average form) as $K_T(b)$, and for the standard preparation, an aligned Kendall's τ statistic is defined by $K_S(b)$, where we allow b to vary over the entire real line. Let then

$$K^*(b) = K_T(b) + K_S(b), \quad -\infty < b < \infty. \tag{6}$$

Note then that $K_T(b)$, $K_S(b)$, and hence $K^*(b)$ are all nonincreasing in b and have finitely many step-down discontinuities. Equating $K^*(b)$ to 0 [20], we obtain the pooled estimator $\hat{\beta}$ of β. Let us then write

$$\mathcal{L} = \frac{\{[K_T(\hat{\beta})]^2 + [K_S(\hat{\beta})]^2\}}{V_n}, \tag{7}$$

where V_n is the variance of the Kendall τ statistic under the hypothesis of no regression (and is a known quantity). This statistic has, under the hypothesis of homogeneity of β_T and β_S, closely central **chi-square distribution** with one **degree of freedom**. $\mathcal{L}$ is used as a suitable test statistic for testing the validity of the fundamental assumption of a parallel-line assay where the normality of the error components is not that crucial. In that sense it is a robust test. Moreover, having obtained the pooled estimator $\hat{\beta}$ of β, under the hypothesis of homogeneity of the slopes, we consider the residuals

$$\hat{Y}_{Ti} = Y_{Ti} - \hat{\beta}x_i, \quad \hat{Y}_{Si} = Y_{Si} - \hat{\beta}x_i, \tag{8}$$

for different i, and treating them as two independent samples, as in the case of dilution direct assays, we use the Wilcoxon–Mann–Whitney rank-sum test statistic to estimate the difference of the intercepts $\alpha_T - \alpha_S$ in a robust manner. As in the direct dilution assay, this estimator is the median of the differences of all possible pairs of **residuals** from the test and standard preparation respectively. A robust, **consistent** and asymptotically normally distributed estimator of $\log \rho$ is then obtained by dividing this estimator by the pooled estimator $\hat{\beta}$.

For drawing a confidence interval for $\log \rho$ (and hence, ρ), we can then use the Fieller Theorem by an appeal to the asymptotic normality of the estimator, or as in [21], consider a rectangular confidence set for β and $\alpha_T - \alpha_S$ by computing a coordinate-wise confidence interval for each with coverage probability $1 - \gamma/2$, and as in Figure 1, draw a robust confidence set for $\log \rho$ with coverage probability $1 - \gamma$.

Though this does not have an exact coverage probability, it is quite robust and works out well even for quite nonnormal error distributions. In the above setup, instead of the Kendall τ and the two-sample rank-sum statistics, we may use a general linear rank statistic for regression and a two-sample linear rank statistic for difference of location parameters, and obtain similar robust estimation and testing procedures. It is also possible to use general (aligned) M-statistics for this purpose (*see* **Robust Regression**). In general, such solutions

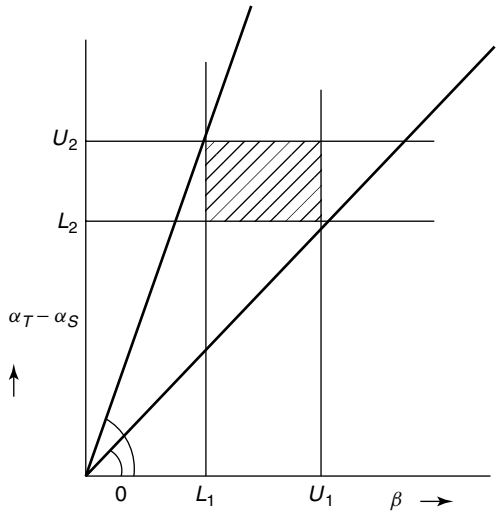

Figure 1 Graphical procedure for obtaining a nonparametric confidence interval for the log potency ratio in a parallel-line assay

are to be obtained by iterative methods, and hence, for simplicity and computational ease, we prescribe the use of the Kendall tau and two-sample rank- sum statistics for the desired statistical inference.

Next, we proceed to the case of slope-ratio assays, and consider first a nonparametric test for the validity of the fundamental assumption (of a common intercept but possibly different slopes). We define the Kendall tau statistics $K_T(b)$ and $K_S(b)$ as in the case of the parallel-line assay, and equating them to 0, we obtain the corresponding estimates of β_T and β_S, which are denoted by $\hat{\beta}_T$ and $\hat{\beta}_S$ respectively. Consider then the residuals

$$\tilde{Y}_{Ti} = Y_{Ti} - \hat{\beta}_T x_i, \quad \tilde{Y}_{Si} = Y_{Si} - \hat{\beta}_S x_i, \ \forall i. \tag{9}$$

We pool all these residuals into a combined set, and use the **Wilcoxon signed-rank** statistic to derive the corresponding rank estimator of the hypothesized common value of the intercept; this estimator, denoted by $\tilde{\alpha}$, is the median of all possible midranges of the set of residuals listed above. Let then $\hat{Y}_{Ti} = \tilde{Y}_{Ti} - \tilde{\alpha}$, $\hat{Y}_{Si} = \tilde{Y}_{Si} - \tilde{\alpha}$, $\forall i$, and for each preparation, based on these residuals, we consider the Wilcoxon signed-rank statistic. These are denoted by $\hat{W}_T$ and $\hat{W}_S$ respectively. As in the case of parallel-line assays, here we consider a test statistic for testing the validity of the fundamental assumption as

$$\mathcal{L} = \frac{\{\hat{W}_T^2 + \hat{W}_S^2\}}{V_n}, \tag{10}$$

where V_n is the variance of Wilcoxon signed-rank statistic under the hypothesis of symmetry of the distribution around 0 (and is a known quantity). When the fundamental assumption holds, the distribution of $\mathcal{L}$ is close to the central chi-square distribution with 1 degree of freedom, and hence a test can be carried out using the percentile point of this chi-square law. This test is quite robust and the underlying normality of the errors may not be that crucial in this context. Note that for the slope-ratio assay, granted the fundamental assumption of a common intercept, a natural plug-in estimator of ρ is given by

$$\hat{\rho} = \left\{ \frac{\hat{\beta}_T}{\hat{\beta}_S} \right\}^{1/\lambda}. \tag{11}$$

We may use the Fieller Theorem under an asymptotic setup to construct a confidence interval for ρ. Alternatively, as in the case of a parallel line assay, for a given $\gamma (0 < \gamma < 1)$, we may consider a distribution-free confidence interval of coverage probability $1 - \gamma/2$ for each of the two slopes β_T and β_S, and obtain a confidence interval for ρ^λ (and hence ρ). The situation is quite comparable to the Figure for the parallel-line assay, excepting that β_T and β_S are taken for the two axes. Here also, instead of the Kendall tau statistics and the Wilcoxon signed-rank statistics, general regression rank statistics and (aligned) signed-rank statistics (or even suitable M-statistics) can be used to retain robustness of the procedures without sacrificing much efficiency. However, the solutions are generally to be obtained by iterative procedures, and hence, we prefer to use the simpler procedures considered above.

Indirect Quantal Assays

In this type of (indirect) assays, the response is *quantal* (i.e. all or nothing) in nature. For each preparation (T or S) and at each level of administered dose, among the subjects, a certain number manifest the response while the others do not; these frequencies are stochastic in nature and their distribution depends on the dose level and the preparation (*see* **Quantal Response Models**). Thus, for a given dosage x, we denote by $F_T(x)$ and $F_S(x)$ the probability of the response for the test and standard preparation respectively. It is customary to assume that both $F_T(x)$ and $F_S(x)$ are monotone increasing in x, and for each $\alpha (0 < \alpha < 1)$, there exits unique solutions of the following

$$F_T(\xi_{T\alpha}) = \alpha, \quad \text{and} \quad F_S(\xi_{S\alpha}) = \alpha, \tag{12}$$

so that $\xi_{T\alpha}$ and $\xi_{S\alpha}$ are the α-**quantile** of the test and standard preparation; they are termed the $100\alpha\%$ effective dosage. In particular, for $\alpha = 1/2$, they are termed the **median effective dosage**. Whenever the response relates to death (as is usually the case with animal and toxicologic studies), the $\xi_{T\alpha}$, $\xi_{S\alpha}$ are also termed $100\alpha\%$-*lethal dosage*. In many studies, generally, low dosages are contemplated so that α is chosen to be small. This is particularly the case with **radioimmunoassays**, and we shall comment on that later on. Estimation of the $\xi_{T\alpha}$ and $\xi_{S\alpha}$ with due attention to their interrelations is the main task in a quantal assay. The concept of parallel-line and slope-ratio assays, as laid down for indirect quantitative assays, is also adoptable in quantal assays, and a

detailed account of the parametric theory based on normal, lognormal, logistic, and other notable forms of the distribution $F_T(x)$ is available with Finney [6, Chapter 17]. In this context, the *probit* and *logit* analyses are particularly notable, and we shall discuss them as well.

To set the ideas, we consider a single preparation at $k(\geq 2)$- specified dosage $d_1, \ldots, d_k$, where $d_1 < d_2 < \cdots < d_k$. Suppose that the dosage d_i has been administered to n_i subjects, out of which r_i respond positively while the remaining $n_i - r_i$ do not, for $i = 1, \ldots, k$. In this setup, the d_i, n_i are nonstochastic, while the r_i are random. The probability of a positive response at dosage d_i, denoted by $\pi(d_i)$, is then expressed as

$$\pi(d_i) = \pi(\theta + \beta d_i), \quad i = 1, \ldots, k, \tag{13}$$

where θ and β are unknown (intercept and regression) parameters, and $\pi(x)$, $-\infty < x < \infty$, is a suitable distribution function. In a parametric mold, the functional form of $\pi(.)$ is assumed to be given, while in nonparametrics, no such specific assumption is made. Note that the joint probability law of $r_1, \ldots, r_k$ is given by

$$\prod_{i=1}^{k} \binom{n_i}{r_i} \pi(\theta + \beta d_i)^{r_i} [1 - \pi(\theta + \beta d_i)]^{n_i - r_i}, \tag{14}$$

so that the **likelihood** function involves only two unknown parameters θ and β. The log-likelihood function or the corresponding estimating equations are not linear in the parameters, and this results in methodological as well as computational complications (*see* **Optimization and Nonlinear Equations**).

If $\pi(.)$ is taken as a **logistic distribution**, that is, $\pi(x) = \{1 + e^{-x}\}^{-1}$, then we have from the above discussion

$$\log \left\{ \frac{\pi(d_i)}{[1 - \pi(d_i)]} \right\} = \theta + \beta d_i, \quad i = 1, \ldots, k. \tag{15}$$

This transformation, known as the *logit* transformation, relates to a linear regression on the dosage, and simplifies related statistical analysis schemes. Thus, at least intuitively, we may consider the sample logits

$$Z_i = \log \left\{ \frac{r_i}{n_i} - r_i) \right\}, \quad i = 1, \ldots, k, \tag{16}$$

and attempt to fit a linear regression of the Z_i on d_i (*see* **Logistic Regression**). In passing, we may remark that technically r_i could be equal to zero or n_i (with a positive probability), so that Z_i would assume the values $-\infty$ and $+\infty$ with a positive probability, albeit for large n_i, this probability converges to zero very fast. As in practice, the n_i may not be all large; to eliminate this impasse, we consider the Anscombe correction to a **binomial** variable, and in (16), modify the Z_i as

$$Z_i = \log \left\{ \frac{(r_i + \frac{3}{8})}{(n_i - r_i + \frac{3}{8})} \right\}, \quad i = 1, \ldots, k. \tag{17}$$

Though the r_i have binomial distributions, the Z_i have more complex probability laws, and computation of their exact mean, variance, and so on, is generally highly involved. For large values of the n_i, we have the following

$$\sqrt{n_i}(Z_i - \theta - \beta d_i) \xrightarrow{\mathcal{D}} \mathcal{N}(0, \{\pi(d_i)[1 - \pi(d_i)]\}^{-1}), \tag{18}$$

for each $i = 1, \ldots, k$, where the unknown $\pi(d_i)$ can be consistently estimated by the sample proportion $p_i = r_i/n_i$. Thus, using the classical *weighted* **least squares** *estimation* (WLSE) methodology (*see* **Categorical Data Analysis**), we may consider the quadratic norm

$$Q(\theta, \beta) = \sum_{i=1}^{k} n_i p_i (1 - p_i) \{Z_i - \theta - \beta d_i\}^2, \tag{19}$$

and minimize this with respect to θ, β to obtain the WLS estimators. Although the logit transformation brings the relevance of **generalized linear models** (GLM), the unknown nature of their variance functions makes the WLSE approach more appropriate for the suggested statistical analysis. In any case, the asymptotic flavor should not be overlooked.

If $\pi(x)$ is taken as the standard normal distribution function $\Phi(x)$, whose density function is denoted by $\phi(x)$, then we may consider the transformation

$$Z_i = \Phi^{-1}\left(\frac{r_i}{n_i}\right), \quad i = 1, \ldots, k, \tag{20}$$

known as the *probit* or *normit* transformation. Here also, it would be better to modify Z_i as

$$Z_i = \Phi^{-1}\left(\frac{(r_i + \frac{3}{8})}{(n_i + \frac{1}{2})}\right), \quad i = 1, \ldots, k. \tag{21}$$

Note that by assumption, $\Phi^{-1}(\pi(d_i)) = \theta + \beta d_i,\ i = 1, \ldots, k$, and this provides the intuitive appeal for a conventional linear regression analysis. However, the likelihood approach based on the product-binomial law encounters computational difficulties and loses its exactness of distribution theory to a greater extent. Here also, we would have complications in the computation of the exact mean, variance, or distribution of the Z_i, and hence, as in the logit model, we consider a WLSE approach in an asymptotic setup where the n_i are large. By virtue of the asymptotic normality of the $\sqrt{n_i}(p_i - \pi(d_i))$ (where again we take $p_i = (r_i + 3/8)/(n_i + 1/2)$), we obtain that for every $i \geq 1$,

$$\begin{aligned} &\sqrt{n_i}[Z_i - \theta - \beta d_i] \\ &\xrightarrow{\mathcal{D}} \mathcal{N}(0, \frac{\pi(d_i)[1 - \pi(d_i)]}{\phi^2(\Phi^{-1}(\pi(d_i)))}), \end{aligned} \tag{22}$$

so that we consider quadratic norm in a WLSE formulation

$$Q(\theta, \beta) = \sum_{i=1}^{k} \frac{n_i \phi^2(\Phi^{-1}(p_i))}{p_i(1 - p_i)}[Z_i - \theta - \beta d_i]^2, \tag{23}$$

and minimizing this with respect to θ, β, we arrive at the desired estimators.

For both the logit and probit models, the resulting estimators of θ, β are linear functions of the Z_i with coefficients depending on the n_i and the p_i. Therefore, the asymptotic normality and other properties follow by standard statistical methodology (*see* **Bartlett's Test**). Moreover the (asymptotic) dispersion matrix of these estimators, in either setup, can be consistently estimated from the observational data sets. Thus, we have the access to incorporate standard asymptotics to draw statistical conclusions based on these estimators.

Let us then consider the case of quantal bioassays involving two preparations (S and T), and for each preparation, we have a setup similar to the single preparation case treated above. The related parameters are denoted by θ_S, β_S and θ_T, β_T respectively, and for modeling the response distributions, we may consider either the logit or probit model, as has been discussed earlier. If we have a parallel-line assay, as in the case of an indirect assay, we have then

$$\beta_T = \beta_S = \beta \text{ unknown, and } \theta_T - \theta_s = \beta \log \rho, \tag{24}$$

so that based on the estimates $\hat{\theta}_S, \hat{\beta}_S, \hat{\theta}_T$ and $\hat{\beta}_T$, along with their estimated dispersion matrix, we can incorporate the WLSE to estimate the common slope β and the intercepts θ_S and θ_T. The rest of the statistical analysis is similar to the case of indirect assays. Moreover, this WLSE methodology is asymptotically equivalent to the classical likelihood-function–based methodology, so it can be regarded, computationally, as a simpler substitute for a comparatively complicated one. For a slope-ratio assay, we have similarly a common intercept while the ratio of the slopes provide the measure of the relative potency, and hence, the WLSE based on the individual preparation estimators can be adopted under this restriction to carryout the statistical analysis as in the case of an indirect assay.

Besides the logit or probit method, there are some other quasi-nonparametric methods, of rather an ad hoc nature, and among these, we may mention of the following estimators of the median effective dosage:

(i) The Spearman–Kärber estimator;
(ii) The Reed–Muench estimator, and
(iii) The Dragstedt–Behrens estimator.

These procedures are discussed in [7], p. 43. If the tolerance distribution is symmetric, the Spearman–Kärber estimator estimates the median effective dosage closely; otherwise, it may estimate some other characteristic of this distribution. Miller [13] studied the relative (asymptotic) performance of these three estimators, casting light on their bias terms as well. From a practical point of view, none of these estimators appears to be very suitable. Rather, if the $\pi(d_i)$ do not belong to the extreme tails (i.e. are not too small or close to 1), the logit transformation provides a robust and computationally simpler alternative, and is being used more and more in statistical applications. In passing, we may remark that

Finney [7, Chapter 10] contains some other techniques that incorporate modifications in the setup of usual quantal assays, such as the numbers n_i being unknown and possibly random, multiple (instead of binary) classifications, errors in the doses. In the following chapter, he also introduced the case of doses in mixtures that require a somewhat extended model and more complex statistical designs and analysis schemes. We shall comment on these below.

Stochastic Approximation in Bioassay

In the context of a quantal assay, we have the dosage-response model in terms of the tolerance distribution $\pi(d)$, and the median effective (lethal) dosage, LD50, is defined by the implicit equation $\pi(LD50) = 0.50$. In this context, for each preparation (standard or test), corresponding to initial dosage levels $d_1, \ldots, d_k$, we have estimates $p(d_1), \ldots, p(d_k)$ of the unknown $\pi(d_1), \ldots, \pi(d_k)$. We may set

$$p_i = \pi(d_i) + e(d_i), \quad i = 1, \ldots, k, \tag{25}$$

where the errors are (for large n_i, the number of subjects treated) closely normally distributed with zero mean and variance $n_i^{-1}\pi(d_i)[1 - \pi(d_i)]$. On the basis of this initial response data, we can choose an appropriate d_o for which the corresponding $p(d_o)$ is closest to $1/2$. Then, we let $d_{(1)} = d_o + a_o[p(d_o) - 1/2]$, for some $a_o > 0$, and recursively we set

$$d_{(j+1)} = d_{(j)} + a_j \left[p(d_{(j)}) - \frac{1}{2} \right], \quad \text{for some } \; a_j > 0; \; j \geq 0. \tag{26}$$

(*see* **Up-and-Down Method**) The aim of this **stochastic approximation** procedure, due to Robbins and Monro [15], is to estimate the LD50 without making an explicit assumption on the form of the tolerance distribution $\pi(d)$. But in this setup, the $p(d_{(j)})$ as well as the $d_{(j)}$ are stochastic elements, and for the convergence of this stochastic iteration procedure, naturally, some regularity conditions are needed on the $\{a_i; i \geq 0\}$ and $\pi(d)$ around the LD50. First of all, in order that the iteration scheme terminates with a consistent estimator of the LD50, it is necessary that the a_i converge to zero as i increases. More precisely, it is assumed in this context that

$$\sum_{n \geq 0} a_n \text{ diverges to } +\infty, \quad \text{but } \sum_{n \geq 0} a_n^2 \; < \; +\infty. \tag{27}$$

In addition, the continuity and positivity of the density function corresponding to the distribution function $\pi(x)$ at the population LD50 is also a part of the regularity assumptions. Further assumptions are needed to provide suitable (stochastic) rates of convergence of the estimator of the LD50 and its asymptotic normality and related large sample distributional properties. Once the LD50 values are estimated for each preparation, we may proceed as in the case of a quantal assay, and draw conclusions about the relative potency and other related characteristics. It is not necessary to confine attention specifically to the LD50, and any LD100α, for $\alpha \in (0, 1)$ can be treated in a similar fashion. In fact, Kiefer and Wolfowitz [12] considered an extension of the Robbins–Monro stochastic approximation procedure that is aimed to locate the maximum (or minimum) of a dose–response function that is not necessarily (piecewise or segmented) linear but is typically nonmonotone, admitting a unique extremum (maximum or minimum) of experimental importance. Such dose–response regressions arise in many toxicologic studies where a turn occurs at an unknown level. Often this is treated in a general **change-point** model framework. The main advantage of the stochastic approximation approach over the classical quantal assay approach is that no specific assumption is generally needed on the probability function $\pi(d)$, so that the derived statistical conclusions remain applicable in a much wider setup. On the other hand, the stochastic iteration scheme generally entails a larger number of subjects on which to administer the study, and often that may run contrary to the practicable experimental setups, especially with respect to cost considerations. In this general context, a significant amount of methodological research work has been carried out during the past 40 years, and an extensive review of the literature on stochastic approximation is made by Ruppert [16] where the relevant bibliography has also been cited. The scope of stochastic approximation schemes is by no means confined to quantal assays; they are also usable for quantitative bioassays, and even to other problems cropping up in far more general setups.

Radioimmunoassay

In *radioimmunoassays* antigens are labeled with radioisotopes, and in *immunoradiometric assays* antibodies are labeled. For a broad range of antigens, such radioligand assays enable the estimation of potency from very small quantities of materials and usually with high precision. Radioligand assays are based upon records of radiation counts in a fixed time at various doses, so that potency estimation involves the relation between counts of radioactivity and dose, generally both at low levels [8]. In many such studies, the regression function of the count of radioactivity on dose has been found to be satisfactorily represented by a logistic curve; however, the lower and upper asymptotes of such a curve are not necessarily equal to zero and one, but are themselves unknown parameters. This difference with the classical logistic distribution is reflected in a somewhat different form of the variance function of radiation counts. Unlike the **Poisson process**, the variance function may not be equal to the mean level of the radiation counts $U(d)$ (i.e. their expectation at a given dose level d); in many studies, it has been experimentally gathered that the variance function $V(d)$ behaves like $[U(d)]^{\lambda}$, where $\lambda(>0)$ typically lies between 1 and 2. For this reason, the usual **Poisson regression** model in *generalized linear models* (GLM) methodology may not be universally applicable in radioimmunoassays. Moreover, such radioligand assays may not be regarded as strictly bioassays, since they may not depend upon responses measured in living organisms or tissues. However, the advent of the use of biologic *markers* in mutagenesis studies and in molecular genetics, particularly during the past 20 years, has extended the domain of statistical perspectives in radioligand assays to a much wider setup of investigations, and strengthened the structural similarities between radioimmunoassays and the classical bioassays. They involve statistical modeling and analysis schemes of very similar nature, and in this sense, their relevance in a broader setup of bioassays is quite appropriate (*see* **Radioimmunoassay**).

Dosimetry and Bioassay

As has been noted earlier, a dose–response model exhibits the (mathematical) relationship between an amount of exposure or treatment and the degree of a biological or health effect, generally a measure of an adverse outcome. Bioassay and clinical trials are generally used in such dose–response studies. With the recent advances in **pharmacoepidemiology** (*see* **Dose-response in Pharmacoepidemiology**) as well as in risk analysis (*see* **Dose–Response Models in Risk Analysis**), bioassays have led to another broader domain of statistical appraisal of biological dose–response studies, known as *dosimetry* (or animal study). Pharmacoepidemiology rests on the basic incorporation of *pharmacodynamics* (PD) and *pharmacokinetics* (PK) in the development of the so called *structure–activity relationship information* (SARI) (*see* **Chemometrics**). Though a PD model directly relates to a dose–response model, the PK actions of the exposure or drug needs to be taken into account in the dose–response modeling. This is now done more in terms of SARI where the structure refers to the dose factors and activity refers to the biological reactions that follow the exposure (dose) to a specific species or organism. In a majority of cases, the target population is human, but owing to various ethical and other experimental constraints, human beings may not be usable to the full extent needed for such a dose–response modeling. As such, animal studies are often used to gather good background information, which is intended for incorporation in human studies in bioassay and clinical trials. Dosimetry pertains to this objective.

Dosimetry models intend to provide a general description of the uptake and distribution of inhaled (or ingested or absorbed) toxics (or compounds having adverse health effects) on the entire body system. For judgment on human population, such dosimetric models for animal studies need to be *extrapolated* with a good understanding of the *interspecies differences* (*see* **Dose–Response Models in Risk Analysis**). SARI is a vital component in enhancing such statistical validation of pooling the information from various animal studies and extrapolating to the human population. Most dose–response relationships are studied and through well-controlled animal bioassays with exposure or dose levels generally much higher than typically perceived in human risk analysis. In this respect, dosimetry is directly linked to bioassay, though in dosimetry, the SARI is more intensively pursued to facilitate extrapolation (*see* **Extrapolation, Low Dose**). PDPK aspects not only may vary considerably from subhuman primates to human beings, but also there is much less of control in

human exposure to such toxics. Also, metabolism in the human being is generally quite different from that in subhuman primates. An important element in this context is the *environmental burden of disease* (EBD) factor that exhibits considerable interspecies variation as well as geopolitical variation. Hence, ignoring the SARI part, a conventional dose–response model for a subhuman primate may not be of much help in depicting a similar model for human exposure. For the same reason, conventional statistical extrapolation tools may be of very limited utility in this interspecies extrapolation problems [25]. Finally, in many carcinogenicity studies, it has been observed that *xenobiotic* effects underlie such dose–response relations, and this is outlined in a later section (*see pharmacogenomics*).

Semiparametrics in Bioassays

The GLM methodology has been incorporated in a broad variety of statistical modeling and analysis schemes pertaining to a wide range of applications, and bioassays are no exceptions. Going back to the direct dilution assays, if we had taken both the distributions, F_S and F_T, as **exponentials** with respective means μ_S and μ_T, then the two distributions would have constant **hazard rates** $1/\mu_S$ and $1/\mu_T$ respectively, so that the relative potency ρ is equal to the ratio of the two hazard rates. Inspired by this observation, and by the evolution of the Cox [3] **proportional hazard model** (PHM) (*see* **Cox Regression Model**), research workers have attempted to relate the two survival functions $S_S(x) = P\{X_S > x\}$ and $S_T(x) = P\{X_T > x\}$ as

$$S_T(x) \;=\; [S_S(x)]^{\rho}, \quad x \geq 0, \tag{28}$$

and interpret ρ as the relative potency of the test preparation with respect to the standard one (*see* **Lehmann Alternatives**). Though this representation enables one to import the PHM-based statistical analysis tools for the estimation of the relative potency, for distributions other than the exponential ones, the interpretation of "dilution assays" may no longer be tenable under such a PHM. There is an alternative interpretation in terms of the parallelism of the two log-hazard functions, but that may not fit well with the fundamental assumption in dilution assays. For some related statistical analysis of bioassays based on GLM methodologies, we refer to [24], where indirect bioassays have also been treated in the same manner along with the classical parametrics.

Nonparametrics in Bioassays

The estimators of relative potency and tests for fundamental assumptions in dilution (direct as well as indirect) assays based on rank statistics, considered earlier, spark the first incorporation of nonparametrics in biological assays. However, these may be characterized more in terms of **semiparametrics**, in the sense that the assumed linearity of dose–response regressions was essentially parametric in nature, while the unknown form of the underlying tolerance distribution constitutes the nonparametric component. Thus, together they form the so-called semiparametric models. It is possible to incorporate more nonparametrics in bioassays mostly through the **nonparametric regression** approach. For direct dilution assays, such nonparametric procedures are quite simple in interpretation and actual formulation. We consider the log-dose transformation, so that the dosage for the test and standard preparations have the distributions $F_T^*(x)$ and $F_S^*(x)$, respectively, where $F_T^*(x) = F_S^*(x + \log \rho)$, for all x. If we denote the p-quantile of F_T^* and F_S^* by $Q_T(p)$ and $Q_S(p)$ respectively, then we have

$$Q_S(p) \;-\; Q_T(p) = \log \rho, \;\; \forall \; p \in (0, 1), \tag{29}$$

so that the well-known Q–Q *plot* for the two preparations results in a linear regression form, and this provides the statistical information to test for this fundamental assumption as well as to estimate the relative potency. A similar conclusion can also be drawn from a conventional P–P *plot* (*see* **Graphical Displays**). The classical Kolmogorov–Smirnov statistics (in the two-sample case) can be used for drawing statistical conclusions, and we may refer to Rao and Littell [14] for some related work. The situation is a bit more complex with indirect assays. In the classical parametric setup, we work with the expected response at different dosages, assuming of course a linear regression. In a semiparametric approach, this linearity of dosage-response regression is taken as a part of the basic assumption, but the distribution of the errors is allowed to be a member of a wider class, so that robust procedures based on rank or M-statistics are advocated instead of the classical WLSE. In a pure nonparametric setup, the linearity of the

dosage-response regression is not taken for granted. Therefore the two dosage-response regression functions may be of quite arbitrary nature, and yet parallel in an interpretable manner. The statistical task is therefore to assess this parallelism without imposing linearity or some other parametric forms. Here also, at a given dosage level, instead of the mean response level, we may consider median or a p-quantile, and based on such robust estimators, we draw statistical conclusions allowing the quantile functions to be of a rather arbitrary nature. Asymptotics play a dominant role in this context, and often this may require a relatively much larger sample size. On the other hand, in terms of robustness and validity, such pure nonparametric procedures have a greater scope than parametric or semiparametric ones.

Bioavailability and Bioequivalence Models

As has been explained earlier bioequivalence trials differ from conventional bioassays, as here, generally, the active substances in the drug are the same but the differences in bioavailability reflect the form and manner of administration. Such alternative modes may therefore call for additional restraints in the statistical formulation, and because of anticipated biological equivalence, there is less emphasis on relative potency and more on general equivalence patterns. For such reasons, regulatory requirements for establishing *average bioequivalence* of two preparations (that are variations of an essentially common drug) relate to a verification of the following:

A *confidence interval* for the relative potency, having the *confidence limits* ρ_L, ρ_U, lies between two specified endpoints, say $\rho_o < 1 < \rho^o$, with a high *coverage probability* (or *confidence coefficient*) γ. Generally, γ is chosen close to 1 (namely, 0.95), and also $\rho^0 = (\rho_o)^{-1}$ is very close to one.

These requirements in turn entail a relatively large sample size, and therefore, (group) sequential testing procedures (*see* **Sequential Analysis**) are sometimes advocated [9]. For general considerations underlying such bioequivalence trials, we refer to [1, 11, 29], where other pertinent references are cited. Generally, such statistical formulations are more complex than the ones referred to earlier.

As has been mentioned earlier, the term bioassay is used in a more general form, and this is equally true for bioequivalence and bioavailability models. Kinetic measures of bioavailability and pharmacokinetic parameters have been developed to meet the demand for such recent usage (*see* **Bioavailability and Bioequivalence**). We will illustrate this somewhat differently with *pharmacogenomics*, which is revolutionizing the field of *bioinformatics* and experiments with biological units, in general.

Pharmacogenomics in Modern Bioassays

Following Ewens and Grant [5], we take bioinformatics to mean the emerging field of science growing from the application of mathematics, statistics, and information technology, including computers and the theory surrounding them, to study and analysis of very large biological and, in particular, genetic data sets (*see* **Genetic Markers**). Having its genesis 50 years ago [28], the field has been fueled by the immense increase in the DNA data generation (*see* **DNA Sequences**). Earlier interpretation of bioinformatics with emphasis on *computational biology* by Waterman [27] also merits serious considerations, while Durbin et al. [4] had a view point geared by computer **algorithms** along with some heuristic usage of **hidden Markov models**.

At the current stage, gene scientists cannot scramble fast enough to keep up with the genomics, with developments emerging at a furious rate and in astounding detail. Bioinformatics, at least at this stage, as a discipline, does not aim to lay down some fundamental mathematical laws (which might not even exist in such a biological diversity). However, its utility is perceived in the creation of innumerable computer graphics and algorithms that can be used to analyze exceedingly large data sets arising in bioinformatics. In this context, naturally **data mining** and *statistical learning* tools (under the terminology *Knowledge Discovery and Data Mining* (KDDM)) are commonly used [10], though often in a heuristic rather than objective manner. There could be some serious drawbacks of statistical analysis based on such KDDM algorithms alone, and *model selection* has emerged as a challenging task in bioinformatics (*see* **Model, Choice of**).

Given the current status of bioinformatics as the information technology (advanced computing) based discipline of analyzing exceedingly high dimensional data with special emphasis on *genomics*, and that genomics looks at the vast network of genes, over

time, to determine how they interact, manipulate, and influence biological pathways, networks, as well as physiology, it is quite natural to heed to *genetic variation* (or **polymorphism**) in most studies involving biological units. Moreover, because of the drug-response relationship, basic in bioassay, it is natural to appraise the role of pharmacogenomics in this setup. Pharmacology is the science of drugs including materia medica, toxicology, and therapeutics, dealing with the properties and reactions of drugs, especially with relation to their therapeutic values. In the same vein, *pharmacodynamics*, a branch of pharmacology, deals with reactions between drugs and living structures; *pharmacokinetics* relates to the study of the bodily absorption, distribution, metabolism, and excretion of drugs. In bioequivalence trials, these tools have already been recognized as fundamental. *Pharmacogenetics* deals with genetic variation underlying differential response to drugs as well as drug metabolism. The whole complex constitutes the discipline: *Pharmacogenomics*. In the same way, *Toxicogenomics* relates to the study of gene-environmental interactions in disease and dysfunction to cast light on how genomes respond to environmental stress or toxics.

It is conceived that there are certain genes that are associated with disease phenotype, side effects, and drug efficacy. Also, because of inherent (genetic) variations and an enormously large number of genes as well as a very large pool of diseases and disorders, there is a genuine need of statistical methods to assess the *genetic mapping of disease genes*. Pharmacotoxicogenomics is therefore destined to play a fundamental role in biological assays, in the years to come.

Complexities in Bioassay Modeling and Analysis

There are generally other sources of variations, which may invalidate the use of standard statistical analysis schemes in bioassays to a certain extent. Among these factors, special mention may be made of the following:

(a) *Censoring of various types*,
(b) *Differentiable / Nondifferentiable measurement errors*,
(c) *Stochastic compliance of dose*,
(d) *Correlated multivariate responses*, and
(e) *Curse of dimensionality in genomics*.

It is generally assumed that **censoring** is usually of *Type I* (truncation of the experiment at a prefixed timepoint), *Type II* (truncation following a certain prefixed number or proportion of responses), and *random*, where the censoring time and response time are assumed to be stochastically independent, and moreover, the censoring is assumed to be *noninformative*, so that the censoring time distribution remains the same for both the preparations. In actual practice, this may not be generally true, and hence, effects of departures from such assumptions on the validity and efficacy of standard statistical procedures are therefore needed to be assessed. Measurement of the actual dose levels in quantal assays, or the response levels in an indirect assay may often be impaired to a certain extent by measurement errors. In statistical analysis, usually such measurement errors are assumed to be either *differentiable* or *nondifferentiable* type, and appropriate statistical models and related analysis schemes depend on such assumptions. In radioimmunoassays, dosimetric studies in pharmacokinetics, as well as in other types, not the full amount of a prescribed dose may go into the organ or experimental unit, and the actual consumption of the dose may be (often, highly) stochastic in nature. Therefore, the dose–response regression relation may be subject to *nonidentifiability* (*see* **Identifiability**)and **overdispersion** effects. This calls for more modifications of existing models and analysis schemes. Finally, when there are **multiple endpoints** with possibly binary or **polytomous** responses, a dimension reduction for the model-based parameters becomes necessary from statistical modeling and inference perspectives. Otherwise, an enormously large sample size may be needed to handle adequately, the full parameter model, and this may run contrary to the practical setup of an assay. The situation is worse when some of the responses are quantitative while the others are quantal or at best polychotomous. These naturally introduce more model complexities and call for more complicated statistical analysis tools.

Biological Standardization

Biological products are distinguished from chemical products by the biological nature, singly or in combination, of the source materials, of the production and purification procedures, and of the test methods needed to characterize such products or determine their potency. Biological products differ from chemical products in that they are not adequately characterized solely by their physical and chemical properties. Two biologicals may give the same results in chemical and physical tests but may have different activities when compared in biological tests. Measurement of the amount or concentration of any biological product thus requires an *in vivo* or *in vitro* **biological assay** system and a standard preparation or reference material. A biological standard for a product is a preparation such that the properties of a given amount of it do not change over time, and with which the properties of other samples of the product can be compared. Standards are essential if measurements are to be comparable from one assay to another. The potencies of the standard are customarily defined in arbitrary "units".

The use of biological activity as the basis for analytical, or assay, techniques developed rapidly in the late nineteenth and early twentieth centuries, with the development of vaccines and the discovery of vitamins and hormones. It was quickly recognized that biological test systems were variable, and the principles of biological standardization and quantitative approaches to biological test systems were formulated [6, 7, 10]. Central to these principles were the importance of comparison with a standard and the need to determine the variation of the biological system [2].

In some early uses of biological assays, attempts were made to define units in terms of the amount of product required to produce a specified effect. There are instances in which this continues today with, for example, attempts to define the amount of an antiviral agent in terms of the amount that will protect 50% of a population of cells, and to calibrate botulinum toxin for therapeutic use in terms of "mouse" units. However, it is virtually impossible to standardize a biological system so that whenever and wherever it is used the relation between the amount of a product or material and its response remains constant, and use of a standard thus leads to improved reproducibility [2, 9].

Any biological standard must fulfill certain conditions. All samples of the standard material must be uniform, so that the amount of material required to produce the observed effect or response is known. International standards are thus prepared in ampoules in such a way that the contents of any one ampoule are as nearly as possible identical to the contents of any other. The standard must be representative of the substance for which it is to serve as a standard, but does not necessarily have to be of high purity. A representative batch of product may be selected for the in-house standard by a manufacturer. For an international standard, suitability is usually shown by extensive characterization in an international collaborative study. The standard must be stable so that its effects do not change over time. Because of the nature of biological standards, direct tests for stability – that is, tests in real time – are not possible; predictions of stability may be based on the effects of storage at elevated temperatures on samples of the standard coupled with assumptions about the predictive nature of these effects. The quantity of standard available must be sufficient for the purposes for which it is intended. The **World Health Organization** has published guidelines for the preparation of standards detailing the way in which these conditions may be met, and setting specific requirements for international standards [13].

Biological standards serve a variety of specific purposes. Any laboratory routinely carrying out biological assays will include an in-house standard in these assays, and may also include "quality control samples" that might also be considered to be standards (*see* **Quality Control in Laboratory Medicine**). Although such standards provide comparability between assays within a laboratory, they may differ markedly between laboratories, as has been shown when a common sample is measured by several laboratories in terms of their individual standards (see, for example, [11]). Biological standards may be used in the development and validation of assay systems; for example, failure of an assay system to respond in a dose-related way to the standard would automatically invalidate the system for that material [12]. Standards are an essential part of the various quality assessment schemes which are operated for some types of assay, often by national authorities. International standards are indispensable not only for

measurement of biological materials but also for the controls necessary for modern medicines [8].

The World Health Organization (WHO) plays an important role in developing consensus guidelines on regulatory issues, and the WHO Constitution requires that WHO establish standards to assure the safety and efficacy of products used for the diagnosis, therapy, and prophylaxis of disease. This is a continuation of the development of international standards begun by the League of Nations [3–5]. Various international unions or federations representing individual scientific disciplines have also established commissions on issues related to measurement within their discipline, and may produce standards or recommend standards to WHO. Veterinary biologicals are also subject to regulation [1].

The World Health Assembly recommends that member states of WHO give official recognition to the International Standards and International Units, and publishes a list of these and their custodians [14], which is periodically updated. The majority of International Standards are held and distributed by the National Institute for Biological Standards (Blanche Lane, South Mimms, Potters Bar, Hertfordshire EN6 3QG, UK). The responsibility for the assurance of the quality and potency of biological products lies with the manufacturer, as regulated by the regional or national control authority and detailed in the national pharmacopoeias. The contribution of biological standardization to this assurance is widely recognized, and International Biological Standards are accepted as the primary standards for **calibration** of biologicals.

Biometrical Journal

The *Biometrical Journal* is an international journal for mathematical and statistical methods used in biological sciences in the widest sense: in biology, medicine, psychology, agriculture, forestry, ecology, and others. It is primarily addressed to mathematicians and statisticians working in these fields and to biologists and physicians having extensive contact with biometrical methods.

The *Biometrical Journal* was originally published by the Akademie Verlag, Berlin, and is now published by Wiley. The journal was founded in 1959 by Ottokar Heinisch and Maria Pia Geppert as the German publication *Biometrische Zeitschrift*. In the editorial to the first issue, the founding editors outlined the purpose of biometry as rendering objectivity to empirical results found in the biosciences by mathematical and statistical methods. This characterization of biometry as a joint methodologic concept for the various biological branches of the natural sciences has been well established by the development since 1959. The scope of biometry has been broadened since that time, as is apparent from the emergence of many new biometric methods in medicine, for example. Also, the number of researchers working in biometry has increased enormously, and the store of available biometric theories and practical methods has been extended systematically. The *Biometrical Journal* has participated in this flourishing of the biometric sciences in the past few decades. Consequently, it grew from four issues with a total of 290 pages in its first year to eight issues with 1024 pages by 1996, and a new format was introduced in 2004.

From 1967 to 1969, the journal was edited by Maria Pia Geppert and Erna Weber, from 1970 to 1988, by Erna Weber, and from 1988 to 1995, by Heinz Ahrens and Klaus Bellmann. In 1996, Jürgen Läuter assumed the post of the editor-in-chief, followed by Peter Bauer in 2000 and Edgar Brunner and Martin Schumacher in 2004.

In 1977, the journal's name was changed to *Biometrical Journal*. This change marked the continuous transition from German to English as the primary publication language and much increased the journal's international recognition. The relation with Germany and especially with the German and Austro-Swiss Regions of the **International Biometric Society (IBS)** remained strong without dominating the journal, and the journal is now truly international, as is immediately clear from a look at recent issues. Today, almost all published papers are in English, and contributions in the secondary publication languages, French and German, are a rare exception.

Original papers form the core of the *Biometrical Journal*'s contents, with the aim of trying to provide a link between theory and practice. Papers presenting new mathematical or statistical methods of potential benefit to the biosciences as well as interesting and original applications of existing theory to bioscientific problems are welcome, as are reviews and letters to the editors.

Special emphasis is laid on biomedical applications ranging from quantitative analysis in basic research to **clinical trials** methodology including **drug regulatory** aspects, and to methodological developments for research synthesis, which is of particular importance for the transfer of research results into practice (*see* **Meta-analysis of Clinical Trials**). An active discussion forum has been established.

With the support of a board of internationally well-renowned associate editors, who are chosen specialists in their respective areas of research, a competent and fast evaluation of manuscripts submitted online is guaranteed. Also, some initiatives have been introduced since January 1, 2004 as a part of the editors' intention to accelerate the submission and review process. Thus, electronic submission and handling has been made mandatory for authors and members of the editorial board.

The journal has its own website in order to provide broad accessibility to its online version for the readers to enable them to gain immediate and faster reach. An advanced subject-specific search facility is provided on the website. Authors can use this extensive, full-text search facility on a wide range of journals published by Wiley in order to learn about recent developments in their areas of research and interests, which helps them in preparing their articles.

The website, `www.biometrical-journal.de` provides more details on submission procedures, contact information, templates for manuscripts, and other relevant information for authors and readers.

EDGAR BRUNNER & MARTIN SCHUMACHER

Biometrics

Biometrics, a journal of the **International Biometric Society** (IBS), is published quarterly. The main objectives of the journal, which are listed at the IBS web site `http://www.tibs.org/`, are to promote and extend the use of mathematical and statistical methods in the biological sciences by describing and exemplifying developments in these methods and their application in a form accessible to statistical practitioners, experimenters, and others concerned with the analysis of data. The journal is intended to provide a medium for exchange of ideas by subject-matter specialists, those involved primarily with analysis of data and those concerned with the development of statistical methodology. Published papers may deal with statistical methodology applied to specific biological contexts, topics in mathematical biology, and statistical principles and methodology that are generally applicable to common challenges in the analysis of biological data.

Papers in the journal are currently organized into two main sections. The Regular Communications section includes statistical, authoritative, or review articles; and papers outlining development of novel statistical methods for the planning of experiments or interpretation of data, including demonstrations of utility and performance. Except for papers having to do with **experimental design**, which of necessity cannot refer to data that have not yet been collected, a centerpiece of most Regular Communications articles is a motivating and important data set exemplifying the scientific challenges on which methods are focused. The Consultant's Forum section presents papers illustrating the application of existing methods to new areas where they have not been previously used and permit new biological insights, papers clarifying or contrasting existing methods, or papers providing new guidance or tools for new or common data-analytic challenges.

The journal began in 1945 as the *Biometric Bulletin* of the **American Statistical Association**, and the name was changed in 1947 with Volume 3 onwards being called *Biometrics*. The journal continued to be published by the American Statistical Association until Volume 6, which was published by the Biometrics Society (now the IBS). Initially, the journal had an editor for Regular Communications and a Queries and Notes editor. In 1960, a book review section and dedicated editor were added. *Biometrics* continued in this form until 1974, with the Queries and Notes section becoming the Shorter Communications and Queries section, which was renamed as Shorter Communications in 1976. The Consultant's Forum section was added in 1977 with a view to include papers with novel data sets and novel use of existing methods. Some submissions offer specific comments regarding papers appearing in the journal previously; these are published as Reader Reaction articles. Authors of published articles to which these papers react are offered an opportunity to respond, and the reaction paper and response are published together.

The founding editor of *Biometrics* was **Gertrude M. Cox** (1945–1955), and the founding editor of the Queries and Notes/Shorter Communications section was **George W. Snedecor** (1945–1958). Table 1 lists all editors of the journal through 2004.

By 1999, the volume of submissions had increased to the point where it was no longer feasible for a single editor to handle the Regular Communications section; moreover, the distinction between this section and Shorter Communications had become blurred. Accordingly, on the basis of recommendations of an IBS committee charged with reviewing editorial structure, Shorter Communications was merged with the Regular Communications section; Consultant's Forum was maintained; and the journal adopted a three-editor system, where three "coeditors" handle submissions to both Regular Communications and Consultant's Forum. In addition, a Central Editorial Office was established to coordinate the editorial process among the three coeditors, who may reside in geographically diverse locations. The Office and the able journal Editorial Assistant, Ms Ann Hanhart, are located in Dallas, Texas. The position of "coordinating editor" was also created; this coeditor is responsible, in addition to usual editorial duties, for all administrative tasks (e.g. answering queries, compiling statistics on times to review, monitoring backlog) and serves as the point of contact for the Editorial Assistant regarding administrative matters. Coeditors are appointed to three-year terms according to a staggered entry scheme in which one completes his/her term and is replaced each year.

In accordance with recent technological advances, in 1999 the journal began accepting submissions electronically, and, by 2002, greater than 97% of all

Table 1 Editors of *Biometrics*. From 1999 on, coeditors under the three-editor system are listed by term

Editor	Shorter communications editor	Book review editor
G.M. Cox (1945–1955)	G.W. Snedecor (1945–1958)	
J.W. Hopkins (1956–1957)		
R.A. Bradley (1957–1962)	D.J. Finney (1959–1961)	J.G. Skellam (1960–1963)
M.R. Sampford (1962–1966)	J.A. Nelder (1962–1966)	W.T. Federer(1964–1972)
H.A. David (1966–1971)	P. Sprent (1967–1971)	
F.A. Graybill (1971–1975)	C.D. Kemp (1972–1975)	F.N. David (1972–1977)
F.B. Cady (1975–1979)	J.S. Williams (1976–1979)	R.M. Cormack (1978–1984)
P. Armitage (1979–1984)	J.J. Gart (1980–1984)	
D.L. Solomon (1984–1989)	R. Thompson (1984–1988)	C.D. & A.W. Kemp (1984–1999)
K. Hinkelmann (1989–1993)	N. Keiding (1989–1992)	
C.A. McGilchrist (1993–1997)	B.J.T. Morgan (1992–1996)	
R.J. Carroll (1997–2000)	L. Ryan (1996–1999)	Martin Ridout (2000–2002)
T. Pettitt (1999–2001)		
M. Davidian (2000–2002)		
D. Commenges (2000–2003)		
B. Cullis (2002–2004)		
X. Lin (2003–2005)		Iris Pigeot–Kuebler (2003–)
M. Kenward (2004–2006)		

submissions were electronic; virtually all are today. Moreover, starting with the January 2003 issue, *Biometrics* is available in electronic as well as print form to IBS members and authorized subscribers. In 2001, all issues of *Biometrics* from inception to a five-year lag from the current year were made available on the journal archival web resource JSTOR (`http://www.jstor.org`).

From modest beginnings, *Biometrics* has become a highly regarded international journal, whose papers are among the most referenced in biostatistical research. In 2001, the journal received 452 submissions, a number that continues to increase, and published 157 papers in all sections of the journal together with 66 book reviews and 17 brief book reports.

In 2003, there were approximately 90 associate editors of *Biometrics* drawn from all over the world, reflecting not only the truly international character of IBS but also the diverse range of areas of application and methodological development of published papers. The size and breadth of expertise represented on the editorial board frequently allows submissions to be handled by an associate editor whose interests are closely aligned with those of authors, which facilitates times to review that are among the swiftest in the statistical profession. In 2002, the median time to review for initial submissions was less than 10 weeks, with 98% of all first submissions receiving a review within 6 months.

The type of paper published in *Biometrics* has varied somewhat over the years while staying consistent with the aims of the journal. This variation has reflected the development of different areas of application. In early issues, biometry in agricultural research was the dominant theme. The journal continues to publish papers in this area related to both traditional design and analysis as well as newer topics such as the analysis of spatial data (*see* **Geographic Epidemiology**; **Spatial Models for Categorical Data**). The journal is also a forum for papers in ecology and wildlife statistics. In recent years, papers targeting applications in biomedical research have made up a large proportion of submissions and published papers. Environmental research applications (*see* **Environmental Epidemiology**) and research in genetics (*see* **Genetic Epidemiology**) are also reflected. Important, emerging new areas, such as molecular genetics (*see* **Molecular Epidemiology**; **Bioinformatics**), and medical imaging (*see* **Image Analysis and Tomography**), are frequently covered in the journal. Having methods developed in such a diversity of application areas published in the same journal promotes cross-fertilization of ideas. The journal properly reflects current interests of members of the IBS and at the same time, remains true to the emphasis on practical application as envisaged by its founders.

M. DAVIDIAN & C.A. MCGILCHRIST

Biometrika

Biometrika was founded by **Karl Pearson** and W.F.R. Weldon in consultation with **Francis Galton**. The first issue appeared in October 1901. From 1906 Pearson assumed entire editorial responsibility, until he was succeeded by his son, **E.S. Pearson**, in 1936. D.R. Cox took over in 1966 and acted until 1991. Since then D.V. Hinkley (1991–1992), A.P. Dawid (1992–1996), and D.M. Titterington (1996–) have edited the Journal. The Publication Editor, Ms. B.J. Sowan, has been involved with the Journal since 1971.

The Journal's origin was due in part to the Royal Society's request that, in papers submitted for publication, mathematics be kept apart from biological applications. The early volumes contained many diagrams, photographs, and tables of measurements of parts of the human body, animals, and plants. So far as the founding editors were concerned, they envisaged the Journal as an organ of "a spearhead of enthusiastic workers ... to lead a fight for the recognition of the place of mathematics in the biological field" [1], and this objective dominated the early decades of the Journal. There was a major change of emphasis when E.S. Pearson succeeded K. Pearson as Editor, reflecting the former's strong interest in and involvement with current theoretical and applied interests of the time. Since then the broad character of the Journal has gradually evolved in line with the increasing specialization of the field. Biological applications no longer receive special emphasis, although inevitably a substantial proportion of papers do involve directly or indirectly biomedical applications. Indeed, in his announcement of the changeover in editorship from E.S. Pearson to D.R. Cox, Tippett [2] noted that *Biometrika* "is now a general statistics journal which retains, however, a bias towards papers with a practical application and which are thus connected with the usefulness of statistics in some particular field, biometric or otherwise." With almost no change in this basic philosophy, Biometrika has evolved into a leading international journal for theory and methods across a wide spectrum of statistical topics, although certain specialisms are given emphasis from time to time, according to their current importance in statistical research. The Journal's centenary in 2001 was marked by the publication by a series of special articles that reflected on the contribution of Biometrika papers to the development of statistical science during the twentieth Century. These papers were reprinted in book form [3], together with a selection of particularly seminal articles from past volumes.

The number of papers published over the years is indicated in Table 1. There were in general two issues per year up to 1967, then three per year up to 1986 and four per year thereafter. The years of World Wars I and II, however, led to deviations from the general pattern.

Biometrika currently contains about 75–90 papers per year, in a volume of about 950 pages annually. The Journal is published by the Biometrika Trust, and the four parts of each volume appear in March, June, September, and December. The circulation is about 2300. Subscribers can now obtain online access and there is further rapidly increasing electronic usage of the journal, through institutional subscriptions.

Table 1 Variation in the size of *Biometrika* and the length of papers published, 1905–2003

Year	Pages	Issues	Papers		Main paper (ave. length)
			Main	Miscellanea	
1905	384	2	13	3	28
1920	132	1	7	0	19
1935	471	2	18	6	25
1945	85	1	8	4	9
1950	454	2	41	15	10
1965	675	2	45	30	13
1980	728	3	67	44	8
1995	892	4	55	23	14
2003	994	4	63	18	14

From 1997 the distribution, but not the publication, has been handled by Oxford University Press, who also look after the Journal's webpage, at `http://www.biomet.oupjournals.org`.

In general the Journal aims to publish new statistical theory and methodology that are capable of application in practical problems. As a comparison, the ***Journal of the Royal Statistical Society, Series B*** and the Theory and Methods Section of the ***Journal of the American Statistical Association*** contain material very similar to that in *Biometrika*. Papers that are essentially of mathematical interest only or that are applications of existing theory and methods are excluded; more explicit stress on biological applications is typically laid by and **Biometrics** and Biostatistics. A few review papers have been published, as well as a series on the history of probability and statistics (*see* **Biostatistics, History of**). There is a Miscellanea section for shorter articles. For some years now the submission rate has been at the level of close to 400 papers per year, so that the acceptance rate is about 20%. Nowadays electronic submission of papers, by email to the Editor, is the norm. There are about 15 Associate Editors, who advise the Editor over the bulk of the papers, although the Editor deals directly with some. All correspondence is channeled through the office of the Editor, and referees and Associate Editors act anonymously. The Publication Editor deals with the process of taking scientifically acceptable papers to their appearance on the printed page.

The Editor aims to minimize the time authors have to wait for feedback about their material, and publication takes 5–10 months from the date of final submission of an acceptable typescript.

Biostatistics, History of

From the seventeenth century to the present day, basic biologic phenomena (most notably mortality and morbidity) have been a central concern of those who collected and analyzed statistical data. For this reason, **John Graunt's** pioneering 1662 work *Observations upon the Bills of Mortality* sounds notes that are very similar in kind to biostatistical reports issued today – even though present-day statistical works make use of more sophisticated mathematical methods than their predecessors in earlier centuries. Consequently, the history of biostatistics can best be understood in terms of methodologic developments within statistical thinking. For analytical purposes, these methodologic developments can be divided into four phases: (i) the work of nineteenth-century statisticians who pioneered the concept that social patterns (including incidence of disease) could be shown to have "lawlike" characteristics [13, 15]; (ii) the mathematical work of **Karl Pearson** and his biometric associates at University College London in the early twentieth century; (iii) the interwar years when the methods of **hypothesis testing** (associated initially with the agricultural research of **R.A. Fisher**) were extended into the field of biomedicine; and (iv) the postwar rise of epidemiologic studies focusing on such celebrated discoveries as the association between cigarette smoking and lung cancer (*see* **Smoking and Health**) and the **Framingham study** of heart disease. Each of these four phases will be discussed in turn.

Nineteenth-Century Developments

As its name implies, statistics developed as a science concerned with information important to the state. With the rise of industrialization and democratic reforms in the early nineteenth century, Western governments became overwhelmed with what Hacking [7] has called an "avalanche of printed numbers" about their citizens, thereby leading writers to associate the term "statistics" specifically with information expressed in numeric form. One of the earliest examples from a biomedic context was **Bisset Hawkins'** [8] 1829 work *Elements of Medical Statistics*, which was concerned with "the application of numbers to illustrate the natural history of man in health and disease".

Throughout the course of the nineteenth century this numeric conception of statistics became institutionalized through the founding of statistical societies and the holding of international statistical conferences. In the English-speaking world, two of the most prominent societies were Section F of the British Association for the Advancement of Science (founded in 1833) and the Statistical Society of London (founded in 1834 (*see* **Royal Statistical Society**)). In both of these societies (and in many of the international conferences) one of the leading figures was the Belgian astronomer turned social statistician **Adolphe Quetelet** who helped to pioneer the concept that society had distinctly lawlike characteristics which could be revealed through the amassing of statistical evidence.

Most of the members of these statistical societies were not trained in the physical sciences like Quetelet; rather, they often came from the medical profession. As Lécuyer [10] has argued, several factors may account for the high proportion of physicians within these societies, namely the emergence of public health as a goal through the method of improved hygiene, the medical tradition of local investigation to improve the conditions of the poor, and the physicians' obvious professional association with the phenomena of death and sickness. All of these concerns lent themselves naturally to the amassing of numeric evidence.

In this period, two of the most prominent physicians to study public health problems statistically were the French physician, Louis René Villermé (1782–1863), and the English physician, **William Farr** (1807–1883). As William Coleman [4] has shown, Villermé corresponded with Quetelet as a result of their shared interest in describing society in numeric terms. In 1828, Villermé published a memoir positing a relationship between mortality and economic status, thereby firmly establishing his reputation as an advocate for a statistically based approach to public health problems. Similar concerns informed the work of William Farr who studied medicine in Paris under **P.-C.-A. Louis**, the advocate of the "numerical method". In 1839, Farr was appointed compiler of abstracts to the newly established General Register Office which had been founded to record all births and deaths within Great Britain. During Farr's long 41-year tenure at that institution, he made considerable contributions to the field of **vital statistics**

and developed multiple disease and occupational taxonomies to be used in the collecting of statistical evidence (*see* **Health Statistics, History of**).

The statistical record-keeping of individuals like Farr and his associates at the General Register Office proved to be indispensable for one of the major epidemiologic discoveries of the mid-nineteenth century, namely John Snow's [14] demonstration that cholera was a water-borne disease. After an outbreak of cholera near the Broad Street pump in London in 1854, Snow used data collected by the General Register Office to determine that there had been 83 deaths attributed to the disease during a three-day period. On closer examination Snow determined that in all but 10 of these cases the individuals had lived in households that were closer to the Broad Street pump than any other water source. Furthermore, in five of the households that could get water elsewhere, Snow interviewed the family members and discovered that they did indeed use the water from the Broad Street pump. Of the remaining five cases, three were children who probably also drank water emanating from this source since they attended a nearby school; the remaining two cases were dismissed by Snow as representing "only the amount of mortality from cholera that was occurring before the irruption took place". Although Snow's idea regarding the water-borne nature of cholera received little support during his lifetime (with the notable exception of William Farr), his paper has subsequently attained classic status as one of the most important epidemiologic discoveries prior to the discovery of the germ theory of disease.

The Biometrical School and the Mathematization of Statistics

Throughout the nineteenth century, statisticians conceived of their work as largely descriptive in nature with comparatively little emphasis placed on mathematical reasoning. This orientation was fundamentally changed by the creation of the biometrical school at University College London under the direction of the applied mathematician Karl Pearson (1857–1936). Pearson developed this school with the blessing (and financial backing) of the scientist **Francis Galton**, an English scientist who espoused the view that heredity played a decisive role in individual development. Thus, the primary *raison d'être* of Pearson's research was to provide scientific warrant to Galton's views through statistical analysis. Although Pearson clearly shared the views of his main financial backer, he also developed a full-blown philosophy of statistical reasoning arguing that, since all **inference** is based on the association of antecedents and consequents, all scientific reasoning is at its core fundamentally statistical. As a result, Pearson argued for the extension of statistical methods into potentially all domains of scientific endeavor, actively engaged in debates with other researchers over the proper interpretation of statistical data, and trained students in the biometric techniques that he pioneered.

In the field of biostatistics specifically, Pearson is remembered for engaging in a dispute with Almoth Wright (1861–1947) over the meaning of the statistics Wright had collected to demonstrate that antityphoid inoculation reduced the chance of infection for soldiers in the British Army. In critiquing Wright's conclusions, Pearson made use of one of the statistical constructs for which he is remembered today, namely the **correlation** coefficient, which was designed to measure the degree of association between two phenomena. Specifically, Pearson [12] found that the average correlation between immunity and inoculation was about 0.23, with individual results as high as 0.445 and as low as 0.021 (a one-to-one positive association would have generated a value of 1 and no relationship would have generated a value of 0). Since this was a very low correlation coefficient relative to other common therapeutic interventions (the protective character of vaccination at preventing mortality from smallpox was found to have a correlation coefficient of approximately 0.6), Pearson argued against the introduction of antityphoid inoculation as a standard practice. Although Pearson's criticisms did not convince the leaders of the British Army, who continued to test and use Wright's inoculation procedure, the episode is illustrative of Pearson's desire to show the applicability of his biometric techniques in the biomedical arena.

In addition to his theoretical innovations, Pearson was also important for training the physician **Major Greenwood** (1880–1949) in biometric methods; Greenwood launched his career by criticizing Wright's use of the so-called "opsonic index" for diagnostic purposes. Wright believed that there was a substance in blood serum (opsonin) which prepared bacteria to be ingested by the white blood corpuscles. Wright was able to measure the amount of

opsonin that was present in the blood by comparing the average number of microbes per leucocyte in a blood sample from a normal individual with the average number of microbes per leucocyte from an individual suspected of having a bacterial infection; subsequently, Wright computed the ratio of these two mean values which he called the "opsonic index". In general, Wright believed that if the opsonic index were higher than 1.2 or lower than 0.8, then this would indicate bacterial infection. In his critique of Wright, Greenwood [6] plotted the **frequency distribution** of the number of microbes per leucocyte and found the distribution to be markedly asymmetric or skew. Thus, Greenwood advocated that the **mode**, or most frequently occurring value, would be a better constant with which to measure the opsonic index than the mean. Although Greenwood did not convince Wright, his work did succeed in impressing Charles James Martin who was then director of the Lister Institute of Preventive Medicine; late in 1909 Martin offered Greenwood a position as medical statistician at the Lister Institute thereby helping to legitimate the use of biometric techniques in the analysis of medical statistical results.

Greenwood was not the only individual to draw on Pearsonian methods to study biomedical phenomena; another prominent follower was **John Brownlee**. Brownlee [3] utilized Pearson's insight that the Gauss–Laplace or **normal distribution** curve was, in fact, just a particular case of an entire family of frequency distribution systems. By attempting to fit Pearson's various frequency distributions to medical statistics of disease incidence during an epidemic, Brownlee hoped to classify epidemics according to the type of frequency distributions they approximated; he often found that the type of distribution produced was nearly symmetric (*see* **Epidemic Curve**).

The Interwar Years and the Birth of Experimental Epidemiology

On both sides of the Atlantic the interwar years saw an attempt to forge a new and experimental approach to epidemiology. Rather than continuing to rely solely on vital statistics of human populations, systematic attempts were made to study the rise and fall of epidemic diseases within populations of laboratory animals – most notably mice. In the UK, this work was based at the **Medical Research Council** and consisted of a collaborative endeavor between the bacteriologist W.W.C. Topley and Major Greenwood; Greenwood had become head of the statistical research unit of the Medical Research Council in 1927. In the US, the principal investigator was L.T. Webster and his associates at the Rockefeller Institute. In both countries, researchers focused on mouse typhoid in an attempt to understand the relative importance of environment, host, and agent factors in disease occurrence.

In addition to these experiments on populations of laboratory animals, the interwar years also saw important theoretic developments in the methods of statistical **inference** as pioneered initially by Ronald A. Fisher. Whereas Pearson and the early biometricians had been associated primarily with classifying **observational** data, Fisher was more directly concerned with **experimental** data and **hypothesis testing**. Fisher developed his statistical ideas after being appointed to the Rothamsted Experimental Station where he studied the differing productivity of various types of grain in agricultural field experiments. Drawing on these scientific findings, Fisher published a series of books on statistical methodology. In his 1935 work *The Design of Experiments* [5], he outlined the key importance of **randomization** in assigning different grain types to various tracts of land in order to remove subjective experimenter **bias**.

Fisher's focus on randomization proved to have profound implications for research medicine – especially for the development of the modern **clinical trial** (*see* **Clinical Trials, History of**). When faced with a shortage of the drug streptomycin during World War II, **Austin Bradford Hill** (who had succeeded Greenwood as head of the statistical division of the Medical Research Council) chose to design a rigorous clinical trial of the effect of this drug on bilateral pulmonary tuberculosis. Bradford Hill used random numbers to determine which patients received the experimental drug and which patients were to be controls. Although the trial contained a relatively small number of patients (107 overall with 55 allocated to the streptomycin group and the remaining 52 allocated to the control group), Hill's attention to methodologic detail meant that the results were decisive: 7% of the streptomycin patients died and 27% in the control group died. As Hill and his associates [11] observed in the 1948 report on the trial, "The difference between the two series is

statistically significant; the probability of it occurring by chance is less than one in a hundred" (*see* **Medical Research Council Streptomycin Trial**). Hill's streptomycin trial has often been seen as the standard against which all subsequent clinical trials have been judged.

The Rise of Postwar Epidemiology

Even though the study of epidemiology (or disease within populations) has a long history, the postwar era is significant in at least two respects: the use of more sophisticated statistical techniques in analyzing the etiology of disease; and the increasing shift in focus from infectious to chronic conditions. Although these twin facets of postwar epidemiology are distinguishable for analytical purposes, they actually were historically interwoven. With the transition from infectious to chronic disease as the principal reason for mortality and morbidity, research became centered less on the search for a specific agent (or germ) and more on the analysis of (multiple) environmental factors. Since multiple factors presented the problem of **confounding** causal relationships (*see* **Causation**), epidemiologists increasingly turned to the statistically trained who had dealt with similar issues in the context of social surveys. Of the many epidemiologic claims established through these methods, the two most famous examples were the researches establishing a link between cigarette smoking and lung cancer and the study of cardiovascular disease.

As discussed in Brandt [2], epidemiologic studies began to appear in the late 1940s and early 1950s indicating that cigarette smokers were at a higher risk of lung cancer than nonsmokers. Most of these studies were **retrospective** in nature – meaning that individuals who had already developed lung cancer were interviewed about their smoking habits after the fact; their responses were then compared with a control group of individuals who did not smoke (*see* **Case–Control Study**). However, two pioneering prospective studies were also launched at this time (*see* **Cohort Study**). In 1951, Richard Doll and Bradford Hill sent questionnaires to all British physicians inquiring about their smoking habits. When individuals who responded to their survey died, Doll and Hill obtained data about their cause of death. At about the same time, a similar study was being conducted in the US by E. Cuyler Hammond with the support of the American Cancer Society. Both studies implied conclusions consistent with retrospective studies: cigarette smoking increased one's risk of contracting cancer.

In the US, the most famous postwar epidemiologic investigation has been the Framingham Study, which was initiated in October 1947. As Susser [16] has argued, the Framingham Study has often been cited as the paradigmatic example of a prospective or "cohort study" which follows a specific group (or cohort) of individuals over their life courses to see what factors influence disease development. As its name implies, the researchers selected their study population from the residents of the town of Framingham, Massachusetts. By examining a sample of 30- to 59-year-old persons biennially, the researchers were able to test the role of such factors as cholesterol level, physical activity, diet, and life stress on the development of heart disease. In addition to specific empirical findings, the Framingham Study also generated important methodologic insights of how to deal with the variability of repeated measurements over time (*see* **Longitudinal Data Analysis, Overview**); however, the researchers could not solve the problem of when to terminate the study. As a result, more recent findings have centered on diseases related to aging (e.g. stroke) and follow-up studies of the offspring of the original participants.

Since the 1960s, several factors gave increasing prominence to statistically based ways of studying biomedic phenomena. After the Thalidomide scandal raised the specter of infant deformity, the clinical trial became a standard requirement before experimental drugs could be administered to the general public. In 1965, the *American Journal of Hygiene* changed its name to the *American Journal of Epidemiology* [1] reflecting the "greatly increased importance" of the "epidemiologic approach to disease". Finally, the discipline of epidemiology was put on a secure conceptual foundation by researchers on both sides of the Atlantic who articulated causality criteria for epidemiologic studies; these criteria were designed to serve as the chronic disease analog to Robert Koch's famous postulates for establishing causality for infectious disease. In the US, the most famous list of epidemiologic causality criteria was published as part of the Surgeon-General's 1964 [17] report positing a link between cigarette smoking and lung cancer; in the UK, the most famous list of causality

criteria was published by Austin Bradford Hill [9] early in 1965 (*see* **Hill's Criteria for Causality**).

J. ROSSER MATTHEWS

Biostatistics, Overview

This article presents a personal view of the general field of biostatistics. I describe the overall sense of the field, a few of its roots and principal originators over the past century and more, some of the methods used in biostatistics and types of problems that yield to a biostatistical approach (using as illustrations areas where biostatistics has had noteworthy impact). I also discuss the discipline in general as it exists today and mention some of the more important problem areas in biomedicine where biostatistics is now challenged to provide new methodology. Finally, I describe the profession of biostatistics in terms of its history, the present composition of professionals, its societies and journals, its entry points for new professionals and the current areas of activity of professionals in the field.

Biostatistical Roots, Development, and Examples of the Discipline

It is difficult to trace the roots of a field that has come, only recently, in the early part of this century, to be recognized as a distinct discipline. This difficulty is especially marked if the field is of hybrid character. Biostatistics focuses on the development and use of statistical methods to solve problems and to answer questions that arise in human biology and medicine. Thus it expands statistical theory and adapts it to bring specific methods to bear on questions of importance to the community of scientists, practitioners, and policy makers who have interest in health and in all health aspects of the human community. A few examples best illustrate the roots and development of the discipline.

There has always been interest in the general length of human life and its numerical description. Consideration of human longevity (*see* **Life Expectancy**) quickly prompts careful distinctions between, for example, recorded lengths of usual life (barring "early" death) and expected or average length of life, i.e. age at death, among all persons born in a given epoch and circumstance. Sometimes the interest can become sufficiently intense to prompt careful numerical thought, e.g. when insurance premiums are exacted on condition of further life length, or a plague has afflicted a nation. The biblical three score and ten and rough estimates of variation may not be sufficiently precise or specific to the need. Roman documents contain tables of the expected length of life for persons of various ages, for actuarial use in fixing prices of insurance (*see* **Actuarial Methods**). A millennium later, various Western European countries began to collect information systematically on births and deaths (*see* **Vital Statistics, Overview**). Curiosity prompted some individuals to examine this information and to note interesting characteristics of the collective information and striking regularities in what seemed on the surface as simply random events. **John Graunt's** [11] analysis of the Bills of Mortality, lists of dates of burials, births, and marriages, is an oft-cited landmark in the beginnings of such work, along with the work of **Quetelet**, Huygens, **Halley** and others. Their work led to the development of calculations of birth rates and death rates for various ages and to **life tables** that yielded calculation of the expected lengths of life for populations in well-defined geographic areas and subgroups of these populations, based on increasingly reliable and detailed counts of births and deaths. This early work produced useful information for use in detecting sources of unusual and preventable causes of death, due, for example, to contamination of water supply and sanitation systems.

These statistical methods for the collection and analysis of birth and death data led to many other uses of such data in government and in social sciences, for example in forecasting population size (*see* **Population Growth Models**) and economic conditions of populations and population subgroups. The mathematical and statistical methods of data collection, description, and **forecasting**, with the attendant concern for statistical precision, remain in many fields of application a major area for research by biostatisticians in government, universities, insurance firms, pharmaceutical firms, medical centers, and independent research centers.

Another root of biostatistics as a discipline stemmed from interest in the obvious resemblance of offspring to their parents. The work of Mendel with his pea plants (*see* **Mendel's Laws**), in the mid nineteenth century, is a critical and familiar landmark for all of us, in the beginnings of the use of systematically collected data, scientific speculation, and the application of numerical methods to the description of regularities in heritability amidst striking variation. Mendel's work focused on plants, but rediscovery of his work at the turn of the century

quickly drew the attention of statisticians as well as biologists and scientists to gain an understanding of the variation in human heritability (*see* **Human Genetics, Overview**). **Francis Galton** and **Karl Pearson** were two of the major figures in this area of science at the turn of the century. They were foremost contributors to the development of new concepts and statistical methods for describing and drawing inferences from data on the resemblance of parents to offspring. They were interested in resemblances in physical, psychological, and behavioral features of offspring to their parents. They developed concepts and statistical theory still basic to understanding this form of data. Central among these contributions were the concepts of **correlations** among variables and **regression** methods for predicting the characteristics of offspring from those of their parents. These concepts continue to be basic in the study of such relationships among variables in general. The concepts and methods continue to find new application in old areas of scientific research and in the newest areas of science, and are central in much of the work of biostatisticians today.

A still more recent, but most important area of biostatistical activity stems again first from agriculture, where **R.A. Fisher**, at Rothamsted Agricultural Station, in the 1920s, worked with agricultural scientists on their experimental studies. Even the most fastidiously controlled experiments involving animals (or plants) manifest responses that vary widely from one experimental animal to the next. Fisher proposed the method of randomizing the animals to the several treatments under study in the experiment, using specified probabilities of assignments (*see* **Randomization**). Of course, this would tend to balance treatment groups in terms of the characteristics, known or unknown, that cannot be controlled precisely. At the same time, through the probabilities used in the random assignments, a firm experimental basis in probability theory is provided for measuring the reliability of **inferences** drawn in comparing the effects of the treatments under study. The concept became firmly imbedded in experimental agriculture. A decade and more later, the method was introduced into experimental science in biomedicine, where the same problem of experimental control is encountered in laboratories and in experiments with patients. Where the experimental unit is the test tube, unwanted variation from tube to tube may be small and tolerable, though this is not always the case. Variation from animal to animal may not. Variation from one patient to the next, treated with the same experimental maneuver, even with the greatest care in patient selection and treatment, is rarely negligible (*see* **Experimental Design**).

Randomization of treatments to patients as a means of securing a controlled comparison of treatments, with statistical evaluation of the results came gradually into use (*see* **Clinical Trials, Overview**), beginning in the 1930s, following a few years after Fisher's introduction of the idea in the 1920s for use in studies in agricultural science. **Bradford Hill** [12] was among the foremost leaders in advocating the method for general use in clinical science. Randomization is now a hallmark of reliable experimental method in evaluating new and experimental medical treatments and in other medical maneuvers for prevention, for therapy, and for study of medical policies in general. Biostatisticians continue to work on the development and adaptation of these ideas for special applications in medicine, working to develop new experimental designs for the collection and use of clinical trial data for valid inference, and at the same time deriving safeguards that assure validity of the inferences and protection of the safety of the patients in these experiments (*see* **Ethics of Randomized Trials**). This is an area of intense development for theory, and for use in current clinical research and in much of medical research ranging from laboratory experiments to community interventions of public health maintenance. Meinert [17] and Pocock [21] provide some interesting notes on early clinical trials and broad discussion of statistical aspects of the organization, design, implementation, and analysis of the results of randomized clinical trials. Many books have been published over the last several decades on these topics.

Another area where biostatistics has been key to the advancement of a scientific area of inquiry, bringing statistical concepts, principles, and methods to bear on a specific question, is the indirect measurement of the strengths of compounds by administration of the compound to living organisms. Vitamins and hormones provide specific examples of the general problem. If a vitamin can be produced, for example, as an extract of some natural product, but the chemical composition of the ingredient(s) is unknown, then the resulting efficacy might be ascertainable by testing in animals. For example, many early vitamins were produced in this way and the strength of the

product was measured by the rate of growth among animals fed the product. It then remains to develop a systematic experimental method to measure the strength of a given "batch" of the material, so that uniform batches can be produced for research and clinical use. Otherwise, doses cannot be defined and efficacy and safety cannot be controlled. Variation from animal to animal, even in the closest of controlled experiments, makes the problem of measuring strength in this way problematic. Here biostatisticians [2, 7, 8] were able to bring statistical concepts and methods to the problem, developing definitions of strength and designing experiments and methods of statistical analysis to estimate the strength of a compound with a measure of the reliability of the estimate. The methods allowed calculation of the sizes of studies necessary for reliable use in the manufacture of various vitamins, hormones, and other pharmaceuticals that would allow comparisons of strength of compounds across manufacturers and time. These methods of bioassay (*see* **Biological Assay, Overview**) are essential, and in current use whenever the strength of the target compound cannot easily and specifically be characterized and measured by standard chemical or physical instrumentation. The methods have been adopted in many other areas where analogous questions have arisen, e.g. in measuring the strengths of toxic substances in the environment (*see* **Risk Assessment for Environmental Chemicals**), and in psychophysics (where, indeed, some of the basic concepts and methods had parallel early development). The methods have been adapted for use in psychological and educational testing theory (*see* **Psychometrics, Overview**) [14], where it is important to have tests of measurable performance and precision across time and across varied populations of subjects to be tested.

Nature of the Discipline

As is clear from the above examples, biostatistics is problem oriented. It is specifically directed to questions that arise in biomedical science. The methods of biostatistics are the methods of statistics (*see* **Statistics, Overview**) – concepts directed at variation in observations and methods for extracting information from observations in the face of variation from various sources, but notably from variation in the responses of living organisms and particularly human beings under study. Biostatistical activity spans a broad range of scientific inquiry, from the basic structure and functions of human beings, through the interactions of human beings with their environment, including problems of environmental toxicities and sanitation, health enhancement and education, disease prevention (*see* **Preventive Medicine**) and therapy, the organization of health care systems (*see* **Health Services Organization in the US**) and **health care financing**.

The details, depth, and breadth of modern biomedical and social science and the span of knowledge of mathematical, statistical, and calculational theory compel team approaches to the solution of modern scientific problems. Biostatisticians are members of many of these teams. The role of the biostatistician requires a special combination of tastes: a taste for quantitative methods, an understanding of and tolerance for variation in the data of scientific investigation, enjoyment in communication and in collaborative work with applied scientists, and a knowledge of statistical theory and methods.

The concepts and principles of mathematical statistics are the methods for describing regularity in the presence of variation, methods for prediction in the face of uncertainty, and methods for efficient study and experimentation when the results for the individual case or observation are uncertain. The biostatistician brings the characteristics of scientific curiosity to the specific question, a collegial bent, pleasure in dealing with scientific problems and an ability to communicate with the applied scientist, along with the skills and background in statistics necessary to invent, develop, or recognize special statistical methods that can aid in the solution and a knack for implementation of the new method to the problem.

As an illustration of this role of biostatistics in biomedical science I have cited above four areas where biostatistics has played a major, even a critical developmental role: life tables as a tool for adapting probability theory and statistical inference to the generation and use of birth and death data, as a method for measuring and comparing the health status (*see* **Health Status Instruments, Measurement Properties of**) of populations and for identifying health factors affecting populations and subgroups of populations (*see* **Analytic Epidemiology**); **correlation** and **regression** as measures of the strength of heritability, tools that have now been extended

throughout science to the study of cause and effect (*see* **Causation**); the clinical trial as a method for valid assessment of the efficacy of medical treatments of patients, again a tool that now plays a pervasive role in all of clinical science and beyond; and bioassay as an indirect method for precise measurement of the strength of biologically active compounds, such as hormones and vitamins.

There are many more areas where biostatistics has contributed greatly to the development of an area of scientific investigation, to the point where the special methods developed have become a large and essential part of the scientific armamentarium of the investigators in a specific scientific area and in the training of new investigators in that field. Genetics (*see* **Genetic Epidemiology**) is a special discipline in itself. **Demography**, actuarial science, and experimental methods in clinical trials, as well as bioassay are others.

One area of special importance is the area of design of randomized clinical trials. Much of the current interest in the comparison of medical therapies involves large numbers of patients, randomized to two or more treatments. These treatment groups or cohorts are followed for extended lengths of time to compare survival rates (or some other outcome such as disease recurrence) (*see* **Survival Analysis, Overview**). At the end of a prescribed length of study time the data present a length of time for each patient, the time to the event of interest, say death, or successful survival to the end of the study. The study data then present the statistical problem of summarization, comparison of the survival experience for each group, and inference regarding the meaning of the results. Such data appear much like those gathered centuries ago in John Graunt's Bills of Mortality [11] and first formed into life tables by Halley and others, as described previously. These early methods have been adapted and elaborated in detail for the design and analysis of clinical trials within the last half century. This body of statistical theory and practical methodology forms the basis for much of the statistical planning and analysis in both clinical therapeutics and prevention (*see* **Prevention Trials**) today.

Another area standing as a discipline in itself, but where biostatistics continues to play a central role, is epidemiology, the study of epidemics and the causes of infectious diseases (*see* **Communicable Diseases**), and more recently, the study of the causes and control of chronic diseases, such as cancers and heart disease [13]. The field of epidemiology has grown rapidly and investigators now focus and specialize on such diverse areas as injuries and deaths as a result of accidents – due to automobiles and traffic in general, sports, accidents in the home, and in special occupational activities. Environmental risk factors and their consequences is another area of study of great importance and interest to epidemiologists. We are all familiar with the public health importance of risk factors associated with life styles and behavior modes, e.g. in diet, exercise, sexual, and drug behaviors. These sources of health risk, and more, attract the epidemiologist. They present challenges to develop new methodologies that will allow efficient and valid inferences in identifying risks, estimating the magnitudes of the risks to the population, identifying subgroups of the population who are at extreme risk, and providing useful information to avoid such risks. The challenges are especially sharp and often subtle because randomized experiments are rarely possible. Instead, innovations in study design in the gathering of observations that will assure unbiased inference within reasonable limits of cost and time become all-important [13, 24] (*see* **Observational Study**).

Psychometrics [26] is yet another area, stemming, in part, from several strong biostatistical roots, and reaching back more than a century. One root goes back to the German psychophysicists who puzzled about the measurement of the relationship between physical stimuli, such as light rays and sound waves, and the reactions reported by human subjects. These scientists developed methods for describing the strength of the stimulus and the response of the subject. Their experimental approaches and the statistical methods they developed to describe their results yielded some of the concepts and techniques for bioassay as described earlier. Another root goes back to the work of Galton in the description of "correlations" (a word coined by Galton and Pearson in reference to this work) between human behavior of parent and child. These roots have led to much fundamental work in the broad field of psychology and to the development of the subfield called psychometrics, which concentrates on the use of statistical methods in research in human behavior, and the use of statistical techniques in areas such as educational testing.

Today there is much interest in the applications of psychology to the behavior of populations

and techniques for changing behavior toward more healthful life styles, e.g. with regard to drug and eating habits, exercise, sexual practices, systematic resort to **screening** for early detection of diseases such as breast cancer and prostate cancer, vaccinations (*see* **Vaccine Studies**) for disease prevention, and early maternal care in pregnancy. The techniques used in research in this area of behavioral medicine derive from many areas of biostatistics, particularly sample survey methods and clinical trial methods, as well as related fields that are heavily biostatistical, such as demography, vital statistics, epidemiology, and psychometrics.

Another area of renewed scientific research and application that draws heavily on biostatisticians and the use and development of new biostatistical methods is environmental toxicology. The statistical methods of epidemiology originated in questions of epidemics of contagious diseases spread to human from human, and from insects, rodents, and other sources in the environment. Epidemiologic questions today involve more subtle mechanisms of contamination and dysfunction, the detection and effects of noxious chemicals in the air and the soil, and the causes and effects of chronic disease in populations. The methods again are a blend of tried and of new statistical tools of epidemiology, but also new statistical tools adapted and developed from diverse areas of theory and scientific application for answering specific scientific questions in this area of investigation; for example, the concomitant variations of air pollutants and disease rates as air pollutants and disease rates vary through time on daily, weekly, and seasonal bases.

Yet another old but very new area of research that has developed with help from biostatistics is **health services research**. The questions concern just how medicine handles the health needs of the population it serves, what impact the medical system has, how to measure the impact, what factors are important in the effectiveness of a system for financing and caring for a population, and how the system might be altered for greater cost effectiveness. An excellent introduction to this field is the volume prepared under the direction of Kerr L. White, *Health Services Research: An Anthology* [27]. The work on the National Halothane Study [3] resulted in statistical methods for measuring and comparing the outcome of health care (for example, surgical mortality rates) among health care institutions (e.g. hospitals). Flood & Scott [10] described a study that exemplifies the methods by measuring factors in the organization of a hospital that affect outcomes of surgery and medical care. Health Services Research is central now in studying and informing health care finance and delivery. It draws on statistical methods in fields as diverse as medical economics, design and analysis of clinical trials, medical informatics and the design of medical data banks [25], the use of data banks (*see* **Data Archives**) for measurement and comparisons of **quality of care** among medical care systems, measurements of the **quality of life**, and the measurement of the health status of populations.

Current Focuses and Challenges in Biostatistics

The discipline of biostatistics is broad, its borders vague. This is necessarily so for any discipline that links a more theoretical or basic discipline to a spectrum of applied sciences. This is clearly true for other derivative disciplines, such as biochemistry and biophysics. The greatest contributors to the development of biostatistics have been, almost by definition, those leaders with a strength and interest in statistical theory but also with a clear vision of the methods and needs of scientific investigators in the pursuit of science, either generally or in a specific area of study. These central figures in the development of biostatistics mastered the art of compromise, developed methods that were and are the right blend of general theory but scientific specificity to problems common within and across areas of medical investigation and application. They developed methods that have the appeal of scientific and practical utility, bringing simplicity to the design and description of scientific experimentation and observation that are easily communicated and amenable to replication and testing.

For the reader interested in the flavor of current biostatistics, the first chapter of the book by Cox & Hinkley [5] gives a very nice description of how the statistician who has an eye on scientific applications thinks about the work. The book by Miller [18] is a personal view of the way an applied statistician goes about the work of bridging the gap between theory and practice.

What are the current research problems faced by the biostatistician? What are the needs of the biomedical investigator and applied scientist and practitioner? Where are the current challenges? The most important and lasting contributions of the future will come from biostatisticians who combine statistical power with scientific insight and curiosity about the important and general problems of medical research. Predicting new and fundamental breakthroughs in any field is problematic indeed. Who could have predicted the seminal work of K. Pearson, Galton, and Fisher?

Seminal contributions spring from genius, but there is much work yet to be done also at a lower and less innovative level, in further testing, adapting, extending, and exploring the new methods already proposed over the last few decades.

A further source of new biostatistical progress lies in new technologies in other fields that offer increments in explanatory power and insight when incorporated into biostatistical methodology. The most important and obvious example is the tremendous growth in computing power (*see* **Computer-intensive Methods**) and in medical informatics [25].

In addition, there is the important business of reviving methods of the past, ignored in their time or left relatively dormant, but attracting attention as possibly holding answers to new questions and new needs in scientific investigation. Here, for example, Bayes procedures (*see* **Bayesian Methods**) and **decision theory** assume a new luster in the eyes of the applied medical scientist and biostatistician. There is a growing interest and, indeed, a modestly growing use of Bayes' method and decision theory for quantitatively formulating knowledge, belief and cost estimates available at the planning stage of a clinical trial into detailed plans for the trial and the analysis of the results of the trial. The aim is an efficient wedding of what is known at the start of the trial with the results gathered, the whole then to be summarized and the detailed implications reported. Issues in the development of these methods for modern scientific experimentation, communication, and needs, in clinical trials and other areas, are interesting and will certainly continue [1]. It is clear, however, that if these methods are to be incorporated into routine and popular practice there will be a demand for more complex and flexible computer **software** and computational methods.

Focusing on the explosion in computer power over the past two decades as an example for exploitation, one can trace the roots of resampling methods back to the 1930s and earlier, with Fisher's description of the lady tasting tea [9] and the permutation tests of Pitman [20] (*see* **Exact Inference for Categorical Data**), the Quenouille [22] **jackknife method** for correcting bias through systematic resampling of the given data set, and the later **bootstrap methods** [6].

These ideas for testing, for estimation and for measuring the statistical precision of an estimate through resampling the data under analysis, were limited half a century ago by the computational work required in setting them to practical use, even though many of the examples were drawn from medical research settings. With the surge in computer power in the last two decades, measurement of the statistical precision of an estimate based on a sample, by repeated sampling of the sample itself, is indeed feasible for complex data sets, and in many cases these methods finesse the need for complex mathematical theory and approximations. It remains to further the theoretical work needed to draw the guidelines for the use of these methods, to set them on firm theoretical footings, to explore and define the areas of medical science where the methods can be used, and to incorporate the methods in software packages for routine use by biostatistical practitioners and medical scientists. With regard to the latter, some suggestions and currently available help appear in the appendix to Efron & Tibshirani [6].

The controlled randomized clinical trial was mentioned above as a central contribution of statistics to modern experimentation. It was gradually incorporated into the clinical sciences in medicine, and firmly adopted in clinical research and in regulatory affairs, setting the standards for approval of medical drugs (*see* **Drug Approval and Regulation**), devices and other medical accoutrements, for marketing and for medical practice. Currently, a drug proposed for marketing and practice may be subjected to study in thousands of patients, comparing groups treated with the experimental drug with groups treated with a standard drug, to reveal, if true, superiority in effect of the new drug over the standard drug (e.g. in preventing death following a heart attack). This approach to medical experimentation has seen much statistical work in developing designs of these experiments, particular to the medical clinic and to the kinds of problems in execution, analysis and decision making

that arise. The costs of the experiments can be huge; the future costs of erroneous decision even greater. The problems, ethical and otherwise, of working with human study subjects and preserving the validity of the study and the statistical inferences based on the results have presented, and continue to present, challenges to the biostatistician. Deep and useful further work is needed.

The preceding discussion of the clinical trial leads to another area of important focus for the biostatistician. Clinical trials are very expensive. Yet clinical knowledge becomes all important in these times, for several reasons. New drugs, new methods of surgery, the expansion of organ transplantation techniques and practice all lead to greater demand for more expensive medical care. It becomes essential that treatments be evaluated carefully for efficacy and safety, and that treatments be tailored to needs and to the balancing of cost with benefit. The randomized clinical trial plays a central role in obtaining reliable answers; but answers can also be obtained from information gathered in medical practice. Carefully gathered data on medical practice in both hospital and clinical settings, accessible by computer, can be a valuable basis for statistical comparisons of treatment outcomes, for patients with various degrees of illness and other concomitant characteristics (e.g. age, ancillary diseases, history of disease). The problems of statistical inference from such data banks are complex and have to do with the definitions of the variables, the number of variables, the collection of the data, computer storage and access, and prudent and valid statistical analysis of the data. Byar [4] cautions that in light of the difficulties in these complex nonrandomized studies, inferences that are drawn can be far from convincing. The statistical methods available to the investigator are not adequate to deal with the questions asked and the precision required of the answers. The classical methods of **multivariate analysis** are helpful and will continue to grow in their power and use, but new methods are needed. Biostatisticians draw ideas from the past, using the ideas of Bayes to correct hospital estimates from each of a group of hospitals for **regression to the mean** for the group, before drawing inferences about differences in practice effects from one hospital to another. Here, methods of more than a century past can be blended with the power of the modern computer to resample the huge masses of data in the data banks, to merge data from different data banks (*see* **Record Linkage**) to obtain estimates for comparison, and to evaluate the precision of estimates by resampling methods such as the bootstrap approach. Biostatistical work in this area, directed at the collection of data, merging data bank information, and making reliable inferences and decisions from such data is an area that demands the biostatistician's attention.

Chronic diseases themselves pose experimental problems that in turn lead to statistical questions of method. To answer a question regarding the relative efficacy of an experimental treatment to a control treatment, when the event of interest is mortality, patients must be followed for extended periods of time, years or even decades. When the measurement of interest is blood pressure, or physical strength, or kidney function, repeated measures on each individual must be made. The data gathered across subjects are necessarily asynchronous, even if the intention is to measure every patient according to a fixed schedule, say at monthly or annual intervals. Patients miss appointments or appear for extra appointments for various reasons related or unrelated to study goals (*see* **Missing Data**). Some are lost to follow-up, or die of one putative cause or another. Obviously, such data present problems for comparison of the groups with regard to efficacy of a therapy or mode of medical care. The consequent statistical problems in interpreting such longitudinally gathered data have been a concentrated focus of biostatistical research and application over recent years (*see* **Longitudinal Data Analysis, Overview**). The result has been a number of new proposals for analysis. The work has been extremely useful and the work will go on, again it being a blend of new theoretical proposals, much dependent on computer power for both method and for the examination and comparison of methods [14–16].

One final current area of challenge to biostatistics merits mention. It is an area that occupies teams of geneticists, probabilists, biostatisticians, and computer scientists. The new methods of isolating and mapping the human genetic structure (and that of other organisms as well), mapping the genetic structures of inheritance, and grasping the fine relationships between genetic structure and human function (*see* **Genetic Map Functions**) has opened up a huge potential for medical study in the prevention of disease, enhancement of health, and the treatment of disease. But, here again, the questions are new and call for new statistical concepts. The questions start

with the uncertainties in mapping the human genome, a vast undertaking with basic questions of just how to design the mapping efficiently and how to measure the uncertainties in the measurements and the implications of error with regard to the work in progress and to the "final" outcomes. There are questions having to do with the choice of persons to study, the kinds of familial structures to study, and how to weave together the genetic information and the health data to make a predictive model with measurable statistical precision. These results are only now being used in the laboratory and clinic to design vaccines to prevent disease, for example graft-vs.-host disease in bone marrow transplantation, or the conversion of HIV infection to frank **AIDS**, or to tailor a vaccine to a specific cancer in an individual patient as an aid in his/her fight to prevent further development of his/her personal cancer. The questions call for modification in the design and analysis of methods long used, but also the use of new methods aimed at new questions and newer cost and time-efficient approaches to the goals. Jurg Ott gives a comprehensive and thorough introduction to one of the large areas of very active further methodologic research, namely the linkage of genes in humans [19].

In summary, the times present Biostatistics with the triple challenge of completely new areas of science with new kinds of questions, e.g. in genetics, tremendously improved tools for use (notably in both theoretical statistics and computing), and new questions arising from the escalating costs of both medical care and medical research (demanding a closer focus on efficient research and parsimony in monitoring the costs and effectiveness of medical care itself).

Organization of Biostatistics as a Professional Discipline

It was felt by the editors that the focus and breadth of the body of specialized statistical knowledge and the size of the body of professionals in the field of medical and biological statistics justified the organization of an encyclopedia for this now well-established discipline. The general field of statistics itself has been clearly identified for nearly two centuries and the medical and medically related applications – the roots of biostatistics – in genetics, epidemiology, the basic medical sciences, and applications in demography, psychology, and government, have been present for more than a century. The **American Statistical Association (ASA)** was established in 1839, with a regularly published Journal. In England, the **Royal Statistical Society** was established in 1834 as the Statistical Society, with the aim of publishing "facts calculated to illustrate the condition and prospects of society". It publishes three series of journals, dealing with theory and with statistical methods and applications in all areas of science. The **International Biometric Society**, with world organization and membership, was established in 1947 and now has approximately 6200 members. The Biometrics Section of the ASA started a special professional bulletin in 1945, which was adopted by the Biometric Society in 1950 as the official journal of the Society and called ***Biometrics***. There are now journals in many countries devoted at least in part to biostatistics or special aspects of it, e.g. ***Statistics in Medicine***, ***Biometrical Journal*** (Germany), ***Controlled Clinical Trials***, ***Journal of Biopharmaceutical Statistics***, and ***Statistical Methods in Medical Research***.

Academic departments offering specialized statistical courses in the methods and applications of statistics in medicine have existed from the early nineteenth century. In the US, these offerings were generally in schools of public health, where the methods and applications were focused on the areas of sanitation, epidemiology, demography, and vital statistics. Today, most medical schools across the world offer formal instruction in biostatistics to the medical degree candidate (*see* **Teaching Statistics to Medical Students**) and to candidates for degrees in most of the allied medical fields, e.g. dentistry, nursing, health administration, sanitary engineering, where such degrees are offered by the university.

Degrees in biostatistics are offered at a number of universities. These are generally advanced degrees and most are offered in schools of public health. Course work for the master and doctorate degrees is directed to theory and applications of statistics to applications in the broad range of the medical sciences, with an emphasis on clinical and public health areas. Those interested in careers in biostatistics and best suited for satisfying and productive careers will be interested in the mathematical and theoretical aspects of science, will have a curiosity and inclination for the sciences, and will enjoy teamwork and scientific collaboration. Teaching is an important part of the biostatistician's role, whether it is the one-to-one teaching of the consultant to

biomedical colleagues or the more formal teaching of the classroom, to students of biostatistics or students of the biomedical sciences. Of course, specific roles for the biostatistician span the range of applications from government to academia to industry, and involve applications from the most basic of the medical sciences to applications in the clinical practice of medicine and to applications in the organization of health care, as well as to the activities of the government in the planning, financing, and distribution of health care, and the measurement of health care status and health progress in the population.

The reader interested in the field of biostatistics as a career that is located on the bridge between statistical theory and scientific investigation in biomedicine might start with reading selected papers in those professional journals that include occasional expository articles, interviews with professionals, and presidential addresses. *Statistical Science*, the *American Statistician* and the ***Journal of the American Statistical Association*** are several. The professional biostatistics and statistics societies also circulate publications that contain news of the societies and provide a view of activities, the accomplishments of its members, and programs of approaching professional meetings. It will be seen that biostatisticians can be found throughout all biomedical research and application – academia, research institutes, industry, and government.

Biostatistics

Biostatistics, established in 2000 by Oxford University Press, publishes papers that advance statistical reasoning and methods relevant to studies of human health and disease. Authors and readers include academic and professional statisticians as well as other quantitatively oriented biomedical or public health researchers.

The Journal publishes papers of methodologic and substantive consequence. One of the aims of the journal is to achieve review-times that are significantly shorter than are typical of statistics journals, and more competitive with review-times for biomedical journals. The more rapid response to submitted papers is made possible by a small editorial board comprising outstanding scholars who themselves provide critiques of submitted papers and substantially determine what is published. In addition, accepted papers are accessible from the journal website prior to publication in the journal. The website also provides access to supplementary material including data, programs, and text that support the paper publication.

Although *Biostatistics* is a young journal, it is selective, publishing roughly one in four submitted papers. Electronic submissions are encouraged. The journal website `http://biostatistics.oupjournals.org/` provides further details.

PETER J. DIGGLE & SCOTT L. ZEGER

Birth Cohort Studies

Birth cohort studies are those which begin at or before the birth of their subjects, and continue to study the same individuals at later ages, on more than one occasion. They are a type of observational study in which "there is no randomization to exposure classes nor is there any attempt to manipulate the exposure" [10]. They vary in population size from large studies that aim to be nationally representative [12, 24, 33], to those that are area based and with populations of 1000 or more subjects [1, 8, 11, 14, 16, 19, 21, 26, 27, 29, 36]. Currently new, nationally representative birth cohort studies are being started in Denmark and Canada.

Although historical birth cohorts have been imaginatively used in epidemiology [3, 17] they are not discussed here.

Study Population

Selection

Prospective and historical birth cohort studies usually select their populations using time and/or geographical sampling frames. Three British birth cohort studies, which began at the birth of their subjects, each used a sampling frame of all births occurring in one week [12, 24, 33]. The oldest study followed up a class-stratified sample of all the single and legitimate births that occurred during a week, in 1946, and the two later studies followed up all births from the chosen week in 1958 and in 1970. The Avon longitudinal study of all births occurring in one English county used a year's births as a sampling frame, and recruited at antenatal clinics during that period, in order to collect data on risk exposure during pregnancy [14].

Population Size

In a birth cohort study the size of population must be selected at the outset, which may be far in time from some intended outcome measures. Definition of the outcome measures, their age-related incidence, and expected sample attrition at different future times can be used to calculate sample size. Large samples offer the opportunity to study relatively rare occurrences, but not without penalty. Inevitably, sample size is associated with frequency of data collection and with data quality. Large samples are more costly in terms of data collection and subjects can be so costly to contact that time intervals between data collections become long, and undue reliance has then to be given to subjects' recall of events and experiences occurring since the previous data collection.

Contact Maintenance

Contact maintenance is a constant task in a large birth cohort study. Annual contact is the ideal, so that changes of name and address can be kept up to date. In return, information on the study's work helps to maintain the subjects' interest. The two older British studies achieve these ends by means of a birthday card, which is an advantage of the time-based sampling frame. Each also sends an annual description of current work, and an annual request for information on address and name changes.

The tracing of lost contacts is relatively easy during the preschool and school years, when health and education systems may offer assistance, but in the subjects' adult lives investigators have to rely on information given by parents (rapport developed with parents during the school years is of value in these later years), and on agreements with others to forward letters to subjects.

Attrition and Representativeness

None of the British national studies found attrition and its effects on representativeness a serious problem during the preschool and school years, because of the help received from health and education authorities. But, whereas during the childhood and school years of the 1946 national birth cohort study – for instance, data collection was achieved from between 85% (lowest) and 96% (highest) of the live study population resident in Britain – the comparable adult range of response was from 67% to 85% (highest) [33].

Loss of sample members through failure to maintain contact is usually higher in those with the lowest educational attainment or interest in education, those living in the poorest socioeconomic circumstances, those who are single in adult life, and in the mentally ill, but not in those with serious physical illness [35].

Loss of sample members through death can, in Britain, be checked with the National Health Service register, on which study members in the two earlier birth cohorts are "flagged" so that death certification is notified to the study. In other countries similar methods of checking against files of the deceased may be possible (*see* **Death Indexes**).

Attrition in birth cohort studies through emigration, refusal, and loss of contact distort the representation of the study population. Distortion is caused also by inward migration. The 1946 birth cohort, for example, represented at age 43 years the native born, legitimate population, but not those who had been illegitimately born (4% of those born in the chosen week), nor the 5% of the British population of the same age as cohort members at 43 years who (in 1989) were not native born. The 1958 cohort augmented the population selected at birth by including in data collections at ages 7, 11, and 16 years all the children born in the sampled week, even if they had not been included in the original study of births.

Topics of Study

Unique Assets of Prospective Studies from Birth

Two groups of assets of birth cohort studies are conferred by their design. The first is an advantage of having information on individual developmental time passing, and the second is associated with the individual's experience of historical time.

First are assets conferred by prospective data collection. This method provides information on the sequence of events, which is essential to the understanding of causation, and of risk and protective factors. It also provides information which cannot be gained on all cohort members, or even at all in retrospect, or from records – for example, cognitive scores, and information on attitudes, hopes and aspirations, growth, and behavior. This includes information on individuals' physical and mental change over time, and exposure to illness risk. Birth cohorts that are general population samples can provide viable denominator as well as numerator information, and therefore the relative and absolute risks, the effects of differential mortality, and the heterogeneity of outcomes of the hypothesized risk can all be calculated with some accuracy.

The second asset of birth cohort studies conferred by their design is that their populations have passed through known historical times. Thus, for example, the earliest British birth cohort was born at a time of high likelihood of parental smoking, lived the first eight years of life in circumstances of wartime food rationing and the first two years without a national health service, experienced selective entry to secondary schools, and lived all of the infant and childhood years before the Clean Air Act greatly reduced atmospheric pollution. The later-born cohorts, by contrast, lived in less austere times, with increasing awareness of the risks of smoking, less atmospheric pollution from coal burning, and comprehensive education. Members of each cohort came to the historical high period of unemployment, which began in the 1980s, at different career stages. Members of the 1946 cohort lived through the early postwar polio epidemics, and mothers of the 1958 cohort were pregnant during the influenza epidemic in the winter of 1957–1958. These differences of experience can be used to investigate the effects of different kinds of risk and exposure to risk. For example, a study of schizophrenia in the 1958 cohort confirmed that exposure to influenza in pregnancy was associated with raised risk of schizophrenia in offspring [6]. Comparative studies of perinatal mortality in the three British cohorts have been used to examine the effects of changes in obstetric care over the 24 year period [5], and these studies of maternity and childbirth were why the national cohort studies began.

Effects of Historical Time on Topics of Study

Although birth cohort studies are necessarily science-led, they are also inevitably products of their time. This is seen in the population size, which has been conditioned in the past by available information technology and in the selection of data collected, as well as in the initial decision to begin the studies, as already described.

In retrospect, in a long running study it is easy to see what appear later to be omissions in data collection. For example, in the 1946 birth cohort no information was collected during the early years on parental smoking, because the recognition of its damaging effects came almost a decade after the study began. Similarly, in the same study the data on child health collected by school nurses followed the pattern of the current school medical examinations; with hindsight, information on biological function, such as

blood pressure and respiratory function, would have been invaluable.

Some kinds of information were perceived as important in the early years of the 1946 cohort, but there were no suitable research instruments for their collection. The importance of postweaning nutrition in childhood, for instance, although recognized, was very little studied in any of the British birth cohorts. None of the British studies has information on the parents' relationships with one another during the child's early years, because it was thought to be impossible to assess at earlier times, and later because available instruments were too time-consuming. In consequence, whilst each has been able to study the associations of parental divorce and separation with the child's health and well-being, it has not been possible to compare the apparent effects of divorce with those of living in harmonious and disharmonious family circumstances.

Not only is the choice of variables and measurement instruments a product of the time, so also is the general direction of the studies [27]. Current scientific and political expediency are vital forces that shape long-running studies. The 1946 cohort continued to be viable in the children's first five years because of current questioning of the value of home visiting undertaken by nurses involved in maternal and child welfare: the study was able to show the good effects of such a service [33]. During the cohort's school years, the effectiveness of the selective process for entry to secondary school (at age 11 years) was questioned. By having measures of cognitive attainment taken at age 8 years, three years before the selection process, the 1946 study was able to show that the method of selection was, as had been feared, biased in favor of the middle-class child. Furthermore, the study showed that the origins of this problem lay not simply with the selection process itself, but also in child–parent–teacher relationships from the earliest times at school, and in parent attitudes to education [7, 33]. Similarly, the 1958 cohort was well-placed to undertake studies of primary school education for the contemporary government enquiry into education in primary schools [13, 23]. In more recent times, the 1958 study has been ideally placed to investigate the effects of unemployment and preexisting circumstances on mental and physical health and on the acquisition of social capital in early adulthood, since cohort members were in their early years of work when the national rise in unemployment began [20]. The 1946 study is now contributing to understanding the processes of aging, and is well-placed to do so, not only because of its lifetime data, but also because this population represents the beginning of the boom years in the population of the elderly.

Previous and Later Generations

The two older British birth cohorts have some information on the parents of study members, particularly their educational attainment, occupation, marital status and stability, concern for the study child's education, and cause of death, as well as some information about health. This has made it possible to study social mobility, the effects of parental ill health on the life of the study child, and intergenerational differences in religious and political adherence, as well as the effect of some important aspects of family of origin, and cohort members' educational attainment [25, 34].

The first two British cohorts also have information on the offspring of cohort members. The 1946 study interviewed mothers of all first children born to male and female cohort members between ages 19 and 25 years. Information on these second-generation children was collected at the end of the preschool period, at age 4 years, and again at 8 years, because the purpose of the study was to explore further the finding in the previous generation that parental concern for education was strongly associated with attainment scores [32, 33]. The 1958 study, on the other hand, interviewed a randomly selected one in three of the cohort members who were parents at age 33 years about all their children ($n \simeq 4000$), to compare differences in a wide range of aspects of childhood in two generations.

Now that the 1946 cohort members are in middle life, questions have been included at the interview at 43 years about their relationships with, and (where necessary) care of, their elderly parents, who were by that time aged 71 years, on average [34].

Although these studies of the two generations adjacent to cohort members are useful for the study of intergenerational relationships, their populations cannot be regarded as representative of those generations.

Forward Planning

Forward planning is difficult in a long-term prospective study because the variables selected for current

data collection will be used for two purposes. They will be used as outcome measures in relation to data collected at earlier times. They will also become precursor variables used to test hypotheses about risk. It is therefore necessary, in planning data collections, to consider the needs of future hypothesis testing. For example, planning midlife data collection in the 1946 cohort has had to include consideration of requirements for testing hypotheses about health in later life. For instance, current hypotheses about skeletal fractures and repair in old age implicate smoking, diet, and exercise in midlife, and so information on these health-related habits will be collected. The risk is that by the time the cohort reaches old age, hypotheses will change, and new ideas will develop. Although that is an inevitable problem, in practice, for biological questions, measures of current function and its change over time, and the preservation of blood samples, provide a range of data possibilities for future use. In general, once a future biological, psychological, or social outcome has been defined, then, the demands of current hypotheses having been taken into account, the most detailed possible measures available should be taken to make future accurate assessments of change, and not to constrain future analyses.

In retrospect, it is clear that the 1946 study has been fortunate. Investigations of midlife cognitive function, for example, have been able to use data on this topic collected in childhood, adolescence, and early adulthood for the study of educational attainment. Similarly, information on birth weight and infant growth and development, originally collected to study social variation in physical development, has proved to be of unanticipated value in the study of midlife blood pressure and respiratory function, and of schizophrenia.

Other Sources of Data

In addition to cohort members themselves, and in childhood their parents, birth cohort studies have found it invaluable to collect information from other sources, for four reasons.

First, confirmatory information can usefully be collected, with permission, for example, from hospital records and educational certification bodies. Secondly, information can be collected to provide another view of the circumstance. For instance, in the 1946 study, teachers' comments added considerably to the information given by cohort members and by parents. Thirdly, information from other sources, including census data, can provide information on an area basis about exposure to such things as atmospheric pollution and the nature of water supplies, as well as local rates of unemployment, educational attainment, and socioeconomic structure. The fourth kind of information concerns the current social and scientific context. In a long-running prospective study it is difficult to know in retrospect the political and scientific pressures and social concerns of the day that affected the direction that the study took. They are difficult to ascertain years later, because histories of the period are usually concerned with political pressure and events rather than social and scientific histories, although there are notable exceptions. In trying to account for earlier choice of subjects, measures, and direction of analyses, a study logbook is needed to supplement such other sources as reports of funding bodies, government enquiries, and commissions.

Analysis

Coding

The effects of historical time in a long-running study can also be problematic in terms of how information is coded and stored. Classifications of illnesses and socioeconomic position change over time, and it is often necessary to recode information already coded, and to retain two or more sets of classifications both to study change over time and to be comparable with current work in other studies.

Concepts of Analysis

Now that birth cohorts, historical cohorts, and other forms of longitudinal studies have been collecting data for 50 years and more, the long-term nature of these investigations has brought a life-span perspective to analysis [15, 22, 31]. This has generated new ideas about the nature of psychological and biological aging, and raised the question of the role and measurement of adaptation with age [2]. So far, this has been largely a matter of psychological study, but questions about variation in biological vulnerability in relation to age are now being discussed in view of the data available from prospective and historical studies that encompass many years of life [3].

The most commonly used approach to analysis in birth cohort and other long-term investigations is concerned with variables, and the most commonly used method is linear regression. More recently, **structural equations models** have also been used to handle interactions between variables that measure function or environment [9]. Alternatively, a person-oriented, as compared with a variable-oriented, approach has been advocated [4, 18]. This method compares individuals' profiles of characteristics determined by analysis of clusters or patterns (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**). Magnusson and Bergman [18] illustrate this approach in comparison with variable-based analysis, which in a study of precursors of crime and aggression would show how

> each of a number of single aspects of individual functioning – aggressiveness, hyperactivity, low school motivation, poor peer relations – is significantly related to various aspects of adult maladjustment. . . .Applying the pattern approach to this research area, the focus instead becomes: what typical patterns or configurations of adjustment problems of this kind actually exist in childhood; how are major adjustment problem areas in adult age interconnected; and what are the relationships between typical problem patterns in childhood and typical problem patterns in adulthood?

This account of the nature of birth cohort studies cannot describe all aspects, nor refer to every study. Broader summaries and reviews are given by Sontag [30], Mednick et al. [19], Schneider & Edelstein [28], and Young et al. [37].

Birth Defect Registries

Birth defects registries can be used to determine the newborn prevalence of birth defects and they can provide cases for studies [3]. Both of these functions are important foundations for the prevention of birth defects.

A birth defects registry is an organized database containing information on individuals born with specified congenital disorders, ascertained from a defined source. Birth defects are a heterogeneous group of conditions, present at birth, and not generally considered to include injuries suffered in and around the birth process. In the US, the March of Dimes Birth Defects Foundation defines a birth defect as "an abnormality of structure, function or body metabolism (inborn error of body chemistry) present at birth that results in physical or mental disability, or is fatal" [9].

There are more than 4000 known types of birth defects. These include conditions ranging from congenital malformations of unknown etiology, to genetic conditions due to abnormal genes or chromosomes, to conditions due to damage to the developing fetus related to prenatal maternal exposure to hazardous environmental agents. Thus, this term includes a range of disorders such as cleft lip and palate, heart malformations, clubfoot, Down syndrome, phenylketonuria (PKU), fragile X-linked mental retardation, fetal alcohol syndrome and the thalidomide syndrome. Not all of these conditions are necessarily medically or cosmetically significant. Some "minor" defects, such as small birthmarks or skin tags, are of no significant consequence.

Causes of Birth Defects

Birth defects may be caused by genetic or environmental factors (including drugs and chemicals, infectious agents, physical agents, and maternal health or nutritional factors) acting singly or in combination. The causes of more than half of all birth defects are unknown at present. Collectively, birth defects are a major cause of disability and morbidity, and in the US, represent the leading cause of infant mortality.

Information in Birth Defects Registries

Birth defects registries systematically collect information such as identifiers and demographic information, description of the defects present, family history, history of the pregnancy (including prenatal exposures), and other information potentially related to risk factors. This information may be gathered from vital records, hospital or clinic records, or other sources of case ascertainment. Registries that rely upon records collected for other purposes (e.g. birth certificates) are sometimes referred to as using "passive" methods of ascertainment, while those that use multiple sources and collect information from patient records are said to use "active" ascertainment. Information stored in birth defects registries is typically stored as both paper files and in electronic systems, often using a relational database. Considerable effort is expended to ensure data security, as well as the confidentiality and privacy of the individuals and families who are participants in the registry.

Usually, information collected is restricted to a defined age range such as the neonatal period or the first year of life. Indeed, since many defects are not identified before neonatal hospital discharge, the longer the ascertainment period used, the higher the frequency of children identified with birth defects in a particular birth cohort. Systems actively ascertaining cases throughout the first year of life typically find that 3.5%–5% of infants have such conditions.

Birth defects registries generally collect cases from a defined population, such as that in a specified geographic area. When they do, the registry can use birth certificate data collected for governmental purposes on all babies as the denominator. Thus, it becomes possible to determine the newborn prevalence of birth defects in this geographic area. Such population-based registries also permit case–control studies. Many countries have national registries. These programs share information through an International Clearinghouse for Birth Defects Monitoring Programs [4]. This organization has contributed to standardized terminology and methods and has helped in the organization of international collaborative research efforts. Non population-based registries can provide cases for studies that do not need a population base. Such collections of patients have been particularly useful for studies seeking to identify the gene responsible for a single gene cause of a birth defect.

Uses of Birth Defects Registries

Registries that are population-based permit the rates of birth defects to be determined. Such rates can be

monitored to look for changes that would suggest a newly introduced environmental/drug agent. It has been argued that had there been registries established prior to the thalidomide epidemic, the cause may have been determined sooner than it was. On a more positive note, when there is the possibility to prevent birth defects like rubella and folic-acid-preventable spina bifida and anencephaly, monitoring the trends can determine the effectiveness of prevention programs. There is currently great interest to determine whether or not the folic acid fortification plan in the US will provide full protection from folic-acid-preventable birth defects.

Given that we do not know the causes of the birth defects in the majority of infants born with them, a major function of birth defects registries has been to supply cases for studies seeking to find the causes of birth defects. The most common kind of epidemiologic study seeking to find causes is the **case–control study**. In these studies the exposures and family history of cases are compared with those of controls selected from the same population from which the case is drawn.

One notable example of such a study is the one from France that found that cases of spina bifida were much more likely to have been exposed to valproic acid than controls. This study led rapidly to a health warning in the US [6]. Another useful example is provided by the Atlanta Case–Control Study conducted by the US Centers for Disease Control and Prevention (CDC). This study provided the opportunity to examine possible associations between many kinds of birth defects and many drug and environmental exposures. The protective association between regular multivitamin consumption and the reduction in spina bifida and anencephaly shown in Atlanta and other observational studies, provided critical data for public health policy [8]. These studies led to a recommendation by the US Public Health Service (PHS) that women of reproductive age consume 400 μg of synthetic folic acid daily, rather than the 4000 μg that was used in the randomized controlled trial [2, 7]. Because data on so many exposures were collected, there remain data yet to be analyzed that may provide insight to other etiologies of these and other birth defects [5].

Recently, investigators have sought to improve the search for causes of birth defects by using both molecular markers of exposure and outcomes [10]. With the genome project soon to provide data on all genes, investigators will have even more powerful tools to try to understand the interplay between environmental and genetic risk factors in the cause of birth defects. Thus, registries are a rich resource for clinical and family studies, for health outcomes and services research, and for public health planning and programming [1].

Authority for Operation of Birth Defects Registries

Birth defects registries are generally established and operated under the authority of public health agencies. In the US, authority for such public health surveillance programs is generally the responsibility of the states. As a consequence, there are specific statutes authorizing such a registry or surveillance system, and there is considerable variation in specific goals, methods of financing, operational policies, and scope of disorders covered. Furthermore, other state and federal policies (e.g. health information and privacy policies) affect the type and circumstances under which research can proceed.

Birthweight

The **World Health Organization (WHO)** defines birthweight as the first weight of the fetus or baby after birth. Although parents commonly include the baby's birthweight on the cards they send to friends and relatives to tell them of the new arrival, there have been times when people considered it unlucky to weigh babies [1].

Throughout the nineteenth century, "prematurity" was often cited as a cause of death among babies, but attempts at definition do not appear to have been made before the twentieth century. In 1906, George Newman made a distinction between prematurity and immaturity, but quoted views that prematurity should be defined as having a birthweight under 2500 g or perhaps 3000 g [3].

Arvo Ylppo, a Finnish doctor working in Germany, suggested in 1919, in his review "On the physiology, care and fate of newborn babies", that "premature birth" should be defined as having a birthweight of 2500 g or less. He acknowledged, however that the term *frühgeburt*, or "premature birth", was inappropriate and suggested instead the term *unreifes kind*, or "immature child". Despite the fact that he acknowledged that the cutoff point of 2500 g was arbitrary and not necessarily related to other indicators of immaturity, it was adopted internationally as a definition of "prematurity" [6]. Countries using imperial weights substituted the corresponding weight of $5\frac{1}{2}$ lb.

By the 1970s the limitations of this definition of "prematurity" were becoming increasingly apparent. To distinguish between short gestation and slow fetal growth, separate definitions of "low birthweight" and "preterm" birth (*see* **Gestational Age**) were published in 1977 in the ninth revision of the **International Classification of Diseases (ICD)** [4] and repeated in the tenth revision [5]. At the same time the definition was changed from 2500 g or less to under 2500 g. Because of "digit preference"; that is, the tendency to choose round numbers, the change affected the continuity of time series [2]. WHO recommends that birthweight should preferably be measured within the first hour of life and the actual weight should be recorded to the degree of accuracy to which it is measured [5]. The classifications are as follows.

1. Low birthweight: less than 2500 g; that is, up to and including 2499 g.
2. Very low birthweight: less than 1500 g; that is, up to and including 1499 g.
3. Extremely low birthweight: less than 1000 g; that is, up to 999 g.

The mortality of babies varies considerably according to birthweight, with very high mortality rates among very small babies (*see* **Infant and Perinatal Mortality**). On average, babies from multiple births are lighter than singletons and a higher proportion of them have low birthweights. Average birthweight and the proportion of low-weight births also varies between socioeconomic groups. Among babies born to less favored sections of populations there is a tendency for lower mean birthweights and higher proportions of low-weight births than among babies born in more favored circumstances. There are also differences between **ethnic groups**. Studies using **record linkage** have shown successive babies born to the same women tend to have similar birthweights.

Research done by people concerned with evaluation of maternity care tends to center on the survival rates of low and very low birthweight babies and the health status (*see* **Quality of Life and Health Status**) of the surviving children. Among epidemiologists there is currently a keen interest in associations between the health of adults and their birthweight. The relative importance of circumstances at birth and in later life is hotly debated.

Biserial Correlation

Biserial correlation coefficients are measures of bivariate association that arise when one of the observed variables is on a measurement scale and the other variable takes on two values. There are several biserial coefficients, with appropriate choices based on the nature of the underlying bivariate population. Two common forms are the Pearson biserial correlation (hereafter referred to as the biserial correlation) and the point biserial correlation.

Pearson [9] developed the biserial correlation to estimate the product moment **correlation** ρ_{YZ} between two measurements Y and Z using data where Z is not directly observed. Instead of Z, data are collected on a categorical variable X which takes on the values $X = 1$ if Z exceeds a threshold level, and $X = 0$ otherwise. In many applications, the latent variable Z is conceptual rather than observable. The actual values used to code X do not matter, provided the larger value of X is obtained when Z exceeds the threshold. The point biserial correlation is the product moment correlation ρ_{YX} between Y and X.

We use data adapted from the study by Karelitz et al. [7] of 38 infants to illustrate ideas. Table 1 gives a listing of the data. The categorical variable X corresponds to whether the child's speech developmental level at age three is high ($X = 1$) or low ($X = 0$). The child's IQ score at age three is Y. The biserial correlation ρ_{YZ} is a reasonable measure of association when X can be viewed as a surrogate for an underlying continuum Z of speech levels. The point biserial correlation ρ_{YX} might be considered when the scientist is uninterested in the relationship between IQ and the underlying Z scale, or cannot justify the existence of such a scale.

The remainder of this article discusses methods for estimating the point biserial and the biserial correlation. Other forms of biserial correlation are briefly mentioned.

The Point Biserial Correlation

Suppose that a sample $(y_1, x_1), (y_2, x_2), \ldots, (y_n, x_n)$ is selected from the (Y, X) population. Let s_{YX} be the sample covariance between the $y_i s$ and the $x_i s$, and let s_Y^2 and s_X^2 be the sample variances of the $y_i s$ and the $x_i s$, respectively. The population correlation ρ_{YX} is estimated consistently by the sample point biserial correlation

$$r_{YX} = \frac{s_{YX}}{s_Y s_X} = \frac{(\overline{y}_1 - \overline{y}_0)}{s_Y}[\hat{p}(1-\hat{p})]^{1/2}, \quad (1)$$

where $\overline{y}_1$ and $\overline{y}_0$ are the average y values from sampled pairs having $x_i = 1$ and $x_i = 0$, respectively, and $\hat{p}$ is the observed proportion of pairs with $x_i = 1$.

The sampling distribution of r_{YX} is known only for certain models. Tate [12] derived the distribution of $T = (n-2)^{1/2} r_{YX}/(1 - r_{YX}^2)^{1/2}$ under the assumption that the conditional distributions of Y given $X = 1$ and given $X = 0$ are normal with identical variances. Tate [12] noted that T is equal to the usual two-sample Student's t statistic for comparing the means of the y samples having $x_i = 1$ and $x_i = 0$. The hypothesis $\rho_{YX} = 0$ is usually tested using this standard t test. Tate's [12] results are more complex for testing nonzero values of ρ_{YX}. In large samples, hypothesis tests and confidence intervals for ρ_{YX} can be based on a normal approximation to r_{YX} with mean ρ_{YX} and estimated variance

$$\widehat{\text{var}}(r_{YX}) = \frac{(1 - r_{YX}^2)^2}{n}\left\{1 - 1.5 r_{YX}^2 + \frac{r_{YX}^2}{4\hat{p}(1-\hat{p})}\right\}. \quad (2)$$

Das Gupta [5] generalized Tate's [12] results to nonnormal populations.

For the IQ data, the distributions of the IQ scores for the samples with $X = 0$ and $X = 1$ are slightly skewed to the right and have similar spreads. The mean IQ scores in the two samples are $\overline{y}_1 = 2779/22 = 126.318$ and $\overline{y}_0 = 1676/16 = 104.750$. With $\hat{p} = 22/38 = 0.579$ and $s_Y = 19.383$, we obtain

Table 1 IQ data for a sample of 38 children: X = speech developmental level (0 = low; 1 = high) and Y = IQ score

$X = 0$	Y:	87	90	94	94	97	103	103	104	106	108	109	109
		109	112	119	132								
$X = 1$	Y:	100	103	103	106	112	113	114	114	118	119	120	120
		124	133	135	135	136	141	155	157	159	162		

$r_{YX} = 0.557$, $\widehat{\text{sd}}(r_{YX}) = 0.103$, and $T = 4.024$ under Tate's assumptions.

A limiting feature of the point biserial correlation is that the range of ρ_{YX} is smaller than the usual reference range of -1.0 to 1.0. For example, the magnitude of ρ_{YX} cannot exceed 0.798 when Y is normally distributed. This restriction can lead to misinterpreting the strength of the sample correlation. Shih & Huang [10] examined this problem in a general setting, and offer a useful method to calibrate point biserial correlations.

Pearson's Biserial Correlation and Generalizations

Suppose that X is obtained by **categorizing a continuous variable** Z with $X = 1$ if $Z > \omega$ and $X = 0$ otherwise, where ω is a fixed but possibly unknown threshold. Let $f(t)$ and $F(t)$ be the pdf for Z and the cdf for Z, respectively. We assume without loss of generality that $\text{E}(Z) = 0$ and $\text{var}(Z) = 1$. The threshold ω is the upper pth percentile of Z, i.e. $\omega = F^{-1}(1 - p)$, where

$$p = \Pr(X = 1) = \Pr(Z > \omega) = 1 - F(\omega). \quad (3)$$

If the regression of Y on Z is linear, then the biserial correlation and the point biserial correlation are related by

$$\rho_{YZ} = \rho_{YX} \frac{[p(1-p)]^{1/2}}{\lambda(\omega, F)}, \quad (4)$$

where

$$\lambda(\omega, F) = \text{E}(XZ) = \int_{\omega}^{\infty} t f(t)\, \text{d}t = \int_{\omega}^{\infty} t\, \text{d}F(t). \quad (5)$$

The linear regression assumption is satisfied when (Y, Z) has a bivariate normal distribution, a common assumption, but holds for other elliptically symmetrical bivariate distributions as well.

Eq. (4) provides a way to estimate the biserial correlation from a sample of $(y_i, x_i)s$ when the cdf of Z is known. Bedrick [2] proposed a simple method-of-moments estimator,

$$\tilde{r}_{YZ} = r_{YX} \frac{[\hat{p}(1-\hat{p})]^{1/2}}{\lambda(\hat{\omega}, F)}, \quad (6)$$

where $\hat{\omega} = F^{-1}(1 - \hat{p})$ is the estimated threshold based on the proportion $\hat{p}$ of sampled pairs with $x_i = 1$. If Z is normally distributed, then (6) is Pearson's biserial estimator

$$r_{\text{Pb}} = \frac{r_{YX}}{\phi(\hat{\omega})}[\hat{p}(1-\hat{p})]^{1/2} = \frac{(\overline{y}_1 - \overline{y}_0)}{s_Y \phi(\hat{\omega})}\hat{p}(1-\hat{p}), \quad (7)$$

where $\phi(t)$ is the standard normal pdf.

Bedrick [2] showed that the asymptotic distribution of $\tilde{r}_{YZ}$ is normal with mean ρ_{YZ} and gave an expression for the large sample $\text{var}(\tilde{r}_{YZ})$. In earlier work, Soper [11] gave an estimator for $\text{var}(r_{\text{Pb}})$ when (Y, Z) is normal:

$$\widehat{\text{var}}(r_{\text{Pb}}) = \frac{1}{n}\left\{ r_{\text{Pb}}^4 + \frac{r_{\text{Pb}}^2}{\phi^2(\hat{\omega})}[\hat{p}(1-\hat{p})\hat{\omega}^2 + (2\hat{p}-1)\hat{\omega}\phi(\hat{\omega}) - 2.5\phi^2(\hat{\omega})] + \frac{\hat{p}(1-\hat{p})}{\phi^2(\hat{\omega})} \right\}. \quad (8)$$

Unlike the point biserial estimator, the magnitudes of r_{Pb} and $\tilde{r}_{YZ}$ can exceed 1.0. For the IQ data, $r_{\text{Pb}} = 0.694$ and $\widehat{\text{sd}}(r_{\text{Pb}}) = 0.135$.

Brogden [3] and Lord [8] generalized Pearson's estimator by relaxing the assumption that the distribution of Z is known. Bedrick [1, 2] gave a detailed study of Brogden and Lord's estimators. Cureton [4] and Glass [6] proposed versions of Brogden's estimator that are based on the ranks of the y sample.

As a final point, note that a **maximum likelihood estimator** (MLE) of ρ_{YZ} can be computed iteratively whenever a joint distribution for (Y, Z) can be specified. Tate [13] proposed the MLE of ρ_{YZ} as an alternative to Pearson's biserial estimator with bivariate normal populations. Although MLEs are fully efficient, Bedrick's [1, 2] results show that the asymptotic variances of Lord's estimator and the MLE are often close in normal and nonnormal populations.

Bivariate Distributions

The study of the joint statistical behavior of pairs of random variables gives rise to bivariate distribution theory. For instance, Halperin et al. [1] examine the effect of systolic blood pressure and the number of cigarettes smoked per day on the probability of death. In this case the random variables of interest are the systolic blood pressure and the number of cigarettes smoked per day. While the ideas involved in the study of bivariate distributions follow along the lines of univariate distributions, the mathematical development of the results is more complicated. Three distinct types of bivariate distributions that arise in practical situations are identified and presented in this article.

Continuous Distributions

Random variables (X_1, X_2) are said to have a continuous distribution if and only if $\Pr\{X_i$ lies in the infinitesimal interval $(x_i, x_i + \mathrm{d}x_i)$ for $i = 1, 2\} = f(x_1, x_2)\,\mathrm{d}x_1\,\mathrm{d}x_2$, where $f(x_1, x_2)$ is called the probability density function (pdf) of (X_1, X_2) at the point (x_1, x_2) lying in the two-dimensional Euclidean space. Alternatively, it is possible to represent the probability that (X_1, X_2) lies in the two-dimensional region I as $\int\int f(x_1, x_2)\,\mathrm{d}x_1\,\mathrm{d}x_2$, with the integration running over the region I. The **moment generating function** (mgf) is defined by $M(t_1, t_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} t_1^{x_1} t_2^{x_2} f(x_1, x_2)\,\mathrm{d}x_1\,\mathrm{d}x_2$, with its existence requiring that $\{-h_1 < t_1 < h_1, -h_2 < t_2 < h_2\}$ (see Hogg & Craig [2, p. 97]). As in univariate distributions, the mgf has a one-to-one relationship with the pdf. The marginal distributions of X_1 and X_2 have the mgfs given by $M(t_1, 0)$ and $M(0, t_2)$, respectively. A necessary and sufficient condition for the independence of X_1 and X_2 is that $M(t_1, t_2) = M(t_1, 0)M(0, t_2)$. Under the assumption of the existence of the mgf, the **moments** of (X_1, X_2) can be determined as $\mathrm{E}[X_1^r X_2^s] = \mathrm{the}(r, s)\mathrm{th}$ mixed partial derivative of the mgf evaluated with each of the arguments set equal to zero. The inversion of the mgf is mathematically complicated, involving, in most instances, the use of transform theory. However, in many practical problems it is of a recognizable form leading to a simple way for its inversion. The mgf can be used to find the distributions of functions of (X_1, X_2). Thus, for example, for a random sample of size n the mgf of $\left(\sum_{i=1}^{i=n} X_{1i}, \sum_{i=1}^{i=n} X_{2i}\right)$ is $[M(t_1, t_2)]^n$, while that of $\{\overline{X}_1, \overline{X}_2\}$ is $[M(t_1/n, t_2/n)]^n$. At this point we introduce a few special types of continuous distributions:

1. The **bivariate normal distribution**. The standard form of the bivariate normal distribution is defined by the pdf $f(z_1, z_2) = c\exp\{-[z_1^2 - 2\rho z_1 z_2 + z_2^2]/2(1-\rho^2)]\}$, where the constant $c = 1/[2\pi(1-\rho^2)]^{1/2}$. For this form of distribution, the mean of each of the random variables is zero, the variances are each equal to one, with the coefficient of **correlation** ρ. A more general form of the distribution arises when we replace z_i by $(x_i - \mu_i)/\sigma_i$, $i = 1, 2$, and c by $c/\sigma_1\sigma_2$. It can shown that the means in this case are μ_i and the standard deviations are σ_i for $i = 1, 2$. The coefficient of correlation, being location and scale-free, remains at ρ. The distribution enjoys the regenerative property in that if (X_{1i}, X_{2i}) are n independent random variables having a standard bivariate normal distribution, then $\left[U = \sum_{i=1}^{n} X_{1i}/\sqrt{n}, V = \sum_{i=1}^{n} X_{2i}/\sqrt{n}\right]$ also have the standard bivariate normal distribution. Similar results can be established for the general bivariate normal distribution. In each case the marginal distributions are univariate normals. The bivariate normal distribution finds extensive applicability in studies involving two characteristics. Hutchinson & Lai [3, Chapter 19] have listed a wide variety of applications to medical research of the bivariate normal distribution and its modifications.
2. The **exponential distribution**. While a variety of forms of this distribution have been suggested in the literature, their applicability is, in all cases, directed toward a study of the reliability of competing systems. A widely used form is that of Marshall & Olkin [5]. Unfortunately, the pdf is quite complicated and as such will not be reproduced here. The cumulative distribution function is given by $F(x_1, x_2) = \exp[-\lambda_1 x_1 - \lambda_2 x_2 - \lambda_3 \max(x_1, x_2)]$. An interesting application of the distribution in the medical context is given by Rai & Van Ryzin [6]. They consider in a **quantal response** context, the tolerance distribution for the occurrence of bladder and liver tumors as a consequence of exposure to various

levels of a carcinogen (see Hutchinson & Lai [3, Chapter 9]).

Discrete Distributions

Random variables (X_1, X_2) are said to have a discrete distribution if and only if the probability of the event $\{X_1 = x_1 \text{ and } X_2 = x_2\}$ is nonzero and is equal to $f(x_1, x_2)$, the probability function (pf) at (x_1, x_2), where x_1 and x_2 each assumes values over a finite set or a countable infinity of points in the Euclidean space. However, usually, the pf is taken to be positive over the non-negative integer values of x_1 and x_2. In most discrete distributions the probability **generating function** (pgf) is preferable because it has a simpler form than the mgf. The pgf is given by $\prod(t_1, t_2) = \sum_{x_2=0} \sum_{x_1=0} t_1^{x_1} t_2^{x_2} f(x_1, x_2)$, which can be readily seen to exist for all values of each of t_1 and t_2 in the interval $[-1, 1]$. There is a one-to-one relationship between the pgf and the pf. Thus, the pf at (r, s) can be determined from the pgf either as the ratio $\{[(r, s)\text{th mixed partial derivative of the pgf evaluated at } t_1 = t_2 = 0]/r!s!\}$ or as the coefficient of $t_1^{x_1} t_2^{x_2}$ in an expansion of the pgf in powers of t_1 and t_2. In addition, it is possible to determine, $\mathrm{E}[x_1^{(r)} x_2^{(s)}]$, the factorial moment (*see* **Moments**) of order (r, s), from the same mixed partial by setting $t_1 = t_2 = 1$. The marginal pgfs are given by $\prod(t_1, 1)$ and $\prod(1, t_2)$, respectively. A necessary and sufficient condition for independence is $\prod(t_1, t_2) = \prod(t_1, 1) \prod(1, t_2)$. Two of the most commonly occurring discrete distributions are the bivariate **Poisson** and the bivariate Neyman type A (*see* **Accident Proneness**). Reference may be made to Kocherlakota & Kocherlakota [4] for a discussion of the bivariate discrete distributions and their various forms.

Mixed Distributions

Although in most situations both of the random variables have distributions that are similar in form, in some instances one of the random variables could have a continuous distribution while the other is of a discrete form. The example cited at the beginning of this article typifies this situation. In this case the blood pressure has a continuous distribution while the number of cigarettes smoked per day is a discrete random variable. In situations of this type we may be particularly concerned with the **regression** of the continuous variable on the discrete variable.

Bivariate Normal Distribution

The bivariate normal distribution of the random variables X and Y has the joint density function

$$\begin{aligned}\phi(x, y) = {} & [2\pi\sigma_1\sigma_2(1-\rho^2)^{1/2}]^{-1} \\ & \times \exp\{-1/2[(x-\mu_1)^2/\sigma_1^2 \\ & - 2\rho[(x-\mu_1)/\sigma_1][(y-\mu_2)/\sigma_2] \\ & + (y-\mu_2)^2/\sigma_2^2]/(1-\rho^2)\},\end{aligned}$$

for x and y defined over the entire plane $-\infty < x < \infty$ and $-\infty < y < \infty$. The five parameters determining the location, dispersion, and orientation of the bivariate normal probability surface are the means $\mathrm{E}(X) = \mu_1$ and $\mathrm{E}(Y) = \mu_2$, the variances $\mathrm{var}(X) = \sigma_1^2$ and $\mathrm{var}(Y) = \sigma_2^2$, and the **correlation** $\mathrm{corr}(X, Y) = \rho$. For the density to be defined it is necessary that $-1 < \rho < 1$. Otherwise, when $\rho = \pm 1$ the distribution is *singular*, and the density function does not exist. The density is unimodal, with its peak at $x = \mu_1$ and $y = \mu_2$. The contours of planes through the density at constant elevations are elliptical, since each has the form

$$\frac{(x-\mu_1)^2}{\sigma_1^2} - \frac{2\rho(x-\mu_1)(y-\mu_2)}{\sigma_1\sigma_2} + \frac{(y-\mu_2)^2}{\sigma_2^2} = \text{constant}.$$

The random variable defined by the quadratic form has the **chi-squared distribution** with two degrees of freedom. When $\rho > 0$ the major axes of the ellipses have positive slopes in the (X, Y) plane, and negative orientation if $\rho < 0$. If $\rho = 0$ the axes of the ellipses are parallel with the coordinate axes of X and Y. When $\rho = 0$ and $\sigma_1^2 = \sigma_2^2$, the concentration ellipses are circular.

The transformations $Z_1 = (X - \mu_1)/\sigma_1$ and $Z_2 = (Y - \mu_2)/\sigma_2$ give the standardized bivariate normal distributions with zero means, unit variances, and the single parameter ρ. The **orthogonal** transformation of the standardized variates,

$$\begin{bmatrix} U_1 \\ U_2 \end{bmatrix} = \begin{bmatrix} \sqrt{2}/2 & \sqrt{2}/2 \\ -\sqrt{2}/2 & \sqrt{2}/2 \end{bmatrix} \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix},$$

leads to the independent random variables U_1 and U_2, regardless of the value of ρ. If $\rho > 0$, U_1 corresponds to the major axis of the concentration ellipse of the density of Z_1 and Z_2, while U_2 is the minor axis variate.

The bivariate normal distribution arises from the **central limit theory** for a sequence of independent pairs of correlated random variables. It was first proposed in 1808 by Adrain [1] in the "circular" case of equal variances and zero correlation. **Laplace** [5] published a general normal density expression in 1812, based on his earlier work on the central limit theorem. Some 70 years later, **Galton** [3] noticed a pattern of concentric ellipses in tables of bivariate data. His request of the mathematician J.D.H. Dickson [2] for a distribution with that property led to the bivariate normal density.

Properties

The random variables X and Y are independent if and only if $\rho = 0$. The marginal distributions of X and Y are univariate normal with means and variances as in the bivariate distribution. The *conditional* distribution of Y for $X = x$ is also normal, with mean $\mathrm{E}(Y|X) = \mu_2 + (\rho\sigma_2/\sigma_1)(x - \mu_1)$ and variance $\mathrm{var}(Y|x) = \sigma_2^2(1 - \rho^2)$. The conditional mean, or *regression function* (*see* **Regression**), is linear in the values x of the fixed variable. Furthermore, the conditional variance is constant for all x. Those properties are the basis for regression analysis when both variables are random and are jointly bivariate normally distributed.

Johnson & Kotz [4] have given an extensive treatment of the history, properties, and inferential aspects of the bivariate normal distribution. They include several plots of the bivariate normal density surface for different values of ρ.

Probability Calculations

Tables were published by the National Bureau of Standards [7] of the probabilities

$$\begin{aligned}L(h, k, \rho) &= \int_h^\infty \int_k^\infty \phi(x, y)\,\mathrm{d}y\,\mathrm{d}x \\ &= \Pr[(X > h) \cap (Y > k)]\end{aligned}$$

for bivariate normal (X, Y). Another related function $V(h, k)$ for computing probabilities over triangular and polygonal regions is also tabulated. Owen [8] published tables of a slightly different version of $V(h, k)$. Zelen & Severo [9, 10] expressed $L(h, k, \rho)$ in terms of $L(h, 0, \rho)$, and provided charts of the latter function. Mehta & Patel [6] have developed statistical computer software that will calculate the probability function $L(h, k, \rho)$.

DONALD F. MORRISON

Blinding or Masking

The term *blinding* (sometimes *masking*) applies primarily to **clinical trials** but is also commonly and increasingly used with reference to **analytic epidemiologic** studies. Most explanations of the term are in the context of clinical trials, and the majority of this article is focused towards trials, although various sections also describe blinding epidemiologic studies.

The fundamental idea in blinding is that the study patients, the people involved with their management, and those collecting the clinical data from studies should not be influenced by knowledge of the assigned treatment or, in an epidemiologic study, by knowledge of the main risk factors or outcomes. For example, if the factor being investigated is a treatment in a prospective trial, then neither patients, their physicians, nor those assessing their medical condition should know which treatment any particular patient is or has been receiving. It is not sufficient to argue that any individual patient cannot know the treatment identity because they only see their own medication and cannot compare it with medication given to other patients. If this were the case, a study comparing red tablets with green capsules could be described as patient blind. It is true that a patient given red tablets would not know that other patients may be given green capsules but this would not be sufficient to describe a study as blinded. As another example, if the factor being investigated is exposure to an environmental toxin in a **case–control study**, then whether a subject is a case or a control should be unknown to those who are collecting the data on exposure.

Reasons for Blinding

Patient Bias

Blinding patients to which treatment they have received in a clinical trial is particularly important when many of the parameters are subjective both in patient response and with more formal clinical assessment of response. One reason for this is described as the "placebo effect". It is a rather broad and ill-defined term encompassing a variety of responses that occur when patients are being "treated" with inactive placebo medication that, theoretically, should have no therapeutic impact. Use of the term is so broad that it covers psychological responses that should be expected as well as physical ones that should not. Various studies have described how placebos can give both positive (therapeutic benefit) and negative (adverse events) effects. Moscucci et al. [13] describe how, in an obesity trial of active medication (phenylpropanolamine) vs. placebo, some of the patients randomized to placebo indicated that they had improved control of their appetite. One area prone to such effects is antiemetic (control of nausea and vomiting) studies where the main outcome can be strongly influenced by psychological processes. Another obvious example is trials in **psychiatry**. Even in therapeutic areas where assessments are more objective, Schulz et al. [18] have reported that trials that are not double-blinded are more likely than blinded studies to show benefit (falsely) for the active intervention group.

Physician Bias in Clinical Management

Where possible, the managing physician should be blinded to prevent any possible bias in patient management. For example, the decision to withdraw patients from a study could be influenced by knowledge of which treatment they are receiving. If there has been a poor response and it is known that the patient has been assigned to placebo, then there could be a greater tendency to withdraw the patient. If adverse events are present and it is known that the patient has been assigned to active therapy, then a similar increased tendency to withdraw the patient may exist.

Another aspect of patient management that could be influenced by knowledge of which treatment a patient is receiving is the decision regarding dose adjustment. Similarly, a general problem exists in the comparison of complementary (or **"alternative") medicine** with other complementary medicines or with "conventional" medicine. Anthony [2] highlights a fundamental problem in this area of research, that often complementary medicine, properly administered, is designed individually for each patient, so that blinding the managing physician is impossible. In such cases it is best to ensure that the person assessing the response is blinded.

Bias in Evaluation

Whenever there is subjective judgment in evaluating clinical response, it is preferable to blind the person making the evaluation. In the field of periodontal trials, Imrey & Chilton [9] describe the need for blinding, because blinded evaluation greatly increases credibility and usually only marginally increases costs.

In guidelines for trials in scleroderma, White et al. [22] briefly but firmly state the need for blinding of clinical evaluations. They state that "assessments of global functioning and functional disability cannot be assured to be unbiased". Their terminology (the words *"cannot be assured"*) is pertinent since unblinded assessments do not necessarily lead to biased assessments, but the lack of blinding means that a lack of **bias** cannot be assumed: credibility and reliability are both compromised.

Bias in Data Management

Even away from the patient and clinic environment, bias is still possible and is a potentially important source of error within the various stages of **data management**. Stages include coding of adverse events, interpretation of ambiguous handwriting, and decisions on whether or not to query unlikely (but possibly correct) data values. Beyond the initial aspects of data management, bias can be introduced in the choice of statistical methods that are used or presented (or even in the order in which they are presented) and, indeed, in the choice of style and content of presentation of the data, regardless of any formal statistical methodology that may be applied. For these reasons, some statisticians consider that every detail of data presentation and analysis should be specified before the database is unblinded. Others disagree and argue that the most effective presentation and analysis requires complete knowledge and understanding of the data. This, necessarily, includes knowledge of the treatment groups.

Bias in Decisions Regarding Stopping a Trial

If interim analyses are planned and a data monitoring committee (*see* **Data and Safety Monitoring**) is to review accumulating trial results with a view to recommending continuing or stopping a study, Rockhold & Enas [15] suggest that the committee be presented with results in the form of "treatment A" and "treatment B" without revealing which is which. If more than one set of results is presented to the monitoring committee, some might suggest that the labels A and B are not necessarily kept the same across all sets of results so as to try to prevent accumulating evidence across a variety of efficacy and safety parameters from giving clues as to the treatment identity. A completely opposite view is taken by others, who argue that the welfare of the patients is more important, and that the data monitoring committee should be unblinded so as to make properly informed decisions.

Whichever way the data monitoring committee is presented with the data, it is important that other staff (particularly investigators) are still kept blind. In particular, the blinding should be maintained for each patient until all patients have completed the study: then the blind can be broken for all patients. This is often not liked in cases in which the first patient may finish the study several years before the last patient: still, the first patient's treatment allocation should not be revealed until all patients have completed the study. There are many reasons to justify this stance. If the blind were broken as each patient completed the study, then the response to treatment (the size of the treatment effect) could begin to emerge; many informal interim analyses might be carried out; some investigators might decide not to continue in the study based on their opinions of early results; some investigators may (consciously or subconsciously) change the type of patient they recruit to the study, and so on.

Bias in Treatment Allocation

Blinding is important in allocating treatments to trial subjects (*see* **Randomized Treatment Assignment**) since **randomization** alone will not necessarily ensure that different treatment groups are balanced at baseline. Spriet & Dupin-Spriet [20] illustrate this, showing how randomization may fail if blinding is not in place, and give suggestions for how to overcome the problem. Schemes such as alternate allocation have been suggested as adequate alternatives to true randomization, but the nonblinded (and therefore open to bias) mechanism of such a method argues against its use. A distinction has sometimes been drawn between *concealment* up to the point of allocation of treatment and *blinding* (or masking) for

steps taken to conceal group identity after allocation [17]. This is a helpful distinction, particularly in single-blind studies: total concealment may be possible, even if total blinding is not.

Bias in Reviewing Studies

In reviewing studies (particularly if the objective is to carry out a formal **meta-analysis**), the procedures for abstracting data should be highly standardized to help to eliminate bias. If the abstractor is to be blinded to, for example, the journal of publication or to the results when abstracting data on the methods, the method for ensuring blinding should be agreed beforehand and described in a written protocol. In a different context, Jadad et al. [10] conducted a randomized controlled study to investigate the impact of blinding on peer-review. They found that blinded assessments produced consistently lower (worse) and less variable ratings than unblinded assessments (*see* **Statistical Review for Medical Journals**).

Bias in Epidemiology

In data collection, Rose et al. [16] were concerned about the potential for bias in assessing blood pressure in case–control studies, where the assessor may know if a patient is a "case" or a "control". Blood pressure has a high measurement error due to factors including systematic observer bias, terminal digit preference and observer preference. To overcome these, they describe a modification of the standard sphygmomanometer that has a "random zero". The random zero sphygmomanometer is now standard in epidemiologic studies involving blood pressure measurements. Generally speaking, when exposure assessments have some subjective element, it seems sensible to use blinded assessment in case–control studies (*see* **Bias in Case–Control Studies**).

Levels of Blinding

The term "double-blinding" is widely accepted and understood to mean that both the patients and the treating physicians are unaware of which treatment is being used. Here we identify four levels of blinding and describe each. The terminology for all but double-blind is not standard, and in these cases, additional detail should be provided to explain what is meant in any particular setting.

Single-Blind

Many authors describe this as meaning that the patient is unaware of which treatment he or she is receiving. However, we may also use the term single-blind when the treating physician is unaware of the treatment assignment. This can happen if the study medications are different in appearance and it is arranged that the patient collects the medication from a pharmacy rather than from the treating physician. Neither interpretation of single-blind is wrong and for clarity the term ought, generally, to be stated as "single (patient) blind" or "single (investigator) blind".

Double-Blind

This is a very common term and is widely accepted to mean that the patient and the investigator are each blinded to the treatment allocation. The investigator is generally assumed to be both the provider (or at least the prescriber) of the medication and the assessor of its effect. When this is not the case, further levels of blinding as described below may be appropriate.

Triple-Blind

This is a less common term but its use is increasing. It is generally accepted to mean that, in addition to the patient and investigator each being blinded, those handling the data are also kept blinded until all decisions about data validity and classification have been made. Marginal decisions regarding patient eligibility or assessment are then made (and are seen to be made), independently of knowing the treatment assignment.

It is, of course, possible that the clinical aspects of a study could be carried out single (patient or investigator)-blind or even unblinded but that the **data management** is performed blinded. Strictly speaking, the study should then be called double-blind or single-blind, but not in the context of the interpretation of those terms given above. This highlights the importance of specifying exactly who was blinded and at what stages in the study.

Quadruple-Blind

This is a very unusual term but Chalmers et al. [4] use it to describe the situation where the patient, the

treating physician, the physician (or other person) assessing the response, and the data handlers are all kept blinded. The additional blinding is relevant when the person assessing the clinical outcome is different from the one who administers the treatment. For example, an oncologist may request a radiologist to assess an X-ray, or a general physician may request a swab sample to be assessed by a microbiologist.

As suggested above, the large number of different parties who may be blinded in a study necessitates one clearly explaining what is meant in the description of blinding, rather than relying on a simple phrase such as "single-blind study".

Methods of Blinding

Placebos

Placebos are commonly used in comparative controlled clinical trials. They are chemically inert compounds that closely resemble the active compound in all physical characteristics such as taste, smell, and appearance. The term "placebo" is also used more broadly to include medical procedures that are still "inert" but that also resemble the true procedure. In such cases, the term "sham" is often used instead of placebo (see later in this Section). One instance where a compound is used that is not a true placebo (that is, it does have some active ingredient) but takes the place of a placebo is in studies of topical skin preparations. In these studies, the term "vehicle" is sometimes used. This vehicle is the base compound used as a delivery mechanism. The base compound might have therapeutic benefits such as soothing and moisturizing or it may have adverse effects such as stinging or irritation. By using the vehicle as a comparator, rather than a pure placebo, the true therapeutic effect of the pharmaceutic compound can be measured over and above that of the base (delivery) compound.

Placebos for Comparison of Active Drugs

Placebos are not usually used when comparing two active compounds. However, it may be difficult to manufacture two active compounds so that they appear and taste identical. Prozac® (fluoxetine hydrochloride) and Haldol® (haloperidol) may, for example, be compared for their relative efficacy in treating obsessive compulsive disorder. The former is normally presented in a green and white enteric coated capsule; the latter is a pale blue tablet. The difference in appearance is the first and perhaps most frequent problem faced in blinding. There are two common approaches to solving the problem.

The first is to disguise the presentation of one or both medications. It may be possible to fit the Haldol tablets (either whole or dissected) into an enteric coating so that they resemble capsules of Prozac. An immediate problem is that the efficacy of "disguised" Haldol may have to be compared with that of "true" Haldol to demonstrate that no harmful (or beneficial) effect has been introduced by changing its presentation. Studies to confirm that the changed presentation of a medication has not affected its potency are known as **bioequivalence** studies. These have their own special blinding problems and are discussed later.

The second approach, often easier, is to use a "double-dummy" method whereby each patient takes both a tablet and a capsule. Patients assigned Haldol tablets also receive a placebo capsule that looks and tastes like a Prozac capsule; patients assigned Prozac capsules also receive a placebo tablet that looks and tastes like a Haldol tablet. Every patient, therefore, receives both capsules and tablets but no patient knows whether they are receiving active tablets or active capsules.

Sham Procedures

The blinding of physical treatments is often difficult. Deyo et al. [6] give an example of treating chronic low back pain using transcutaneous electrical nerve stimulation (TENS), and using "dummy" TENS units. This appeared to have been less successful for blinding the patient than for blinding the investigators. The study evaluated 125 randomized patients. Clinicians guessed the allocation correctly in 61% of cases (only just better than the chance value of 50%); but patients randomized to TENS all guessed that their units were functioning, while most (84%) patients randomized to dummy TENS guessed that their units were not functioning.

Also difficult is the blinding of surgical procedures, particularly the blinded comparison of surgical vs. nonsurgical procedures. The ethics of sham operations are clearly questionable and could rarely, if ever, be justified. It is worth noting, however, that

sham surgery has been used as a placebo and was reported by Cobb et al. [5]. The procedure was for internal mammary artery ligation to treat angina pectoris, and patients were randomized to the full surgical procedure or to a sham surgical procedure that ended at the point immediately after making the initial incision. Patients were informed that they were taking part in an evaluation of the surgical procedure but were not informed of its double-blind nature. Randomization was after the incision had been made (that is, as late as possible), and both groups were (therefore!) subjected to anesthesia (although it was a local – not general – anesthetic). In all respects, therefore, patients were blinded to the randomization scheme. The study was small (only 17 patients) and concluded no effect of ligation over that of the sham operation in terms of exercise tolerance.

It may be less difficult to blind patients in trials of alternative surgical procedures, and blinded assessment of the patient could also be arranged. Blinding surgeons is clearly impossible, and conflicting results of similar trials comparing early vs. delayed surgery for acute cholecystitis, reported by van der Linden & Sunzel [21] and Lahtinen et al. [12], have been attributed to the lack of blinding of the surgeons.

Blinding of Evaluators

We have already mentioned under "Levels of Blinding" that, when it is not possible to blind the treating physician, a blinded evaluator may be used to record patients' responses to treatment. Such procedures are particularly applicable when the assessment has a subjective element and when the investigator is likely to recall the treatment given to the patient. Examples include: comparing alternative surgical procedures, since a surgeon often recalls which patients received which procedure; comparing alternative counseling procedures for patients suffering from post-traumatic shock; and comparing alternative instructional programs for patient self-care (in dental hygiene, for example).

Difficulties of Blinding

Drawbacks of Blinding

The advantages of blinding (generally relating to the "fairness" or "lack of bias" of patient assessments) are important, but blinding is not without disadvantages. Drawbacks include: the practical difficulty of formulating placebos (see the example in the section on "Placebos for Comparison of Active Drugs"); the dangers associated with emergency situations in which someone, possibly having no connection with the trial, may need to know which treatment a patient is taking; and the ethical problems of assigning (some) patients placebo while they remain ignorant of whether they are receiving the experimental or the inert compound. Allen [1] argues that "double-blinding of drug trials to prevent bias deprives physicians of information they need in order to comply with their duty to treat patients and do them no harm", and claims that a physician cannot properly treat a patient without knowing what treatment the patient is already receiving (*see* **Ethics of Randomized Trials**). However, see below the Section entitled "Other Issues" regarding arrangements for breaking the blinding when clinically necessary.

Ineffectiveness

Reference has already been made to some assessment of how well blinding actually worked in specific studies. Ney [14] strongly challenges the effectiveness of blinding. He reports that in a review of clinical trial reports published over a 10-year period, in fewer than 5% of studies described as double-blind was the blinding actually checked. He states that, "In most instances where they were checked they were found not to be blind, and in many instances when they were not checked, they could not have been blind".

Other authors have also challenged the effectiveness of blinding. Greenberg & Fisher [7], for example, discuss trials of antidepressants. Many antidepressants induce dry mouth or constipation and when compared to placebo, the question of which patients are on which treatment arm may not be difficult to answer. They draw the extreme (and perhaps debatable) conclusion that "in the main, all past studies of antidepressant effectiveness are open to question". Known side-effect profiles of other drugs in other therapeutic areas may create similar problems.

The difficulty of genuinely matching treatments in trials intended to be double-blind is described in a study by Hill et al. [8], who used a panel of four observers, each to assess 22 pairs of agents that had been used in double-blind trials. In only five pairs was the match described as "excellent", and in seven there were obvious differences that were detectable

by all four observers. Color and taste were the most frequent causes of mismatching.

Ironically, it may be most difficult to maintain blinding in comparative trials that show the largest clinical effects. Even if that is true, the possibility of the blind being broken during the study does not necessarily justify abandoning plans to blind the study at the outset.

Other types of ineffective blinding have also been described. Senn [19] considers comparing two transdermal patches, A and B. The patches are different in appearance so that placebo patches for each (PA for placebo A and PB for placebo B, respectively) need to be prepared. A three-arm double-dummy study may be envisaged with randomization to A + PB or B + PA or PA + PB. However, to circumvent the practical difficulty of patients wearing two patches, an alternative four-arm randomization could be to A or B or PA or PB. Now, although a patient (or observer) will not know if the patch A or PA is active or placebo, they will know that they are not receiving medication B. Similarly, patients using patches B or PB will know they have not been randomized to A. Thus, this scheme will not necessarily allow an unbiased comparison of A with B.

James et al. [11] have approached the assessment of the effectiveness of blinding from a methodologic point of view and arrive at an index of success of blinding ranging from 0 (complete lack of blinding) to 1 (complete blinding). Subjects are asked to guess whether the treatment was active or placebo. Unlike the common **kappa** statistic, their method incorporates the "don't knows" as well as the correct and incorrect guesses. The "don't knows" are, of course, the ideal response, implying complete success of the blinding. Like the kappa statistic, their method allows assessment of whether the knowledge of the treatment in any given study is significantly greater than chance. Even if "statistical significance" is demonstrated, it is not always easy to interpret the meaning of the index's value; for example, it is unclear if a value of 0.7, say, represents a good or a poor level of blinding.

Other Issues

Arrangements for Breaking Blinding

It is necessary to make arrangements for breaking the blind for any particular patient. When a patient experiences an adverse event that may be medication-related, or a patient requires medication for a concurrent illness where drug interaction is possible, the blind may need to be broken. Occasionally the situation may constitute an emergency. Trials in hospitalized patients generally pose fewer problems since the hospital's own pharmacy is likely to be dispensing all medication and would itself hold a master copy of the randomization codes. In an outpatient setting there is a greater danger that immediate access to the randomization codes might not be possible. In such cases, all patients participating in the trial might carry an identifying card with them that gives details of the trial they are in, the group organizing it (whether that be a hospital, academic institution, or a pharmaceutical company), and an emergency 24-hour telephone number. An alternative arrangement is to provide a tear-off label on the patient's medication that reveals details of the true identity of the medication (and further contact details). This ensures that immediate identification of medication is possible but also allows patients (or others) to break the code for nonessential reasons.

Regulatory Issues

Guidelines within the regulated pharmaceutical industry clearly describe the requirement for blinding. The US **Food and Drug Administration (FDA)** requires that the specific procedures for blinding should be included in clinical study reports, including a description of the labeling on bottles, the appearance, shape, smell, and taste of different medications, and the circumstances in which the blind may be broken (and by whom). They comment on what special precautions should be taken if blinding cannot be achieved and require justification from the sponsor if blinding is deemed unnecessary. The International Conference on Harmonization (ICH) mirrors quite closely the comments of the FDA. In Europe, the Committee on Proprietary Medicinal Products (CPMP) makes similar comments but also addresses some different aspects of the problem. They refer to the possible influence of the "attitudes of patients to the treatments". By this they mean that, although double-blinding is the ideal approach, if this involves double dummy methods, then the administration scheme may be sufficiently different from clinical practice to influence patient motivation and compliance. In such a case, double-blinding

may not necessarily be optimal and some compromise between the level of blinding and similarity of the dosage regimen to be used in routine practice may be preferable (*see* **Drug Approval and Regulation**).

Reporting Blinding

Bailar & Mosteller [3] suggest that a "statement that a study was 'blind' or 'double-blind' is rarely enough". Details of the methods of blinding should be given along with an assessment of the effectiveness (or otherwise) of the blinding. Chalmers et al. [4] have reported on how to assess the quality of clinical trials and consider that blinding ("quadruple-blinding", as described earlier) is the most important feature. "It is not sufficient", they state, "to assume that a double-blind procedure is effective." They propose that the effectiveness of the blinding should always be investigated and reported.

Equivalence Trials

Blinding fails to protect against bias in trials aiming to test whether two treatments are equivalent (*see* **Equivalence Trials**). The same problem applies to a study that fails to demonstrate a treatment difference and, retrospectively, consideration moves to whether the treatments could be considered (reliably) to have a similar therapeutic effect. The problem is that blinding is intended to avoid a false conclusion that one treatment is superior to the other when in fact they are equivalent. However, it does not adequately protect against falsely concluding that the two treatments are equivalent when in fact one is superior. This is because such bias can be introduced by factors such as treatment **noncompliance** and **measurement error** even when they apply equally to the two treatment groups.

Psychological Resistance

The objective of blinding is to contribute to the elimination of bias that may be introduced intentionally or unintentionally by the many individuals involved in a research project. Some take the view that they need not be blinded. Physicians treating a patient may claim that their assessment of the disease is not influenced by knowing which treatment a patient has received; patients may feel that their reactions to the treatment are not colored by knowledge of which treatment they have been given. Insistence on blinding may be seen as casting doubt on the integrity of these individuals. This attitude sometimes presents an obstacle. Blinding makes it more difficult to bias results and helps to ensure the credibility of the results of a study. For this reason, efforts to overcome psychological resistance to blinding are worthwhile.

SIMON J. DAY

Bliss, Chester Ittner

Born: 1899, in Springfield, Ohio.
Died: 1979.

Photograph supplied by Yale University Archives

Chester Bliss studied entomology at Ohio State University, earning a B.A. in 1921. He continued these studies at Columbia University where he was awarded an M.A. in 1922 and a Ph.D. in 1926. Upon his graduation, he took a position as an entomologist in the Department of Agriculture, which he held until 1933 when his work was cut short by the depression. Moving to London, he attended lectures given by **R.A. Fisher** and collaborated with him on research over the next two years [6]. It was during this period that he did much of his work on probit analysis (*see* **Quantal Response Models**).

From London, he took a position at the Institute of Plant Protection in Leningrad in 1936. In 1938, he returned to the US, where he became a biometrician at the Connecticut Agricultural Experiment Station in New Haven, Connecticut until he retired in 1971. In 1942, Dr Bliss was appointed Lecturer at Yale University, where he taught and collaborated on research projects throughout his career [6].

Dr Bliss was convinced of the value of sound statistical methods in biology, and he devoted his career to developing practical approaches to data analysis, and making these methods available to scientists in the field. His research focused on estimating the potency of biological agents (*see* **Biological Assay, Overview**), his best known being contributions to the development of probit analysis. He played a major role in founding the **International Biometric Society**, and was appointed as the principal statistical contributor to the *U.S. Pharmacopeia*.

Chester Bliss' work on the use of the probability integral **transformation**, or probit, was done in collaboration with R.A. Fisher. The response at a given dose is the proportion of observations in which the specified outcome was observed. To linearize the sigmoid curve that is often observed for such data, the proportion was transformed using the inverse of the standard normal distribution function. As this transformation is undefined for 0 or 1, their first approach was to eliminate these observations from the analysis. This troubled Bliss a great deal, because these were, after all, valid observations, so one would then be ignoring some of the data. Bliss' persistence lead Fisher to derive the full **maximum likelihood** solution for probit analysis. A hallmark of Bliss' work was in making these methods accessible to biologists, and, in his books, examples of these techniques were described in painstaking detail, so that they could be readily followed by those in the field.

While the **American Statistical Association** had formed a Biometrics Section in 1938, Dr Bliss was appointed to a committee in 1945 to report on the merits of a separate American Biometric Society. However, following the committee's report in 1946, it was decided to postpone a decision on the formation of a separate society. Bliss was once again galvanized to press for a separate society devoted to statistics in biology when the program for the fall 1947 meeting of the **International Statistical Institute** in Washington, DC, appeared and was found to contain virtually no biological applications. On short notice, organizational and financial arrangements were made for the first International Biometric Conference at the Marine Biological Laboratory in Woods Hole, Massachusetts, on September 5–6, 1947. Dr Bliss served from 1948 to 1955 as the first Secretary for the Biometric Society, and was its Treasurer from 1951 to 1956. Together with **Gertrude Cox**, the editor of ***Biometrics***, the society was nurtured and grew into a vital organization with a diverse worldwide membership.

The editors of the *U.S. Pharmacopeia* recognized that accurate estimates of potency for biological agents required not only careful laboratory work, but also sound methods for analyzing the data. For many years, Dr Bliss provided advice on the methods of data analysis that should be used for the various agents, bringing his training in biology, as well as his insights into the application of statistical methods, to this standard reference.

During his career, he wrote over 130 articles, most of which dealt with various aspects of bioassay. These included work on methods for analyzing vitamins, analgesics, insulin, digitalis, penicillin, thiamin, radiation, parathyroid extract, adrenal cortex extract, cardiac glucosides, insecticides, and anthelmintics [1, 2]. In 1952 he published a book entitled *The Statistics of Bioassay, With Special Reference to the Vitamins* [3], which was to be followed by a three-volume work on *Statistics in Biology* [4, 5]. The first two volumes appeared in 1967 and 1970, respectively, and he was working on the third volume at the time of his death. His style was always meticulous and clear so that it could be followed readily by nonmathematicians.

In recognition of his contributions to biostatistics, he was elected an honorary life member of the Biometric Society, an Honorary Fellow of the **Royal Statistical Society**, and a Fellow of the Institute of Mathematical Statistics and of the American Statistical Association.

THEODORE R. HOLFORD & C. WHITE

Blocking

Blocking is a term describing strategies that are used in the design of experiments (*see* **Experimental Design**) and of **sample surveys**. It is also used to describe certain statistical methods that are used in the statistical analysis of data that can arise from **observational studies** as well as experimental studies (*see* **Clinical Trials, Overview**).

In the planning of experimental studies, the term *blocking* refers to the strategy of taking into consideration characteristics of the experimental units in the assignment of experimental treatments to units. The overall objectives of this strategy are to ensure that the assignment would result in minimization of **biases** caused by relationships between the outcome or dependent variable and the properties of the experimental units. For example, in a randomized trial of three treatments for carcinoma of the breast, it is possible that premenopausal women might differ from postmenopausal women in their response to these therapies. To ensure that each treatment has the same (or close to the same) proportion of premenopausal and postmenopausal women, one might perform **randomization** separately by menopausal status (i.e. *block* by menopausal status and randomize separately within each block). The various specific methods of blocking are discussed elsewhere (*see* **Balanced Incomplete Block Designs**; **Lattice Designs**; **Randomized Complete Block Designs**).

In the design of sample surveys, the blocks are generally called *strata*, and the objective of *blocking* in this scenario is to allocate the sample to strata in such a way that the resulting estimates have low **standard errors** under the cost constraints imposed on the survey (*see* **Stratified Sampling**; **Stratified Sampling, Allocation in**).

In analysis of data from observational studies, *blocking* is an analysis strategy used to control for **confounding** by variables that are measured on the **nominal** or ordinal scale, or by variables grouped on the basis of some variable (*see* **Stratification**). Examples of techniques of stratified analysis for quantitative dependent variables include two or higher way **analysis of variance**, and for categorical dependent variables include **contingency table** methods such as the Cochran–**Mantel–Haenszel** class of tests.

PAUL S. LEVY

Blood Groups

The term *blood groups* encompasses the products of **genes** expressed as molecules on the surface of erythrocytes in humans. Beginning in 1901 with Landsteiner's discovery of the ABO blood group system, these markers have been the subject of intense interest, primarily because of their clinical importance in the transfusion of blood, but secondarily because of their usefulness as **genetic markers**. The major impetus for study, of course, was the need to match for some of these groups in the transfusion of blood products. Included in the classification of major blood groups are the ABO, Rhesus(Rh), MNSs, P, Kell, Duffy, Kidd, Lutheran, and Lewis groups. All blood units transfused must be matched for the A and B antigens of the ABO system because of naturally occurring antibodies against them. All units are also matched for the D antigen of the Rh system because of the extreme immunogenicity of that antigen.

The chemical nature of these molecules has been worked out during the last 20 years with the Rh antigens being characterized only with the tools of molecular biology. Since the A and B substances of the ABO group appear in body secretions, such as saliva in some persons, as well as on the surface of the red cell, these antigens were among the first to be well characterized chemically. The two genes in the system (A and B) control the production of enzymes that place carbohydrates on specific sites of a precursor molecule, which itself is under genetic control (the H gene). The O gene produces no enzyme. Inheritance in the ABO system follows a simple co-dominant pattern for A and B with O being a true recessive. The Rh system, originally thought to be controlled by one gene producing three factors (or alternatively by three closely linked genes) is now known to be made up of two distinct proteins controlled by two genes. One gene controls the presence or absence of factor D and the second controls a molecule that at the serological level displays two factors C/c and E/e. The presence of factor D produces the familiar Rh positive when tested serologically. The problem with characterizing the Rh molecules was the absence of any secreted form and the intimate relationship between the Rh molecules and the cell membrane (see [1] for more details on systems, methods, and biochemistry).

Before the advent of molecular biology, the ease of the techniques used to detect blood group antigens (simple agglutination or agglutination augmented with an antiglobulin reagent) made the red cell blood groups the most important tools in the study of human **population genetics**. Blood groups could be studied both in families and populations and their genetics (in most cases) followed **Mendel's laws**. Population studies involving blood groups allowed the characterization of both historical movements of populations and present-day population isolates. Examples of the former are the pattern of blood group B in populations of Eastern Europe reminiscent of the Mongol invasions of the early post-Roman world. Examples of the latter might be the characterization of pockets of Rh negative populations such as the Basques of northern Spain. (For more information see [2].)

Although their use in population genetics is being partially supplanted by molecular techniques, blood groups remain of paramount importance in the provision of blood products for transfusion.

Bonferroni Inequalities and Intervals

Let $A_1, A_2, \ldots, A_n$ be any random events. Boole's inequality, or the first-order Bonferroni inequality, states that the probability that at least one of these events occurs is less than or equal to the sum of the probabilities of the individual events:

$$\Pr\left(\bigcup_{i=1}^{n} A_i\right) \leq \sum_{i=1}^{n} \Pr(A_i). \tag{1}$$

The majority of statistical applications of (1), commonly referred to as Bonferroni's inequality, deal with testing of multiple hypotheses (*see* **Hypothesis Testing**) and related **simultaneous confidence intervals** (*see* **Multiple Comparisons**; **Simultaneous Inference**). Suppose that n hypotheses are tested and that all of the hypothesis are true: the *complete* null hypothesis. If the ith hypothesis is tested at the α_i level of significance (*see* **Level of a Test**), where

$$\alpha_1 + \alpha_2 + \cdots + \alpha_n = \alpha, \tag{2}$$

then it follows from (1) that the probability of falsely rejecting at least one of the null hypotheses is at most α. The most common choice of α_i are α/n.

Similarly, the Bonferroni technique yields simultaneous confidence intervals for a set of n parameters by adding and subtracting the required estimated standard error multiplied by the $\alpha_i/2$ percentile point of an appropriate distribution from the point estimates of interest, where (2) holds. In a related encyclopedia article, Alt [2] presents formulas for the most commonly used Bonferroni confidence intervals.

In addition to always yielding simultaneous confidence intervals, it is also particularly easy to obtain adjusted simultaneous ***P* values** when we apply the easily understood Bonferroni technique [76].

In the multiple comparison setting where the **analysis of variance** (ANOVA) is used, methods superior to the Bonferroni method are often available. For example, Tukey's multiple comparison procedure is superior to the Bonferroni procedure for comparing all pairwise means in a one way ANOVA [40, 47]. The Bonferroni method of multiple comparisons is often the method of choice when a small subset of all possible comparisons is of interest [20], in settings where **covariate** adjustments are employed [20, 49], in situations in which distributions other than the **multivariate normal** or **multivariate *t*** are employed [59], or in discrete data settings such as obtaining simultaneous confidence intervals for **multinomial** proportions [4].

The major advantage of the Bonferroni procedure is its generality and flexibility. In the multiple endpoint setting it can be employed when some outcomes are quantitative and others are qualitative, unlike most multivariate techniques. In the multiple comparison with **multiple endpoints** setting, the Bonferroni technique can be applied to control for the multiple endpoints in conjunction with any technique to control for the multiple comparisons for each endpoint [49]. Consequently, corrections are made for the multiplicity of endpoints without making assumptions about the joint distributions of the outcomes.

The Bonferroni technique is also employed in a variety of research areas, such as spatial correlations [28], **nonparametric regression** [19], simultaneous confidence intervals for survival probabilities [1] (*see* **Survival Analysis, Overview**), obtaining optimal cutpoints [29], and detecting outliers in growth curve modeling [9] (*see* **Nonlinear Growth Curve**).

Textbooks by Neter et al. [49] and Fleiss [20] present an overview of the uses of Bonferroni's inequality in basic statistical applications. More detailed applications in multiple comparison settings are provided in texts by Hochberg & Tamhane [32], Hsu [40], and Miller [47]. The first two references are good sources for stepwise multiple testing procedures based on Bonferroni's inequality. Books by Morrison [48] and Srivastava & Carter [66] present applications of Bonferroni's inequality in **multivariate analysis**.

Multiple Comparisons for a Single Outcome

A competitor to the Bonferroni technique in the general linear model is the F projection method of Scheffé, the S-method. The S-method, which can be used to control the family-wise error rate for all possible contrasts, is useful in a hypothesis generating framework. Alt [2] presents more detail of the S-method. Both the Bonferroni and S-method

are applicable regardless of the correlation structure present. Applications in which both methods are applicable, in which more powerful methods do not exist, and in which it is valid to calculate both and use the least conservative include the **analysis of covariance** (ANCOVA) [20, 49], inverse prediction [49] (*see* **Calibration**), simultaneous **prediction** intervals [15, 47, 49], and simultaneous **tolerance intervals** [43, 47]. The S-method should be employed if some comparisons are not specified in advance. The Bonferroni method is generally less conservative than the S-method, unless a large number of comparisons is made [3, 16, 21]. However, when the error degrees of freedom is very low, the S-method is superior to the Bonferroni method [46].

Whenever the product inequality

$$\Pr\left(\bigcap_{i=1}^{n} A_i^c\right) \geq \prod_{i=1}^{n} \Pr(A_i^c) \tag{3}$$

is valid, then it follows from De Morgan's law that

$$\Pr\left(\bigcup_{i=1}^{n} A_i\right) \leq 1 - \prod_{i=1}^{n} \Pr(A_i^c). \tag{4}$$

Whenever (4) is satisfied it yields a less conservative correction for multiple testing problems than (1), although the improvement is slight for small values of α [16]. Sidak [63] showed that this is the case for two-sided significance tests based on the multivariate normal and multivariate t distribution, including ANOVA applications. Sidak [64] showed that the Studentized maximum modulus yields a slightly less conservative procedure than the product inequality which controls the **experiment-wise error rate** for two-sided testing problems in the ANOVA setting. This procedure, known as the GT2 method, is available in SAS.

Additional applications in which the Bonferroni technique of simultaneous inference is the method of choice include three-decision problems [11] and **randomization tests** [51].

Sverdrup [68, 69] and Hjort [30] show how the S-method and the Bonferroni method are applicable in simultaneous inference settings whenever **generalized maximum likelihood** estimators, which are asymptotically normally distributed with a **covariance matrix** which can be consistently estimated, are employed. They show that the Bonferroni method is usually superior to the S-method in such applications, which include categorical data.

The Bonferroni bound is accurate when the number of comparisons is not large, when the $\Pr(A_i)$ are less than 0.1, and when the positive dependence among the A_i is not large. The technique also works better for continuous data than for discrete data. Tarone [71] shows how the Bonferroni inequality can be modified to obtain less conservative corrections for multiple testing of **categorical data**.

Multiple Outcomes for Two Groups

A sequentially rejective procedure of Holm [34] controls the experiment-wise error rate and is less conservative than the classical Bonferroni procedure. With the Holm procedure, one first tests the outcome with the largest observed difference at the α/n significance level, the usual Bonferroni adjustment. If one fails to reject the largest observed difference at the α/n significance level, then one fails to reject each of the null hypotheses. Otherwise, the endpoint with the second largest observed difference is tested at the $\alpha/(n-1)$ significance level. Testing progresses from the strongest to the weakest observed difference and stops with failure to reject the remaining hypotheses as soon as one fails to reject a null hypothesis. At each stage the significance level is increased, with the ith significance test being performed at the $\alpha/(n-i+1)$ significance level. For example, if five outcomes are tested, then significance levels of $\alpha/5, \alpha/4, \alpha/3, \alpha/2$, and α are employed. Wright [76] and Troendle [72] argue for more widespread use of sequentially rejective procedures instead of the classical Bonferroni correction. An extensive literature is available on modifications of Holm's sequentially rejective procedure and applications of the procedure in new situations [6, 7, 14, 17, 18, 31, 33, 35, 56–58, 65].

When many hypotheses are tested, even sequentially rejective procedures are overly conservative. In such applications one may wish to control the false discovery rate [8], the expected proportion of falsely rejected hypotheses, rather than the experiment-wise error rate.

A competitor to Bonferroni adjustments, which takes advantage of the correlation between outcomes and accommodates distributional characteristics of the individual outcomes, is based on resampling and **Monte Carlo** simulation [74].

A single global test statistic based on all of the individual outcomes may also be employed [50, 53, 70] in place of the Bonferroni procedure (*see* **Multiple Endpoints, Multivariate Global Tests**).

Higher Order Bonferroni Inequalities and Extensions

We define the first- and second-order Bonferroni sums as

$$S_1 = \sum_{i=1}^{n} \Pr(A_i) \quad \text{and} \quad S_2 = \sum_{j=1}^{i-1} \sum_{i=2}^{n} \Pr(A_i \cap A_j).$$

The second- (first-)order Bonferroni bound is a lower (upper) bound to the probability of a union:

$$b_2 = S_1 - S_2 \leq \Pr\left(\bigcup_{i=1}^{n} A_i\right) \leq S_1 = b_1. \quad (5)$$

Higher-order Bonferroni bounds are obtained by alternately adding odd order Bonferroni sums and subtracting even order Bonferroni sums from lower order bounds. Even (odd) order Bonferroni bounds are lower (upper) bounds to the probability of a union. A related class of bounds, sometimes known as Galambos bounds [22], are obtained by taking linear combinations of Bonferroni sums. Unlike Bonferroni bounds, odd (even) order Galambos bounds are lower (upper) bounds.

Second or lower order bounds are often preferred in applications due to computational considerations. A useful second order lower bound [22], referred to as an extended Bonferroni-type bound by Galambos (23), is

$$\Pr\left(\bigcup_{i=1}^{n} A_i\right) \geq \frac{2S_1}{k} - \frac{2S_2}{[k(k-1)]} = b_G, \quad (6)$$

where $k = 2 + [2S_2/S_1]$ and $[y]$ indicates the largest integer less than y. When $k = 2$, $b_G = b_2$, the second-order Bonferroni bound, and otherwise $b_G > b_2$.

The most widely used second-order upper bound among a class of bounds based on Hunter's inequality [41] is

$$\Pr\left(\bigcup_{i=1}^{n} A_i\right) \leq S_1 - \sum_{i=2}^{n} \Pr(A_i \cap A_{i-1}). \quad (7)$$

Stoline [67] advocates the use of Hunter's inequality in ANOVA applications where there is a strong positive dependence structure. In most situations in which ANOVA is applied, the improvement of (7) over (1) is moderate [32, 40]. However, Bauer & Hackl [5] and Worsley [75] show that (7) is a substantial improvement over (1), which is very accurate, in many other situations with a strong degree of positive dependence.

When both upper and lower bounds of order 2 or less are required, then one should use (6) and (7) rather than (5), as in Bjornstad & Butler [10].

The bound given in (7) has been extended to higher-order bounds by Bolviken [12], Schwager [61], and Hoover [36]. This class of bounds exhibit nesting: the accuracy of the bounds increases as the order increases. Higher-order Bonferroni bounds are not nested [61]. When high-dimension multivariate probabilities need to be accurately estimated, these higher-order bounds are required. One such application involves scan statistics [24, 25, 42, 73]. If precision is required and computational considerations are not limiting, then higher order bounds produce substantially narrower simultaneous confidence intervals and simultaneous prediction intervals [26, 27, 55].

The bound in (6) has been extended to higher order bounds [2, 13, 22, 23, 54].

Improvements to higher-order bounds have been developed [37, 39, 44, 45, 62].

Bonferroni-type bounds are also available for the probability of exactly r or at least r of n events occurring [2, 13, 23, 38, 52, 60].

A comprehensive treatment of Bonferroni inequalities is presented in the book by Galambos [23].

T. COSTIGAN

Bonferroni, Carlo Emilio

Born: January 28, 1892, in Bergamo, Italy.
Died: August 18, 1960, in Firenze, Italy.

Carlo Emilio Bonferroni studied for the degree of *laurea* in Torino (Turin) under Peano and Segre, became *incaricato* (assistant professor) at the Turin Polytechnic, and then in 1923 took up the chair of financial mathematics at the Economics Institute in Bari. In 1933, he transferred to Firenze (Florence) where he held his chair until his death.

The obituary of him by Pagni [5] lists his works under three main headings: **actuarial** mathematics (16 articles, 1 book); **probability** and statistical mathematics (30, 1); and analysis, geometry, and rational mechanics (13, 0). His name is known in the statistical world for the contents of just two of these papers.

The two articles cover similar ground, but the 1935 article [3] is directed to a specific application, that is, life assurance, whereas the 1936 article [4] is more abstract. In the latter he developed formulas for the probability that of n events, exactly r, at least r, at least 1, at most r occur. He finally arrived at the sets of inequalities [his formulas (27) and (28)] which bear his name (*see* **Bonferroni Inequalities and Intervals**). As he noted, his formula (28) is a generalization of the inequality of Boole.

Apart from these, he also had interests in the foundations of probability. Two relevant articles are an inaugural lecture [2] and a more formal article published earlier, but written about the same time [1]. He developed a strongly frequentist view of probability (*see* **Inference**), denying that subjectivist views can even be the subject of mathematical probability. A quote from the lecture perhaps gives the flavor.

> A weight is determined directly by a balance. And a probability, how is that determined? What is, so to say, the probability balance? It is the study of frequencies which gives rise to a specific probability [2, p. 32].

After this point his statistical work moved on to work on relationship. He does not seem to have returned to probability again.

Bootstrap Method

Bootstrap methods are procedures for the empirical estimation or approximation of **sampling distributions** and their characteristics. Their primary use lies in the estimation of accuracy measures, such as bias and variance, for parameter estimators, and in construction of **confidence sets** or **hypothesis tests** for population parameters. They are applied in circumstances in which the form of the population from which the observed data have been drawn is unknown. They prove particularly useful where very limited sample data are available and traditional parametric modeling and analysis are difficult or unreliable.

Bootstrap methods are closely related to other data resampling methods of error assessment, such as the **jackknife**, but are more widely applicable and can provide more accurate inference, although they generally require more computation. An introduction to bootstrap methodology which stresses applications is given by Efron & Tibshirani [6], while detailed accounts of theory are given by Hall [9] and Shao & Tu [11]. A critical evaluation of the importance of bootstrap methods in different contexts is given by Young [13]. A concise summary of the methods is given by Efron & Tibshirani [5], while the revolution that they offer for statistical practice is discussed in very accessible terms by Diaconis & Efron [3].

The bootstrap principle was formalized by Efron [4]. It may be summarized for a general situation as follows. We have data $Y = (Y_1, \ldots, Y_n)$ (not necessarily independent and identically distributed) and a statistical model P under which the data are obtained. Usually, P can be described by the joint distribution of Y, or by some quantities that uniquely determine this joint distribution. Suppose that we wish to estimate the distribution of a **random variable** or "pivot" $R_n(Y; P)$, or some characteristic of that distribution. Then the data Y are used to estimate P by $\hat{P}$. Letting Y^* be a bootstrap data set generated from $\hat{P}$, then the bootstrap estimator of the distribution of $R_n(Y; P)$ is the conditional distribution of $R_n(Y^*; \hat{P})$, given Y. Where this conditional distribution is not expressible as an explicit function of Y, **simulation** by **Monte Carlo Methods** can be used to construct an approximation to the bootstrap estimator. The bootstrap can therefore be applied to any situation in which an underlying model P can be postulated and estimated and where one can sample from the estimated model $\hat{P}$.

Bootstrap methods are most fully developed for the case in which $Y_1, \ldots, Y_n$ are an independent and identically distributed (iid) sample. Extensions to independent, but not iid, data problems, such as **regression** problems, are often straightforward. Extensions to the dependent data setting are less well developed. In that context, care must be taken to account for the dependence structure in the data: some remarks are made below. We concentrate here mainly on the case of an iid sample.

The bootstrap may be applied parametrically or nonparametrically. With the former, we assume some parametric form for P, estimate any unknown parameters in its specification, typically by **maximum likelihood**, and so obtain $\hat{P}$. With the latter, we assume nothing about the form of P, and $\hat{P}$ is taken as the "empirical distribution function", usually denoted by F_n, of the given sample data. This distribution puts an equal point mass n^{-1} on each observed data point $Y_i, i = 1, \ldots, n$. Then a "bootstrap sample" $Y^* = (Y_1^*, \ldots, Y_n^*)$ is generated by independently sampling, with replacement, from the given data points (*see* **Sampling With and Without Replacement**).

We illustrate the *bootstrap* for the problem of variance estimation, adopting the notation of Shao & Tu [11]. Let $Y_1, \ldots, Y_n$ be iid from an (unknown) distribution F and let $T_n \equiv T_n(Y_1, \ldots, Y_n)$ be a given statistic, such as a parameter estimator. Then the variance of T_n is $\mathrm{var}_F(T_n) = \beta(F)$, say, a function of the unknown F.

If T_n is simple, then we can obtain an explicit expression for $\beta(F)$ as a function of unknown quantities, such as population **moments**, and then estimate $\mathrm{var}_F(T_n)$ by substituting estimates, constructed from the sample, for these unknowns. But, usually, this standard approach to variance estimation is too complicated to be useful. Bootstrap methods enable $\beta(F)$ to be estimated quite generally.

The bootstrap estimator of $\mathrm{var}_F(T_n)$ is

$$v_{\mathrm{BOOT}} = \mathrm{var}_*[T_n(Y_1^*, \ldots, Y_n^*)|Y_1, \ldots, Y_n],$$

where $\{Y_1^*, \ldots, Y_n^*\}$ is an iid sample from $\hat{F}$, an estimator of F, and $\mathrm{var}_*(\cdot|Y_1, \ldots, Y_n)$ denotes the conditional variance, given $Y_1, \ldots, Y_n$. An appealingly simple choice is to take $\hat{F} = F_n$.

In circumstances in which $\beta(F)$ is available explicitly, as a known function of F, the bootstrap

estimator v_{BOOT} is just a substitution estimator $\beta(\hat{F})$, and may be computed exactly and analytically. Usually $\beta(F)$ is not known explicitly, so we cannot evaluate v_{BOOT} exactly. However, in this case, Monte Carlo simulation can be used to approximate v_{BOOT} numerically. We repeatedly draw data samples from $\hat{F}$ and then use the sample variance of the values of T_n computed from these bootstrap samples as an approximation to v_{BOOT}.

We draw $\{Y_{1b}^*, \ldots, Y_{nb}^*\}, b = 1, \ldots, B$, for suitable B, independently from $\hat{F}$, conditional on $Y_1, \ldots, Y_n$; compute $T_{n,b}^* = T_n(Y_{1b}^*, \ldots, Y_{nb}^*)$ and approximate v_{BOOT} by the Monte Carlo approximation

$$v_{\mathrm{BOOT}}^{(B)} = \frac{1}{B}\sum_{b=1}^{B}\left(T_{n,b}^* - \frac{1}{B}\sum_{l=1}^{B}T_{n,l}^*\right)^2. \qquad (1)$$

Then $v_{\mathrm{BOOT}} = \lim_{B\to\infty} v_{\mathrm{BOOT}}^{(B)}$.

The traditional approach to variance estimation when $\beta(F)$ is unavailable explicitly is to first obtain an explicit asymptotic approximation to $\beta(F)$ and then estimate the unknown quantities in this asymptotic formula. Bootstrap methods therefore (i) avoid the need for analytic calculation and approximation, and (ii) avoid the errors associated with asymptotic approximation. This may lead to greater accuracy than is obtained from classical approaches to error assessment.

The standard error of T_n is $[\mathrm{var}_F(T_n)]^{1/2}$. Its bootstrap estimator is $\sqrt{v_{\mathrm{BOOT}}}$, approximated by $\sqrt{v_{\mathrm{BOOT}}^{(B)}}$ in circumstances in which Monte Carlo approximation is necessary.

Example 1

Efron & Tibshirani [6] present the following small data set, representing the survival times in days of seven mice receiving a new medical treatment after a test surgery: 94, 197, 16, 38, 99, 141, 23. Denote the observations by $Y_1, \ldots, Y_n$, where $n = 7$, so that $Y_1 = 94$, $Y_2 = 197$, and so on. Let the ordered observations be $Y_{(1)} < \cdots < Y_{(n)}$, so that $Y_{(1)} = 16$, $Y_{(2)} = 23$, and so on. We consider use of the bootstrap to estimate the standard error of three statistics: $T^{(1)} = n^{-1}\sum_{i=1}^{n} Y_i$, the mean survival time, the value of which is 86.9 for these data; $T^{(2)} = Y_{(4)}$, the median survival time, here equal to 94; and $T^{(3)} = (n-2)^{-1}\sum_{i=2}^{n-1} Y_{(i)}$, a trimmed mean (*see* **Trimming and Winsorization**), which takes the value 79.0. For the statistics $T^{(1)}$ and $T^{(2)}$ no Monte Carlo simulation is necessary, as the bootstrap variance estimator v_{BOOT} has an explicit expression in terms of $Y_1, \ldots, Y_n$. In the case of the mean $T^{(1)}$, for example, $v_{\mathrm{BOOT}} = \sum_{i=1}^{n}(Y_i - \overline{Y}_n)^2/n^2$, where $\overline{Y}_n = n^{-1}\sum_{i=1}^{n} Y_i \equiv T^{(1)}$. The bootstrap variance estimator for $T^{(2)}$ is given by a more complicated formula: see Efron & Tibshirani [6, Chapter 2]. The bootstrap standard error estimates are 23.36 and 37.83 for $T^{(1)}$ and $T^{(2)}$ respectively. In the case of $T^{(3)}$ the Monte Carlo approach must be used to obtain an approximation to v_{BOOT}. A series of B bootstrap samples are drawn from the given data and an approximation $v_{\mathrm{BOOT}}^{(B)}$ to v_{BOOT} computed from (1). A bootstrap sample is drawn by randomly sampling, with replacement, from the original datapoints $Y_1, \ldots, Y_n$. A typical bootstrap sample might be, for instance, $Y^* = (38,\ 99,\ 16,\ 99,\ 99,\ 16,\ 94)$. A bootstrap estimate of the standard error of $T^{(3)}$ computed from $B = 200$ randomly drawn bootstrap samples was 31.45. The statistic $T^{(3)}$ is therefore estimated to be more variable than the mean, but less variable than the median, for this situation.

Our description of the bootstrap variance and standard error estimators is easily generalized to other more complicated problems. Of particular importance is bootstrap distribution estimation. Often, an accuracy measure of a particular statistic T_n is a characteristic of the sampling distribution of T_n. If the bootstrap is used to estimate this sampling distribution, an estimator of the accuracy measure is provided by the corresponding characteristic of the estimated sampling distribution. Viewed in these terms, the bootstrap variance estimator v_{BOOT}, for example, is just the variance of a bootstrap estimator of the sampling distribution of T_n.

Consider the problem of estimating the sampling distribution of a pivot $R_n(Y_1, \ldots, Y_n; F)$:

$$H_F(x) = \Pr[R_n(Y_1, \ldots, Y_n; F) \le x], \qquad (2)$$

where $Y_1, \ldots, Y_n$ are iid from F.

The bootstrap estimator is

$$\begin{aligned} H_{\mathrm{BOOT}}(x) &\equiv H_{\hat{F}}(x) \\ &= \Pr_*[R_n(Y_1^*, \ldots, Y_n^*; \hat{F}) \le x | Y_1, \ldots, Y_n], \end{aligned}$$

where $Y_1^*, \ldots, Y_n^*$ are iid from $\hat{F}$ and $\Pr_*(\cdot|Y_1, \ldots, Y_n)$ denotes the probability under $\hat{F}$, conditional on $Y_1, \ldots, Y_n$. If $H_{\mathrm{BOOT}}(x)$ is not available explicitly as a function of $Y_1, \ldots, Y_n$, we may use a Monte Carlo approximation to $H_{\mathrm{BOOT}}(x)$:

$$H_{\mathrm{BOOT}}^{(B)}(x) = \frac{1}{B}\sum_{b=1}^{B} I[R_n(Y_{1b}^*, \ldots, Y_{nb}^*; \hat{F}) \le x],$$

where $\{Y_{1b}^*, \ldots, Y_{nb}^*\}, b = 1, \ldots, B$, are independent bootstrap samples from $\hat{F}$, and I is the indicator function.

For estimating the sampling distribution of T_n, we simply set $R_n(Y_1, \ldots, Y_n; F) = T_n$. When T_n is used to construct a confidence set for a parameter θ related to F, we might use $\sqrt{n}(T_n - \theta)$ or the studentized pivot $(T_n - \theta)/S_n$, where S_n is an estimator of the standard deviation of T_n. The confidence set may be derived from the sampling distribution of $R_n(Y_1, \ldots, Y_n; F) = \sqrt{n}(T_n - \theta)$ or $(T_n - \theta)/S_n$, as indicated below.

The classical approach to distribution estimation obtains a simple theoretical formula for $H_F(x)$, exact or approximate, and substitutes estimators for unknown quantities in the theoretical formula. When $R_n(Y_1, \ldots, Y_n; F) = \sqrt{n}(T_n - \theta)$, usually $H_F(x)$ can be approximated by $\Phi(x/\sigma)$, where Φ is the distribution function of N(0,1) and σ is an unknown parameter related to F. If $\hat{\sigma}$ is an estimator of σ, then we estimate $H_F(x)$ by $\Phi(x/\hat{\sigma})$. When $R_n(Y_1, \ldots, Y_n; F) = (T_n - \theta)/S_n$, $H_F(x)$ can often be approximated by $\Phi(x)$. But use of the bootstrap can provide a better (more accurate) approximation to $H_F(x)$ simply, without analytic calculation.

Example 2

As an example, consider the case in which $R_n(Y_1, \ldots, Y_n; F) = \overline{Y}_n - \mu$, where $\overline{Y}_n = n^{-1}\sum_{i=1}^n Y_i$ and $\mu = \mathrm{E}(Y_1)$. Then, with $\hat{F} = F_n$, the empirical distribution function of $Y_1, \ldots, Y_n$,

$$H_{\mathrm{BOOT}}(x) = \Pr_*(\overline{Y}_n^* - \overline{Y}_n \le x|Y_1, \ldots, Y_n),$$

where $\overline{Y}_n^* = n^{-1}\sum_{i=1}^n Y_i^*$ denotes the mean of an independent sample of size n drawn from F_n.

As an illustration, consider the case in which $n = 10$ and the given data $Y_1, Y_2, \ldots, Y_{10}$ are a random sample from the normal distribution N(0, 1). The objective is to use the bootstrap to estimate the sampling distribution of $R_n(Y_1, \ldots, Y_n; F) = \overline{Y}_n - \mu$, without assuming anything about the population from which the sample has been drawn. The true sampling distribution is actually N(0, 0.1), so we may check how the bootstrap performs. We consider the data set in which the Y_is are: -2.03, -0.58, 0.60, 0.45, 1.22, -0.69, 0.33, -1.69, 0.57, and -0.62. The bootstrap estimate of the sampling distribution was constructed from $B = 1000$ bootstrap samples, and is shown in Figure 1. Superimposing the (true) N(0, 0.1) normal curve on the bootstrap histogram shows that the bootstrap provides a very accurate estimate of the sampling distribution of $\overline{Y}_n - \mu$.

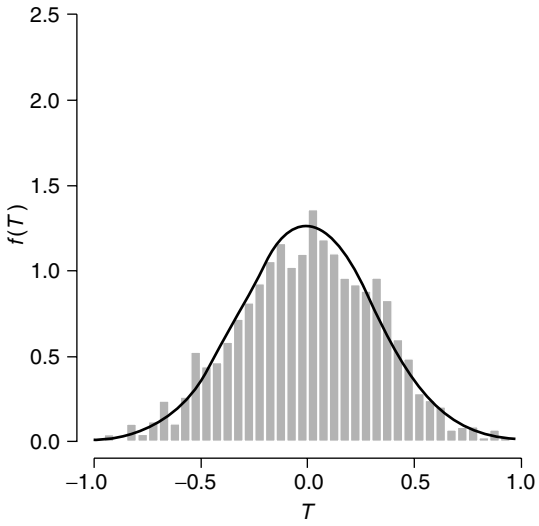

Figure 1 Bootstrap simulations, mean example

We now sketch other applications of the bootstrap. Further details are given by Shao & Tu [11, Chapter 1].

Bias Estimation

The bias of T_n as an estimator of θ is

$$\mathrm{bias}_F(T_n) = \int x \, \mathrm{d}H_F(x) - \theta,$$

with $H_F(x)$ given by (2), with $R_n = T_n$ (*see* **Unbiasedness**). The bootstrap bias estimator is obtained by substituting $\hat{F}$ and T_n for the unknown F and θ,

and is

$$b_{\mathrm{BOOT}} = \int x \, \mathrm{d}H_{\mathrm{BOOT}}(x) - T_n.$$

In situations in which the estimator b_{BOOT} has no explicit analytic form, it is approximated, using the Monte Carlo technique, by

$$b_{\mathrm{BOOT}}^{(B)} = \int x \, \mathrm{d}H_{\mathrm{BOOT}}^{(B)}(x) - T_n$$

$$= \frac{1}{B} \sum_{b=1}^{B} T_n(Y_{1b}^*, \ldots, Y_{nb}^*) - T_n.$$

Confidence Sets

Bootstrap confidence sets for an unknown parameter θ can be obtained using the percentiles of H_{BOOT} (or $H_{\mathrm{BOOT}}^{(B)}$).

As an illustration, let H_F be as given by (2), with $R_n(Y_1, \ldots, Y_n; F) = \hat{\theta}_n - \theta$, where $\hat{\theta}_n \equiv \hat{\theta}_n(Y_1, \ldots, Y_n)$ is an estimator of θ. An exact $1 - 2\alpha$ confidence interval for θ is

$$[\hat{\theta}_n - H_F^{-1}(1-\alpha), \hat{\theta}_n - H_F^{-1}(\alpha)].$$

Under repeated sampling of $Y_1, \ldots, Y_n$ from F, this interval contains the true value of θ with probability $1 - 2\alpha$. Approximating H_F by H_{BOOT} gives the bootstrap confidence interval for θ

$$[\hat{\theta}_n - H_{\mathrm{BOOT}}^{-1}(1-\alpha), \hat{\theta}_n - H_{\mathrm{BOOT}}^{-1}(\alpha)],$$

of *approximate* coverage $1 - 2\alpha$, under repeated sampling of $Y_1, \ldots, Y_n$ from F. This confidence interval is often called a "hybrid bootstrap" confidence interval [8]. A commonly used alternative is the "percentile bootstrap" confidence interval

$$[K_{\mathrm{BOOT}}^{-1}(\alpha), K_{\mathrm{BOOT}}^{-1}(1-\alpha)],$$

where $K_{\mathrm{BOOT}}(x)$ is the bootstrap estimator of the sampling distribution of the estimator $\hat{\theta}_n$.

Various alternative techniques for constructing bootstrap confidence sets, and their asymptotic properties, are described by Shao & Tu [11, Chapter 4].

Theoretical results on the performance of bootstrap methods are summarized by Shao & Tu [11]. In particular, it is known that for the iid case and bootstrap sampling from F_n, bootstrap estimators of the distributions of many commonly used regular statistics (such as means, functions of means, ***U*-statistics**, and sample **quantiles**) are consistent for the true sampling distributions and therefore give estimates that approach the correct values as the sample size n increases. Consistency of the bootstrap distribution estimator requires, roughly speaking, smoothness conditions that are almost the same as those required for asymptotic normality of the statistic, and certain further moment conditions. How good the bootstrap approximation is depends on the statistic to which it is applied. For nonstudentized statistics, the convergence rate of bootstrap estimators is the same as that for normal approximations. For a studentized statistic (*see* **Studentization**), the bootstrap estimator is better than a normal approximation. For the nonparametric bootstrap, consistency of bootstrap variance estimators requires stronger moment conditions than required for consistency of the bootstrap distribution estimator. Inconsistency of the bootstrap estimator in nonregular cases can often be rectified by the device of drawing bootstrap samples not of size n, but of size $m(n)$, which diverges to infinity more slowly than n. See [11, Chapter 3] for more detail of these asymptotic properties.

For confidence sets, of crucial importance is coverage accuracy. The coverage is the probability, under repeated sampling of Y from the underlying population, that the set contains the true value of the parameter of interest, and the confidence set is accurate if the actual coverage is close to the nominal desired coverage. Compared with confidence sets obtained by using the classical normal approximation, some sophisticated bootstrap confidence sets have greater theoretic accuracy, while simpler bootstrap confidence sets, such as the percentile and hybrid procedures, have the same accuracy, but are observed to work well in practice, and have the advantage of simplicity. See [8] and [11, Chapter 4].

The choice of the number of bootstrap samples B to be drawn in the Monte Carlo approach to the construction of bootstrap estimators is a delicate one. Shao & Tu [11, Section 5.4.1] consider the question in detail. As a rule of thumb, for moment estimators B should be between 50 and 200, while B should be considerable larger, of the order of at least 1000, for bootstrap distribution estimation and construction of confidence intervals. Other simulation approaches which reduce the computational costs

in bootstrap estimation are summarized by Shao & Tu [11, Chapter 5]: see also [9, Appendix I].

Procedures for bootstrap hypothesis testing are less well-developed than those for estimation and confidence set construction. The main point to be considered in the use of bootstrap procedures in this context is determination of the distribution from which bootstrap samples are drawn. The key principle is that bootstrap data should be generated from a distribution that satisfies the restrictions specified by the null hypothesis under test. Some of the methods used for determining this distribution are summarized by Shao & Tu [11, Section 4.5].

While our discussion so far has focused on the use of bootstrap methods with iid data, their implementation with non-iid data problems is often easy.

A key example concerns the simple **linear regression** model. Suppose that the data $Y_1, \ldots, Y_n$ are independent, of the form $Y_i = (Z_i, x_i)$, with the Z_i and x_i scalar. There are two representations of the model, and corresponding bootstrap procedures, depending on whether the x_i are considered random or fixed.

If the x_i are random, then the Y_i are iid from an unknown **bivariate distribution** P, and $\mathrm{E}(Z_i|x_i) = \beta x_i$, say. In this case P is estimated by the empirical distribution function of the Y_i. Bootstrap samples, used, for example, to estimate the sampling distribution of the **least squares** estimator $\hat{\beta}$, are drawn from this empirical distribution.

If the x_i are considered fixed, the model is that in which $Z_i = \beta x_i + \varepsilon_i$, with the ε_i iid from an unknown distribution F_ε with mean zero. Then F_ε can be estimated by the empirical distribution $\hat{F}_\varepsilon$ of the centered **residuals** $\tilde{\varepsilon}_i = \hat{\varepsilon}_i - n^{-1}\sum_{j=1}^{n} \hat{\varepsilon}_j$, where $\hat{\varepsilon}_j = Z_j - \hat{\beta} x_j$. Bootstrap data $Z_1^*, \ldots Z_n^*$ are generated from iid data $\varepsilon_1^*, \ldots, \varepsilon_n^*$ with distribution $\hat{F}_\varepsilon$ by setting $Z_i^* = \hat{\beta} x_i + \varepsilon_i^*$.

Shao & Tu [11, Chapters 7 and 8] consider application of bootstrap methods to linear models, including **generalized linear models, nonlinear regression**, and **Cox regression models**. The same authors detail use of bootstrap methods in estimation problems arising in nonparametric and multivariate models, such as **nonparametric regression** models. A further important application of bootstrap methods lies in the analysis of **sample surveys**; see [11, Chapter 6].

To illustrate some of the key points relevant to bootstrapping dependent data, consider again Example 2 above, but now suppose the simplest dependence structure in statistical applications, that the Y_i are m-dependent; see [11, Section 9.1] for a formal definition. In these circumstances $\sqrt{n}(\overline{Y}_n - \mu)$ converges in distribution to $\mathrm{N}(0, \sigma_\infty^2)$, where $\sigma_\infty^2 \neq \mathrm{var}(Y_1)$ in general. This asymptotic distribution may be used to construct confidence intervals for μ, but only provided that a consistent estimate of σ_∞^2 is available. This may be far from straightforward to obtain: bootstrap methods are an attractive alternative.

While the bootstrap can bypass difficult problems associated with use of asymptotics (*see* **Large-sample Theory**), use of a bootstrap resampling scheme appropriate to independent data will fail to provide consistent approximation even in the case of weakly dependent processes. In our example, for instance, the simple bootstrap estimator of the variance of $\sqrt{n}\overline{Y}_n$ converges in probability to $\mathrm{var}(Y_1)$ and is therefore inconsistent for σ_∞^2, in general. Identification of a valid resampling scheme requires knowledge of the dependence structure of the observations.

As in the independent setting, the bootstrap can be applied parametrically to structured dependent data models, often with improvement over standard asymptotic procedures. Most developments to dependent data problems have considered such structured models; see, for example, [11, Chapter 9].

Considerable interest, however, lies in nonparametric resampling schemes. Künsch [10] proposed a "moving blocks" resampling scheme for stationary time series data. The basic idea here is to break the observed data series Y up into a collection of overlapping blocks of observations. Bootstrapped data series are obtained by independent sampling, with replacement, from among these blocks.

We illustrate this procedure in the context of the example above. Let b be a given block size. Define $\xi_i = (Y_i, \ldots, Y_{i+b-1})$ to be the block of b consecutive observations starting from Y_i, $i = 1, \ldots, n-b+1$. The moving blocks bootstrap is based on sampling with replacement from the collection $\{\xi_1, \ldots, \xi_{n-b+1}\}$. Suppose that k is an integer such that kb is approximately n, and let $\xi_1^*, \ldots, \xi_k^*$ be sampled independently and with replacement from $\{\xi_1, \ldots, \xi_{n-b+1}\}$. Let the $l = kb$ elements of $\xi_1^*, \ldots, \xi_k^*$ be concatenated into a single vector $(Z_1, \ldots, Z_l) \equiv (\xi_1^*, \ldots, \xi_k^*)$. Then $(Z_1, \ldots, Z_l)$ is

the bootstrap sample under the moving blocks bootstrap scheme and, for example, a bootstrap estimate of $\Pr[\sqrt{n}(\overline{Y}_n - \mu) \le z]$ is $\Pr[\sqrt{l}(\overline{Z}_l - \overline{Y}_n) \le z]$, where the probability is computed under the moving blocks resampling scheme, and where $\overline{Z}_l = l^{-1}\sum_{i=1}^{l} Z_i$. Consistency under the model of m-dependence is now achieved if b is allowed to grow to infinity with n.

The rate of approximation by the moving blocks method may be worse than the rate of normal approximation: the normal approximation yields better estimates of the sampling distribution of interest in this context. However, with suitable modification in the definition of the bootstrapped statistic, an improved approximation may be obtained. In the above example, such modification amounts to estimating $\Pr[\sqrt{n}(\overline{Y}_n - \mu) \le z]$ by $\Pr[\sqrt{l}(\overline{Z}_l - \mathrm{E}^*\overline{Z}_l) \le z]$, where $\mathrm{E}^*\overline{Z}_l$ denotes the expectation of $\overline{Z}_l$ under the moving blocks resampling scheme.

We conclude by reiterating the major considerations in use of bootstrap methods and with a data example.

1. Crucial to the practical effectiveness of bootstrap methods is how the model P is defined and estimated. Incorrect assumptions in postulating the model P, such as assuming independence for data which are actually correlated, may lead to incorrect conclusions.
2. Even if the model P is postulated correctly, the performance of the bootstrap relies on how well we can estimate it. In the iid case for example, it may be more effective to use a smoothed version of the empirical distribution function F_n in constructing the bootstrap estimator, rather than F_n itself; see [12] and [2]. The bootstrap itself may be applied to choose between different bootstrap estimators that with the smallest (bootstrap estimated) error. This *iterated bootstrap*, while in general demanding great computational expense, can also be used for the fine tuning of basic bootstrap procedures, by quantitative adjustment of the bootstrap estimator to account for estimated error; see [9, Chapter 1]. An important application of this method is in the refinement of bootstrap confidence sets, by bootstrap estimation of coverage error, and adjustment of the nominal coverage of the confidence set; see [7] and [1].
3. In cases in which parametric assumptions are justified, the bootstrap will do no better in general than the correct parametric technique. Bootstrap methods are also crucially conditioned by the available sample data. They are therefore only as good as the data with which they are provided. If the data set has **outliers** or influential points (*see* **Diagnostics**), and if the statistic being bootstrapped is nonrobust (*see* **Robustness**), bootstrap procedures can produce bad results, in the same way as classical approaches.

Example 3 (Bootstrap Bioequivalence)

The following application of the bootstrap is described by Efron & Tibshirani [6]. A drug company has applied each of three hormone supplement medicinal patches to eight patients suffering from a hormone deficiency. One of the three is "Approved", having received approval from the US **Food and Drug Administration (FDA)**. Another is a "Placebo" containing no hormone. The third is "New", being manufactured at a new facility, but otherwise intended to be identical to "Approved". The three wearings occur in random order for each patient and the blood level of the hormone is measured after each patch wearing: results are given in Table 1. The FDA requires proof of **bioequivalence** before approving sale of the product manufactured at the new facility.

Technically, let x be the difference between Approved and Placebo measurements on the same patient and let y be the difference between New and Approved:

$$x = \text{Approved} - \text{Placebo}, \qquad y = \text{New} - \text{Approved}.$$

Let μ and ν be the expectations of x and y and let

$$\rho = \frac{\nu}{\mu}.$$

Table 1 Bioequivalence data

Placebo	Approved	New	x	y
9 243	17 649	16 449	8 406	−1200
9 671	12 013	14 614	2 342	2601
11 792	19 979	17 274	8 187	−2705
13 357	21 816	23 798	8 459	1982
9 055	13 850	12 560	4 795	−1290
6 290	9 806	10 157	3 516	351
12 412	17 208	16 570	4 796	−638
18 806	29 044	26 325	10 238	−2719

The FDA criterion for bioequivalence is that the new facility matches the old facility within 20% of the amount of hormone that the old drug adds to the placebo blood levels, $|\rho| \leq 0.2$.

For the given data

$$(\overline{x}, \overline{y}) = (6342, -452) = (\hat{\mu}, \hat{\nu}),$$

giving an estimate of the ratio ρ as

$$\hat{\rho} = \frac{\hat{\nu}}{\hat{\mu}} = -0.071.$$

In formal terms, the FDA bioequivalence requirement is that a 90% central confidence interval for ρ lies within the range $(-0.2, 0.2)$. We use the percentile method to construct a nominal 90% confidence interval for ρ.

Let $\hat{F}$ be the distribution putting point mass 1/8 on each original data point (x_i, y_i), $i = 1, \ldots, 8$. Let $\{(x_1^*, y_1^*), \ldots, (x_8^*, y_8^*)\}$ be a sample drawn from $\hat{F}$. Such a sample gives a bootstrap replication of $\hat{\rho}$:

$$\hat{\rho}^* = \left(\sum_{i=1}^{8} y_i^*/8\right) \Big/ \left(\sum_{i=1}^{8} x_i^*/8\right).$$

A nominal 90% confidence interval for ρ is $(\hat{\rho}^*[0.05], \hat{\rho}^*[0.95])$, in terms of the lower 0.05 limit and upper 0.95 limit of $\hat{\rho}^*$ under the drawing of such bootstrap samples. An interval based on the drawing of 5000 random bootstrap samples (nearly exhaustive over all possible bootstrap samples) is $(-0.209, 0.123)$; see the bootstrap histogram in Figure 2, where the limits of the interval are shown by the broken lines.

The bioequivalence criterion is (just) violated. But is this interval to be trusted? The accuracy, under repeated sampling from the underlying population, of the chosen confidence interval procedure is an important part of the way the FDA decision making operates, and we must therefore be concerned at the accuracy of our percentile method interval. The iterated bootstrap can be used to refine the interval, by estimating the coverage error of the percentile method. In effect, we adjust the nominal level of the confidence interval, through the bootstrap, to deliver an interval that we believe will have coverage nearer to the required level 90%.

In Figure 3 is shown the graph of a bootstrap estimate of the coverage of the percentile method confidence interval, as a function of nominal coverage,

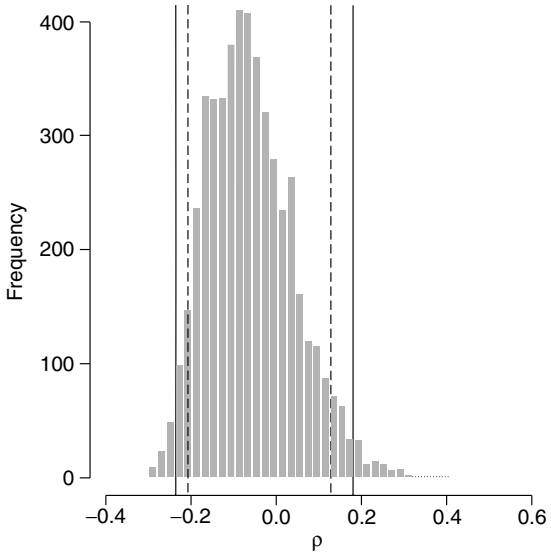

Figure 2 Bootstrap distribution, hormone data

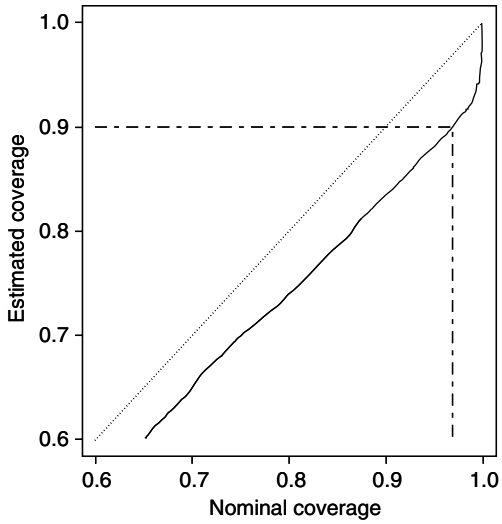

Figure 3 Calibration, hormone data

constructed from a Monte Carlo simulation. This simulation generated $B = 5000$ bootstrap samples from the given data. From each, the percentile method confidence interval of any given nominal coverage may be constructed, by drawing $C = 5000$ (second level) bootstrap samples. The proportion containing the observed value $\hat{\rho}$ estimates the coverage of the

percentile method interval, for that nominal coverage. This calibration curve shows that the percentile method confidence interval of nominal coverage 0.9 has estimated coverage 0.833: the percentile interval of nominal coverage 0.970 has estimated coverage equal to the required coverage 0.9. The iterated bootstrap confidence interval is therefore the percentile method interval of nominal coverage 97%. This interval, shown by the solid lines in Figure 2, is wider: the interval for ρ is now $(-0.237, 0.177)$. There is rather good evidence that the bioequivalence criterion is violated.

Bootstrapping in Survival Analysis

Right Random Censoring

Let $Y_1, \ldots, Y_n$ be independent and identically distributed (i.i.d.) **random variables** (r.v.), called lifetimes. Such data in **survival analysis** have the typical feature that some of the Y_i are not fully observable due to various types of **censoring** and/or **truncation**. We restrict here to the model of random right censorship, which is described by considering another sequence $C_1, \ldots, C_n$ of i.i.d. r.v., called *censoring times*. The observations are the pairs $(T_1, \delta_1), \ldots, (T_n, \delta_n)$, where for $i = 1, \ldots, n$, $T_i = \min(Y_i, C_i)$ and $\delta_i = I(Y_i \le C_i)$. As is mostly the case in survival analysis, we will assume that the Y's and C's are nonnegative, although this is not essential. The distribution functions of Y and C are denoted by F and G respectively. The model of random right censorship assumes that Y_i and C_i are independent for each i. This assumption entails that the T_i are i.i.d. with distribution function $H = 1 - (1 - F)(1 - G)$ and the δ_i are Bernoulli distributed with $\gamma = \mathrm{E}(\delta_1) = P(\delta_1 = 1) = \int_0^\infty (1 - G(s-))\,\mathrm{d}F(s)$. The **nonparametric maximum likelihood** estimator for the lifetime distribution F is the **Kaplan–Meier** [29] estimator $F_n(t)$ defined by

$$1 - F_n(t) = \prod_{T_i \le t} \left(1 - \frac{m_i}{M_i}\right)^{\delta_i} \tag{1}$$

where $m_i = \sum_{j=1}^n I(T_j = T_i)$ is the number of failures observed at T_i, and $M_i = \sum_{j=1}^n I(T_j \ge T_i)$ is the number at risk at T_i. If all T_i are different, then each $m_i = 1$ and $M_i = n - rank(T_i) + 1$, and in this case

$$1 - F_n(t) = \prod_{T_{(i)} \le t} \left(\frac{n - i}{n - i + 1}\right)^{\delta_{(i)}} \tag{2}$$

where $T_{(1)} \le T_{(2)} \le \cdots \le T_{(n)}$ are the **order statistics** of $T_1, \ldots, T_n$ and $\delta_{(1)}, \ldots, \delta_{(n)}$ are the corresponding δ's.

It is easy to see that F_n reduces to the usual empirical distribution function (*see* **Goodness of Fit**) if there is no censoring (all $\delta_i = 1$).

Efron's Bootstrap in the Right Random Censorship Model

It was Efron [17] who first proposed **bootstrap** procedures for right randomly censored observations. His first proposal is to take independent resamples from the Kaplan–Meier estimators of the lifetimes and the censoring times, and to combine them by taking minima and indicators.

Efron's bootstrap procedure I:

(1) Resample independently

$Y_1^*, \ldots, Y_n^* \overset{\text{i.i.d.}}{\sim} F_n$ (Kaplan–Meier estimator for F)

$C_1^*, \ldots, C_n^* \overset{\text{i.i.d.}}{\sim} G_n$ (Kaplan–Meier estimator for G)

(2) Form $(T_1^*, \delta_1^*), \ldots, (T_n^*, \delta_n^*)$, where $T_i^* = \min(Y_i^*, C_i^*)$ and $\delta_i^* = I(Y_i^* \le C_i^*)$.
(the definition of $G_n(t)$ is obtained from that of $F_n(t)$ by replacing δ_i by $1 - \delta_i$).

Efron's second proposal is to resample from the empirical distribution function of the observed minima and indicators.

Efron's bootstrap procedure II:
Resample $(T_1^*, \delta_1^*), \ldots, (T_n^*, \delta_n^*)$ as a random sample with replacement from the pairs $\{(T_1, \delta_1), \ldots, (T_n, \delta_n)\}$.

The first procedure could be called "model-based" since it uses the specific structure of random right censorship. The second procedure is more naive and could be called "model-free". An interesting result is that both procedures are identical if we assume that there are no ties between censored and uncensored values in the original sample. This means that both procedures give the same bootstrap values with the same probabilities. This equivalence no longer holds for left-truncated and right-censored data (see [6, 20,40]).

The Kaplan–Meier estimator based on the bootstrapped observations $(T_1^*, \delta_1^*), \ldots, (T_n^*, \delta_n^*)$ is then given by

$$1 - F_n^*(t) = \prod_{T_i^* \le t} \left(1 - \frac{m_i^*}{M_i^*}\right)^{\delta_i^*} \tag{3}$$

where $m_i^* = \sum_{j=1}^n I(T_j^* = T_i^*)$ and $M_i^* = \sum_{j=1}^n I(T_j^* \geq T_i^*)$.

Throughout, we will use the notations P^*, E^*, Var^*, ... for probability, **expectation**, **variance**, ... under the proposed resampling procedure (i.e. conditional on the original observations).

Weak Convergence of the Bootstrapped Kaplan–Meier Process

We consider the Kaplan–Meier process $n^{1/2}(F_n(t) - F(t))$, $0 \leq t \leq T_0$, where $T_0 < T_H = \min(T_F, T_G)$.

(Throughout, we use the following notation: for any distribution function L, we write $T_L = \inf\{t : L(t) = 1\}$ for the right endpoint of support). Let $D[0, T_0]$ denote the space of right continuous functions with left hand limits. The strong **consistency** of Efron's bootstrap for $n^{1/2}(F_n - F)$ has been established by different techniques ([33, 1]). The method in [1] uses **point processes** and martingale theory (*see* **Counting Process Methods in Survival Analysis**) to show the weak convergence result: if $T_0 < T_H$, then almost surely (a.s.) as $n \to \infty$,

$$n^{1/2}(F_n^*(\cdot) - F_n(\cdot)) \Rightarrow W(\cdot) \text{ in } D[0, T_0] \quad (4)$$

where $W(\cdot)$ is the same Gaussian process as for the original Kaplan–Meier process (obtained in [7]) (*see* **Large-sample Theory**). In [1] also, bootstrap versions of the **confidence** bands in [22] are obtained. The basic idea is the following: from the weak convergence result $n^{1/2}(F_n(\cdot) - F(\cdot)) \Rightarrow W(\cdot)$, we have that $\sup_{0\leq t\leq T_0} n^{1/2}|F_n(t) - F(t)| \xrightarrow{d} \sup_{0\leq t\leq T_0} |W(t)|$. Hence, an approximate $100(1-\alpha)\%$ confidence band can be obtained as $F_n(t) \pm c_\alpha n^{-1/2}$ $(0 \leq t \leq T_0)$, where c_α is such that $P(\sup_{0\leq t\leq T_0} |W(t)| \leq c_\alpha) = 1 - \alpha$. By the above result, c_α can be approximated by the $1-\alpha$ **quantile** of the bootstrap distribution of $\sup_{0\leq t\leq T_0} n^{1/2}|F_n^*(t) - F_n(t)|$. For related results, we also refer to the paper [24] on strong approximations and to [41] on the bootstrap for **multivariate survival** data.

Other Resampling Plans

There exist other resampling methods for censored data, different from the one of Efron [17] used above. Reid [35] proposed (in a context of estimation of the **median**) to take an i.i.d. resample from the Kaplan–Meier estimator of F and to work with the corresponding empirical distribution function.

Reid's bootstrap procedure

Resample $\widetilde{T}_1, \ldots, \widetilde{T}_n \overset{\text{i.i.d.}}{\sim} F_n$.

It is clear that such a resample always consists entirely of originally uncensored T_i. If $\widetilde{F}_n$ is the empirical distribution function of $\widetilde{T}_1, \ldots, \widetilde{T}_n$, then it is shown in [1] that for $T_0 < T_H$, a.s. as $n \to \infty$,

$$n^{1/2}(\widetilde{F}_n(\cdot) - F_n(\cdot)) \Rightarrow \widetilde{W}(\cdot) \quad \text{in } D[0, T_0] \quad (5)$$

but the Gaussian process $\widetilde{W}$ does not agree with the limiting process W of the original Kaplan–Meier estimator. It follows that Reid's bootstrap cannot be used to approximate the quantile that is needed in the construction of the confidence band for F.

Hjort [23] (in the context of **Cox's regression model**) proposed a resampling method as in Efron's Procedure I but with different construction of the censoring variables: if $\delta_i = 0$, then we observe the exact value of C_i and take $C_i^* = T_i$; if $\delta_i = 1$, then we know only that $C_i > T_i$ and we generate C_i^* from the Kaplan–Meier estimator of G, conditional on $C_i > T_i$.

Hjort's bootstrap procedure:

(1) Resample $Y_1^*, \ldots, Y_n^* \overset{\text{i.i.d}}{\sim} F_n$.
(2) Independently, resample $C_1^*, \ldots C_n^*$ as follows
- if $\delta_i = 0$, let $C_i^* = T_i$
- if $\delta_i = 1$, generate C_i^* from G_{T_i}, where

$$G_{T_i}(t) = \frac{G_n(t) - G_n(T_i)}{1 - G_n(T_i)} (t \geq T_i) \quad (6)$$

(3) Form $(T_1^*, \delta_1^*), \ldots, (T_n^*, \delta_n^*)$, where $T_i^* = \min(Y_i^*, C_i^*)$ and $\delta_i^* = I(Y_i^* \leq C_i^*)$.

If F_n^* is the Kaplan–Meier estimator formed with the above (T_i^*, δ_i^*), then in [30] (see also [16]) it is shown that for $T_0 < T_H$, a.s. as $n \to \infty$,

$$n^{1/2}(F_n^*(\cdot) - F_n(\cdot)) \Rightarrow W(\cdot) \text{ in } D[0, T_0] \quad (7)$$

where W is the same Gaussian process as for the original Kaplan–Meier process. Also, **Bayesian** bootstrapping and weighted bootstrapping have been suggested and studied; see, for example, [32] and [26]. It should also be mentioned that bootstrap methods

for arbitrary **counting process** models are discussed in [2].

Bootstrapping Kaplan–Meier Quantiles

For $0 < p < 1$, we denote the pth quantile of the lifetime distribution F by $\xi_p = F^{-1}(p) = \inf\{t : F(t) \geq p\}$. A simple estimator for ξ_p is the p-th quantile of the Kaplan–Meier estimator $F_n : \xi_{pn} = F_n^{-1}(p) = \inf\{t : F_n(t) \geq p\}$. Many large sample properties for quantile estimators can be derived from the asymptotic representations (Bahadur representations). They represent ξ_{pn} as follows:

$$\xi_{pn} = \xi_p + \frac{p - F_n(\xi_p)}{f(\xi_p)} + R_n(p) \qquad (8)$$

where $f = F'$ and $R_n(p)$ is a remainder term.

Weak convergence of the quantile process $n^{1/2}(\xi_{pn} - \xi_p)$ $(0 < p \leq p_0)$, where $0 < p_0 < \min(1, T_{G(F^{-1})})$ can be obtained. The limiting process is given by $-W(\xi_p)/f(\xi_p)$ $(0 < p \leq p_0)$, where W is the limiting Gaussian process of the Kaplan–Meier process.

Efron's bootstrap for Kaplan–Meier quantiles was studied in [33]. Let F_n^* be the Kaplan–Meier estimator based on the bootstrapped observations $(T_1^*, \delta_1^*), \ldots, (T_n^*, \delta_n^*)$ and let $\xi_{pn}^* = F_n^{*-1}(p) = \inf\{t : F_n^*(t) \geq p\}$. Their key result is a bootstrap version of the above representation theorem, from which weak convergence of $n^{1/2}(\xi_{pn}^* - \xi_p)$ follows. This, and the application to confidence bands for the quantile function is also discussed in [16].

A Practical Example

As a simple illustration of the use of the bootstrap in survival analysis, we consider the calculation of a confidence interval for the median survival time. We perform this on the Channing House data (see [25]) using the *R* software. Figure 1 shows the Kaplan–Meier survival estimator $1 - F_n(t)$ for the 97 men who lived in this retirement center. Of the 97 lifetimes, 46 were observed completely ($\delta = 1$) and 51 were censored ($\delta = 0$).

It follows that the median survival time is 1044 months. From each of 2000 resamples from the data $\{(z_1, \delta_1), \ldots, (z_{97}, \delta_{97})\}$, we calculated the Kaplan–Meier median. For the percentiles of these 2000 replicas of the median, we obtained

2.5%	5%	10%	25%	50%	75%	90%	95%	97.5%
1025	1029	1031	1036	1044	1055	1060	1080	1080

These values can be used be obtain simple confidence intervals for the median survival time. For example, a 90% confidence interval is given by [1029, 1080]. This method is called the percentile method. This and other results can also be found in [17].

Accuracy of the Bootstrap with Censored Data

Second-order asymptotics for the bootstrap have been studied to find the rate at which the bootstrap error tends to zero a.s. For uncensored data,

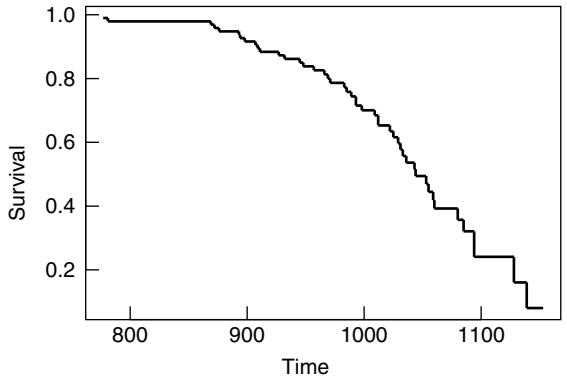

Figure 1 Kaplan–Meier survival curve $1 - F_n(t)$ for the Channing House data (time in months)

it is well known that for several classes of statistics, the bootstrap approximation is more accurate than the normal approximation. While the error of the normal approximation is typically $o(n^{-1/2})$ (by a Berry–Esseen theorem), the rate of convergence of the bootstrap estimator can, in some situations, be shown to be $o(n^{-1/2})$ a.s. (which is typically that of a one-term **Edgeworth expansion**). Edgeworth expansions for the **Studentized** Kaplan–Meier estimator $n^{1/2}(F_n(t) - F(t))/\widehat{\sigma}_G(t)$ and for the bootstrapped version $n^{1/2}(F_n^*(t) - F_n(t))/\widehat{\sigma}_G^*(t)$ have been derived in [10]. Here, $\widehat{\sigma}_G^2(t)$ is the Greenwood estimator of the variance given by

$$\widehat{\sigma}_G^2(t) = (1 - F_n(t))^2 n \sum_{T_i \le t} \frac{\delta_i}{M_i(M_i - m_i)} \tag{9}$$

and $\widehat{\sigma}_G^{*2}$ is the bootstrapped version (*see* **Kaplan–Meier Estimator**).

An important corollary is that (under the conditions: F and G continuous, $G(t) > 0$, and $1 - H(t) > 0$), we have a.s. as $n \to \infty$,

$$\sup_x \left| P^* \left(\frac{n^{1/2}(F_n^*(t) - F_n(t))}{\widehat{\sigma}_G^*(t)} \le x \right) - P\left(\frac{n^{1/2}(F_n(t) - F(t))}{\widehat{\sigma}_g(t)} \le x \right) \right| = o(n^{-1/2}). \tag{10}$$

This shows that bootstrapping the Studentized Kaplan–Meier estimator offers a better alternative than the normal approximation.(Compare with the $o(n^{-1/2})$ rate of the Berry–Esseen theorem in [9] and [28]).

In [27], it has been shown that modified bootstrapping (i.e. choosing a resample size m, which is possibly different from n) may lead to improved consistency rates for Kaplan–Meier quantiles. Modified bootstrapping for doubly censored data has also been considered in [5].

Bootstrapping in the Proportional Hazards Regression Model of Cox

Very often it happens that together with the observation of the ith individuals lifetime Y_i or censoring time C_i, one has also information on other characteristics Z_i (**covariates**, **explanatory variables**, design variables). Regression models study the effect of these covariates on the conditional distribution function of the true lifetimes $F_z(t) = P(Y \le t \mid Z = z)$.

In the **proportional hazards** model of Cox [11], the relation between a, possibly right censored, lifetime Y and the covariate Z is modeled via the **hazard rate** function

$$\lambda_z(t) = \lim_{\substack{h \to 0 \\ > }} \frac{1}{h} P(Y \le t + h \mid Y > t; Z = z). \tag{11}$$

(For simplicity, we assume here that the covariate Z is one-dimensional, but generalizations are possible). Cox's proportional hazards model specifies that $\lambda_z(t)$ is given by

$$\lambda_z(t) = \lambda_0(t) \mathrm{e}^{\beta z} \tag{12}$$

where $\lambda_0(t)$ is an unspecified baseline hazard function (the hazard for an individual with $z = 0$) and β is an unknown regression parameter.

Suppose that there are n individuals in the study and that the observations are given as $(Z_1, T_1, \delta_1), \ldots, (Z_n, T_n, \delta_n)$, where for individual i, Z_i denotes the covariate and where, as before, $T_i = \min(Y_i, C_i)$ and $\delta_i = I(Y_i \le C_i)$.

Cox's maximum **partial likelihood** estimator for β ([12]) is the value for β maximizing the partial likelihood function

$$L_n(\beta) = \prod_{i=1}^{n} \left(\frac{\mathrm{e}^{\beta Z_i}}{\sum_{j=1}^{n} \mathrm{e}^{\beta Z_j} I(T_j \ge T_i)} \right)^{\delta_i} \tag{13}$$

(or the log partial likelihood function $\log L_n(\beta)$).

The large-sample properties of Cox's maximum partial likelihood estimator were established in [36] (see also [3] for a counting process approach). The paper [36] shows strong consistency of the estimator $\widehat{\beta}_n$, and also asymptotic normality

$$n^{1/2}(\widehat{\beta}_n - \beta) \xrightarrow{d} N(0; \sigma^2(\beta))$$

where $\sigma^2(\beta) = \frac{1}{I(\beta)}$ with

$$I(\beta) = \int \left[\frac{\alpha_2(t, \beta)}{\alpha_0(t, \beta)} - \left(\frac{\alpha_1(t, \beta)}{\alpha_0(t, \beta)} \right)^2 \right] \times \alpha_0(t) \lambda_0(t) \, \mathrm{d}t$$

$$\alpha_k(t, \beta) = \int z^k e^{\beta z} P(T \geq t | Z = z) f(z)\, dz$$
$$k = 0, 1, 2 \qquad (14)$$

and f is the density of the covariate Z.

The asymptotic variance $\sigma^2(\beta) = 1/I(\beta)$ can be consistently estimated by $n/I_n(\widehat{\beta}_n)$, where $I_n(\beta) = -\partial/\partial\beta U_n(\beta)$ is the **information** function. Hence, the Studentized estimator is $(I_n(\widehat{\beta}_n))^{1/2}(\widehat{\beta}_n - \beta)$.

As suggested by Efron and Tibshirani [18], an obvious bootstrap procedure for Cox's proportional hazards regression model is to resample from the triples, then calculate the partial likelihood and then maximize it.

Efron and Tibshirani's bootstrap procedure

(1) Resample $(X_1^*, T_1^*, \delta_1^*), \ldots, (X_n^*, T_n^*, \delta_n^*)$ i.i.d. from the empirical distribution function of $(X_1, T_1, \delta_1), \ldots, (X_n, T_n, \delta_n)$.
(2) Calculate $\widehat{\beta}_n^*$: the value of β such that $L_n^*(\beta)$ is maximized.

A one-term Edgeworth expansion for $n^{1/2}(\widehat{\beta}_n - \beta)$ and related quantities is established in [21]. It is also shown that the bootstrap approximation is second-order correct: a.s. as $n \to \infty$,

$$\sup_{x \in \mathbb{R}} \left| P^* \left(\sqrt{I_n^*(\widehat{\beta}_n^*)}(\widehat{\beta}_n^* - \widehat{\beta}_n) \leq x \right) - P\left(\sqrt{I_n(\widehat{\beta}_n)}(\widehat{\beta}_n - \beta) \leq x \right) \right| = o(n^{-1/2}). \qquad (15)$$

Bootstrap confidence intervals for the regression parameter β, the distribution function $F_x(t)$, and the quantile function $F_x^{-1}(t)$ were studied by Burr [8]. The author performs a **Monte Carlo** study to compare different types of confidence intervals.

Bootstrapping in Nonparametric Regression Models

The relation between the distribution of the lifetime Y and the value of the covariate Z has also been analyzed in a completely **nonparametric** way, that is, without assuming any condition on the regression function. Beran [4] extended the definition of the Kaplan–Meier estimator to the regression context by proposing an entirely nonparametric estimator for $F_z(t) = P(Y \leq t \mid Z = z)$ based on a **random sample** of observations $(Z_1, T_1, \delta_1), \ldots, (Z_n, T_n, \delta_n)$. It is assumed that the r.v. Y_i and C_i are conditionally independent, given Z_i. This ensures **identifiability** of $F_z(t)$.

This estimator has been studied by several people. Uniform consistency has been shown in [4]. Weak convergence results and quantile functions were studied in [13, 14] and [15]. The paper [34] provides the counting process treatment and an extension of the regression model. Almost sure asymptotic representations in the fixed design case (i.e. nonrandom covariates Z_i) were obtained in [19] and [39]. In [37, 38] and [39], a further study was made of this Beran extension of the Kaplan–Meier estimator, the corresponding quantile estimator and the bootstrap versions.

The Beran estimator $F_{zh}(t)$ for $F_z(t)$ is given by

$$1 - F_{zh}(t) = \prod_{T_{(i)} \leq t} \left(1 - \frac{w_{n(i)}(z; h_n)}{1 - \sum_{j=1}^{i-1} w_{n(j)}(z; h_n)} \right)^{\delta_{(i)}}. \qquad (16)$$

where $\{w_{ni}(z; h_n)\}$ is a sequence of **smoothing** weights depending on a kernel density and a positive bandwidth sequence $\{h_n\}$. We use the notation $w_{n(i)}(z; h_n)$ for the weight corresponding to $T_{(i)}$. The bootstrap procedure suggested in [39] consists of drawing the pairs $(T_1^*, \delta_1^*), \ldots, (T_n^*, \delta_n^*)$ with replacement from $(T_1, \delta_1), \ldots, (T_n, \delta_n)$, giving probability $w_{nj}(z_i; g_n)$ to (T_j, δ_j) for $j = 1, \ldots, n$. The bandwidth sequence $\{g_n\}$ is typically such that $g_n/h_n \to \infty$ as $n \to \infty$ ("oversmoothing"). In [38], strong consistency of this bootstrap is shown; see also [31] for a martingale approach.

NOËL VERAVERBEKE

Bortkiewicz, Ladislaus von

Born: August 7, 1868, in St Petersburg, Russia.
Died: July 15, 1931, in Berlin, Germany.

Bortkiewicz studied initially in Russia, then in Gottingen under Wilhelm Lexis (1837–1914). From 1901, he was a professor at the University of Berlin, teaching statistics and economics. He contributed widely in theoretic, social, and economic statistics, developing especially the ideas of Lexis on dispersion in heterogeneous **binary data**.

He is best known in biostatistics for his presentation [1] of data on deaths from horse-kicks in 14 corps of the Prussian Army over a 20-year period. The variation in number of deaths is closely represented by a **Poisson distribution** (Table 1).

Table 1

Deaths	0	1	2	3	4	5-	Total
Frequency	–	–	–	–	–	–	–
Observed	144	91	32	11	2	0	280
Expected	139.0	97.3	34.1	8.0	1.4	0.2	280.0

The "Law of Small Numbers" [1] implied that for low **expectations** in **binomial** or Poisson data, considerable heterogeneity in the expectation could remain undetected from the marginal distribution. In this example, heterogeneity must exist, if only because the corps differed greatly in size. Further analysis of a reduced set of two-way data categorized by year and by corps [2, 4] reveals clear evidence of variation in expectation between both years and corps.

See [3] for further biographical details. The spelling of his name is variable.

Bradford Hill Lectures

Sir Austin Bradford **Hill** has been described as "the greatest medical statistician in the twentieth century" [1]. He pioneered the randomized controlled trial as *the* method of evaluating new treatments (*see* **Clinical Trials, Overview**) [3, 4], established criteria for evaluating evidence of **causation** in **epidemiology** [5], and collaborated on many key medical and public health research studies, both experimental and observational. Notably, the cohort study of British doctors [2] led by Sir Austin and Sir Richard Doll provided the first definitive evidence linking cigarette **smoking** with risks of lung cancer and coronary heart disease, and the British **Medical Research Council Streptomycin trial** in tuberculosis [6] is generally considered to be the first well-executed randomized clinical trial.

Sir Austin's genius lay in creating a collaborative spirit whereby statistical skills became truly appreciated by medical researchers. His key text "Principles of Medical Statistics", first published in 1937 as a series of *Lancet* articles, is still today considered essential reading; its enlarged 12th edition [7] with his son David Hill as joint author appeared shortly after Sir Austin's death in 1991.

Much of Sir Austin's career was at the London School of Hygiene and Tropical Medicine, where he was Professor of Medical Statistics from 1946 to 1961 and Dean of the School from 1955 to 1957. His legacy has led to the School being one of the world's leading academic centers for medical statistics and epidemiology both in research and teaching. To honor his memory, the School established the Bradford Hill Memorial Lecture series, which each year provides an opportunity for a leader in the field to give a perspective on our discipline and its relevance to key public health issues. The Bradford Hill Memorial lecturers have been as follows:

1992 Richard Doll
Sir Austin Bradford Hill and the progress of medical science

1993 Peter Armitage
Before and after Bradford Hill: Some trends in Medical Statistics

1994 David Cox
Causality

1995 Richard Peto
Clinical trials: where Bradford Hill went wrong

1996 Nick Day
Quantification and causality in epidemiology: beyond Bradford Hill

1997 Iain Chalmers

STUART J POCOCK

Bradley, Ralph A.

Born: November 28, 1923 in Smith Falls, Ontario, Canada.
Died: October 30, 2001, in Athens, Georgia, USA.

Photo provided by Marion Bradley

Ralph Bradley's contributions to the world of statistics fall under two headings: his statistical research (especially the Bradley–Terry test used extensively in taste-testing experiments) and his professional leadership role in statistical science, as evidenced by his development of statistical programs, by his presidency (1981) of the American Statistical Association (ASA) and by his editorial efforts. The conversation in Statistical Science [5] provides more details of his views and life.

Ralph Bradley grew up in Wellington, Ontario, and received his B.A. degree with honors in mathematics and physics from Queens University, Canada, in 1944. After serving in the Canadian army (1944–1945), he completed an M.A. in mathematics and statistics in 1946, also at Queens University. He completed his Ph.D. degree in statistics in 1949 at the University of North Carolina at Chapel Hill under the direction of Harold **Hotelling** as his major professor. After a year at McGill University in Montreal, Canada, Ralph returned to the United States and joined the new department of statistics at Virginia Polytechnic Institute (VPI) under Dr Boyd Harshbarger. Ralph stayed in the department for 10 years (1950–1959), became Boyd's right-hand man and with him laid the foundations and developed the department. Building upon this experience, Ralph traveled further south from his beloved Canada to Tallahassee, Florida, to become the head of a new statistics department at Florida State University (FSU). In the ensuing 19 years (1959–1978) as head, he developed the department and made it first-rate. He stayed another four years at Florida State before moving to the University of Georgia in 1982, where he remained until his death, first as a research professor (1982–1992) and then as research professor emeritus after his retirement.

While at VPI, Ralph Bradley collaborated with Milton Terry on a statistical test for paired comparisons, which became known as the **Bradley–Terry** test. The test involves ranking a series of two (of a total of t) treatments in **incomplete blocks** of size two. The test was motivated by a problem encountered when judges were asked to assess the relative merits of t treatments, making the comparisons two treatments at a time and expressing a preference for one treatment in each pair of two treatments (e.g. taste testing). Bradley and Terry [4] developed a model and the related **hypothesis testing** procedures, including developing rating estimates, and also conquered the not inconsiderable computational difficulties (in the days long before modern computing capabilities were freely available). This work was widely cited and led to several awards, including the 1957 J. Shelton Horsley Research Award. An elegant exposition of the universality of the application of the test was given in [6], which is an excellent illustration of Bradley's commitment to the importance of both theoretical and applied statistics in the advancement of statistical science. This balancing of theory and application permeated his research throughout his career, culminating with his work in meteorology in the late 1970s to the early 1980s [2] and his work on trend-free block designs and **blocking** criteria in later years (see, e.g. [3, 7]). Ralph Bradley had broad interests in statistics throughout his research career, including **nonparametric** statistics, **sequential analysis**, computational methods, design of experiments (*see* **Experimental Design**), and **multivariate** methods.

Though Ralph made important contributions to statistical research, his leadership in the development of statistics departments distinguished him from his peers. He played a key role in the growth of the department at VPI; he was the driving force of the department of statistics at FSU, as the founding head; and he provided senior leadership at the University

of Georgia. He wrote extensively on how to achieve and develop viable degree programs (see, e.g. [1]). His career was also distinguished by his editorial efforts, highlighted by his 6-year term (1957–1962) as an editor of **Biometrics** and his 44-year term (1954–1998) as a consulting editor of the Wiley Series in probability and statistics. He contributed mightily to these high-quality statistical publications.

Bradley's leadership capabilities were recognized by his election as President (1981) of the **American Statistical Association** (ASA), a singular honor recognizing his leadership skills and insights in guiding the future development of the profession. A major contribution was his leadership role in ASA's purchasing and moving to its own building in Alexandria, Virginia. Earlier, Bradley served the ASA in a variety of roles, including as vice president, as a member of the board of directors, and as a member of the publication committee. His overall contributions were recognized in 1992 with a Founders Award. Bradley's other contribution to the profession included being president (1965) of the Eastern North American Region of the **International Biometric Society** (IBS), with three terms (over three decades) on the IBS council, and a term as chair and member (1982–1988) of the National Research Council's Committee on Applied and Theoretical Statistics.

A mark of a true leader includes a willingness to seek advice and learn from the experiences of other leaders, and Ralph Bradley was such a leader. He often looked to Gertrude **Cox**, Boyd Harshbarger, Harold Hotelling, and Frank **Wilcoxon**, among others, for inspiration and advice. He understood and practiced the art of collaboration, especially as it pertained to professional leadership. The marks of his leadership are visible in the establishments of departments and degree programs not only where he held rank but also where he played related advisory roles. Further, he sought to instill in others the same ideals of cross-communication between colleagues and aided the development of leadership abilities when the potential excited him. His insistence on excellence from himself and those around him was a thread throughout his work that enhanced his contributions and defined his accomplishments.

Ralph's dedication to perfectionism enabled him to be a craftsman par excellence. He built a swivel chair from discarded parts of broken chairs, and he also built a roll-top desk. This involved the craftsmanship and patience that was typical of Ralph. He loved to fish; he loved to play bridge, even maintaining a noon-time game (maximum playing time 70 minutes!) with departmental faculty at FSU; and he loved sports, especially tennis, never allowing age to deter his enthusiasm for playing as hard as he could. His family supported him fully; his wife Marion was tireless, serving, for example, as his editorial assistant during his *Biometrics* editorship. He has two children Allan and Linda and four grandchildren. Ralph Bradley was an all-around man! He has left behind a rich and enduring legacy to the statistical profession, a legacy to be embraced and enjoyed by those who follow him.

LYNNE BILLARD

Bradley–Terry Model

The Bradley–Terry model is an elegant unidimensional scaling method for summarizing purely ordinal data on paired "objects" (*see* **Paired Comparisons**). Such data are ubiquitous in the match-by-match records of individual and team sports involving paired competition. In biometry they are intrinsic to analyses of dominance behaviors in some animal species, and occur more generally in the study of subjective or objective phenomena that are not directly measurable, therefore requiring that objects be scaled by comparative ranking. Paired comparisons are used when it is psychologically impracticable or burdensome to rank triads or larger groups, or when operational difficulties may compromise validity or reliability of such rankings.

The Basic Model

Consider a set of objects $\mathcal{O} = \{O_i, i = 1, \ldots, I\}$, from among which certain pairs (O_j, O_k) are ordered, either by nature or by one or more observers ("judges"), as either $(O_j > O_k)$ or $(O_j < O_k)$. The judgments are presumed to be guided by the same criterion, which may be frankly subjective (e.g. judge's personal preference) or invoke a clearly objective quality. Pairs may be judged more than once, with the same or different outcomes. The Bradley–Terry model associates with each O_i a parameter $\lambda_i > 0$. Any single comparison between O_j and O_k is modeled as a Bernoulli trial with probabilities of the two outcomes $(O_j > O_k)$ and $(O_j < O_k)$ proportional to λ_j and λ_k (*see* **Binary Data**). Thus, the **odds** of O_j being "preferred" to O_k are λ_j/λ_k, and

$$\pi_{jk} = \Pr\{O_j > O_k\} = \frac{\lambda_j}{(\lambda_j + \lambda_k)}. \qquad (1)$$

For **identifiability** the λ_i are conventionally scaled to sum to 1, so that they satisfy the most basic formal properties of probabilities. However, only their ratios are consequential and interpretation as probabilities is generally inappropriate.

The model was proposed by Zermelo [41] with a view to resolving incomplete round-robin tournaments, and independently developed by Bradley & Terry in the early 1950s while studying sensory difference testing methods for evaluating food quality [12, 39]. It has since been widely applied to biometric and psychometric problems. Ford [27], who also rediscovered the model, clarified aspects of the asymptotic theory and convergence properties of algorithms for **maximum likelihood** estimation (*see* **Large-sample Theory**).

Guided by the principle of "independence of irrelevant alternatives", Luce [33] proposed a general model for choices among groups of objects that reduces to the Bradley–Terry model when the objects are judged only in pairs. Luce's model posits that the probabilities of ranking O_j or O_k first have a constant ratio λ_j/λ_k, whether O_j and O_k are being compared as a pair, or are included in any larger subset of $\mathcal{O}$. Since $\mathcal{O}$ itself is such a subset, in the Luce model λ_i actually is the probability that O_i is ranked first amongst the I objects. Thus, although it is applicable to complex data structures beyond paired comparisons, the Luce model incorporates very restrictive assumptions about the choice process.

Table 1 relates the Bradley–Terry model to antecedents in (i) the tradition of **psychometric** paired-comparison (or paired-choice) research dating back to psychophysical studies of Fechner [36], and (ii) the **quantal response bioassay** literature of the 1930s and 1940s that proved seminal to modern **categorical data** modeling [26].

To see the relationships, consider the general linear paired-comparison model [15, pp. 7–9]. This represents the π_{jk} as differences between intrinsic "true merits" M_j and M_k of O_j and O_k on an underlying continuum, transformed by a continuous and symmetric cumulative distribution function (cdf) F centered at zero. Thus,

$$\pi_{jk} = F(M_j - M_k). \qquad (2)$$

The merits constitute a latent unidimensional interval scaling of the objects, and form the structural portion of the linear model. The stochastic component

Table 1 Relationship of the Bradley–Terry model to analogous paired comparison and quantal bioassay methods

	Latent distribution	
	Gaussian	Logistic
Paired comparison	Thurstone–Mosteller	Bradley–Terry
Quantal bioassay	Probit analysis	Logit analysis

F follows from assuming that a paired-comparison judge observes M_j and M_k only after perturbation by additive random errors ε_j and ε_k. These errors vary across judges, observation times, or both, as appropriate to the situation, following a single continuous **bivariate distribution** for all pairs. If judges order pairs using the resulting observed merits $M_j + \varepsilon_j$ and $M_k + \varepsilon_k$, then the linear model follows by taking F as the marginal distribution of $\varepsilon_j - \varepsilon_k$.

The Gaussian (**normal**) and **logistic distributions** are natural candidates for F, the former yielding the classical Thurstone–Mosteller psychometric model [38], and the latter the Bradley–Terry model (for which one may take $M_i = \ln \lambda_i$). These are related, respectively, to probit and logit models for quantal bioassay, wherein the minimal drug dose required to produce a well-defined response in a test animal, when measured on an appropriate scale, is presumed to follow a normal (probit model) or logistic (logit model) distribution within the animal population. Both conceptually and formally, the difference in true merits in a Bradley–Terry model plays the same role as does the log dose in logit modeling of a quantal bioassay (*see* **Quantal Response Models**).

The Thurstone–Mosteller model arises simply from a **bivariate normal distribution** of merit perturbations, and so is a comfortable choice if a linear paired-comparison model is to be selected on the basis of first principles. In contrast, the Bradley–Terry model has the unappealing property that independent merit perturbations within pairs are type I **extreme value** (double-exponential) variates. Thompson & Singh [37] generate this distribution from an underlying psychophysical model in which perturbations are maxima rather than means of many independent identically distributed components. Despite this apparently substantial difference, however, the Gaussian and logistic distributions of perturbation differences are virtually indistinguishable in practice. Hence, the choice between them is rarely consequential for substantive inference.

In another respect, the Bradley–Terry model is most appealing. It is common in a tournament or other paired-comparison setting to rank the objects by their total "victory" counts, v_i. In a balanced round-robin tournament, $\mathrm{E}(v_i) = r\pi_i. = \sum_{j \neq i} \pi_{ij}$, where r is the number of replications. In any linear paired-comparison model, H_0: equality of these $\pi_{i\cdot}$ implies H_0': equality of the M_i. Hence, indifference may be tested using the v_i. But when some M_i are unequal, formal modeling may not support the naive ordering that the v_i suggest, especially when data arise from incomplete tournaments. Nevertheless, inference about the M_i is considerably simplified if one confines attention to these marginal scores. Among all linear paired-comparison models, only the Bradley–Terry model allows this. The v_i are **sufficient** for the M_i under this model, so one can always find the maximum likelihood ordering from the v_i, even when they do not themselves display it. Daniels [14] shows that the Bradley–Terry model also arises directly from some intuitively appealing approaches to "fair" scoring of round-robin tournaments.

Inference

Independent Choices

Inference is greatly simplified when all choices are viewed as statistically independent. This occurs (i) in the rare situation of randomly chosen judges who each separately view a single pair, or (ii) when no comparisons are influenced by common random effects, or by the results of any other comparisons. It is sometimes reasonable to assume independence under other circumstances, at least to a first approximation.

In this situation, data may be summarized without loss of information using either of two **contingency table** formats. We illustrate these using data from Davidson & Bradley [20] on overall quality of three chocolate puddings. In the "population-response" format (Table 2), each comparison is counted in the cell of the row labeled by the pair and the column labeled by the winner.

In the "repeated measures" format (Table 3), each comparison is counted in the cell of the winner's

Table 2 Population–response representation of paired-comparison results on overall quality of chocolate puddings A, C, and D

	Better			
Pair	A	C	D	Total
AC	10	10		20
AD	7		15	22
CD		14	9	23
Total	17	24	24	65

Table 3 Repeated-measures representation of paired-comparison results on overall quality of chocolate puddings A, C, and D

		Worse			
		A	C	D	Total
Better	A		10	7	17
	C	10		14	24
	D	15	9		24
	Total	25	19	21	65

row and the loser's column. Tables 2 and 3 are both "incomplete" contingency tables, inasmuch as a diagonal of each must be empty, by nature of the paired-comparison design. The Bradley–Terry model is equivalent to both the **quasi-independence** model for the nonzero cell counts of Table 2 and the **quasi-symmetry** model for the nonzero cell counts of Table 3 [25, 30]. These are **loglinear models**, equivalently expressible as **logistic regression** models or, in a broader context, as **generalized linear models** (GLMs) with a logit link function.

Under either the quasi-independence or the quasi-symmetry model, the row and column marginal totals of Table 1 (equivalently, the $n_{jk} + n_{kj}$ and the row sums from Table 2) form a complete set of sufficient statistics for the λ_i. If the design is connected, in that there is no proper subset of $\mathcal{O}$ whose members are compared only to each other, then maximum likelihood estimates of the λ_i, M_i, π_{jk}, and all contrasts among them may be obtained by algorithms employing **iterative proportional fitting** (IPF), the Newton–Raphson method, or Fisher's method of scoring (*see* **Optimization and Nonlinear Equations**). Essentially any **software** for loglinear contingency table analysis, multiple logistic regression, or generalized linear models may be used.

When the fitted cell counts for a counterpart of Table 2 and Table 3 are sufficiently large to validate asymptotic inference, the usual maximum likelihood machinery may be applied to obtain confidence intervals for linear contrasts among the π_{jk}, λ_i, or M_i, and for associated **hypothesis testing**. Other best asymptotically normal **(BAN) estimators** and asymptotically efficient test statistics (e.g. score and Wald statistics; *see* **Likelihood**) may also be used, and a locally asymptotically most stringent test of equivalence is available [4]. For example, the maximum likelihood estimates of λ_A, λ_C and λ_D from the chocolate pudding data in Tables 2 and 3, with estimated asymptotic standard errors, are $\hat{\lambda}_A = 0.253 \pm 0.060$, $\hat{\lambda}_C = 0.387 \pm 0.073$, and $\hat{\lambda}_D = 0.360 \pm 0.070$.

When the likelihood approach is taken and the number of choices between each pair in the design is not small, the deviance **chi-square statistic** (*see* **Generalized Linear Model**) based on the fitted counts may be used to test the fit of the Bradley–Terry model. The deviance for the pudding data is 2.50 with one df ($P = 0.11$), consistent with adequate fit. Parameters or parameter sets may be compared across groups of judges by incorporating appropriate nested or interaction terms into the corresponding logistic regression model.

Bradley & Terry [39] suggest that 15 judgments per pair are needed in a balanced design before the large-sample χ^2 approximation is satisfactory for the distribution of the **likelihood ratio** statistic for testing equivalence, $H_0 : \lambda_i = I^{-1}, i = 1, \ldots, I$. With smaller samples the approximation is unacceptably liberal, yielding higher than nominal type I error (*see* **Level of a Test**). While the small-sample distributions of this and related test statistics are generally analytically intractable and tedious to compute, tables have been prepared for common hypotheses and balanced designs [8, 12]. Regardless of balance, fast computational algorithms for exact small-sample logistic regression analysis may now also be applied to the multiple logistic regression formulation of a Bradley–Terry model, provided that the number of objects is not so large as to exceed available computational resources [29] (*see* **Exact Inference for Categorical Data**).

Correlated Choices

Inference is more challenging in the context of correlated choices, which generally occur due to heterogeneity of judges or of conditions under which comparisons occur. Evidence for such correlation may appear in the form of **overdispersion**, as reflected by an estimated scale parameter substantially greater than unity in a GLM fit. Such overdispersion produces liberality in hypothesis tests, spuriously narrowing confidence intervals and exaggerating the lack of fit. Corrections for overdispersion based on the scaled deviance do not

account for the underlying correlation structure. Several of the available approaches when correlations arise only from random judge effects are described briefly below.

For the case when each judge rates all pairs, the judges may be classified by their response patterns into an $I^{I(I-1)/2}$ sparse incomplete contingency table. Iterative algorithms for constrained optimization under **Poisson** sampling may then be used to obtain maximum likelihood estimates for a Bradley–Terry model of the marginal distributions of this table [3]. Happily, there is no need to model the nuisance correlation structure induced by the judge effects. Or, suppose each judge ranks a subset of all possible pairs, with the number of such subsets in the design small relative to the number of judges. Then the response pattern of each judge may be similarly classified into a contingency table whose margins are the pairs ranked by that judge. We may thus use joint weighted **least-squares** analysis of the sets of correlated marginal logits from these tables [30]. Covariances of choices are estimated by unrestricted maximum likelihood.

Generalized estimating equation (GEE) methods may be employed conveniently when all judges rank the same set of pairs. This approach can accommodate **covariates** associated with the judges and objects. Simple GEE (GEE1) with an independence "working" covariance structure may be used, with inference from a robust covariance estimator to account for the true association structure. Extended GEE (GEE2), which seeks increased efficiency in estimators of the M_i by modeling the association structure, may also be employed. Caution is indicated, however, as resulting estimators $\hat{M}_i$ may be biased if the association model is misspecified.

Prior distributions may also be introduced to model heterogeneity. The most natural approach, though computationally burdensome, is through the generalized linear mixed model (GLMM) [13], which introduces additive $\mathrm{MN}(\mathbf{0}, \boldsymbol{\Sigma}(\boldsymbol{\theta}))$ **random effects** on the M_i. Just as the random perturbations in the linear paired comparison model, these random effects produce multipliers of the choice odds λ_j/λ_k, yielding in essence a **variance components** model for the perturbations on the latent merit scale. The above use of multivariate Gaussian random effects on the M_i is traceable to the full **Bayesian** treatment of Leonard [32].

Design

Several workers, beginning with Abelson & Bradley [1], have considered **experimental design** aspects of paired comparison studies. The merits are usually presumed linear in the **explanatory variables**. Where the O_i embody factorial combinations of classification variables, factorial modeling is obviously desirable (*see* **Factorial Experiments**). More generally, **response surface** fitting and associated efficient designs are of interest when the objects are distinguished by interval-scaled variables (*see* **Measurement Scale**). El-Helbawy [24] reviews much of this body of work. Dillon et al. [23] consider the simultaneous estimation of Bradley–Terry parameters and classification of judges into latent groups, in the presence of covariates. David & Andrews [16] and Bhandari et al. [6] give sequential procedures for selecting the best treatment under a Bradley–Terry model. Advances in estimation for correlated choices and mixed models, mentioned in passing above, will likely stimulate more extensive work on efficient design.

Extensions

Ties and Preference Strengths

The Bradley–Terry model has been generalized to allow for a third "tied" outcome category, to extend further to multicategory ordinal judgments, to incorporate effects of the order in which objects are presented, and to include correlated judgments on multiple criteria.

Following the work of Glenn & David [28] on the Thurstone–Mosteller model, Rao & Kupper [35] extended the Bradley–Terry model by introducing a threshold of perception below which objects appear indistinguishable, and must be declared ties. Suppose objects differing in perceived merits by no more than τ are judged indistinguishable. Writing $\theta = \exp(\tau)$ and $\pi_{j=k}$ for the probability of a tie between O_j and O_k yields

$$\pi_{jk} = F(M_j - M_k - \tau) \tag{3}$$

for the general linear paired-comparison model, and

$$\pi_{jk} = \frac{\lambda_j}{(\lambda_j + \theta\lambda_k)} \tag{4}$$

for the Bradley–Terry model, with $\pi_{j=k} = 1 - \pi_{jk} - \pi_{kj}$ in each case.

In this model the ratio π_{jk}/π_{kj} no longer equals λ_j/λ_k, and depends on the discrimination threshold τ. Davidson [17] gives an alternate single-parameter model for ties that preserves the straightforward connection of π_{jk}/π_{kj} to the merits, at the price of assuming that $\pi_{j=k}$ is proportional to the geometric **mean** of π_{jk} and π_{kj}. The threshold parameter, τ, is replaced by a proportionality constant, ν, which must also be estimated.

The Bradley–Terry model assumes that O_j is preferred to O_k when the perceived difference in merits exceeds a "cut-point" of zero. Agresti [3] generalizes the Bradley–Terry and Rao–Kupper models to an arbitrary number of ordered response categories (e.g. much worse, worse, equal, better, much better) by assuming multiple cut-points for the perceived difference, producing an indifference zone and increasing degrees of preference (*see* **Ordered Categorical Data**). This leads in essence to simultaneous Bradley–Terry models for odds-ratios (i) comparing the perception that O_j is much better than O_k with the perception that O_k is much better than O_j, (ii) comparing the perception that O_j is at least better than O_k with the perception that O_k is at least better than O_j, and so on. These are proportional cumulative odds models in the spirit of McCullagh [34] and Walker & Duncan [40] (*see* **Polytomous Data**). The same structural models may be applied to "local" odds ratios formed after conditioning on a pair of adjacent response categories, e.g. the odds of considering O_j better vs. equal to O_k, relative to the odds of considering O_k better vs. equal to O_j. Maximum likelihood analysis of such models is straightforward [2].

Presentation Order

Models involving both additive and multiplicative adjustments have been proposed to incorporate a presentation order effect into the Bradley–Terry model. The additive approach assumes that a fixed proportion of choices, specific to each pair, is swayed by the order of presentation. If π^*_{jk} is the probability of choosing j over k given a specific order of presentation, then under this model

$$\pi^*_{jk} = \pi_{jk} \pm \delta_{jk}, \qquad \delta_{jk} \leq \min(\pi_{jk}, \pi_{kj}), \qquad (5)$$

depending on whether O_j is presented respectively first or second [5]. Thus, the range of admissible δ_{jk} depends on λ_j and λ_k.

The **multiplicative model** [18] applies the same concept to the log(odds) rather than the choice probabilities. In this case,

$$\ln\left(\frac{\pi_{jk}}{\pi_{kj}}\right) = \ln\lambda_j - \ln\lambda_k \pm \gamma_{jk}, \quad \gamma_{jk} > 0, \qquad (6)$$

depending, respectively, on whether O_j is presented second or first. In contrast to the additive model, simplifications such as $\gamma_{jk} = \gamma$, or intermediate modeling, are straightforward. In a particularly interesting earlier paper, Kousgaard [31] discusses models incorporating both ties and order effects, where the discrimination threshold and order effect may vary across judges. Conditional maximum likelihood inference is proposed (*see* **Logistic Regression, Conditional**).

Multiple Criteria

The Bradley–Terry model may be applied separately to choices using c different criteria, or under different conditions. This requires accounting for the correlation structure among multiple binary responses, for which direct modeling is difficult. Davidson & Bradley [19] propose a direct model in which the probability of a response pattern under independent Bradley–Terry selections is perturbed by a function of the underlying marginal preference parameters and $c(c-1)/2$ correlation parameters generalizing Pearson's ϕ coefficient for **two-by-two contingency tables** (*see* **Association, Measures of**). However, since the association structure is generally a nuisance rather than an object of inference itself, much success has been gained by large-sample approaches such as weighted least squares that adjust for the covariance structure without modeling it [30], or that incorporate covariance modeling into **robust** estimation of marginal parameters, such as GEE. In general, the large-sample techniques discussed above for handling correlated responses in univariate paired-comparison studies may be similarly applied to handle multivariate responses, sample size permitting.

The literature on Bradley–Terry models is large, as suggested by the comprehensive bibliographies of Davidson & Farquhar [21] and David [15]. The

reader is referred to the reviews by Bradley [9–11] and the classic monographs of David [15] and Bock & Jones [7]. Diggle et al.'s [22] discussion of recent work on **correlated binary** regression, though written in the context of **longitudinal data analysis** rather than paired comparisons, is useful for the reader interested in modeling correlated and/or multivariate choices.

PETER B. IMREY

Branching Processes

A branching process is a description of the evolution of populations of individuals, which reproduce independently. In the most general cases, individuals inherit a *type* from some type space at birth; this type determines a probability measure on a set of possible life careers, which in their turn determine a **point process** giving the ages of bearing and the types of the children.

There is a whole array of different branching processes:

1. In classical (*Bienaymé-)* **Galton–Watson**, or *simple*, processes, there is only one type of individual and all individuals live for one time unit (season), giving birth to independent, identically distributed (iid) numbers of children living through the next season.
2. In Bellman–Harris, or *age-dependent*, processes, this pattern is generalized so that individuals can have iid lifespans according to an arbitrary distribution. At death they split into iid numbers of offspring, and so forth.
3. A special case of these are the *Markov branching* processes, obtained by choosing the lifespan distributions to be **exponential**.
4. *Sevastyanov* processes generalize Bellman–Harris processes by allowing dependence between lifespan and offspring numbers.
5. In *general* processes, births need no longer occur only at the end of a lifetime, but could be spread out randomly according to any point process.
6. All of these populations exist in single and multitype versions. In much literature the latter term indicates that there is a finite number of different types of individuals, but generally this need not be the case. In particular, much mathematically oriented literature deals with populations in which "type" is position in space. Biologically, "type" could be **genotype**; but it could also be a property such as mass or DNA content at birth.

Historically, branching processes originate from biologically or **demographically** motivated problems. There are, however, many other natural phenomena exhibiting a branching character, such as cascades of splitting particles, or polymerization processes. Lately, branching processes have been used in the study of **algorithm** performance. They occur in the formation of random fractal sets (*see* **Chaos Theory**). Limits of branching processes form so-called superprocesses, measure-valued random processes that are used to interpret nonlinear differential equations. The area thus also contains many aspects of pure mathematics, both analytic and more probabilistic.

The first problem of branching processes proper was that of determining extinction probabilities. In the single-type Galton–Watson case, this can be formulated and solved as follows.

If q denotes the probability that a population that started from one ancestor dies out, then, by independence (and since all individuals are the same type), the probability that a population with k ancestors dies out must be q^k. Hence if p_k is the probability of begetting k children, then

$$q = \sum_k p_k q^k.$$

In the interval [0, 1] this equation has exactly one solution, namely $q = 1$, if $m := \sum_k k p_k < 1$, or $m = 1$ and $p_1 < 1$, the *subcritical* and *critical* cases. It has one more solution if $m > 1$, and this is the real extinction probability in that *supercritical* case. The extinction problem of more general branching processes can be reduced to the Galton–Watson case through counting the numbers of individuals in successive generations.

In the subcritical and critical cases, it is of interest to study the conditional distribution of the population size, given that the population has not yet died out. For both of these cases limit theorems, as time passes, exist. In the subcritical case, it is the population size itself that has a limiting distribution; in the critical case, it behaves like the time since the population started multiplied by an exponentially distributed random variable.

In the cases in which extinction is not necessary, one can prove that nonextinction implies growth beyond all limits, at the exponential rate already argued by **Malthus**. The exponent in this exponential growth is called the *Malthusian parameter*, and it is determined by the reproduction laws of individuals of the various types. In branching processes it is usually denoted by α, and in deterministic population dynamics by r.

To see how the parameter is determined, consider one-type general processes and let $\mu(t)$ denote the expected number of children obtained by a t-aged

mother. Then the Malthusian parameter is defined by the equation

$$\int_0^\infty \exp(-\alpha t)\mu(\,\mathrm{d}t) = 1,$$

which usually has one (and only one) solution. The sub- and supercritical cases correspond to $\alpha < 0$ and $\alpha > 0$, and the critical to $\alpha = 0$. In multitype populations it is a more complicated object that should equal one, the so-called Perron root of the kernel, describing the expected numbers of children of various types from mothers of various types.

If z_t denotes population size at time t in a supercritical process, Malthus' law of growth then reads

$$z_t \sim cw \exp(\alpha t), \quad t \to \infty,$$

where c is a constant determined by the way in which population size is measured and w is a random variable which is not identically zero, if the individual offspring distributions have a finite first and logarithmic moment; that is, a condition of the form $\mathrm{E}[X \log^+ X] < \infty$ holds, X being basically the number of children per individual.

During the exponential growth the age distribution will stabilize to a distribution also determined by the individual reproduction distributions (a fact already known to Euler). Similarly, other aspects of population composition will stabilize, so that the properties of a typical individual (i.e. one sampled at random) converge, while time passes and the population grows. A particular aspect of this is the emergence of a typical history of individuals; for example, a typical mutation history. Such results can be used to infer properties of individuals from the composition of the whole population.

The applications of branching processes to biology predominantly concern either systems of rather simple organisms such as cells (*see* **Cell Cycle Models**) or bacteria (*see* **Bacterial Growth, Division, and Mutation**), reproducing at a rapid rate so that the asymptotic assertions of theory become relevant, or they concern conceptual matters, say in evolution. Branching processes can also be applied to approximate genetic and epidemic processes (*see* **Epidemic Models, Stochastic**).

Breslow–Day Test

The case–control method is a popular way to study the association between exposure and disease in epidemiology. Under the presence of nuisance factors, one could stratify the data into a series of 2×2 tables to control confounding. For example, one might study the relationship between lung cancer and smokers, controlling for age. If the association between exposure and disease is constant from stratum to stratum, then the **Mantel–Haenszel** (MH) summary odds ratio estimator is usually used to estimate the relative risk. Breslow & Day [2] provided a test for assessing the homogeneity of the odds ratios across tables.

Table 1 shows the data in the kth of a series of 2×2 tables, where $k = 1, \ldots, K$. The MH estimator is defined by $\hat{\psi} = \sum_k R_k / \sum_k S_k$, where $R_k = a_k d_k / N_k$ and $S_k = b_k c_k / N_k$. Breslow & Day [2, p. 142] proposed a statistic for testing the null hypothesis of homogeneity of the K true odds ratios. It sums up the squared deviations of observed and fitted values, each standardized by its variance:

$$\sum_{k=1}^{K} \frac{(a_k - A_k(\hat{\psi}))^2}{\mathrm{var}(a_k; \hat{\psi})}, \tag{1}$$

where $A_k(\hat{\psi})$ and $\mathrm{var}(a_k; \hat{\psi})$, denote the expected number and the asymptotic variance of exposed cases based on the MH fitted odds ratio $\hat{\psi}$, respectively.

Tarone [4] noted that by replacing the MH estimator $\hat{\psi}$ by the conditional maximum likelihood estimator, the Breslow–Day test statistic (1) becomes the conditional likelihood score test. Since the MH estimator is inefficient, Tarone [4] and Breslow [1] noted that the test statistic (1) is stochastically larger than a χ^2 random variable (*see* **Chi-square Distribution**) under the homogeneity hypothesis. The correct form for the test was derived by Tarone as

$$\sum_{k=1}^{K} \frac{[a_k - A_k(\hat{\psi})]^2}{\mathrm{var}(a_k; \hat{\psi})} - \frac{[\Sigma_k a_k - \Sigma_k A_k(\hat{\psi})]^2}{\Sigma_k \mathrm{var}(a_k; \hat{\psi})}, \tag{2}$$

where $A_k(\hat{\psi})$ is obtained from the quadratic equation

$$\frac{A_k(\hat{\psi})[N_{0k} - t_k + A_k(\hat{\psi})]}{[N_{1k} - A_k(\hat{\psi})][t_k - A_k(\hat{\psi})]} = \hat{\psi}, \tag{3}$$

and the asymptotic variance is given by

$$\mathrm{var}(a_k; \hat{\psi}) = \left[\frac{1}{A_k(\hat{\psi})} + \frac{1}{N_{1k} - A_k(\hat{\psi})} + \frac{1}{t_k - A_k(\hat{\psi})} + \frac{1}{N_{0k} - t_k + A_k(\hat{\psi})} \right]^{-1}. \tag{4}$$

When the number of strata is small and each table has large frequencies, Tarone's test statistic (2) follows an approximate χ^2 distribution on $K - 1$ degrees of freedom, under the homogeneity hypothesis.

The computer package StatXact [3] provides the Breslow–Day test, as does SAS (PROC FREQ) (*see* **Software, Biostatistical**). Unfortunately, they are both currently based on the incorrect test statistic (1).

Table 1 Notation for the kth of a series of 2×2 tables

	Observed frequencies		
Exposure	Case	Control	Total
Exposed	a_k	b_k	t_k
Unexposed	c_k	d_k	$N_k - t_k$
Total	N_{1k}	N_{0k}	N_k

Broadband Smoothing

Broadband smoothing is a procedure to reduce the estimation variance of **fast Fourier transform (FFT)** power spectra (*see* **Spectral Analysis**), which results in estimation variance and frequency resolution not constant over the frequency axis, as in conventionally smoothed spectra.

Because of their stochastic nature, spectra of most biological processes are affected by large estimation variance. Smoothing decreases this variance. Typically, a smoothed spectrum is estimated by splitting a **time series** of length T into L shorter data segments of length $T_L < T$, by computing a spectrum over each segment, and by averaging the L spectra thus obtained. If $P_i(f_k)$ is the FFT spectrum in the ith segment, where $f_k = k/T_L$ is the frequency of the kth spectral line, the smoothed spectrum $P^S(f_k)$ is

$$P^S(f_k) = \frac{1}{L}\sum_{i=1}^{L} P_i(f_k). \tag{1}$$

If the number of independent spectra to be averaged increases, then the reduction of estimation variance is greater. On the other hand, if L increases, T_L decreases with a loss of frequency resolution. Thus, a compromise should be found between estimation variance and frequency resolution. When the spectrum is estimated over a broad band of frequencies, however, it is difficult to find a satisfactory compromise because the optimum trade-off in a frequency band might be unacceptable at other frequencies. In this case, broadband smoothing may considerably improve spectral analysis because resolution and estimation variance actually change with the frequency.

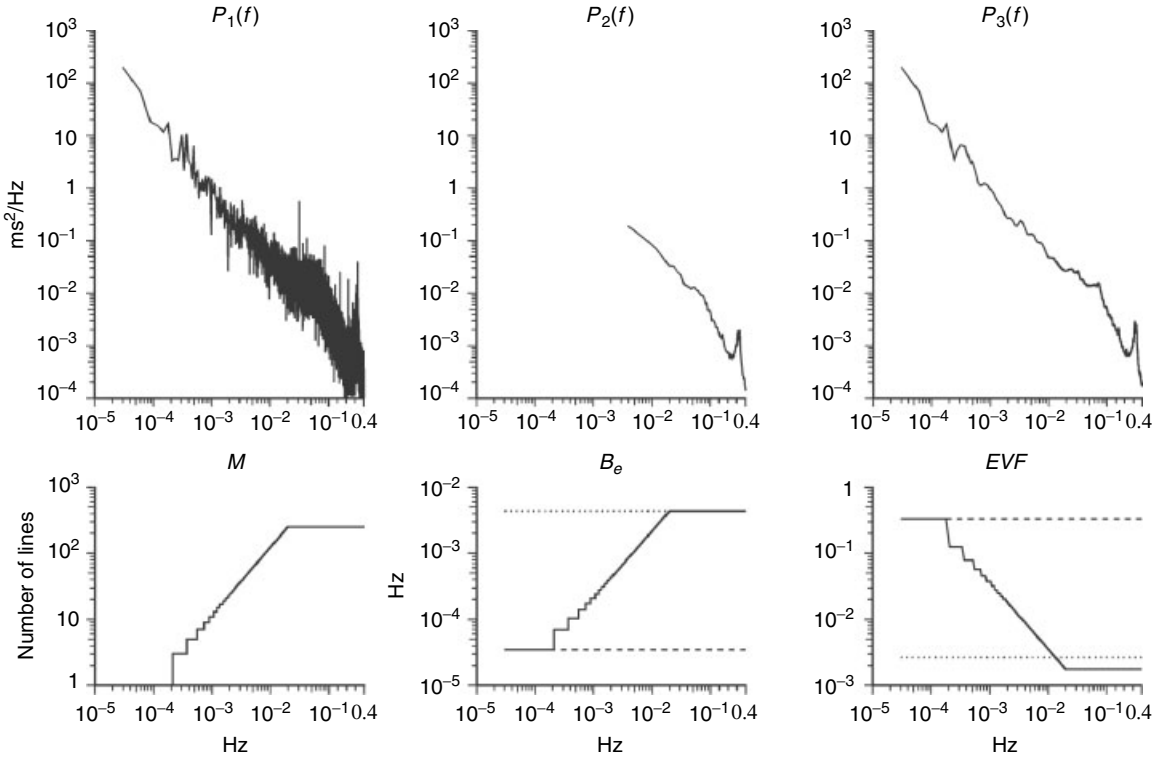

Figure 1 Comparison of traditional and broadband smoothing: data are the RR intervals from a 24 h Holter recording. *Upper panels*: $P_1(f)$ and $P_2(f)$ smoothed as in (1) with $L = 3$, $T_L = 8$ h (*left*) and $L = 378$, $T_L = 228.5$ s (*mid*); $P_3(f)$ smoothed by broadband smoothing of $P_1(f)$ (*right*). *Lower panels*: features of the broadband smoothing used for $P_3(f)$ plotted as functions of f: M is the number of averaged spectral lines; B_e is the equivalent bandwidth; EVF is the estimation variance factor; straight lines also show B_e and EVF for $P_1(f)$ (dashed) and $P_2(f)$ (dotted)

Broadband smoothing consists of a **moving average** of the raw spectrum $P(f_k)$:

$$P^S(f_k) = \sum_{i=-N(f_k)}^{N(f_k)} w_i(f_k) P(f_{k+i}), \qquad (2)$$

where the number of averaged spectral lines $M(f) = 2N(f) + 1$ increases with f to get the highest resolution at the lower frequencies and the more consistent variance reduction at the higher frequencies. A typical choice for $M(f)$ is

$$M(f) = \begin{cases} m_1 & \text{for } f < f^1 \\ int(af^b) & \text{for } f^1 \le f \le f^2 \\ m_2 & \text{for } f > f^2 \end{cases} \qquad (3)$$

with $m_1 \ll m_2$, $b = \log(m_1/m_2)/\log(f^1/f^2)$ and $a = m_1/(f^1)^b$.

The weights w_i are usually selected as:

$$w_i(f) = \frac{N(f) + 1 - |i|}{(N(f)+1)^2} \quad \text{for } -N(f) \le i \le N(f). \qquad (4)$$

An approximation of the variance of the smoothed estimate is [1, 3]

$$\text{Var}[P^S(f)] \cong \text{Var}[P(f)] \sum_{i=-N(f)}^{N(f)} w_i^2. \qquad (5)$$

The Estimation Variance Factor, $EVF = \sum_{i=-N(f_k)}^{N(f_k)} w_i^2$, quantifies the reduction in estimation variance. The frequency resolution can be measured by the equivalent bandwidth, B_e [2]. With the choices (3) and (4), EVF is lower than 1 and decreases with f, while B_e increases with f and is equal to $(N(f) + 1)\Delta f$, with Δf the resolution of the raw spectrum. Figure 1 illustrates the performances of broadband smoothing by comparing three RR-interval spectra from the same 24-hour Holter recording. The first two spectra are estimated by applying traditional smoothing schemes, one preserving high frequency resolution, the other providing consistent variance reduction, while the third spectrum is obtained by broadband smoothing.

PAOLO CASTIGLIONI

Brownian Motion and Diffusion Processes

Brownian motion, or Brownian movement, was named after the English botanist Robert Brown who, in 1827, reported an experiment with pollen of a certain herb in an aqueous suspension. The particles contained in the pollen performed a continuous, haphazard zigzag movement. This movement, Brown pointed out, could not be attributed to life in the particles. During the remainder of the nineteenth century, various experiments showed that the movement depends on the size and mass of the particles. The smaller and lighter the particles, the faster the movement. The movement also depends on the medium. The movement of the particles in gases is faster than the movement in liquids, and the movement in smoke is faster still. The velocity of the movement increases as the temperature increases. (These points formed the basis of the **Ornstein–Uhlenbeck** processes described later in this article.)

Another aspect of the Brownian movement is *diffusion*. In physical science, diffusion is the random molecular movement by which matter is transported. Diffusion occurs in all forms of matter. The diffusion process is slower in liquids than in gases. It takes place also in solids. Generally, there are two parties to every diffusion process. When smoke bursts into the air, diffusion follows; smoke and air are the two parties to the diffusion process. If two bodies of liquids of different colors are placed in two adjacent compartments of a tank, separated by a center divider, then diffusion occurs as soon as the center divider is removed. The two bodies of liquids are the two parties to the diffusion process. If two disks of lead and gold are placed in such a position that their edges meet, the migration of lead into gold and of gold into lead will eventually take place. These are good examples of diffusion processes. A diffusion process will end, but the Brownian movement will continue. In reality, the diffusion processes are a form of the Brownian movement when two or more distinguishable groups of particles are involved. If there were no Brownian movement, then there would be no diffusion processes.

While the various physical characteristics of Brownian motion were discovered in the late nineteenth century, basic questions about Brownian motion remained unanswered until much later. What makes the minute particles engage in a perpetual movement was not determined for the next three-quarters of a century.

It was not until 1905 that Einstein [6] showed that the Brownian motion could be explained by assuming that the particles are subject to continual bombardment of the molecules in the surrounding medium. His pioneering work was generalized, extended, and experimentally verified by various physicists [13]. Brownian motion has since become a popular research topic in theoretical physics. It is now well explained by statistical mechanics and kinetic theory. Wiener [18] also developed the theoretical foundation of Brownian motion and explored its applications. For a history of the theory of Brownian motion, the reader is referred to Einstein [6] and the collected papers edited by Wax [17].

In the theory of stochastic processes, Feller [7] was among the first to study Brownian motion, and he extensively discussed diffusion processes as a major topic in the field. Feller also considered Brownian motion as a limiting case of a random walk as presented in the following section (see also [3]). One may find discussions on Brownian motion and diffusion processes in [1, 2, 4, 5, 9–14]. It should be noted, however, that in stochastic processes we often consider the movement of only *one particle*, in *one dimension*, and the net displacement in *one time period*. This is hardly a fair description of the Brownian movement, much less of diffusion processes. But such a simplification is necessary to make the basic concept clearer and the mathematics simpler. A good understanding of a simple case often makes it easier to understand the complicated real picture.

The purpose of this article is to give a brief review of the one-dimensional Brownian motion and diffusion processes. In the following sections we describe the processes in terms of net displacement from three different perspectives.

1. As a limiting case of a random walk.
2. As a mathematical model.
3. As a stochastic process.

Limiting Case of a Random Walk

Consider a random walk on the real line during the time interval $(0, t]$. At the initial time, $t = 0$, the particle is at the origin. A move of length Δx occurs with every time element Δt.

Let δ be the corresponding **random variable** with $\Pr\{\delta = +\Delta x\} = p$ and $\Pr\{\delta = -\Delta x\} = q$, where $q = 1 - p$. The expectation and the variance of δ are, respectively,

$$\mathrm{E}(\delta) = (p - q)\Delta x \quad \text{and} \quad \mathrm{var}(\delta) = 4pq(\Delta x)^2.$$

There are $t/\Delta t$ moves during the interval $(0, t)$ and $t/\Delta t$ independent and identically distributed random variables δ_i. The sum $\sum_i \delta_i = Z_t$ is the total net displacement on the real line during the interval $(0, t]$, or the position of the particle at time t. According to the **central limit theorem**, when $t/\Delta t$ becomes infinitely large, Z_t has a **normal** distribution with expectation and variance:

$$\mathrm{E}(Z_t) = \frac{(p - q)t\Delta x}{\Delta t}$$

and

$$\mathrm{var}(Z_t) = \frac{4pqt(\Delta x)^2}{\Delta t}.$$

In Brownian motion, we have $\Delta x \to 0$ and $\Delta t \to 0$, and both p and q close to 1/2. For Z_t to have a finite expectation and a bounded variance, we have $\Delta x \to 0$, $\Delta t \to 0$, and $p \to 1/2$ in such a way that

$$\frac{(p - q)\Delta x}{\Delta t} = c \quad \text{and} \quad \frac{(\Delta x)^2}{\Delta t} = D, \qquad (1)$$

where both c and D are positive constants. It follows that

$$\frac{(p - q)}{\Delta x} = \frac{c}{D},\ p = \frac{1}{2} + c\frac{\Delta x}{2D},$$
$$q = \frac{1}{2} - \frac{c\Delta x}{2D},$$

and

$$\mathrm{E}(Z_t) = ct \quad \text{and} \quad \mathrm{var}(Z_t) = Dt + o(\Delta x).$$

Consequently, the limiting probability density function of Z_t is

$$f_{Z_t}(x) = \frac{1}{(2\pi Dt)^{1/2}} \exp\left[-\frac{(x - ct)^2}{2Dt}\right]. \qquad (2)$$

Mathematical Model

For the total net displacement Z_t, we now write the probability

$$\Pr(Z_t = x) = v(x, t),$$

which is a function of both the value x and the length of time t. The purpose is to derive a formula for $v(x, t)$.

Consider $v(x, t + \Delta t)$, the probability of the particle being in position x at time $t + \Delta t$. For the particle to be in position x at $t + \Delta t$, it must be either at $x - \Delta x$ at time t followed by a shift of Δx to the right in $(t, t + \Delta t)$, or at $x + \Delta x$ at time t followed by a shift of Δx to the left in $(t, t + \Delta t)$. As a result,

$$v(x, t + \Delta t) = pv(x - \Delta x, t) + qv(x + \Delta x, t). \qquad (3)$$

Using Taylor's expansion for $v(x, t + \Delta t)$, $v(x - \Delta x, t)$, and $v(x + \Delta x, t)$ at (x, t), defining c and D from (1), and letting $\Delta t \to 0$ and $\Delta x \to 0$, we obtain the following partial differential equation:

$$\frac{\partial}{\partial t}v(x, t) = -c\frac{\partial}{\partial x}v(x, t) + \left(\frac{1}{2}\right)D\frac{\partial^2}{\partial x^2}v(x, t). \qquad (4)$$

This is a partial differential equation of second order; see [1] and [2] for its solution. It is easy to check that the following normal density function satisfies the partial differential equation (4):

$$v(x, t) = \frac{1}{(2\pi Dt)^{1/2}} \exp\left[-\frac{(x - ct)^2}{2Dt}\right]. \qquad (5)$$

Therefore the normal density (5) is the solution of the differential equation (4). We recognize, in passing, that (5) is the same as (2).

The differential equation (4) is the Fokker–Planck diffusion equation, well known in physics. The constant c is the drift coefficient and D is the diffusion coefficient.

Stochastic Process

In **Markov processes** the random variable $X(t)$ assumes discrete values. For $s < t$, the transition (conditional) probability is $P_{ij}(s, t) = \Pr[X(t) = j | X(s) = i]$, where $X(s) = i$ is the condition. In

Brownian motion and diffusion processes, both the time t and the random variable $X(t)$ are continuous. Instead of transition probabilities, we speak of transition density functions. Given $X(s) = x$, the transition density function of $X(t)$ at $X(t) = y$ is denoted by $f(x, s; y, t)$.

A process is time-homogeneous if the transition density, $f(x, s; y, t)$, depends only the difference, $t - s$, and not on s and t separately. A process is additive if $f(x, s; y, t)$ is a function of $y - x$ and not of x and y separately. Generally $(t - s) > 0$, but the difference, $y - x$, is not always positive. The Brownian motion diffusion processes discussed here are assumed to be both time-homogeneous and additive. For nonoverlapping time intervals, the corresponding transitions are assumed independent. For simplicity, we let the process start from the origin, with $X(0) = 0$, and write $f(0, 0; x, t)$ for the transition density function of $X(t)$ at $X(t) = x$.

Following the general practice in Markov processes, we derive the formula for $f(0, 0; x, t)$ in three steps:

1. establish a Chapman–Kolmogorov equation;
2. derive Kolmogorov differential equations; and
3. solve the differential equations for the transition density function $f(0, 0; x, t)$.

Chapman–Kolmogorov Equation

Consider three points on the time axis: $0 < s < t$, and the two adjacent intervals $(0, s)$ and (s, t). In addition to the transition density function $f(0, 0; y, t)$, there are two additional transition density functions: $f(0, 0; x, s)$ and $f(x, s; y, t)$. According to the conditions underlying Brownian motion, the transition during the time interval (s, t) is independent of the transition in the interval $(0, s)$. This essentially is the Markovian property. It follows that the product $f(0, 0; x, s) f(x, s; y, t)$ is the transition density of $X(t)$ at $X(t) = y$ given $X(0) = 0$, by way of $X(s) = x$ at time s. Since the random variable $X(s)$ must assume some value at s,

$$f(0, 0; y, t) = \int_{-\infty}^{\infty} f(0, 0; x, s) f(x, s; y, t) \, \mathrm{d}x, \tag{6}$$

which is the Chapman–Kolmogorov equation for the continuous process $X(t)$.

The Differential Equation

For a detailed account, see [1] and [2].

Consider the time interval $(0, t + \Delta t)$ and two adjacent intervals $(0, t)$ and $(t, t + \Delta t)$. Write two equations,

$$f(0, 0; x, t + \Delta t) = \int_{\infty}^{\infty} f(0, 0; z, t) f(z, t; x, t + \Delta t) \, \mathrm{d}z$$

and

$$f(0, 0; x, t) = f(0, 0; x, t) \int_{\infty}^{\infty} f(z, t; x, t + \Delta t) \, \mathrm{d}z,$$

and hence,

$$f(0, 0; x, t + \Delta t) - f(0, 0; x, t) = \int_{\infty}^{\infty} f(z, t; x, t + \Delta t)[f(0, 0; z, t) - f(0, 0; x, t)] \, \mathrm{d}z.$$

Using Taylor's expansion for the difference, $f(0, 0; z, t) - f(0, 0; x, t)$, we write

$$c = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{\infty}^{\infty} (x - z) f(z, t; x, t + \Delta t) \, \mathrm{d}z$$

and

$$D = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{\infty}^{\infty} (x - z)^2 f(z, t; x, t + \Delta t) \, \mathrm{d}z,$$

where c and D are the infinitesimal mean and variance of $X(t)$, respectively. In the present case, the process is homogeneous and additive: c and D are constants.

Letting $\Delta t \to 0$, we obtain the partial differential equation:

$$\frac{\partial}{\partial t} f(0, 0; x, t) = -c \frac{\partial}{\partial x} f(0, 0; x, t) + \frac{1}{2} D \frac{\partial^2}{\partial x^2} f(0, 0; x, t). \tag{7}$$

Formula (7) is the (forward) Kolmogorov differential equation for the diffusion process.

Solution for the Transition Density

The final step is to solve the differential equation (7) to find the formula for the transition density function

$f(0, 0; x, t)$. Once again we refer to [2] for details of the solution of the differential equation (7).

Eq. (7) is identical to formula (4) in the preceding section when $f(0, 0; x, t)$ is identified with $v(x, t)$. Therefore, the solution of the partial differential equation is

$$f(0, 0; x, t) = \frac{1}{(2\pi Dt)^{1/2}} \exp\left[-\frac{(x - ct)^2}{2Dt}\right]. \quad (8)$$

Identical formulas, in (2), (5) and (8), have thus been found by three different approaches.

Wiener–Levy Process

If the instantaneous distribution of $X(t)$ is "standardized" so that the mean $c = 0$ and the variance $D = 1$, then the differential equation (7) reduces to

$$\frac{\partial f(0, 0; x, t)}{\partial t} = \frac{1}{2} \frac{\partial^2 f(0, 0; x, t)}{\partial x^2},$$

and the solution is

$$f(0, 0; x, t) = \frac{1}{(2\pi t)^{1/2}} \exp\left(-\frac{x^2}{2t}\right),$$

which is the Wiener–Levy process [2].

Ornstein–Uhlenbeck Process

The Ornstein–Uhlenbeck process describes another aspect of Brownian motion, namely the velocity of the movement of a particle. As we noted in the introduction, there are many factors affecting the velocity of the movement, namely the particle's physical characteristics and the surrounding environment. The process is much more complicated than the simple displacement on the real line discussed above. Specifically, in the Ornstein–Uhlenbeck process we wish to determine the velocity of the movement between x and $x + \mathrm{d}x$ after time t, when at $t = 0$ the velocity was $x = x_0$. Let $X(t)$ denote the velocity of the particle at time t and let

$$f(x_0; x, t) = \Pr[X(t) = x | X(0) = x_0].$$

Uhlenbeck & Ornstein [15] established a partial differential equation for $f(x_0; x, t)$ and provided the solution:

$$f(x_0; x, t) = \left\{\frac{m}{2kT[1 - \exp(-2\beta t)]}\right\}^{1/2} \times \exp\left\{-\frac{m}{2kT} \frac{[x - x_0 \exp(-\beta t)]^2}{1 - \exp(-2\beta t)}\right\},$$

where $\beta = \overline{f} m^{-1}$. Here, m is the mass of the particle, $\overline{f}$ is the coefficient of friction, k is the coefficient of viscosity, and T is the absolute temperature.

In addition to the original publication [15], there was a second later publication [16]. A convenient reference for this process is [2].

A Final Remark

The above description covers a small but fundamental part of the Brownian motion and diffusion processes. A more extensive study of the processes requires advanced mathematics. However, even at this level of description, the Brownian motion and diffusion processes have many practical applications. For example, they have been used in studies of **population growth** [2] and in **population genetics** [8].

CHIN LONG CHIANG

Brownlee, John

Born: 1868.
Died: March 20, 1927.

Brownlee was qualified in both mathematics and medicine. He became Director of the Statistical Department of the (British) **Medical Research Council** in 1914, housed in the National Institute for Medical Research in London. He wrote several papers on **vital statistics**, including an important publication in 1916 [1], in which he demonstrated the value of displaying age-specific death rates from tuberculosis by the cohort or generation method (*see* **Age–Period–Cohort Analysis**). He wrote also on mathematical epidemiology, especially in relation to the periodicity of epidemics.

PETER ARMITAGE

BSE and vCJD

The transmissible spongiform encephalopathies constitute a group of uniformly fatal neurological degenerative diseases with the abnormal isoform of the cellular prion protein present. They include Creutzfeldt–Jakob Disease (CJD) and kuru, among others, and now also a new variant CJD (vCJD, formerly nvCJD) in humans, scrapie in sheep, and "mad cow disease" or bovine spongiform encephalopathy (BSE) in cattle. A 10-year history introduces salient biostatistical issues in BSE and vCJD.

The first confirmed diagnosis of BSE [54] was made in the UK on November 26, 1986. BSE became a notifiable disease on June 21, 1988 (*see* **Surveillance of Diseases**; **Disease Registers**). The ruminant feed ban [56] came into force on July 18, 1988, and the Bovine Offal (Prohibition) Regulations in November 1989 (in England and Wales) and January 1990 (in Scotland and Northern Ireland).

The first case of BSE after the ruminant feed ban in the offspring of a BSE-infected dam was announced on March 27, 1991. A BSE maternal **cohort study** of over 300 calf pairs with birth dates from August 1987 to November 1989 had been under way on three study farms since July 1989 [59]. All calves of BSE-affected dams in this study were born within 13 months of clinical onset in their dam. Other investigations of risk factors for BSE [12, 37, 55] included **case–control studies**. Despite concentration on BSE cases born after the introduction of the feed ban, there was **confounding** because exposure to contaminated feed had continued well beyond July 1988; reported **confidence intervals** for the **odds ratios** on dam-to-calf BSE transmission overlapped 1 and had upper bounds which excluded high overall rates.

Meanwhile, as a precaution in respect of human health, prospective UK surveillance of CJD was reactivated in May 1990. The remit of the CJD Surveillance Unit was to alert to any changes in the presentation, age-specific incidence, occupational distribution, or dietary correlates of CJD cases that might suggest that humans were affected by exposure to BSE. By November 1995, Gore considered that cases of CJD in five UK farmers and three young adults since May 1990 were more than happenstance: they signalled an epidemiological alert (*see* **Case Series, Case Reports**) [25].

On March 20, 1996, 10 UK cases of a new variant of Creutzfeldt–Jakob disease (vCJD, formerly known as nvCJD) [59] with distinctive neuropathology, methionine homozygosity at codon 129, comparative youth, longer survival from clinical onset, and psychiatric presentation were announced in a statement by the Spongiform Encephalopathy Advisory Committee (SEAC). In a *British Medical Journal* editorial on March 30, 1996, actions necessary to safeguard the public health and properly to acquire data to quantify risks were suggested, and interim analysis of the BSE maternal cohort study called for [26], calls which were initially spurned [2].

On July 29, 1996, SEAC announced that an interim analysis of 273 calf pairs in the BSE maternal cohort study had revealed a significantly enhanced risk of BSE among the offspring of BSE-affected dams compared with matched (*see* **Matching**) **controls** (controls were born in the same herd and calving season to dams which had reached at least six years of age without developing clinical signs of BSE). The risk difference was 10% (95% confidence interval 5 to 14%) when the cohort study ended [19, 57], and **relative risk** 3.2 (95% confidence interval 1.8 to 5.9). In August 1996, UK donors with a family history of CJD were asked to abstain from blood and tissue donation.

By the end of August 1996, a comprehensive account of the transmission dynamics and epidemiology of BSE in British cattle had been published by Anderson et al. [1]; they estimated that approximately 1 million cattle had been infected in the UK, over 160 000 having survived to develop clinical signs of BSE. Underreporting of BSE was substantial before July 1988 (that is, before BSE became notifiable and was compensated for) with an estimated two cases of BSE not reported for every reported case. The epidemiological parameters which Anderson et al. took into account were: age-dependent exposure/susceptibility; five-year mean incubation period; age-specific survivorship of cattle in Great Britain; decline in total herd size from over 13 million in 1974 to under 10 million in 1995; maternal and horizontal transmission [37] with several – but not all – scenarios chosen to reflect that, for BSE in cattle, high infectivity may be restricted to the late or symptomatic stage of the incubation period. **Back-calculation** from BSE cases [1] – without knowledge of (dam–offspring) relatedness and having made allowance for substantial underreporting of BSE

cases before July 1988 – could not distinguish compellingly between no maternal transmission, 10% maternal transmission in the six months before BSE onset in dam, and 10% maternal transmission in the year before dam's onset; **goodness-of-fit chi-square** differed by 10 on 219 degrees of freedom across the foregoing three scenarios but the fit became very substantially worse if the period over which maternal transmission took place was assumed to be three years (change of 240 in goodness of fit).

Meanwhile, medical scientists were giving priority to diagnostic tests for CJD: in September 1996, Hsich et al. [39] reported that, in patients with dementia, a positive immunoassay for the 14-3-3 brain protein in cerebrospinal fluid strongly supported a diagnosis of CJD. October 1996 heralded an even more important breakthrough. Collinge et al. [6] published a molecular analysis of prion strain variation: vCJD has a specific pattern of protease-resistant prion protein (PrP) on Western blot analysis which is distinct from other types of CJD and which resembles those of BSE transmitted to mice, domestic cats, and macaques [43]. These results were consistent with BSE being the source of vCJD, see also [5, 6, 31].

Collinge's molecular analysis has since been used by Deslys et al. [16] to confirm that the first vCJD patient in France had an indistinguishable electrophoretic pattern to UK cases (type 4) while another French patient, a possible case of vCJD – a 52-year-old methionine homozygous female with florid plaques in a brain specimen but dura-mater graft 11 years previously – had a type 2 pattern similar to that described by Collinge in an iatrogenic dura-mater linked CJD case. Molecular analysis of brain tissue from now-six farmer CJD cases in the UK did not find type 4; all from whom tissue was analyzed had classical CJD neuropathologically [37]. Importantly, Hill et al. [33] showed that it was possible to make the specific diagnosis of vCJD by Western blot analysis from frozen tonsillar tissue, see also [34, 35, 41, 47, 49]. These scientific developments, together with Europe's highly assessed geographical BSE risks [50], heralded both Swiss [17] and the European Union's rapid TSE testing in adult cattle and sheep [3, 46, 51]. Postmortem BSE testing, since 2001, of apparently healthy cattle aged over 30 months and risk stock aged over 24 months throughout Europe has transformed our understanding of BSE epidemiology. Active surveillance in cattle showed that clinical BSE cases account for one-third only of all BSE-test positives *and* that BSE positivity is 10 to 15 times higher in risk stock. Assuming differential mortality in late-stage BSE led to Great Britain's having had nearer 4 millions than 1 million BSE-infected cattle [20]. Higher scrapie positivity was also confirmed in fallen sheep [3] *and* apparent positives discovered in ARR/ARR sheep previously considered as scrapie-resistant: their somewhat unusual TSE test profile is being further investigated.

Not only has active BSE surveillance led to a three-fold increase in previous estimates for the extent of Great Britain's BSE epidemic in cattle [20] but, in man too, retrospective [34] and unlinked, anonymous, and ungenotyped testing of stored operative tissue (appendix or tonsil from 1995 to 2000) has discovered an unusual positivity pattern for abnormal prion, PrP^{SC} [36]. Because, to date, all vCJD phenotyped patients have been methionine homozygotes at codon 129, we do not know whether humans' abnormal PrP^{SC} profile in tonsil or appendix tissue is altered by phenotype. There is about a three-fold discordance in prevalence between back-calculation from vCJD cases [22, 23] and testing of tissues for abnormal PrP^{SC}, if *all positives* detected are assumed methionine homozygous and exposed dietarily.

Degree of belief in the proposition "BSE causes vCJD", as elicited from audiences of scientists, legislators and public health specialists in June to August 1996, was highly variable [27]: **modal** score was 8 out of 10, **median** 6, but the **mean** score was 5.4 with **standard deviation** of 2.8. And this despite headlines in the UK press in the week of March 20, 1996, which ranged from the *Daily Mirror*'s scoop on March 20 ("Official: Mad Cow Can Kill You. Govt to admit it today") to the *Evening Standard*'s on March 21 ("French Ban British Beef. Germany calls for Europe boycott as Dorrell warns 11m cattle may have to die") and the *Independent*'s on March 23, 1996 ("Beefgate").

Information on dietary exposure to BSE is critical, but difficult to obtain. CJD patients being too unwell, a relative is asked to recall the patient's diet over a lifetime and since 1985; the CJD Surveillance Unit itself places little confidence in the data so generated. Four indirect sources of information on dietary exposure to BSE may therefore be important: UK nutrition surveys conducted in the 1980s and 1990s (for evidence on strongly age-related dietary consumption, of beefburgers, for example [30]); unannounced

inspections at abattoirs by the State Veterinary Service (for evidence on the frequency and nature of breaches of regulations concerning specified bovine materials [28, 45]); an audit commissioned in the spring of 1996 by the Ministry of Agriculture, Fisheries and Food (for information by quinquennia on which bovine and ovine tissues went into which foods when); and back-calculation from BSE cases to infer the BSE infection curve [1] and annual numbers of BSE-infected bovines which were within one year of clinical onset (say) when slaughtered for human consumption. Cooper and Bird's synthesis [7–9] of the foregoing data sources predated upward revision by Ferguson et al. [20] of annual numbers of BSE-infected bovines, which were within one year of clinical onset when slaughtered for human consumption. Changes in the estimated preclinical BSE incidence pattern (not just level) could have implications for Cooper and Bird's predicted incidence of vCJD from the United Kingdom dietary exposure to BSE for the 1940–1969 and post-1969 birth cohorts [10]. Their projections suggested: that about three-fifth of predicted dietary vCJD onsets would be in males, see also [11]; and, over and above dietary exposure, that an age-dependent susceptibility function – as first conjectured by Valleron et al. [53] – or other exposure was required to match the age distribution of vCJD patients in the 1940–1969 birth cohort. Although the risk of infection with prion diseases increases with repeated challenges, Gravenor et al. [24] have found that it does so to a lesser extent than is expected if challenges combined independently or in a cumulative manner. This finding could also be a part explanation for implied age-dependent susceptibility.

Cousens et al. [14] hazarded [42] projections of vCJD by assuming simply that, until 1989, the number of people newly infected with the BSE agent was proportional to the number of BSE cases with onset in that year, as may be reasonable if bovine material is infectious to humans for only a short period before cattle develop clinical BSE. These very preliminary projections do not explain the apparently age- and genetics-related susceptibility to vCJD. Dates of onset of vCJD (seven in 1994, six in 1995), referral to the CJD Surveillance Unit, death and confirmation of diagnosis were plotted by Cousens et al. for the first 14 cases of vCJD in the UK: given the typically long delay between onset and confirmation, the final number with onset in 1994 or 1995 could be about 23 [14]. Regular updating – at least annually – of these crucial date data is epidemiologically essential, and by a variety of methods as reflected, or referenced, in a special TSE issue (Volume 12, Number 3) of Statistical Methods in Medical Research in 2003.

Unlike in **AIDS** [15, 26, 48], an independent group of statisticians and subject-matter specialists was not convened prior to 1996 to work on, and publish, BSE projections, but this investigative format did apply for UK's review in 2002–2003 of its Over Thirty Month Rule, whereby from April 1996, no part of UK's cattle slaughtered at 30+ months of age could enter human food or any feed chain [20]. A reinforced feed ban came into force from August 1, 1996 in the United Kingdom (and from January 1, 2001 elsewhere in European Union), after which it was hoped that maternal transmission would be the only route of cattle's BSE exposure. Events proved otherwise with maternal transmission being effectively ruled out for about a third of BSE cases born after the reinforced feed ban (BARBs) [52] so that in 2004, the United Kingdom was designing a BARB-controls study to investigate a low-level, third wave of BSE exposure (prior to original ruminant feed was first, between initial and reinforced feed bans was the second).

Three statistical teams had been invited to undertake further analyses [29] of the BSE maternal cohort study to determine whether the elevated risk of BSE among offspring of BSE-affected dams was due to a genetically enhanced risk of food-borne infection, to vertical transmission of the etiologic agent from dam to calf, or some combination of the two. Evidence of an enhanced BSE risk in calves born closer to disease onset in their dams would provide support for vertical transmission; and corroboration of the "infectious interval" could be sought from the BSE database in respect of calves born well after the feed ban to dams which ultimately developed BSE [18, 29]. Analysis of the BSE database was complicated by misidentification of dam–calf pairs and by the lack of survival data, which pointed up the need for improved cattle-tracing systems, such as Northern Ireland had and have subsequently come into force in Great Britain. To date, separate analyses of the BSE maternal cohort study and BSE database have been undertaken. A **Bayesian** formulation would allow for full propagation of uncertainty [21] with consideration also of lateral transmission and of regional exposure to contaminated feed in 1989 or later: the

BSE maternal cohort study is seen as external data and **sensitivity analysis** of assumptions about calf survivorship according to BSE status of dam would be crucial.

Statistical plans [28] for unannounced inspections at abattoirs by the State Veterinary Service were an outstanding issue in the aftermath of vCJD. Contrary to reporting standards in 1995 [45], they would allow defendable estimates of the extent of compliance with BSE and other regulations intended to safeguard public or animal health. Statistical planning in determining which brain and other tissue to preserve or test from cows in the over-30-month slaughter program and selective cull was only fully addressed under the auspices of the European Union's Scientific Steering Committee [3, 51]. Such tissue, particularly from UK cows born either between feed bans or after July 31, 1996, could be extremely valuable in studying age-specific pathogenesis and in determining the performance of diagnostic tests in asymptomatic animals.

Three main statistical issues in vCJD are acquisition of key data to underpin projections; evolution of a risk score for highly suspect vCJD; and follow-up of children born to parents with vCJD, of healthcare workers who attended the delivery of a mother with vCJD, and of healthcare or other workers who have had percutaneous exposure to vCJD or to BSE. Probable blood-borne vCJD transmission [4, 44], announced to both Houses of Parliament in December 2003, has underlined rights and responsibilities for limiting human-to-human transmission of vCJD and for surveillance. Blood-borne vCJD transmission had been anticipated by BSE (and scrapie) transmission risks of 10 to 20% in sheep [38, 40] via blood transfusion: of 24 sheep-recipients of BSE-infected transfusions, two were confirmed BSE cases (8%) and two others suspect; and of 21 sheep-recipients of scrapie-infected transfusions, at least four had succumbed (21%) [40].

From 5 April 2004, the United Kingdom excluded recipients of blood or tissue from donation. Preventing operative transmission of vCJD *and* quantifying human-to-human vCJD transmission risks need additional measures. Quantification of human-to-human vCJD transmission risks requires *identification of index patients* (incubating vCJD, positive for abnormal prion protein PrP^{SC} or otherwise at risk) *and their recipients* (of vCJD-implicated blood or tissue or surgical instruments), a *recipients' database*, which records exposure risk classification and donor, together with *flagging of recipients for mortality* and *recipients' agreement in life* that they be tested postmortem for abnormal PrP^{SC} and phenotyped at codon 129 since all vCJD cases to date have been methionine homozygous at codon 129, but only 40% of UK population is.

Surveillance options include attributable tonsil biopsy for abnormal PrP^{SC} at all autopsies [4] under 50 years of age (with positives phenotyped at codon 129), which would facilitate identification, follow-up, and risk quantification for recipients of "at-PrP^{SC}-risk" blood or tissue or implicated in a surgical web spun out from deceased positives.

Key data to underpin projections have been marshaled, such as: those from patients with kuru or iatrogenic CJD or from repeated challenge experiments in rodents to estimate the incubation period, its age dependence (if any), and possible dose-responsiveness [24]; age-specific and temporal changes in the consumption of foods, which may have contained the BSE agent [7–11, 20] to estimate dietary BSE exposure; those, including costs, from feasibility study on estimating the prevalence of abnormal prion in 10–50 year olds by molecular analysis of stored tonsillar or appendix tissue as forerunner of a national tonsil archive to facilitate testing or postmortem testing in the course of autopsies routinely performed for other reasons ranging from road traffic accidents to drugs overdose.

A second issue was to evolve, and update, a risk score for highly suspect vCJD, including for determining a suitable, if not optimal, sequence of investigations that is likely to reach a correct, definitive diagnosis quickly and with minimal trauma for the patient. Tonsil biopsy, now accepted in differential diagnosis of vCJD, has resolved this issue to such an extent that the postmortem rate has fallen considerably in vCJD-diagnosed patients. Careful documentation of the sequence of neurological signs was considered important [58]. The setting-up of a patient-preference protocol under Medical Research Council auspices at least affords all patients the option of standardized follow-up whether they elect for randomization or not. (see under "other studies" on `http://www.ctu.mrc.ac.uk/browse.asp` for initial options such as: "choice = to receive quinacrine now", "choice = to reject quinacrine now" and "choice = randomization to receive/not receive quinacrine now").

Finally, to quantify the risk (if any) of mother-to-child or of percutaneous transmission of vCJD [26] we need outstandingly to register exposed individuals so that the relevant denominators are knowable.

SHEILA M. BIRD

Burden of Disease

"Burden of disease" is the name given to a concept dealing with a range of medical statistics. It aims to give a comprehensive picture of how different diseases impact on society. Some analysts use this concept to allocate health care and research resources. Because it covers a range of impacts of disease on society, the burden is often referred to in the plural, a practice followed in this article.

"Burdens of disease" aims to give an account of the dimensions of damage inflicted by ill health on society. The main burdens covered are mortality, morbidity, and resources costs of care and treatment. Applications were developed first in the US, but examples here are based on experience in the UK. The main interest is in how the burdens of different diseases compare. It aims to answer questions like: Is heart disease a bigger killer than cancer? Which diseases afflict women especially? Which diseases impose greatest cost on healthcare services? Table 1 is taken from the latest UK table of burdens of disease [4] and summarizes the main results. Answering such questions raises a host of problems. Some of them arise from one of the burdens and some arise from attempts to bring them all together.

Mortality

What do we mean when we say that one disease is a bigger killer than another? Looking simply at unadjusted death rates will not capture the flavor of the question. Since all must die, the simple causing of death does not impose a burden on society. It is premature death that is the burden. One commonly adopted solution is to look at deaths below a certain age. Choosing the age is not simple. If it is set very low, then it will focus attention on a very narrow range of causes of death such as sudden infant death syndrome (SIDS), accidents, etc. Set too high and it loses any focus on policy issues. Over the age of, say, one hundred, the precise cause of death is of less interest than the survival thus far. Recent presentations have looked not at simple death rates, but weighted them by the years below a certain age. Thus SIDS deaths are given a high weight because they are seen as destroying almost a whole lifespan. While the usual presentation focuses on life-years lost, there is no reason in principle why both crude and weighted death rates should not be used. They reflect different concerns. Even though inevitable, the event of death is always painful to survivors and fearful to the dying. The curtailing of life is an additional loss. A further difficulty is whether the life-years lost calculation should use different age standards for men and women, to reflect their different **life expectancy**.

Compared with other burdens, the data difficulties of mortality statistics are relatively few. In many developed countries the measurement has become simpler with the recording of several **causes of death** on death certificates. There remain problems with causes like **AIDS** and suicides, where there will be a *bias* against recording such conditions on death certificates.

Morbidity

Data on morbidity tend to come from three main sources: administrative records associated with welfare benefits, surveys of physicians, and household surveys (*see* **Surveys, Health and Morbidity**). In the UK these are represented by sickness benefit records, the morbidity survey of general practitioners, and surveys like the Disability Survey and the Health Survey. The first dataset records total days of certificated sickness absence. The second source records the patient consulting rate for a given condition. Household surveys will, in principle, obtain a direct measure of the number of people suffering from a given condition at a particular point in time, and so come closest to a measure of the extent to which the population at a given moment is suffering from ill health. While certificated sickness measures the same thing in principle, it suffers, besides the problems associated with administrative sources like policy change, from the problem that only those otherwise in work will be recorded. It therefore omits most of the population who are ill, the old, and many of the chronically sick. The number of people consulting primary physicians gives a useful indication of something between incidence and prevalence of disease, but requires additional weighting to give a useful picture of the burden of morbidity. Chronic conditions clearly impose a greater burden than short-lived conditions, so this measure of prevalence has to be adjusted by some estimates of average duration.

Table 1 Twenty leading causes of mortality, patients consulting in general practice, and expenditure by ICD-9 subchapter. England except MSGP = England and Wales, GHS = Great Britain [4]

Rank	Mortality (1991)	(%)	Patients consulting in general practice[a] by cause[b] (1991/92)	Rate per 1000	NHS hospital expenditure (1992/93)	(%)	NHS primary care expenditure[c] (1992/93)	(%)	Community health and social care for adults net expenditure (1992/93)	(%)
1	Ischemic heart disease	26.2	Acute respiratory infections	242.0	Injury and poisoning	5.8	Mouth disease[e]	26.0	Learning disability	12.5
2	Stroke	12.1	Skin diseases	159.6	Learning disability	5.2	Acute respiratory infection	7.7	Stroke	7.1
3	Lung cancer	6.0	Infectious diseases other than TB	156.2	Symptoms	4.3	Eye disorders[d]	6.3	Other arthropathies	6.5
4	Pneumonia	5.0	Injury and poisoning	139.0	Stroke	4.2	Symptoms	5.7	Eye disorders	5.2
5	Chronic obstructive pulmonary diseases (COPD)	4.8	Symptoms	138.7	Schizophrenia	4.0	Injury and poisoning	3.8	Dementla	5.2
6	Colorectal cancer	3.0	Preventive medicine	138.0	Normal delivery	3.1	Infections other than TB	3.0	Neuroses	3.8
7	Arteries	2.8	Screening	121.0	Dementia	2.7	Skin diseases	3.0	Ear disorders	3.7
8	Cancer of other sites	2.7	Ear disorders	101.2	Ischemic heart disease	2.4	Heart failure	2.7	Rheumatism	3.7

10	Other heart	2.0	Other neuroses, etc.	64.9	Procedures and aftercare	2.3	Osteoarthritis	2.1	Alcohol, drugs, etc.	3.1
11	Dementia	1.7	Eye disorders	63.7	Skin diseases	2.0	Screening	2.0	Multiple sclerosis	2.7
12	Prostatic cancer	1.5	Social and social marital	61.3	Arteries and veins	2.0	Ear disorders	2.0	Other CNS and disorders of the PNS	2.7
13	Stomach cancer	1.5	Other back diseases	59.1	Other nonorganic psychoses	1.9	COPD	2.0	Osteoarthritis	2.3
14	Diabetes	1.4	Dorsopathies	59.1	Other neuroses, etc	1.9	Hypertension	1.8	Rheumatoid arthritis	2.1
15	Urinary cancer	1.3	Female genital tract	57.4	Female genital tract	1.9	Ischemic heart disease	1.8	Pregnancy	1.8
16	Pancreatic cancer	1.1	Sprains and strains	55.0	Social and social marital, etc.	1.8	Other urinary	1.6	Old age	1.7
17	Suicide and unknown motive	1.0	Rheumatism	49.0	Heart failure	1.6	Stroke	1.5	Other heart disease	1.6
18	Genito-urinary cancers female	1.0	Upper respiratory tract diseases	43.0	Pneumonia	1.6	Intestines and peritoneum	1.4	Schizophrenia	1.6
19	Other systemic cancers	1.0	Asthma	42.5	Eye disorders	1.5	Asthma	1.4	Epilepsy	1.6
20	Heart failure	1.0	Hypertension	41.9	Other respiratory	1.4	Other back disorders	1.2	Symptoms	1.6
Total leading causes		79.5				53.7		79.1		73.8
All other causes		20.5				35.4[f]		20.9		26.2[g]

Sources: Mortality: OPCS 1991.
Patient consultations: Morbidity Statistics from General Practice (MSGP4) 1991–92.
Expenditure: MSGP4, HES and Programme Budget.
[a]Patient consulting rates are based on consultations with general practitioners and practice nurses.
[b]78% of patients consult their GP at least once per annum. If a patient consults for more than one cause, they will be recorded once for each cause. Therefore, rates should not be added as there will be an element of double counting.
[c]NHS Primary care expenditure excluding pharmaceutical expenditure.
[d]Primary care expenditure relating to eye disorders include all costs attributable to General Optical Services.
[e]Primary care expenditure relating to mouth disease include all costs attributable to General Dental Services.
[f]Includes expenditure on day patients in hospitals, Accident and Emergency, Teaching Hospital Uplift (SIFTR) and "other" hospital expenditure.
[g]Includes unallocated expenditure.

Another weighting that is required is an adjustment for severity. A frequently used measure is the QALY or quality-adjusted life-year (*see* **Quality of Life and Health Status**). The implied days of sickness are weighted by the degree of suffering caused. A variety of scales have been developed such as the Euroqol [5], and estimates of discomfort and disability impact have been attached to different conditions.

While statistics on certificated sickness days may be of limited value in obtaining an overall picture of such suffering, they provide valuable subsidiary information on the burden imposed on the economy from not having workers available, on those who depend on the income they might otherwise have earned, and on the agencies that pay benefit.

Resource Costs

Societies devote considerable resources both to curing disease and to remedying some of its consequences. In most industrial countries much of this burden falls on the state, while in some there is considerable private finance of health insurance. However financed, these represent a use of resources which could otherwise perform some other useful function. Simplest to measure in most **health services** are the number of beds devoted to different conditions, and the average cost of bed occupancy. Slightly more difficult is out-patient (ambulatory) care, where records of conditions seem to be less systematically maintained. Where morbidity data are based on surveys of primary carers, these sources can also be used to estimate the cost burden of primary care. Here, of course, it is the consultation rate rather than the number of patients consulting which is relevant. Separate estimates are often required for dental care.

The disease classification of pharmaceuticals requires a certain amount of judgment to align with conditions. Classification becomes progressively more difficult with care which requires support against disability rather than curative interventions where the recording of causes of such conditions may be limited.

As well as pecuniary burdens borne both by the public and private sectors, there are nonpecuniary burdens – particularly in terms of caring. While such burdens are less often recorded in official compilations of burdens of disease, there are sources of such information in general and in dedicated household surveys.

There is conceptual difficulty with measuring the resource burden. It reflects what is considered appropriate by current medical practice. There is an implied but incorrect assumption that the scale of resources devoted to different conditions is such as to bring every sufferer back to a similar kind of condition. This is clearly far from the case. One of the conditions that imposes the heaviest burden on in-patient care is **stroke**, although it is unclear that the scale of those resources reflect the effectiveness of the interventions, compared, with, say, interventions in heart disease. The cost burdens therefore reflect a combination of prevalence and medical practice. If it were decided that more care should be devoted to mental illness, say, then there would be a perceived rise in burden, which might be accompanied by an unrecorded abatement in the severity of morbidity.

Uses and Abuses

In a 1996 publication the UK Department of Health presents burdens in a range of different categories [4]. There is no attempt to combine these into one overall indicator of burden. This was not the practice adopted in the first attempt by Black & Pole [1]. They combined all burdens together using implicit weights reflecting both the severity of disease relative to full health and death, and an implied pecuniary value of death. While it is always open to users to make such combinations using their own assumptions, the attribution of a money value to life is seen as too controversial to form the basis of a statistical publication.

Black & Pole, and many of those who have followed them, have seen burdens of disease as of potential value in decisions on where to direct preventive or curative resources and research which might develop them. While the epidemiologic mapping contained in burdens of disease provides an essential component of any system for making such allocations, it must be combined with indicators of the effectiveness of interventions. There is no point in throwing a large amount of resources at a disease, however burdensome, if it makes no difference to that burden.

Indicators of cost effectiveness are now available for a range – albeit still a fairly limited range of conditions [4]. The technique for effective resource allocation depends on a combination of burdens of disease statistics and cost-effectiveness information.

In practice nearly all interventions vary in their effectiveness depending both on the condition of the sufferer, the general circumstances, and the quality of the medical practitioner. An effective allocation of interventions will depend on the scale of the condition and the extent to which further intervention is likely to be effective in reducing the burden. It turns out that making such an allocation is relatively complicated. One scheme for doing so is described in Neuburger & Fraser [2].

Another potential use of burdens is to indicate the burden of a particular risk factor. Thus it would be possible to show the burden of smoking or car exhaust fumes by weighting together appropriate fractions of the burden of those disease associated with such risk factors. In terms of policy these could then be compared with interventions which might be taken to abate them.

Conclusion

Burdens of disease provides a valuable framework for compiling a range of data on different diseases. Used with care it can provide an invaluable tool for the development of health policy.

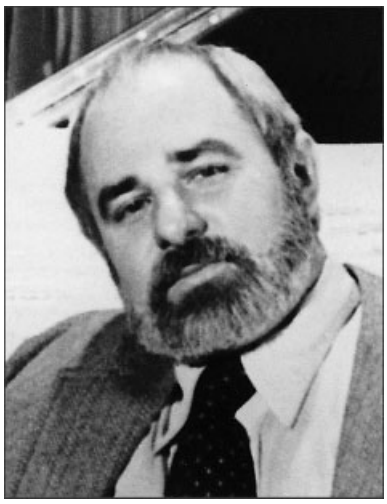
Byar, David P.

Born: February 23, 1938, in Lockland, Ohio.
Died: August 8, 1991, in Washington, DC.



David Byar was a leading **clinical trials** methodologist and proponent of structured experiments for making treatment **inferences**. He played an important role in teaching and advocating the strengths of clinical trials through his positions at the National Cancer Institute. He also made substantial contributions to epidemiology and studies of disease prevention.

David Byar was born in Lockland, Ohio, and attended high school in Maryville, Tennessee, where he graduated as valedictorian. He received an AB degree from Emory University in 1960 and went on to graduate from Harvard Medical School in 1964. After a surgical internship in Denver, Colorado, Dr Byar worked for three years at the Armed Forces Institute of Pathology. It was at this time that he became interested in genitourinary tumors and learned the fundamentals of laboratory experimentation. He became increasingly interested in the sources of variation in laboratory experiments and the statistical methods for coping with them. He began studying statistics and, in 1968, he joined the National Cancer Institute at the invitation of his teacher, Dr John Bailar. Dr Byar assumed the responsibility as statistician for several clinical trials being conducted by the Veterans Administration Cooperative Urological Group. These trials were to be influential in both the clinical treatment of prostate cancer and the methodology of human experiments.

These studies indicated that diethylstilbestrol (DES) was an effective treatment for patients with advanced prostate cancer. The drug was associated with increased mortality from heart disease, so that the treatment was not appropriate for patients with early stage prostate cancer. These data illustrated to biostatisticians the necessity for studying **treatment–covariate interactions** in clinical trials.

In 1972, Dave Byar was appointed Head of the newly formed Clinical and Diagnostic Trials Section at the National Cancer Institute. He would remain in that position for 13 years. The section combined methodologic work in biostatistics and clinical trials with consultation on specific real-world biostatistical problems. Dr Byar built a strong program in methodology and recruited excellent colleagues to this Section. In keeping with one of Dr Byar's favorite quotes by Voltaire, "The price of freedom is eternal vigilance", he was repeatedly called upon to defend the merits of randomized (*see* **Randomization**) clinical trials at a time when emerging computer and database technology suggested that treatment inferences from such sources (*see* **Administrative Databases**) might replace designed experiments.

In 1981, Dr Byar was elected a fellow of the **American Statistical Association**. He was cited "for rare capacity, reflecting an unusual combination of medical and statistical expertise, to bring scientific rigor to clinical testing; for work in statistical theory; and for effectiveness as a communicator between statisticians and medical researchers". In 1984, the Clinical and Diagnostics Trial Section in the Biometry Branch moved to the National Cancer Institute's Division of Cancer Prevention and Control. Dave was subsequently named Branch Chief. During this time, he was very influential in the development of important cancer **prevention trials**, including dietary modification, **screening**, and smoking cessation studies (*see* **Smoking and Health**). He also became active in modifying clinical trial designs for the treatments of **AIDS**.

Dr Byar was elected to the **International Statistical Institute** in 1984. In 1991, he was named an Honorary Fellow of the **Royal Statistical Society** "in recognition of services to statistics".

Dr Byar's academic achievements were widely known and respected. However, he was equally well known as a teacher, friend, and person who enjoyed many aspects of life. He was a particularly accomplished pianist, and once considered a career in music. He loved good food, reading, theater, and engaging friends in stimulating conversation. Dr Byar traveled extensively internationally and had many friends all over the world.

David Byar died on August 8, 1991, following a long illness. He will be remembered always for his scientific contributions and as a source of inspiration to those who learned from and worked with him. On November 7–8, 1991, a scientific symposium titled "David Byar: An Accidental Career" was held at the **National Institute of Health**. David Byar's distinguished career and engaging personality were remembered by his colleagues and friends. The proceedings of this symposium were published in ***Controlled Clinical Trials*** (Vol. 16(4), 1995).

STEVEN PIANTADOSI

Calibration

Introduction

Statistical calibration, sometimes called inverse regression, is often used in biomedicine to estimate the value of one measurement (x) by some other measurement(s) (y) using a **regression** model. The need for calibration arises when the quantity to be calibrated is harder, or more expensive, to measure, or when the value was not recorded and cannot be retrieved. For example, instead of direct analysis through the "wet chemistry" methods, the **radioimmunoassay** (RIA), immunoradiometric assay (IRMA), or enzyme-linked immunosorbent assay (ELISA) can be used to estimate the minute concentration of hormones, enzymes, plasma tissue proteins, and monoclonal antibodies from the measurement of a radioactive count (RIA experiments) or an optical density (ELISA experiments) [29, 32, 77]. Near-infrared (NIR) spectroscopy is commonly used to assay the molecular contents of a sample through the absorbance spectra in a range of wavelengths [47, 57]. For example, in NIR spectroscopy, the spectral readings (x) are very precise but more expensive, while the chemical measurements (y) are less expensive to obtain but not as precise. Oman & Wax [61] describe how multivariate calibration can be applied to estimate fetal age by measuring the femur length and biparietal diameter of the fetus using ultrasound.

A calibration experiment is typically conducted in two stages, namely, the calibration stage and the inverse prediction stage. In the calibration stage, n pairs of training samples $(x_1, y_1), \ldots, (x_n, y_n)$ with known measurements are acquired to estimate the regression function $y = f(x)$, where x corresponds to the compositional variable to be calibrated (e.g. concentration) and y corresponds to the **instrumental variable** (e.g. absorbance of a certain wavelength in the NIR spectroscopy). In the inverse prediction stage, the objective is to estimate the unknown x_0 in a new sample by taking one or more measurements of y_0 from the same sample. The classical estimator of x_0 can be computed by taking $\hat{x}_0 = f^{-1}(y_0)$. Depending on the nature of the variables to be studied, calibration can be classified as the "absolute calibration", in which x is assumed to be measured without error, and the "relative or comparative calibration", in which both x and y are subject to measurement error (*see* **Errors in Variables**). Calibration experiments can also be characterized as the "controlled or designed calibration", where $x_1, \ldots, x_n$ in the training sample are prespecified to cover the range of all possible x_0 or the "nature or random calibration", where a sample of $(x_1, y_1), \ldots, (x_n, y_n)$ pairs is conveniently obtained.

A large collection of literature relating to the calibration problem addresses many areas, such as classical versus inverse estimators, point and **confidence interval** estimation, linear and nonlinear calibration, parametric and **nonparametric methods**, frequentist and **Bayesian** modeling, univariate and multivariate calibration, and many other issues such as measurement error, heteroscedasticity, and **optimal design**. Selected topics are discussed below, followed by a brief description of instrumental calibration and survey sampling. A comprehensive literature review of calibration can be found in [5, 62].

Classical Versus Inverse Estimators

Assume a **simple linear regression** model holds for the training sample: $y_i = \beta_0 + \beta_1 x_i + \varepsilon_i$, where ε_i are independent identically distributed (i.i.d.) N(0, σ^2), $i = 1, \ldots, n$. The **least square** estimates of β_0 and β_1 are $\hat{\beta}_1 = S_{xy}/S_{xx}$ and $\hat{\beta}_0 = \overline{y} - \hat{\beta}_1 \overline{x}$, where $\overline{x}$ and $\overline{y}$ are sample means and

$$S_{xx} = \sum_{i=1}^{n} \frac{(x_i - \overline{x})^2}{n},$$

$$S_{xy} = \sum_{i=1}^{n} \frac{(x_i - \overline{x})(y_i - \overline{y})}{n}. \tag{1}$$

The classical estimator of the unknown x_0 is

$$x_C = \frac{y_0 - \hat{\beta}_0}{\hat{\beta}_1} = \overline{x} + (y_0 - \overline{y}) \frac{S_{xx}}{S_{xy}}. \tag{2}$$

Alternatively, Krutchkoff [40, 41] proposes estimating x_0 by regressing x on y: $x = \hat{\gamma}_0 + \hat{\gamma}_1 y$, where

$$\hat{\gamma}_1 = \frac{S_{xy}}{S_{yy}}, \hat{\gamma}_0 = \overline{x} - \hat{\gamma}_1 \overline{y}, \text{ and}$$

$$S_{yy} = \sum_{i=1}^{n} \frac{(y_i - \overline{y})^2}{n}. \tag{3}$$

The resulting inverse regression estimator of x_0 is

$$x_I = \overline{x} + (y_0 - \overline{y})\frac{S_{xy}}{S_{yy}}. \quad (4)$$

It can be shown that except when $y_0 = \overline{y}$, $\hat{x}_I$ is always closer to $\overline{x}$ than $\hat{x}_C$ and can be considered as a **shrinkage estimator** shrinking toward $\overline{x}$. By taking a compound estimation approach, Lwin & Maritz [45] show that the classical and the inverse estimators can be derived with and without the asymptotic **unbiasedness** constraint, respectively. Therefore, the classical estimator is a **consistent estimator** but the inverse estimator is not. However, the inverse estimator has a smaller **mean square error** (MSE) than the classical estimator when the unknown x_0 is in the neighborhood of $\overline{x}$, defined as $(x_0 - \overline{x})^2 < S_{xx}[2 + (\sigma/\beta_1)^2/S_{xx}]$ [48]. The classical estimator is the **maximum likelihood** estimator under the appropriate model, while the inverse estimator corresponds to the Bayesian solution under a particular informative **prior distribution** [34]. Perng [64] shows that the inverse estimator can also be derived by **cross-validation** without any distributional assumptions. The difference between the classical and inverse estimators is quantified in [14]. Naszódi [58] proposes another estimator to correct the bias of the inverse estimator and claims that it is more efficient than the classical estimator. Srivastava [71] considers comparison of the inverse and classical estimators in the controlled linear calibration with a multivariate response and univariate **explanatory variable** when the **covariance matrix** is unknown. Later, Oman & Srivastava [60] derive exact expression for the MSE of the inverse estimator and compare with the ones previously derived for the MSE of the classical estimator in multi-univariate linear calibration.

Interval Estimation

The standard method of constructing a confidence interval for x_0 is to apply **Fieller's theorem** [26, 27] for estimating the ratio of two **normally distributed** random variables. The procedure leads to solving a quadratic inequality, and the resulting confidence interval can be a finite interval, a union of two semi-infinite intervals, or the whole real line. Intervals with infinite length occur when the slope of the calibration line is close to zero, where the validity of calibration is questionable. Graybill [31] advocates a two-stage conditional approach: Step 1: test the **null hypothesis** of zero slope at α level, H_0: $\beta_1 = 0$; and Step 2: if the test is not rejected, do not construct the confidence interval because x_0 cannot be estimated well when β_1 is close to zero. If the test is rejected, a $(1 - \alpha) \times 100\%$ interval can be constructed in the usual way and the resulting interval will have finite width. The coverage rate of the conditional confidence intervals is studied independently in [42, 72]. Approximate conditional inference with the angular **transformation** is discussed in [20] (*see* **Delta Method**). In multivariate calibration problem using a multivariate linear model, Mathew & Zha [52] construct some conservative confidence regions, which are nonempty and invariant under nonsingular transformations. Theoretic treatment of the interval estimation can be found in [69].

Cox [15] discusses the direct **likelihood** estimation of ratio parameters and gives the asymptotic variances of the maximum likelihood estimates. For confidence interval estimation, direct likelihood estimation offers a useful alternative to the standard method in linear models with large samples and can also be used for nonlinear models. Rosen & Cohen [67] propose a **bootstrap** confidence interval that is applicable to both parametric and nonparametric calibration curves. Müller & El-Shaarawi [55] investigate M-estimation (*see* **Robustness**) and bootstrapping techniques in the simple linear controlled calibration model and provide different types of confidence intervals for the calibration estimator. Simultaneous calibration intervals are described in [54, 69]. Methods for obtaining confidence bands for **polynomial regression** and **nonparametric regression** are given in [38]. Mathew & Sharma [51] consider the univariate calibration problem of constructing confidence regions for the unknown values of the explanatory variable. An exact confidence region for the multivariate calibration problem is proposed in [49]. Mathew & Zha [53] consider the calibration problem, that is, the calibration data will be used repeatedly in order to construct a sequence of confidence regions for a sequence of unknown values of the explanatory variables. Recently, Schechtman & Spiegelman [68] show that a nonlinear approach to single-use calibration curves gives confidence intervals centered at MLE. The nonlinear approach produces intervals even when the classical approach fails to do so. Mathew & Sharma [50] construct joint confidence regions for several unknown values of explanatory

variable in a normal multivariate linear model (*see* **Multiple Linear Regression**), when the variance covariance matrix is a scalar multiple of the identity matrix or a completely unknown positive definite matrix (*see* **Matrix Algebra**).

Multivariate Calibration

The advance in analytical methods and the wide use of computers have allowed investigators to collect enormous amounts of data easily and quickly; for example, in chromatography, infrared spectroscopy, or flow cytometry. Suppose a set of q instrument responses $\mathbf{Y} = (\mathrm{Y}_1, \ldots, \mathrm{Y}_q)$ are determined from a set of known p-dimensional compositions $\mathbf{X} = (\mathrm{X}_1, \ldots, \mathrm{X}_p)$. The multivariate calibration is to estimate a single unknown $\mathbf{X}_0$ from the observed $\mathbf{Y}_0$. Brown [4] discusses the multivariate calibration in the context of random calibration, controlled calibration, forward and inverse regression, and Bayesian methods. Martens & Naes [47] give a comprehensive treatment on the subject in their book. Two introductory papers [3, 76] also provide useful overviews. Sundberg [74] reviews multivariate calibration in two approaches: the estimation approach (indirect regression – controlled calibration) and the prediction approach (direct regression – natural calibration). Bilinear and other less standard models are also briefly reviewed.

The central idea in multivariate calibration involves dimension reduction. Because the instrument responses $\mathbf{Y}$ are often measured in high dimension and are highly correlated, the standard multiple regression can result in unestimable or unstable models. Two approaches have been used to resolve the problem. One approach is through the principal component regression (PCR) (*see* **Reduced Rank Regression**), which performs the **principal component analysis** first on $\mathbf{Y}$ followed by regressing $\mathbf{X}$ on the principal component scores for calibration. The other approach is the partial least square regression (PLSR), which simultaneously estimates the underlying components in both $\mathbf{X}$ and $\mathbf{Y}$ and then performs the regression. Stone & Brooks [73] show that PCR and PLSR belong to a general class of "continuum regressions".

A generalization of the classical estimator in multivariate calibration can be found in [43]. When $q = 1$, the classical estimator has an infinite mean and mean square error. However, the classical estimator has a finite mean when $q > 2$ and a finite MSE when $q > 4$. The **profile likelihood** approach for multivariate calibration can be found in [6, 7]. Generalized least squares and covariance adjustment approaches are proposed by Naes [56]. Methods applying a stationary autoregressive process (*see* **ARMA and ARIMA Models**) to model serial dependence (*see* **Serial Correlation**), regression **splines**, and minimum length least squares are discussed in [18].

Nonlinear Calibration, Nonparametric Calibration, Robust Calibration, Measurement Errors, and Heteroscedasticity in Calibration

In immunoassay or **bioassay** applications, the **dose–response** curves are often nonlinear (*see* **Quantal Response Models**). For example, a fairly standard approach is to apply the four-parameter **logistic** model: $f(x) = \beta_1 + (\beta_2 - \beta_1)/\{1 + \exp[\beta_4(\log x - \beta_3)]\}$ [28]. Giltinan & Davidian [29] construct a general framework for nonlinear calibration by the nonlinear mixed effects model, which can account for the intra-assay variability. They also study the Bayesian approach and find that the **empirical Bayes** methods can gain considerable efficiency in a **simulation**. Schwenke & Milliken [70] compare interval estimation methods in nonlinear calibration derived from the distribution of $\hat{x}_0$ or the distribution of $\hat{\beta}$. They indicate that, although both methods attain the desired confidence coefficient, the method based on the distribution of $\hat{\beta}$ is more general because it does not depend on a closed-form solution of the inverse function.

Knafl et al. [39] apply the nonparametric regression technique to calibration when the functional form of $f(x)$ is not specified. Chambers et al. [12] study extensively the **robustness** and **efficiency** of various nonparametric estimators derived from the sample empirical distribution, kernel smoothing, and bias-calibrated predictors. They conclude that the nonparametric predictors are more robust and less biased against the model misspecification, but the loss of efficiency is unavoidable. Gruet [32] proposes a new approach leading to a direct statistical inference on the parameter of interest to solve calibration problems in a nonparametric setting. The method combines kernel and robust estimation techniques. Tiede

& Pagano [77] derive an **algorithm** for obtaining the M-estimates of nonlinear calibration curves occurring in radioimmunoassay. They recommend fitting the calibration curve by such a robust **nonlinear regression** procedure, especially when an **outlier** is present in the data. Kitsos & Müller [37] introduce estimators of robust linear calibration based on robust one-step M-estimators, which have a bounded asymptotic bias. Cheng & Van Ness [13] propose robust methods for the random calibration problem. Several approaches based on the standard regression model, the inverse regression model, and the measurement-error model are investigated to robustify calibration. When some assumptions for ordinary least squares are violated, regression techniques including nonparametric and robust approaches to regression analysis are reviewed in [2].

To account for the errors in working standards, Lwin & Spiegelman [46] develop an accurate calibration curve procedure as an extension of calibration intervals. Methods for correcting measurement errors can be found in [9, 10], while Thomas [75] derives a consistent maximum likelihood estimator of x_0 in multivariate calibration with measurement errors. For assays exhibiting variance heterogeneity, Davidian et al. [16] discuss the generalized least square approach of estimating the heteroscedasticity parameter and the calibration parameters. Liski & Nummi [44] consider the problem of prediction and inverse estimation in repeated measures models (*see* **Longitudinal Data Analysis, Overview**).

Bayesian Calibration

A Bayesian approach to calibration is discussed in Dunsmore [23]. He shows that the classical estimator is a special case of Bayesian estimators in which the error due to under- or overestimation is equally punishable in the **loss function**. He also points out that the width of the interval estimator is unaffected by y_0 in the Bayes' methods, while it increases as $|y_0 - \overline{y}|$ increases in the classical method. Hoadley [34] shows that in the simple linear calibration with standardized x_i's and one observed y_0, the inverse estimator is a Bayesian solution when the prior distribution of x_0 is a t distribution with $n - 3$ degrees of freedom, mean 0, and scale parameter $[(n + 1)/(n - 3)]^{1/2}$ (*see* **Student's *t* Distribution**). A thorough discussion of Bayesian methods can also be found in [35] and [17]. Eno & Ye [24] derive a reference prior and corresponding posterior inferences in calibration problem for polynomial regression models. Later, probability matching priors and a reference prior for the linear calibration problem are presented with the constant variance assumption relaxed in [25]. A Bayesian solution to nonlinear calibration is given in [66]. Multivariate Bayesian calibration, including the use of the Gibbs sampler approach to computing the posterior distribution in complex settings, is studied in [21, 22] (*see* **Computer-intensive Methods**; **Markov Chain Monte Carlo**).

Optimal Design and Residual Analysis

The optimal design for calibration is discussed in [63] to minimize the expected MSE $E(\hat{x}_0 - x)^2$. Buonaccorsi [8] gives the optimal design to minimize the asymptotic variance of $\hat{x}_0$. Barlow [1] describes the computation of the optimal design under the Bayesian framework. Oman [59] derives a statistic similar to the Cook's distance in the usual regression setup to measure the influence of a particular observation in calibration (*see* **Diagnostics**). They illustrate the use of **residual** analysis to assist the data analysis and improve the study design. Kitsos [36] considers the simple linear calibration problem through an optimal design theory to evaluate the approximate variance of the calibrating value and provide approximate confidence intervals.

Instrumental Calibration and Survey Sampling

The above sections describe statistical calibration for situations in which the calibration model is obtained to estimate inversely the compositional variable x_0 from the observed instrumental variable y_0. Another type of calibration, instrumental calibration, is also commonly applied in laboratories and industry to calibrate the accuracy and precision between instruments and to establish standards (*see* **Quality Control in Laboratory Medicine**). Cembroski et al. [11] outline approaches to assure optimal proficiency testing in hematology laboratory. Graves [30] gives procedures and criteria to standardize immunoassays for the prostate-specific antigen. Plummer et al. [65] discuss the application of calibration in multicenter cohort studies for correcting the bias at the cohort level and

the subject level. Sample size tables are provided to facilitate the design of multicenter cohort studies.

The application of instrumental calibration with categorical variables in survey sampling (*see* **Sample Surveys in the Health Sciences**) is studied in [33], where a measurement-error model for the data in registers is introduced (*see* **Disease Registers**). Deville & Särndal [19] discuss the use of the generalized raking (or **iterative proportional fitting**) in multiway tables and derive the general regression estimators to estimate the finite population totals in survey sampling on the basis of auxiliary information.

Call-backs and Mail-backs in Sample Surveys

Call-backs in face-to-face and telephone surveys, and mail-backs in surveys conducted by mail (*see* **Surveys, Health and Morbidity**), are indispensable for achieving high response rates and lowering **nonresponse** error. Regardless of survey method, making only one attempt to contact a sampled household or individual will result in unacceptably low response rates and a very high likelihood that respondents will differ from nonrespondents [1, 7]. However, the role of additional contacts in reducing survey error differs somewhat by method.

For interview surveys the first contact is likely to result in substantial numbers of not-at-homes, an outcome that is related to multiple characteristics of the prospective respondent. Younger people, households with more occupants in the labor force, individuals who hold multiple jobs, and those whose life activities keep them away from home during the typical interviewing hours of late afternoon and early evening or for days at a time, are likely to be underrepresented when only one contact is made. For this reason protocols for well-designed telephone interviews often specify that 20 call-back attempts, or even more, be made before declaring that a sample unit is unavailable. In recent years the widespread use of answering machines and telephone number recognition devices that result in telephones not being answered even when people are at home, leaves additional call-backs, which may come at a time when calls are not being screened, as one of the few means with potential for reaching respondents. Furthermore, calls to a multiple-person household may reach a person who is not the desired respondent so that additional calls must be made to obtain that person (*see* **Telephone Sampling**).

Face-to-face household interview protocols are less likely to specify 20 or more call-backs because of the high costs associated with returning to a household that many times. In addition, face-to-face call-backs are more effective than telephone call-backs [8]. The appearance of a face-to-face interviewer at the door is more compelling than a telephone call. And, when no one is at home, clues from neighbors or household indicators (e.g. toys in the yard, newspapers not picked up) may help the interviewer plan the next attempted contact so that it will be more effective.

For mail surveys the situation is somewhat different. If addresses are correct, all sampled households or individuals will, in theory, receive the first contact. However, single mailings inevitably produce response rates that are unacceptably low. In addition, there is no feedback or clues, as is often the case for face-to-face interviews, as to why a questionnaire has not been returned.

Attempting to recontact sample units is only one of the factors that influence attempts to improve response rates and thereby reduce nonresponse error. For all types of surveys, attributes of the survey design, characteristics of the sampled individual, characteristics of the interviewer or mail-out materials, and the interaction between interviewer (or researcher) and prospective respondent are important [9]. For interviews it has been shown that longer questionnaires, survey topics that are uninteresting or threatening to respondents, and the interviewer's lack of experience can all reduce response rates. In addition some types of people, e.g. young adult males and people with poor heath status, are less likely to be interviewed successfully regardless of number of contacts [7] (*see* **Response Effects in Sample Surveys**).

The essential role of a survey design that emphasizes multiple contacts has been articulated by Groves et al. [9]. Their theory of survey participation posits that interviewers can increase response by tailoring their strategies to different individuals and maintaining interaction with them. This strategy suggests seeking another time to recontact the person rather than pressing the interviewee into a decision to be interviewed or not interviewed, thus using additional contacts as a means of avoiding refusals.

For mail surveys it has been shown that structural characteristics such as greater salience of the survey topic, sponsorship of the survey by government or university as opposed to market research company, and type of population (school or employee vs. general public) are likely to improve response rates [10]. Characteristics of the multiple contacts that have been shown to improve response rates include: prepaid token financial incentives [11], special postage (e.g. special delivery or certified),

stamped (vs. business reply) return envelopes, and personalization of correspondence [2], as well as respondent-friendly questionnaire layout [4] (*see* **Questionnaire Design**). Nonetheless, by far the most powerful influence of mail survey response rates is the number of attempts to contact respondents.

Research has also shown that contacts by a different survey mode can improve response rates to both interview and mail surveys. For example, sending a prior letter to prospective telephone respondents explaining the survey can improve response rates significantly [3, 7]. Similarly, a follow-up telephone call to mail nonrespondents can improve response rates by increasing the number of returned questionnaires and identifying ineligible sample units [2]. In addition, a strategy frequently used to increase response rates is to switch from one survey mode to another; for example, starting with the less expensive mail method and contacting nonrespondents in person to obtain the needed information as used for the US Decennial **Census**. However, it has been shown in the case of the Census that offering respondents the alternative of responding by mail or telephone to a mail contact will not improve response [5]. Rather, it is the fact that additional contacts are made by another mode that results in improved response rates.

The indispensable nature of call-backs and mail-backs across survey modes has been convincingly summarized by Goyder [6]. In a **meta-analysis** of nearly 500 different surveys, mostly conducted from the 1940s to the 1970s, he found on average that the mail surveys obtained response rates 7.5% lower than was the case for face-to-face interviews. He also found that the greater number of contacts used for face-to-face surveys partly accounted for this small difference. He models the determinants of response across methods, and shows that responses to different modes are influenced by similar factors, ranging from salience of topic to sponsorship. In this model, the number of call-backs or mail-backs is not only revealed to be an important determinant of response for all methods, but a unifying one that underlies the ability of each method to achieve high response rates.

DON A. DILLMAN

Cancer Registries

History of Cancer Surveillance

Early forms of cancer surveillance involved registering cancers diagnosed in a population of interest for the purpose of providing accurate statistics on the morbidity and prevalence of cancer. The first attempts to do this were in the early 1700s in London, in Hamburg in 1900, and subsequently in the Netherlands, Spain, Portugal, Hungary, Sweden, Denmark, and Iceland during the period 1902–1908. These efforts were unsuccessful because doctors often refused to fill out the questionnaires needed to document each diagnosed cancer [27].

The first successful attempt at cancer registration took place in Mecklenberg in 1937. The data recorded on each cancer included the name of the patient, which facilitated the elimination of multiple records on the same case. Also, registration cards were sent to all medical practitioners, hospitals, and pathological institutes and there was telephone follow-up for the purpose of obtaining complete ascertainment as well as complete data on each case. Subsequently, similar surveys were conducted in Saxony-Anhalt, Saarland, and Vienna in 1939, but were soon discontinued because of political developments [27].

In the US, the first attempt to register cancers was initiated by the American College of Surgeons (ACOS) in 1921, and involved only malignancies of the bone [2]. Registration was expanded in the next decade to include other malignancies. The first cancer morbidity survey was conducted in 1937–38 in 10 metropolitan areas by the National Cancer Institute (NCI), and subsequent surveys were conducted in 1947–48 and 1969–71. In principle, all cancers diagnosed in residents of these areas during a one-year period were registered during each of the three time periods. A problem with surveys of this type was that the fate of cancer patients was not known. The lack of information on the survival of cancer patients indicated the need for alternative approaches to cancer registration.

In 1971, the National Cancer Act, announced as the "War on Cancer", called for the NCI to "collect, analyze, and disseminate all data useful in the prevention, diagnosis, and treatment of cancer. . .". This legislation led to the creation of the Surveillance, Epidemiology, and End Results (SEER) Program which was based at the NCI.

Case ascertainment for the SEER Program began on January 1, 1973, in several geographic areas of the US and its territories. Those areas that have participated in the program since 1975 include the states of Connecticut, Iowa, New Mexico, Utah, and Hawaii, and the metropolitan areas of Detroit, San Francisco/Oakland, Seattle, and Atlanta. Subsequent additions to the program included 10 predominantly black rural counties in Georgia in 1978, and American Indians residing in Arizona in 1980. In 1992, the program was further expanded to increase coverage of minority populations, especially Hispanics. The two new areas added were Los Angeles County, and four counties in the San Jose/Monterey area south of San Francisco. Alaskan natives in Alaska have been added to those populations covered by SEER. The SEER Program currently includes population-based data from about 14% of the US population and is reasonably representative of subsets of the different racial/ethnic groups residing in the US. Figure 1 provides a map of the SEER areas and Figure 2 gives the percentages and sizes of various populations included in geographic areas covered by SEER [13].

The SEER database contains records on more than two million cancers and is growing at the rate of more than 160 000 records per year. Other data resources used by the SEER Program include cancer mortality data by county for the total US, obtained from the National Center for Health Statistics (NCHS). To provide for the calculation of incidence and mortality rates, population estimates are obtained through an interagency agreement with the Census Bureau.

Other organizations are also involved in cancer surveillance activities in the US. The North American Association of Central Cancer Registries (NAACCR) was organized in 1987 as an umbrella organization for cancer registries, governmental agencies, professional organizations, and private groups in North America interested in enhancing the quality and use of cancer registry data. Most population-based cancer registries in the US and Canada are members. The mission of NAACCR is to support and coordinate the development, enhancement, and application of cancer registration techniques in population-based groups, so that data of high quality and completeness may be used for epidemiologic research, public health programs, and patient care to reduce the burden of cancer in North America.

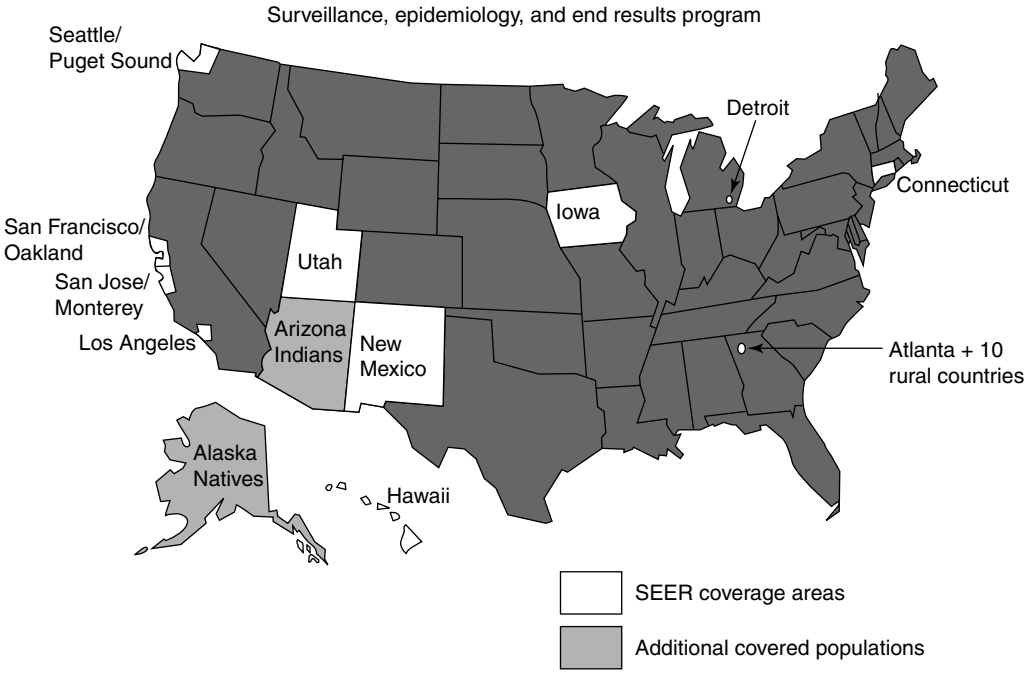

Figure 1 Map of US indicating areas and populations covered by the SEER Program

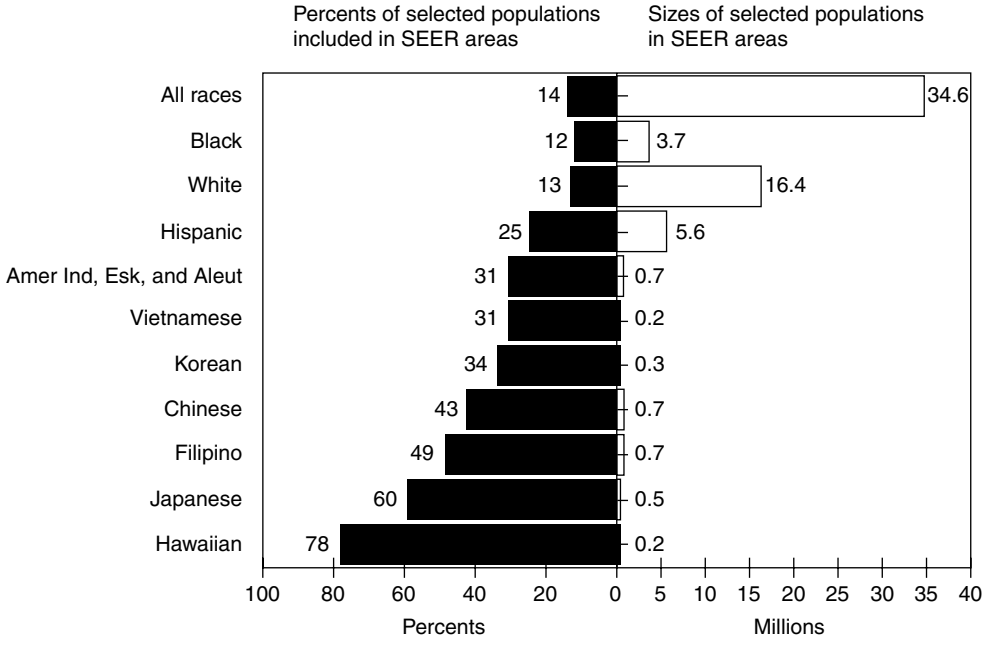

Figure 2 Percentages and sizes of various populations covered by the SEER Program

The American College of Surgeons Commission on Cancer and the American Cancer Society jointly founded the National Cancer Data Base (NCDB), which is a nationwide oncology outcomes database that includes data from over 1500 hospitals in 50 states, and is in its tenth year of operation. This database can be used to study patterns of care and factors associated with patient outcome, and patient care evaluation studies are periodically carried out in participating cancer registries [25]. Uses of this database focus on clinical surveillance of people with cancer, and cannot be used to calculate incidence rates.

Current Cancer Registration Practices

Cancer registration is the process of collecting data about patients with malignant diseases. The data collected identify the demographics of the patient with the disease, the type of cancer, how it is treated and the outcome of the patient. The data collected reside in a cancer registry, a term which can mean simply the database or data system that manages and analyzes the information or the data system and all of the associated systems and personnel who perform cancer surveillance and cancer control. Cancer registries serve several purposes.

A *hospital-based cancer registry* is a cancer data base maintained in a health care facility to collect pertinent information on all cancer patients who use the services of that facility for diagnosis, staging, and treatment. The service area for a hospital-based registry varies from facility to facility, depending on the types of specialty treatment it offers, the types of third-party payors it attracts, and a number of other factors. As a result, the number of potential patients in the facility's customer base can only be estimated. A hospital-based cancer registry can calculate frequency of cases and measure outcomes for the patients it monitors. A hospital-based cancer registry cannot calculate incidence rates because the denominator population is not known.

A *population-based cancer registry* is a centralized cancer database covering a known population, usually residents of a defined geographic area, such as a county or state. Because the population denominator can be counted or estimated by a census, a population-based registry can calculate incidence rates. Population-based registries are the principal source of cancer surveillance data.

Population-based registries must gather information on cancer patients from a variety of sources, including registries in hospital and other healthcare facilities, physician offices, pathology laboratories, and facilities outside the defined geographic area to which residents travel for cancer diagnosis and treatment. Population-based registries can be of two types: (1) those that report incidence only (the first report of a new cancer) or (2) multipurpose registries that collect data on incidence and subsequent outcomes.

A population-based registry is one type of *central registry*. A central registry collects data from a variety of sources but it may not be population-based. For example, a provider of cancer registry software may maintain a pooled database of all the cancer cases submitted by its customers, or a hospital corporation may pool the cases from all facilities it owns. In each of these cases, it is not possible to determine an appropriate denominator, so these central registries are not population-based.

Registry Operations

The four main aspects of registry operations are: case ascertainment, abstracting and coding, follow-up or mortality follow-back, and quality control. Data collection procedures will also be reviewed.

Case Ascertainment

Case ascertainment, also called casefinding, is the process of identifying patients with malignant disease who meet the criteria for inclusion in the registry. Because cancer surveillance requires monitoring of cancer incidence and mortality, case ascertainment must identify all cases of the disease in a defined population, regardless of where the cancer patient encounters the healthcare system; including hospitals, independent treatment centers, clinics, pathology laboratories, physician offices, and nursing homes. For practical purposes, the principal source of cancer information is the hospital health information or medical record, which includes all contacts with the hospital inpatient, outpatient and clinic. The medical record contains reports of diagnostic and staging procedures, physical examination, operations and other treatments. In addition, consultation reports from

outside pathology departments and physicians are usually retained as part of the medical record. Medical records are maintained as legal documents in most facilities where patients are treated; the exception is the pathology laboratory.

Most cancer patients come to a hospital at some point in their disease process, usually for a biopsy or treatment; thus, hospital medical records are an important source of casefinding. In hospitals, medical records are coded and indexed by disease and procedure so that patient records can be retrieved for analysis. The database containing these codes is one of the principal sources of case ascertainment in a healthcare facility. Specific codes for cancer diagnosis and treatment permit retrieval of records pertaining to reportable neoplasms that must be included in the registry.

A neoplasm is a "new growth" or tumor that develops somewhere in the body. The term neoplasm refers to either benign or malignant (having the potential to spread from the site of origin and ultimately kill the patient) tumors. A *reportable neoplasm* is a tumor that meets the inclusion criteria for a registry. Reportable neoplasms are well defined in the *International Classification of Diseases for Oncology*, a coded nomenclature published by the World Health Organization (WHO). This coding system defines each type of tumor and its behavior: benign, uncertain malignant potential, *in situ*, invasive, or metastatic. The reportable neoplasms collected by all general-purpose cancer registries are those that are malignant (*in situ* or invasive). Metastatic tumors (malignancy growing in a site at a distance from the organ in which it started) are not reported individually; rather, metastases are reported as progression of the tumor at the site of origin. Occasionally a central registry will require that another type of tumor be reported, such as benign brain tumors, which cannot spread but do have the potential to be lethal, and tumors of uncertain malignant potential, such as carcinoids of the appendix. On the other hand, a few cancers are very common and are associated with such a good prognosis that it is generally not necessary to monitor their outcomes, such as basal cell and squamous cell carcinomas of the skin and carcinoma *in situ* of the cervix.

All the inclusion and exclusion guidelines for case ascertainment are compiled into a *reportable list*, which the data collector uses to identify cases to be abstracted for the registry.

Abstracting and Coding

Abstracting is the process of deriving and recording pertinent data about each reportable case. The resulting document, the *abstract*, is an abridgment or summary of what happened to the patient, and may be in paper or electronic form. Data items include demographics of the patient, a description of the disease (site of origin, type of malignancy), stage at diagnosis (documentation of how far the cancer had spread when it was diagnosed), treatment, and the course of the disease from the time it was diagnosed. Parts of the abstract are encoded, such as site and type of cancer, stage, and treatment. In addition to the standard data items, some registries collect information on items of special interest, such as smoking history, family history of cancer, or co-morbid conditions.

The abstracting process is exacting and highly technical, requiring great attention to detail. The aim of abstracting is to collect the data about each cancer case as accurately as possible (high correlation between source document and abstract) and as consistently as possible for similar cases (all cases following the same rules). Abstracting rules and guidelines have been developed to cover nearly every situation, but human interpretation of both the facts of the case and the rules of abstracting can sometimes cause problems, and there is always the danger of incorrect data entry. As a result, a series of edits have been developed and included in most cancer registry database systems.

There are several types of edits, including range checks and logic checks. The simplest edits are range checks or allowable codes. Logic checks are a type of inter-item edit where the program looks at two or more data fields to ensure that they make sense together. For example, an error message should be generated when "sex" is male and "primary site" is cervix. Inter-item edits can be quite complex, such as looking at a morphologic diagnosis code as noninvasive, the corresponding stage at diagnosis coded as *in situ*, the method of diagnostic confirmation coded as histologic, and the sites of distant metastasis fields that should be left blank. Computer edits such as these are the first line of defense against inaccurate data. Other editing mechanisms and preventive measures such as training and standardization of procedures are described in the following sections on data collection and quality control.

An additional function of population-based central registries is case consolidation or case matching.

Because the registry receives reports from many sources, it is necessary to identify multiple reports on the same patient so that the case is not counted more than once. Case consolidation involves not only various computer algorithms but human review as well. For example, Hospital A might send in a report on Ric Smith with a birth date of 11-19-35 and a diagnosis of sigmoid colon cancer, and Hospital B might send in a report on Frederic Smith with a birthdate of 11-18-35 or 11-19-36 and a diagnosis of rectal cancer. The registry must decide whether these reports are about the same patient, and, furthermore, whether they are about the same cancer. Without a case consolidation operation in the registry, the numerator (newly diagnosed cases) of the incidence rate may be inflated.

Data Collection Procedures

When data collection for the SEER Program began in 1973, it was imperative that data be collected uniformly and systematically in all participating areas. As a result, the SEER Program published a series of manuals providing specific rules for case inclusion and staging. The most recent of these is the *SEER Program Code Manual, 3rd Ed.* [20]. Since its inception, the SEER Program has been a leader in documentation of data collection rules, training of data collectors, and quality assurance of the data collected. Many central registries in the US follow SEER rules even though they are not funded by the National Cancer Institute.

In addition to these coding guidelines developed in the US, an international body established definitions of what was considered to be cancer. The WHO has been publishing revisions of the International Classification of Diseases (ICD) on a decennial basis since 1893. Originally developed to code mortality, ICD has been modified to code all types of diseases and conditions, and the current edition, ICD-9-CM (Ninth Revision, Clinical Modification) is the coding standard for health care facilities and reimbursement through federal Medicare programs [26]. The next edition, ICD-10, is in use in vital statistics offices to code death certificates [30]. As the WHO began development of the ninth revision in the early 1970s, clinicians expressed a desire for a more complete coding system for neoplasms, one that would describe both where the tumor started (topography) and what the tumor was (morphology). ICD contained a coded list of anatomic sites for the topography, and another coding system, the *Systematized Nomenclature of Pathology* (SNOP), published by the College of American Pathologists, contained the codes for cell types or morphology [4]. SNOP was a functional descendant of the *Manual of Tumor Nomenclature and Coding* (MOTNAC), published in 1951 and revised in 1968 by the American Cancer Society. The WHO used the topography code structure from ICD-9 and selected the code structure from SNOP for the morphology codes. The first edition of the *International Classification of Diseases for Oncology* (ICD-O) was published in 1976 by the WHO [28]. A second edition using the alphanumeric topography codes from ICD-10 was published in 1990 and implemented in the US in 1992 [29]. A third edition of ICD-O is scheduled for publication in 2000. The College of American Pathologists maintains the descendant of SNOP, called the *Systematized Nomenclature of Medicine* (SNOMED) [5,6], now in its fourth generation as SNOMED RT (Reference Terminology) [24]. By international treaty, the neoplasm sections of SNOMED and ICD-O are identical, although the topography codes differ between the two coding systems.

US cancer organizations collected data for specific purposes; the American College of Surgeons for quality management of patient care, and the SEER Program for incidence, survival, and mortality statistics. For many years there was no effort on the part of these organizations to collaborate on the development of data-collection rules. An example of the resulting problems relates to the collection of data pertaining to stage of disease at diagnosis. There are currently four major staging systems in use in the US: Tumor–Node–Metastasis (TNM), a product of the International Union Against Cancer and the American Joint Committee on Cancer [1]; SEER Extent of Disease (EOD) [19]; Summary Staging [16] and SEER Historic Stage (local–regional–distant) [18]. These staging systems are not comparable for a number of cancers.

The American College of Surgeons Commission on Cancer (COC) uses TNM as the standard for coding stage of disease for hospitals participating in its approvals program. The SEER Program uses EOD as its data-collection standard and some versions of TNM can be derived from it [19], and SEER historic stage as its reporting standard which can be derived from EOD [18]. The National Program

of Cancer Registries (NPCR) uses Summary Stage as its standard [16]. As a consequence, a registry approved by the American College of Surgeons COC in a state receiving NPCR funds and an area where SEER data is collected must stage each case using three different systems, each having their own codes, timing rules, and inclusion/exclusion criteria. Efforts are in progress to define a single data set for staging and a single set of rules [10], but these efforts are far from fruition, much less implementation, data collection and analysis.

In the early 1980s, the SEER Program and the American College of Surgeons COC began meeting to resolve differences in data fields, such as field lengths, definitions, and code structures. The 1988 publications of the COC's *Data Acquisition Manual* [7] and *The SEER Program Code Manual*, 2nd Ed. [17] were in substantial agreement.

In 1987, the population-based central registries in the US and Canada formed an "organization of organizations" to share information on coding practices, registry operations, standards and other factors that affect the accuracy and reliability of published cancer information. One of the first activities of the NAACCR was to establish the Uniform Data Standards Committee (UDSC). The UDSC formalized the standardization efforts begun by SEER and the COC. This committee, consisting of representatives from all the standard-setting organizations, central registries, data collectors, registry software vendors, and other users of registry data, serves as a forum for identifying and resolving problems in data collection. The committee compiled all the rules regarding data collection and identified areas of discrepancy, publishing four volumes of standards in 1994: *I. Data Exchange Standards and Record Description*; *II. Data Standards and Data Dictionary*; *III. Standards for Completeness, Quality, Analysis and Management of Data*; and *IV. Standard Data Edits*.

Adherence to coding rules established by the UDSC and the NAACCR in general is voluntary. However, in the current practice of cancer registration in the US and Canada, all revisions to existing data fields, coding guidelines and data-collection rules, as well as proposed new data fields, data record layouts, and other enhancements, are discussed and voted upon by the members of the UDSC. An implementation date for approved changes is widely published so that software vendors can make changes in sufficient time to meet the needs of cases diagnosed after the implementation date, and the standard setters can publish necessary revisions to their data-collection manuals.

Outcome Measurements and Quality Control

As noted previously, a population-based cancer registry can be either incidence-only or multipurpose. If the registry is incidence-only, then the registry does no outcomes assessments. Outcomes measurement is the current vernacular for describing the results of treatment and the disease process in terms of survival rates and mortality. Outcomes processes include follow-up and mortality follow-back, two specific additional operations performed by multipurpose central registries. Follow-up is long-term surveillance of cancer patients. Once a patient is treated and rehabilitated, he or she resumes a relatively normal life, but monitoring for disease recurrence or sequelae of treatment must continue for the patient's lifetime. Follow-up is the process of contacting someone – either the patient directly or the patient's physician – to obtain current information on the status of the cancer. Ideal follow-up information includes a recent date of last contact, vital status (alive or dead), and disease status (free of disease, recurrent disease, a subsequent primary cancer, additional treatment, etc.). Most registries prefer to contact the patient's physician for this information as it will be more accurate, technical, and specific than that received from the patient. However, response rates are generally good when patients are contacted directly. Either type of direct contact is called *active follow-up*.

If a registry chooses not to contact the patient, follow-up information less complete than the ideal can be obtained by linking the cancer registry database with other governmental databases, such as voter registration, local tax rolls, and Department of Motor Vehicles (DMV) drivers' license renewal files. Little can be determined from these linkages other than the patient's vital status, and that might only be at the last point of contact with the agency. For example, DMV would only have a record of the last time the patient renewed his driver's license (possibly several years previously) or reported a change of address. This indirect method of obtaining the vital status of the patient is called *passive follow-up*. Another method of obtaining follow-up is linkage to Social Security Administration death lists and to the National Death

Index; this linkage will update only deceased patients, however.

Tracing a patient who no longer regularly visits a physician for his disease is both an art and a science. Confidentiality guidelines must be observed when information is requested about any patient, but the higher the percentage of complete follow-up, the more reliable are estimates of survival rates. The SEER standard for complete follow-up is to have current information (within the past 15 months) on at least 95% of all cases.

Occasionally a patient with cancer will be missed in the case ascertainment process and not be abstracted into the registry database. Missing a case lowers the incidence rate for that particular cancer; thus high standards of case completeness are important for accurate and reliable cancer data. If a previously unreported cancer patient dies, a cancer diagnosis on the death certificate may be the first and only report of the cancer case. It is good policy for a registry to follow-back a Death Certificate Only (DCO) case to see where it was missed in the casefinding process. Follow-back is the process of contacting physicians and facilities noted on the death certificate to review their medical records to determine any earlier diagnosis or treatment of the cancer. In many instances the case was simply missed, so the abstract is processed as a late report and reporting-source procedures are investigated. In other instances the death certificate diagnosis is the only identification of the case. These cases are tagged as DCO in the database, and usually very little information is known about them. A registry monitors its percentage of DCOs as part of its quality control processes.

Quality control encompasses all registry activities that monitor and resolve data problems. Quality control usually deals with facts and data items. On the other hand, quality improvement or quality management usually deals with procedures and processes. Quality control is performed on all aspects of registry operations. Standards have been established for case completeness, database completeness, accuracy and reliability of data, and timely reporting of cases to the registry. The purpose of quality control is to determine whether these standards are being met.

Quality has been defined as "fitness for use". Analysis of data which are not fit for use can result in incorrect conclusions and inappropriate cancer control and cancer surveillance activities. The principal components of data quality are accuracy, completeness and timeliness [9].

Completeness has at least two aspects: completeness of the database and completeness of the data in each record. Completeness of the database means that all cases in the population under investigation have been included for the specified time period. Without a complete database, incidence rates and relative frequencies may be inaccurate. Completeness of the database is a function of thorough case ascertainment, described above. Completeness is assessed by several techniques, including re-casefinding studies, projections of the number of cases reported in previous years, and the ratio of incidence to mortality for all cancers combined and for selected cancers. The SEER Program's target rate for database completeness is 98% complete reporting for a diagnosis year at the time the data are first submitted (14 months after the end of the diagnosis year).

Completeness of the data is a function of abstracting. This means that all data have been reported and there are no omissions, unnecessary blanks, or fields coded as unknown that should have been completed. It is possible to have a data field considered complete because there are no blanks, but unusable because the data are coded as unreportable or unknown. However, a data collector must find a balance between tracking down every last data item for 100% completeness, and coding unknown if the data are not easily obtained.

Timeliness is a corollary to completeness. It is presumed that every case may eventually be found, but the issue is how long to wait before using the data. There is a tradeoff between having potentially incomplete data available for use quickly, and having complete data available after so long a wait that the data are no longer current or useful. To meet the needs of most (if not all) data users, it is necessary to set a cut-off date and assess completeness at that time. Thus, timeliness is determined by setting a final date for data submission, and ensuring that all records have been submitted by that date.

Accuracy is the quality measure that establishes the reputation for a registry. Accuracy is necessary in all parts of registry operations. Accurate incidence rates neither overcount nor undercount the number of cases in the population. Accurate abstracting ensures that results are appropriate for research. Accurate follow-up permits survival rates and other outcomes to be measured correctly.

The SEER Program performs quality control studies annually that are designed to provide quantitative assessments of accuracy and completeness of the data collected by the various participating registries. Some findings from these studies have been published [31]. In the near future, findings from all quality control studies designed to provide estimates of completeness and accuracy both at the registry level and for all registries combined will be available on the Internet at `http://www-seer.ims.nci.nih.gov/`

Current Cancer Surveillance Activities

The discussion here will focus on the activities of the NCI, since it has been in the forefront of cancer surveillance activities for more than 60 years. As previously mentioned, other organizations are involved in cancer surveillance; however, an attempt will not be made to associate specific activities with specific organizations. At this time it is not clear how cancer surveillance responsibilities in the US will ultimately be divided, as that is currently being negotiated by the parties involved. However, it is reasonable to assume that the NCI will continue to play a major role in all aspects of cancer surveillance.

The fundamental tool of cancer surveillance is the population-based cancer registry. The establishment of the SEER Program in 1972 was the beginning of a new era in cancer surveillance in the US. Beginning in 1973, the continuous registration of all cancers diagnosed in residents of geographic areas initially covered by SEER allowed the calculation of incidence rates for calendar years beginning in 1973. Follow-up to determine vital status for all cancer patients in SEER areas, including the coding of cause of death, allowed the calculation of survival rates as the SEER database matured.

A question frequently raised is: How representative are the SEER areas of the total US population? To address this question, it is necessary to define "representativeness" in this context. It is certainly desirable to be able to derive cancer rates from SEER areas that approximate those for the total US by age, sex, and racial/ethnic group. But it is probably more important to be able to establish that the trends in cancer rates in SEER areas approximate those for the total US. SEER rates have been assumed to be reasonably representative of those from the total US. However, in the future, cancer rates in SEER areas will be modeled using ecologic data available from the census in order to refine national estimates.

Cancer mortality data for the total US have been used to examine the representativeness of trends in SEER areas versus those for the total US. This was done by systemically comparing trends in cancer mortality for selected cancer sites in SEER areas with those for the total US. It was concluded that, with few exceptions, mortality trends for selected cancers in SEER areas were representative of those for the total US [11]. Therefore, it seems reasonable to assume that trends in SEER incidence rates approximate those for the total US. Further information on the representativeness of SEER areas is given in Figure 3, which compares selected ecologic data from the 1990 census in SEER areas with that for the total US.

A variety of reports are available on cancer rates in SEER areas, the most recent of which includes data for the time period 1973–1996 [21]. There are also reports on cancer incidence rates published by the NAACCR which include data from SEER registries plus other US and Canadian registries that have been found to have data of high quality. The most recent NAACCR publication is for the time period 1992–1996 [3].

The scope of cancer surveillance has broadened considerably since the early attempts at cancer registration. Current cancer surveillance activities include: developing and reporting estimates of cancer

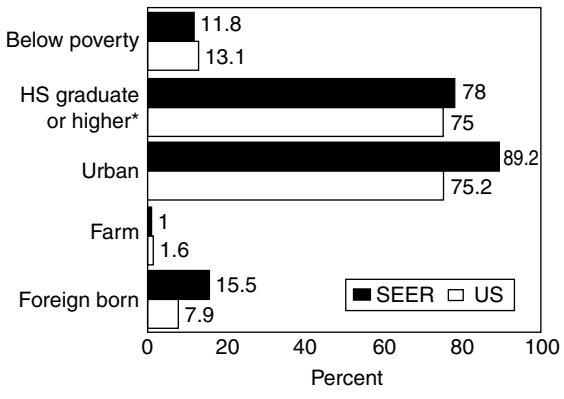

Figure 3 Comparison of selected ecologic variables from the 1990 census for the total population in SEER areas versus the total US population

incidence, prevalence, and mortality on a periodic basis for the total US; monitoring annual cancer incidence trends to identify unusual changes in specific forms of cancer occurring in population subgroups defined by geographic, demographic, and social characteristics and providing insight into their etiology; and providing continuing information on changes over time in the extent of disease at diagnosis, trends in therapy, and associated changes in patient survival. Of particular importance is the inclusion of sufficient numbers of various racial/ethnic populations, and other populations defined by a variety of measures including access to medical care, urban versus rural, and measures of poverty and socioeconomic status. Such research can benefit cancer prevention and control activities, and identify areas where improvements in treatment may be needed. Other uses of incidence, prevalence and survival data include identifying cancer sites showing unusual rates of increase or decrease that would warrant special etiologic investigation (e.g. non-Hodgkin's lymphoma increases associated with the acquired immune deficiency syndrome (AIDS) epidemic); helping health policy-makers set priorities for spending on research and for allocating resources among etiologic, prevention, diagnosis, treatment and control areas; and informing the general public and Congress on the extent and trends in the cancer burden. These data also have direct clinical relevance for advising individual patients. For example, age- and race-specific SEER data were used (together with other data on specific risk factors) to help develop a model for projecting the chance that a woman with particular risk factors would develop breast cancer in a given time period [8].

Other important research components to cancer surveillance include promoting studies designed to identify cancer risk factors amenable to cancer control interventions. These studies may pertain to the environment, occupation, socioeconomic status, tobacco, diet, screening practices, patterns of care, and determinants of the length and quality of patient survival. Other areas of investigation include planning, conducting, and supporting research related to evaluating patterns and trends in cancer rates and cancer-related risk factors. Also studied are health behaviors, cost of care, patient outcomes, health services as part of an attempt to determine the influence of such factors at the individual, societal, and systems level on patterns and trends in the various measures of cancer burden. Also included in this activity are identifying, improving and developing databases and methods for cancer-related surveillance research; maintaining, updating, and disseminating these databases and methods; and promoting and facilitating their use among investigators within the extramural research community and federal agencies. No attempt will be made to document all of these activities; however, information about them can be obtained from the following Internet sites: `http://www-dccps.ims.nci.nih.gov/arp/` and `http://www-dccps.ims.nci.nih.gov/srab/surveillance/survdesc.html`

The SEER contracts are primarily with cancer research organizations affiliated with universities. Thus, they provide an infrastructure for conducting analytic epidemiologic studies on a variety of emerging issues in cancer prevention and control which can be used by the NCI. The ability to do special studies was established in the early 1990s. The workscopes of SEER contracts were modified to include the capabilities of interviewing patients, conducting surveys of the covered populations, obtaining biological materials from patients and survey respondents, conducting methodologic research which utilizes cancer registry data, and establishing tissue banks. Standard competitive procurement procedures within the SEER framework have been used to plan and fund studies on a wide range of topics that have included identification of risk factors, quality of life, statistical modeling, etiology of trends in cancer rates, and operational issues pertaining to data collection and reporting. No attempt will be made to document the findings from these studies here, but they have resulted in a large number of peer-reviewed publications in scientific journals on a variety of issues pertaining to etiology, cancer control, quality of life, and registry operations [13].

There have also been significant efforts to involve the general research community in cancer surveillance activities. This has been done by distributing to cancer researchers public use files that include SEER data. The files are made available on CD-ROM and include more than two million individual records of cancers registered in SEER areas from 1973 to the most recent year for which complete data are available, population data, and documentation of all files. Also included is SEER*Stat which

is a free Windows-based computer program developed by the SEER Program to calculate incidence rates, frequencies, trends, and survival rates. Another program, called SEER*Prep, allows registries outside of the SEER Program to put their data into SEER*Stat, greatly facilitating analysis of their data. Currently, about 1500 SEER public use files are distributed annually, and a number of non-SEER registries are using the SEER*Stat software via SEER*Prep. More information about this software can be obtained on the Internet at: `http://www-seer.ims.nci.nih.gov/scientific systems/SEERStat/`

Recent developments in statistical methodology pertaining to the analysis of trends in age-adjusted rates deserve mention, since the analysis of trends is a fundamental activity of cancer surveillance. The first is the use of join point regression using log linear or linear models to describe trends in age-adjusted rates [14]. Models of this type assess the statistical significance of recent changes in trends as well as describe the trends over the period for which they are fit. Figure 4 presents a fit of a log linear join point regression model to the age-adjusted (1970 US Standard) mortality rates for all cancers combined for the total US for the total population and by sex. Annual percent changes and join points are given to describe the trends.

A second methodology of interest partitions a trend based on fitting linear regression models [12]. For example, it is possible to derive the relative contributions of various individual cancers or groups

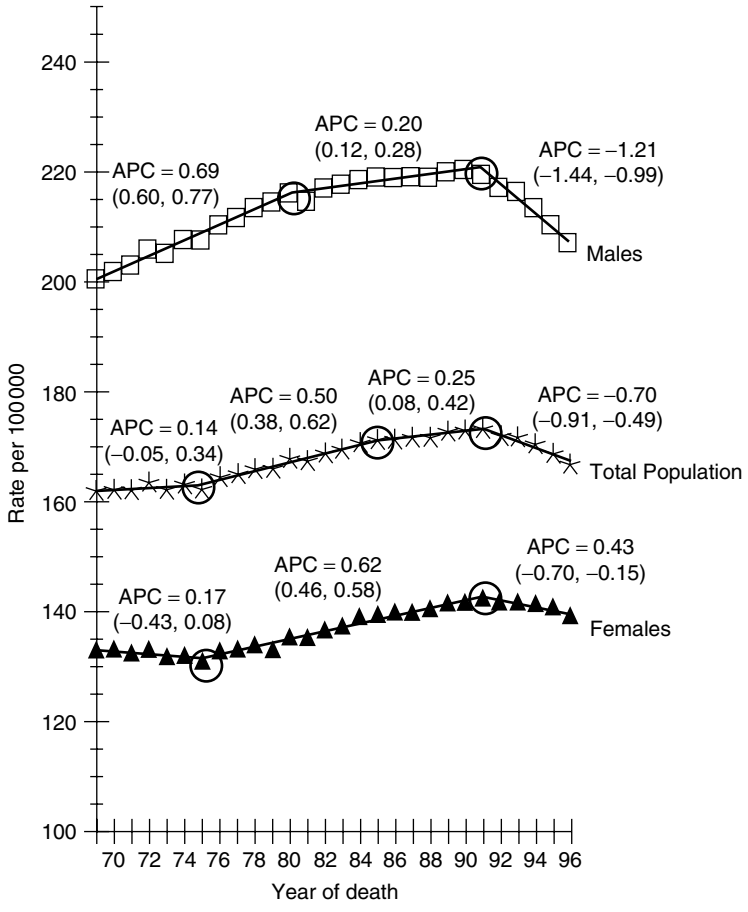

Figure 4 Fits of log linear join point regression models to cancer mortality trends based on age-adjusted rates (1970 US Standard) for the total population of the US and by sex. The linear segments are indicated by a solid line, and the join points are circled. The observed points are also given

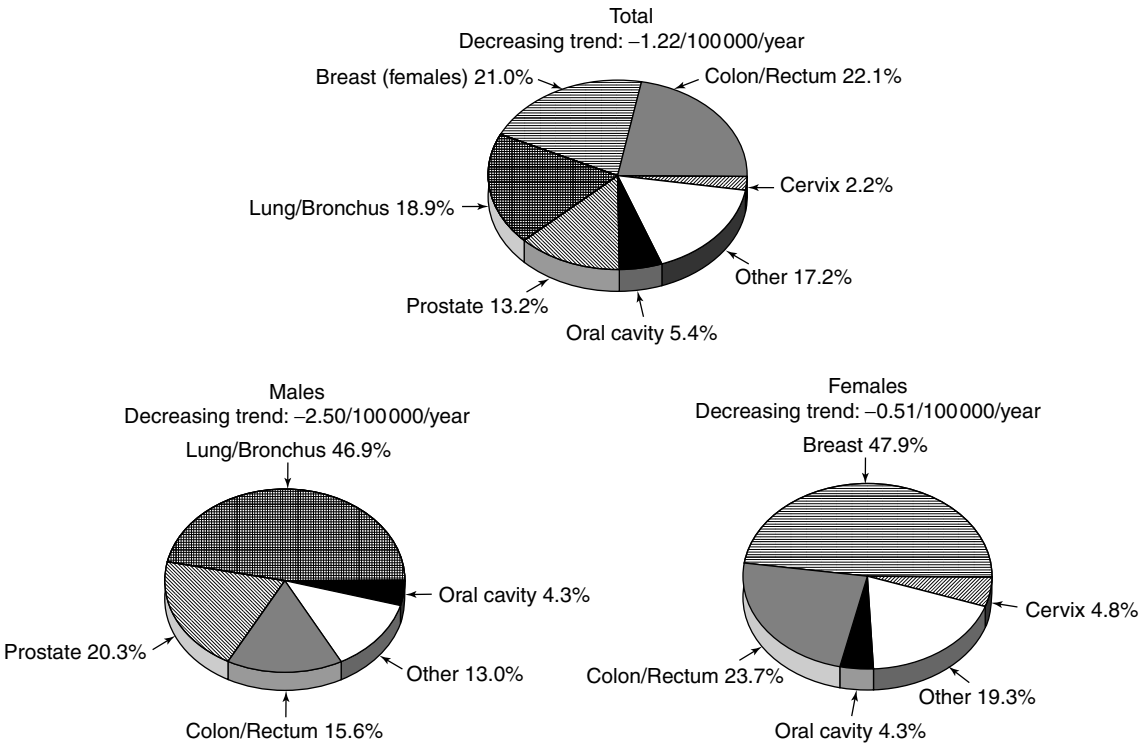

Figure 5 Partition of the cancer mortality trend from 1991 to 1996 based on fits of a linear regression model to the age-adjusted rates (1970 US Standard) for the total US population and by sex

of cancers to an increasing or decreasing trend in the age-adjusted rate for all cancers combined. This type of analysis provides useful information about the impact of targeted interventions on the overall trend in age-adjusted rates for a group of diseases of interest. Figure 5 presents a partition of the most recent cancer mortality decrease for the total population and by sex based on rates adjusted to the 1970 US Standard. The contributions of cancers for which interventions have been introduced into the general population are given. Thus, it is possible to quantify the contributions of cancers of the lung, oral cavity, colon and rectum, female breast, cervix, and prostate to the decreasing trend.

The Future of Cancer Surveillance

Medical practices have led to a new role for cancer surveillance. In theory, prevention, screening, and treatment interventions are tested for efficacy by randomized controlled trials. If such trials demonstrate that an intervention is efficacious, then it is introduced into the general population. An important role for cancer surveillance is to make an assessment of the impact of the intervention in the population by analyzing trends in incidence, survival, or mortality rates as appropriate. This paradigm has been violated in some cases in the past, particularly in the development of new screening tests where new tests have been introduced into the general population before establishing their efficacy in regard to reducing mortality. A prime example is the Prostate Specific Antigen (PSA) test for detecting prostate cancer [15]. The use of Spiral CT for diagnosing lung cancer may be a second example [23]. This practice has resulted in the use of surveillance data to not only establish some measure of the impact of the introduction of such a new test on population cancer rates, but to also make some assessment of its efficacy. If such practices continue, it will likely result in the establishment of more sophisticated surveillance systems directed toward accommodating this expanded role.

Cancer surveillance activities at the NCI have been reviewed by a committee of researchers from within and outside the Institute [22]. Recommendations for future directions have been made in a number of areas. The first priority is to expand the scope of surveillance research through additional data collection and methods development. Specific activities will include collection of data on patterns of care, health status, and quality of life, as well as cohort studies of newly diagnosed cancer patients for the purpose of documenting levels and trends in these parameters; collection of risk factor and screening data in defined populations, particularly those covered by high quality cancer registration; development of research methods to measure the dimensions of the cancer burden and factors affecting the burden, as well as methods to explain patterns and trends in cancer rates; and exploration of the feasibility and utility of employing geographic information systems for geocoding surveillance data and reporting geographic relationships among screening measures, risk factors (including environmental exposures), and improved cancer outcomes.

A second area of focus is to expand the scope of surveillance to improve the representativeness of cancer burden estimates. Specific activities will include expanding SEER population coverage to improve representation of ethnic minority and underserved populations including rural African Americans, Hispanics from Caribbean countries, American Indians, residents of Appalachia and other rural areas, especially those of lower socioeconomic classes; developing methods for improving national estimates of the cancer burden; and working with other organizations involved in cancer surveillance to develop a national cancer surveillance plan.

A third area to be addressed is the production and dissemination of a national report card on the cancer burden. Specific activities will include the collection, analysis, and dissemination of data on important cancer outcomes and trends in risk factors, screening, and treatment to be incorporated into a national cancer report card; and the development of improved methods for disseminating information via the report card and other NCI communications.

The fourth area to be addressed is the support of molecular and genetics research for surveillance. Specific activities will include the development of valid tools to assess family history of cancer, which will provide for the collection of data on the population prevalence of familial cancers; and the investigation of the feasibility of expanding population-based molecular and genetic biomarker studies within the Cancer Surveillance Research Program.

The final area to receive attention is the development of a training strategy for individuals interested in cancer surveillance research. Specifically, training pertaining to the needs of surveillance sciences will be developed along with a plan to incorporate surveillance training as a priority in mechanisms for training cancer prevention and control scientists. Much more detail is provided in the Cancer Surveillance Research Implementation Plan [22] which can be obtained at `http://camp.nci.nih.gov/dccps/`

Thus, in addition to their basic goals of supplying timely information on trends in site-specific cancer incidence, prevalence, and survival, cancer surveillance programs are evolving to provide improved quantitative benchmarks to document the impact of research advances in cancer prevention, detection, and treatment, and to identify problems that can be addressed through cancer prevention and control efforts.

B. HANKEY & APRIL FRITZ

Candidate Gene

A candidate gene is a **gene** that is guessed to underlie a disease on the basis of a metabolic pathway thought to be involved in the pathogenesis of the disease. Each protein in such a pathway must have one or more genes involved in its synthesis, and these are thus candidates for the gene(s) underlying the disease. Thus the "candidate gene approach" to finding a disease gene presupposes that we have prior information that the disease under study is probably caused by a particular gene, which we try to confirm by studying allelic variation at a genetic marker locus. If the marker locus is in fact the disease locus, then a **disease–marker association** can be sought to determine the particular allele(s) involved. Similarly, there may be a disease–marker association if the candidate marker locus is close to the disease locus and the two sets of alleles are in **linkage disequilibrium**. However, it is possible for the polymorphisms of the candidate locus studied to be in gametic equilibrium with the disease locus, even if the two loci are in almost the same position, and in this case **linkage analysis** is necessary to detect the (intrafamilial) association between the two loci. Finding an association or tight linkage between a disease and a candidate marker locus supports, but does not prove, the belief that the candidate gene does in fact cause the disease being studied.

ROBERT C. ELSTON

Canonical Correlation

Multivariate observations are characterized by various characteristics of their marginal distributions (such as their location, dispersion, and functional forms), as well as by their stochastic interrelations. These **associations** can be assessed only from their joint distributions, often in terms of suitable parameters associated with them. In the same way that the location or scale measures of marginal distributions may not necessarily correspond to some algebraic constants appearing in their functional forms, measures of association also may not correspond to a finite dimensional vector of algebraic constants appearing in the joint distribution. The situation with the **multivariate normal distribution** is, of course, entirely different because here all the measures of location, dispersion, **skewness**, **kurtosis**, and (total, partial, multiple or subset) association of all the coordinate variables can be formulated explicitly in terms of the *mean* vector and *dispersion* matrix (*see* **Covariance Matrix**), which are the only natural parameters appearing in the functional forms of the distributions. To appreciate this picture thoroughly, consider a (finite) mixture of several multivariate normal distributions with possibly different mean vectors and/or dispersion matrices, where the nonnegative mixing coefficients add up to one (yielding a convex combination). The mixed–normal distribution in this setup is characterized by means of the mixing coefficients as well as the component mean vectors and dispersion matrices. Therefore the measures of location, dispersion, as well as association are all functions of a finite set of parameters, though some of the basic linearity properties of the conditional or joint distributions may no longer be tenable. A more complex situation arises with general nonnormal distributions even if we confine ourselves to the so-called *elliptically symmetric* distributions (such as the multivariate t distribution). Thus, it seems quite natural to introduce such measures in the most simple and classical cases of multinormal distributions, interpret them properly, and then proceed to more complex situations and examine how such interpretations are affected by these underlying complexities. This picture is more complex in the case of association measures than in location or scale measures.

The (Karl) Pearsonian *total* or *product-moment* **correlation** *coefficient* in the bivariate case provides the genesis of canonical correlations in the multivariate case, as well as its generalizations for more complex models. If $(X_1, X_2)'$ is a bivariate random vector (rv) with a bivariate cumulative distribution function (cdf) $F(x, y)$, $(x, y) \in \Re^2$, such that F admits finite moments of order one and two, then we may write the correlation coefficient ρ as

$$\rho = \frac{\mathrm{cov}(X_1, X_2)}{[\mathrm{var}(X_1)\mathrm{var}(X_2)]^{1/2}},$$

and this definition does not entail any particular form of the cdf F. In this setup, X_1 and X_2 are uncorrelated when $\rho = 0$, and they are positively or negatively correlated/associated when ρ is positive or negative, respectively. Note, furthermore, that in a general setup, uncorrelation may not imply independence, although the converse is always true. In the case of a normal F, however, uncorrelation and independence are equivalent. Furthermore, by the use of the classical *Cauchy–Schwartz* moment inequality, it follows that $-1 \leq \rho \leq 1$, where the upper bound is attained only when X_1 and X_2 are strictly linearly related with a positive slope (except perhaps on a set of null probability measures), and a similar case with a negative slope leads to the attainment of the lower bound. The *regression function* of X_2 on X_1 is $m_2(x) = \mathrm{E}[X_2|X_1 = x]$, $x \in \Re$, and X_2 is said to have a **linear regression** on X_1 if $m_2(x)$ is a linear function of x for all x (except on a set of null measures). Similar notations and definitions hold for $m_1(x) = \mathrm{E}[X_1|X_2 = x]$. If both these regression functions are linear with respective slopes β_{12} and β_{21}, then it is easy to verify that

$$\rho^2 = \beta_{12} \times \beta_{21}.$$

It is also easy to verify that $\mathrm{E}(X_2 - \mathrm{E}X_2)^2 = \mathrm{E}[X_2 - m_2(X_1)]^2 + \mathrm{E}[m_2(X_1) - \mathrm{E}X_2]^2$, so that for the linear regression case, we have

$$\rho^2 = \frac{\mathrm{E}[m_2(X_1) - \mathrm{E}X_2]^2}{\mathrm{E}(X_2 - \mathrm{E}X_2)^2}.$$

Thus, ρ^2 is interpreted as the *component of variation* of X_2, which can be ascribed due to the regression on X_1. This component is null only when $\rho = 0$. If the underlying distribution is **bivariate normal**, then the conditional distribution of X_2, given X_1, is also normal with the mean linearly dependent on X_1 and (conditional) variance equal to $[\mathrm{var}(X_2)](1 - \rho^2)$, which is independent of X_1. A similar property holds

for the conditional distribution of X_1, given X_2. These are referred to as the *linearity of regression* and *homoscedasticity* (*see* **Scedasticity**) properties of bivariate normal distributions, and a similar characterization holds in the general multivariate normal case as well. In this homoscedastic case, we have

$$1 - \rho^2 = \frac{\mathrm{E}[X_2 - m_2(X_1)]^2}{\mathrm{E}(X_2 - \mathrm{E}X_2)^2},$$

although such a conditional variance component interpretation may not generally hold in the absence of the homoscedasticity condition.

Let us now proceed to the case of two subsets of variates, one containing a single element X_1, and the other one having $p(\geq 1)$ elements $\mathbf{X}_2 = (X_{21}, \ldots, X_{2p})'$. Suppose that we want a single measure for the association between X_1 and $\mathbf{X}_2$. To motivate this measure, suppose that $\mathbf{X}' = (X_1, \mathbf{X}'_2)$ has a multivariate normal distribution. Then, the conditional distribution of X_1, given $\mathbf{X}_2$, is also univariate normal with the mean linear in $\mathbf{X}_2$ and a constant (conditional) variance γ^2 (independent of $\mathbf{X}_2$). If we denote the variance of the marginal distribution of X_1 by σ_{11}, then we can write

$$\gamma^2 = \sigma_{11}(1 - R^2),$$

where R^2 is nonnegative and is bounded from above by 1. It is equal to zero only when X_1 and $\mathbf{X}_2$ are stochastically independent, while it attains the upper bound 1 when $\gamma = 0$, i.e. X_1 is perfectly linearly dependent on $\mathbf{X}_2$ (except possibly on a set of null measures). We can partition σ_{11} into two **orthogonal** components $R^2\sigma_{11}$ and γ^2, representing respectively the variation due to the regression of X_1 on $\mathbf{X}_2$, and the residual unexplained by this regression. This R^2 is a natural extension of ρ^2 to the pseudo-multivariate situation, and is known as the squared *multiple correlation coefficient* of X_1 on $\mathbf{X}_2$. There is another interpretation of this multiple correlation coefficient that is particularly appealing to the development of our study of canonical correlations. Consider an arbitrary linear combination of the second set, namely, $\mathbf{a}'\mathbf{X}_2$, where $\mathbf{a} \in \Re^p$. Let $\boldsymbol{\sigma}_1$ denote the covariance vector between X_1 and $\mathbf{X}_2$, and $\boldsymbol{\Sigma}_{22}$ be the dispersion matrix of $\mathbf{X}_2$; then the Pearsonian correlation coefficient of X_1 and $\mathbf{a}'\mathbf{X}_2$ is given by

$$\rho(\mathbf{a}) = \frac{\mathbf{a}'\boldsymbol{\sigma}_1}{[\sigma_{11}(\mathbf{a}'\boldsymbol{\Sigma}_{22}\mathbf{a})]^{1/2}}.$$

Consider the problem of choosing $\mathbf{a}$ in such a way that $\rho(\mathbf{a})$ is a maximum. We may normalize $\mathbf{a}$ by setting $\mathbf{a}'\boldsymbol{\Sigma}_{22}\mathbf{a} = 1$. Thus, we need to maximize $\mathbf{a}'\boldsymbol{\sigma}_1$ with respect to $\mathbf{a}$, subject to the above normalizing constraint. The desired solution is given by

$$\mathbf{a}_0 \propto \boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\sigma}_1,$$

and as a result we obtain

$$\rho^2(\mathbf{a}_0) = \frac{\boldsymbol{\sigma}_1'\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\sigma}_1}{\sigma_{11}},$$

which can be shown to be equal to the R^2 introduced earlier. In this setup, $\mathbf{a}_0'\mathbf{X}_2$ is the best fit to X_1, in the sense that the mean square of the residuals from this fit is a minimum among all possible choices of linear combinations of $\mathbf{X}_2$. The variance component due to regression for this fit yields the multiple correlation between X_1 and $\mathbf{X}_2$. Although in the above discussion we were primarily motivated by the linearity of regression and homoscedasticity characterizations of multinormal distributions, the latter interpretation of the multiple correlation does not crucially depend on the multinormality assumption. The canonical correlations, introduced by Hotelling [30, 31], relate to the case of two or more subsets of variates, each having possibly more than one variate, and hence contain the total and multiple correlation measures as particular cases.

Foundation of Canonical Correlations

Hotelling's original idea was to extend the Pearsonian product–moment correlation for studying stochastic dependence or association between two groups of variables. In multivariate analysis, often we may have two (or more) sets each containing multiple variates. Their dependence picture, even when completely determined by second-order moments, rests on a complex of high dimensional covariance matrices. In many studies, particularly exploratory, there may be too many variates within each subset, and this may smudge the overall picture to a greater extent. To reduce the dimensionality of the data set by eliminating *redundant* or less important variates, Hotelling [29], led by Pearson's [46] idea of fitting planes by *orthogonal least squares*, introduced two basic concepts in multivariate analysis for analyzing correlation structures: (i) **principal component analysis**

and (ii) canonical correlation analysis (CCA). Though the principal component analysis relates to an *internal analysis*, i.e. within-group orthogonal decomposition for the study of dispersion, and the canonical correlations to an *external analysis*, i.e. between-group interrelations or correlations, conceptually they are interrelated, and hence we motivate the canonical correlation analysis through the concepts of principal component analysis as well.

Suppose that $\mathbf{X}$ is a stochastic $p(\geq 1)$ vector having mean vector $\boldsymbol{\theta}$ and dispersion matrix $\boldsymbol{\Sigma}$. Note that in this setup there are p unknown elements in the mean vector and $p(p+1)/2$ unknown elements in the dispersion matrix, so that there are in all $p(p+3)/2$ unknown parameters in the model (even if multinormality is imposed on the distribution of $\mathbf{X}$). If the underlying distribution is not multinormal, then we may have an even larger parameter space. The emphasis in both the cases of principal component and canonical correlation analysis is on linear combinations of the variables that capture essentially the entire statistical information and at the same time preserve some interpretable properties. The justification for such linear transformations of course stems from multivariate normal distributions which characteristically possess some *equivariance* properties under such transformations. Nevertheless, the results to follow may still be interpreted without the underlying multinormality assumption. The principal component analysis aims to reduce the dimension of a given distribution by linear orthogonal transformations which may summarize the dispersion picture without losing any significant information. Let $\mathbf{b}$ be a p-vector of unit length in L_2 norm (i.e. $\mathbf{b}'\mathbf{b} = 1$), and consider the linear compound $\mathbf{b}'\mathbf{X}$ which has mean $\mathbf{b}'\boldsymbol{\mu}$ and variance $\mathbf{b}'\boldsymbol{\Sigma}\mathbf{b}$. We choose the particular vector $\mathbf{b}_0$ which leads to the largest possible variance. For this, we maximize $\psi(\mathbf{b}) = \mathbf{b}'\boldsymbol{\Sigma}\mathbf{b} - \lambda(\mathbf{b}'\mathbf{b} - 1)$ with respect to $\mathbf{b}$, where λ is a Lagrangian multiplier. This leads to the following estimating equation:

$$(\boldsymbol{\Sigma} - \lambda\mathbf{I})\mathbf{b} = \mathbf{0}, \tag{1}$$

so that λ satisfies the equation $|\boldsymbol{\Sigma} - \lambda\mathbf{I}| = 0$ (*see* **Eigenvalue**). If we denote the solutions (in λ) of (1) by $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_p (\geq 0)$ and identify them as the ordered *characteristic roots* of $\boldsymbol{\Sigma}$, then we may simultaneously introduce the *characteristic vectors* $\mathbf{b}_j$, $j = 1, \ldots, p$, by setting

$$\boldsymbol{\Sigma}\mathbf{b}_j = \lambda_j\mathbf{b}_j, \quad j = 1, \ldots, p$$

(*see* **Eigenvector**). Then $\mathbf{b}'_1\mathbf{X}$ is termed the *first principal component* and its variance is equal to λ_1. In general, for $j = 1, \ldots, p$, $\mathbf{b}'_j\mathbf{X}$ is the jth principal component with variance λ_j, which is the highest possible subject to the constraint(s) that the jth component is uncorrelated with all the previous $j-1$ components. If $\boldsymbol{\Sigma}$ is singular, of rank $q < p$, then $\lambda_j = 0$, for all $j > q$, so that q orthogonal components describe the structure completely. In many anthropometric, biometric and psychometric problems, there may be a large number of variables either having multi-**collinearity** or almost degeneracy. In such a case the prominent principal components convey a clear picture of the relevant compounds, obtainable by orthogonal transformations, that capture the essential statistical information. Of particular statistical importance are the so-called *biplots* which relate only to the first two principal components and sacrifice the others (*see* **Graphical Displays**). In that way a high-dimensional model is reduced virtually to a two-dimensional one, so that a statistical analysis can be performed with greater clarity.

Let us look into the canonical correlation problem in the same vein. We partition the p-vector $\mathbf{X}$ into two subvectors $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ of dimension p_1 and $p_2 (p = p_1 + p_2)$ reflecting two sets of variables. Adopt a similar partition for $\boldsymbol{\mu}$, and the dispersion matrix $\boldsymbol{\Sigma}$ is then partitioned into p_1 and p_2 rows and columns, i.e. $\boldsymbol{\Sigma} = ((\boldsymbol{\Sigma}_{ij}))_{\{i,j=1,2\}}$. Although it is not necessary, for simplicity, we assume that both $\boldsymbol{\Sigma}_{11}$ and $\boldsymbol{\Sigma}_{22}$ are nonsingular, while the rank of $\boldsymbol{\Sigma}_{12} = m[\leq \min(p_1, p_2)]$. If $m = 0$ (i.e. $\boldsymbol{\Sigma}_{12}$ is a null matrix), then the canonical correlations to be derived will be all equal to 0, and hence we assume that $m \geq 1$. Whenever m is small compared with p_1 and p_2, we shall see that the canonical correlations lead to substantial data reduction with respect to such between-group dependence studies. If p_1 and p_2 are both equal to 1, then their product moment correlation explains their interrelations. If either p_1 or p_2 is equal to 1, while the other is larger, then we can appeal to the multiple correlation measure to study their interdependence. If both p_1 and p_2 are greater than 1, then it may be more practical to consider only a few linear combinations from each set, chosen in such a way that they contain as much dependence structure as possible. This would then amount to a reduction in the dataset (dimension) for the study of between-group dependence structures with only insignificant loss of information. With this motivation, within each

subset we consider linear compounds chosen in such a way that they have unit variance, and then we desire to maximize their correlation. Thus, let $\mathbf{a}$ and $\mathbf{b}$ be two (p_1 and p_2) vectors such that

$$\mathbf{a}'\boldsymbol{\Sigma}_{11}\mathbf{a} = 1 \quad \text{and} \quad \mathbf{b}'\boldsymbol{\Sigma}_{22}\mathbf{b} = 1.$$

Subject to these constraints, $\mathbf{a}'\boldsymbol{\Sigma}_{12}\mathbf{b}$ is a maximum. Using Lagrangian multipliers λ and ν, we consider the function

$$\psi(\mathbf{a}, \mathbf{b}) = \mathbf{a}'\boldsymbol{\Sigma}_{12}\mathbf{b} - \left(\frac{\lambda}{2}\right)(\mathbf{a}'\boldsymbol{\Sigma}_{11}\mathbf{a} - 1) - \left(\frac{\nu}{2}\right)(\mathbf{b}'\boldsymbol{\Sigma}_{22}\mathbf{b} - 1).$$

Taking the gradients with respect to $\mathbf{a}$ and $\mathbf{b}$, and equating them to zero, we arrive at the solution that $\lambda = \nu$ with

$$-\lambda\boldsymbol{\Sigma}_{11}\mathbf{a} + \boldsymbol{\Sigma}_{12}\mathbf{b} = 0,$$
$$\boldsymbol{\Sigma}_{21}\mathbf{a} - \lambda\boldsymbol{\Sigma}_{22}\mathbf{b} = 0,$$

so that the solution λ_1^2 is the largest characteristic root of either of the matrices

$$\boldsymbol{\Sigma}_{11}^{-1}\boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}, \qquad \boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}\boldsymbol{\Sigma}_{11}^{-1}\boldsymbol{\Sigma}_{12} \tag{2}$$

or their other cyclic permutations. If we choose the characteristic vectors $\mathbf{a}_1$ and $\mathbf{b}_1$ corresponding to the largest characteristic root λ_1, then we obtain that the Pearsonian product–moment correlation of $U_1 = \mathbf{a}'_1\mathbf{X}^{(1)}$ and $V_1 = \mathbf{b}'_1\mathbf{X}^{(2)}$ is equal to λ_1, which is the largest possible correlation between a linear compound of $\mathbf{X}^{(1)}$ and another one of $\mathbf{X}^{(2)}$. That is why it is termed the *first canonical correlation* between $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$. We can consider then a second linear combination of $\mathbf{X}^{(1)}$ and a second one of $\mathbf{X}^{(2)}$, say U_2 and V_2, such that among all linear combinations uncorrelated with U_1 and V_1, λ_2, the correlation between U_2 and V_2, is the maximum. A little algebra shows that λ_2^2 is the second largest characteristic root of the same matrix in (2) for which λ_1^2 is the largest root, and the corresponding characteristic vectors are the coefficient vectors for U_2 and V_2. This process can continue until we have m of the characteristic roots $\lambda_1^2 \geq \lambda_2^2 \geq \ldots \geq \lambda_m^2 > 0$, and the corresponding sets of canonical variates U_j and V_j, $j = 1, \ldots, m$. Note that as the rank of $\boldsymbol{\Sigma}_{12} = m$, $\lambda_j^2 = 0$ for every $j > m$. Also note that like the product–moment, partial and multiple correlations, the canonical correlations are all scale-invariant with respect to each of the p coordinate variates.

At this stage we set, without loss of generality, $m \leq p_1 \leq p_2$, and denote by $\boldsymbol{\Lambda}$ the diagonal matrix of order $p_1 \times p_1$ with the leading elements $\lambda_1, \ldots, \lambda_m, 0, \ldots, 0$. Then the process of finding the canonical correlations leads to two sets of canonical combinations $\mathbf{U} = (U_1, \ldots, U_{p_1})'$ and $\mathbf{V} = (V_1, \ldots, V_{p_2})'$, such that the dispersion matrix of the p-vector with the two components $\mathbf{U}$ and $\mathbf{V}$ is given by

$$\begin{pmatrix} \mathbf{I} & \boldsymbol{\Lambda} & \mathbf{0} \\ \boldsymbol{\Lambda} & \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} \end{pmatrix}, \tag{3}$$

where the last pivotal $\mathbf{I}$ is of order $(p_2 - p_1) \times (p_2 - p_1)$, and hence is a null matrix when $p_2 = p_1$, and $\boldsymbol{\Lambda}$ has $(p_1 - m)$ null diagonal elements when $p_1 \geq m$. This provides a clearly interpretable picture of CCA.

This latter representation of the canonical variates and their (canonical) correlations can also be interpreted in the light of *affine equivalence* studied in detail in [21, Chapter 10]. Recall that an affine transformation on a vector rv $\mathbf{X}$ is defined by $\mathbf{Y} = \mathbf{A}\mathbf{X} + \mathbf{a}$, where $\mathbf{A}$ is nonsingular and $\mathbf{a}$ is some vector. The **Hotelling T^2** and other likelihood-based **multivariate analysis of variance** tests are affine invariant in the sense that affine transformations on the observable random vectors leave the statistic invariant. Eaton interpreted that if $\mathbf{Y} = \mathbf{A}\mathbf{X} + \mathbf{a}$ with probability one, where $\mathbf{A}$ is nonsingular, then $\mathbf{Y}$ and $\mathbf{X}$ are affinely equivalent. Consider now measures of *affine dependence* between the two subvectors $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ which are functions of the covariance matrix $\boldsymbol{\Sigma}$ and are invariant with respect to affine transformations on $\mathbf{X}$. For example, if $\mathbf{Y}^{(j)}$ is affinely equivalent to $\mathbf{X}^{(j)}$, for $j = 1, 2$, then the measure of affine dependence between $\mathbf{Y}^{(1)}$ and $\mathbf{Y}^{(2)}$ should be the same as between $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$. Since the elements of the covariance matrix $\boldsymbol{\Sigma}$ are translation invariant, one may as well take the shift vector $\mathbf{a} = \mathbf{0}$. Then, following Eaton [21], we may verify that the characteristic roots of (2) constitute the maximal invariant function under the compound group of affine transformations on the individual subset vectors. Since the canonical correlations are the squares of these characteristic roots, it follows that any invariant measure of affine dependence has to be a function of these canonical correlations. The canonical vectors $\mathbf{U}$ and $\mathbf{V}$ defined before (3) are affinely equivalent to $\mathbf{X}^{(1)}$

and $\mathbf{X}^{(2)}$, respectively, and (3) reveals their affine dependence through the diagonal matrix $\mathbf{\Lambda}$. Following Dempster [16] and Eaton [21], we note that the canonical correlations also have a natural geometrical interpretation as **cosines of the angles** between appropriate vector spaces. With biostatistical perspective in mind, we refrain from such abstractions. However, we refer to the two texts by Morrison [42] and Mardia et al. [39] for nice applications-oriented illustrations of canonical correlations and related topics. Below we consider some extension of canonical correlations to the case of more than two subsets of variates, as well as to some restricted type of dependence patterns.

Relationships with Other Multivariate Measures

One of the reasons for the broad appeal of canonical correlation analysis in practical applications is its ability to subsume many other multivariate measures, concepts, and methods. We have already commented on the relevance of the principal component analysis. Besides this, CCA brings together techniques like *multiple correlation* and *regression analysis, canonical discriminant analysis*, **correspondence analysis**, *analysis of* **contingency tables**, and **multivariate analysis of variance** and *covariance*. Some of these items are covered in greater detail in other articles, and hence we omit their definitions here. **Linear discriminant analysis** has also been covered as a special case under canonical correlation analysis by Takeuchi et al. [59]. In this particular case the canonical variables of one of the sets turn out to be the discriminators, while those of the other set provide the optimal scores to be assigned to the different populations. **Factor analysis**, another important area in multivariate analysis with special emphasis on **psychometry** and *mental testing*, also has affinity to canonical correlation analysis. To illustrate this relationship we consider the following problem, which uses canonical correlation analysis in a spirit somewhat similar to that in factor analysis. Suppose that $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ are linearly dependent on a number m, of common, uncorrelated, unobservable factors $\mathbf{F} = (F_1, \ldots, F_m)'$ in the following way:

$$\mathbf{X}^{(j)} = \mathbf{A}_j \mathbf{F} + \mathbf{G}_j, \quad j = 1, 2,$$

where $\mathbf{G}_1$ and $\mathbf{G}_2$ are the specific factors, and we assume that $\mathbf{F}$, $\mathbf{G}_1$, and $\mathbf{G}_2$ are all uncorrelated (orthogonal). The goal is to determine the minimum m, the *effective number of common factors* for which such a representation is possible. It is known [49] that m is equal to the rank of $\mathbf{\Sigma}_{12}$, and hence canonical correlation analysis can be adapted to appraise this situation. As we consider the sample counterparts of the canonical correlations, we will observe that there are certain difficulties in attaching any reliability to the rank of the sample counterpart of $\mathbf{\Sigma}_{12}$, and the canonical correlation analysis has some advantages in this respect.

Let us examine the role of CCA in a related **prediction** problem, which is essentially allied to the **multivariate multiple regression** problem. We have the same partitioning, $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$, as before, and in the same way we find the partitioning $\boldsymbol{\mu}^{(1)}$ and $\boldsymbol{\mu}^{(2)}$ and the $\mathbf{\Sigma}_{ij}$, $i, j = 1, 2$, of the mean vector and covariance matrix, respectively. In a multivariate normal model the regression of $\mathbf{X}^{(1)}$ on $\mathbf{X}^{(2)}$ is given by

$$\mathrm{E}[\mathbf{X}^{(1)}|\mathbf{X}^{(2)}] = \boldsymbol{\mu}^{(1)} + \mathbf{\Sigma}_{12}\mathbf{\Sigma}_{22}^{-1}[\mathbf{X}^{(2)} - \boldsymbol{\mu}^{(2)}],$$

and the dispersion matrix of the residual vector $\mathbf{X}^{(1)} - \mathrm{E}[\mathbf{X}^{(1)}|\mathbf{X}^{(2)}]$ is given by

$$\mathbf{\Sigma}_{11.2} = \mathbf{\Sigma}_{11} - \mathbf{\Sigma}_{12}\mathbf{\Sigma}_{22}^{-1}\mathbf{\Sigma}_{21}.$$

It is easy to verify that the characteristic roots of $\mathbf{\Sigma}_{11}^{-1}\mathbf{\Sigma}_{11.2}$ are nothing but the complements of the squared canonical correlations, namely $1 - \lambda_j^2$, $j = 1, \ldots, p_1$. Without this multinormality condition, one may still fit a linear regression of $\mathbf{X}^{(1)}$ on a linear compound $\mathbf{a} + \mathbf{B}\mathbf{X}^{(2)}$, and verify that the best fit, in the sense of having the minimum characteristic roots of the standardized dispersion matrix of the residual vector, corresponds to $\mathbf{a} = \boldsymbol{\mu}^{(1)} - \mathbf{\Sigma}_{12}\mathbf{\Sigma}_{22}^{-1}\boldsymbol{\mu}^{(2)}$ and $\mathbf{B} = \mathbf{\Sigma}_{12}\mathbf{\Sigma}_{22}^{-1}$. Therefore, either way the canonical correlations tell us about the dispersion of the predicting vector, as well as the errors due to deviation from the predictor. Thus, we may use the canonical variates for the set $\mathbf{X}^{(2)}$ and come up with predictions under dimension reduction. We refer to Brillinger [8] for some allied studies. Note that in this setup the roles of the two sets are not the same, although in CCA we have a symmetric formulation.

The above development also leads us to two important concepts in multivariate analysis, namely the *canonical loadings* and *redundancy coefficient*. Canonical loadings can be introduced through the

canonical weights, which in optimum canonical correlations express the importance of a variable from one set with regard to the other set in obtaining a maximum correlation between the two sets. In a sense these canonical weights are related to the canonical variables introduced earlier [see (2) and the discussion following it]; we denoted these canonical variates for the two sets by $\mathbf{U}$ and $\mathbf{V}$, respectively. We write $\mathbf{U} = \mathbf{A}_1\mathbf{X}^{(1)}$ and $\mathbf{V} = \mathbf{A}_2\mathbf{X}^{(2)}$. To interpret CCA appropriately, one needs to look into these canonical coefficients along with the canonical loadings as defined below. A canonical loading, or structure, is the product–moment correlation between an original variable and its respective canonical variable, so that it reflects the degree to which a variable is represented by its canonical variable. Thus, if we denote the ith intragroup correlation matrix by $\mathbf{R}_{ii}$, $i = 1, 2$, then for the p_i canonical variables in the ith group, the canonical loadings are given by the rows of $\mathbf{R}_{ii}\mathbf{A}_i$, $i = 1, 2$. At this stage we treat the first set of variables as the *predicting* set, and the second one as the *criterion* set. While the proportion of variance in the criterion set explained by its canonical variates can be expressed in terms of the canonical loadings, we may like to study the proportion of variance in the criterion set which is explained by the predictor set. Here canonical correlations and canonical variables do not capture the full information, and we need redundancy analysis. The redundancy coefficient, proposed by Stewart & Love [57], represents the amount of variance in the criterion set that is redundant to the amount of variance in the predictor set. They showed that the redundancy coefficient is equivalent to regressing each variable in the criterion set in turn on all the variables in the predictor set, and then averaging the p_2 squared multiple correlation coefficients.

Canonical weights or patterns are used to assess the relationship between the original variables and the canonical variables so that they indicate the contribution of each variable to the respective within-set canonical variables. However, these weights do not necessarily accurately reflect the relative importance of the different variables. This may happen mainly due to the presence of *multicollinearity*, where some variable may obtain a small, even negative, weight because of the presence of some other variables yielding the degeneracy of the dispersion matrix. Also, because of multicollinearity, these coefficients may become very unstable. That is why some researchers have advocated the use of canonical loadings (structure) instead of canonical weights (pattern). But these measures can also suffer from similar drawbacks. The main difficulties surrounding CCA in such nonregular cases have not been well assessed, and hence one should exercise caution in interpreting canonical correlations in any particular setting. In passing, we may also remark that the canonical variables, for either set, are not observable, and hence may not always attach interpretable physical meanings. This drawback of CCA is of some concern in applied fields, particularly in biostatistics, because derived statistical results should be capable of being understood and interpreted by researchers from other fields who seek to make use of them. It is to be noted though that the canonical variables are of interest in their own right; they help to deepen the understanding of the original variables and in some cases may even suggest new measures. Kshirsagar [37] remarked that if canonical analysis had no other practical use, it could at least be used as a descriptive and exploratory tool. It summarizes the complex relationship and provides a useful method of reduction in the dimensionality problem.

Sample Canonical Correlation(s) and their Sampling Distributions

Suppose that $\mathbf{X}'_i = (\mathbf{X}_i^{(1)'}, \mathbf{X}_i^{(2)'})$, $i = 1, \ldots, n$ are n independent identically distributed (iid) random variables having the same partition of the mean vector $\boldsymbol{\mu}$ and dispersion matrix $\boldsymbol{\Sigma}$ as before. We define the sample mean vector $\overline{\mathbf{X}}_n$ and sample covariance matrix $\mathbf{S}_n$ as

$$\overline{\mathbf{X}}_n = n^{-1}\sum_{i=1}^{n}\mathbf{X}_i,$$

$$\mathbf{S}_n = (n-1)^{-1}\sum_{i=1}^{n}(\mathbf{X}_i - \overline{\mathbf{X}}_n)(\mathbf{X}_i - \overline{\mathbf{X}}_n)'.$$

Then $\mathbf{S}_n$ is translation-invariant and affine equivariant, and is unbiased for $\boldsymbol{\Sigma}$ whenever the latter exists. If we sample from a multivariate normal population, then the $\mathbf{X}_i$s have finite moments of all orders, and $\overline{\mathbf{X}}_n$ and $\mathbf{S}_n$ are jointly sufficient for $(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. Hence the estimators of canonical correlations (which are functions of these natural parameters) can be based solely on such sufficient statistics. Such a motivation may not be rational if the underlying pdf is not

multinormal; these statistics then may not lead to the maximum likelihood estimators of the canonical correlations, although from the point of view of affine equivariance and unbiasedness, $\overline{\mathbf{X}}_n$ and $\mathbf{S}_n$ may still be considered appropriate for such data reduction.

With this motivation, and recalling the affine equivariance property of the sample covariance matrix, we partition $\mathbf{S}_n$ into $\mathbf{S}_{ij,n}$, $i, j = 1, 2$, in the same way as was done for $\mathbf{\Sigma}$, and consider the derived matrix

$$\mathbf{S}_n^* = \mathbf{S}_{12,n}\mathbf{S}_{22,n}^{-1}\mathbf{S}_{21,n}\mathbf{S}_{11,n}^{-1};$$

we also could have taken the permutation version of order $p_2 \times p_2$. Here also we take $p_1 \leq p_2$, and hence prefer to use the above definition of $\mathbf{S}_n^*$. It is easy to see that $\mathbf{S}_n^*$ satisfies the affinely equivalence property, and is translation invariant. Consider the characteristic roots $l_{1,n}^2 \geq l_{2,n}^2 \geq \ldots \geq l_{p1,n}^2 (\geq 0)$ of $\mathbf{S}_n^*$, and define the sample canonical correlations as their nonnegative roots:

$$l_{j,n} = j\text{th sample canonical correlation},$$
$$\text{for } j = 1, \ldots, p_1.$$

Note that the sample canonical correlations are all (ordered) stochastic (nonnegative) variables, and even if the population canonical correlations are zero for some $j (\geq 1)$ and onwards, the corresponding sample canonical correlations may not be identically equal to zero with probability one. Therefore for drawing statistical conclusions on the canonical correlations based on their sample counterparts, it is necessary to incorporate the **sampling distribution** of the latter in the statistical decision procedures.

For finite sample size n, the marginal (and certainly joint) distributions of the sample canonical correlations are, in general, extremely complicated, even if we confine ourselves to sampling from a multivariate normal distribution. However (in the case of a multinormal distribution), when the population canonical correlations are all null (so that the two subsets $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ are independent, implying $\mathbf{\Sigma}_{12} = \mathbf{0}$), the sampling distribution is much more manageable; an elegant derivation of this can be found in Kshirsagar [37]. This special case relates to the independence of the two subsets, and the classical **likelihood ratio test** statistic, $\mathfrak{L}_n$, can be easily shown to be given by

$$\mathfrak{L}_n = n[\ln|\mathbf{S}_{n,11}| + \ln|\mathbf{S}_{n,22}| - \ln|\mathbf{S}_n|]$$
$$= n \ln|\mathbf{I} - \mathbf{S}_n^*| = n\sum_{j=1}^{p_1} \ln(1 - l_{j,n}^2).$$

The null hypothesis distribution of this test statistic can be quite well approximated by the central **chi-square distribution** with $p_1 p_2$ degrees of freedom (df), and this approximation can be improved further, particularly for moderate values of n, by using the conventional Bartlett correction. For details we refer the reader to any standard multivariate statistical analysis text; Anderson [2] is an excellent source. A similar likelihood ratio test for the null hypothesis that all but the first $k (\leq p_1)$ characteristic roots are equal to 0, can be worked out in the same manner. The latter test of the hypothesis problem is of significant interest in deciding on the number of canonical correlations to be used in a given situation, or to estimate the rank of $\mathbf{\Sigma}_{12}$. The asymptotic distribution is again chi-square, this time with df $(p_1 - k)(p_2 - k)$; appropriate Bartlett correction works out along the same line. Constantine [10] derived the density of the sample canonical correlations in the general (multivariate normal) case when the population of canonical correlations are not necessarily null, and involves a hypergeometric function of two matrix arguments (and thereby is very difficult to implement in actual applications). From statistical considerations, therefore, there was a pressing need for suitable approximations to sampling distributions of sample canonical correlations, and, led by the pioneering work of T.W. Anderson in the late 1940s and early 1950s, a considerable amount of research work has been accomplished in this area. The first phase relates to the large-sample case and yet retaining the underlying multinormality assumption, and demonstrates the asymptotic normality of the $\sqrt{n}(l_{j,n} - \lambda_j)$, for different j, treating separately the cases of distinct population canonical correlations and their multiplicity. The parameters appearing in these asymptotic normal distributions themselves may depend in a rather complex manner on the unknown λ_j. Therefore in setting suitable confidence sets or testing composite null hypotheses on the canonical correlations, it may be necessary to estimate these functional parameters reliably from the sample data, and this may make it necessary to have an enormously large sample size – a postulation that is not always met in practice.

The second phase of development started with the observation that CCA is a meaningful tool for the study of between-group dependence, even when the underlying multinormality assumption may not be tenable. However, without the multinormality assumption the canonical correlations relate to measures of correlation vs. noncorrelation, but not necessarily independence. In such a general nonnormal case the asymptotic distribution of the sample canonical correlations has been studied by Muirhead & Waternaux [44] under the assumption that the population pdf admits finite fourth-order moments and that its canonical correlations are all distinct, i.e. the sample canonical correlations have a jointly asymptotically multinormal distribution. While the finiteness of the fourth-moment condition is not that stringent (needed even for the total correlation in a bivariate nonnormal distribution), without the distinctness of the population canonical correlations, the asymptotic distribution may not be normal without the latter condition. When the asymptotic normality holds, Muirhead & Waternaux were able to verify that the asymptotic variance of $\sqrt{n}(l_{j,n} - \lambda_j)$ is equal to

$$\begin{aligned}\gamma_j^2 = \{&4\lambda_j^2(1-\lambda_j^2)^2 + \lambda_j^4(\kappa_{j:4} + \kappa_{j+p_1:4}) \\ &+ 2\lambda_j^2(2+\lambda_j^2)\kappa_{j,p_1+j:2,2} \\ &- 4\lambda_j^3(\kappa_{j,p_1+j:3,1} + \kappa_{j,p_1+j:1,3})\},\end{aligned}$$

where the κ_j are different fourth-order cumulants of the population (*see* **Characteristic Function**). The formulas for the asymptotic covariances are even more cumbersome (see [44]). In practice, for setting **confidence intervals** or **hypothesis testing**, even for the canonical correlations in isolation, one would require a good estimator of the γ_j^2, and therefore the presence of the unknown cumulants signals further complications in the practical use of this asymptotic approximation. One possible way to eliminate this shortcoming is to estimate the unknown cumulants from the sample by the method of moments, and substitute these estimators in the above expression. Alternately, *resampling methods*, such as the **jackknife** or the **bootstrap**, can be used to estimate the γ_j nonparametrically with considerable computational ease. Das & Sen [14] have studied such resampling plans. Since characteristic roots typically relate to certain (implicit) equations involving polynomial functions, it is easy to verify that the canonical correlations, the λ_j, are all *smooth* functions of the population covariance matrix $\mathbf{\Sigma}$, and likewise, the sample canonical correlations are smooth functions of the sample covariance matrix $\mathbf{S}_n$. Furthermore, the elements of $\mathbf{S}_n$ are all $\boldsymbol{U}$**-statistics**, and hence are asymptotically jointly multinormal whenever the fourth moments are all finite. This provides an easy way to verify the asymptotic normality of the sample canonical correlations as well as to incorporate resampling plans to estimate their asymptotic dispersion matrix in a nonparametric manner.

It may also be remarked that the canonical correlations are invariant under multiplication of the original variables with nonsingular matrices. Hence, in most sampling theory works it is assumed without loss of generality that the population covariance matrix $\mathbf{\Sigma}$ is of the canonical form given in (3).

Generalizations and Excursions

Generalizations of the notion of canonical correlations to three or more subsets of variates were proposed by Roy [51]; he also developed the notion of partial canonical correlations between two subsets of variates when the others are held fixed, and proposed a test for the same. Anderson [2] incorporated the minimization of the Wilks *generalized variance* or determinant criterion to define the canonical correlations in the case of two or three subsets of variates. However, a more systematic approach to multigroup canonical correlation analysis was initiated by Horst [28] with further feedback from Kettenring [34, 35] and Sengupta [54]. Most of these methods call for the selection of canonical variables, one from each subset, such that some function of their correlation matrix is maximized. The different methods typically considered are

1. Maximization of the sum of the correlation coefficient (SUMCOR).
2. Maximization of the sum of squares of the elements of the correlation matrix (SSQCOR).
3. Maximization of the largest characteristic root of the correlation matrix (MAXVAR).
4. Minimization of the smallest characteristic root of the correlation matrix (MINVAR).
5. Minimization of the generalized variance of the correlation matrix (GENVAR).

Several computational **algorithms** that work satisfactorily in practice are available for these methods (see [54] and the references therein), although there is some need to justify their convergence properties theoretically.

The developments on CCA reported above all relate to the case where the dispersion matrix $\mathbf{\Sigma}$ is positive definite, and singular covariance matrices resulting from multicollinearity and/or redundancy are thereby excluded from this setup. Intuitively, at least, this study should not depend on the positive definiteness of the subset dispersion matrix, and incorporation of suitable *generalized inverses* (*see* **Matrix Algebra**) indeed validates the canonical correlation analysis in the case of a possibly singular dispersion matrix, without essentially any additional regularity assumptions over the conventional positive definite case. To illustrate this point, consider a $2p$-vector $\mathbf{X}$ partitioned into two p-vectors $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$, where the dispersion matrix of each subset is singular, say of rank $q(< p)$. Then we first write $\mathbf{X}^{(j)} = \mathbf{B}_j \mathbf{Y}^{(j)}$, $j = 1, 2$, where the $\mathbf{Y}_j$ are q-vectors having nonsingular dispersion matrices $\mathbf{\Gamma}_j$, $j = 1, 2$, while the $\mathbf{B}_j$ are $p \times q$ matrices of rank q. This way we have

$$\mathbf{\Sigma}_{jk} = \mathbf{B}'_j \mathbf{\Gamma}_{jk} \mathbf{B}_k, \quad j, k = 1, 2,$$

and the canonical correlation analysis can be performed on the $\mathbf{Y}^{(j)}$ which satisfy the nonsingularity condition on their dispersion matrix. Note that in this way the number of nonzero canonical correlations will be less than or equal to q, although $p_1 = p_2 = p > q$. Khatri [36], Rao [50], Jewell & Bloomfield [33], Sengupta [55], and Baksalary et al. [5] have all incorporated different generalized inverses for such singular cases in various frameworks. In a nutshell, they have shown that no changes are needed from the traditional approach. However, in the canonical reduction of the dispersion matrix in (3) the three block-diagonal matrices $\mathbf{I}$ are replaced by $\mathbf{I}$ of lower order and a null complementary part.

In the same way as the product–moment correlation has been extended to *part*, *partial* and *bipartial* correlations, canonical correlations also have been extended to such part, partial, and bipartial forms. For example, with (the usual extension of notations and) three groups of variates $\mathbf{X}^{(1)}$, $\mathbf{X}^{(2)}$, and $\mathbf{X}^{(3)}$, the partial canonical correlations between $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ after the linear effect of $\mathbf{X}^{(3)}$ is removed can be obtained from the conditional covariance matrix between $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$. Given $\mathbf{X}^{(3)}$, in the same way the usual canonical correlations are obtained from the unconditional covariance matrix. Thus, in essence, $\mathbf{\Sigma}_{ij}$ gets replaced by $\mathbf{\Sigma}_{ij.3} = \mathbf{\Sigma}_{ij} - \mathbf{\Sigma}_{i3} \mathbf{\Sigma}_{33}^{-1} \mathbf{\Sigma}_{3j}$ for $i, j = 1, 2$. Similarly, an example of part canonical correlations would be when the effect of $\mathbf{X}^{(3)}$ is removed from $\mathbf{X}^{(2)}$, but not from $\mathbf{X}^{(1)}$. This would require working with

$$\begin{pmatrix} \mathbf{\Sigma}_{11} & \mathbf{\Sigma}_{12.3} \\ \mathbf{\Sigma}_{21.3} & \mathbf{\Sigma}_{22.3} \end{pmatrix}.$$

Bipartial canonical correlations are relevant when there are four groups of variates and the effects of $\mathbf{X}^{(3)}$ and $\mathbf{X}^{(4)}$ are removed respectively from $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ (but not from both). See Rao [48] and Timm & Carlson [61] for more details on these topics.

In many problems, some structural symmetry is reflected in the correlation matrix $\mathbf{R}$, and this can simplify the computational algorithm for the canonical correlations. For example, if $\mathbf{R}$, a $2p \times 2p$ matrix, is partitioned into four matrices $\mathbf{R}_{ij}$, $i, j = 1, 2$, where

$$\mathbf{R}_{ii} = (1 - \rho_1)\mathbf{I} + \rho_i \mathbf{J}, \quad i = 1, 2;$$
$$\mathbf{R}_{12} = \rho_3 \mathbf{J}; \qquad \mathbf{J} = \mathbf{1}\mathbf{1}',$$

and the ρ_i, $i = 1, 2, 3$, are real numbers assuming values on $(-1, 1)$, then $\mathbf{R}_{12}$ is of rank 1, and hence only the first canonical correlation is nonzero. This computation can be carried out much more conveniently than in the general case of an arbitrary correlation matrix. Das & Sen [14] give additional illustrations of this type.

It is important to study how significant the changes in canonical correlations are when the entries of the covariance matrix shift by a small amount. An account of such perturbation analysis in this context can be found in Golub & Zha [25]. Styan [58] and Bérubé et al. [6] have studied the CCA in three-way layouts exploring orthogonality and connectedness.

Among other excursions in the field of canonical correlation analysis, *constrained* and *restricted* variations deserve special mention. As discussed earlier, one of the most common reservations held against the traditional analysis is the lack of interpretability of the canonical coefficients. In the context of categorical data models, DeSarbo et al. [17] introduced the idea of constrained canonical correlations to address this problem. They proposed allowing the coefficients for each cell (in the linear compound/canonical variable) to be either of the three entries $\{-1, 0, 1\}$. Thus,

for p_1 and p_2 categorical variables in the two subsets, there are in all $(3^{p_1}-1)(3^{p_2}-1)$ choices of the two (nonnull) coefficient vectors, and optimization is to be achieved within this finite set. They also discussed relevant computational aspects, comparing the complete enumeration with two algorithms that reduce the computation further. This simple alternative may have been more appealing because of the discrete nature of the data set they studied. Yanai & Takane [66] discussed the algebra of restricted canonical correlations with additional linear constraints (on the coefficient vectors $\mathbf{a}$ and $\mathbf{b}$ for the two subsets) in the form

$$\mathbf{Aa} = \mathbf{0} \quad \text{and} \quad \mathbf{Bb} = \mathbf{0},$$

where $\mathbf{A}$ and $\mathbf{B}$ are $r_1 \times p_1$ and $r_2 \times p_2$ given matrices with $r_1 \leq p_1$ and $r_2 \leq p_2$. In view of the linear nature of these subspaces, they considered the projection technique to solve the optimization problem in this setup. A more general restricted canonical correlation analysis arises in many psychometric and biological problems, wherein the coefficients appearing in the linear compounds are restricted by certain inequalities, such as that these are all nonnegative or ordered within each subset (*see* **Isotonic Inference**). The most common restriction of this type relates to the case where all the coefficients $\mathbf{a}$ and $\mathbf{b}$ are set to be nonnegative, so that the derived canonical variables are *convex combinations* of the original variables. In this context, suitable interpretations, perhaps being better *representatives* of their respective group of variates, can be made of these canonical variables. Das & Sen [13] formulated the algebraic derivations of such restricted canonical correlations. It was shown how some general restricted models (including cases where only *some* of the coefficients are constrained by inequality-type restrictions) can be reduced to such convex combination models by simple transformations. It follows from their discussion that the largest squared restricted canonical correlation between $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ is equal to one of the squared canonical correlations between ${}_{\mathbf{a}}\mathbf{X}^{(1)}$ and ${}_{\mathbf{b}}\mathbf{X}^{(2)}$, for some $\mathbf{a} \in \mathbf{W}_{p_1}$ and $\mathbf{b} \in \mathbf{W}_{p_2}$, with $\mathbf{W}_p = \{\mathbf{a} : \emptyset \neq \mathbf{a} \subseteq \{1, \ldots, p\}\}$ and ${}_{\mathbf{a}}\mathbf{X}$ stands for the $|\mathbf{a}|$-component vector consisting of those components of $\mathbf{X}$ whose indices belong to $\mathbf{a}$. This result also holds for the case of sample canonical correlations in the restricted case, and is of pivotal importance in the study of the sampling properties of such statistics. This was handled in a follow-up study, Das & Sen [15], along with the effectiveness of resampling plans in such restricted canonical correlation schemes. In a recent book, Hastie et al. [23] dealt with nonlinear canonical variables in neural network and flexible discriminant analysis. Friman et al. [27] used the above constrained analysis technique in adaptively filtering the functional MRI data.

Issues Related to Applications in Biostatistics

At present, biostatistics covers a broad domain of basic as well as applied sciences, wherein biological, medical and clinical, pharmacologic, environmental, epidemiologic, neural, and socioeconomic aspects have all mingled with statistical concepts and perspectives in a harmonious way. The advent of modern computers has opened up a wide avenue of **computer-intensive**, application-oriented research in this fertile field (see, for example, Sen [53]). Typically, in view of the high dimensionality and high volume of acquired data sets in such studies, it is often necessary to implement effective dimension reduction techniques, such as **projection pursuits**, etc. In many such studies it may be possible to identify multiple subsets of variates on suitable experimental grounds, and interrelations of (two or more) subsets of variates constitute the prime objective of the study. For example, in a therapeutic study, certain body characteristic variables (such as blood sugar, cholesterol and other lipids) are to be recorded before and immediately after a therapeutic course is complete, and sometimes to judge its long-term efficacy, also after a certain lapse of time. Provided the measurements at each stage conform to a set of biologically or medically contiguous variables, the concept of CCA, or its various ramifications considered above, can be incorporated to draw meaningful statistical conclusions. In this respect, often restricted analysis appears to be more appropriate from an interpretational point of view. If the measurements have a nonnegativity dependence (association) structure (within each set), then it is quite natural to work with convex CCA through nonnegativity conditions on the coefficients in the canonical variables. In **neural networks** such a phenomenon occurs quite often, and Das & Sen [14] have pointed out the relevance of restricted CCA along with the related sampling theory (in an asymptotic setup with due emphasis on applicable

resampling plans). Although such formulations are more appropriate for (nearly) multinormal distributions, they remain asymptotically quite viable for a large class of continuous distributions (having finite moments up to the fourth order at least). To cope with plausible departures from multinormality, both nonlinear and semilinear (where only powers of the linear combinations are allowed), versions of canonical correlation analysis have also been studied in the literature; see, for example, Gambus et al. [24], and Tielemans et al. [60].

In the period from 1985 to 1995 alone, there have been more than 200 published works that use canonical correlations in various branches of biostatistics. Clearly, any summary of all of them is beyond the scope of the current study. Instead, in what follows we address several key issues related to using CCA in biostatistics applications in general.

1. Typically with measurements related to nonnegative variates, even the marginal distributions are (mostly, positively) skewed, and hence suitable **transformations** on the coordinate variables (which are usually highly nonlinear) are advocated to induce more symmetry (if not normality) in the distributions of the transformed variables. This does not, however, guarantee that the joint distribution of the transformed variables would be closely multinormal. Thus the conventional multinormality assumption based canonical correlation analysis may not always be appropriate in such applications. The picture with nonnormal canonical correlations is comparatively better.
2. The motivation behind the use of CCA rests heavily on the linearity structure, and transformations mentioned before may distort such relationships even if the original variables had such structural properties. However, the very rationality of choosing the canonical variables as linear compounds of within-subset variates may be questionable, and without this linearity the foundation of CCA may not be firm enough. Even if such a linearity structure is tenable, but a linear combination of (within-set) variates is not that physically interpretable, motivations for CCA would be diffused to a certain extent. Therefore, in practice, before a CCA is adopted, the suitability of linear compoundability of (transformed) variable has to be examined carefully.
3. In classical CCA, underlying the normality and linearity structure there is the basic assumption that all the variables are quantitative in nature, and are continuous. For discrete variables, generally the linearity of regression and/or normality approximations may not always be feasible. This calls for alternate canonical measures of such association patterns. We illustrate this point with two important examples from biostatistics. First, consider the case of a *multivariate Poisson distribution*, which we introduce as follows. Consider a stochastic $t(\geq p)$ vector $\mathbf{Z} = (Z_1, \ldots, Z_t)'$ of independent **Poisson** variates with positive parameters $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_t)'$, not necessarily all equal. We then express the observable stochastic vector $\mathbf{X}$ as

$$\mathbf{X} = \mathbf{B}\mathbf{Z},$$

where $\mathbf{B}$ is a suitable $p \times t$ matrix of real constants. In order that $\mathbf{X}$ has a multivariate Poisson distribution, all the marginal ones need to be univariate Poisson, so that the elements of $\mathbf{B}$ are all nonnegative. Moreover, for the increments of the marginal distributions to be concentrated to the set of all nonnegative integers, we need to assume that the elements of $\mathbf{B}$ are binary (i.e. 0 or 1). Finally, in order that the distribution of each X_j is nondegenerate, we need that each row of $\mathbf{Z}$ is nonnull. All these conditions imply that the elements of $\mathbf{X}$ can only be associated nonnegatively, and that even in a pairwise case, these association parameters may not always be in the entire interval $(-1, 1)$. Clearly, if we need to incorporate CCA in this context, we need to consider the restricted version, where the restrictions facilitate the verification of the regularity conditions needed for $\mathbf{B}$. In this case, the restricted CCA makes more sense than its classical counterpart based on the usual matrix $\mathbf{S}_n^*$. Even so, the adequacy of normality approximation remains to be checked thoroughly. In the univariate case, usually the *square root* transformation is used for Poisson-type variables to stabilize the asymptotic variance and accelerate the normality approximations, although the rationality of linear compoundability of these transformed variables may not always be clear in practice (*see* **Power Transformations**). As a second illustration, consider *multivariate counting processes* that arise in survival analysis,

neural networks, and also reliability networks. In this context, too, there are certain structural constraints that may block the direct adaptation of CCA.

4. Clinical and educational psychometry, mental testing, and psychiatry have all been identified as vital domains requiring (bio)statistical methodology to a considerable extent. Multivariate analysis is a vital discipline for modeling and analyzing of experiments or studies in this broad domain. Interestingly, some of the classical illustrations in canonical correlations, principal components, and factor analysis have a distinctly psychometric or educational testing flavor, and hence it is worthwhile to examine the relevance of CCA in this domain. Typically, we conceive of some underlying *traits*, and convert the count data set on a dichotomous or **polytomous** classification to suitable **scores**, such as the Z scores or **normal scores** in psychometry, and use standard CCA (or multivariate analysis, in general) on such score data. Even if we have an adequately large sample size, such a conversion may not usually validate the use of conventional canonical correlations. For example, in a multidimensional contingency table, say a **two-by-two table**, these normal scores leading to the *tetrachoric correlations* (*see* **Association, Measures of**) do not capture the linearity of the regression, and hence the linear compoundability of the scores from different characteristics or tests remains open to question – the nonlinear/semilinear ramifications of canonical correlations may be adopted in these cases. The picture is quite different for external analyses, such as the multivariate analysis of variance and covariance models. In this setup, more basic categorical data models with latent continuous variates could provide an alternate and valid approach to (restricted) CCA.
5. In psychometric research, as well as in other areas of biostatistics, it is not uncommon to encounter a purely ranked data set in one or more dimensions. **Rank correlations** and measures of association have all received due attention in the literature, and CCA remains pertinent to this domain as well. Puri & Sen [47, Chapter 8] contains a broad coverage of such rank measures of association along with their statistical properties and sampling distributions. The emphasis has been mainly on the testing of statistical hypotheses, although the matrix of rank-based correlations amends readily to such complex measures of between-group association. One of the basic drawbacks of rank methods is their possible lack of affine invariance, and hence the linear compoundability of the original variables again may not be suitable. Nevertheless, the asymptotic joint multinormality of these sample rank correlations can at least intuitively justify the adoption of CCA when the sample size is large.
6. Mixed models relating to partly quantitative (continuous) responses and partly qualitative (categorical) ones are often encountered in biostatistical analysis. The classical **biserial correlation** is the precursor of such measures of association in the bivariate case. Their generalizations to canonical correlations need a considerable amount of care in formulation so that mathematical manipulations may not preclude statistical interpretations.

At the present time, some of the applications made in **pharmacokinetics**, biopharmaceutics, ecology, epidemiology, and environmetrics deserve critical appraisal for their validity; nevertheless, these represent commendable attempts to gain insight into the phenomena under study (see [1, 3, 4, 7, 9, 11, 12, 18, 20, 22, 24, 26, 28, 38, 40, 41, 43, 45, 52, 56, 60, 62–66].

Capture–Recapture

In a typical capture–recapture experiment in biological and ecologic sciences, we place traps or nets in the study area and sample the population several times. At the first trapping sample a number of animals are captured; the animals are uniquely tagged or marked and released into the population. Then at each subsequent trapping sample we record and attach a unique tag to every unmarked animal, record the capture of any animal that has been previously tagged, and return all animals to the population. At the end of the experiment the complete capture history for each animal is known. Such experiments are also called mark-recapture, tag-recapture, and multiple record systems in the literature. The simplest type only includes two samples; one is the capture sample and the other the recapture sample. This special two-sample case is often referred to as a "dual system" or a "dual-record system" in the context of census undercount estimation.

The capture–recapture technique has been used to estimate population sizes and related parameters such as survival rates, birth rates, and migration rates. Biologists and ecologists have long recognized that it would be unnecessary and almost impossible to count every animal in order to obtain an accurate estimate of population size. The recapture information (or the proportion of repeated captures) by marking or tagging plays an important role because it can be used to estimate the number missing in the samples under proper assumptions. Intuitively, when recaptures in subsequent samples are few, we know that the size is much higher than the number of distinct captures. However, if the recapture rate is quite high, then we are likely to have caught most of the animals.

According to Seber [15], the first use of the capture–recapture technique can be traced back to Laplace, who used it to estimate the population size of France in 1786. The earliest applications to ecology include Petersen's and Dahl's work on fish populations in 1896 and 1917, respectively, and Lincoln's use of band returns to estimate waterfowl in 1930. More sophisticated statistical theory and inference procedures have been proposed since the paper by Darroch [5], who founded the mathematical framework of this topic. See [15]–[17] and references therein for the historical developments, methodologies, and applications.

The models are generally classified as either closed or open. In a closed model the size of a population, which is the main interest, is assumed to be constant over the trapping times. The closure assumption is usually valid for data collected in a relatively short time during a nonbreeding season. In an open model, recruitment (birth or immigration) and losses (death or emigration) are allowed. It is usually used to model the data from long-term investigations of animals or migrating birds. In addition to the population size at each sampling time, the parameters of interest also include the survival rates and number of births between sampling times. Here we concentrate on closed models because of their applications to epidemiology and health science.

Applications to Epidemiology

The capture–recapture model originally developed for animal populations has been applied to human populations under the term "multiple-record systems". A pioneering paper is that of Sekar & Deming [18], who used two samples to estimate the birth and death rates in India. Wittes & Sidel [19] were the first to use three-sample records to estimate the number of hospital patients. Related subsequent applications were given in an earlier overview by El-Khorazaty et al. [7].

Epidemiologists recently have shown renewed and growing interest in the use of the capture–recapture technique. As LaPorte et al. [13] indicated, the traditional public-health approaches to counting the number of occurrences of diseases are too inaccurate (surveillance), too costly (population-based registries; *see* **Disease Registers**), or too late (death certificates) for broad monitoring. They felt that it was time to start counting the incidences of diseases in the same way as biologists count animals. Two recent review articles [11, 12] by the International Society for Disease Monitoring and Forecasting proposed that the capture–recapture method would provide a technique for enhancing our ability to monitor disease. Reference [12] also reviewed its applications to the following categories: birth defects, cancers, drug use, infectious diseases, injuries, and diabetes as well as other areas of epidemiology.

The purpose of most applications to epidemiology is to estimate the size of a certain target population by merging several existing but incomplete lists

of names of the target population. If each list is regarded as a trapping sample and identification numbers and/or names are used as "tags", then it is similar to a closed capture–recapture setup for wildlife estimation. Now the "capture in a sample" corresponds to "being recorded or identified in a list", and "capture probability" becomes "ascertainment probability". Two major differences between wildlife and human applications are (i) there are more trapping samples in wildlife studies, whereas in human studies only two to four lists are available; and (ii) in animal studies there is a natural temporal or sequential time order in the trapping samples, whereas for epidemiologic data such order does not exist in the lists, or the order may be different for some individuals. Researchers in wildlife and human applications have respectively developed models and methodologies along separate lines. Three of these approaches are discussed after the data structure and assumptions are explained.

Data Structure and Assumptions

Ascertainment data for all identified individuals are usually aggregated into a categorical data form. We give in Table 1 a three-list hepatitis A virus example for illustration. The purpose of this study was to estimate the number of people who were infected by hepatitis in an outbreak that occurred in and around a college in northern Taiwan from April to July 1995. Our data are restricted to those records from students of that college. A total of 271 cases were reported from the following three sources: (i) P-list (135 cases): records based on a serum test conducted by the Institute of Preventive Medicine of Taiwan. (ii) Q-list (122 cases): records reported by the National Quarantine Service based on cases reported by the doctors of local hospitals. (iii) E-list (126 cases): records based on questionnaires collected by epidemiologists.

In Table 1, for simplicity, the presence or absence in any list is denoted by 1 and 0, respectively. There are seven observed cells Z_{100}, Z_{010}, Z_{001}, Z_{110}, Z_{011}, Z_{101}, and Z_{111}. Here $Z_{111} = 28$ means that there were 28 people recorded on all three lists; $Z_{100} = 69$ means that 69 people were recorded on list P only. A similar interpretation pertains to other records. Let n_1, n_2, and n_3 be the number of cases in P, Q and E, respectively. Then $n_1 = Z_{111} + Z_{110} + Z_{101} + Z_{100} = 135$. Similar expressions hold for n_2 and n_3. There is one missing cell, Z_{000}, the number of uncounted. The purpose is to predict Z_{000} or to estimate the total population size.

Table 1 Data on hepatitis A virus

Hepatitis A virus list			
P	Q	E	Data
1	1	1	$Z_{111} = 28$
1	1	0	$Z_{110} = 21$
1	0	1	$Z_{101} = 17$
1	0	0	$Z_{100} = 69$
0	1	1	$Z_{011} = 18$
0	1	0	$Z_{010} = 55$
0	0	1	$Z_{001} = 63$
0	0	0	$Z_{000} = ??$

A crucial assumption in the traditional approach is that the samples are independent. Since individuals can be cross classified according to their presence or absence in each list, the independence for two samples is usually interpreted from a 2×2 categorical data analysis in human applications. This assumption in animal studies is expressed in terms of the "equal-catchability assumption": all animals have the same probability of capture in each sample. However, this assumption is rarely valid in most applications. Lack of independence among samples leads to a bias for the usual estimators derived under the independence assumption. The bias may be caused by the following two sources:

1. List dependence within each individual (or substratum): that is, inclusion in one sample has a direct causal effect on any individual's inclusion in other samples. For example, an individual with a positive for the serum test of hepatitis is more likely to go to the hospital for treatment and thus the probability of being identified in local hospital records is larger than that of the same individual given as negative by the serum test. Therefore, the "capture" of the serum test and the "capture" of hospital records become positively dependent. This type of dependence is usually referred to as "list dependence" in the literature.
2. Heterogeneity between individuals (or substrata): even if the two lists are independent within individuals, the ascertainment of the two lists may become dependent if the capture probabilities

are heterogeneous among individuals. This phenomenon is similar to **Simpson's paradox** in categorical data analysis. That is to say, aggregating two independent **2 × 2 tables** might result in a dependent table. Hook & Regal [10] provided an example.

The above two types of dependences are usually confounded and cannot be easily disentangled in a data analysis without further assumptions. We discuss three approaches (the ecologic model, the **loglinear model**, and the sample coverage approach) that allow for the above two types of dependences.

Ecologic Models

Pollock, in his 1974 Ph.D. thesis and subsequent papers (e.g. Pollock [14]), proposed a sequence of models mainly for wildlife studies to relax the equal-catchability assumption. This approach aims to model the dependences by specifying various forms of "capture" probability. The basic models include (i) model M_t, which allows capture probabilities to vary with time; (ii) model M_b, which allows the capture of behavioral responses; and (iii) model M_h, which allows heterogeneous animal capture probabilities. Various combinations of these three types of unequal capture probabilities (i.e. models M_{tb}, M_{th}, M_{bh}, and M_{tbh}) are also proposed.

Only for model M_t are the samples independent. List dependence is present for models M_b and M_{tb}; heterogeneity arises for model M_h; and both types of dependences exist for models M_{bh} and M_{tbh}. For any model involving behavioral response, the capture probability of any animal depends on its "previous" capture history. However, there is usually no sequential order in the lists, so those models have limited use in epidemiology. Models M_h and M_{th} might be useful for epidemiological studies. Various estimation procedures have been proposed. See [15]–[17] for reviews.

Loglinear Models

The loglinear model approach is a commonly used technique for epidemiological data. Loglinear models that incorporate list dependence were first proposed by Fienberg [8] for dealing with human populations. Cormack [4] proposed the use of this technique for several ecologic models.

In this approach the data are regarded as a form of an incomplete 2^t **contingency table** (t is the number of lists) for which the cell corresponding to those individuals uncounted by all lists is missing. A basic assumption is that there is no t-sample **interaction**. This assumption implies an extrapolation formula for the number of uncounted. For three lists, the most general model is a model with main effects and three two-sample interaction terms. Various loglinear models are fitted to the observed cells and a proper model is selected using deviance statistics and the **Akaike information criterion**. The chosen model is then projected onto the unobserved cell.

List dependences correspond to some specific interaction terms in the model. As for heterogeneity, **quasi-symmetric** and partial quasi-symmetric models of **loglinear models** can be used to model some types of heterogeneity, i.e. **Rasch models** and their generalizations; see [1] and [6]. Since the quasi-symmetric or partial quasi-symmetric models are equivalent to assuming that some two-factor interaction terms are identical, the heterogeneity corresponds to some common interaction effects in loglinear models. Details of the theory and development are fully discussed in [11] and [12].

Sample Coverage Approach

The idea of sample coverage, originally from I.J. Good and A.M. Turing (Good [9]), has been used in species and animal population size estimation; see Chao & Lee [2]. The same approach was also applied to epidemiologic data in [3].

This approach aims to model dependences by some parameters, which are called "coefficients of variation", defined for two or more samples. The magnitude of the parameters measures the degree of dependence of samples. The two types of dependences are confounded in these measures. In the independent case, all dependence measures are zero. This general model encompasses the Rasch model and the ecologic models as special cases.

A common definition for the sample coverage of a given sample is the probability-weighted fraction of the population that is discovered in that sample. For multiple-sample type of data the sample coverage is

modified to be the probability-weighted fraction of the population that is jointly covered by the available samples. See [3] for a formal definition. The basic motivation here is that sample coverage can be well estimated even in the presence of two sources of dependences. Thus an estimate of population size can be obtained via the relation between the population size and sample coverage. Chao et al. [3] have shown that an estimator of C is $\hat{C} = 1 - (Z_{100}/n_1 + Z_{010}/n_2 + Z_{001}/n_3)/3$, which is one minus the average of the proportion of individuals listed in only one sample (i.e. singletons). Let D be the average of the distinct cases for three pairs of samples. In this approach, when all three samples are independent, a valid estimator is $\hat{N}_0 = D/\hat{C}$. If any type of dependence arises, then Chao et al. [3] attempt to account for the dependences by adjusting $D/\hat{C}$ based on a function of the estimates of the coefficients of variation. In the same reference, estimators of population size are proposed separately for high sample coverages (e.g. if $\hat{C}$ is over 55%) and low sample coverages.

Analysis of the Hepatitis Example (Low Sample Coverage)

Several loglinear models were fitted to the hepatitis data given in Table 1. Except for the saturated model, the loglinear models that do not take heterogeneity into account (e.g. models with one or two interaction terms) do not fit the data well, whereas all other models that take heterogeneity into account (quasi-symmetric and partial quasi-symmetric models) fit well. All those adequate models yielded very similar estimates – 1300 with an approximate estimated standard error of 520.

The coverage estimate is $\hat{C} = 51.27\%$, which is considered to be low. The average of the distinct cases for three pairs of samples is $D = 208.667$. If the incorrect independence is assumed, then an estimate would be $\hat{N}_0 = D/\hat{C} = 407$. (The loglinear independent model yields a similar estimate of 388.) It follows from Chao et al. [3] that the estimates for dependence measures are relatively large, which indicates that the three samples are pairwise positively dependent and $\hat{N}_0$ would generally underestimate. However, one cannot distinguish which type of dependence is the main cause of the bias. Incorporating the bias due to dependences along the sample coverage approach results in an estimate of 508. An estimated standard error of 40 is calculated by using a **bootstrap method** based on 1000 replications. The resulting 95% **confidence interval** is (407, 591) based on the same bootstrap replications.

This example shows that the loglinear and sample coverage approaches may give widely different estimates. Moreover, the example in [11] further shows that several loglinear models that fit the data equally well might also result in quite different estimates. **Simulation** comparisons of the two approaches and other examples with high sample coverages are provided in Chao et al. [3].

ANNE CHAO

Cardiology and Cardiovascular Disease

Cardiology is the study of the heart and its diseases. Medical treatises give long lists of potential causes of heart diseases. However, as the functioning of the heart hinges on a constant and adequate blood supply, many heart diseases can be traced back to diseases of the vessels bringing blood to the heart. Thus, in biomedical textbooks and in epidemiology, heart diseases and vascular diseases are usually treated under the common heading of cardiovascular diseases (CVDs). Cardiovascular diseases comprise all diseases classified according to the **International Classification of Diseases**, 9th Revision.

Cardiovascular diseases are one of the major causes of morbidity and mortality worldwide with a death count of around 14 million per year. As reported by the **World Health Organization** [41], in spite of a very marked decline over the last few decades (for instance, male mortality from CVD dropped by 60% in Japan, and by 50% in Australia, Canada, France, and the US), CVDs are responsible for 20% of all deaths worldwide: 50% of all deaths in industrialized countries and 16% of all deaths in developing countries. Absolute estimates for 1990 are as follows: 10.9 million deaths occurred in developed countries, and 45 million deaths in developing countries; of these, the deaths attributed to CVDs were 5.3 million for developed countries and 9 million for developing countries. However, mortality is not sufficient to describe the impact of CVDs. It is also estimated that 25%–30% of the CVD burden arises from their disabling sequelae other than death. The American Heart Association translated these mortality and morbidity considerations into **health economics** and predicted that the cost of CVDs in the US for the year 1996 would be US$151.3 billion [1].

The most common serious heart disease is indeed a disease of the vessels: coronary heart disease (CHD), defined as cardiac ischemia (insufficient blood supply) due to atherosclerosis of the coronary arteries. The American Heart Association, in its 1996 statistical supplement, reports that in 1993 CHD caused 489 970 deaths in the US, or 1 of every 4.6 deaths. Angina (chronic chest pains due to cardiac ischemia) is often the first symptom of CHD. Angina may evolve as a distinct disease, or a heart attack may follow its onset. On the other hand, a heart attack may strike asymptomatic subjects: indeed, there are no previous signs of CHD in 48% of men and in 63% of women who die of a heart attack. The end stage of CHD may be Congestive Heart Failure (CHF), which manifests as a failure of the heart to pump blood as needed. CHF is also seen as the last stage of other heart diseases such as valvular diseases and cardiomyopathies (diseases of the heart muscle). Besides contributing to an estimated 250 000 deaths a year, CHF is also listed as a direct cause of death (36 387 US deaths in 1992).

Arrhythmia (irregularities of the heart rhythm, 40 843 US deaths in 1992) may appear as a consequence of CHD or may have a distinct cause. The most serious arrhythmia is ventricular fibrillation (quivering of the heart, replacing its regular pumping function, 1461 US deaths in 1992). Although it represents a relatively modest burden as an official cause of death, it is thought to cause the overwhelming proportion of sudden deaths, estimated at about 250 000 per year in the US.

Not all heart diseases are vascular diseases, for example: rheumatic heart disease, valvular diseases, infectious cardiomyopathies and idiopathic cardiomyopathies. Similarly, not all vascular diseases directly affect the heart. **Stroke** (brain attack) is the second most important CVD: it caused 149 740 deaths in 1993 in the US, or 1 in 15 deaths. Hypertension, an underlying condition of many CVDs and indeed a contributing factor to atherosclerosis, is also considered a disease in its own right: as such, it killed 37 520 in 1993 in the US.

CVDs, in particular CHD, are in principle both treatable and preventable. The problem with treatment is that often patients die before getting the needed intervention. Hence, the emphasis is on developing diagnostic tools for cardiovascular diseases with the aim of preventing sudden episodes like heart attacks and, more generally, of slowing down the aggravation of subclinical pathological processes. The evolution of cardiac diagnostic devices has proceeded at great speed. Starting in the nineteenth century with Laënnec's invention of the stethoscope (1816) and with the introduction by Riva & Rocci (1896) of the modern blood pressure measuring device (sphygmomanometer), techniques have become increasingly sophisticated in the

twentieth century. Electrocardiography, developed by Einthoven in 1903, introduced a relatively simple measure of the heart's rhythm from which the functioning of the heart could be studied, while radiography and angiocardiography (radiography of arteries by means of appropriate contrasting substances) allowed visualization of the heart (1919). Cardiac catheterization (1931) allowed direct access to diseased areas of the heart, and the combination of catheterization with angiography is the basis of contemporary invasive, but very accurate, diagnostic devices, such as selective angiography, coronary arteriography, and digital subtraction angiography. Concern for reducing the invasive character of these procedures without sacrificing accuracy has spurred the most recent developments: echocardiography or noninvasive ultrasonography in the mid 1960s and magnetic resonance imaging in the early 1980s are good examples. For other historical milestones in cardiology, see Table 1.

In parallel with diagnostic advances, surgical or invasive treatment of CHD has also made impressive progress in the twentieth century. The 1950s saw the introduction of artificial aortic valves, open heart surgery, and regulation of arrhythmias by implantation of pacemakers. Progress continued in the following three decades with the 1967 first heart transplant by Barnard, the 1977 development of angioplasty (opening of blocked arteries using balloon catheter) by Gruentzig, and the first implant of an artificial heart in 1982 by DeVries. At the same time, pharmacologic approaches aimed at impeding the progress of CHD and at controlling arrhythmias have become increasingly sophisticated and effective. Control of hypertension, one of the leading causes of CHD progress, may now be achieved by several classes of medications, involving very different modes of action (e.g. thiazide diuretics, alpha, beta, calcium channel blockers, ACE inhibitors). Several classes of medications have also been developed to control hyperlipidemias (e.g. nicotinic acid, resins, statins, Gemfibrozil, probucol). To treat arrhythmias there are also several classes of drugs available, with varying modes of action. As another example, aspirin has been proved effective in prevention of a second heart attack, stroke, and mortality in patients who had survived a first heart attack. The great variety of potentially successful therapeutic approaches has prompted, since the mid 1960s, the development of large-scale, **multicenter trials** in cardiology to test the efficacy of these drugs. As for other areas of medicine, the randomized **clinical trial**, double-blinded whenever possible (*see* **Blinding or Masking**), is now considered the norm for monitoring progress and comparing alternative strategies. Table 2A summarizes some of the most important clinical trials in cardiology.

The successes sketched above are considered at least partially responsible for the decline in CHD mortality, which has been reduced by 49% since 1970. This reduction is attributable mostly to secondary prevention, i.e. prevention in patients with clinical manifestations of CHD. However, costs, both human and monetary, remain enormous: for instance, Haltky et al. [15], estimated the 5-year total medical cost of bypass surgery at US$58 498 and that of angioplasty at US$56 225. Clearly, these costs could be greatly reduced if the development of CHD could be prevented altogether (primary prevention).

The need for a major effort in the area of primary prevention, i.e. prevention of the development of CHD in healthy subjects, has become increasingly apparent since the first decades of the twentieth century, with the first description by Herrick (1912, see Table 1) of the relationship between atherosclerosis and CHD, and with the work of Muller (1930, see Table 1), who reports on the relationship between CVD and elevated cholesterol serum level. This awareness has culminated in the historic **Framingham Heart Study** [17]. Framingham is a small community of about 65 000 people, situated 21 miles from Boston. Over 5000 subjects from this community, aged between 30 and 62, were followed for 30 years, starting in 1948, with the aim of addressing a complete picture of the epidemiologic aspects of CHD, its major risk factors, and its evolution. The Framingham study helped identify the risk factors that are now common knowledge, such as heredity, sex, age, cigarette smoking, high cholesterol blood levels, hypertension, sedentary life-style, obesity, diabetes [1]. The Framingham study has served as a model for several similar large-scale endeavors, increasingly including active interventions to modify risk factors or to enhance prevention: a brief summary is given in Table 2B.

As a result of these major studies, our knowledge of CHD has progressed to a point where effective prevention is possible. For example, the National Heart, Lung and Blood Institute (US) estimated in 1994 that

Table 1 Historical events in cardiology

Event	Attributed to	Year
First description of blood circulation	William Harvey	1628
First intravenous injection in a human	Major	1667
First description of the heart structure	Raymond de Vieussens	1706
First known cardiac catheterization	Stephen Hales	1711
First blood pressure measurement	Stephen Hales	1733
Stethoscope	René T.H. Laënnec	1816
First human to human blood transfusion published	James Blundell	1818
Electric current accompanies each heart beat	Carlo Matteucci	1842
Describes an "action potential" accompanying each muscular contraction	Emil Dubois-Reymond	1843
Publication of work on action potential of the heart	Eudolph Albert Von Kolliker	1855
Record the heart's electrical current and shows it consists of two phases	J.B. Sanderson & F. Page	1878
Description of myocardial infarction	Karl Weigert	1880
Description of angina pectoris	Frederick Winsor	1880
Discovery of X-rays	Wilhelm C. Röntgen	1895
Sphygmomanometer	Riva, Rocci	1896
First successful closure of a stab wound of the heart (birth of cardiac surgery)	Ludwig Rehn	1897
Discovery of the first three human blood groups: A, B, and O	Karl Landsteiner[a]	1900
Anastomosis of small blood vessels	Alexis Carrel	1902
Discovery of the fourth blood group, AB	A. Decastello & A. Sturli	1902
Invention of the electrocardiograph	Williem Einthoven[b]	1903
Discovery of the sino atrial node (the origin of heartbeat)	Keith & Flack	1907
Publication of "The mechanism of the heart beat"	Thomas Lewis	1911
First description of heart disease resulting from hardening of the arteries	James B. Herrick	1912
First angiogram in a living person using potassium iodide	Heuser	1919
First soundly established surgical technique for severe mitral stenosis	Souttar	1925
First use of radioactive tracers in human	Blumgart	1926
Relation between CVD and elevated cholesterol serum level was first described	Muller	1930
First blood bank established in London		1930
First human right heart catheterization	Frostmann[c]	1931
First heart surgery	Robert E. Gross	1938
Discovery of angiotensin	Irvine H. Page	1938
Identification of the Rh factor	Karl Landsteiner et al.	1939
Invention of the ambulatory ECG	John Holter	1940
Isolation of albumine	Edwin Cohn	1940
Demonstration of the changing oxygen saturation in blood	Cournand & Richards[c]	1945
Invention of a plastic valve to repair aortic valve	Charles Hufnagel	1951
First successful open heart surgery	F. John Lewis	1952
First report of transthoracic pacing	Paul Zoll	1952
First use of a mechanical heart and blood purifier ECC (Extra Corporal Circulation)	John H. Gibbon	1953
First entirely implantable rechargeable pacemaker	Senning & Elmqvist	1958
First attempt to use fibrinolytic therapy (streptokinase) of MI intravenously	Fletchet	1958
Development of selective coronary angiography	Sones	1959
First real-time instrument for two-dimensional echocardiography	Hertz	1960
First external cardiac massage to restart a heart	J.R. Jude	1961
First Percutaneous Transluminal Coronary Angioplasty (PTCA)	Dotter & Judkins	1964
First radionuclide technique for measuring human myocardial blood flow	Ross	1964
First heart transplant	Christiaan Barnard	1967
First experimental PTCA balloon	Andreas Gruentzig	1974
First human coronary angioplasty	Andreas Gruentzig	1977

(*continued overleaf*)

Table 1 (*continued*)

Event	Attributed to	Year
Introduction of new immunosuppressant: cyclosporine		1978
First cardiac image using magnetic resonance imaging	Lauterbur	1978
First implant of a cardioverter defibrillator	Watkins, Reid, Mirowski et al.	1980
First successful heart lung transplant	Norman Shumway	1981
Invention of the artificial heart	Robert Jarvik	1982
First artificial heart (Jarvik-7) recipient, Barney Clark	Williem De Vries	1982
First real-time two-dimensional color-flow Doppler	Bommer et al.	1982
First use of coronary stent in humans	Sigwart et al.	1987

[a]Won the 1930 Nobel Prize for physiology and medicine for this discovery.
[b]Won the 1924 Nobel Prize for physiology and medicine for this invention.
[c]With Prossmann won the 1956 Nobel Prize for physiology and medicine for their contribution to the advancement of catheterization.

by modifying the major known risk factors for CVD, it would be possible to increase the rate of the decline in CVD mortality to around 6% per year for an overall reduction of 50% in 10 years [25]. However, at the present state of knowledge, the cost of controlling risk factors such as hypertension and hyperlipidemias is formidable, since effective control would require lifelong medical treatments for very large subpopulations with these risk factors. For other risk factors such as life-style changes, control implies behavior modification. This is notoriously difficult and, for certain target groups, ineffective. As research continues towards the development of more powerful and less costly preventive approaches, further study concerning established and new potential risk factors is necessary. A deeper knowledge in this area could lead to the identification of smaller subpopulations at very high risk, in which it would be cost–effective to concentrate preventive efforts.

Statistics and Cardiovascular Diseases

The level of statistical sophistication present in the cardiology literature has radically improved since the 1980 paper by Glantz [12], owing, at least in part, to its impact on the editorial policies of two of the most prestigious journals in the field, *Circulation* and *Circulation Research*. In practical terms, this has meant that all papers are now scrutinized for correctness of their data analytic sections by a statistician, and that tests and procedures beyond the elementary *t*- (*see* **Student's *t* Statistics**) and chi-square tests have become prevalent. In a rapid survey of the present status of statistical methodology in cardiology, we have randomly selected 150 articles from volume 91 of *Circulation* (1995); the results are summarized in Table 3.

The figures in Table 3, compared with what is considered state-of-the-art in clinical biostatistics, show that there is an important time lag between development of new statistical methodologies and their current use in cardiology, as is indeed the case in many other highly specialized areas. For example, we find limited use of techniques for the analysis of survival times (18/150) (*see* **Survival Analysis, Overview**) and repeated measurements (26/150) (*see* **Longitudinal Data Analysis, Overview**). This is rather surprising, in view of the fact that improving survival is a major aim of clinical studies in

Table 2 Some of the most important CVD studies

A Clinical trials	Landmark publications[a]
ACME (Angioplasty Compared to MEdicine)	*New England Journal of Medicine* **326** (1992) 10–16

[b]Other than t tests and chi-square tests.
[c]One-way ANOVA with more than two groups.

cardiology and that most studies entail repeated assessment of cardiac function and/or **quality of life**. Moreover, several general techniques of data analysis, considered important in biostatistics, are absent from Table 3. Among these are: **Generalized Estimating Equations** (GEE), for the analyses of continuous and/or discrete longitudinal outcomes; **point processes**, for the analysis of multiple failures; signal analyses, to study, for example, cardiac rhythms in a clinical context; and trees or **neural networks**, for the development of powerful predictors or decision rules. At an even more general level, the total absence of **Bayesian methods** of analysis should also be noted.

By contrast, even a cursory look at the historical development of biostatistics in the last 50 years shows that some important methodological advances have originated from the need to treat CVD data. The Framingham study [17] greatly contributed to the development of multivariate methods for binary longitudinal data; an example is the seminal paper by Truett et al. [38], where **logistic regression** was introduced and its relationship to **discriminant analysis** discussed. The association of **Cornfield** with Framingham also contributed to the development of methods for the analysis of cross-classified data (*see* **Contingency Table**) [19].

The introduction of heart transplantation as a current surgical procedure generated the need to account properly for waiting time as a predictor of survival for patients receiving a new heart. The need was met by several papers culminating in the work by Crowley & Hu [9], who modeled heart transplant as a **time-dependent covariate** and modified the **proportional hazards** model for survival data so that time-dependent covariates could be properly treated. Other advances in survival analysis have also been stimulated by CVD data: Beck [2] looked at survival models with **competing risks** to analyze heart transplant data: Senthilselvan [33] used **penalized likelihood** to obtain a **nonparametric, spline**-based estimator of the hazard function for heart transplant

data, and Wassell & Moeschberger [40] and Pickles & Crouchley [27] studied **frailty** models for the analysis of bivariate survival data.

More recently, an important application to cardiology was at the origin of the development of Classification and Regression Trees (CART) (*see* **Tree-structured Statistical Methods**). Two cardiovascular related examples were examined. In the first, a prognostic tree was developed to identify patients at high risk of short-term mortality following a heart attack (less than 30 days), using 19 noninvasive, initial 24-hour variables. In the second example, a diagnostic tree was constructed from 40 noninvasive variables to classify patients as suffering from ischemic heart disease or not.

The advances in signal and **image analysis** in cardiology have been providing new challenges to statisticians since the 1970s. Cornfield's name is also associated with early work on the statistical analysis of electrocardiograms (ECG) (see [8] and [18] for reviews). The introduction of 24-hour blood pressure monitoring has provided yet another potentially important "signal" to analyze [21]: several approaches have been proposed; see Turney et al. [39] (weighted **least square analysis of covariance**), Selwyn & Difranco [32] (Gaussian mixed model), Gaffney et al. [11] (harmonic analysis), Somes et al. [35] (Fourier analysis). As for image analysis in cardiology, Bozzini et al. [3] studied the problem of heart potential mapping and Puterman et al. [28] studied the prognostic value of echocardiography; see also [37].

Bayesian methods, despite their appeal, are not the most popular approach in biostatistics, due, in part, to lack of software. This is reflected in the area of CVDs, in spite of the central role of Cornfield, who was a Bayesian [5]. However, some recent works should be cited: Christensen & Johnson [4] analyzed heart transplant survival data by a fully Bayesian method; Sharples [34] used the Gibbs sampler (*see* **Markov Chain Monte Carlo**) to estimate the marginal posterior distribution of the transition rates between grades of coronary heart disease and from each grade to death; L'Italien et al. [20] developed and validated a Bayesian model for perioperative cardiac risk assessment; and Spiegelhalter et al. [36] discussed a Bayesian methodology for evaluating prior beliefs about frequencies, with application to a case study in congenital heart diseases. Finally, Palmas et al. [26] developed a Bayesian approach to the enhancement of scintigraphic images by integration of diagnostic information.

Beside influencing major developments in data analysis, the problems arising from CVD studies have also stimulated much of the methodological advances in the design and the conduct of clinical trials. Cornfield's name appears again in a central role: see [6] for a review or early contributions. More recently, **Halperin** et al. [14] reviewed the field again, identifying four areas: (i) organizational structure for **multicenter** studies; (ii) design considerations related to patient risk, **noncompliance**, lag in treatment effect, and changing risks (the "**intention to treat** principle" seems to have originated from these considerations); (iii) periodic reviews of accumulating data (this stimulated developments of **sequential analysis** methods); (iv) design and analysis of longitudinal studies. In each of these areas, current research continues to be very active. Examples of recent contributions to (ii) are Efron & Feldman [10] on compliance, McMahon et al. [23] on **sample size** calculations for count outcomes, and Yateman & Skene [43] on computational intensive sample size calculations in complex situations. For some recent papers in area (iii), see Hallstrom et al. [13] on sequential monitoring (*see* **Data and Safety Monitoring**). For area (iv), see Hathaway & D'Agostino [16].

The design of epidemiologic studies to assess risk factors and community intervention effectiveness has also spurred important methodological advances. A primary example is another influential work by Cornfield [7] on **group randomization**. More recent examples are: Rehm et al. [30] on omitted variable bias, Marshall & Jackson [22] on the case–crossover design, and Schouten et al. [31] on risk and rate ratios estimation in the **case–cohort** design.

Meta-analysis (the analysis of the results of several studies for the purpose of integrating them) was only recently introduced in the health field, and one of the earliest applications was in the area of CVDs (see, for example, [44]). In spite of its limitations, including the important one linked to publication bias, meta-analysis must be credited for having accelerated the creation of national and international registries of clinical trials and epidemiologic studies, published or not, such as those of the Cochrane Controlled Trials Register (*see* **Cochrane Collaboration**).

Future Perspectives

The increasing computerization of biomedical and health-related data is introducing new and unforeseen developments in the study of CVDs, as it is in other areas of human activity. Availability of data has generally driven innovation in data analytic methodology. Since CVDs constitute the most important health burden in countries where computerization is most advanced, they can be expected to provide the most important single source of problems around which new methodology will be developed. The type of data that are being collected in the course of clinical trials, epidemiologic studies and, indeed, in daily medical practice and health care delivery, will most likely determine the future directions of progress in biostatistics.

What are the general characteristics of CVD data? Perhaps the first is the abundance of subjects. We are increasingly faced with situations in which sample size is not an issue. Instead, the problem is to extract reliable information from large quantities of data, with only vague and unstructured questions as a guide. Whether studying the **prognosis** for patients with a first major cardiovascular episode, or trying to understand the role of multiple risk factors in determining the development of CVD, the analyst is faced with the problem of constructing from data a predictor that is not only accurate, but also interpretable in the light of biomedical concepts. Traditional statistical techniques, which excel in obtaining reasonable answers to extremely pointed questions, are not adequate for the task. More promising are recent techniques such as the already mentioned CART, **generalized additive modeling**, and MARS (multivariate adaptive regression splines) which go under the general term of adaptive model building. These techniques aim at constructing prediction models directly from the data by means of flexible, data-dependent strategies. They are similar to methods like induction trees and neural networks, independently developed by researchers in machine learning and other areas of **artificial intelligence** (AI). Indeed, the exchanges between statisticians and AI researchers seem to be very fruitful, as witnessed, for example, by Michie et al. [24].

A second characteristic of CVD data is the multiplicity of sources. It is increasingly common to pool data from several large studies or private practices to find common features or in an attempt to resolve controversies arising from discordant findings. To meet this challenge, the establishment of a Bayesian perspective in cardiology would be of great utility. For instance, meta-analysis would benefit from such a perspective, which would offer a general framework within which various approaches could be compared.

A third characteristic of CVD data is their increasing complexity. For example, as prognosis improves, both outcome and predictor variables will have a richer longitudinal structure, since they are collected from subjects on repeated occasions, e.g. in the course of clinical trials or prevention studies. Further development in the area of longitudinal modeling will be necessary to analyze repeated measurements of continuous and discrete variables. Similarly, the analysis of event history data will require increasingly sophisticated application of the theory of point processes. Also, as the instrumentation for monitoring heart rhythms and blood pressure over time becomes accessible at relatively low cost, data of the future will include more and more signals, i.e. continuous functions of time, one or more for each of a large number of subjects. To treat such data without oversimplification will require major developments in the new research area known as functional data analysis. Even more complex data are those that take the form of functions on two- or three-dimensional space, such as images resulting from echocardiography or magnetic resonance. The theory of random fields has been recently applied to the analysis of medical images [42]. This could be the opening of an extremely fruitful new direction for research in biostatistics with important applications in CVDs.

Clearly, in the future, we can expect to see an increasing cooperation between clinical and statistical sciences toward the solution of major problems in the area of CVDs. It is not unreasonable to hope that the result of this cooperation will be a substantial alleviation of one of the major health burdens afflicting human populations.

Case Fatality

The concept of case fatality refers to patients with a common defined index disease or other medical problem, not to healthy people. Case fatality indicates how serious a disease condition is in causing death to the patients, usually within a defined period of time. It is common to hear about case fatality without reference to the time period of follow-up of the patients, but this should be avoided for reasons of ambiguity. There can, nevertheless, be applications in which the follow-up time may be virtually zero as, for example, with heart attacks or automobile accidents.

Technically, case fatality is expressed as the proportion of the number of patients dying in the follow-up interval out of all patients under observation. This concept is useful only under a fairly complete follow-up, where the proportion of persons lost to follow-up or otherwise withdrawn alive is small. Moreover, **competing risks** of death can, in addition to the index disease, cause deaths among the patients. If the follow-up period is short, deaths due to competing risks unrelated to the index disease may be uncommon, and the case fatality indeed reflects the seriousness of the disease in an adequate way.

Conceptually, case fatality may be seen as a complement to survival. Thus, the methods of survival analysis can be employed in assessing case fatality. For example, the proportion of survivors after a one-year follow-up among patients diagnosed in Finland in 1967–1974 with cancer of the tongue was 64%. The case fatality within the first year was thus 36%.

The models in survival analysis generally are based on assumptions concerning the risk of dying for the patients. Thus, it would also be natural to express case fatality in terms of fatality or lethality rate of the disease by defining any death or death due to index disease as the main outcome event in survival analysis. This rate is the incidence of death or death due to disease and as a rate is calculated as the number of outcome events in the follow-up period divided by the appropriate person-time denominator (*see* **Person-years at Risk**). Although this may sound theoretically appealing, a conversion to a proportion-type measure produces a quantity with an easier numerical interpretation for clinical medicine.

T. HAKULINEN

Case Mix

Case mix refers to the characteristics of the patients and/or the medical problems treated by a *provider*, a term we will use generically to refer to any of the following: an individual clinician, a health care delivery "team" (such as a hospital or clinic or group of hospitals or clinics), or an entire health care delivery system (such as an HMO or a statewide program of subsidized care).

Utilization rates reflect case mix. For example, hernias do not require the same resources as heart attacks, and even among heart attack patients, need may substantially depend upon patient age, other medical problems (comorbidities) present, and the severity of the heart attack itself (disease-specific severity).

An informal sense of case mix is conveyed via distributions of patient characteristics or summary statistics (such as percentage of cases with diabetes, mean and standard deviation of patient age).

Some case-mix classification systems assign each case (e.g. an individual hospital admission, or a person enrolled in a health care delivery system) to one and only one category, which is relatively homogeneous with respect to the expected level of health care need. To facilitate comparisons of case mix across groups of cases (e.g. admissions occurring at distinct hospitals, or the patient panels of different providers), each category may be assigned a "weight" indicating the expected utilization of these cases in comparison with an average case. Thus, the weight 1.00 is used for average cases, while a weight of 1.10 indicates 10% higher expected utilization. Such a classification of hospital admissions into **diagnosis related groups (DRGs)** is used to calculate the payment for an individual **Medicare** hospital admission, proportional to its DRG weight. (*see* **Health Care Financing**) Some authors equate a hospital's case mix with its average DRG weight.

Differences in case-mix can be large and are addressed using **risk adjustment**.

Case Series, Case Reports

Case reports are used by clinicians to describe responses to treatment, among other things. Epidemiologists may rely on case reports to find clues to disease etiology. Case reports can be very informative for rare diseases. Such reports identified chimney sweeping as a risk factor for scrotal cancer [1] in 1775, and many modes of transmission of the human immunodeficiency virus were identified in the early 1980s from case reports of the Acquired Immune Deficiency Syndrome (**AIDS**). For more reliable **inferences**, however, it is usually necessary to compare rates of exposure in cases with rates of exposure in disease-free controls to develop etiologic evidence (*see* **Case–Control Study**).

Case–Cohort Study

The case–cohort design is a method of sampling from an assembled epidemiologic **cohort study** or **clinical trial** in which a **random sample** of the cohort, called the *subcohort*, is used as a comparison group for all cases that occur in the cohort. This design is generally used when such a cohort can be followed for disease outcomes but it is too expensive to collect and process **covariate** information on all study subjects. Though it may be used in other settings, it is especially advantageous for studies in which covariate information collected at entry to the study is "banked" for the entire cohort but is expensive to retrieve or process (see examples below) and multiple disease stages or outcomes are of interest. In such circumstances, the work of covariate processing for subcohort members can proceed at the beginning of the study. As time passes and cases of disease occur, information for these cases can be processed in batches. Since the subcohort data are prepared early on and are not dependent on the occurrence of cases, statistical analyses can proceed at regular intervals after the processing of the cases. Furthermore, staffing needs are quite predictable. Motivated by the case–base sampling method for simple **binary** outcome data [15, 23], Prentice described the design and a **pseudo-likelihood** method of analysis (see below) for the case–cohort design.

Design

The basic components of a case–cohort study are the *subcohort*, a sample of subjects in the cohort, and *nonsubcohort cases*, subjects that have had an event and are not included in the subcohort. The subcohort provides information on the **person-time** experience of a random sample of subjects from the cohort or random samples from within strata (*see* **Stratification**) of a **confounding** factor. In the latter situation, differing sampling fractions could be used to align better the person-time distribution of the subcohort with that of the cases. Methods for sampling the subcohort include sampling a fixed number without replacement [26] (*see* **Sampling With and Without Replacement**) and sampling based on independent Bernoulli "coin flips" [34] (*see* **Binomial Distribution**). The latter may be advantageous when subjects are entered into the study prospectively; the subcohort may then be formed concurrently rather than waiting until accrual into the cohort has ended [30, 34]. Simple case–cohort studies are the same as case–base studies for simple **binary** outcome data. But, in general, portions of a subject's time on study might be sampled. For example, the subcohort might be "refreshed" by sampling from those remaining on study after a period of time [26, 36]. These subjects would contribute person-time only from that time forward. While the subcohort may be selected based on covariates, a key feature of the case–cohort design is that the subcohort is chosen without regard to failure status; methods that rely on failure status in the sampling of the comparison group are **case–control studies**.

Examples

Study of Lung Cancer Mortality in Aluminum Production Workers in Quebec, Canada. Armstrong et al. [1] describe the results of a case–cohort study selected from among 16 297 men who had worked at least one year in manual jobs at a large aluminum production plant between 1950 and 1988. This study greatly expands on an earlier cohort mortality study of the plant, which found a suggestion of increased rates of lung cancer in jobs with high exposures to coal tar pitch [12]. Through a variety of methods, 338 lung cancer deaths were identified. To avoid the expense associated with tracing subjects and abstraction of work records for the entire cohort, a case–cohort study was undertaken. To improve study efficiency a subcohort of 1138 subjects was randomly sampled from within year-of-birth strata with sampling fractions varying to yield a similar distribution to that of cases. This was accommodated in the analysis by stratification by these year-of-birth categories. The random sampling of subcohort members resulted in the inclusion of 205 cases in the subcohort. Work and smoking histories were abstracted for the subcohort and the additional 133 nonsubcohort cases. Cumulative exposure to coal tar pitch volatiles was estimated by linking worker job histories to measurements of chemical levels made in the plant using a **"job-exposure matrix"**. The analyses confirmed the lung cancer–coal pitch **association** observed in the earlier study and effectively ruled out confounding by smoking.

Women's Health Trial. To assess the potential health benefits of a low fat diet, a randomized trial of women assigned to low fat intervention and control groups has been undertaken. Of particular interest is the effect of this intervention on the risk of breast cancer. The study, as described in Self et al. [30], includes a cohort of 32 000 women between ages 45 and 69 whose percent calories from fat is greater than the **median** and who have at least one of a list of known risk factors for breast cancer. The study will involve 20 clinics across the US for a period of 10 years of follow-up. At two-year intervals, each participant will fill out four-day food records and food frequency questionnaires and blood will be drawn and stored. While evaluation of the intervention will be based on the full cohort, questions that require abstraction and coding of the questionnaires and blood lipid analyses are being addressed in a case–cohort study with a 10% sample serving as the subcohort. It was calculated that, relative to the entire cohort, this sample avoids about 80% of the cost of the analyses requiring these data with only a modest reduction of efficiency. The subcohort can also be used for making other comparisons between intervention and control groups. For example, the case–cohort sample could be used to investigate the joint relationship of blood hormone and nutrient levels and dietary intakes to breast cancer risk. Also, questions relating to other outcomes, such as cardiovascular disease, could be explored using the same subcohort as the comparison group, although additional data processing would be required for cases that occur outside the subcohort.

Statistical Analysis

Several methods have been developed to analyze case–cohort samples. Essentially, each of the methods available for the analysis of complete cohort data has an analog for the case–cohort sample. For point **estimation** of rate ratio parameters, the **likelihood** for full cohort data applied to the case–cohort data yields a valid estimator. However, estimation of the **variance** of point estimates, or tests of hypotheses (*see* **Hypothesis Testing**), requires adjustment to the standard full cohort variance estimators, as these will be too small. For likelihood-based methods, case–cohort sampling induces a covariance between score terms so that the variance of the **score** is given by $\Sigma + \Delta$, where Σ is the full cohort score variance and Δ is the sum of the covariances between the score terms. Since the subgroup used to compute the score terms has less variability than the full cohort, this covariance is positive. This leads to a larger variance for the parameter estimates, taking into account the subcohort sampling variability [19, 26, 29, 36]. Estimation of **absolute rates or risk** requires incorporation of the subcohort sampling fraction (or fractions) into the estimator.

Pseudo-likelihoods for Proportional Hazards Models

Assume the underlying model for disease rates has a **multiplicative** form:

$$\lambda[t, z(t); \beta_0] = \lambda_0(t) r[z(t); \beta_0],$$

where $r[z(t); \beta_0]$ is the rate ratio of disease for an individual with covariates $z(t)$ at time t and $r(0; \beta) = 1$, so $\lambda_0(t)$ is the rate of disease in subjects with $z = 0$. The pseudo-likelihood approach described by Prentice [26] parallels the **partial likelihood** approach to the analysis of full cohort data. We start with the full cohort situation and then return to the analysis of the case–cohort sample. The partial likelihood approach is illustrated in Figure 1 for a small hypothetical **cohort study** of 15 subjects. Each horizontal line represents one subject. A subject enters the study at some *entry time*, is *at risk*, denoted by the horizontal line, over some time period, and exits the study at some *exit time*. A subject may contract or die from the disease of interest, and thus be a *failure* (represented by "•" in Figure 1 or be **censored**, i.e. be alive at the end of the study, died never having had the disease of interest, or be lost to follow-up. At each failure time a *risk set* is formed that includes the *case*; namely, the failure at that failure time, and all *controls*, namely, any other cohort members who are at risk at the failure time (these are denoted by a "|" in Figure 1). The partial likelihood for full cohort data is based on the **conditional probabilities** that the case failed given that one of the subjects in the risk set failed at that time. With r_k the rate ratio and Y_k the "at risk" indicator for subject k at the failure time, and r_{case} the rate ratio associated with the case, the full cohort partial likelihood is

$$\prod_{\text{failure times}} \frac{r_{\text{case}}}{\sum_{\text{case and all controls}} Y_k r_k}.$$

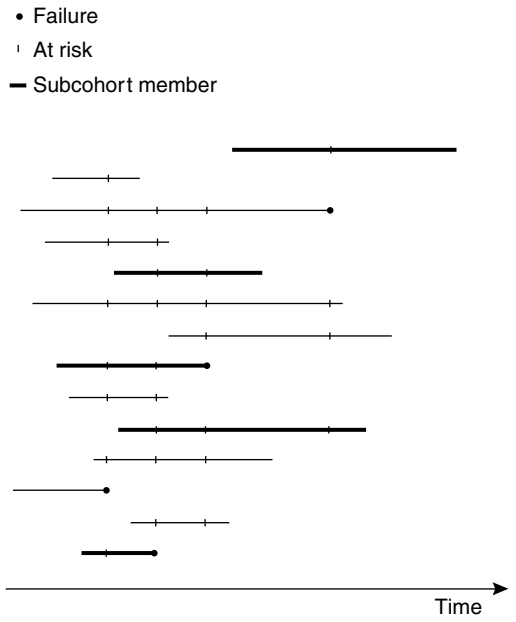

Figure 1 Prentice pseudo-likelihood approach to the analysis of case–cohort data. Pseudo-likelihood contributions are conditional probabilities based on the case and the subcohort members at risk at the failure time

Now in a case–cohort sample, covariate information is obtained for the subcohort and all nonsubcohort failures and only these subjects can contribute to the analysis. Prentice's pseudo-likelihood approach is illustrated in Figure 1 in which subcohort members are denoted by a thick horizontal line. For each failure, a *sampled risk set* is formed by the case and the controls who are in the subcohort (those with thick lines and a "|" at the failure time). As the figure indicates, subcohort members contribute to the analysis over their entire time on study, but the nonsubcohort failures contribute only at their failure times. Analogous to the full cohort partial likelihood, a pseudo-likelihood contribution is based on the conditional probability that the case fails given that someone fails among those in the sampled risk set. The pseudo-likelihood is then the product of such conditional probabilities over failure times:

$$\prod_{\text{failure times}} \frac{r_{\text{case}}}{\sum_{\text{case and subcohort controls}} Y_k r_k}, \qquad (1)$$

where the sum in the denominator is over the subcohort members when the case is in the subcohort and over the subcohort and nonsubcohort case when the case is not in the subcohort. This "likelihood" has the property that the expected value of the score is zero at β_0 but, as discussed above, the inverse information does not estimate the variance of the maximum pseudo-likelihood estimator. Prentice provided an estimator of the covariance Δ from the covariance between each pair of score terms, conditional on whether or not the failure occurring later in time was in the subcohort [17]. This is a rather complicated expression and only one software package has implemented it (Epicure, Hirosoft International Corp., Seattle, WA). Development of other methods of variance estimation has been an area of much research. These include "large sample" [29], **bootstrap** [37], "empirical" [9, 28], and influence function based [2, 21] methods. Simpler alternatives are the "asymptotic" [29] and the "robust" estimators [2, 21, 22]. Either may be computed by the simple manipulation of *delta beta* diagnostic statistics, which are an output option in many software packages [31]. The asymptotic estimator requires the sampling fractions, while the robust version estimates these from the data. Other methods of variance estimation have been proposed [9, 28, 37].

Absolute Risk Estimation

Estimation of the cumulative baseline hazard and related quantities parallel the nonparametric estimators based on the **Nelson–Aalen estimator** for full cohort data. Since the subcohort is a random sample from the full cohort, a natural estimator of the cumulative baseline hazard $\int_0^t \lambda_0(u)\,\mathrm{d}u$ is given by summing contributions for failure times up to t of the form:

$$\frac{1}{1/f \sum_{\text{subcohort}} r_k(\hat{\beta})},$$

where f is the proportion of the cohort in the subcohort [26, 29]. Again, adjustment of the cohort variance estimator is required. Cause-specific baseline hazard estimates for multiple outcomes have also been developed [25].

Other estimation methods and further developments

Alternative pseudo-likelihoods for the estimation of rate ratios of a similar form to (1) have been proposed. These involve differential weightings of the

r_k terms on the basis of the sampling fractions of those associated with subject k [2, 13, 29]. Iterative mean score methods have been proposed, which may yield more efficient estimators than (1) [8]. A method for analysis of generalized case–cohort sampling imputes rate ratio values for each cohort member using a "local averaging". Theoretically, this method is shown to have a superior efficiency to other methods, with methods for making the estimator optimal. Further research is needed to ascertain whether the increases are of practical importance. Methods for estimating standardized mortality ratios (*see* **Standardization Methods**) with a case–cohort sample have been described [35]. These involve "boosting up" the subcohort person-time in each age-year-exposure group "cell" by the inverse sampling fraction. Methods of variance adjustment are also discussed. When disease is rare and there is little censoring, methods of analyses for case-base studies with simple binary outcome data [23] will approximate the failure time analyses (e.g. [11, 17, 27, 33]). When exposure (or treatment) information is available on cohort members and additional information is to be collected for the case–cohort sample, an exposure-stratified subcohort may offer substantial efficiency advantages over random sampling. The analysis of this design uses a weighted variation of the pseudo-likelihood (1) and a generalization of the asymptotic variance estimator has been described [4].

Asymptotic Properties and Efficiency

Self & Prentice [29] give conditions for the **consistency** and asymptotic **normality** of the Prentice pseudo-likelihood for simple (stratified) case–cohort sampling. They show that the asymptotic variance of the maximum pseudo-likelihood estimator of relative risk parameters has the form $\Sigma^{-1} + \Sigma^{-1}\Delta\Sigma^{-1}$, where Σ is the full cohort variance of the score, and they provide a formula for the asymptotic sampling-induced covariance Δ. This covariance depends on the censoring distribution even when $\beta_0 = 0$, so that efficiencies relative to the full cohort analysis must take the censoring distribution into account. Assuming a cohort with complete follow-up over a fixed observation period, an **exponential** relative risk model for a single binary covariate, a subcohort that is a simple $100\alpha\%$ random sample of the cohort, and probability of failure during the observation period of d, they calculate the **asymptotic relative efficiency** as

$$\left\{1 + 2\frac{1-\alpha}{\alpha}\left[1 + \frac{1-d}{d}\log(1-d)\right]\right\}^{-1}.$$

A number of papers have derived the asymptotic variance and semiparametric efficiency bounds for the case–cohort design [7, 8, 37, 38]. These indicate that, although the pseudo-likelihood (1) is not generally semiparametric efficient, the potential loss of efficiency appears to be small, unless disease is common or the size of the subcohort is much smaller than the number of cases.

Comparison with Nested Case–Control Sampling

Nested case–control and case–cohort methods are the two main approaches to sampling from assembled cohort studies. The former takes a retrospective point of view by sampling time-matched controls after the outcome (failure) occurs. In contrast, case–cohort sampling is prospective and unmatched in the sense that the comparison group, the subcohort, is picked without regard to failure status. Considerations for choosing between the designs have been the subject of some interest [10, 18, 20, 24, 26, 32, 34]. We summarize some of these considerations below.

Prospective Studies

If the study is **retrospective** and has been assembled, the major consideration in choosing between sampling designs is the statistical efficiency for the proposed analyses and the information to be collected on the sample, as this will translate quite directly into cost. If the study is prospective in that the study group will be assembled as time passes and outcomes occur in the future, the decision about which design to choose will depend on whether it is advantageous to have a comparison group early on in the study or whether it is better to wait until near the end. If the sample is to be chosen at the beginning, or concurrent with accrual into a prospective study, the case–cohort study has a number of advantages. First, as discussed above, processing of covariate information for the subcohort may proceed early on in the study during the accrual period. During the follow-up period, data for cases arising outside the

subcohort could be processed in batches at various times. A nested case–control study requires waiting until cases occur and controls are selected for them, delaying the processing of covariate information until later in the study than would be required in the case–cohort design. Thus, the case–cohort study can potentially be completed sooner than the nested case–control study. Secondly, although subcohort members should not be treated differently from cases occurring outside the subcohort, the subcohort can serve as a sample for assessing compliance, or quality control, as the study proceeds. However, a nested case–control sample may be advantageous if it is important that processing of information be "blinded" (*see* **Blinding or Masking**) to case-comparison group status. Since case–control covariate information can be processed simultaneously, potential information bias can be avoided. This is not always possible with a case–cohort sample when subcohort data are processed early in the study.

Statistical Efficiency

Comparison of statistical efficiency for studying a single outcome has been a topic of much research. It has been conjectured that the case–cohort design should be more efficient than the nested case–control design. This belief has been based on a comparison of the contribution of a failure to the pseudolikelihood (1) with that of the corresponding nested case–control contribution. The former uses all subcohort members at risk at the failure time, whereas the latter uses only the controls selected for that case, usually resulting in the case–cohort having many more "controls per case". In fact, analytic and empirical efficiency comparisons indicate that in most situations encountered in practice, nested case–control sampling will be more efficient than the case–cohort, although often not by a large amount [18, 19, 34, 36]. The reason for the lower-than-anticipated relative efficiency is that the large number of controls per case in the case–cohort sample, which by itself increases efficiency, is offset by the sampling-induced positive **correlation** in score terms (see above), which lowers efficiency. The nested case–control design has relatively few controls per case, but there is no sampling-induced correlation between score terms [19].

Multiple Disease Outcomes

Since the subcohort is chosen without regard to failure status, it may serve as the comparison group for multiple disease outcomes. This would seem to be a great advantage over the nested case–control design, since controls are selected for specific cases. In fact, there are few published studies that exploit this feature of the design. Nevertheless, the most cost-effective use of the case–cohort design would seem to be to study a single set of explanatory factors and multiple outcomes. Thus, it seems likely that the case–cohort design may have application in clinical investigations in which researchers are often interested in multiple-event outcomes such as relapse, local and distant recurrence, and death as a function of a single set of treatment and **prognostic factors**. If, for instance, the prognostic factors involve expensive laboratory work, a case–cohort sample would be a natural way to reduce costs associated with the laboratory work, but still allow a full analysis of multiple endpoints. Using the same comparison group will result in correlation between estimates of the same parameter for different endpoints. Appropriate methods for the variance adjustment and hypothesis testing with multiple outcomes have been developed [25].

Matching

Often, it is desirable to match (*see* **Matching**) comparison subjects closely on certain factors, either to control for **confounding** or so that information of comparable quality may be obtained. For instance, it is common to compare a case with controls close in year of birth to adjust for secular trends in behavior. Fine matching, and matching based on time-dependent factors is accommodated in a natural way in a nested case–control sample. Matching may only be done crudely for case–cohort sampling and must be based on factors available at the time the subcohort is sampled.

Analysis Flexibility

The nested case–control design is inherently associated with methods for analysis of cohort data based on **semiparametric proportional hazards** models. Estimation of rate ratio parameters is based on partial likelihood methods and estimation of absolute-risk-related quantities is based on the Nelson–Aalen

estimator of the **cumulative hazard**. (One interesting exception to the restriction to proportional hazards models is estimation of excess risks using the **Aalen linear model** [3].) The case–cohort design is not associated with any particular model or method of analysis. Thus, in theory, "Poisson likelihood" or "grouped time" case–base analysis approaches, as well as the risk-set-based pseudo-likelihood (1), may be used for parameter estimation. Examples of estimation of parameters in nonproportional hazards models from case–cohort data include the additive hazards, proportional odds, and transformation regression models [5, 6, 14]. For a subcohort that is a simple random sample, changing time scales and analysis stratification variables poses no difficulties in the analysis. Since the nested case–control sample is bound to the risk set defined by the time scale and stratification variables used in matching controls to failures, these must be fixed in the analysis. However, **inference** from case–cohort samples is complicated by the need to adjust **standard errors** and test statistics for the sampling-induced covariance. Further, for testing, adjusted Wald and score tests are adapted in a natural way using the variance estimator [31], but a "pseudo-likelihood ratio test" is not available.

Computation

Standard conditional logistic regression software, for the analysis of matched case–control data, may be used to analyze rate ratio parameters from nested case–control studies (*see* **Software, Biostatistical**). Furthermore, if the numbers of subjects in the risk sets are known, absolute risk estimators and standard errors are relatively simple to compute [16]. Since the latter are based on standard nonparametric cumulative hazard and survival estimators, standard software for the analysis of full cohort data may be "tricked" into computing the nested case–control estimators. For case–cohort samples, standard **Cox regression** software may be used to estimate parameters but, as discussed above, special software is needed to estimate corresponding variances.

Case–Control Study, Hospital-based

A hospital-based case–control study is a **case–control study** in which cases with a given disease are selected from persons with that disease in a given hospital or group of hospitals, and **controls** are patients with other diseases from those hospitals. Hospital-based case–control studies are relatively convenient to conduct and offer some advantages, compared with **population-based case–control studies**. First, a higher proportion of persons invited to join a hospital-based case–control study may agree to participate, especially when biologic samples such as blood specimens are required. This reduces the chance for one type of **selection bias** known as **nonresponse** bias. Secondly, cases and controls with other diseases may provide a similar quality of information when asked about previous exposures, thus reducing the chance of **recall bias** compared with **population-based studies** in which most controls are healthy.

There are two serious sources of **bias** that may affect hospital-based case–control studies and that are not present in population-based case–control studies. First, the pattern of referral of cases to a hospital may differ from the pattern of referral for persons with control diseases, resulting in selection bias because the controls are not representative of the source population from which the cases arise. Secondly, the exposure under study may affect the risk of the control conditions, causing a distortion of the **relative risk**.

(*See also* **Bias in Case–Control Studies**; **Bias in Observational Studies**; **Bias, Overview**)

MITCHELL H. GAIL

Case–Control Study, Nested

A nested **case–control** study is comprised of subjects sampled from an assembled epidemiological **cohort study** in which the sampling depends on disease status. Nested case–control studies are generally used when disease is rare and, at the minimum, disease outcome has been obtained for all cohort subjects, but it is too expensive to collect and/or process information on **covariates** of interest for the entire cohort. By sampling a small proportion of the nondiseased subjects, there is high cost efficiency for assessing associations between exposures and disease. "Standard" case–control studies, the most common study design in epidemiologic research, may often be viewed as nested case–control studies in which a portion of underlying cohort (usually among the nondiseased) has not been identified [15]. The distinction between standard and nested case–control studies is often ambiguous and, in fact, analysis methods appropriate to standard case–control studies are directly applicable to nested case–control studies. However, depending on the amount of information available in the assembled cohort, there may be a much wider range of design and analysis options for nested case–control studies than for a standard case–control study. So, **confounder** information available in the cohort data is often used to select controls that closely match cases. Also, unlike standard case–control studies, **absolute risk** may often be reliably estimated. Further, it is often possible to compare characteristics of participants to nonparticipants to assess the potential magnitude of selection or information bias (*see* **Bias in Case–Control Studies**). The advantages of nesting a case–control study in a cohort include convenience, cost-efficiency, high validity, and analytic flexibility, for example, [15, 16, 21, 30, 32, 35, 42, 59]. Methodologically, the paradigm of nested case–control sampling is *prospective*, with disease outcome random with probability dependent on covariates. In contrast, the paradigm for standard case–control studies is *retrospective*, with covariates random with distribution depending on disease status. To the extent that standard case–control studies can be viewed as having been sampled from a (perhaps poorly defined) cohort, nested case–control design and analysis developments apply to case–control studies generally.

Data Model for Nested Case–Control Studies Based on Risk Sets

Cohort data arises by observing a population for disease occurrence over some period of time. So, it is natural to represent nested case–control studies in relation to cohort generation. Figure 1 represents the basic features of a small hypothetical cohort study of 14 subjects. Each subject enters the study at some *entry time*, is *at risk*, denoted by the horizontal line, over some time period, and exits the study at some *exit time*. A subject may contract or die from the disease of interest, and thus be a *failure* (represented by "•" in Figure 1) or be *censored*, that is be alive at the end of the study, died never having had the disease of interest, or be lost to follow-up.

The link to nested case–control studies is in the organization of the cohort data into **risk sets** [19]. At any time, the *risk set* is defined to be all subjects under observation. Risk sets may be defined at single points in time, *continuous time risk sets* as in Figure 2 or in time intervals, *grouped time risk sets* as in Figure 3. Risk set members are identified by the "|" at the given time (or time interval). Continuous and grouped risk sets have the structure of individually matched (*see* **Matching**) or unmatched case–control sets, respectively. *Cases* in the risk set are failures at the failure time or time interval, while *controls* are the nonfailures. The nested case–control sample is drawn by sampling from the controls (and possibly from the cases) in the risk sets. Individually matched nested case–control studies arise by sampling from continuous time risk sets at the failure times, while unmatched nested case–control studies arise from sampling from the grouped time risk sets. These are illustrated in Figures 2 and 3, in which ○ represent sampled controls.

Examples

Occupational Cohort Study of TCDD Exposure and STS and NHL. **The International Agency for the Research of Cancer** (IARC) maintains an international register of 21 183 workers exposed to phenoxy herbicides, chlorophenols, and dioxins [52]. In

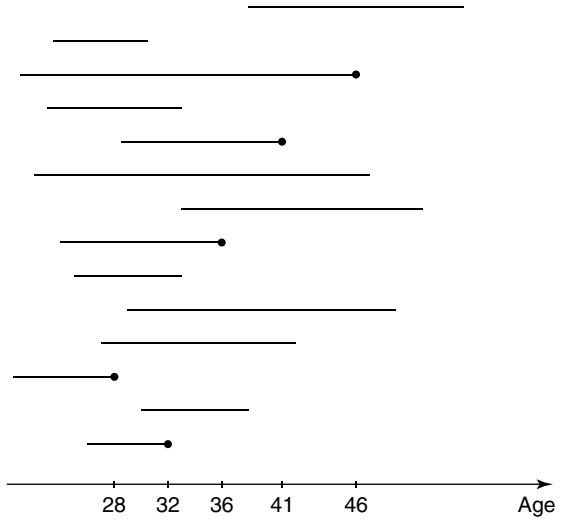

Figure 1 Cohort of 14 subjects. Each line represents the time on study for one subject. Subjects can either fail (represented by the •) or be censored (no •)

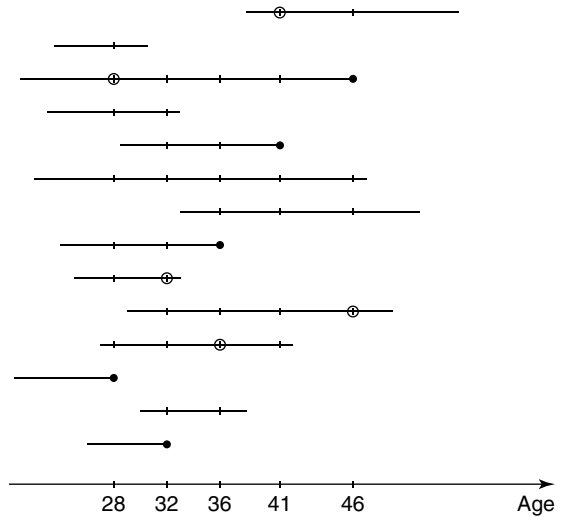

Figure 2 Continuous time risk sets at each failure time are represented by the "|" marks. The failure is the case in the risk set and the nonfailures are the controls. Single controls, sampled for each case are represented by the ○

a cohort mortality study analysis, standardized mortality ratios (SMRs) (*see*, **Standardization Methods**) of 1.96 and 1.29 were found for soft-tissue sarcomas (STS) and non-Hodgkin's lymphoma (NHL), respectively, comparing exposed to unexposed workers. In

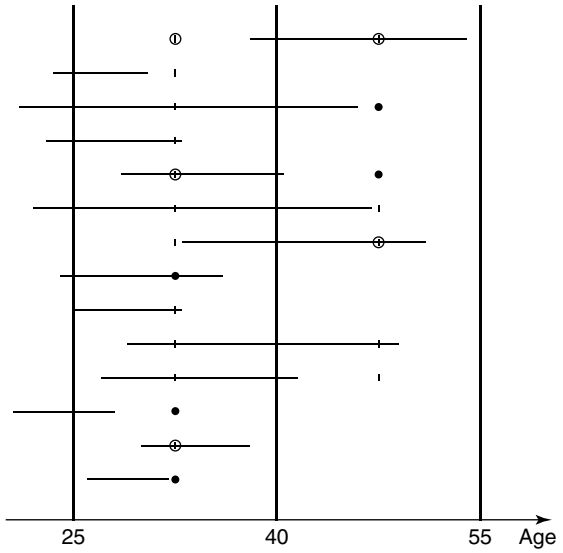

Figure 3 In this example, grouped time risk sets for 25 to 39 and 40 to 55 age groups are defined as subjects that are on study for any portion of the age interval and are indicated by the "|" marks. Nested case–control sampling in grouped time yields an unmatched case–control study structure with multiple cases per set (the •s) and sampled controls (indicated by ○s). Illustrated here, the number of sampled controls sampled to the number of cases

order to explore the effect of exposure to various agents more fully, a nested case–control study was undertaken in which for each of the 11 STS and 32 NHL cases, five controls were sampled from those from the same country, of the same gender, and same year of birth as the case [27]. For each subject in the nested case–control study, industrial hygienists assessed the degree of exposure to 21 chemicals or mixtures based on company records. Increasing trends of risk of STS and NHL were observed for a number of phenoxy herbicides including 2,4D, and TCDD. This study illustrates a number of potential advantages of nested case–control studies. First, having already assembled the workers cohort, the nested case–control study was a natural follow-up design in order to obtain more detailed exposure information. Second, the workers cohort has much higher **prevalence** of TCDD exposure than general population. Thus, the case–control study selected from this cohort will have much higher statistical **power** to investigate TCDD (and other chemical) associations with STS and NHL than a study of similar size from the general population. Third, on

the basis of the $(m-1)/m$ relative efficiency rule [16, 58], this nested case–control study of 258 subjects provides $5/6 = 83\%$ efficiency relative to an analysis of entire cohort of 21 183 for testing associations between single exposures and disease. Finally, because exposure assessment did not require contact with study subjects, recall and selection bias (*see* **Bias in Case–Control Studies**), common problems in standard case–control studies, were avoided.

Nested Case–control Study of Hypertensive Drugs and the Risk of Myocardio-infarction (MI) within a HMO Cohort. In this study, the cohort is defined to be patients within the Group Health Cooperative of Puget Sound who were prescribed hypertensive medication for some time during July 1989 through December 1993 [48]. Failures in the cohort were 623 MI cases. Grouped time risk sets were formed on the basis of calendar year and controls were randomly sampled (about 3 times the number of cases) within matching strata based on 10 year age group and gender. For each case–control study member, the types of antihypertensive drugs used were ascertained through computerized records, chart review, and interview. It was found that risk of MI was 60% higher among calcium channel blocker users compared to that among users of either diuretics alone or β-blockers, a finding that has resulted in a change in treatment strategy. Nesting this case–control study within the HMO cohort had similar advantages to the IARC study. First, the HMO computerized database allowed the identification of cohort members and MI outcome information in a fairly efficient way. There was a high participation rate and, since the type and period of use of drugs could be assessed using the pharmacy database, this information is not subject to information bias.

Residential Magnetic Field Exposure and Breast Cancer. The Multiethnic Cohort is a large population-based cohort from Los Angeles and Hawaii of men and women aged 45 to 74 at enrollment between 1993 and 1996. There were 52 112 female Los Angeles County residents who enrolled in the cohort and completed a self-administered questionnaire that included questions about menstrual and reproductive history, use of oral contraceptives and hormone replacement therapy, diet, and physical activity. For the nested case–control study, 751 breast cancer cases diagnosed by 1999 were ascertained through the National Cancer Institute's Surveillance and End Results (SEER) registry in Los Angeles (*see* **Cancer Registries**). Because the study duration was relatively short, the entire study period was considered as a single grouped time risk set. Controls were approximately **frequency matched**, according to the expected number of breast cancer cases, within self-reported ethnicity. Information on traditional breast cancer risk factors was obtained from the cohort baseline questionnaire (100% participation), and each case or control was invited to have an in-home interview about magnetic field exposures (75% participation). Using the baseline residence for questionnaire participants, wire code was obtained for 99% of all case–control subjects, but because permission was required, magnetic field measurements were obtained in homes of only 44% of subjects. No association between magnetic field measures or wire-code and breast cancer were found [36]. Although covariate information obtained through the interview would be subject to the same information biases as a standard case–control study, there was no selection or information bias for the baseline questionnaire and wire-code data. Further, potential bias, in particular, with regard to the missing patterns for magnetic field measurements, could be assessed using the other variables in the baseline questionnaire.

Nested Case–control Study of the Colorado Plateau Uranium Miners. The Colorado Plateau uranium miners cohort data were collected to assess the effect of occupational radon exposure on the mortality rates (e.g. [25, 39, 41]) (*see* **Radiation Epidemiology**). The cohort consists of 3347 Caucasian male miners who worked underground at least one month in the uranium mines of the four-state Colorado Plateau area and were examined at least once by Public Health Service physicians between 1950 and 1960. These miners were traced for mortality outcomes through December 31, 1982, by which time 258 lung cancer deaths had occurred. Miner radon exposure histories were estimated using job histories and mine radon levels. Although radon and smoking information are available on all cohort members, nested case–control samples with as many as 40 controls per case have been used to reduce the computational burden required to fit complex models exploring the timing of exposures and lung cancer mortality rates [24, 34, 57]. Each of the risk sets was formed by all those who were alive and had entered the study by the

age of death of the case and had attained that age in the same five-year calendar period as the case's date of death (matching by calendar time). The analyses based on the nested case–control data closely approximates the corresponding **Cox regression**, but fitting the models required a fraction of computing time; in the case of the latency models, this meant a reduction from a few days to less than an hour. Further, in the nested case–control data, radon and smoking summaries need only be computed at a fixed (failure) time rather than dynamically in a Cox regression. This makes it much easier to identify data errors and check exposure calculation routines. Absolute risk of lung cancer death, given radon and smoking histories, were estimated from nested case–control data from this cohort [29].

Statistical Analysis Based on the Proportional Hazards and Odds Models for Sampled Risk Set Data

Any of the analysis methods available for "standard" case–control studies, including **conditional** and unconditional **logistic regression** and **Mantel–Haenszel** methods may be used to estimate rate or **odds ratios** from a nested case–control study when the sampling is "simple". Here, we describe methods that are based on the risk set sampling data model that accommodates quite general sampling.

Proportional Hazards and Odds Models

The standard methods for analysis of nested case–control data correspond to and are generalizations of estimation methods for cohort data based on risk sets. Data analysis methods are derived from **semiparametric** models for disease occurrence, the **proportional hazards** or **proportional odds models** being appropriate to continuous or grouped time data, respectively [19]. Each is assumed to have **multiplicative** form

$$\lambda(t; z(t)) = \lambda_0(t) r(z(t); \beta_0) \tag{1}$$

where $r(z(t); \beta)$ is the rate (odds) ratio of disease for an individual with covariates $z(t)$ at time t and $r(0; \beta) = 1$, so $\lambda_0(t)$ is the rate (odds) of disease in subjects with $z = 0$. In continuous time, t refers to any time, while in grouped time the t is discrete and indexes the time intervals. The proportional hazards model may be obtained as the limit to the proportional odds model as the time interval lengths go to zero. As a consequence, the rate ratio parameter and odds ratio parameter in grouped time structure will be close when the probability of failure (rare disease) in each time interval is small.

Estimation of Rate Ratio Parameters from Continuous Time Data

The **partial likelihood** method for cohort data is based on the probability that a subject is a case given the risk set [19, 20]. Similarly, the partial likelihood for nested case–control data is based on the probability that a subject is a case given the case–control set [6, 35, 43, 55]. This will depend on the sampling method and leads to a **likelihood** of the form

$$\prod_{\text{failure times}} \frac{r_{\text{case}}(\beta)\pi_{\text{case}}}{\sum_{k \in \tilde{\mathcal{R}}} r_k(\beta)\pi_k} \tag{2}$$

where $\tilde{\mathcal{R}}$ is the case–control set, the r_k are computed at the failure time, and π_k is the probability of picking the particular case–control set if k was the case. These will generally be replaced by a convenient weights w_k that are proportional to the π_k.

For instance, for **simple random sampling** of $m-1$ controls from the $n-1$ in the risk set, $\pi_k = \binom{n-1}{m-1}^{-1}$. In this case, the π_k are the same for all case–control set members so we may take $w_k = 1$, which yields the "unweighted" conditional likelihood for standard matched case–control data (*see* **Matched Analysis**). Standard conditional logistic regression software may be used to estimate the rate ratio (β_0) parameters (*see* **Software, Biostatistical**).

Estimation of Odds Ratio Parameters from Grouped Time Data

Parallel to the continuous time situation, a partial likelihood is based on the probability that a set of subjects **D** are the cases given that the case–control set is $\tilde{\mathcal{R}}$ and is given by

$$\prod_{\text{grouped times}} \frac{\lambda^{|\mathbf{D}|}\, r_{\mathbf{D}}(\beta)\pi_{\mathbf{D}}}{\sum_{\mathbf{s} \subset \tilde{\mathcal{R}}} \lambda^{|\mathbf{s}|} r_{\mathbf{s}}(\beta)\pi_{\mathbf{s}}}, \tag{3}$$

where $r_{\mathbf{s}}(\beta) = \prod_{j \in \mathbf{s}} r(Z_j; \beta)$, $|\mathbf{s}|$ is the number of elements in **s**, and $\pi_{\mathbf{s}}$ is the probability of picking the case–control set given that **s** is the set of

cases. For analysis, the $\pi_{\mathbf{s}}$ can be replaced by convenient weights $w_{\mathbf{s}}$ that are proportional to $\pi_{\mathbf{s}}$ [31]. For instance, in $1 : m-1$ frequency matching, the number of controls randomly sampled is $m-1$ times the number of cases. Then, the $\pi_{\mathbf{s}} = \binom{n-|\mathbf{D}|}{m-|\mathbf{D}|}^{-1}$ for all subsets $\mathbf{s}$ of the case–control set $\tilde{\mathcal{R}}$ that are of the same size as the case set. Cancellation of the common π from numerator and denominator leads to the standard (unweighted) conditional logistic likelihood for unmatched case–control data. On the other hand, case–based sampling (for example, [28]) in which a random sample of $m|\mathbf{D}|$ subjects (without regard to failure status) is drawn from the cohort and additional failures are included is "weighted" with $w_{\mathbf{s}} = \binom{|\mathbf{s}|}{m|\mathbf{D}|-(|\tilde{\mathcal{R}}|-|\mathbf{s}|)}$ [31].

Conditional Logistic Likelihood. A likelihood estimator that is closely related to the partial likelihood conditions on the number of cases so that the *conditional logistic likelihood* is given by

$$\prod_{\text{grouped times}} \frac{r_{\mathbf{D}}(\beta)\pi_{\mathbf{D}}}{\sum_{\mathbf{s}\subset\tilde{\mathcal{R}}:|\mathbf{s}|=|\mathbf{D}|} r_{\mathbf{s}}(\beta)\ \pi_{\mathbf{s}}}. \tag{4}$$

Unlike the partial likelihood (3) from which the baseline odds may often be estimated, the baseline odds parameter is conditioned out of (4). Also, unlike the partial likelihood, for each of the standard (simple) control selection methods, including frequency matching, Bernoulli trials (*see* **Binary Data**) and case-base, the conditional likelihood is the same, "unweighted" version [3]. The conditional likelihood is often used when the number of cases and/or controls in all or some case–control sets is small or when there are tied failure times in continuous time analyses (*see* **Tied Survival Times**).

Unconditional Logistic Regression. This is the most commonly used alternative for analysis of grouped time nested case–control studies with random sampling and is based on the product of "marginal" case/control probabilities within the case–control set

$$\prod_{\text{grouped times}} \prod_{j\in\tilde{\mathcal{R}}} \frac{[\lambda\ w_j\ r_j(\beta)]^{D_j}}{1+\lambda\ w_j\ r_j(\beta)}, \tag{5}$$

where D_j is a case–control status indicator, w_j is a marginal "inverse control sampling probability". The w_j depend both on β_0 and j, but for common situations, this dependence is small for "large samples". Further, because the probabilities are only marginal, the variance cannot generally be estimated as the "inverse information" (e.g., [11, 31]). The unconditional logistic likelihood also arises from two-phase studies, closely related to nested case–control studies, in which the cohort is taken as a fixed set of cases and controls from which a second stage sample is drawn from the first, for example, [11, 13, 53, 62, 67] (*see* **Case–Control Study, Two-phase**). In the case of simple random sampling (with $m-1$ controls per case), the w_j are approximately all equal to $(n-|\mathbf{D}|)/(m|\mathbf{D}|-|\mathbf{D}|)$ and a **nuisance parameter** θ_0 can be used in place of $\lambda_0\ w_j$ in the likelihood. In this special case, the variance of the odds ratio parameter may be estimated using the standard inverse information estimator [3].

Absolute Risk Estimation

Unlike a standard case–control study in which the cohort cannot be identified from a nested case–control study, it is possible to estimate the baseline **hazard rate** and, more generally, absolute risk quantities that are functions of the hazard.

Estimation of Risk from Continuous Time Data. If the number at risk n and the control selection probabilities π_k are known at each failure time, then **cumulative hazard** functions and survival functions may be estimated using a generalization of the Breslow estimator of the baseline hazard [1, 19, 29] (*see* **Hazard Ratio Estimator**). Let $z^0(t)$ be a covariate history and $r^0(t) = r(z^0(t); \beta_0)$ be the rate ratio (as a function of time) associated with z^0 according to the model. The basic components for estimators of risk are the jumps in the hazard at the failure times. With n the number at risk and $\hat{r}_k = r(z_k, \hat{\beta})$, the relative risk for individual k predicted using $\hat{\beta}$, the hazard jump from a case–control set is estimated by

$$\hat{r}^0 \Big/ n \sum_j \frac{\pi_j}{\sum_k \pi_k} \hat{r}_j, \tag{6}$$

where the sums are over case–control set members [29]. Note that setting $m = n$ and $z^0(t) \equiv 0$ yields the Breslow estimator of the baseline hazard for the full cohort [19]. For simple random sampling of $m-1$ controls, $\pi_j / \sum_k \pi_k = m$ so the denominator is given by $n/m \sum \hat{r}_k$. Cumulative hazard

and **Kaplan–Meier-type estimators** of risk and an **Aalen–Johansen-type estimator** of risk in the presence of **competing** causes of failure, as well as corresponding variance estimators have been described with application to the Colorado Plateau uranium miners study [9, 29].

Estimation of Risk from Grouped Time Data. Estimation of absolute risk from grouped time nested case–control data with general sampling is a topic of continuing research. When the overall risk of disease is known in the cohort, one approach uses the distribution of covariates in controls as representative of the cohort rates to infer risk within exposure subgroups [4]. When the w_j can be specified, then the baseline odds (and hence the risk) can evidently be estimated using the grouped time partial (3) or the unconditional (5) likelihoods.

Asymptotic Properties and Efficiency

The "likelihoods" for both continuous and grouped time are "partial" in the same sense as the Cox partial likelihood for full cohort data [19] in that the same subject may appear in multiple sets. In an extension to the **counting process** and martingale theory approach for full cohort data [2], nested case–control data is represented by a counting process $N_{i,\mathbf{r}}(t)$ for occurrences of both subject i becoming diseased and $\mathbf{r}$ the case–control set. Within this framework, the case–control set variability is constant, with sample size and the asymptotics driven by the increasing number of case–control sets. Conditions for the consistency and asymptotic normality of the partial likelihood rate ratio and baseline hazard estimators have been described for a wide range of sampling methods [6, 23]. Also provided are expressions for the asymptotic variance from which **efficiency**, statistical **power**, and **sample size** calculations can be made. For simple sampling, these are refinements of those for standard individually matched case–control studies that take into account the underlying failure time structure [23]. Performance of the partial likelihood under model **misspecification** under simple sampling has also been studied [63, 64]. For grouped time case–control data, the framework can be similarly defined with $N_{\mathbf{d},\mathbf{r}}(t)$ now indicating the set $\mathbf{d}$ of diseased subjects and $\mathbf{r}$ the case–control set. However, the asymptotic theory will depend on if and how the time intervals "shrink" as a function of sample size. For fixed time intervals, the number of case–control sets is fixed and the asymptotics are driven by increasing sample size within case–control sets and thus, the asymptotic theory is very different than in the continuous time situation. The theory for the "unweighted" conditional logistic (4) and unconditional logistic (5) likelihoods based on rejective sampling has been described [3]. However, a general theory has not been derived in the grouped time setting.

Other Approaches to Estimation and Other Models

Proportional Hazards Models. **Mantel–Haenszel** estimators for nested case–control studies with simple random sampling have been described and shown to be consistent [65, 66]. Methods for estimation of relative mortality have been described on the basis of an extension of the proportional hazards model [7, 14, 54].

Another class of estimators seeks to use case and control information at times other than when they were sampled, all with the goal of capturing more information from the case–control sample than the partial likelihood. There have been a number of methods that enlarge or restrict the controls used in the unweighted version of (2) in order to increase efficiency [33, 45, 49, 60]. Interestingly, even though these methods made "better" use of the sample, it was found that efficiency gains were modest at best, and often were worse in situations of practical importance [33]. Another method incorporates external rates and estimation is based on joint cohort Poisson and nested case–control partial likelihoods [56]. Methods have been proposed using an "inverse weighting" method [18, 51] as well as an estimator based on "local averaging". The latter was shown to be more efficient than earlier extensions and is more efficient than the partial likelihood in a range of situations [17]. All these methods show some improvement when disease is common and/or the rate ratio is large. Further work is necessary to establish the practical guidelines for when these methods offer significant benefits over the standard methods.

Nonproportional Hazards Models and Extensions. Methods for modeling **excess risk** and estimation of absolute risk based on the Aalen linear regression

model, from nested case–control studies have also been developed [8]. Nested case–control studies with appropriately sampled controls can be used to estimate transition rate ratio parameters for recurrences or multiple outcomes [37, 38] and for **Markov** transition probabilities [5]. A useful method for estimation of parameters in parametric models has been described [51].

Control Sampling Methods

General Guidelines. The likelihood methods are all valid (and most useful) if the risk sets are sampled independently over time so that subjects may serve as controls in multiple case–control sets and failures may be controls in "earlier" risk sets. Restricting controls to be used only once or using "pure" controls, those that never become cases, will, in theory, result in biased estimation [40] unless special analysis methods are used [45]. However, if disease is rare, this bias is generally negligible. Very general sampling methods can be accommodated by the risk set sampling likelihoods but a general guideline for useful designs is that the structure of the case–control set should not reveal the identity of the case [30].

Matching and Random Sampling. The most commonly used methods for selecting controls is to randomly sample from risk set members who "match" on a set of factors. For continuous time case–control studies, this means that the sampled controls will be similar to the individual case on these factors. For grouped time studies, the risk set will be partitioned into matching strata and controls (and cases) are sampled from within these strata. Although the choice of matching criteria will depend on the needs of the study, common matching factors include gender, race/ethnicity, calendar year, and/or year of birth. The latter is often desirable because, as in the hypertensive drug-MI example, a natural timescale is age but matching on year of birth aligns the cases and controls with respect to calendar time and thus assures comparable data quality and control for "secular trends" in diagnostic treatment practices [12].

Fine Matching. When a continuous matching factor is available on all cohort members, nearest neighbor and caliper matching are possible as continuous time control selection options [26]. For instance, in a study of occupational exposure to chemical agents and pancreatic cancer, for each case, the four controls in the risk set who most closely matched on date of birth were enrolled into the nested case–control study [22]. In this study, there was no random sampling at all and the nearest neighbor matching completely determined the control selection. The unweighted partial likelihood is not strictly correct under this sampling, but conditions have been described when it is asymptotically valid, as well as other analysis options when the matching factor is included as a covariate in the proportional hazard model [26].

Exposure Stratified Sampling Methods. Until recently, it was thought that control selection could not depend on exposure related variables [50]. In fact, unbiased estimation is possible if the appropriate control selection probabilities (weights) are specified in the likelihood. Such designs include **counter-matching**, variants of quota sampling, two-stage sampling, and exposure stratified case-base (**case–cohort**) sampling [6, 10, 11, 30, 31, 61].

Issues Related to Grouped Time Studies

Continuous Time as a Limiting Case of the Grouped Time Model. Parallel to the approach of Cox for cohort data organized into risk sets, individually matched case–control study designs and methods can be obtained from unmatched studies by "shrinking the time interval" to zero. Thus, the proportional odds model converges to the proportional hazards, $1 : m - 1$ frequency matching becomes $1 : m - 1$ individual matching and the grouped time partial (or conditional) likelihood converges to the continuous time partial likelihood.

Grouped Time as an Approximation to Reality. Because time is in reality "continuous", the grouped time approach necessarily involves a number of approximations, which may be critical when the grouped time intervals are large. One issue is the ambiguity in the definition of who is in the risk set, in particular, among those who are censored during a grouped time interval. The problems that can arise correspond to those associated with ignoring censoring in failure time data (but on the scale of the time interval). In Figure 3, we have defined subjects as being at risk in the interval if they are at risk during any part of the interval. Another problem with

grouping time is that there is not a single unambiguous "reference time" from which to compute time-dependent covariates. Various strategies have been to use the average time for the cases, as was done in the residential magnetic fields breast cancer example [36] or to randomly assign times to the controls based on the case failure time distribution within the interval. Unless there are large changes in at-risk status and/or covariate values over time intervals, strategies that reasonably approximate the continuous time risk sets will yield estimates that are close to the corresponding continuous time estimator.

Failure Time Analysis of Grouped Time Case–control Studies. A number of methods have been developed to estimate rate ratio parameters when the case–control study is sampled from grouped time risk sets. Most notable of these is the case–cohort method [44]. To see that this is a grouped time sampling, note that the sampling is the "case-base" method [28] in which a random sample of subjects (without regard to failure status) is drawn from the cohort and additional failures are included. The grouped time analysis methods based on estimation of *odds ratios* for exposures apply with the time interval taken as the entire study period; this analysis is subject to the pitfalls associated with grouping time described above. The case–cohort *analysis* method allows estimation of the *rate ratios* appropriately accounting for censoring and **time-dependent covariates** from the case-based sampled data. This idea was generalized to estimators of rate ratios from "simple" unmatched case–control data from the cohort [17]. A comparison of nested case–control and case–cohort approaches is given in the article **Case–Cohort Study**.

Nested and Standard Case–control Studies

Relevance of Nested Case–control Studies. Standard case–control studies may often be viewed as a nested case–control study within a nonassembled (and perhaps poorly defined) cohort. Thus, methods developed for nested case–control studies that do not require further knowledge of cohort information will apply to standard case–control designs. So, a number of study designs, including quota sampling, modified randomized recruitment, and individually matched two-stage studies have been proposed on the basis of the nested case–control study paradigm that do not require an assembled cohort [6, 30, 31]. Another example is a robust (*see* **Robustness**) variance estimator derived for continuous time $1 : m - 1$ nested case–control studies that may be used in standard individually matched case–control study analysis [64].

Difference in Methodological Approach for Nested and Standard Case–control Studies. Methodologically, perhaps the biggest difference between nested and "nonnested" case–control studies is the data model used to develop methods. Traditionally, case–control data is viewed as generated "retrospectively", with individual exposure independent random quantities, with distribution conditional on disease status (e.g. [46]). A key result is that, even under the retrospective model, odds ratio parameters are estimable using the unconditional logistic likelihood (5), (e.g. [47]). For simple sampling, either approach leads to similar methods and inference about odds ratio parameters in grouped time data [3]. However, methods developed under the risk set sampling model provide a connection to failure time cohort data and associated methods and, further, provide a natural framework for the development of methods for individually matched case–control data.

Case–Control Study, Population-based

A population-based **case–control study** is based on a well-defined source population from which all cases that arise in a given time period can be enumerated. **Controls** consist of **random samples** of persons without the disease of interest from the source population. Cases consist of all cases or a random sample of those cases. Because the total number of cases is known and the size of the source population can usually be estimated from **census** data or other sources, a population-based case–control study yields information not only on **relative risk**, but also, by combining information on relative risk with information on overall disease risk, on exposure-specific **absolute risk**.

Compared with **hospital-based case–control studies**, population-based case–control studies can, in principle, avoid **selection biases** that produce nonrepresentative samples of cases and controls. Moreover, there is no ambiguity about what constitutes an appropriate control. In practice, however, selection biases can arise if all cases are not identified or if persons selected for inclusion in the study refuse to participate. In addition, **recall bias** can distort the results of such a study if persons with disease provide a different quality of information on exposure from healthy controls selected from the general population.

(*See also* **Bias in Case–Control Studies**; **Bias in Observational Studies**; **Bias, Overview**)

MITCHELL H. GAIL

Case–Control Study, Prevalent

Incident cases represent the change from a nondiseased to a diseased state. For research purposes, a population at risk is defined as one whose members are, as of some arbitrary time point, disease free. Over time, incident cases emerge from that population. In a study with incident cases, the underlying assumption is that either all of the cases produced by the population are available for study, or that the study includes what may be taken as a **random sample** of all of the cases [18]. In this way the experience of the cases and the population at risk can, in principle, be used to investigate the etiology of the disease, conditional on adjustment for potential **confounding** [16, 18, 24]. When, for efficiency, a **case–control study** is done, the measure of effect estimated by the exposure **odds ratio** will be either the **incidence density ratio**, the **cumulative incidence ratio**, or the disease odds ratio, depending upon the sampling scheme that was used to select the **controls** [17, 20, 23]. However, whatever the estimated parameter, the potential for etiologic inference remains, conditional on adjustment for potential confounding.

The situation is more complex when prevalent cases are included and the intent of the research remains etiologic. Prevalent cases have made the transition from a nondiseased to a diseased state. However, they also *survived* to the time the study sample was obtained [6, 16, 29]. All prevalent cases were once incident cases; but not all incident cases survive long enough to become prevalent cases.

When a study includes prevalent cases, the question arises as to whether the prevalent case series can reasonably be taken to represent a random sample of all incident cases with respect to the distribution of etiologically relevant factors (and potential confounders). For the answer to be "yes", incident cases that did not survive long enough to become prevalent cases must be assumed to have been etiologically similar to the incident cases that survived and became prevalent cases [3]. Survival would thus be unrelated to any etiologically important factor [16, 17, 24]. For this special situation, the prevalent case–control study is interchangeable with the incident case–control study with respect to the validity of the relative measure of effect, though it may differ with respect to **power** [2].

In the more likely situation, the prevalent case series cannot reasonably be taken to represent a random sample of all incident cases [2, 16, 29]. In particular, cases with short survival times will be under represented; longer surviving cases will be over represented; and most significantly, the duration of survival may well be related to etiologically relevant factors. Risk factors for the disease therefore will be simultaneously related to etiology *and* prognosis [6, 17, 29]. The exposure odds ratio will not directly estimate the incidence ratios that are the target for etiologic research. Table 1 illustrates how estimates of relative effects from a case–control study with prevalent cases will or will not validly duplicate the estimate from a case–control study with incident cases.

Linking Prevalence- and Incidence-Based Studies

Freeman & Hutchison [7, 8] have demonstrated the interrelations between incidence and prevalence (*see* **Incidence–Prevalence Relationships**)–in particular, that

> prevalence, incidence, and duration of a condition or illness ... are interrelated in such a way that two of these quantities may be used to obtain the third. Data may be collected in the most expedient manner and the results expressed as both incidence and prevalence [7, p. 707].

At the core of these interrelationships is the assumption that the population is "steady" or "stationary" [1, 2, 7, 8, 16, 17, 21, 24]. For a population in a steady state, the immigration rate into the candidate pool equals the emigration rate from the candidate pool, so that the size of the candidate pool is constant over time. Similarly, the immigration rate into the prevalence pool equals the emigration rate from the prevalence pool, so that the size of the prevalence pool is constant over time. A corollary of these conditions is that the distribution of survival of incident cases remains constant. A practical consequence is that if the population is in a steady state, then estimates of disease incidence are not dependent upon the time period of the study. In a steady-state population, the prevalence odds (PO) equals the product of incidence density (ID) and the average duration ($\overline{D}$)

Table 1 Estimation of relative effects in incident and prevalent case–control studies

Frame A: Hypothetical data from an incident case–control study:

	Exposed	Unexposed	
Cases	50	50	
Controls	100	900	$OR = 9.0$

Frame B: Hypothetical data from a prevalent case–control study, where 50% of all cases do not survive long enough to be included in the study. Survival, however, is unrelated to exposure status:

	Exposed	Unexposed	
Cases	25	25	
Controls	100	900	$OR = 9.0$

Frame C: Hypothetical data from a prevalent case–control study, where 50% of exposed cases do not survive long enough to be included in the study. Survival is therefore related to exposure status:

	Exposed	Unexposed	
Cases	25	50	
Controls	100	900	$OR = 4.5$

Frame D: Hypothetical data from a prevalent case–control study, where 50% of unexposed cases do not survive long enough to be included in the study. Survival is therefore related to exposure status:

	Exposed	Unexposed	
Cases	50	25	
Controls	100	900	$OR = 18.0$

of the illness or condition (see Appendix A). If this relation is calculated for the exposed and unexposed segments of the population (with a subscript 1 indicating exposure and a subscript zero indicating nonexposure), then the prevalence odds ratio (POR) is

$$POR = \frac{PO_1}{PO_0} = \frac{ID_1 \times \overline{D}_1}{ID_0 \times \overline{D}_0} = IDR \times \frac{\overline{D}_1}{\overline{D}_0}. \quad (1)$$

In a case–control study with prevalent cases, the prevalence odds ratio (POR) estimates the incidence density ratio (IDR) if the population is in a steady state, and if the duration of disease among the exposed equals the duration of disease among the unexposed, that is, if survival is not related to an etiologically important factor (as in Table 1, Frame B).

Example 1: Nosocomial Infections

Freeman and his coauthors have used data from a "bed-to-bed" prevalence survey at a municipal hospital to illustrate the relations between prevalence and incidence [7, 8] and to study predictors of nosocomial infection [9–11]. They argue that it is reasonable to expect a hospital population to be in a steady state. Moreover, since admission, discharge, and occupancy data are collected daily, the conditions underlying a steady state can be empirically checked.

Data from their report on risk factors for nosocomial infection [9] are reproduced in Table 2, Frame A. Suppose the data represent a complete **cross-sectional** survey, and, for illustrative purposes, that the relation between use of an endotracheal tube and nosocomial infection is unconfounded. We can compute the prevalence ratio (PR) and the prevalence odds ratio (POR).

Table 2 Prevalence data on the relation between the need for an endotracheal tube and nosocomial infection

Frame A: Prevalence survey data:[a]

	Need for an endotracheal tube	
	Present	Absent
Nosocomial infection		
Present	7	90
Absent	4	544
$POR = 10.6$		

Frame B: Prevalent case–control data, with 50% sampling of controls:

	Need for an endotracheal tube	
	Present	Absent
Nosocomial infection		
present	7	90
absent	2	272
$POR = 10.6$		

[a]The data are from [9, Table 1, p 814].

The $PR = [7/11]/[90/634] = 4.5$; the $POR = [7/4]/[90/544] = 10.6$. While both point estimates are large, the POR is not a good estimate of the PR because the overall prevalence is not low (15%) and the exposure rate in the noncases is less than half the exposure rate in the total population surveyed (0.7% and 1.7%, respectively).

Table 2, Frame B shows data from a potential case–control study drawn from this prevalence survey. Suppose, for example, that determination of the exposure status of the 645 subjects was expensive. For efficiency, the exposure status could be determined for all cases and for a 50% sample of controls (again assuming no confounding). Since the parameter of interest is the *POR* (because of its relation to the *IDR*), the controls are drawn from the noncases. The *POR* of 10.6 will be a valid estimate of the incidence density ratio *if*:

1. the hospital population is in a steady state, i.e. if "the rate at which patients were admitted equaled the rate at which they were discharged, and the rate at which patients acquired active nosocomial infections and entered the prevalence pool equaled the rate at which they left the prevalence pool through recovery, death, or discharge ... [and] the rates at which new patients entered the hospital and new infections were acquired were ... constant ... [and the] distributions of durations of hospitalization and durations of infections were also ... constant" [11, p. 734]

and

2. the duration of nosocomial infection is equal for those who acquire an infection and have had an endotracheal tube and those who acquire an infection and have not had an endotracheal tube, i.e. that the exposure is not associated with the duration of the disease.

Freeman & McGowan [9, p. 815] report that the duration of nosocomial infection in the incident cases did not differ by the need for an endotracheal tube. The duration of infection was estimated from durations-to-date in the prevalent cases (the time from the onset of the infection to the time of the prevalence survey). Suppose, however, for illustrative purposes, that the durations of infection differed. The distribution of observed durations-to-date in the prevalent series can be converted into the distribution of durations of infection *from disease incidence* in the same steady-state population, as shown by Freeman & Hutchison [7]. In particular:

$$p_i(D) = \frac{[\overline{D}_i \times p_p(D)]}{D}, \qquad (2)$$

where

$p_i(D)$ = the proportion from the incidence series (designated by i) with duration D;
$\overline{D}_i$ = the average duration of the disease or condition from a series of incident cases;
$p_p(D)$ = the proportion from the prevalence series (designated by p) with duration D; and
D = a specific duration of the disease or condition from onset to termination of the disease or condition, or to removal from observation.

Suppose infections associated with a poor underlying condition have a longer duration than infections associated with a less serious underlying condition, and that the need for an endotracheal tube is a marker for a poor underlying condition. Table 3 (Frame A) shows hypothetical data from a prevalent case–control study, along with information on the distribution of durations-to-date for the prevalent cases, by exposure categories.

From (2) we obtain the distribution of durations from disease incidence in exposed and unexposed cases (Table 3, Frame B) up to a constant multiplier $\overline{D}_\mathrm{i}$. For example, $p_\mathrm{i}(5) = \overline{D}_\mathrm{i} \times 0.057/[\overline{D}_\mathrm{i} \times 0.057 + \overline{D}_\mathrm{i} \times 0.071] = 0.45$ for exposed cases. Using these distributions, we calculate $\overline{D}_\mathrm{i} = 7.8$ days for the group needing endotracheal tubes and 5.9 days for the group not needing endotracheal tubes (Table 3, Frame B).

A comparison of the observed distribution of durations-to-date from the prevalent series and the calculated distribution of the durations of disease in the incident series illustrates the length-biased sampling (*see* **Screening Benefit, Evaluation of**) that can occur when prevalent rather than incident cases are studied [16, 25, 29]. In particular, cases of long duration represent 71% of the prevalent series of exposed cases, but would constitute only 55% of the incident series. For the unexposed group, the cases of long duration represent 30% of the prevalent series, but would constitute only 18% of the incident series.

By using (1) and solving for the incidence density ratio, the prevalence odds ratio can be adjusted by the *inverse* average duration ratio to provide an estimate of the incidence density ratio. In particular:

$$IDR = POR \times \frac{\overline{D}_0}{\overline{D}_1}. \tag{3}$$

For the example in Table 3, the prevalence odds ratio of 10.6 can be adjusted by a factor of 0.76 to provide an estimate of the incidence density ratio of 8.0 (Table 3, Frame C).

Example 2: Neural Tube Defects

Length-biased sampling can be especially problematic in the study of risk factors for congenital malformations [12–15, 22, 28]. In principle, the goal

Table 3 Use of duration-to-date data to estimate duration of disease

Frame A: Hypothetical duration-to-date data:

	Need for an endotracheal tube	
	Present	Absent
Nosocomial infection		
present	7	90
absent	4	544
Duration		
10 days	5	27
5 days	2	63

Frame B: Calculation of distribution of duration of disease:

$p_\mathrm{i}(D) = [\overline{D}_\mathrm{i} \times p_\mathrm{p}(D)]/D$

For exposed cases:

$p_\mathrm{i}(5) = [\overline{D}_\mathrm{i} \times (2/7)]/5 = \overline{D}_\mathrm{i} \times 0.057$

$p_\mathrm{i}(10) = [\overline{D}_\mathrm{i} \times (5/7)]/10 = \overline{D}_\mathrm{i} \times 0.071$

For unexposed cases:

$p_\mathrm{i}(5) = [\overline{D}_\mathrm{i} \times (63/90)]/5 = \overline{D}_\mathrm{i} \times 0.14$

$p_\mathrm{i}(10) = [\overline{D}_\mathrm{i} \times (27/90)]/10 = \overline{D}_\mathrm{i} \times 0.03$

Distribution of duration for incidence series:

exposed cases: 5 days for 45%; 10 days for 55%

unexposed cases: 5 days for 82%; 10 days for 18%

Average duration of disease for incidence series:

exposed cases: $\overline{D}_{\mathrm{i}1} = 7.8$ days

unexposed cases: $\overline{D}_{\mathrm{i}0} = 5.9$ days

Frame C: Calculation of IDR:

$IDR = POR \times \overline{D}_0/\overline{D}_1$

$IDR = 10.6 \times 5.9/7.8 = 8.0$

would be to enroll women from the time of pregnancy and follow all of them through the termination of the pregnancy. All incident cases of malformations could be captured, and etiologic factors could be investigated. In practice, however, the situation is quite different. Women are often enrolled at the time of delivery of live or stillborn infants, so that only *prevalent cases* of malformations are available for study. Malformations at birth represent the *survivors* of early pregnancy, a time during which spontaneous and induced abortions occur, both of which are more likely in the presence of fetal malformations [13, 14, 22, 27, 31, 33]. If the duration of survival (early pregnancy loss versus survival to birth) is associated with an etiologically relevant factor, then the estimate of effect using only birth data will be biased because of either a toxic or a protective effect of the exposure on the fetus during the early prenatal period [13, 14, 22].

Consider the example of neural tube defects (NTDs), which include anencephaly, spina bifida, craniorrhachischisis, and iniencephaly. Leaving aside the issue of early spontaneous abortions [34], over the last two decades prenatal screening for these malformations has increased, and as a result, induced abortions post screening have also increased [30, 33]. Prevalent cases of NTDs at birth may thus be systematically different from incident cases with respect to any etiologic factor that is associated with obtaining prenatal screening and acting on the results of the screen. Velie & Shaw [32] demonstrate the magnitude of this bias by comparing the estimates of effect for a number of variables from a typical birth prevalence case–control study and from a case–control study that is more "incident-like" in that cases from induced abortions are included along with cases ascertained at birth. For illustrative purposes, we consider estimates of the effect of folic acid use on the occurrence of NTDs. Table 4 presents data adapted from Velie & Shaw [32].

Data from the prevalence case–control study show a strong protective effect of folic acid on the prevalence of NTDs, $POR = 0.37$. When the study is broadened to include early fetal deaths due to induced abortions following screening for NTDs that have been excluded from the birth prevalence study, the protective effect of folic acid remains, but it is considerably attenuated, $POR = 0.61$. The reason for this attenuation is that folic acid use is strongly and negatively associated with the odds of surviving early pregnancy and thereby being available for inclusion in the prevalence at birth study ($OR = 0.24$). Folic acid use may be associated with early prenatal care, which itself is associated with prenatal screening; and prenatal screening is associated with termination of affected fetuses.

The availability of data from "incident-like" and prevalence studies from the same population, in which the duration of survival is associated with a number of potential etiologic factors, allows for a demonstration of the way length-biased sampling can bias the estimate of effect. In particular:

1. From Eq. (1), $POR = IDR \times \overline{D}_1/\overline{D}_0$, the duration ratio can be estimated to be 0.61.
2. Alternatively, (4) below (from Freeman & Hutchison [8]) can be used to estimate the duration ratio:

$$\frac{\overline{D}_{i1}}{\overline{D}_{i0}} = \frac{[\pi_p(1)/\pi_i(1)]}{[\pi_p(0)/\pi_i(0)]}, \tag{4}$$

where

$\overline{D}_{i1}$ = the average duration of the disease or condition from a series of incident cases from the exposed group;
$\overline{D}_{i0}$ = the average duration of the disease or condition from a series of incident cases from the unexposed group;
$\pi_p(1)$ = the proportion of exposed cases in a prevalence series;
$\pi_p(0)$ = the proportion of unexposed cases in a prevalence series;
$\pi_i(1)$ = the proportion of exposed cases in an incidence series; and
$\pi_i(0)$ = the proportion of unexposed cases in an incidence series.

Again, the duration ratio would be estimated to be 0.61. From this calculation, the POR of 0.37 can be adjusted by the inverse duration ratio of 1.65 to obtain an estimate of the IDR of 0.61.

For this last sequence of calculations, information about the exposure frequency of the prevalent cases might be obtained from data on hand. A series of potential exposure frequencies of the *un*observed incident cases could be postulated, based on the best available extra-study information. These frequencies could then be used to estimate a range of plausible

Table 4 Prevalence and "incidence-type" data on the relation between folic acid and neural tube defects (NTDs)[a]

Frame A: Prevalent case–control data (cases from still and livebirths only):

	Folic acid use	
	Yes	No
Cases	151	164
Controls	374	149

$POR = 0.37$

Frame B: "Incidence-type" case–control data (cases from electively aborted fetuses as well as still and livebirths):

	Folic acid use	
	Yes	No
Cases	319	207
Controls	374	149

$POR = 0.61$

Frame C: The association of survival and exposure:

	Folic acid use	
	Yes	No
Survival to birth		
Yes	151	164
No	168	43

$OR = 0.24$

[a]Data are adapted from [32, Tables 2 and 3, pp. 476–477].

duration ratios. These ratios could then be used to produce a band of plausible incidence density ratios. The main purpose of this exercise would be to show the sensitivity of the observed POR to length-biased sampling when the potential etiologic factor under investigation could plausibly be related to survival.

Separating Prevalence- and Incidence-Based Studies

We have illustrated some of the relations between estimates based on prevalence data and those based on incidence data when the steady-state assumption holds [7, 8]. Provided exposures are not strongly related to survival, the calculations suggest that qualitative conclusions from prevalence studies will often agree with those from incidence-based data. Experience confirms this expectation. Yet, in "strict logic, ... there is no reason why [incidence based and prevalence based studies] should yield even qualitatively similar results" [5, p. 524].

Neyman illustrates this point with hypothetical data which he describes as "somewhat implausible" [19, p. 404]. Using only prevalent cases to study the relation between smoking and lung cancer, it is possible that a positive association in the prevalent series could mask a protective effect in the population as a whole, if the majority of cases in nonsmokers were highly lethal and therefore did not survive long enough to be included in the prevalence study. However implausible the substance of this example, the point is that in such situations the duration of survival will be strongly associated with the exposure and thereby bias the POR as an estimate of the IDR. In principle, the bias may be so large as to reverse the direction of the effect.

The plausibility of "balancing" or "off-setting" effects of a potential risk factor among a segment of the population that does not survive long enough to be eligible for prevalence studies has been examined in detail in the study of risk factors for congenital malformations [13, 14, 22]. Evidence for potential teratogens typically comes from studies of livebirths, which involve prevalent cases. However, the object of these studies is to discover the potential teratogenic effects on *all* the products of conception, in principle, through incident cases. The results from studies of livebirths may not agree *even qualitatively* with results applicable to all conceptuses. For example, regarding the relation between maternal cigarette smoking and the occurrence of Downs syndrome, Hook & Regal [14] have shown that an apparent protective relative effect as low as 0.3 among livebirths could be consistent with a null effect among all conceptuses if smoking increased the risk of embryonic and fetal deaths by a factor of only 1.1. Regal & Hook [22] provide general formulas for estimating the magnitude of effect on embryonic and fetal deaths that could account for the observed effect in livebirths. Hook & Regal [13] also describe the following variant of the "Yule–Simpson" paradox (*see* **Simpson's Paradox**). The relative exposure effects can be protective among embryonic and fetal deaths and protective among livebirths, yet among all conceptuses the effect is null. Alternately, the exposure can increase the risk both among embryos and fetuses who died and among livebirths, yet among all conceptuses the exposure effect is null. (This situation is statistically similar to confounding, but it is substantively distinct since the "confounding" variable is duration of survival.) Appendix B contains an example of data embodying the "Yule–Simpson" paradox. Hook & Regal [14] develop the concept of a "boundary value", namely a value such that if the observed risk from a suspected teratogen derived from a prevalent series of livebirths exceeds this value, then the explanation of the finding is unlikely to be due solely to selection factors related to the exclusion of cases that did not survive long enough to be included in the prevalence study. The boundary value is a function of the following: the proportion of unexposed subjects that do not survive to be included in the prevalence study; the proportion of unexposed cases that do not survive to be included in the prevalence study; and the proportion of exposed subjects that do not survive to be included in the prevalence study. Where estimates of these quantities are available, a boundary value can be calculated. Tables of boundary values are given for a range of determinants.

Conducting and Interpreting Prevalence-Based Studies

Bias from the inclusion of prevalent cases is a concern when the goal of the study is to discover potential etiologic factors. In this case, if the exposure is related to the duration of survival, then a series of prevalent cases will not mirror the targeted series of incident cases. However, there are situations where etiologic research is not the goal [18]. At times one may be mainly interested in factors that influence disease *prevalence*. The question, for example, may not be, "What factors *cause* infection in neonatal intensive care units (NICUs)?" but rather, "What factors *predict* the number of NICU beds needed to treat the infections that occur?" Concern with length-biased sampling is central to the etiologic question, but irrelevant for estimating factors that influence prevalence. For determining required medical services, the prevalent series is the direct research target; it is not intended to duplicate the incidence series.

The assumption of steady-state conditions is import ant for both descriptive and etiologic research with prevalent cases. If a population is in a steady state, then the size of the prevalence pool is constant. In this case a prevalence-based study of service needs at time t will be applicable to $T > t$, provided the population remains in a steady state. For etiologic research, the steady-state assumption underlies the conversion formulas presented by Freeman & Hutchison [7, 8]. While the assumption of steady-state conditions may well be "unrealistic in a literal sense, it [may well] be approximately true in many applications" [2, p. 194]. For example, in a steady-state population, there should be "a stable pattern in terms of how disease gets diagnosed," [6, p. 1110], and treatment should be reasonably stable. Medical advances that change the way a disease is diagnosed or treated will perturb, at least temporarily, the steady state of the population. Studies done with prevalent cases during the early introduction of AZT for the treatment of AIDS, or with livebirths following the introduction of prenatal screening, can

be misleading. For more detailed arguments regarding the difficulties of studying the risk factors for AIDS in a setting of changing criteria for diagnosis and methods of treatment, see Brookmeyer & Gail [4]. Hook & Regal [12–14, 22] offer cautions concerning the effects of changing prenatal practices on the study of risk factors for congenital malformations.

When the assumption of a steady-state population is plausible, the formulae from Freeman & Hutchison [7, 8] can be used to convert information obtained from prevalence studies to estimates that would result from incidence studies from the same population. The formulas are applicable where exposure–outcome relations are either unconfounded or can be conveniently stratified on confounders. Begg & Gray [2] have developed **multivariate** methods and proposed **quasi-likelihood** estimates for bias correction that can be obtained using GLIM with a log link function and a **gamma** error distribution. (When the exposure is dichotomous, and there is no confounding, the correction factor proposed by Begg & Gray reduces to the inverse duration ratio as described by Freeman & Hutchison [7, 8].)

When a population is in a steady state (or stationary), the size of the candidate pool and the prevalence pool are constant, and the age distribution of the population is stable [1, 2, 7, 8, 16, 17, 21, 24]. The population, or segment of the population considered, is not growing. Alho [1] considered the basic relation examined by Freeman & Hutchison [7, 8] and Begg & Gray [2] in the more general situation where the size of the population is either increasing or decreasing, that is, a situation where the population is "stable" but is not "stationary" or in a "steady state". Under this situation, when, for example, incidence is increasing with age and duration of disease is declining with age, the standard relation of the prevalence odds as the product of incidence density and average duration of disease will be an overestimate. Instead, the prevalence odds will equal "a weighted average of the age specific products of incidence and (discounted) expected duration" [1, p. 587] (*see* **Incidence–Prevalence Relationships**).

Suppose that a population (or a segment of a population) can be assumed to approximate a steady state, such that the relations described by Freeman & Hutchison [7, 8] and Begg & Gray [2] hold. In this case inferences about incidence densities can be made from either incidence- or prevalence-based studies. Begg & Gray [2] have compared the relative efficiency of prevalence studies to incidence studies, where the determinants of efficiency included the proportion of cases in the sample, the exposure frequency among controls, the true relative effect, and the duration of disease ratio. There was substantial variation in the relative efficiency of the prevalence-based study compared with the incidence-based study over a wide range of these determinant values. However, the authors conclude that

> for less extreme configurations [of the determinants of efficiency], the relative efficiency ranges from about 50% to 90%, so that an approximate rule of thumb is that on average, to achieve comparable precision, a prevalence study will require about three subjects for every two in an incidence study [2, p. 194].

While a prevalence-based study should be larger than the corresponding incidence-based study, it may be easier and less costly to enroll prevalent cases. However, the concerns about the precision of the study should always be subordinated to concerns about the validity of the study. Moreover, the validity of the study based on prevalent cases and aimed at etiologic investigation will depend on two factors: (i) the feasibility of obtaining accurate duration-to-date information on the duration from the onset of disease to the enrollment in the prevalence study, and (ii) the plausibility that the population (or population segment) approximates the steady-state requirements.

Conclusion

Examples from research on plausible teratogens highlight the importance of considering the possibility that prevalent studies can yield misleading estimates of exposure effects on incident disease. A comment from Sartwell & Merrell [26, p. 583] broadens this concern beyond studies that are traditionally described as "prevalence based":

> While the foregoing illustrations have dealt with limitations of prevalence and mortality rate, the interpretation of observed incidence rates also offers a challenge. What is actually obtained may more properly be termed a discovery rate, which may be quite different from the true incidence rate. Of the

cases with onset in any time period, some will be discovered early, others late, perhaps at death, and still others will escape recognition entirely. Thus, the discovery rate of any period will include cases with onsets covering a long time span, and moreover will be influenced by the clinical level at which cases are recognized.

Sartwell & Merrell [26] remind us that even a typical incidence series may well contain a trace of prevalence. To the extent that any survival (or persistence) criterion is required to allow the diagnosis of a disease, estimates of exposure effect may be distorted, as in the prevalent case–control study.

Appendix A: Derivation of $PO = ID \times \overline{D}$

Prevalence (P), incidence density (ID), and average duration ($\overline{D}$) are readily linked when the population is in a "steady state" [1, 2, 7, 8, 16, 17, 21, 24]. In a steady state the number of people entering the prevalence pool from the population at risk is equal to the number of people exiting the prevalence pool, through recovery or death.

At any time, the total population (N) can be divided into those individuals who have the disease (P) and those who are at risk for the disease ($N - P$). Entry into the prevalence pool is governed by the size of the population at risk ($N - P$), the rate of disease (ID), and the time period (δt) such that

$$\text{inflow} = ID \times \delta t \times (N - P).$$

Exit from the prevalence pool is governed by the size of the prevalence pool (P), the exit rate (ID_{exit}), and the time period (δt) such that

$$\text{outflow} = ID_{\text{exit}} \times \delta t \times P.$$

In a steady state, any rate is equal to the reciprocal of the average time to the event. Therefore, $ID_{\text{exit}} = 1/\overline{D}$, where $\overline{D}$ is the average duration of disease. In a steady state, inflow (to the prevalence pool) equals outflow (from the prevalence pool). Therefore

$$ID \times \delta t \times (N - P) = \frac{1}{\overline{D} \times \delta t \times P}.$$

By algebraic manipulation:

$$ID \times \overline{D} = \frac{P}{(N - P)} = PO.$$

Appendix B: Hypothetical Data Embodying the "Yule–Simpson" Paradox

The data in this appendix are from [13, Table 2, p. 56].

Stratum 1: Embryonic and fetal deaths

	Exposed	Unexposed	Total
Downs syndrome	732	1251	1983
Unaffected	58 359	89 658	148 017
All	59 091	90 909	150 000

Relative risk of Downs syndrome = 0.9

Stratum 2: Livebirths

	Exposed	Unexposed	Total
Downs syndrome	213	637	850
Unaffected	274 029	575 121	848 150
All	274 242	575 758	850 000

Relative risk of Downs syndrome = 0.7

Total population: All (recognized conceptuses)

	Exposed	Unexposed	Total
Downs syndrome	945	1888	2833
Unaffected	332 388	663 834	997 167
All	333 333	666 667	1 000 000

Relative risk of Downs syndrome = 1.0

Case–Control Study, Sequential

Many **case–control studies** are based on previously identified cases and **controls**, together with their information on exposure and **confounders**. Some studies, however, require that data on newly **incident cases** and controls be collected and accumulated prospectively, not unlike the data collection for a controlled **clinical trial**. For example, when a new drug or exposure is introduced into a population, there may be no medical database (*see* **Administrative Databases**) or method to link records (*see* **Record Linkage**) to determine exposure and case status. When a concern exists about risk associated with these exposures and a case–control design is capable of addressing the issue, the conduct of a case–control study to evaluate and test the hypothesis requires the accumulation of new records and exposure information.

In these situations an investigator may wish to test the hypothesis (*see* **Hypothesis Testing**) repeatedly as the data accumulate in order to reduce the average sample size required by the study and obtain results sooner. Sequential case–control designs (*see* **Sequential Analysis**) are proposed first, to take account more efficiently of the accumulating collection of exposure data on cases and controls and, thus, decide when sufficient data are in hand to address the question and, secondly, to preserve the integrity of the **inferences** drawn from case–control studies when these studies are repeatedly analyzed as data accumulate.

The statistical methods developed for monitoring randomized clinical studies (*see* **Data and Safety Monitoring**) can be applied to the analysis of accumulating data in matched or unmatched case–control designs, and to the repeated analyses of measures of **association**, such as the **odds ratio** or **relative risk**. In a clinical trial, ethical concerns usually drive the need to terminate a study early in order to minimize exposure of study subjects to harmful treatments (*see* **Ethics of Randomized Trials**). The ethical concerns are different for case–control studies, but there may be ethical motivations for trying to terminate a case–control early. For example, a case–control study may be used to identify or confirm an important risk that requires expeditious public health policy decisions.

Sequential methods can also be used to continue accumulating data until the odds ratio has been estimated with acceptable precision. In this article, we concentrate on hypotheses testing, though we discuss applications to sequential **estimation**.

Implementing the Sequential Approach

The following discussion is based upon O'Neill & Anello [13]. Assume that an investigator is interested in studying whether or not there is an increased risk of an adverse outcome (cases) associated with exposure to a specified factor. Assume that there is a mechanism for uniformly identifying and collecting cases with the adverse outcome from a defined population and then, according to predetermined criteria, **matching** each case with respect to a matching variate to a control (person without the adverse outcome) at the time the case becomes available. Furthermore, assume that there is a mechanism for identifying in an unbiased manner the exposure to a risk factor for both case and matched controls. Thus, case and control matches become available over time, and at any point in time T a cumulative set of N_T cases and their matched controls is available. While it is not necessary that all cases be matched to the same number of controls, the example we provide assumes a constant matching ratio for ease of exposition. We will also assume that the relative risk is constant and independent of the matching variables and/or other covariables.

For one-to-one matching, the information is in the case–control pairs that are discordant with respect to the presence or absence of the risk factor. For multiple matching on **confounding** variables, the situation is somewhat more complex (e.g. [6]).

We illustrate two sequential designs with one-to-one matching. The first design monitors outcomes after each case–control pair is ascertained and uses the Wald [21] sequential probability ratio test (SPRT). The second design analyzes the data after successive groups of matched pairs have been accrued and is based on the theory of repeated significance testing for group sequential data. The group sequential approach can also be used for multiple-matched and unmatched case–control designs, as discussed in Pasternack & Shore [14, 15].

The Wald SPRT for a One-to-One Matched Design

For the ith case–control pair, let Y_{11} denote the exposure value (1 if exposed, 0 otherwise) assumed by the case and Y_{21} denote the value assumed by the control. For the ith case–control pair, let $P_{1i} = \Pr(\text{case is exposed to the factor under study})$ and $P_{2i} = \Pr(\text{control is exposed to the factor under study})$. The data from N matched case–control pairs may be summarized as in Table 1, where Z_{11} denotes the number of pairs in which both case and control are exposed, Z_{10} the number of pairs where only the case is exposed, and so forth.

In an individually matched retrospective case–control study, the **maximum likelihood** estimate of relative risk ρ is based upon the pairs with discordant exposure and is given by $\rho = Z_{10}/Z_{01}$. Thus, the effective sample size for **interval estimation** of ρ is $Z_{10} + Z_{01} = n$. In testing whether this estimate of the relative risk differs significantly from one, attention is restricted to the discordant pairs. In the ith such pair, the probability that the case is exposed and the control is not exposed is

$$\pi_i = \frac{P_{1i}(1 - P_{2i})}{P_{1i}(1 - P_{2i}) + (1 - P_{1i})P_{2i}}. \qquad (1)$$

The relative risk is $\rho = \pi/(1 - \pi)$ and is assumed constant for all pairs. The test of whether ρ differs significantly from one is equivalent to testing whether the conditionally **binomial** variate Z_{10}, based on n observations, has probability $\pi = \frac{1}{2}$ against an alternative that $\pi \neq \frac{1}{2}$.

To carry out the SPRT, it is essential that one specifies two simple hypotheses before the data are collected. That is, one specifies that the **null hypothesis** is $\rho_0 = 1$ and chooses a value of ρ for the alternative hypothesis H_1, call it ρ_1, which is of interest to detect. Furthermore, one must specify the type I and type II errors, α and β, respectively. Since we choose to examine the one-sided test in which the alternative of the form $\rho > 1$ is of interest (*see* **Alternative Hypothesis**), the SPRT tests the null hypothesis that $H_0 : \rho = 1$ vs. $H_1 : \rho = \rho_1$, which is equivalent to $H_0 : \pi = \frac{1}{2}$ vs. $H_1 : \pi_1 = \rho_1/(1 + \rho_1)$.

Table 1 Summary of data from N matched case–control pairs

		Control (Y_2)		
		1	0	Total
Case (Y_1)	1	Z_{11}	Z_{10}	Z_1
	0	Z_{01}	Z_{00}	$N - Z_1$
	Total	Z_2	$N - Z_2$	N

The SPRT is carried out as each case–control pair becomes available over time. The cumulative number of cases exposed to the factor, Z_{10}, among the subset of n exposure-discordant pairs is then compared with two parallel boundaries (see [13, Appendix A]). Crossing one boundary causes rejection of H_0 and crossing the other causes rejection of H_1.

The Group Sequential Design for a One-to-One Matched Design

Rather than analyze the data after each matched pair accrues, one can perform only K analyses after successive groups of M discordant pairs have accrued, giving rise to a maximum total sample size of $KM = N$ discordant pairs. Pasternack & Shore [16] described this group sequential approach for repeated tests of a hypothesis. The approach is based on the sequential use of the signed square root of the **McNemar test** statistic χ for accumulating discordant case–control pairs, namely

$$\chi_k^2 = \frac{(|Z_{10} - Z_{01}| - 1)^2}{Z_{10} + Z_{01}}. \qquad (2)$$

While we emphasize this application, one could also use the estimate of the log odds ratio from the conditional logistic model (*see* **Logistic Regression, Conditional**) divided by its **standard error**.

Letting χ_k denote the signed square root of (2) after k groups, the decision rule for the kth ($1 \leq k \leq K$) group sequential test of $\rho = 1$ vs. $\rho \neq 1$ is

1. If $\chi_k > Z_\alpha$ reject the null hypothesis that $\rho = 1$ in favor of the alternative, $\rho \neq 1$; then no additional accumulation of data is required.
2. (i) If $\chi_k < Z_\alpha$ and $k < K$, accumulate additional discordant pairs and then apply the $(k + 1)$th group sequential test.
   (ii) If $\chi_k < Z_\alpha$ and $k = K$, end the study and do not reject the null hypothesis that $\rho = 1$.

Note that Z_α is a constant in this "repeated testing design". To control the overall type I error at α, Z_α at each interim analysis will need to be adjusted.

For example, for planned three-group sequential analyses controlled at $\alpha = 0.05$, $Z_\alpha = 2.289$, corresponding to a nominal $\alpha' = 0.022$ for each analysis (see Pocock [17, Table 2]). Other group sequential designs, referred to in the discussion section, allow for varying the boundary with k.

A Comparison of Sample Sizes for Fixed and Sequential Designs

One of the main benefits of a sequential design is that fewer observations are needed on average than for a fixed sample size plan to reject the null hypothesis when the alternative hypothesis is true, thereby being a more efficient design by offering the chance of yielding a conclusion before the final fixed sample size is needed. The difference in sample size needed for the fixed and sequential designs for the one-to-one individually matched design method was described by O'Neill & Anello [13] for the SPRT, and by Pasternack & Shore [16] for the group sequential designs using repeated significance-testing methods.

For the SPRT, formulas exist [13, Appendix A] to calculate the average number of exposure discordant pairs needed to arrive at a decision when the null and alternative hypotheses are assumed true and for a value of ρ; namely, $\overline{\rho}$, midway between ρ_0 and ρ_1. These sample sizes can be compared with those needed in a fixed sample design. Table 2, adapted from O'Neill & Anello [13], presents the average number of exposure discordant pairs required in a SPRT and fixed sampling design for selected protocol parameters. The SPRT offers a substantial advantage in average required sample size, although there is no upper limit on the sample size.

For the group sequential designs based upon repeated significance testing, one can calculate the maximum sample size N needed and the average sample size $\overline{N}$ needed for a prespecified number, K, of interim analyses of accruing case–control exposure discordant pairs. This calculation depends on the number of interim analyses, K, or independent groups of exposure discordant pairs, planned in advance, and on the per-test significance level α' and its corresponding **standard normal deviate** Z for use in normal group sequential testing ([16, Table 2]). Table 3, extracted from Pasternack & Shore [16], who provide further discussion of the calculations, presents a comparison of the number of discordant pairs needed for the group sequential design relative to a fixed sample plan for a two-sided hypothesis test. For example, for $\rho = 2$, the fixed sample plan ($K = 1$) requires $N = 91$ pairs, compared with an average of only 64 pairs with $K = 4$. Note, however, with $K = 4$, the maximum trial size, 108, exceeds the fixed sample size, 91.

Table 2 Average number of exposure discordant pairs for SPRT and fixed sample designs, for selected relative risk $\rho : \alpha = 0.05, \beta = 0.10$ (one-sided)[a]

	$\rho = 2$			$\rho = 3$		
Fixed plan	73			30		
SPRT	H_0	H_1	H_ρ^-	H_0	H_1	H_ρ^-
	34	42	56	14	18	23

[a]Extracted from O'Neill & Anello [13]

Table 3 Comparison of the number of discordant pairs needed for the group sequential design relative to a fixed sample plan for a two-sided hypothesis test: $\alpha = 0.05$, $\beta = 0.10$ (two-sided). N = Maximum number of discordant pairs per group; $\overline{N}$ = Average number of discordant pairs per group[a]

Number of interim analyses (groups)	$\rho = 2$		$\rho = 3$	
K	N	$\overline{N}$	N	$\overline{N}$
1	91	91	38	38
2	100	71	42	30
3	105	66	45	28
4	108	64	44	27

[a]Extracted from Pasternack & Shore [16].

In Tables 2 and 3, the sample sizes presented for the average number of discordant pairs using the SPRT, the group sequential design, and the fixed sample design need to be adjusted to arrive at the expected total number of pairs required. To make the adjustment, one needs to divide the sample sizes in Tables 2 and 3 by the probability of obtaining a discordant pair, which is

$$Y = P_1(1 - P_2) + P_2(1 - P_1). \tag{3}$$

values for which are provided in [13, Table 3].

Discussion

To date, there are few examples of sequentially designed and analyzed case–control studies, though there are many examples of prospective collection

of exposure information on cases and controls that could easily adapt the sequential strategy. Several variants of the group sequential approach can be used for monitoring case–control studies. Rather than using the same boundary (i.e. the same nominal Type 1 error) at each interim analysis as proposed by Armitage et al. [3] and Pocock [17], we can use different critical levels for each k. For example, O'Brien & Fleming [11] proposed a monotonically decreasing set of nominal α levels, and Lan & DeMets [10] introduced a flexible method for allocating the Type 1 error over the number of testing times used. Rather than applying group sequential statistic methods to simple statistics such as the McNemar statistic, one can also use **score** statistics derived from logistic models in sequential tests, as described by Whitehead [22].

Despite the attractiveness of the group sequential design for reducing required sample sizes when performing hypothesis testing in case–control studies, we are unaware of completed case–control studies that formally use this methodology.

Only in unusual circumstances will there be a pressing need to terminate an **observational study** early, unlike a clinical trial. It may be important to obtain a large number of cases and controls to pursue analyses of the effects of confounding. Issues of data quality and case ascertainment may play a role also. For example, it may be necessary to validate exposure assessments and histopathologic diagnoses of disease. Such quality control activities may be logistically difficult to accomplish during the conduct of the sequential acquisition of cases and controls. These factors may make it more attractive to design and conduct a large fixed sample size study rather than to attempt a sequential design. However, one should be aware that if one initiates a fixed sample design but terminates the study early on the basis of interim analyses, one risks increasing the chance of type I error.

More often, an epidemiologist may be interested in obtaining a precise estimate of a risk parameter rather than in rejecting a null hypothesis expeditiously. To the extent that precise and valid estimation of exposure effects is the dominant goal of the observational study, sequential strategies may play a greater role in the future by requiring that data continue to be accrued until precise estimates of exposure risks are obtained.

Generally, sample sizes to test a hypothesis will be inadequate to provide a **confidence interval** for the odds ratio whose width is sufficiently narrow for precise estimation [12]. Many authors have considered sequential estimation procedures in a univariate and **multivariate** context, which may be relevant for the medical and public health applications for which case–control studies have found utility [1, 2, 4, 5, 7–9, 18–20].

ROBERT T. O'NEILL

Case–Control Study, Two-phase

Double sampling, also known as two-phase sampling, is a standard technique for **stratification** [23]. The investigator first draws a **random sample** from the population to measure the **covariates** needed for stratification. At phase two, random subsamples of varying size are drawn from within each stratum and the collection of data is completed for subjects selected at both phases. By using larger sampling ratios for the most informative strata, the efficiency of estimates of population parameters is enhanced.

The **case–control study** embodies a stratified sampling design where the strata depend on the outcome [5]. Case–control studies in epidemiology typically sample a large fraction of the **incident cases** of disease and a much smaller fraction of disease-free **controls** to evaluate the association between disease outcome and risk factors. This design is much more efficient than alternative **cohort** or **cross-sectional designs** for the study of a rare disease.

More complex double-sampling techniques offer the potential to enhance efficiency further and to reduce cost. White [37] proposed studying the **association** between a rare exposure and a rare disease by sampling at phase two on the basis of *both* disease and exposure status. She noted that the initial sample might itself be stratified by outcome, as in a case–control study, or not, as in a cohort or cross-sectional study. Another example of double sampling arises from studies of gene-environment interaction [1]. Efficiency is enhanced by limiting expensive genotyping to a sample stratified both by disease and by family history or a rare environmental exposure. A third example is the **validation study**. Here subsamples of cases and controls are drawn to make error-free measurements, so that parameter estimates may be adjusted for the attenuation caused by **measurement error** [9]. In all three examples, subjects not sampled for phase two have a portion of their data missing by design. There is a strong connection with the literature on **missing data** [21, 28].

This article reviews double sampling techniques for the study of **binary** outcomes, with particular emphasis on methods of fitting **logistic regression** models that appropriately utilize the data from both phases of sampling.

Stratified Sampling

Under the usual **superpopulation model**, the population from which subjects are sampled at phase one is regarded as infinite. Let S denote a **random variable** defined on this population whose values $S = j$ indicate the stratum and set $\pi_j = \Pr(S = j)$, $j = 1, \ldots, J$. Suppose for the moment that the object is to estimate the **mean** value, μ, of another random variable, U, and note that $\mu = \sum_j \pi_j \mu_j$, where $\mu_j = \mathrm{E}(U|S = j)$. Assuming that the π_j are known, appropriately **stratified sampling** yields a more informative estimate than does a **simple random sample** of like size [14].

Double Sampling for Stratification

Often the information needed for classification of population units into strata is not known in advance. Neyman [23] developed the theory of double sampling to handle this problem. At the first phase of sampling one draws a simple random sample of size N for stratum ascertainment and observes N_j, the number of sampled subjects, with $S = j$. At the second phase, subsamples of specified size n_j are drawn at random and without replacement from among the N_j in stratum j, for a total sample size of $n = \sum_j n_j$. Denote by U_{jk} the value of U for the kth subject in stratum j, $k = 1, \ldots, n_j$; by $f_j = n_j/N_j$ the known sampling fraction; and by $\overline{U}_j = n_j^{-1} \sum_k U_{jk}$ the stratum specific sample mean. With $\hat{\pi}_j = N_j/N$ and $\hat{\mu}_j = \overline{U}_j$, an obvious estimate of μ is

$$\hat{\mu} = \sum_{j=1}^{J} \hat{\pi}_j \hat{\mu}_j = N^{-1} \sum_{j=1}^{J} f_j^{-1} \sum_{k=1}^{n_j} U_{jk}. \qquad (1)$$

The Horvitz–Thompson Estimator

When regarded as an estimator of the (unknown) finite population mean of the N values of U for subjects sampled at phase one, $\hat{\mu}$ weights each of the n phase two observations by the inverse of its selection probability. This is the defining property of the famous **Horvitz–Thompson [17] estimator**. The **variance** as given in standard texts [11] is

$$\mathrm{var}(\hat{\mu}) = \frac{1}{N} \sum_{j=1}^{J} \pi_j (\mu_j - \mu)^2 + \sum_{j=1}^{J} \frac{\pi_j^2 \sigma_j^2}{n_j}$$

$$+ \frac{1}{N} \sum_{j=1}^{J} \frac{\pi_j (1 - \pi_j) \sigma_j^2}{n_j}, \qquad (2)$$

where $\sigma_j^2 = \text{var}(U|S = j)$. The first two terms dominate under an asymptotic scheme where each of the n_j increases proportionately with N. For fixed n, efficiency is enhanced by oversampling large strata or those with large σ_j^2 since this will reduce the value of the middle term in (2).

Weighted Likelihood and the Horvitz–Thompson Estimator

In case–control studies the parameters of interest are not the mean values of random variables but rather the **regression** coefficients in probability models for the association between a binary outcome variable Y and a vector $\mathbf{X}$ of explanatory variables. Suppose that

$$\begin{aligned} \Pr(Y = 1|\mathbf{X} = \mathbf{x}, S = j) &= \Pr(Y = 1|\mathbf{X} = \mathbf{x}) \\ &= F(\mathbf{x}'\beta), \end{aligned} \qquad (3)$$

where F denotes a known cumulative distribution function. Typical choices for F are the **logistic distribution** for logistic regression and the unit **normal distribution** for probit regression. The assumption of conditional independence between Y and S given $\mathbf{X}$ means simply that any dependence of the outcome probability on stratum is modeled in $\mathbf{X}$.

Under standard regularity conditions, **likelihood** theory tells us that β satisfies the expected score equation

$$\mu(\beta) = \text{E}[\mathbf{U}(\beta)] = \text{E}\left[\frac{\partial \log \Pr(Y|\mathbf{X}; \beta)}{\partial \beta}\right] = 0, \quad (4)$$

where $\mathbf{U}(\beta)$ is defined as the term in brackets. Even if (3) does not hold, the solution to (4) defines a parameter of interest since it identifies that member of a set of hypothesized models that best describes the population association. If observations on $(Y_t, \mathbf{X}_t)$ were available for all N subjects sampled at phase one, then β would be estimated by solving the score equations $\mathbf{U}(\beta) = \sum_{t=1}^{N} \mathbf{U}_t(\beta) = 0$. In a two-phase study, the unknown $\mathbf{U}$ is estimated using (1). Thus, following Whittemore [38], we define the Horvitz–Thompson estimator, $\hat{\beta}$, as the solution to the Horvitz–Thompson estimating equations

$$\hat{\mathbf{U}}(\beta) = \sum_{j=1}^{J} f_j^{-1} \sum_{k=1}^{n_j} \mathbf{U}_{jk}(\beta) = 0, \qquad (5)$$

where $\mathbf{U}_{jk}(\beta)$ denotes the **score** for the kth subject sampled from stratum j. The **consistency** and asymptotic normality of $\hat{\beta}$ follow from Huber's [19] theory of M-estimation. The asymptotic variance is given by the "**information** sandwich"

$$\begin{aligned} \text{var}_A(\hat{\beta}) = &\left[\frac{\partial \hat{\mathbf{U}}(\beta)}{\partial \beta}\right]^{-1} \\ &\times \text{var}_A[\hat{\mathbf{U}}(\beta)] \left\{\left[\frac{\partial \hat{\mathbf{U}}(\beta)}{\partial \beta}\right]'\right\}^{-1} \Bigg|_{\beta=\hat{\beta}}, \end{aligned} \qquad (6)$$

where the middle expression is obtained by extending (2) to vector-valued random variables.

The Horvitz–Thompson estimator and its analog have a long history. In econometrics it is known as the weighted exogenous sampling **maximum likelihood** estimator [22]. A finite population version was studied by Binder [4] and Chambless & Boyle [12]. Others have referred to the weighted likelihood method as **pseudo-likelihood** [15, 20], and mean score [25].

Two-phase Case–Control Studies

The distinguishing feature of a case–control study is that the variables used for stratification and sample selection include the outcome (case–control) status. Were this not the case, and the sample was stratified using explanatory variables alone, standard methods of binary regression analysis could be used to estimate the regression coefficients in the model (3). Such methods generally yield biased estimates, however, when applied to case–control data. Horvitz–Thompson **estimation** solves the **bias** problem.

Population-based Case–Control Samples

Suppose the population from which the cases and controls are sampled has been completely enumerated and that disease status Y and stratum S are known for everyone. This (finite) population may itself then be regarded as the preliminary random sample in the two phase design. Since the sampling fractions are known for both cases and controls, no restrictions need be placed on F and both **absolute** and **relative risk** parameters may be estimated [3].

To apply the Horvitz–Thompson estimator to **population-based case–control studies**, we extend the notation to allow the phase one strata to depend on both Y and S. Thus, denote by N_{1j} the number of cases ($Y = 1$) and by N_{0j} the number of controls ($Y = 0$) with $S = j$ at phase one, and let n_{ij} denote the numbers in the corresponding subsample at phase two. The Horvitz–Thompson estimator is the solution to

$$\hat{\mathbf{U}}(\beta) = \sum_{i=0}^{1} \sum_{j=1}^{J} f_{ij}^{-1} \sum_{k=1}^{n_{ij}} \mathbf{U}_{ijk}(\beta) = 0, \qquad (7)$$

where now $f_{ij} = n_{ij}/N_{ij}$ and $\mathbf{U}_{ijk}(\beta)$ denotes the likelihood score for the kth subject in stratum (i, j).

Separate Preliminary Samples of Cases and Controls

More typically, a complete enumeration of the population at risk is not available, and one simply samples controls from the same communities or hospital service areas in which the cases arose. Then the appropriate model treats the phase one subjects as separate random samples of N_1 cases and N_0 controls. Since the case and control sampling fractions are not known, the only quantities that may be estimated **consistently** are **odds ratio** (**relative risk**) parameters in "multiplicative intercept" models [18]. Attention is confined here to the logistic model $F(x) = 1/(1 + \mathrm{e}^{-x})$. Provided that the linear predictor $x'\beta$ includes a constant term β_0, the remaining βs represent log relative risks that are in principle estimable from the case–control sample. The logistic scores appearing in (7) are given by $\mathbf{U}_{ijk}(\beta) = \{Y_{ijk} - 1/[1 + \exp(-\mathbf{X}'_{ijk}\beta)\}\mathbf{X}_{ijk}$.

Assume momentarily that the marginal outcome probabilities are known and set $\alpha = \log[\Pr(Y = 1)/\Pr(Y = 0)]$. If the constant term $\log(N_1/N_0) - \alpha$ is added to β_0, then the Horvitz–Thompson estimating equations (7) are unbiased for all parameters, including the intercept, and the corresponding estimator is consistent [15]. The equations are easily solved using standard programs for logistic regression by treating the inverse sampling fractions f_{ij}^{-1} as prior weights (*see* **Software, Biostatistical**). The asymptotic variance is again given by (6), except that now the middle term is estimated by

$$\sum_{i=0}^{1} \sum_{j=1}^{J} f_{ij}^{-2} \left\{ \sum_{k=1}^{n_{ij}} \mathbf{U}_{ijk}^{\otimes 2} - \frac{1 - f_{ij}}{n_{ij}} \left(\sum_{k=1}^{n_{ij}} \mathbf{U}_{ijk} \right)^{\otimes 2} \right\} - \sum_{i=0}^{1} \frac{1}{N_i} \left(\sum_{j=1}^{J} f_{ij}^{-1} \sum_{k=1}^{n_{ij}} \mathbf{U}_{ijk} \right)^{\otimes 2},$$

where $\mathbf{u}^{\otimes 2}$ for any vector $\mathbf{u}$ denotes the matrix $\mathbf{u}\mathbf{u}'$. The last expression involving the N_i, which only affects the variance of $\hat{\beta}_0$, reflects the extra information obtained by assuming α to be known and has no counterpart in (2). In practice, α is not known. Since its value only affects the free parameter β_0, however, this does not matter. One simply ignores $\hat{\beta}_0$ and its **standard error**.

Maximum likelihood estimation

Scott and Wild [31, 32] derived the nonparametric maximum likelihood estimator of regression coefficients for the population based study. Breslow and Holubkov [8, 9] derived the nonparametric maximum likelihood estimator for logistic regression coefficients for the study with separate samples of cases and controls at phase one. The two estimators are identical, and semiparametric efficient, when the binary response model (3) is specified as logistic [28]. Although they can be substantially more efficient than Horvitz–Thompson under certain conditions, in many practical settings, the loss of information is slight [7, 28, 29]. Many researchers prefer the Horvitz–Thompson approach because, at least for the **population-based study**, it provides a consistent estimator of a meaningful population parameter even if the model (3) does not hold.

Pseudo-likelihood and pseudo-score estimators

Other methods of estimation of logistic regression coefficients have been developed that are typically of intermediate efficiency. Breslow & Cain [6] and Schill and colleagues [29, 30] developed closely related pseudo-likelihood estimators, deriving unbiased estimating equations by maximization of a product of conditional probabilities. For the Breslow–Cain version one fits the logistic regression model (3) to the phase two data, using as offsets in the

linear predictor the terms $\log(n_{1j}N_{0j}) - \log(n_{0j}N_{1j})$ for observations in stratum j to adjust for the biased sampling. A matrix formula is available that corrects the usual asymptotic variance matrix to account for the additional information coming from the phase one data. The Schill version involves fitting a logistic regression model jointly to the phase one and phase two data and also requires offsets. Whenever the linear predictor contains a separate term for the main effect of each stratum, the two pseudo-likelihood estimators and the maximum likelihood estimator are identical.

Chatterjee and colleagues [13] developed an estimator they termed pseudo-score. This uses the regression model to *estimate* the scores for subjects *not* sampled at phase two more efficiently than they are estimated by the mean score method [25], which as already noted is equivalent to Horvitz–Thompson estimation in the present setting. The pseudo-score estimator has the important practical feature that it may be implemented in situations where the phase two sample consists entirely of cases or entirely of controls. This may be particularly valuable when the covariates ascertained at phase two involve an invasive medial procedure. However, because of the near impossibility of checking model assumptions from the collected data, this feature should be exploited only if absolutely necessary and then with considerable caution.

Fixed vs. Random Phase Two Sample Sizes

So far we have assumed that the sample sizes, n_{ij}, at the second phase of sampling are fixed by the investigator after considering results of the phase one data collection. An alternative sampling strategy uses a random device to decide independently for each phase one subject, using selection probabilities p_{ij} that depend on (Y, S), whether to include the subject at phase two. This is known by econometricians as Manski–Lerman [22] sampling. In the context of case–control studies, Weinberg & Sandler [35] called it the randomized recruitment method and suggested it as an alternative to **frequency matching**. Others have referred to it as Bernoulli sampling. The associated sampling theory is simplified by the fact that the phase two observations are rendered statistically independent.

Both Horvitz–Thompson and pseudo-likelihood estimation procedures may be applied to data collected in randomized recruitment designs. Instead of dividing the log likelihood contributions by the observed sampling ratios, f_{ij}, one divides by the expected ones, p_{ij}. Use of the observed ratios is also justified; just condition on the n_{ij} and use the previous theory. Both empirical [36] and theoretical [28] studies show that use of the known selection probabilities results in less efficient estimates, however, so it is best to treat the phase two sample sizes as fixed even when they are not.

An Example

Table 1 shows sample sizes at phases one and two for a study of the association of operative mortality and gender in patients undergoing coronary bypass surgery. Two different designs were used at phase two: a "case–control" design in which the subsamples of 100 cases (deceased) and 100 controls (alive) were drawn without consideration of the stratum variable gender; and a "balanced" design in which equal numbers ($n_{ij} = 50$) were drawn from within each of the four cells defined by both outcome and gender. More generally a balanced design involving n phase two subjects would set $n_{ij} = \min(n/2J, N_{ij})$. Since the "case–control" design involves sampling only with regard to outcome, fitting ordinary logistic regression models yields valid estimates of relative risk parameters [24]. Fitting of ordinary logistic regression models to data from the "balanced" design, however, results in biased estimates of the gender effect since the association between outcome and gender at phase two is completely distorted by the nonproportional sampling ratios.

Table 1 Sample sizes for a study relating operative mortality to gender for patients undergoing coronary artery bypass surgery

	Male ($S = 1$)	Female ($S = 2$)
First phase sample (N_{ij})		
Alive ($Y = 0$)	6,666	1,228
Deceased ($Y = 1$)	144	58
Second phase sample: case–control (n_{ij})		
Alive	81	19
Deceased	67	33
Second phase sample: balanced (n_{ij})		
Alive	50	50
Deceased	50	50

Table 2 reports results of estimating logistic regression coefficients for gender and other covariates by two methods: ordinary logistic regression and "adjusted" logistic regression. Since gender is included in the model, simple adjustments may be applied directly to the results from ordinary logistic regression programs to calculate the maximum likelihood estimates and their standard errors [10]. Furthermore, adjusted and unadjusted results for the covariates other than gender are identical [6]. Note the severe distortion of the gender coefficient for the unadjusted analysis of the balanced data, and the substantial reduction in its standard error, when adjustment is made for the information available at phase one. Results of fitting the same model to the entire phase one data set, for which all the covariate values were in fact known, are shown for comparison.

Efficiency Gains from Stratification

The standard errors shown in Table 2 suggest there was little benefit with these data from use of the balanced design at phase two. In other situations one should expect the balanced design to yield more **efficient** estimates of coefficients that model stratum effects and their **interactions**, at the possible cost of some mild loss of efficiency for estimates of the other covariate effects. This conclusion is based on the asymptotic efficiencies shown in Table 3 for models with a binary stratum coefficient, β_1, and a binary covariate, β_2, with and without an interaction term, β_3. The table shows results for a study where all cases identified at phase one are also used at phase two. Here the principal efficiency gain is for the interaction effect. When subsamples of both cases and controls are taken at phase two, stratum and interaction effects are both estimated more efficiently using the balanced design.

While the balanced design seems reasonable on general grounds and has good efficiency properties over a large region of the parameter space, other designs offer greater efficiency in particular circumstances [10, 16]. For the measurement error problem with Horvitz–Thompson estimation, Reilly & Pepe [25] derived expressions for the optimal sampling fractions, f_{ij}, needed for estimation of a particular regression coefficient. They presented numerical results for a logistic regression model with a single explanatory variable, X, assumed to have a **standard normal distribution**.

Table 3 Large-sample efficiencies of the balanced design relative to the case–control design when the second phase sample contains all the cases but only a fraction of the controls from the first phase sample

		Relative efficiency		
e^{β_2}	θ[a]	β_1	β_2	β_3
0.2	0.2	1.02	0.83	1.43
0.2	1.0	1.18	0.88	1.45
0.2	5.0	1.34	0.93	1.65
1.0	0.2	0.99	0.74	2.30
1.0	1.0	1.00	0.81	2.09
1.0	5.0	0.98	0.82	2.06

[a]Relative to elective surgery.

Stratification was based on a binary, S, indicating whether or not X, when measured with normally distributed error, is positive. Although intended for cohort sampling at phase one, their results apply also to the two-phase case–control study provided that the intercept parameter, β_0, is interpreted as applying to the case–control sample rather than the source population.

Table 4 shows the optimal sampling fractions for a study involving $N = 500$ phase one subjects, 25% of whom are to be selected for the validation sample at phase two. Note that the balanced design here is optimal only when $\beta_0 = \beta_1 = 0$. As with all design problems, the optimal sampling fractions depend on the values of unknown parameters, so that prior information or a good guess is needed to achieve near optimality. Holcroft and Spiegelman [16] used numerical methods to determine optimal sampling fractions when regression parameters are estimated by maximum likelihood.

In addition to varying the sampling fractions used for the selection of the phase two sample, efficiency may be further increased by posthoc stratification in the analysis of the data [7]. The stratum factor S is constructed to represent combinations of levels of any covariate factors available at phase one, not just those used to stratify the sampling. The main limitation is the necessity for each stratum to contain both cases and controls at phase two, which means that continuous valued covariates available for all subjects cannot be utilized fully. Since the phase one data enter the Horvitz–Thompson estimation procedure only through the sampling ratios f_{ij}, post hoc stratification increases the amount of phase one information that is actually used in the analysis. This information is of particular value when stratification is based on surrogate explanatory variables that are highly correlated with those used in the regression model.

Table 4 Optimal sampling fractions f_{ij} when $\sigma = 0.25$[a]

(β_0, β_1):	(0,0)	(0,1)	(0,2)	(1,0)	(1,1)	(2,2)
f_{01}	0.25	0.46	0.12	0.28	0.11	0.21
f_{02}	0.25	0.47	0.52	0.61	0.75	0.80
f_{11}	0.25	0.17	0.54	0.43	0.72	0.56
f_{12}	0.25	0.17	0.12	0.04	0.11	0.06

[a]σ = standard deviation of measurement error distribution.

Other Complex Sampling Designs

Whittemore [38] studied Horvitz–Thompson estimation for designs with three or more sampling phases based on nested partitions of the sample space into increasingly fine strata. Noting that the selection probabilities for observations with complete covariate data were given by products of the inverse sampling fractions at each phase, she derived an explicit expression for the variance of the scores used in the information sandwich formula (6). Results were given for both fixed sample size and random recruitment at the second and each succeeding phase.

Whittemore & Halpern [39] gave an example of a three-phase study of the association between prostatic cancer and lifestyle factors. The first phase involved a case–control sample of men with and without a history of prostate cancer. Each was asked if he had a brother with the disease, and subsamples were drawn at phase two according to whether or not there was a positive reply. A complete family history was taken for those so selected. In a third phase of sampling all the subjects whose families had three or more cases of prostate cancer were asked to provide blood or tissue specimens for DNA analysis. Data of interest for statistical modeling included the complete family histories and the DNA results. Variance formulas were used to determine optimal sampling fractions at phases two and three for estimation of parameters in genetic models. Stratification of the phase two sample, using the reply to the simple question posed at phase one, remarkably improved efficiency.

Benichou et al. [2] provided another example of three-phase sampling involving women participating in a large-scale breast cancer demonstration project. Data on age, treatment center, and date of entry into the study were available initially for 280 000 women. The second phase involved selection of approximately 3000 breast cancer cases and 3000 controls with data on family history and clinical and reproductive risk factors. At the third phase, subsamples were selected on the basis of the availability of mammographic information. This example is best characterized as a problem with a complex pattern of **missing data**, because at phases two and three only those cases and controls with complete data on the relevant

covariates were retained. The authors developed their own pseudo-likelihood analysis, using the parametric **bootstrap** for calculation of standard errors.

The essential feature of the multiphase sampling design [38] that makes it amenable to simple Horvitz–Thompson estimation is the fact that the resulting data are subject to a *monotone* pattern of *missingness* [21]. The covariates may be ordered so that the groups of subjects missing each one of them are nested within each other. For other complex sampling designs the data analysis is inherently more difficult and may require additional parametric assumptions. Wacholder et al. [34], for example, proposed the *partial questionnaire* design for case–control studies as a means of reducing the length of the questionnaire administered to most subjects. Different subgroups of subjects are given distinct questionnaires that are missing different blocks of questions, so that the missingness pattern is *nonmonotone*. They developed a pseudo-likelihood estimation procedure that requires explicit estimation of the joint covariate distribution in the sample. Consequently, the technique is currently restricted to studies with a small number of discrete covariates.

Conclusions

Epidemiologists, especially those working in genetic epidemiology, have begun to recognize the value of two- and three-phase stratified sampling designs for case–control studies [1]. By incorporating available data into the design and analysis to the fullest possible extent, great savings in cost can be achieved with little or no sacrifice in statistical precision. Computational tools are now available that facilitate such designs and analyses. Horvitz–Thompson estimation of logistic regression coefficients has been implemented for data collected in complex sample surveys [33]. Macros for Horvitz–Thompson estimation in two-phase studies, and for the determination of optimal sampling fractions from pilot data, are now available for the popular package STATA [26, 27]. S-Plus functions are available for implementation of the more efficient pseudo-likelihood and maximum likelihood estimators [7].

This article has described two-phase stratified sampling designs and analyses for estimation of logistic regression parameters from binary outcome data. Similar methods have been developed for estimation of relative risk parameters in the Cox proportional hazards model for failure time data. Horvitz–Thompson estimation procedures are available, for example, for covariate stratified versions of the nested case–control study and of the case–cohort study. Further work is needed to implement more efficient estimation methods for these and other complex sampling designs.

Case–Control Study

The case–control design provides a framework for studying the relationship between possible risk factors and a disease by collecting information about exposure from those with disease but only from a fraction of the individuals under study who do not develop disease. When the disease is rare, this approach offers a major gain in efficiency relative to the full **cohort study**, in which an investigator seeks information on exposure for everyone. The savings compensate handsomely for the loss in the precision of estimates of parameters describing the relationship between exposure and disease that could have been obtained from studying everyone. In fact, the reduction in precision often is marginal. By collecting data on exposure about *cases*, the subjects who have developed disease, and **controls**, specially selected subjects without disease, the case–control design also compresses the time needed to complete the study. In a classic case–control study, Doll & Hill [10] recruited 649 male lung cancer cases and 649 male controls during an 18-month period in London. They were able to show a clear increase in **risk** with increasing daily cigarette consumption in this case–control study (*see* **Smoking and Health**). By contrast, in a cohort study of an equal number of men at the very highest risk – that is, very heavy smokers above age 70 – one would expect to find only a handful of lung cancer cases within 1.5 years, not nearly enough to draw convincing conclusions about the relationship between smoking and lung cancer.

A hypothetic example illustrates the extent of the savings. In Table 1 are displayed the results of a cohort study of 1 000 000 individuals who are followed for disease for one year; 10% of them are exposed.

The expected results from a case–control study in which all 56 of the cases from this cohort are studied are displayed in Table 2. Expected cell counts are also shown in Table 2. For example, the expected number exposed among the 56 studied controls is calculated as $56 \times (99\,984/999\,944) = 5.6$.

The estimate of the **odds ratio** for disease, (16/40)/(99 984/899 960) in Table 1, equals the estimate of the exposure odds ratio in Table 2, (16/40)/(5.6/50.4). Both odds ratios equal 3.6004, and approximate the risk ratio (*see* **Relative Risk**) $(16/100\,000)/(40/900\,000) = 3.60$ to four significant digits. Thus, the study of 112 individuals would give the same estimate as the study of 1 000 000, apart from random variation. While the 95% **confidence interval** (CI) for the odds ratio from the case–control study, (1.3–10.3), is substantially wider than the CI (2.0–6.4) from the full cohort study, using $5 \times 56 = 280$ controls instead of only 56 would narrow the CI for the case–control study to (1.8–7.2), which is notably closer to that of the full cohort study. This minor loss of precision is a small price to pay for the savings in exposure assessment costs and in time that may make feasible a study that would otherwise be too expensive.

In principle, although not always in practice, all case–control studies yield an **unbiased** estimate of the odds ratio and other functions of the odds. Most are designed so that the odds ratio directly estimates the relative risk or the incidence-rate ratio. However, only **population-based case–control studies** that yield estimates of overall disease risk or

Table 2 Expected values from case–control study in same setting as Table 1

	Diseased (cases)	Nondiseased (controls)	Relative odds
Exposed	16	5.6	3.60
Unexposed	40	50.4	1.00
Total	56	56	

Table 1 Hypothetical full cohort study

	Diseased	Nondiseased	Total	Relative risk[a]	Relative odds[b]
Exposed	16	99 984	100 000	3.60	3.60
Unexposed	40	899 960	900 000	1.00	1.00

[a]Relative risk = (16/100 000)/(40/900 000).
[b]Relative odds = (16/99 984)/(40/899 960).

rate in the population permit estimation of exposure-specific **incidence rates** and thus of all parameters that could be estimated from studying the entire cohort.

Along with these considerable design strengths, the case–control study has several weaknesses. Incomplete or inaccurate ascertainment of outcome and improper selection of controls can cause **selection bias**. Retrospective assessment of exposure history can lead to **nondifferential** and **differential** measurement error and **biased** estimates of exposure effects. As in any nonexperimental or **observational study**, **confounding** can distort the estimates of effect from a case–control study (*see* **Bias in Case–Control Studies**; **Bias in Observational Studies**; **Bias, Overview**; **Measurement Error in Epidemiologic Studies**; **Misclassification Error**).

The Range of Case–Control Studies

A MEDLINE search for papers published since 1992 found over 1500 entries per year mentioning case–control or one of its cognates, usually case–referent. The case–control study is a fundamental tool of epidemiology with broad application in areas as diverse as the etiology of cancer and birth defects, the effectiveness of vaccination and **screening** for disease, and the causes of automobile accidents.

Case–control studies vary greatly in scope, sources of data, and complexity. At one extreme are investigations of an outbreak, which may include fewer than ten cases (*see* **Communicable Diseases**). These studies often encompass a wide-ranging, open-ended examination of many exposures and host characteristics of the cases. Often, the selection of controls can precisely correspond to the source of cases because there is a roster of the source population (for example, in a hospital outbreak) or a convenient collection of willing participants. At the other extreme are multicenter, multiyear, highly focused studies of tens of thousands of cases and controls. These are not common, because of their high cost. More typical are studies of a few hundred cases and an equal number of controls selected without a roster, but with an algorithm intended to represent the population from which the cases arose. These intermediate-sized studies provide a practical approach when the relative risk is expected to be around 2 or greater and the exposure is reasonably common (10% or more).

Weaknesses of the Case–Control Approach

Case–control studies, like **cross-sectional** and observational cohort studies, suffer from the common drawbacks of all nonexperimental, or observational, research, stemming from the investigator's lack of control in assigning exposure. Foremost is the absence of **randomization** as a tool for reducing confounding. An observational study will not be as reliable as a **clinical trial** for investigating questions such as the effectiveness of a new treatment or screening program.

Even though a case–control study has no intrinsic shortcomings compared exposuto a nonexperimental full cohort study that collects information on everyone in the same setting, the case–control design has often been disparaged as fundamentally weaker than the full cohort study. Several conceptual, statistical, and practical reasons explain this negative attitude. Many early observers saw the case–control study as a "backward cohort study", with inference made from effect to cause. It was not obvious how to translate a difference in exposure between cases and controls into a parameter describing prospective risk until **Cornfield** in 1951 [7] showed theoretically that the exposure odds ratio from a case–control study approximates the disease risk ratio from a case–control study when the outcome is rare. Selection bias can arise from poor study design or poor implementation in choosing cases and controls. Retrospective ascertainment of information about exposure and confounders may yield inaccurate data leading to bias. These issues are discussed in detail later in this article.

Another apparent weakness of the case–control approach is that ordinarily it yields relative but not absolute measures of the effect of exposure on disease. It is possible, however, to estimate exposure-specific **absolute risk** and risk differences when the crude risk of disease is known in the study population [1, 7, 10, 30].

Case–Control Study as a Missing-Data Problem

A population-based case–control study can be regarded as a cohort study with many nondiseased subjects missing at random [30]. This view of the case–control study helps to resolve many conceptual issues.

It reveals when and how a broader class of parameters, including absolute risk and risk difference, can be estimated. It clarifies the requirements for proper control selection (*see* **Missing Data in Epidemiologic Studies**; **Missing Data**).

Consider a population-based case–control study to examine the effect of an exposure on the risk of developing disease. In the ideal study, the investigator is able to identify all cohort members newly diagnosed with disease during a specified follow-up period. These people with disease, or a random subset, become the cases in the study. Controls are a **random sample** of the noncases. The investigators obtain information on exposure that preceded the time of onset of disease from these cases and controls. Exposure information for those noncases who never develop disease during the study period will be *missing at random* if the investigator determines whose exposure will be collected, based only on disease status, which is known for individuals during the specified time. Thus, the case–control study is a missing-data problem, albeit with two unusual features: the "missingness" is a planned maneuver rather than an uncontrollable accident, and the ratio of missing to observed data can be extraordinarily high.

Under these assumptions, the cases and controls will have the same exposure distribution as the diseased and nondiseased, respectively, in the cohort, and the investigator can estimate from the case–control data all of the parameters estimable from the full cohort study. Indeed, under these assumptions, there are no intrinsic weaknesses to the case–control design. This outlook recognizes the prospective nature of the study, allows estimation of all parameters available from the full cohort, including absolute risk and risk difference, and demonstrates why the controls selected should have the same exposure distribution as other nondiseased individuals in the study population [30]. The inference from the missing data approach is identical to standard case–control **inference** in this setting [30].

Case–Control Studies to Estimate a Hazard Ratio

In the idealization described above, risk is described as the probability of developing disease during a fixed interval. If the study aims to estimate functions of **hazard rates** of disease, or numbers of new events per unit of person–time (*see* **Person-years at Risk**), the time element must be incorporated more precisely. For instance, in the standard **proportional hazards** analysis of the full cohort study designed to estimate the hazard ratio, the **partial likelihood** compares the exposure of a case to that of the members of the *risk set*; namely, all other members of the cohort who are at risk at the time of the event that defines when the cohort member became a case.

In the nested case–control study that would be undertaken in the same cohort, as first described by Thomas [27], exposure from only a few randomly selected members of each risk set is collected and used in a time-matched case–control analysis, an analog to partial likelihood. Again, except for the use of fewer individuals, there is no intrinsic difference between the full cohort and nested case–control analyses. All noncases in the risk set should be eligible and equally likely to be sampled as controls, even those who were previously selected as controls or who later develop disease [15]. Sampling at event times should be mutually independent in the nested study.

The **case–cohort design**, first described by Prentice [21], is a useful alternative with several practical advantages. The controls are selected as a single sample or *subcohort* from the entire cohort, including cases. While the sampling is not time-matched, in the analysis the **likelihood** at each event time uses the exposures of the case and of the subcohort members who are in the risk set at the event time. The fact that the subcohort is a random sample of the cohort leads to more flexibility in the analysis and allows the same controls to be used for analyses of several endpoints.

Design

There are three interlocking steps in planning the design of a case–control study:

1. Investigators must decide whether a cohort or case–control study is appropriate.
2. Investigators must determine who will be cases and controls in the study and how to assess exposure.
3. Investigators must decide on all the specific details to be included in the study protocol.

Full Cohort vs. Case–Control?

The first decision required in planning a case–control study is to determine whether the case–control design is more appropriate than a full cohort design [29]. The reasons for preferring a case–control study to the full cohort study are almost always practical, revolving around feasibility, economy, speed, and the need to study multiple exposures or their joint effects. On the other hand, a prospective cohort study sometimes affords an opportunity to collect more reliable exposure information, and can be used to study **multiple health outcomes** simultaneously. It can offer slightly more statistical precision. Finally, justifiably or not, the cohort study has more credibility.

Lower Cost vs. Higher Statistical Efficiency. Studying fewer subjects reduces the cost but also lowers the precision of the estimate of effect. When the disease is rare, the impact will be very modest, as the above example demonstrates. The **variance** estimate of the log-odds ratio estimate from **two-by-two tables** of the form in Table 1 or Table 2 is the sum of the reciprocals of the cell entries, so the size of the smallest cell in the two-by-two table is the factor limiting precision. When exposure is rare, this smallest cell almost always will be the number of exposed cases. This quantity is the same in the full cohort or in the case–control study performed in the same setting. Thus, the relative efficiency of the case-control study with k controls per case is $k/(k+1)$ compared to the full cohort [28]. The choice of design often boils down to whether to look for cases among the exposed (as in a cohort study) or exposed among cases (as in the case–control approach).

The clearest advantage for the case–control study occurs when the outcome of interest is rare and the exposure of interest is common. As the percentage of individuals experiencing the outcome during the follow-up period increases, the efficiency advantage of the case–control design diminishes. As the exposure of interest becomes rare, the ability of the case–control study to estimate an effect diminishes and a cohort design that ensures that individuals with the rare exposure will be followed for disease may become more advantageous.

Data Quality. Exposure assessment is the Achilles heel of the case–control study. If information collected retrospectively about exposure is of lower quality than concurrent data, more *nondifferential* **misclassification** or error, and consequently, attenuation of estimates of effect, almost inevitably ensue. Worse still, exposure information that is self-reported is susceptible to *differential* error or misclassification, namely different error patterns in cases and controls.

The resulting bias can work to exaggerate, attenuate, or reverse the direction of an effect. While differential error from interviews has been difficult to establish conclusively in particular situations, it seems realistic to assume that the accuracy and thoroughness of reports from cases, who are touched by the research question and whose lifestyle may be affected by the disease, will be greater than for controls. The effect of differential error is often called report or **recall bias**. Some nutritional epidemiologists are extremely skeptical of dietary data collected from cases and controls retrospectively, for fear of differential misclassification (*see* **Nutritional Exposure Measures**). By contrast, when previously written records are the source of exposure information, the errors are no different from those in a full cohort study. So a retrospective or even a prospective full cohort study would not automatically have higher data quality. Correspondingly, collection of reliable information on outcomes in all members of a cohort or a case–control study is also a challenge, especially for softer endpoints, such as infertility.

Other Scientific Issues. Apart from considerations of efficiency, reflecting the rarity of disease and exposure, other considerations come into play. When confounding poses a major problem for a study, accurate **confounder** assessment may dictate one design or the other. The need to study multiple exposures magnifies the advantage of the case–control design, while a cohort study allows additional outcomes to be included in the study with little increase in cost. Some well-established cohorts [37] have demonstrated that results on the relationships between multiple exposures and multiple exposures from a full cohort study can justify its substantially greater cost relative to a single case–control study.

Credibility. While most researchers and journals now appreciate the case–control design, some still consider case–control studies automatically suspect [11]. While this attitude is becoming less widespread, it may affect how one's work is accepted.

Choice of Setting

The specific setting for the study must be chosen within constraints imposed by logistics, convenience, and cost. Investigators must also consider the key factors that determine the quality of a case–control study in a particular location. How complete and accurate will the case ascertainment be? How rapidly will investigators receive reports of cases, thereby reducing the influence of the postdiagnosis period, such as effects of treatment, and the number of fatal or debilitated cases who might be excluded or whose exposure information may need to be collected from a proxy, such as a spouse or child? Is there a roster or **sampling frame**, possibly from electoral lists or a health insurance plan (*see* **Administrative Databases**), from which to select suitable controls? Are written records available to evaluate exposure, thereby reducing the possibility of differential misclassification? Are participants likely to give reliable information on exposure or confounders, including perhaps family medical history, prescription drug use, or highly personal questions about sexual history or a previous abortion? Are participation rates likely to be high? (*see* **Nonresponse**). Will participants be amenable to a procedure needed for the study, such as blood drawing for assessing a biomarker? What is the rate of occurrence of events and how will it affect the amount of time needed in the field? Is there enough heterogeneity of exposure to reduce the cost of a study and the number of subjects needed to achieve a specified precision?

Case–control studies can be oriented toward measuring the effect of exposure on disease **prevalence**, **cumulative hazard**, or **incidence rate**. Thus, the temporal perspective must be considered. Ought the study be limited to future cases, or can previously diagnosed individuals be used? Using only those cases that are newly diagnosed (**incident cases**) generally works to improve case ascertainment and participation, reduce reliance on proxy respondents for deceased or disabled cases and simplify control selection, but is slower and more costly. One subtly different definition of cases produces an estimate of cumulative risk rather than **incidence density ratio**; namely, when cases are all subjects who developed disease throughout the duration of follow-up of a population. Finally, diseases with poorly defined onset and long duration call for prevalence studies, with the definition of cases correspondingly changed to subjects who have the disease at the specified point in time, regardless of when they first developed it (*see* **Case–Control Study, Prevalent**).

Case and Control Selection

Case and control selection must be defined together because they are intrinsically linked. Miettinen's [20] concept of the *study base* helps to clarify this connection. The study base at a given time consists of those individuals who would become cases in the study if they developed disease at that time. When the study base is well-defined, the study is called a *primary-base* study or a *population-based case–control* study; cases are simply those members of the study base who experience the outcome and controls can be a random sample from the base. In this situation, it is possible to determine whether any individual is in or out of the study base at a given time and whether that individual is eligible to be a case or control in the study. The problem is making sure that all cases in the base come to the attention of the study investigators. The alternative starts with a set of cases, perhaps chosen for convenience, as in a *hospital-based case–control* study of lung cancer diagnosed at a single hospital during a single year. In these *secondary-base* studies, the study base is poorly defined because it is not always clear whether an individual who did not develop disease would have been a case in the hypothetic circumstance of development of disease. With no way to know whether a potential control would have come to the study hospital upon development of disease, random sampling for control selection is impossible. Thus, these secondary-base controls must be *assumed* to be an approximation to a hypothetic random sample that could characterize the study base. So in the primary base study, the difficulty is finding the cases, while, in the secondary base study, the difficulty is ensuring an appropriate set of controls.

Case Selection. In the idealized case–control study, all subjects with disease in the study base (or a random sample of them) become cases. In reality, some cases do not come to the attention of the investigators, some individuals are falsely called cases when in fact they do not meet the diagnostic criteria, and some eligible cases refuse to participate. In a study of male infertility, factors that lead to someone to regard lack of children as a problem might appear as

risk factors because of differential case ascertainment [31]. Inaccurate and incomplete case ascertainment can create selection bias as well as reduce precision. When there is ambiguity as to whether someone truly developed disease, as in the absence of a definitive pathology report, the standard practice of excluding the case is not harmless, if those lacking information have different exposure distributions than those with the information, perhaps because they are seen at a hospital in a poorer area [29].

Principles of Control Selection. There are three principles that underlie control selection: *study-base, comparable-accuracy*, and *deconfounding* [31]. The essence of the study-base principle is that controls can be used to characterize the distribution of exposure in the study base from which the cases arise. The comparable-accuracy principle calls for equal reliability in the information obtained from cases and controls so that there is no *differential* misclassification. Thus, a study of drug use during pregnancy as a risk factor for a specific type of birth defect might call for a control group of children who experienced a comparably serious outcome at birth so that the mothers of cases and controls would be equally likely to recall exposure during pregnancy accurately. The deconfounding principle allows elimination of confounding through control selection, such as through matching or **stratified sampling**, to be a consideration in control selection. These principles may conflict with one another and may have strong negative impacts on efficiency. They should not be regarded as absolute, but rather as points to consider in choosing a control group.

Controls for Studies with a Roster. In fortuitous situations, the investigator can use a roster listing all individuals and the period when they are in the study base. Investigators can then sample at random from the roster to satisfy the study-base criterion.

Controls for Primary-base Studies without a Roster. When a roster is not available and cannot be created from electoral or town residence lists, it is impossible to generate a random sample directly. A commonly used approach when there is no roster is **random digit dialing** (RDD) [34], an efficient way to generate a near-random sample often used in public opinion polling. RDD relies on dialing telephone numbers according to a strategy that yields representative samples. RDD suffers from several potential biases. RDD will not select individuals without phones, although it can compensate for households with multiple telephone lines. Furthermore, many people refuse to respond to telephone surveys, especially since the advent of answering machines (*see* **Telephone Sampling**). Empirically, controls chosen by RDD seem to be of higher socioeconomic class than a truly random sample would be. This violation of the study-base principle may be alleviated by adjustment for income or socioeconomic status.

Requirements for individual controls vary. In *incidence-density sampling* [14, 19, 22], used most commonly in primary-base studies, controls must be disease free at the time of diagnosis of the case to which they are matched. As in the nested case–control study, this design allows estimation of an incidence rate-ratio (and **relative hazard**) and eliminates the need for the rare-disease assumption [14, 19]. For *cumulative-incidence sampling*, controls are selected from among those who survive the study period without developing disease. Cumulative-incidence sampling of controls allows estimation of the risk ratio (**relative risk**), which approximates the relative hazard only when the rate of disease is low.

Secondary-Base Studies. Some diseases, including those not consistently detected in the general population, dictate an alternative to primary-base studies. For example, when case identification is incomplete, population controls may not be appropriate when completeness of case identification is differential by exposure and the selection bias cannot be corrected by adjustment for another variable. The most common secondary-base study is the *hospital-based case–control* study. Controls are patients seen at the same hospital as the cases, but for a different condition. This approach works well when two requirements are met. First, both cases and controls must be people who would have presented at the same hospital if they had *either* the case-defining illness or the control-defining condition. Secondly, the conditions used to select controls cannot be associated with the exposure. If these requirements are met, the distribution of the exposure in the controls reflects the distribution in the study base. The investigator seldom knows with certainty that both criteria are met, so compliance with the study-base criterion remains hard to verify convincingly.

A possible advantage of the hospital-based control group is more confidence that the equal accuracy criterion will be met. With equally serious illnesses, cases and controls ought to provide similarly complete and accurate reporting of past exposures. Thus, for the study of a specific birth defect, controls could be chosen from babies born with another birth defect of similar severity but known not to be related to the exposure of interest. Using controls with cancer at other sites for a study of a form of cancer may help with the equal-accuracy principle, but care must be taken so that cancer at the control site is not related to exposure.

Other Kinds of Control Groups. While population and hospital controls are the most commonly used kinds of control groups, investigators have used other options [32]. Use of patients from the *same primary care provider* as the case helps to insure that a control who developed the disease of interest would have become a case in the study. Use of *friends* of the cases can lead to bias in studies of factors related to sociability. Use of *relatives*, often siblings, as controls may reduce confounding by genetic factors. Each of these control groups requires a careful selection procedure to make sure that individuals are not being picked to be controls in a way that is related, directly or indirectly, to the factors under study.

Design Options. Matching on well-established confounders is a common practice in case–control studies. In case–control studies, matching serves to increase the precision of the estimated effect of exposure by making the distribution of the confounder identical in the cases and controls. Usually, the efficiency advantage from matching is small, and may not compensate for the extra cost and complexity, the exclusion of cases for whom no match is found, and the reduced flexibility of the analysis [33]. Other justifications of matching include control for nonquantitative variables such as neighborhood and the ability to control for confounding without making assumptions about the effect of the confounder in the risk model [33].

Only strong confounders should be considered as matching variables. Two-phase designs, discussed below, are more appropriate if one wants to estimate the effect of a variable considered for matching. Demographic variables such as race and sex and temporal variables such as age and calendar year (or decade) of first employment are the most suitable matching variables. Matching is always inappropriate on a factor that is a consequence of exposure.

Two-Phase Designs. These techniques [2, 36] (*see* **Case–Control Study, Two-phase**) are a more flexible generalization of matching, also used to increase efficiency or to reduce the cost of exposure assessment. In two-phase designs, detailed information on exposures and confounders is not ascertained for everyone, but only for subsets of cases and controls, with the selection probability depending on case status and on the value of another variable that is available for everyone. Instead of requiring, as in matching, that the distribution of the variable be the same in the control as in the cases, essentially arbitrary distributions in each group are specified. These two-stage designs allow the estimation of both main effects and **interactions**. For example, in a study designed to investigate the joint effects of domestic radon exposure, requiring expensive measurements, and smoking, which is easier to ascertain, on the risk of lung cancer, taking all cases and a random sample of controls would lead to a study with a preponderance of smoking cases and nonsmoking controls; matching controls to cases on smoking status would lead to small numbers of control nonsmokers as well. The assessment of interaction is much more efficient in the two-phase design where nonsmoking cases and smoking controls are oversampled [35].

Sample Size. There is an extensive literature on **sample size determination** for case–control studies [4, 24, 25]. As in the full cohort study, needed sample size is dependent on the variation in exposure in the study base. A key point is that increasing the ratio of controls to the harder-to-find cases increases the precision of the odds ratio estimate in an increasingly marginal way, especially for small effects. Ratios of controls to cases beyond four or five are usually not advisable because the successive gains in efficiency diminish. Indeed, the **asymptotic relative efficiency** for a study involving k controls per case is $k/(k+1)$, which takes on values of 0.5, 0.67, 0.75, 0.8, and 0.83 for k from 1 through 5 [28].

Fieldwork

The best-designed study will not be convincing unless the fieldwork is sound. In the field, case–control studies face the usual challenges of observational research: identifying all members of the study population, achieving an adequate response rate, collecting accurate data, and measuring potential confounders.

Most case–control studies include a questionnaire, because seldom have all of the exposure variables of interest been recorded in documents easily available to the investigator. Sometimes the study subject, or his surrogate, completes the questionnaire ("self-administered"); alternatively, an interviewer can pose the questions. A questionnaire can be computerized or on paper; an interview can be in person or by telephone (*see* **Interviewing Techniques**; **Questionnaire Design**). Depending on the hypotheses, investigators may also collect biologic specimens, samples of the study subject's present or past environment, and permission to contact agencies that have documented data about the exposures.

The case–control design poses some specific problems, as well. Since the cases have already developed the disease, it will not be possible to estimate the effects of exposure measures that are distorted by the disease, including weight and body biochemistry, unless the investigator has access to stored measures that were collected before disease onset. If it is not clear whether a measure is likely to be valid once the disease is clinically manifest, the investigator may conduct a specific methodologic pilot study. Sometimes, it is possible to examine the effects specific for stage of disease, in the expectation that post-onset distortions will be more pronounced with more advanced disease. In a similar fashion, the investigator will consider whether therapy influences the level of the exposure variable. If so, then cases need to be studied before therapy begins, or well after any of its influence has waned.

Just as diagnosis and treatment of a serious disease can cause biological changes in exposure variables, they also can cause changes in a patient's recollection or willingness to report various exposures. The resulting **recall bias** does not always go in a particular direction; the specific exposure needs to be considered, preferably with data on reporting bias from ancillary sources. Some exposures lend themselves to internal validation by studying a higher-quality exposure variable on a subset of subjects or by collection of validation data from other sources, such as medical records (*see* **Validation Study**). In that circumstance, some or all of the subjects reporting an illness or hospitalization will be asked to give permission for review of records; ideally, some of the reports of no hospitalization ought to be selected for review, too, although this is seldom practical. To minimize recall bias, the investigator also attends to the exact phrasing of questions, trying to leave very little room for interpretation or rumination. Sometimes investigators attempt to blind the interviewer to the case–control status of subject, but often the status of the subject becomes apparent anyway (*see* **Blinding or Masking**).

With access to prospectively collected data stored in records, the investigator can avoid the problem of differential misclassification stemming from the fact of diagnosis. Even with stored records, however, one source of differential misclassification could be present: minor abnormalities noted because of greater medical surveillance of the exposed may not have been detected in the unexposed (*see* **Bias From Diagnostic Suspicion in Case–Control Studies**; **Bias from Exposure Suspicion in Case–Control Studies**).

Analysis

The goal of the analysis of case–control studies is almost always to identify risk factors that are related to disease and to determine whether in fact the risk factors are causes of the disease (*see* **Causation**). As in other nonrandomized situations, the analysis must address the possibility of *confounding* and **effect-modification** by measured **covariates**.

The primary difficulty that is inherent to analysis of case–control studies is that the sampling is based on disease status while the parameters of interest relate to risk or rate of disease. Thus, it is not the difference in exposure frequency or **means** between cases and controls that is of direct interest, but estimates of the effect of determinants of disease on the rate of disease or on the probability of developing disease.

The analysis of case–control data can be exquisitely simple or tremendously complex. When the exposure and disease are each dichotomous (*see* **Binary Data**) and there are no other factors to

consider, the analysis reduces to a **two-by-two table** of exposure by disease status. Originally, Cornfield [7] proposed that the *odds ratio*, or cross product ratio in the two-by-two table could be used as an estimate of the risk ratio (or relative risk) when the disease was rare. **Mantel & Haenszel** [16] developed an estimator and a test statistic that could be used when combining tables over several strata, thereby controlling for confounding. Exact conditional approaches, not relying on asymptotic theory, are also available for obtaining inference on the common odds ratio, adjusted for confounders by **stratification** [3, 13, 18].

While **discriminant analysis** seems a natural tool to distinguish cases and controls, **logistic regression**, in which the dependent variable is the logarithm of the odds of disease, has two distinct advantages. It allows for exposures, confounders and effect-modifiers that are discrete or continuous, regardless of distribution [9] and yields valid estimates of relative-odds parameters from case–control data. Prentice & Pyke [23] proved that prospective logistic modeling – that is, of disease as a function of exposure – estimated relative risk parameters correctly and with full efficiency. If the sampling fractions of cases and controls are known, as in some population-based case–control studies, the intercept estimate from the case–control analysis can be combined with the ratio of the sampling fractions to yield a valid estimate of absolute risk. Logistic regression is now the most commonly used approach to analyze case–control data. Carroll et al. [6] extended the Prentice–Pyke result to show that many variations of case–control designs could be analyzed by logistic regression and given a prospective interpretation. Extensions to the logistic framework allow the handling of more complex sampling schemes, such as two-phase designs, of **nonlinear regression** effects of covariates, and of alternative models of joint effects of two risk factors, such as **additive** rather than **multiplicative** effects.

Control for a small number of categorical confounders can be achieved by the Mantel–Haenszel estimator of the odds ratio and corresponding **hypothesis test**. These simple procedures have excellent statistical properties. Nonetheless, logistic modeling is used routinely, because of its greater flexibility, for instance, in handling continuous variables [3]. In most modern studies, there will be more than two levels of exposure or one or more confounders and effect-modifiers to consider.

The analysis of matched pairs with a single dichotomous exposure variable uses only discordant pairs. It takes the ratio of pairs with the case exposed to those with the control exposed as the odds ratio estimate. The corresponding test of the **null hypothesis** that the odds ratio is one is equivalent to the hypothesis that the number of pairs with exposed cases among the discordant ones is **binomial** with probability 0.5 (*see* **Matched Analysis**; **McNemar Test**). While several extensions to more complex exposure variables and matching schemes were developed, the breakthrough in the analysis of matched data was the introduction by Breslow et al. [5] of **conditional logistic regression**, which allows general matching schemes, arbitrary exposures, continuous or discrete confounders (other than those used in the matching), and effect-modifiers.

An important variation of the analysis of case–control data allows for estimation of a hazard ratio rather than an odds ratio or risk ratio, as in nested case–control and case–cohort studies [21, 26, 27]. These designs are particularly useful when exposures vary with time, as does, for example, lifetime exposure to an environmental or occupational chemical. A conditional **likelihood** approach can be used here as well as where the matching is on time. In the contribution to the conditional likelihood at each event time, the exposure is accumulated only until the event time, exactly as if the analysis were prospective and no future data were available [21]. Furthermore, the same structure of the conditional likelihood as in the matched case–control study is used. As long as the controls are selected randomly from those at risk – that is, including future cases and independently of past use as a control or time of follow-up – the estimates of hazard ratio are valid, again reflecting the close relationship to the full cohort design. When the same controls are used for each case diagnosed during the control's follow-up, as in the case–cohort design, the estimates of the hazard ratio are also valid, but the variance estimate is more complex because the scores at each event time are not independent.

In most reports of case–control studies, no estimate of *absolute risk* or *absolute rate* is given. Methods are available for population-based case–control studies when the crude risk of disease is known [1, 7], and generally for nested case–control and case–

cohort studies [17, 37]. Furthermore, risk or rate difference and other nonlogistic models can be fit [30]. Methods for estimating the attributable risk and its variance in a general setting are also available [8].

Summary

The case–control study remains the most popular approach in **analytic epidemiology** because of its relatively low cost and high speed. Ascertainment of disease, selection of controls and measurement of exposure present substantial difficulties in almost every case–control study, but a large body of epidemiologic theory and experience provides guidance to meet these challenges.

Case-only Gene Mapping

Genetic mapping of human disease **genes** refers to the identification of **markers** that are linked to the loci affecting disease status. When pedigree data are available, linkage studies are used to estimate the recombination fractions between marker and disease genes (**Linkage Analysis, Model-based**). This approach has proven to be very successful, although the relatively limited size of pedigrees does not allow very small recombination fractions to be estimated because of the lack of recombinants. Fine-scale mapping rests on the indirect approach of estimating population genetic parameters whose size depends on the recombination fraction, and these parameters are referred to collectively as "**association** parameters".

When individuals can be characterized as being affected or unaffected by a disease, marker–trait association can be addressed by comparing marker frequencies between these two categories (**Disease-marker Association**). The **case–control** approach compares frequencies between people with the disease and those chosen to be their matched controls. Alternatively, a comparison of the frequencies with which alternative marker alleles are transmitted to affected offspring forms the basis for the transmission disequilibrium class of tests.

It is also possible to infer linkage or association on the basis of marker data from affected individuals only. The extent to which individuals of a specified relationship share marker alleles can be predicted from classic **population genetics**, and linkage is inferred when there is more sharing than expected among affected relatives. This article describes procedures based on association among marker alleles within the affected population, and shows how these marker associations allow inferences to be drawn for marker–disease associations. Some of these ideas have been presented previously [1, 2].

Population Genetic Model

A disease is supposed to be affected by a locus **A**, with alleles A_r, in the sense that the probability of an individual of **genotype** A_rA_s being affected is $\phi_{rs} = \phi_{sr}$. If the population proportion of A_rA_s genotypes is P_{rs}, then the disease prevalence ϕ is $\sum_{r,s} P_{rs}\phi_{rs}$. When multiple loci contribute to disease susceptibility, the quantities P_{rs} and ϕ_{rs} would need to be extended. For a random-mating population, genotype proportions can be expressed as products of allele proportions, p_r for A_r, so that $\phi = \sum_{r,s} p_r p_s \phi_{rs}$. Unless a **candidate gene** is being considered, the disease genotypes and genotype-specific susceptibilities are unknown. This means that the number of alleles at the disease locus is also unknown.

Data can be collected on **marker** loci **M** with alleles M_i. If the proportion of individuals in the population formed from the union of A_rM_i and A_sM_j gametes is written as P_{sj}^{ri}, then the proportion of M_iM_j marker genotypes among affected or unaffected individuals is

$$\begin{aligned}\Pr(M_iM_j|\text{Aff.}) &= \sum_{r,s} P_{sj}^{ri}\frac{\phi_{rs}}{\phi},\\ \Pr(M_iM_j|\text{Unaff.}) &= \sum_{r,s} P_{sj}^{ri}\frac{1-\phi_{rs}}{1-\phi}.\end{aligned} \tag{1}$$

Under the **null hypothesis** of no marker–disease gene association, $P_{sj}^{ri} = P_{rs}P_{ij}$ and both these proportions reduce to the marker genotype proportion P_{ij}. The case–control test based on marker genotypes, therefore, is actually a test of the hypothesis $P_{sj}^{ri} = P_{rs}P_{ij}$. In the special case of a random union of gametes, one-locus genotype proportions are products of allele proportions and two-locus genotype proportions are products of gamete proportions: $P_{sj}^{ri} = p_{ri}p_{sj}$. Writing gamete frequencies in terms of allele frequencies and **linkage disequilibrium** coefficients, $p_{ri} = p_rq_i + D_{ri}$, leads to

$$\begin{aligned}\Pr(M_iM_j|\text{Aff.}) &= q_iq_j + \frac{1}{\phi}(q_i\delta_j + q_j\delta_i + \delta_{ij}),\\ \Pr(M_iM_j|\text{Unaff.}) &= q_iq_j - \frac{1}{1-\phi}(q_i\delta_j + q_j\delta_i + \delta_{ij}),\end{aligned} \tag{2}$$

where the marker allelic and genotypic association parameters are defined as

$$\begin{aligned}\delta_i &= \sum_{r,s} p_sD_{ri}\phi_{rs},\\ \delta_{ij} &= \sum_{r,s} D_{ri}D_{sj}\phi_{rs}.\end{aligned} \tag{3}$$

The marker-genotype case–control test is therefore a test of no marker–disease allele and genotype association, $\delta_i = \delta_{ij} = 0$. The random mating assumption has allowed three- and four-allele disequilibrium coefficients to be ignored. Only in the special case of two alleles at the disease locus can the test said to be one for linkage disequilibrium.

Adding more marker genotypes to recover marker allele frequencies provides, in the random-mating case,

$$\Pr(M_i|\text{Aff.}) = q_i + \frac{\delta_i}{\phi},$$
$$\Pr(M_i|\text{Unaff.}) = q_i - \frac{\delta_i}{1-\phi}, \qquad (4)$$

showing that the case–control test on marker allele frequencies is actually a test for no marker–allelic association, $\delta_i = 0$.

Case-only Tests

From the results in the previous section it is possible to express marker-genotype proportions in terms of marker allele proportions among affected or unaffected people. For the random-mating case,

$$\Pr(M_iM_i|\text{Aff.}) = \Pr(M_i|\text{Aff.})^2 + \frac{\phi\delta_{ii} - \delta_i^2}{\phi^2},$$
$$\Pr(M_iM_j|\text{Aff.}) = 2\Pr(M_i|\text{Aff.})\Pr(M_j|\text{Aff.}) + 2(\phi\delta_{ij} - \delta_i\delta_j)\phi^2, \qquad (5)$$

showing that a test for **Hardy–Weinberg** proportions among marker genotypes in the affected population is actually a test about marker allele and genotype associations with the disease locus. The test is not strictly a test that these associations are zero, as the marker locus will have Hardy–Weinberg proportions among affected people even if it is associated with the disease locus when the susceptibilities are multiplicative, $\phi_{rs} = \alpha_r\alpha_s$, for then $\phi\delta_{ij} = \delta_i\delta_j$.

The absence of a linkage disequilibrium between marker and disease loci results in Hardy–Weinberg equilibrium for the marker in the affected population. The converse does not hold unless there are only two alleles at the disease locus. Parallel results apply to the unaffected population, so that either population could be used. For rare diseases, however, $\phi < (1-\phi)$, and the departures from Hardy–Weinberg at the marker locus are expected to be greater among affected than unaffected people.

If the disequilibrium coefficients involving marker and disease alleles are all zero, whether these are for one or two alleles at each locus, then the amount of Hardy–Weinberg disequilibrium at the marker locus is the same for affected people, unaffected people, and the whole population. Rejecting Hardy–Weinberg at the marker locus in the affected population, therefore, may simply reflect nonrandom mating in the whole population. Preliminary tests for marker Hardy–Weinberg for a random sample taken without regard to disease status should therefore be conducted. If this test gives a significant result, then it is necessary to go back to case–control tests although even for those tests the power will be affected by nonrandom mating.

The analysis of marker-only associations can be extended to multiple marker loci. Tests of linkage disequilibrium for pairs of marker loci among affected people, for example, are actually tests for association of marker **haplotypes** with the disease locus in the whole population. These associations are functions of the linkage disequilibrium coefficients for each marker allele and each disease allele, and of the three-locus linkage disequilibrium coefficient for alleles from each of the three loci.

Categorical Data Analysis

Introduction

Categorical variables separate observations into groups, within which members share a common trait. This may be a nominal attribute, level of an ordinal scale, or numerical value or range derived from an interval or ratio scale (*see* **Measurement Scale**). In practice, the number of groups (categories) per variable is usually small to moderate, no more than 20. However, finer classifications are often defined by combinations of several variables. Procedures such as **Student's *t*-tests**, **analyses of variance** (ANOVAs), and their **nonparametric** analogues employ categorizations as independent or **explanatory variables** to study how continuous **random variables** vary between groups. *Categorical data analysis,* in contrast, involves categorical **response variables** and draws inferences to probability distributions of random category counts, or functions of them.

For instance, Table 1 reports the pretreatment percent labelling index (LI, continuous) and posttreatment remission status (RS, dichotomous) of acute myeloblastic leukemia patients. LI, which reflects the proportion of cells undergoing DNA synthesis, might be expected to predict RS. The relevant **null hypothesis** of independence implies mathematically that the conditional densities of LI, in the two groups differentiated by subsequent remission status ($RS = 1$ or $RS = 0$), are identical. However, testing for a difference in LI densities between these two *ex post facto*-differentiated populations with the usual Student's t or **Wilcoxon** rank sum test *is not* categorical data analysis, because these tests do not treat variation across the categories stochastically. It is biologically more natural, though, to view the RS outcomes for different patients as resulting from independent Bernoulli trials (*see* **Binary Data**) with fixed but unknown conditional probabilities $\pi_{LI} = \Pr\{RS = 1|LI\}$. One might then examine the **regression** of π_{LI} on LI. This latter approach incorporates the randomness of the RS dichotomy into analysis, and hence, falls within our scope.

When all variables are categorical, the cumbersome "list" or "case-record" format of Table 1 may be condensed by combining observations with identical values, that is, "levels", of all variables. Each observed pattern is listed once, with an added column for the count of such observations. When analysis is focused on one dependent variable, patterns identical for all independent variables share the same row, with added columns for counts in each dependent category (Table 2). A **contingency table** is a multiway cross-tabulation of counts for nonoverlapping groups. The dimensions correspond to categorical variables, the levels of which combine to define the groups. Such tables are usually more interpretable than condensed list formats, when most possible patterns of levels have been observed at least once. Table 3 shows the simplest example, a **two-by-two table** defined by combinations of levels of variables A and B. Rows and columns are labelled at tabular edges, or "margins", by levels of the corresponding variables. The physical intersection of a row and column is the "cell" corresponding to the combination of corresponding levels of each variable, and contains the count n_{ij} of observations with this pattern. Row and column sums are often placed at the right or bottom margins, respectively. Throughout, we replace a subscript with "+" to denote a sum of all terms with different values of the subscript. For certain study designs, specific combinations of levels may be unobservable or logically impossible. Corresponding cells are marked with a dash or other placeholder, or left empty, and the tables containing them are called "incomplete".

These concepts extend directly to tables of three or more variables. For convenience, counts from a contingency table of any dimension may be viewed in a two-dimensional rectangular array by nesting categories of some variables within those of others to form the rows (e.g. Table 2), columns, or both. Analogies between contingency tables and their counterpart tables of means in ANOVAs for **factorial experiments** have contributed greatly to the development of categorical data models.

Several features combine to give categorical data analysis a distinct flavor. Probability modeling is primarily confined to the **Poisson distribution**, for which the variance equals the mean, and its conditional descendants for which variability remains analytically inseparable from location. Hence, efficient analyses require weighting of observations. The dimension of the data space is tied to the number of observable category combinations rather than the number of categorical variables. Consequently, models are frequently of high dimension, requiring reliance on asymptotic inference (*see* **Large-sample**

Table 1 Pretreatment percent labelling index and posttreatment remission status (1 = in remission, 0 = relapsed) of acute myeloblastic leukemia patients; excerpted from [3]

Level two	n_{21}	n_{22}	n_{2+}
Marginal totals	n_{+1}	n_{+2}	n_{++}

Theory) and/or complex computations. Most models for expected counts are inherently nonlinear, so **maximum likelihood estimates** (MLEs) for parameters are implicit nonlinear functions, rather than explicit linear functions, of observed marginal distributions or other summary statistics. This introduces subtle issues of model interpretation, and brings computational complexity into even low-dimensional settings. Lastly, complex structures of counts are modeled and smoothed by imposing symmetry constraints, analogous to those of factorial ANOVA or **polynomial regression**, on sets of either probabilities or model parameters. However, the inherent plausibility of constraints such as linearity in classical regression extends only infrequently to the categorical data setting, where a thoroughgoing empiricism flourishes by necessity.

Nevertheless, the same scientific questions about relationships among variables prompt continuous and categorical data analyses, which have been conceptually unified to a remarkable degree. For inference about a single proportion, *see* **Proportions, Inferences, and Comparisons**. Below, we treat the 2×2 table at length, since the most important concepts appear in simplest form at this level. Parallels with continuous data analysis are noted in discussions of general two- and three-dimensional tables. We then broadly survey categorical data modeling via unifying paradigms: **generalized linear models** (GLMs), weighted **least-squares** (WLS) functional modeling, **generalized estimating equations** (GEE), and **generalized linear mixed models** (GLMMs). Some attention is also given to **exact inference**, conditional logistic regression (*see* **Logistic Regression, Conditional**), and **Bayesian methods**. The need for brevity requires neglect of history. For sake of readability given the voluminous literature, we also omit detailed citation, providing instead a selected bibliography of texts, monographs, and a few papers, primarily reviews. For historical discussion and further references, see [2] and specific entries cross-referenced below. For additional remarks on comparison of two proportions, *see* **Proportions, Inferences, and Comparisons**. We confine our discussion to data that have been fully and accurately observed. Categorical data may also be missing or misclassified. (*See* **Missing Data**; **Misclassification Error**; **Misclassification Models**.)

The discussion of 2×2 tables is more detailed and in some portions more mathematical than the sections that follow. The reader desiring to learn the flavor of the subject with a bit less intensity may prefer to skim the sections entitled "Exact Inference for 2×2 Tables" and "Likelihood Ratio, Score and Wald Statistics," in favor of easier sledding beyond, and perhaps also refer to the entry on **Proportions, Inferences and Comparisons**.

Probability Models for 2 × 2 Contingency Tables

Four basic sampling models, the product-Poisson, multinomial, product-binomial, and noncentral hypergeometric, are commonly used to describe how data

in 2×2 tables such as Table 3 originate. We write m_{ij} for $E(n_{ij})$ under such a model. The general product-Poisson model, employed in spatial distribution and **incidence density** studies, assumes that four independent Poisson streams of events or individuals are counted over possibly different regions of space and/or time. Then

$$\Pr(\{n_{ij}\}) = \prod_{i=1}^{2}\prod_{j=1}^{2} \Pr(n_{ij}) = \prod_{i=1}^{2}\prod_{j=1}^{2} \frac{(N_{ij}\lambda_{ij})^{n_{ij}} e^{-N_{ij}\lambda_{ij}}}{n_{ij}!}, \quad (1)$$

the product-Poisson distribution with rate parameters $\{\lambda_{ij}\}$ and known space-time "exposures" $\{N_{ij}\}$. For such data, $m_{ij} = N_{ij}\lambda_{ij}$. Typically, one is interested in how the λ_{ij} depend upon the levels of A and B, and particularly in how the ratios $\lambda_{i1}/\lambda_{i2}$ change with i, or how the ratios $\lambda_{1j}/\lambda_{2j}$ change with j. If these ratios do not change, then $\psi = \lambda_{11}\lambda_{22}/\lambda_{12}\lambda_{21} = 1$, and the $\ln \lambda_{ij}$ satisfy the additive model

$$\ln \lambda_{ij} = \mu + \gamma_{i*} + \gamma_{*j} \quad (2)$$

for some μ, γ_{i*}, and γ_{*j}. Such linear models for logarithms are also called **loglinear models**.

A simpler model results when the observational region is the same for all streams, with individuals or events classified jointly by variables A and B as they are observed. Then all $N_{ij} = N$ can be absorbed into the scale of the λ_{ij} and dropped from consideration. After rescaling, $m_{ij} = \lambda_{ij}$. Unless stated otherwise, "product-Poisson" below will refer to this simplified version.

The product-Poisson model for Table 3 generates other models through conditioning on marginal totals when these are fixed by design. For studies such as cross-sectional surveys that collect precisely n_{++} observations,

$$\Pr(\{n_{ij}\}) = n_{++} \prod_{i=1}^{2}\prod_{j=1}^{2} \frac{\pi_{ij}^{n_{ij}}}{n_{ij}!}, \quad (3)$$

a four-category **multinomial** distribution with the *unconditional* probabilities $\pi_{ij} = \Pr(A = i, B = j) = \lambda_{ij}/(\sum_{i=1}^{2}\sum_{j=1}^{2}\lambda_{ij})$. Here, $m_{ij} = n_{++}\pi_{ij}$. Central to such studies is whether the row and column categorizations A and B are informative about one another or independent. The answer lies with the ratio of the conditional **odds** π_{11}/π_{12} that $B = 1$ given $A = 1$ to the conditional odds π_{21}/π_{22} that $B = 1$ given $A = 2$,

$$\psi = \frac{\pi_{11}\pi_{22}}{\pi_{12}\pi_{21}} = \frac{m_{11}m_{22}}{m_{12}m_{21}} = \frac{\lambda_{11}\lambda_{22}}{\lambda_{12}\lambda_{21}}. \quad (4)$$

Since ψ is invariant when the roles of A and B are reversed, it is known simply as the **odds ratio**; $\psi = 1$ under independence and is higher or lower respectively when A and B have the same levels more or less often than independence would imply.

Two-group comparative designs, such as **case–control** or **cumulative incidence** cohort studies, have predetermined sums along one margin (e.g. n_{1+}, n_{2+}). Conditioning on these yields

$$\Pr(\{n_{ij}\}|\{n_{i+}\}) = \prod_{i=1}^{2} \binom{n_{i+}}{n_{i1}} \pi_i^{n_{i1}}(1-\pi_i)^{n_{i2}}, \quad (5)$$

the product of binomial distributions with sample sizes n_{i+} and **conditional probabilities** $\pi_i = \Pr(B = 1|A = i) = \pi_{i1}/(\sum_{j=1}^{2}\pi_{ij}) = \lambda_{i1}/(\sum_{j=1}^{2}\lambda_{ij})$. Under (5), $m_{i1} = n_{i+}\pi_i$ and $m_{i2} = n_{i+} - m_{i1}$. The object of these designs is comparison of π_1 and π_2 through inference about the difference $\Delta = \pi_1 - \pi_2$, the ratio $RR = \pi_1/\pi_2$, or the ratio $OR = \Omega_1/\Omega_2$ of the corresponding conditional odds $\Omega_i = \pi_i/(1-\pi_i)$. The first two measures of disparity are known to epidemiologists as the "risk difference" (*see* **Absolute Risk**) and "risk ratio" (*see* **Relative Risk**), respectively, while the latter is known as the risk odds ratio (ROR) for **cohort** designs, and as the exposure odds ratio (EOR) for case–control designs. Simple algebra shows that $OR = \Omega_1/\Omega_2$ is ψ, equal to unity under the homogeneity null hypothesis H_0 : $\Delta = \pi_1 - \pi_2 = 0$, and higher or lower depending on the sign of Δ. A fourth probability model is used when either "exact" or randomization analysis (*see* **Randomization Tests**) is desirable, as with small samples or some randomized **clinical trials**. In such a trial, one may hypothesize that a dichotomous outcome such as survival or death is preordained in the patient sample studied, in the sense of being unaffected by therapy. Once patients are selected, results then depend only on the outcome of **randomization**. Under this null assumption of no therapeutic impact, conditioning on *both* the designed treatment group sizes *and* the predetermined outcome counts for the selected patient group yields a null **hypergeometric distribution**. More generally, when the

row and column variables are dependent, the same conditioning gives the noncentral hypergeometric distribution

$$\Pr(\{n_{ij}\}|\{n_{i+}\},\{n_{+j}\},\psi) = \frac{\binom{n_{1+}}{n_{11}}\binom{n_{2+}}{n_{+1}-n_{11}}\psi^{n_{11}}}{\sum_u \binom{n_{1+}}{u}\binom{n_{2+}}{n_{+1}-u}\psi^u}, \quad (6)$$

where $\max(0, n_{1+}+n_{+1}-n_{++}) \le u \le \min(n_{1+}, n_{+1})$, and ψ is again the odds ratio $\pi_{11}\pi_{22}/\pi_{12}\pi_{21} = \lambda_{11}\lambda_{22}/\lambda_{12}\lambda_{21}$. Since ψ is the only unknown quantity, inferences based on (6) are free of **nuisance parameters**. When $\psi = 1$, (6) is the hypergeometric distribution, for which $m_{ij} = n_{i+}n_{+j}/n_{++}$.

Inference for 2 × 2 Tables

The odds ratio ψ is central to all probability models for 2×2 tables. Under a product-Poisson law, ψ reflects nonadditivity of the effects of A and B on the $\ln \lambda_{ij}$. The multinomial, product-binomial, and noncentral hypergeometric admit equivalent formulations of ψ as a measure of **association** between A and B. In each case, writing $\ln \psi = \ln m_{11} - \ln m_{12} - \ln m_{21} + \ln m_{22}$ expresses $\ln \psi$ as the usual **interaction** contrast for a two-way layout in the general linear model, applied here to the $\ln m_{ij}$ rather than to cell means of Gaussian variates. Thus, ψ is the interaction parameter of a loglinear model for variation among the $\ln m_{ij}$ that is structurally identical to the 2×2 factorial ANOVA model for expected cell means in the two-way layout. Conveniently, the MLE of ψ under Poisson, multinomial, and product-binomial laws is just the sample odds ratio $\widehat{\psi} = n_{11}n_{22}/n_{12}n_{21}$. It is thus attractive to characterize association in a 2×2 table by ψ, although the risk difference Δ or the risk ratio RR at times represent the association on a more practically relevant scale. We now describe methods of estimation and testing for these parameters, using **likelihood** inference or related asymptotically equivalent methods.

Exact Inference for 2 × 2 Tables

Under (6), $\Pr(\{n_{ij}\})$ is known for any specified value of ψ, the only unknown parameter. This allows exact probability calculations, and hence **exact inference**, either when both margins have been fixed by design so that (6) applies directly, or after conditioning on random margin(s) under (1), (3), or (5). The MLE under (6), $\widehat{\psi}_c (\neq \widehat{\psi})$, is known as the "conditional MLE" of ψ, and may be found iteratively as a root of the polynomial equation $n_{11} = E(n_{11}|\{n_{i+}\},\{n_{+j}\},\psi)$. The hypothesis $H_0 : \psi = \psi_0$ may be tested against $H_a : \psi \neq \psi_0$, using as ***P* value** the summed probabilities of the observed $\{n_{ij}\}$ and all tables $\{n^*_{ij}\}$ with identical margins $\{n_{i+}\}$ and $\{n_{+j}\}$ for which $\Pr(\{n^*_{ij}\}) \le \Pr(\{n_{ij}\})$ under H_0 (*see* **Hypothesis Testing**). For $\psi_0 = 1$, this is **Fisher's exact test**. For a one-tailed test, only tables in the direction of the alternative ($n^*_{11} \le$ or $\ge n_{11}$, as applies) contribute to the P value. Lower and upper $100(1-\alpha)\%$ confidence limits ψ_L and ψ_U for ψ may be found by inverting the two-tailed test. This requires iteratively solving $\alpha/2 = \sum_{u' \ge n_{11}} \Pr(u'|\{n_{i+}\},\{n_{+j}\},\psi_L)$ and $\alpha/2 = \sum_{u' \le n_{11}} \Pr(u'|\{n_{i+}\},\{n_{+j}\},\psi_U)$, where $\Pr(u'|\{n_{i+}\},\{n_{+j}\},\psi)$ is given by (6) with $n_{11} = u'$.

The above method may be extended to a broader class of procedures, and from 2×2 to $r \times c$ tables through the multivariate hypergeometric generalization of (6), as follows: (i) Order all possible tables with the observed $\{n_{i+}\}$ and $\{n_{+j}\}$ by a measure of discrepancy from H_0; (ii) test H_0 against H_a, using as P value the summed probabilities of all tables at least as compatible with H_a, under the selected ordering, as the observed table; (iii) form a $100(1-\alpha)\%$ two-sided **confidence interval** for the relevant unknown parameter θ (ψ in this instance), by including in the interval all θ_0 retained by such a two-sided α-level test of $H_0 : \theta = \theta_0$. Analogous methods can be used whenever a distribution giving exact probabilities under a simple hypothesis for all observable tables, and a reasonable method of ordering tables, are both available. For Fisher's exact test, the ordering criterion is the probability of the table under H_0 and (6). Other ordering criteria of interest include the asymptotic test statistics discussed in the following section and measures of row by column association. Computational barriers to such tests are falling rapidly.

Owing to the discreteness of (6), hypothesis tests that reject H_0 when an exact P value is $\le \alpha$ are conservative, in the sense that the actual type I error probability is typically below α, sometimes considerably so. For instance, for the famous tea tasting experiment Fisher used in presenting his exact test, the true type I error probability of the nominal $\alpha = 5\%$ level test

is 1.4%. Several approaches are available for gaining statistical power by more closely approaching the nominal level. One is to randomize Fisher's exact test. Under this approach, rejection or retention of H_0 for an outcome yielding the lowest nonsignificant P value under the exact test is determined randomly, with rejection probability set just sufficient to increase type I error to the desired level. This is rarely done in practice, however, because it allows researchers with identical data to reach discordant results based on a random process containing no information relevant to the scientific question.

A second approach, for data collected under (1), (3), or (5), is to enlarge the probability space, and thus, the set of possible P values, by testing under (5) rather than under (6). Such an "unconditional exact test" is accomplished by (i) exact testing under (5), conditional on each member of an interval $\pi\varepsilon[\pi_L, \pi_U]$ of presumed common probabilities $\pi_1 = \pi_2 = \pi$, and (ii) using the supremum of the conditional P values across the collection to determine the P value for inference. The fully unconditional approach takes $\pi_L = 0, \pi_U = 1$ and the supremum itself, $\sup_{\pi_0\varepsilon[0,1]}(P_{H_0:\pi=\pi_0})$, as the unconditional P value, while the formulation reduces to Fisher's exact test for the degenerate interval $\pi_L = \pi_U = n_{1+}/n_{++}$. Increased power over either of these extreme choices may often be obtained by maximizing only over a confidence interval for π, and adding the error probability of the interval to the supremum to obtain the unconditional P value; *see* **Proportions, Inferences, and Comparisons** for more detail.

A third approach bases inference on the "mid-P value", obtained through reducing the exact P value by half the probability of the observed table. Mid-P values mimic the null behavior of P values based on continuous sampling distributions more closely than do exact P values. A mid-P value has expectation 0.5 under H_0; mid-P values for one-sided tests in opposing directions sum to 1.0; and Pr(mid-P value $\leq \alpha$) is frequently much closer to α than Pr(exact P value $\leq \alpha$). However, type I error control for tests based on a mid-P value is less stringent than for conditional or unconditional exact tests, randomized tests, or for any hypothesis test properly constructed from a valid continuous sampling distribution, in the sense that Pr(mid-$P \leq \alpha$) can exceed α for some sample sizes. Similarly, the coverage probability of a confidence interval constructed by inverting mid-P-based hypothesis testing may fall short of its nominal confidence coefficient for some combinations of true probabilities and sample sizes. The mid-P value appears to be a satisfactory approximate remedy for the conservatism of Fisher's exact test in that the type I error from its repeated use in different situations can be expected to approximate the nominal level better than the error rate of Fisher's exact test. But the looser form of type I error control may compromise the suitability of mid-P values for use in settings where precise type I error control is essential to the integrity of a regulatory standard. *See* **Continuity Correction**; **Proportions, Inferences, and Comparisons**.

While inference should clearly be based on (6) when both margins of a 2×2 table are fixed by experimental design, there is no clear consensus on the best level of conditioning, and hence distributional model, to employ for inference from data generated by (1), (3), or (5). However, large-sample methods have been developed, based primarily though not exclusively on these less-conditional distributions, that are computationally simpler than exact methods, and more easily generalized to higher-dimensional contingency tables and statistical modeling of association structures involving several variables. Such large-sample methods dominate statistical practice. For moderate to large samples, these methods tend to give results close to those based on (6) and its multivariate extensions. They may not be reliable for use with sparse samples or in the context of highly eccentric distributions, but in such situations, often still provide a framework for exact analyses.

Approximate Large-sample Inference for 2 × 2 Tables

A hypergeometric-based large-sample test depends on the asymptotically Gaussian (**normal**) distribution of n_{11} as $n_{++} \uparrow \infty$ with $n_{1+}/n_{++} \to \pi_{1+}$ and $n_{+1}/n_{++} \to \pi_{+1}$. Then, by randomization **central limit theory**, the **Mantel–Haenszel** chi-square statistic

$$X^2_{\mathrm{MH}} = \frac{(n_{++}-1)(n_{++}n_{11} - n_{1+}n_{+1})^2}{n_{1+}n_{2+}n_{+1}n_{+2}} = \frac{[n_{11} - (n_{1+}n_{+1}/n_{++})]^2}{\mathrm{Var}_{H_0}(n_{11})} = \frac{(n_{11} - m_{11})^2}{\mathrm{Var}_{H_0}(n_{11})} \tag{7}$$

has a limiting χ^2_1 distribution (**chi-square distribution** with one **degree of freedom**). Several other test statistics have the same null limiting distribution under product-Poisson, multinomial, or product-binomial models. Under these models, the MLE of m_{ij} remains $\widehat{m}_{ij} = n_{i+}n_{+j}/n_{++}$ under $H_0 : \psi = 1$, and is n_{ij} under the general alternative $H_a : \psi \neq 1$. The **chi-square likelihood ratio test** statistic for testing H_0 against H_a reduces in each case to $G^2 = -2 \ln \Lambda = 2 \sum_{i=1}^{2} \sum_{j=1}^{2} n_{ij} \ln(n_{ij}/\widehat{m}_{ij})$. G^2 is sometimes abbreviated as $2 \sum \sum O \ln(O/\mathrm{E})$, where O and E respectively represent an observed cell count and its estimated expected value under H_0. However, the Pearson chi-square statistic $X^2_P = \sum_{i=1}^{2} \sum_{j=1}^{2} (n_{ij} - \widehat{m}_{ij})^2/\widehat{m}_{ij} = \sum \sum (O - \mathrm{E})^2/\mathrm{E}$, like X^2_{MH} a normalized, squared-error comparison of the n_{ij} with the $\widehat{m}_{ij}$, is more commonly used than either G^2 or X^2_{MH}. Since $X^2_{\mathrm{MH}} = [(n_{++} - 1)/n_{++}]X^2_P$, the distinction between these tests is minimal except when large-sample approximation is difficult to justify. It becomes important, however, in extensions to three-way tables (see Cochran–Mantel–Haenszel Tests below, and **Chi-square Distribution**). X^2_P and X^2_{MH} are sometimes modified to "continuity corrected" versions $X^2_{P_c}$ and $X^2_{\mathrm{MH}_c}$ by reducing each $|O - \mathrm{E}|$ in X^2_P, and equivalently $|n_{11} - m_{11}|$ in X^2_{MH}, by 1/2 to better approximate the behavior of Fisher's exact test (*see* **Yates's Continuity Correction**).

An alternate algebraic form of Pearson's statistic under product-binomial sampling is $X^2_P = z^2_P = (p_1 - p_2)^2/(n^{-1}_{1+} + n^{-1}_{2+})\overline{p}(1 - \overline{p})$, where $p_i = n_{i1}/n_{i+}$ and $\overline{p} = n_{+1}/n_{++}$. Here $p_1 - p_2$ is the MLE $\widehat{\Delta}$ of Δ, the denominator is the MLE $\widehat{\mathrm{Var}}_0(\widehat{\Delta})$ of $\mathrm{Var}(\widehat{\Delta})$ under $H_0 : \Delta = 0$, and z_P is a conventional large-sample **"standard normal deviate"** z-statistic. Since $\widehat{\mathrm{Var}}_0(\widehat{\Delta})$ is not consistent for $\mathrm{Var}(\widehat{\Delta})$ when $\Delta \neq 0$, z_P does not yield closed-form bounds of an asymptotic confidence interval for Δ. Instead, one must numerically invert the more general version of the Pearson criterion,

$$X^2_{P;\Delta_0} = \frac{((p_1 - p_2) - \Delta_0)^2}{\sum_{i=1}^{2} (\widetilde{\pi}_i(1 - \widetilde{\pi}_i)/n_{i+})}, \qquad (8)$$

where the $\widetilde{\pi}_i$ are MLEs of the π_i under the constraint $\widetilde{\pi}_1 - \widetilde{\pi}_2 = \Delta_0$, and the confidence interval is bounded by the lowest and highest values of Δ_0 retained by the hypothesis test.

A more convenient alternative to this computation is to instead estimate $\mathrm{Var}(\widehat{\Delta})$ by either its unrestricted MLE $\widehat{\mathrm{Var}}(\widehat{\Delta}) = \sum_{i=1}^{2} p_i(1 - p_i)/n_{i+}$ or **unbiased** estimator $\widetilde{\mathrm{Var}}(\widehat{\Delta}) = \sum_{i=1}^{2} p_i(1 - p_i)/(n_{i+} - 1)$, to form respective large-sample Gaussian confidence intervals $\widehat{\Delta} \pm z_{1-\alpha/2}\sqrt{(\widehat{\mathrm{Var}}(\widehat{\Delta}))}$ or $\widehat{\Delta} \pm z_{1-\alpha/2}\sqrt{(\widetilde{\mathrm{Var}}(\widehat{\Delta}))}$. Indeed, $\widehat{\Delta} \pm z_{1-\alpha/2}\sqrt{(\widehat{\mathrm{Var}}(\widehat{\Delta}))}$ is the "standard" interval in statistical pedagogy. Unfortunately, this interval is now known to be overly liberal, with slow convergence to its asymptotic coverage, below-nominal coverage in small to moderate samples, and performance notably inferior to that of the interval based on (8) and other alternatives. However, a practical and pedagogically useful replacement for this errant standard results from smoothing the 2×2 table slightly toward uniformity by adding one to each cell prior to calculating the interval. This correction is equivalent to basing the Gaussian interval not on the p_i, but rather on **Bayesian** point estimates of π_1 and π_2, chosen as posterior modes using independent, **uniform prior distributions** for the π_i. The resulting interval has the nominal behavior of its predecessor in large samples, and dramatically improved coverage in small samples, particularly when π_1 or π_2 approaches zero or one. As with any approximate interval, and intervals based on heuristic improvements to exact intervals such as mid-P, coverage can still be below nominal for specific combinations of n_{1+}, π_1, n_{2+}, and π_2.

Confidence intervals for ψ and RR may be obtained by an extension of the basic approach for Δ. The MLEs $\widehat{\psi}$ and $\widehat{RR}$ and their logarithms are smooth functions of the n_{ij}, and thus are asymptotically Gaussian. Convergence is faster on the symmetric logarithmic scale, where intervals including negative (hence inadmissible) values are also routinely avoided. From the **delta method**, the MLEs of the asymptotic standard errors (se's) of $\ln \widehat{\psi}$ and of $\ln \widehat{RR} = \ln[(n_{11}/n_{1+})/(n_{21}/n_{2+})]$ are respectively $\sqrt{(\sum \sum n^{-1}_{ij})}$ and $\sqrt{(n^{-1}_{11} - n^{-1}_{1+} + n^{-1}_{21} - n^{-1}_{2+})}$. Confidence intervals, generally symmetric, are determined on the ln scale using Gaussian critical values, and exponentiated to yield (asymmetric) intervals for ψ and RR. Although still approximate, these intervals behave more satisfactorily than does the Gaussian interval for Δ. Performance of the interval for ψ is improved by (i) extension of the interval to $\pm\infty$ respectively when $\min(n_{12}, n_{21}) = 0, \min(n_{11}, n_{22}) = 0$, and (ii) determining finite

boundaries as above after smoothing slightly toward independence, by distributing across the cells of the table a total of two additional observations in fractions proportionate to the $\widehat{m}_{ij}$. This is an **empirical Bayes** procedure in which the table is smoothed by applying a Dirichlet prior to the cell probabilities, with Dirichlet parameters summing to two and proportional to the estimated expected values under independence.

The confidence intervals for ψ, Δ, and RR, based on their respective MLEs and **consistent** asymptotic variance estimators, may each be used to generate alternative tests of $\psi = 1$. The statistic for Δ, $X_N^2 = \widehat{\Delta}^2/\widehat{\mathrm{Var}}(\widehat{\Delta})$, is of particular interest. X_N^2, known as Neyman's "minimum modified chi-square" statistic (*see* **Ban Estimates**), may be rewritten as $X_N^2 = \sum_{i=1}^2 \sum_{j=1}^2 (n_{ij} - \widetilde{m}_{ij})^2/n_{ij} = \sum\sum(O - \mathrm{E})^2/O$, where $\widetilde{m}_{i1} = n_{i+}\widetilde{p}$, $\widetilde{m}_{i2} = n_{i+} - \widetilde{m}_{i1}$, and $\widetilde{p}$ is the inverse-variance weighted average of the p_i. X_N^2 differs from X_P^2 in estimating expected counts slightly differently, and by weighting each squared deviation inversely to the corresponding observed rather than expected count. Though undefined when any cells are empty, X_N^2 converges in large samples to the same limiting distribution under $H_0 : \Delta = 0$ as do X_P^2 and G^2, as Neyman showed in conjunction with his development of best asymptotically normal (BAN) estimation.

Indeed, this limiting distribution is shared by a much broader class of test statistics, the "**power-divergence** (PD)" family of form

$$\mathcal{DIV}^{\varphi} = \left(\frac{2}{\varphi(\varphi+1)}\right) \sum_{i=1}^{2}\sum_{j=1}^{2} n_{ij}\left[\left(\frac{n_{ij}}{\overline{m}_{ij}}\right)^{\varphi} - 1\right], \tag{9}$$

where the $\overline{m}_{ij}$ are known or estimated expected counts under a null hypothesis. This is X_P^2 for $\varphi = 1$ and X_N^2 for $\varphi = -2$. The **likelihood ratio** G^2 is the limiting case as $\varphi \to 0$, and $\varphi \to -1$ yields a **Kullback–Liebler information** statistic. The minimum power-divergence estimator (mpe) $\{\widehat{m}_{ij}^{\varphi}\}$ minimizes $\mathcal{DIV}^{\varphi}$ under a null hypothesis H_0 for the m_{ij}. Thus, $\widehat{m}_{ij}$ and $\widetilde{m}_{ij}$ are respectively the MLE ($\varphi = 0$), and the "minimum Neyman chi-square" ($\varphi = -2$) estimators of m_{ij} under $H_0 : \Delta = 0$. Quite generally, mpes and PD statistics based on any mpe of m_{ij} share, respectively, common limiting null Gaussian and χ^2 distributions as $n_{++} \uparrow \infty$. (*See* **Power Divergence Methods**; **Proportions, Inferences, and Comparisons**; **Chi-square Tests**).

Likelihood Ratio, Score and Wald Statistics

Further progress requires more powerful and general tools. We therefore briefly sketch, heuristically, some likelihood results in quite general form. Consider a data vector $\boldsymbol{y}$ (e.g. $\boldsymbol{y} = (n_{11}, n_{12}, n_{21}, n_{22})'$) and associated loglikelihood function $l(\boldsymbol{\theta};\boldsymbol{y})$, where $\boldsymbol{\theta} = (\boldsymbol{\theta}_1', \boldsymbol{\theta}_2')'$ is a parameter vector. One might wish to test $H_0: \boldsymbol{\theta}_2 = \mathbf{0}$. For instance, consider the saturated loglinear model for the 2×2 table,

$$\ln m_{ij} = \mu + \gamma_{i*} + \gamma_{*j} + \gamma_{ij} \tag{10}$$

under product-Poisson, multinomial, or product-binomial sampling. We assume that **identifiability** constraints are placed on the γ_{i*}, γ_{*j}, and γ_{ij}, so that μ, γ_{1*}, γ_{*1}, and $\gamma_{11} = \ln\psi$ determine the remaining parameters. Then $\boldsymbol{\theta}_1 = (\mu, \gamma_{1*}, \gamma_{*1})'$ and $\boldsymbol{\theta}_2 = (\gamma_{11})$ places testing of $\psi = 1$ or $\Delta = 0$ in this context.

When $l(\boldsymbol{\theta};\boldsymbol{y})$ is smooth in a neighborhood of $\boldsymbol{\theta}$, the MLE $\widehat{\boldsymbol{\theta}} = (\widehat{\boldsymbol{\theta}}_1', \widehat{\boldsymbol{\theta}}_2')'$ is a solution of the likelihood equations $\partial l(\boldsymbol{\theta};\boldsymbol{y})/\partial\boldsymbol{\theta} = \mathbf{0}$ and **converges in probability** to $\boldsymbol{\theta}$. Let $\boldsymbol{\theta}^{\circ} = (\boldsymbol{\theta}_1', \mathbf{0}')'$ and $\widehat{\boldsymbol{\theta}}^{\circ} = (\widehat{\boldsymbol{\theta}}_1^{\circ\prime}, \mathbf{0}')'$ be, respectively, $\boldsymbol{\theta}$ and its MLE under H_0. Under H_0, $\widehat{\boldsymbol{\theta}}_2$ from a large sample will likely be close to $\mathbf{0}$, a prediction that may be checked to evaluate the plausibility of H_0. Moreover, both $\widehat{\boldsymbol{\theta}}$ and $\widehat{\boldsymbol{\theta}}^{\circ}$ will likely be close to $\boldsymbol{\theta}$, placing them both in the neighborhood of $\boldsymbol{\theta}$, where $l(\boldsymbol{\theta};\boldsymbol{y})$ is smooth. Thus, chances are that $l(\widehat{\boldsymbol{\theta}}^{\circ};\boldsymbol{y})$ will be close to $l(\widehat{\boldsymbol{\theta}};\boldsymbol{y})$, a second verifiable prediction of H_0. Finally, under H_0, the log-likelihood slope in any $\boldsymbol{\theta}_2$ direction has expectation $\mathbf{0}$ when evaluated either at $\boldsymbol{\theta}^{\circ}$ or $\widehat{\boldsymbol{\theta}}^{\circ}$, and should not often depart greatly from that. This may also be checked, evaluating at $\boldsymbol{\theta}^{\circ}$ if $\boldsymbol{\theta}_1$ is known and at $\widehat{\boldsymbol{\theta}}^{\circ}$ otherwise. We may thus test compatibility of the data with H_0 by checking these stochastically usual consequences for the parameter estimates, log-likelihood, and score.

The deviation of $l(\widehat{\boldsymbol{\theta}}^{\circ};\boldsymbol{y})$ from $l(\widehat{\boldsymbol{\theta}};\boldsymbol{y})$ is evaluated through the large-sample null χ_{ν}^2 distribution of $-2\ln\Lambda$, where $\nu = \mathrm{rank}\ \boldsymbol{\theta}_2$. The MLE and log-likelihood slope are evaluated in terms of their limiting **multivariate normal distributions**. The large-sample multivariate Gaussian distribution of $\widehat{\boldsymbol{\theta}}$ has mean $\boldsymbol{\theta}$ and $\mathrm{cov}_A(\widehat{\boldsymbol{\theta}}) = \mathcal{I}(\boldsymbol{\theta})^{-1}$, where $\mathcal{I}(\boldsymbol{\theta}) = -E([\partial^2 l(\boldsymbol{\theta};\boldsymbol{y})/\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}'])$ is Fisher's **information matrix**. Consequently, the large-sample null marginal

distribution of the component $\widehat{\boldsymbol{\theta}}_2$ has mean $\mathbf{0}$ and $\text{cov}_A(\widehat{\boldsymbol{\theta}}_2) = \text{V}_{\widehat{\boldsymbol{\theta}}_2}(\boldsymbol{\theta})$, the lower right block of $\mathcal{I}(\boldsymbol{\theta})^{-1}$. Since this may be estimated consistently by $\text{V}_{\widehat{\boldsymbol{\theta}}_2}(\widehat{\boldsymbol{\theta}})$, the quadratic form $\text{Q}_W = \widehat{\boldsymbol{\theta}}_2' \, [\text{V}_{\widehat{\boldsymbol{\theta}}_2}(\widehat{\boldsymbol{\theta}})]^{-1}\widehat{\boldsymbol{\theta}}_2$ has the same null asymptotic χ^2_ν distribution as $-2\ln\Lambda$. Statistics of form Q_W are "Wald statistics", and corresponding chi-square tests are "Wald tests" (*see* **Likelihood**).

More generally, for estimation of a parameter vector $\boldsymbol{\theta}$, or a subvector $\boldsymbol{\theta}_2$ from a categorical data model, a "best asymptotically normal (BAN)" estimator $\boldsymbol{F}$ is a consistent, asymptotically efficient multivariate Gaussian estimator that has continuous partial derivatives with respect to the observed counts. BAN estimators share the same asymptotic null distribution, and mpes are BAN. Any quadratic form $\boldsymbol{F}'\widehat{\boldsymbol{V}}_{\boldsymbol{F}}^{-1}\boldsymbol{F}$, where $\widehat{\boldsymbol{V}}_{\boldsymbol{F}}$ is a consistent estimate of the asymptotic **covariance matrix** $\text{cov}_A(\boldsymbol{F})$ of $\boldsymbol{F}$, is an extended Wald statistic sharing the same asymptotic properties as Q_W under the null. Different extended Wald statistics for the same hypothesis share the same null asymptotic χ^2 distribution, though their non-null asymptotic cdfs may differ.

The log-likelihood slope $\boldsymbol{S}_2$, defined as $\partial l(\boldsymbol{\theta};\boldsymbol{y})/\partial\boldsymbol{\theta}_2$ evaluated at $\boldsymbol{\theta}_2 = \mathbf{0}$, is called the "likelihood score" or "Rao's efficient score" for $\boldsymbol{\theta}_2$. The large-sample null multivariate Gaussian distribution of $\boldsymbol{S}_2$ has $\text{cov}_A(\boldsymbol{S}_2) = \mathcal{I}_{22}(\boldsymbol{\theta}^\circ)$, the lower right block of $\mathcal{I}(\boldsymbol{\theta}^\circ)$. If $\boldsymbol{\theta}_1$ is known, then so is $\mathcal{I}_{22}(\boldsymbol{\theta}^\circ)$ under H_0. The "score statistic" for testing H_0 is then the quadratic form $Q_S(\boldsymbol{\theta}^\circ) = \boldsymbol{S}_2'(\boldsymbol{\theta}^\circ)[\mathcal{I}_{22}(\boldsymbol{\theta}^\circ)]^{-1}\boldsymbol{S}_2(\boldsymbol{\theta}^\circ)$ reflecting the magnitude of the score relative to its variability, which the "score test" evaluates using the χ^2_ν distribution as above. When $\boldsymbol{\theta}_1$ is unknown and the score is thus evaluated at $\widehat{\boldsymbol{\theta}}^\circ = (\widehat{\boldsymbol{\theta}}_1^{\circ\prime}, \mathbf{0}')'$, the use of the MLE $\widehat{\boldsymbol{\theta}}_1^\circ$ constrains $\boldsymbol{S}_1 = \partial l(\boldsymbol{\theta};\boldsymbol{y})/\partial\boldsymbol{\theta}_1$ to $\mathbf{0}$, and the observed score must be assessed against the conditional distribution under that restriction. The conditional covariance matrix is $\text{cov}_A[\boldsymbol{S}_2|(\boldsymbol{S}_1 = \mathbf{0})] = \mathcal{I}_{\theta_2|\theta_1} = \mathcal{I}_{22} - \mathcal{I}_{21}\mathcal{I}_{11}^{-1}\mathcal{I}_{12}$, and the corresponding score statistic is $Q_S(\widehat{\boldsymbol{\theta}}^\circ) = \boldsymbol{S}_2'(\widehat{\boldsymbol{\theta}}^\circ)[\mathcal{I}_{\theta_2|\theta_1}(\widehat{\boldsymbol{\theta}}^\circ)]^{-1}\boldsymbol{S}_2(\widehat{\boldsymbol{\theta}}^\circ)$, also χ^2_ν under H_0. Equivalently, in terms of the overall score vector $\boldsymbol{S}' = (\boldsymbol{S}_1', \boldsymbol{S}_2')'$, this is $\boldsymbol{S}'(\widehat{\boldsymbol{\theta}}^\circ)\mathcal{I}(\widehat{\boldsymbol{\theta}}^\circ)^{-1}\boldsymbol{S}(\widehat{\boldsymbol{\theta}}^\circ)$.

Some score statistics are extended Wald statistics. For instance, in the **Poisson regression**, **logistic regression**, and loglinear models discussed below, a score statistic is a quadratic form in linear functions of residuals from the likelihood fit of H_0, with kernel the null-based MLE of their inverse asymptotic covariance matrix.

Most asymptotic test statistics in common use for categorical data take the form of either $-2\ln\Lambda$, Q_S, or Q_W, for appropriate distributions and parametric models. Wald and score tests are often substituted for likelihood ratio tests, because they are less computationally demanding when working with multivariable models. Maximum likelihood estimation frequently requires iterative numerical approximation. Each likelihood ratio test requires two MLEs, $\widehat{\boldsymbol{\theta}}$ and $\widehat{\boldsymbol{\theta}}_1^\circ$. In exploratory analyses, one may wish to examine the statistical significance of many individual parameters within a single model, using the results for model reduction. The MLE $\widehat{\boldsymbol{\theta}}$ for the baseline model is needed for every test, but $\widehat{\boldsymbol{\theta}}_1^\circ$ changes with each parameter or parameter set to be tested. In contrast, Wald tests depend only on $\widehat{\boldsymbol{\theta}}$. For instance, for testing 10 parameters individually, likelihood ratio testing requires 11 numerical optimizations as compared to 1 for the Wald test.

Similarly, when many candidate predictor variables are available for initiating a model or augmenting a baseline model, the score test is more convenient than the likelihood ratio test. Defining $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$, respectively, as the parameter vectors of variables already in the model and of candidates for entry, only $\widehat{\boldsymbol{\theta}}_1^\circ$ from the baseline model is needed to construct a score statistic for testing candidate variables, individually or in groups, for incremental explanatory power. Although such computational economies have gradually become less important for individual models with the extraordinary increase in available computational power, computer software has tended to retain these practices to facilitate exploration of larger and more complex models.

The previous results for 2×2 tables can be better understood, and extended, after reinterpretation in the context of this section. Under product-binomial sampling, the hypothesis $H_0 : \Delta = 0$ in terms of probabilities is equivalent to $H_0 : \delta_i = 0$, $i = 1, 2$ in the model for expected cell counts $m_{i1} = n_{i+}(\mu + \delta_i)$, with a suitable identifiability constraint. In contrast to (10), this model may be reexpressed as linear constraints on the m_{ij}, since the n_{i+} are fixed in product-binomial sampling. Neyman chi-squares for such linear hypotheses are Wald statistics. Further, if nonlinear constraints on the m_{ij} in any hypothesis are replaced by their linear Taylor series approximations at $m_{ij} = n_{ij}$, then X^2_N for the "linearized" hypothesis

is a Wald statistic for its nonlinear parent. This gives a particularly simple recipe for asymptotically (first order) optimal inference, since minimum X^2_N estimators and the associated X^2_N may be obtained from one-step WLS computations.

Specifically, in the 2×2 context Neyman's X^2_N, obtained by inverting the large-sample Gaussian confidence interval for Δ, is the Wald test for $\Delta = 0$. Similarly, the **delta method**-based intervals for ψ and RR are inversions of Wald tests, which in this case are also linearized Neyman chi-square tests, for $\psi = \psi_0$ and $RR = RR_0$. G^2, and $X^2_P = X^2_{P;0}$ in (8), are respectively the likelihood ratio and score statistics for $\Delta = 0$, or $H_0 : \gamma_{11} = 0$, in (10).

More generally, Pearson's $X^2_{P;\Delta_0}$ (8) is the score statistic $Q_{S;\Delta_0}$ for testing $\Delta = \Delta_0$. Analogous score tests of $RR = RR_0$ and $\psi = \psi_0$ are obtained respectively from

$$Q_{\mathrm{S;RR}_0} = \frac{n_1(p_1 - \widetilde{\pi}_1)^2}{\widetilde{\pi}_1(1 - \widetilde{\pi}_1)} + \frac{n_2(p_2 - \widetilde{\pi}_2)^2}{\widetilde{\pi}_2(1 - \widetilde{\pi}_2)}, \qquad (11)$$

where $\widetilde{\pi}_i$ is the MLE of π_i under the constraint that $RR = RR_0$, and

$$Q_{\mathrm{S};\psi_0} = Cn_1(p_1 - \widetilde{\widetilde{\pi}}) \left[\frac{1}{n_1\widetilde{\widetilde{\pi}}_1(1 - \widetilde{\widetilde{\pi}}_1)} + \frac{1}{n_2\widetilde{\widetilde{\pi}}_2(1 - \widetilde{\widetilde{\pi}}_2)} \right], \qquad (12)$$

where $\widetilde{\widetilde{\pi}}_i$ is the MLE of π_i under the constraint that $\psi = \psi_0$ and C is a normalizing constant.

Comparative studies of score and Wald tests, and their associated confidence intervals, indicate that the score-based procedures generally approach nominal behavior more rapidly, and therefore, perform more acceptably in small to moderate samples, than the corresponding Wald procedures. As the associated computations have become less intimidating in the light of expanded computing power, the advantages of confidence intervals obtained by inverting two-sided tests based on the above score criteria have increasingly been recognized. Among asymptotically based intervals, these appear to maintain near-nominal coverage for a wide range of sample size and probability configurations.

For situations in which near is not enough, because nominal coverage in all conditions must be guaranteed, exact intervals are required. For this purpose as well, confidence intervals based on score statistics are increasingly used. In these situations, a score statistic is employed, as described earlier, as the criterion for ordering possible outcomes in computing an exact P value. Note that the standardization by estimated variance in the score statistics (8), (11), and (12) produces a finer partition of the sample space than the corresponding unstandardized measure of association, thus rendering exact analysis less discrete, and potentially reducing the conservatism of exact intervals. The difference between the true and nominal coverage of an exact interval can be further reduced, and the interval narrowed correspondingly, by unconditional rather than conditional exact testing, and by further restricting the range of unconditional analysis to values of the nuisance parameter that are not grossly implausible in light of the observed data.

Matched Pairs

The above discussion of 2×2 tables has omitted the simplest categorical analog to paired continuous data, 2×2 tables in which A and B represent a single dichotomy observed under different circumstances, or on members of n_{++} **matched pairs**. In such tables, association between the two dimensions is usually taken for granted, and ψ becomes a nuisance parameter. Interest shifts to discrepancies between the marginal probabilities π_{1+} and π_{+1}, expressed as the marginal risk difference $\Delta_M = \pi_{1+} - \pi_{+1}$, marginal risk ratio $RR_M = \pi_{1+}/\pi_{+1}$, or matched odds ratio $\psi_M = \pi_{12}/\pi_{21}$. Approaches introduced above may be used for inference about Δ_M, RR_M, and ψ_M. For Δ_M, see Marginal Homogeneity in Square Tables below (*see* **Square Contingency Table**). Matched categorical data are more easily treated generally, however, by viewing matched sets of observations as observational strata, with observations cross-classified in a three-way table with dimensions defined respectively by the strata, the condition of observation or other within-stratum factor, and the response variable. (*See* Cochran–Mantel–Haenszel tests below, and **McNemar Test**; **Matched Pairs With Categorical Data**; **Mantel–Haenszel Methods**).

Inference for $r \times c$ Tables

An $r \times c$ table may be viewed as a collection of 2×2 subtables, the challenge being to knit the subtables together in a reasonable structure for inference

that allows adequate error control. Ways of coping with the overparameterization in larger tables depend heavily on whether the variables A, B, or both are ordinal. Ordinality presents special opportunities for combining parameters across cells or incorporating scaling into a model for the m_{ij} (*see* **Ordered Categorical Data**).

The probability distributions defined above apply with $r \times c$ rather than $2 \times 2 = 4$ categories, or generalize directly: the noncentral hypergeometric to the multivariate noncentral hypergeometric, and the product-binomial to the product-multinomial. As with 2×2 tables, there are two distinct spheres of analysis. In the study of association between row and column variables, equivalently expressible as heterogeneity across rows of the conditional column distributions $\Pr(B = j|A = i) = m_{ij}/m_{i+}$, the null hypothesis is independence or conditional homogeneity, and the marginal distributions $\Pr(A = i) = m_{i+}/m_{++}$ and $\Pr(B = j) = m_{+j}/m_{++}$ are either known or of only secondary interest. Numerous indices have been developed to summarize, for particular purposes, the overall level of association in an $r \times c$ table. See **Association, Measures of** for enumeration and discussion of these. In contrast, in the study of repeated measurements or other matched data in square tables, the focus is on differences between these marginal distributions; the null hypothesis is marginal homogeneity and row by column association is of only secondary interest (*see* **Marginal Models**).

Marginal Homogeneity in Square Tables

We consider the simpler repeated measures case first. If the salient variable A is nominal, then H_0 : $m_{i+} - m_{+i} = 0, i = 1, \ldots, r$ is linear in the m_{ij}. In this case, $X_N^2 = Q_W$ is a quadratic form in an arbitrary $r - 1$ of the $(n_{i+} - n_{+i})$, with covariance matrix estimated at $m_{ij} = n_{ij}$, and is asymptotically χ^2_{r-1} under H_0. If A is ordinal with **scores** s_i, then comparison of the mean row score $\mu_r = \mathrm{E}(\overline{s}_r) = \mathrm{E}(n_{++}^{-1} \sum_{i=1}^{r} n_{i+}s_i)$ with the mean column score $\mu_c = \mathrm{E}(\overline{s}_c) = \mathrm{E}(n_{++}^{-1} \sum_{i=1}^{r} n_{+i}s_i)$ may be of primary interest. The corresponding Wald/Neyman χ^2_N for H_0 : $\mu_r - \mu_c = 0$ has null large-sample χ^2_1 distribution and is a contingency table counterpart of the **paired *t*-statistic**. Routine generation of covariance kernels for such tests is straightforward (see Weighted Least-Squares Analysis below). The tests may be inverted to obtain, in the former case, a confidence region for the vector of the $m_{i+} - m_{+i}$, and in the latter, a confidence interval for the scalar $\mu_r - \mu_c$.

When levels have no associated natural scores, it is often reasonable to apply the above methods with equally-spaced scores, especially for **questionnaire** data, with responses such as much improved, improved, the same, worse, and much worse. When linear scaling is unreasonable, data-derived scores may be used with appropriate conditioning. For this purpose, the $n_{ij}, i \neq j$, may be extracted and reformulated as an $(r - 1) \times 2$ table in which, for $k = 1, \ldots, r - 1$, $n^{\dagger}_{k1} = \sum \sum_{i-j=k} n_{ij}$ and $n^{\dagger}_{k2} = \sum \sum_{j-i=k} n_{ij}$. Row k of this table contains all elements of the parent table whose row and column categorizations differ by k levels. Rank scores may then be derived from the row sums $n^{\dagger}_{k+} = \sum_{l=1}^{2} n^{\dagger}_{kl} = \sum \sum_{|i-j|=k} n_{ij}$ of the reformulated table. Conditioning on the $n^{\dagger}_{k+}$, the $(r - 1) \times 2$ table may usually be treated as product-binomial with fixed row scores (see $r > c = 2$ below), yielding for example, categorical counterparts of the **signed-rank test**.

An alternative likelihood ratio approach for nominal data is based on the relationship of marginal homogeneity to two forms of interior symmetry. The model $m_{ij} = m_{ji}$ represents symmetric reflection off the main diagonal, or "total symmetry". The weaker **quasi-symmetry** model specifies that $\gamma_{ij} = \gamma_{ji}$ in (10). Total symmetry is the special case of quasi-symmetry with homogeneous margins. If quasi-symmetry can be justified, either *a priori* or by a nonsignificant **goodness-of-fit** test with adequate power, then the likelihood ratio statistic comparing total symmetry with quasi-symmetry is a valid test of marginal homogeneity. The df of the limiting χ^2_{r-1} distribution is the difference between the $(r^2 - r)/2 = r(r - 1)/2$ linearly independent constraints of total symmetry on the m_{ij} and the $[(r - 1)^2 - (r - 1)]/2$ constraints of quasi-symmetry on the $(r - 1)^2$ linearly independent γ_{ij} (*see* **Matched Pairs With Categorical Data**; **Square Contingency Table**).

$r > c = 2$

G^2, X_P^2, X_N^2, and exact hypergeometric methods extend directly from the 2×2 case, but neglect any ordering of A. Consequently, power functions of the resulting hypothesis tests fail to differentiate important and contextually plausible distributional

shifts or monotonic trend alternatives from irregular alternatives of equal magnitude but negligible plausibility. The appropriate method for incorporating ordinality depends on which margins are fixed by study design or conditioned upon in analysis. When scores s_i are available for the rows with the n_{i+} random and the n_{+j} fixed, it is natural to compare the column mean scores $\overline{s}_1 = n_{+1}^{-1} \sum_{i=1}^{r} m_{i1} s_i$ and $\overline{s}_2 = n_{+2}^{-1} \sum_{i=1}^{r} m_{i2} s_i$. This is readily done using $Q_W = X_N^2$ for the single linear contrast $\overline{s}_1 - \overline{s}_2 = 0$, yielding contingency table counterparts of Student's t-test and its associated confidence interval. When the n_{i+} and n_{+j} are fixed, an equivalent test may be obtained by substituting the null hypergeometric variance of this contrast for the estimated variance in Q_W.

When the n_{+j} are random and the n_{i+} are fixed, models relating the conditional probability $\pi_i = \pi_{i1} / \sum_{j=1}^{2} \pi_{ij}$ to s_i are natural analogs of univariate continuous regression analyses. The Cochran–Armitage trend test (*see* **Trend Test for Counts and Proportions**) is based on an unweighted least-squares fit of the simple linear regression of the p_i on the s_i. This amounts to a partitioning of the Pearson X_P^2, with df = r-1, into a multiple of the squared fitted regression coefficient and a weighted combination of squared deviations of observed from model-predicted proportions, respectively analogous to the regression and residual sums of squares for a continuous response. Under $H_0 : \pi_i = \pi$, both components have large-sample χ^2 distributions, with respectively 1 and $r - 2$ df. The first component is also valid as another t-test counterpart for detecting a difference in mean row scores between columns. Under the same model, the corresponding Wald/Neyman χ_N^2 uses a WLS-based slope estimate, while G^2 iterates the same WLS computation until convergence. These latter approaches are readily extended to polynomial regression models for the π_i, and can provide confidence intervals for estimated regression parameters. The residual X_N^2 and G^2 statistics retain their null χ_{r-2}^2 distribution under simple linear regression alternatives to H_0, and hence may be interpreted as lack-of-fit statistics.

The related partition of chi-square technique (*see* **Chi-square, Partition of**) is useful for isolating heterogeneity in tables of nominal variables where association between rows and columns has been established. If a nested sequence of hypotheses can be developed whose intersection implies independence, or homogeneity of rows or columns, then test statistics for corresponding collapsed versions of the original table are approximately additive, and have asymptotically independent null χ^2 distributions. This is best shown by example. Table 4 relates infant malformations to mother's alcohol consumption. For these data, $X_P^2 = 6.9494$ with df $= 2$, $P = 0.031$, indicating statistically significant variation in the incidence of malformation with alcohol intake during the first trimester of pregnancy. However, the effect is exclusively associated with consumption of at least three drinks daily, as shown by the components of X_P^2 comparing the first two categories of alcohol consumption ($X_P^2 = 0.0984$ with df $= 1$, $P = 0.754$), and comparing the last category of alcohol consumption with these two categories pooled ($X_P^2 = 6.8557$ with df $= 1$, $P = 0.009$). These components are nested because all categories contrasted by the first test are pooled together in the contrast examined by the second test. Although the test statistics for the component single degree of freedom (df) tests do not precisely sum to that for the overall two df test ($6.8557 + 0.0984 = 6.9541 \neq 6.9494$), this does not compromise the validity of the tests individually; exact partitioning may be obtained by analogous use of G^2 or X_N^2. Partitioning requires caution, however, under product-binomial sampling with disproportionately sampled population subgroups. Pooling of such sample subgroups may produce biased estimates of proportions in the pooled population categories, and invalid tests based upon them.

Table 4 Infant malformations, by mother's average number of alcoholic drinks/day in first trimester of pregnancy; adapted from [1]

	Infant malformations		
Drinks/Day	Absent	Present	Total deliveries
0	17 066	48	17 114
1–2	14 464	38	14 502
3+	952	7	959

When the n_{+j} are fixed, the n_{i+} are random, and natural scores are not at hand, equally-spaced (linear) scores may be used *a priori* where that seems reasonable, or rank scores may be derived from the marginal distribution $\{n_{i+}\}$. Binary (zero or one) scores differentiating groups of low and high categories, Wilcoxon **rank** scores, and scores that transform Wilcoxon scores to expected order statistics (*see* **Normal Scores**) or to the inverse of a continuous cdf, are commonly used. For fixed s_i, likelihood

ratio, score or Wald statistics may be obtained for the structural model $H_0 : \bar{s}_1 - \bar{s}_2 = \sum_{i=1}^{r} s_i(m_{i1}/n_{+1} - m_{i2}/n_{+2}) = 0$. When the s_i are rank scores, either the multivariate hypergeometric distribution should be employed or the scores should be treated as random and their variation incorporated into the test statistic. With the former approach, a quadratic form with covariance matrix from the multivariate (central) hypergeometric distribution may be used as test statistic. Under the latter approach, the Wald test, obtained by approximating the nonlinear $\bar{s}_1 - \bar{s}_2$ by a linear function of the n_{ij}, may be used. These statistics have limiting χ_1^2 distributions, and yield categorical data counterparts of the Wilcoxon rank sum and other rank tests for continuous data (*see* **Wilcoxon–Mann–Whitney Test**).

The tests above differ in their handling of nuisance parameters. Some, for example, the two-population likelihood ratio comparison of means of predetermined scores, employ test statistics whose asymptotic distributions are fully specified under the nominal null hypothesis. This is accomplished by collapsing over nuisance parameters, conditioning them out, or optimizing over their possible values. For others, for example, the Cochran–Armitage trend test and the hypergeometric-based comparison of means of data-derived scores, nuisance parameters still influence the distribution of the test statistic when the nominal null hypothesis is true, and are only removed by testing a more restrictive hypothesis. Such procedures are best understood as tests of the more restricted rather than the nominal null hypotheses, but with power concentrated against alternatives to the latter. They may not be unbiased tests of the nominal null, but this deficiency has minimal practical consequences.

Ordinality may also be handled by incorporating category distances, as determined by scores, directly into the structure of the m_{ij}. This allows **parsimonious** summarization and targeted testing of ordinal association. Roughly speaking, a set of statistics $\mathcal{S}$ is **sufficient** for a set of parameters if the likelihood equations for estimating the parameters involve the data only through the members of $\mathcal{S}$. Loglinear models may be constructed with parameters for which simple observed functions of scores, such as means and covariances, are sufficient statistics. In the $r \times 2$ table, writing $\gamma_{\text{loc}}^i = \ln m_{i1} - \ln m_{i2} - \ln m_{i+1,1} + \ln m_{i+1,2} = \ln \psi_i$, where γ_{loc}^i is also γ_{ij} as in (10), the model $\gamma_{\text{loc}}^i = (s_i - s_{i+1})\beta$ is a simple linear regression model for the $\text{logit}(\pi_i) = \ln[\pi_i/(1-\pi_i)]$ as a function of the s_i, with β the regression parameter. The mean score $n_{+1}^{-1} \sum_{i=1}^{r} n_{i1} s_i$ is sufficient for β in this model. When the model fits, the $r-1$ parameters γ_{loc}^i, $i = 1, \ldots, r-1$, reduce to a single β that, in conjunction with parameters for the marginal distributions, completely specifies the m_{ij}. An estimate $\widehat{\beta}$ can then be used to summarize the strength and direction of the change in conditional probability between rows, or the change in mean score between columns, in an observed table.

In biostatistics, this "logit model" was developed for the analysis of quantal **bioassay** data, where a test animal was presumed to respond or not respond to a drug or toxic agent depending on whether or not the animal's individual tolerance threshold was exceeded by the dose. The **logistic distribution** was used to model the distribution of tolerance thresholds across animals because of its similarity to the Gaussian distribution, coupled with its exceptional mathematical convenience. Animals were generally dosed in groups, with $s_i = \ln(\text{dose}_i)$. This analytic advance was seminal for loglinear, **logistic regression**, weighted least-squares, and **generalized linear modeling** (*see* **Quantal Response Models**; **Psychometrics, Overview**).

The odds ratio structure of the logit model may be applied outside the framework (10) of a loglinear model for cell probabilities. Suppose row margins are random. Rather than modeling the logarithms of the "local" odds ratios γ_{loc}^i, that is, the ln odds ratios of expected cell counts from adjacent rows in the $r \times 2$ table, one may model the logarithms of the corresponding cumulative odds ratios of the (r-1) 2×2 tables obtained by collapsing rows 1 through i and rows $(i+1)$ through r, for $i = 1, \ldots, r-1$. The ith of these overlapping, cumulative tables has expected entries $m_{1j}^i = \sum_{l=1}^{i} m_{lj}$, $m_{2j}^i = n_{+j} - m_{1j}^i$. Then the model $\gamma_{\text{cum}}^i = \ln(m_{11}^i m_{22}^i / m_{12}^i m_{21}^i) = (s_i - s_{i+1})\beta$ is a "cumulative" (or "global") odds ratio model. Multifactor linear models for logarithms of global rather than local odds are often called **proportional odds models**. Similarly, the ith of an alternative set of $(r-1)$ 2×2 derived tables may be constructed using the m_{ij} as first and the m_{2j}^i as second rows. The $(r-1)$ "continuation-ratio" odds ratios γ_{cr}^i from these tables are used primarily in analyses of grouped survival data, where $m_{ij} / \sum_{l=i+1}^{r} m_{lj}$ is the conditional odds and $m_{ij} / \sum_{l=i}^{r} m_{lj}$ is the conditional probability of an event such as death in the ith observation period, given survival through the preceding

periods without experiencing the event. Ratios of these probabilities and odds represent discrete data counterparts of **hazard ratios** for continuous survival data, and become essentially equivalent when rows correspond to sufficiently short time intervals. Thus, linear models for the corresponding $\ln \gamma_{\text{cr}}^i$ and $\ln RR_{\text{cr}}^i$ are discrete counterparts of **proportional hazards** models for continuous survival data (*see* **Survival Analysis, Overview**).

Many of the above ordinal models may be further extended by treating the scores as unknown parameters to be estimated rather than as fixed. (*See* **Ordered Categorical Data**).

$c > 2$

General $r \times c$ tables allow the possibilities of **polytomous** nominal and/or ordinal variables on either or both dimensions. The methods above extend readily. For instance, Student's t-statistic counterparts with large-sample χ_1^2 distributions extend directly to counterparts of analysis of variance $\boldsymbol{F}$ **tests** with asymptotic $\chi_{(c-1)}^2$ distributions. Conditional or unconditional exact tests, based either on ordering tables by their multivariate hypergeometric probabilities under independence (thereby generalizing Fisher's exact test), or on orderings according to pivot functions such as X_P^2, are available for tables with cell expectations too low to support inference based on large-sample chi-square approximations.

For tables with nominal columns and ordinal rows with associated fixed scores $\{s_i\}$, we may directly extend the linear logit model for the $r \times 2$ table by applying such models simultaneously within each pair of columns. The model for the full table parameterizes the local odds ratios $\psi_{ij} = \pi_{ij}\pi_{i+1,j+1}/\pi_{i,j+1}\pi_{i+1,j}$ as $\ln \psi_{ij} = (s_i - s_{i+1})(\xi_j - \xi_{j+1})$, where the $\{\xi_j\}$ are unknown column parameters. Within each pair of columns, odds ratios between rows are a multiple of the differences between the fixed row scores. The multiple, however, varies across column pairs according to differences among the ξ_j. Hence, $\beta_{j'j''} = \xi_{j'} - \xi_{j''}$ plays the role of β in the linear logit model of the $r \times 2$ table, for columns j' and j'', by representing the extent to which the row distribution in the column j' is stochastically higher or lower than the row distribution in the column j''.

When both rows and columns are ordinal with respective fixed scores $\{s_i^{(r)}\}$ and $\{s_j^{(c)}\}$, association may be examined through the **correlation** of row and column scores. If the true covariance or correlation is the primary function of the m_{ij} of interest, either a loglinear model may be constructed with an overall association parameter for which the sample covariance is a sufficient statistic, or inference may focus directly on the sample covariance and its distribution.

The model in the first case parameterizes the local odds ratios as $\ln \psi_i = (s_i^{(r)} - s_{(i+1)}^{(r)})(s_j^{(c)} - s_{(j+1)}^{(c)})\beta$. The sample covariance is sufficient for β. Within a given pair of rows, the log odds ratios between pairs of columns vary linearly with the difference in column scores, while within a given pair of columns, the log odds ratios between pairs of rows vary linearly with the difference in row scores. Hence, this "linear by linear association model" simultaneously applies the linear logit model for an $r \times 2$ table within all such tables formed by pairs of columns or pairs of transposed rows, and all these models share the same slope β. When both the $\{s_i^{(r)}\}$ and $\{s_j^{(c)}\}$ are equally spaced, the local log odds ratios for all 2×2 subtables formed from adjacent rows and columns throughout the $r \times c$ table are the same multiple of β, hence identical. In this "uniform association model", the single odds ratio e^β replaces the $(r-1)(c-1)$ parameters necessary to describe the association structure of an arbitrary $r \times c$ table. This representation approaches the simplicity and elegance of the correlation coefficient in the **bivariate normal** Gaussian distribution for continuous data. *A priori* justification for a uniform association model is rare, however, and this model is more useful for approximating a monotonic trend, or as a smoothing device for generating tests with power directed at linear correlation alternatives, than as a full representation of many data sets.

An alternative approach is direct inference from $\widehat{\text{cov}}(s^{(r)}, s^{(c)})$. The random portion of $\widehat{\text{cov}}(s^{(r)}, s^{(c)})$ is nonlinear in the n_{ij} under product-Poisson, multinomial, or product-multinomial sampling but linear, through $\sum\sum s_i^{(r)} s_j^{(c)} n_{ij}$, when conditioning on both row and column margins. Under such dual conditioning, the quadratic form statistic from $\widehat{\text{cov}}(s^{(r)}, s^{(c)})$ and its variance under the multivariate (central) hypergeometric distribution may be used as a test of independence with power function directed at linear correlation. Use of this test, which generalizes X_{MH}^2 in the 2×2 table, is analogous to testing $\rho = 0$ to detect association between continuous variables, when monotonic but not necessarily linear association is anticipated. Null covariance does not imply

independence for any of the relevant distributions, so optimizing the likelihood under $H_0 : \mathrm{cov}(s^{(r)}, s^{(c)}) = 0$ is difficult. Thus, likelihood ratio and score statistics are often obtained after imposing additional structure on the m_{ij}. However, the Wald statistic is straightforward to determine and, as it uses a consistent estimate of the variance of $\widehat{\mathrm{cov}}(s^{(r)}, s^{(c)})$ unrestricted by the null hypothesis, its null χ^2_1 distribution is valid without additional assumptions (*see* **Ordered Categorical Data**).

Three-dimensional Tables

Extensions of many methods for two-way tables are straightforward. Indeed, three-dimensional tables can be reduced to two-dimensional tables whenever two variables, say B and C, are conditionally independent within each level of the third variable A. In that case, the two-way marginal $A \times B$ and $A \times C$ tables are sufficient statistics for the cell parameters of the three-way table, and hence, contain all the information in the data about the joint distribution of A, B, and C. Moreover, extending (10), conditional association structures can be represented by loglinear models whose parameters correspond to the usual deviation contrasts of balanced three-way factorial ANOVA, applied to the $\ln m_{ij}$. Each **hierarchical model** (for which every interaction is accompanied by all lower order interactions and main effects of its members) represents a different association structure. All variables are independent under the main effects model. When a single pairwise interaction is present, the interacting variables are jointly independent of the third. When two pairwise interactions are present, the unpaired variables are conditionally independent of each other, given the third. When all pairwise interactions are present without three-way interaction, each conditional odds ratio relating two variables is constant over levels of the third variable.

Confounding and Effect Modification

However, the loglinear models corresponding to saturated and "no three-way interaction" ANOVA models introduce fundamental issues that occur only in contingency tables of three or more dimensions. These are most easily explained through a 2^3 table of expected counts. Thus, the layers of Table 5 represent two strata of a population, such as men and women (variable A), in which an exposure such as an environmental risk factor or a new clinical treatment regimen (variable B) has been related by observational study to a health outcome such as new disease or death (variable C). The subscript hij refers to the cell in stratum (layer) h, row i, and column j.

Table 5 A 2^3 Contingency table relating exposure to health outcome in two strata

Variable A: Stratum, Stratum 1

	Variable C: Outcome		
Variable B: Exposure	Present	Absent	Total
Exposed	n_{111}	n_{112}	n_{11+}
Not exposed	n_{121}	n_{122}	n_{12+}
Total	n_{1+1}	n_{1+2}	n_{1++}

Variable A: Stratum, Stratum 2

	Variable C: Outcome		
Variable B: Exposure	Present	Absent	Total
Exposed	n_{211}	n_{212}	n_{21+}
Not exposed	n_{221}	n_{222}	n_{22+}
Total	n_{2+1}	n_{2+2}	n_{2++}

The saturated model allows the possibility, as may occur in any observed table, that the odds ratios $\psi_{(h)} = m_{h11}m_{h22}/m_{h12}m_{h21}$ relating exposure to outcome in each stratum may vary. For example, the effect of a treatment on recovery from disease might be different for men than for women. In the presence of such three-way interaction, which epidemiologists term **effect modification**, stratum-specific odds ratios are required to properly summarize the exposure-disease relationship. Neither the marginal odds ratio nor any average of the $\psi_{(h)}$ adequately represents the data when the $\psi_{(h)}$ differ to a scientifically meaningful degree. The stratification variable is called an "effect modifier".

In the "no three-way interaction" model, which includes all two-way interactions, the stratum-specific odds ratios relating exposure to outcome are identical. Nevertheless, as in the saturated model, the relationship may not be reliably represented by the collapsed table formed from pooling the strata. This is garden-variety statistical **confounding** in a categorical data context, where the stratification variable is the "confounder". Owing to the separate relationships of B and C to the stratification variable A, the set of marginal odds ratios $\{\psi^M_{BC}\}$ relating pairs of categories of B to pairs of categories of C in the

collapsed table ignoring A may differ substantially from the set of common within-stratum odds ratios $\{\psi_{BC|A}\}$ relating the same pairs of categories in the three-way table. An extreme case, **Simpson's Paradox**, occurs when, for instance, in a general $h \times 2 \times 2$ table, the sign of $\ln \psi_{BC}^{M}$ differs from the common sign of the stratum specific $\ln \psi_{BC|A=h}$, $h = 1, \ldots, q$. Marginal and conditional odds ratios thereby indicate relationships in opposing directions. In an observational study, one might thus infer benefit to a harmful medical therapy by neglecting to control for such confounding.

When the no three-way interaction loglinear model holds, that is, when confounding occurs without effect modification, $\psi_{BC|A}$ properly adjusts for confounding by A, and its associated MLE may be used to summarize the exposure-disease relationship. When ordinal models apply within strata, a similar interpretation applies to within-stratum association parameters of the ordinal model.

Cochran-Mantel-Haenszel Tests

Cochran–Mantel–Haenszel (CMH) testing is an approach to demonstrate association between two variables after controlling for one or more confounders by stratification. The approach is useful in situations without effect modification such as just described, as well as in others where effect modification is present but within-stratum log odds ratios are predominantly of the same sign. From one perspective, CMH tests are simply score tests of the $\{\psi_{BC|A}\}$, or other indices of association, from conditional likelihood analyses of various loglinear models without three-way interaction. However, they are also simply derived as structurally model-free, multivariate hypergeometric-based tests for association in the presence of confounding. This latter perspective is more helpful in clarifying their broad utility.

We string out a $q \times r \times c$ table as the single vector $\boldsymbol{n} = (\boldsymbol{n}_1', \ldots, \boldsymbol{n}_q')'$ with $\boldsymbol{n}_h = (n_{h11}, \ldots, n_{h1c}, \ldots, n_{hr1}, \ldots, n_{hrc})'$. CMH test statistics take the quadratic form

$$Q_{\mathrm{CMH}} = \left(\sum_{h=1}^{q} \boldsymbol{A}_h(\boldsymbol{n}_h - \overset{\circ}{\boldsymbol{m}}_h)\right)' \left(\sum_{h=1}^{q} \boldsymbol{A}_h \mathrm{cov}(\boldsymbol{n}_h)\boldsymbol{A}_h'\right)^{-1} \times \left(\sum_{h=1}^{q} \boldsymbol{A}_h(\boldsymbol{n}_h - \overset{\circ}{\boldsymbol{m}}_h)\right), \quad (13)$$

where $\overset{\circ}{\boldsymbol{m}}_h = \mathrm{E}(\boldsymbol{n}_h)$ and $\mathrm{cov}(\boldsymbol{n}_h)$ are the mean and covariance matrix of $\boldsymbol{n}_h$ under a null multivariate hypergeometric distribution within-stratum h, and the $\boldsymbol{A}_h$ are typically of full-rank u. Under either (i) independent stratified randomization to the row or column dimension, or (ii) stratified random sampling in the absence of within-stratum row by column association, the distribution of $\boldsymbol{n}$ is product-multivariate hypergeometric and the kernel of Q_{CMH} is the exact covariance matrix of $\sum_{h=1}^{q} \boldsymbol{A}_h(\boldsymbol{n}_h - \overset{\circ}{\boldsymbol{m}}_h)$. Q_{CMH} is then asymptotically χ_u^2, by randomization central limit theory.

CMH tests address conformity with null expectations of across-strata linear combinations of within-stratum pivot functions. The noncentrality parameter of the asymptotic chi-square distribution, under an alternative with $E\boldsymbol{n}_h = \boldsymbol{m}_h$, is an across-strata linear combination of the $\boldsymbol{m}_h - \overset{\circ}{\boldsymbol{m}}_h$, proportional to a weighted average of functions of within-stratum association measures. Thus, CMH tests have substantial power only against alternatives in which the within-stratum associations are predominantly in the same direction, and for this reason are often called "average partial association tests". In addition to a general test against all forms of average partial association, the CMH approach yields more focused extensions of χ_{CMH}^2 to (i) a stratum-adjusted ANOVA F-statistic analog for testing differences among mean column scores between nominal rows; (ii) analogs of partial correlation tests based on *a priori* scores; and (iii) a variety of rank tests using scores based on overall or stratum-specific row and column margins. Since the null distribution is conditional on both margins of each stratum, such derived rank scores may be treated as fixed.

The null large-sample chi-square distribution of a CMH statistic is valid for increasingly large samples within a fixed set of strata, or under a "sparse asymptotic" situation in which the number of strata increases, while the sample sizes within them remain small. A prominent example of the latter is when each stratum consists of a matched case-control pair. This situation prompted development of the original Mantel–Haenszel statistic for q 2×2 tables, each with a single observation per row. The reformulation of a 2×2 table, in which a matched case–control pair is the observational unit and each pair is classified as [+, +], [+, −], [−, +], or [−, −] with respect to an exposure, into a $q \times 2 \times 2$ table in which the individual is the observational unit and classification is by a (i) pair identifier, (ii) exposure,

and (iii) disease, is a productive representation for inference about the matched-data analogues of Δ, RR, and ψ from independent samples. For instance, the Mantel–Haenszel summary odds ratio $\widehat{\psi}_{\text{MH}} = (\sum_{h=1}^{q} n_{h11}n_{h22}/n_{h++})/(\sum_{h=1}^{q} n_{h12}n_{h21}/n_{h++})$, arises naturally from treating matched sets as strata. For matched pairs, using the notation $n^{[+,+]}, n^{[+-]}, n^{[-,+]}, n^{[-,-]}$ for the respective counts in the 2×2 table classifying the matched pairs, $\widehat{\psi}_{\text{MH}} = (\sum_{h=1}^{q} n_{h11}n_{h22}/2)/(\sum_{h=1}^{q} n_{h12}n_{h21}/2) = n^{[+,-]}/n^{[-,+]}$ and, from (13), $Q_{\text{CMH}} = (n^{[+,-]} - n^{[-,+]})^2/(n^{[+,-]} + n^{[-,+]})$, the **McNemar test**. Stratified versions of relative risk and other epidemiologic measures of association are also used in conjunction with CMH statistics (*see* **Mantel–Haenszel Methods**).

Generalized Linear Models

We briefly review unifying paradigms for generalization and extension of methods above to data (i) of arbitrary dimension, and/or (ii) with continuous covariates, or other features incompatible with the assumption $m_{ij} \uparrow \infty$.

Generalized linear models (GLMs) provide a single framework for modeling expectations of Gaussian and other continuous data, Bernoulli indicator variables, Poisson, binomial, and (through a conditional Poisson argument) multinomial counts. This framework exploits the common structure of univariate **exponential families** of distributions, whose pdfs or pmfs may be written as Ke^L, where K and L each may be written as the product of a term depending exclusively on data and another depending exclusively on unknown parameters.

GLMs postulate independent observations $Y_1, \ldots, Y_n$ from a univariate exponential family

$$f_Y(y_i; \theta_i, \phi) = \exp\left\{\left[\frac{y_i\theta_i - b(\theta_i)}{a_i(\phi)}\right] + c(y_i, \phi)\right\}, \tag{14}$$

for known functions $a_i(\cdot), b(\cdot)$, and $c(\cdot, \cdot)$ and fixed scale parameter ϕ. Let $b'(\cdot)$ and $b''(\cdot)$ be the first and second derivatives of $b(\cdot)$. In this case, $\text{E}(Y_i) = \mu_i = \mu_i(\theta_i) = b'(\theta_i)$ and $\text{var}(Y_i) = v_i = v_i(\theta_i, \phi) = b''(\theta_i)a_i(\phi)$. Let $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)'$ be the vector of expectations. A GLM $\boldsymbol{g}(\boldsymbol{\mu}) = \boldsymbol{\eta} = \boldsymbol{X\beta}$ restricts $\boldsymbol{g}(\boldsymbol{\mu}) = (g(\mu_1), g(\mu_2), \ldots, g(\mu_n))'$ to a $u < n$-dimensional linear subspace of $\Re^n$ spanned by columns of an $n \times u$ full-rank model matrix $\boldsymbol{X} = [x_{ik}]$. In the Gaussian case, $\boldsymbol{X}$ is the "design" or "model" matrix in a general linear model, and otherwise is totally analogous. Notationally suppressing the dependence of $\mu_i = \mu_i(\theta_i)$ on θ_i and of $v_i = v_i(\theta_i, \phi)$ on θ_i and ϕ, the likelihood equations for any GLM are

$$\sum_{i=1}^{n} \frac{(y_i - \mu_i)x_{ik}}{v_i}\left(\frac{\partial \mu_i}{\partial \eta_i}\right) = 0, \quad k = 1, \ldots, u. \tag{15}$$

Note that the left-hand side of (15) is an inverse-variance weighted linear combination of the residuals $y_i - \mu_i$, and that these are the standard normal equations for a general linear model with rescaling for the transformation $g(\cdot)$ and inverse-variance weighting, as with weighted least-squares, to account for nonconstant variance. For fixed ϕ, (15) may be solved for $\boldsymbol{\beta}$, by iterated (equivalently, generalized) weighted least-squares (IWLS). When ϕ is known by the form of the distribution, this completes model estimation. When ϕ is an unknown scale parameter, as with Gaussian distributions for which $\phi = \sigma^2$, then ϕ may be estimated from the residuals to obtain a complete solution. The MLE of the covariance matrix $\text{cov}(\widehat{\boldsymbol{\beta}})$, $\widehat{\text{cov}}(\widehat{\boldsymbol{\beta}})$, is a by-product of IWLS estimation. Likelihood ratio, Pearson chi-square, score and Wald statistics are often used to evaluate fit and assess significance of model parameters.

The "canonical link function" $g(\cdot) = b'^{-1}(\cdot)$ produces a linear model $\boldsymbol{\theta} = \boldsymbol{X\beta}$ for the "natural parameter" $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_n)'$ of the exponential family (14). The u linear combinations $\sum_{i=1}^{n}(x_{ik}/a_i(\phi))y_i$ are then jointly sufficient for $\boldsymbol{\beta}$, and the likelihood equations set these sufficient statistics to their expectations. In the absence of differential weighting through the a_i, the sufficient statistics are simply inner products of the response vector with columns of $\boldsymbol{X}$. With convenient parameterizations, these may be means or mean scores, cross-product sums, marginal totals, or analogous functions of the observed data, which the MLEs are then constrained to reproduce.

This formulation is even more powerful than suggested by its exponential family underpinning. The first-order asymptotics of MLEs and likelihood ratios that justify most statistical applications depend upon the likelihood only through the moment-based

properties

$$\mathrm{E}\left(\frac{y_i-\mu_i}{v_i}\right)=0,$$
$$\mathrm{var}\left(\frac{y_i-\mu_i}{v_i}\right)=-\mathrm{E}\left[\left(\frac{\partial}{\partial\mu}\right)\left(\frac{y_i-\mu_i}{v_i}\right)\right]$$
$$=v_i^{-1}. \qquad (16)$$

Consequently, provided the first and second moments $\mathrm{E}(Y_i)=\mu_i(\theta_i)$ and $\mathrm{var}(Y_i)=v_i(\theta_i,\phi)$ are specified correctly, solutions to (15) largely behave like MLEs even if the data do not otherwise follow the distribution from which these moments were obtained. Thus, first-order optimal estimators may also be obtained from these estimating equations (15), when the moment functions are known and sufficiently regular, even in the absence of knowledge about the generating distribution. In such cases, the **quasi-likelihood** function

$$QL(\mu|y)=\int_y^\mu \frac{y-t}{v(\theta\phi)}\,\mathrm{d}t \qquad (17)$$

behaves like a likelihood and "quasi-likelihood analysis" therefore proceeds as if (17) is the true likelihood. Among their other uses, such quasi-likelihood analyses provide a convenient method for adjusting for observed overdispersion relative to what would ordinarily be expected from, for instance, binomial or Poisson variation. Quasi-likelihood thus provides a conceptual bridge between likelihood and weighted least-squares estimation (*see* Weighted Least-Squares (WLS) Functional Models below).

When f is Gaussian with $a_i(\phi)=a_i\phi$ for known a_i, the canonical link is the identity function, maximum likelihood reduces to weighted least-squares, and the IWLS algorithm terminates in one step. Categorical data GLMs include **Poisson regression**, multiple logistic regression, and general loglinear models.

Poisson Regression

For Poisson counts, the canonical link function is $\ln(\cdot)$. If exposure is uniform, the ith natural parameter is $\ln\mu_i=\ln\lambda_i$, and the corresponding GLM is a loglinear model for the Poisson intensity parameters. In epidemiologic studies, the λ_i usually are incidence densities, and an individual β_k often represents the $\ln RR$ associated either with comparison of the kth level of a categorical independent variable to a baseline level, or with a one unit difference of a continuous independent variable, other variables in the model held constant. The WLS iteration step is a regression on $\boldsymbol{X}$ of the residuals from the previous step, weighted inversely to the previous fitted values, which by the Poisson law are the current variance estimates.

In the more usual case of varying exposure measures N_i, the ith natural parameter is $\ln\mu_i=\ln N_i\lambda_i$, where the N_i are known. The linear predictor $\boldsymbol{X\beta}$ for $\ln\boldsymbol{\mu}$ is offset from the predictor for $\ln\boldsymbol{\lambda}$ by $\ln\boldsymbol{N}$, where $\boldsymbol{N}$ is the vector of known exposures. This is easily accommodated by estimating $\boldsymbol{\mu}$ and then rescaling to $\widehat{\boldsymbol{\lambda}}=\boldsymbol{D}_N^{-1}\widehat{\boldsymbol{\mu}}$, $\widehat{\mathrm{cov}}(\widehat{\boldsymbol{\lambda}})=\boldsymbol{D}_N^{-1}(\widehat{\mathrm{cov}}(\widehat{\boldsymbol{\mu}}))\boldsymbol{D}_N^{-1}$, where $\boldsymbol{D}_z$ is the diagonal matrix with main diagonal $\boldsymbol{z}$.

Multiple Logistic Regression

For binomial counts, the canonical link is the logit function, and the GLM generalizes the logit regression model previously described for $r\times 2$ contingency tables. As $\boldsymbol{X}$ may be an arbitrary full-rank design matrix, the model may include a combination of categorical and continuous predictors. Letting n_{i+} be the sample size and π_i be the "success" probability associated with the ith $(i=1,\ldots,r)$ pattern of predictor variables $\boldsymbol{x}_i$, the likelihood equations are simply $\sum_{i=1}^r n_{i1}\boldsymbol{x}_i=\sum_{i=1}^r n_{i+}\widehat{\pi}_i\boldsymbol{x}_i$. The sufficient statistics are means of the predictor variables in the respective outcome groups, and the MLE $\widehat{\boldsymbol{\beta}}$ generates predicted probabilities $\widehat{\pi}_i$ that reproduce these. The iteration step is $\widehat{\boldsymbol{\beta}}^{(t+1)}=\widehat{\boldsymbol{\beta}}^{(t)}+[\sum_{i=1}^r n_{i+}\widehat{\pi}_i^{(t)}(1-\widehat{\pi}_i^{(t)})\boldsymbol{x}_i\boldsymbol{x}_i']^{-1}[\sum_{i=1}^r(n_{i1}-n_{i+}\widehat{\pi}_i^{(t)})\boldsymbol{x}_i]$. The asymptotic covariance matrix for $\widehat{\boldsymbol{\beta}}$, $\mathrm{cov}(\widehat{\boldsymbol{\beta}})=[\sum_{i=1}^r n_{i+}\pi_i(1-\pi_i)\boldsymbol{x}_i\boldsymbol{x}_i']^{-1}$, may then be estimated by substitution.

The β_k are interpreted here similarly as in Poisson regression, but with odds ratios replacing rate ratios. Specifically, an individual β_k often represents the $\ln OR$ associated either with comparison of the kth level of a categorical independent variable to a baseline level, or with a one unit difference of a continuous independent variable, other variables in the model held constant. In an epidemiologic cumulative incidence cohort study or a clinical trial, π_i is usually the probability, in individuals with a known pattern of risk factors, of a disease outcome during a fixed observation period. In an epidemiologic incident case–control study, π_i is the probability of past

exposure to a risk factor in individuals with known current disease status and other sociodemographic factors and/or past exposures. Provided that cumulative incidence during the cohort study is low, in a stable population the odds ratios from these two types of studies should be similar and closely approximate the incidence density ratio, say λ_E/λ_U, between Exposed and Unexposed populations. For this reason, multiple logistic regression has become the most common tool for multivariable investigation in epidemiologic data analysis, particularly for control of confounding and effect modification. In randomized clinical medical trials, logistic regression is often used conventionally as both a primary analysis and, as a routine check for confounding, to simultaneously adjust for all other known predictors of a categorical outcome. This latter use is questionable since these adjusted models often contain dozens of variables, most of which are equitably randomized across treatment groups and unlikely to confound, and little attention is paid to the shapes of the corresponding simultaneous adjustments.

Related multinomial logit and loglinear models have also been developed, to apply the multiple logistic regression structure simultaneously either to dichotomies formed from category pairs from polytomous responses, or (through proportional odds) to cumulative probabilities obtained by dichotomizing ordered polytomies at multiple cut-points.

Loglinear Models

Loglinear models are a symmetric version of polytomous multiple logistic regression models, much as correlation analysis is a symmetric representation of multiple regression analyses for continuous data. When there is no clear "dependent variable" in a categorical data array, loglinear models simultaneously show how local odds relating pairs of levels of each single variable depend upon the levels or values of other variables. Loglinear models provide a basic paradigm for smoothing contingency tables, and for exploring causality through association structures in a spirit similar to that of **path analyses** of continuous data.

Let $\boldsymbol{\pi}' = (\boldsymbol{\pi}_1', \ldots, \boldsymbol{\pi}_r')'$, with $\boldsymbol{\pi}_i = (\pi_{i1}, \ldots, \pi_{ic_i})'$, be the single strung-out vector of probabilities for a product-multinomial distribution with r components, of which the ith has c_i categories. Also, let $\boldsymbol{K}$ and $\boldsymbol{J}$ be block diagonal with respective ith blocks $(\mathbf{1}_{c_i}\mathbf{1}_{c_i}')$ and $\mathbf{1}_{c_i}$. A loglinear model is defined by $\boldsymbol{\pi} = \boldsymbol{D}_\omega^{-1}\exp(\boldsymbol{X\beta})$, where $\boldsymbol{\omega} = \boldsymbol{K}\exp(\boldsymbol{X\beta})$ and $\boldsymbol{X}$ is a full-rank model matrix with columns linearly independent of the columns of $\boldsymbol{J}$. The latter requirement is an **identifiability** condition, since the model equation implies $\mathbf{1}_{c_i}'\boldsymbol{\pi}_i = 1$ for all i.

The multinomial populations represented by i, the response categories represented by j, or both may themselves be defined by combinations of levels of nominal and/or ordinal variables, the latter possibly with fixed scores. Such underlying structure can be represented in the model matrix $\boldsymbol{X}$. Though without columns for intercepts for the respective populations, $\boldsymbol{X}$ may otherwise be identical to model matrices for structures of cell means from continuous data. When all variables are nominal, common choices for $\boldsymbol{X}$ are matrices for a hierarchical factorial ANOVA model with interactions up to a given order.

Although the multinomial distribution does not directly fit the univariate exponential family formulation (14), the GLM machinery may nevertheless be used. For, letting $\boldsymbol{n}$ and $\boldsymbol{m}$ be respectively the strung-out vectors of observed counts n_{ij} and their expectations $m_{ij} = n_{i+}\pi_{ij}$ ordered as in $\boldsymbol{\pi}$, the likelihood equations $[\boldsymbol{J}, \boldsymbol{X}]'\boldsymbol{n} = [\boldsymbol{J}, \boldsymbol{X}]'\widehat{\boldsymbol{m}}$ for the loglinear model $\boldsymbol{X}$ are identical to those of the Poisson regression model $[\boldsymbol{J},\boldsymbol{X}]$. The MLEs reproduce the sufficient statistics $\boldsymbol{X}'\boldsymbol{n}$ while conforming to the population totals $\boldsymbol{J}'\boldsymbol{n}$. For instance, the sufficient statistics for the no three factor interaction hierarchical model of any nominal table are thus seen to be the observed two-way margins of the table, while the sufficient statistics for the linear by linear association model are the row and column marginal counts and the sum of products of row and column scores. This model thus reproduces the Pearson correlation coefficient between row and column scores.

Writing $\boldsymbol{X}_i$ for the submatrix of $\boldsymbol{X}$ corresponding to $\boldsymbol{\pi}_i$, the asymptotic covariance matrix of the MLE $\widehat{\boldsymbol{\beta}}$ is $\operatorname{cov}_A(\widehat{\boldsymbol{\beta}}) = \left[\sum_{i=1}^r n_{i+}\boldsymbol{X}_i'(\boldsymbol{D}_{\boldsymbol{\pi}_i} - \boldsymbol{\pi}_i\boldsymbol{\pi}_i')\boldsymbol{X}_i\right]^{-1}$. Its maximum likelihood estimate, $\widehat{\operatorname{cov}}_A(\widehat{\boldsymbol{\beta}})$, is obtained by substitution of $\widehat{\boldsymbol{\pi}}$ for $\boldsymbol{\pi}$ and emerges as a by-product from the standard GLM Newton–Raphson (IWLS) fitting algorithm (*see* **Optimization and Nonlinear Equations**). For large hierarchical models, where repeated matrix inversion is problematic, the model may be fit by using iterative scaling to determine $\widehat{\boldsymbol{\pi}}$ directly (*see* **Iterative Proportional Fitting**). After substitution of $\widehat{\boldsymbol{\pi}}$ for $\boldsymbol{\pi}$, the model equations

may then be solved for $\widehat{\boldsymbol{\beta}}$, and $\widehat{\mathrm{cov}}_A(\widehat{\boldsymbol{\beta}})$ obtained by direct substitution of $\widehat{\boldsymbol{\pi}}$ for $\boldsymbol{\pi}$ above. (*See* **Loglinear Model**).

Conditional and Exact Logistic Regression

GLM analyses are valid only under large-sample conditions in which MLEs are consistent (*see* **Large-sample Theory**). Classical likelihood theory demonstrates such consistency under asymptotics with indefinitely increasing information *per model parameter*. However, in certain situations involving matched data, the dimensionality of the parameter space increases with sample size, so that the information per parameter is bounded. These include cross-over experiments with parameters for each subject, pair-matched case–control studies with parameters for each matched pair, and clinical trials of rare diseases by large multicenter networks, with parameters for each center and few patients per center. In each of these cases, increasing sample size is accompanied by commensurate increase in parameters. Classical results on normality of the sufficient statistics for the model do not apply, and the MLE based on the full likelihood behaves poorly. Similarly, in small samples, the MLE may be substantially biased. The effects of nuisance parameters on estimation must somehow be controlled.

Conditional logistic regression applies standard likelihood theory after conditioning on the occurrence of precisely the patterns of predictor variables seen in the data from each matched set (*see* **Logistic Regression, Conditional**). The contribution to the conditional likelihood from each matched set is thus the ratio of the product-binomial probability of the observed data, expressed as a function of the linear predictor $\boldsymbol{x}_i'\boldsymbol{\beta}$, to the sum of such probabilities, over all permutations of the predictor variable patterns among individuals in that matched set. The full conditional likelihood is the product of these contributions across the matched sets. For 1:1 matched studies, the GLM computational algorithm may be formally applied by regressing a constant **dummy** outcome on the case–control differences of the predictors, highlighting the close relationship of this analysis, for a single dichotomous predictor, to the matched-pairs t-test. More generally, if each matched set in the logistic regression setting is identified with the **risk set** at an observed failure time in the survival data context, the conditional likelihood takes the same form as Cox's **partial likelihood** for **semiparametric** proportional hazards models for right-censored survival data (*see* **Cox Regression Model**). The linear predictor of the conditional likelihood lacks an intercept term, so that the model does not predict absolute risk. However, the likelihood is free of nuisance parameters, allowing consistent estimation of $\boldsymbol{\beta}$ as the number of matched sets increases, even if each matched set remains small. With the exception of examinations of **residuals**, most aspects of conditional logistic regression analysis are essentially identical to unconditional logistic regression via the GLM.

For quite small samples, however, the large-sample properties of even such conditional MLEs are of no help. Extensions are required of Fisher's exact test and other multivariate hypergeometric-based procedures for two-way tables. Estimators and hypothesis tests may be based on distributions that condition out not just nuisance parameters representing matched sets (as in conditional logistic regression), but *all parameters not being estimated or restricted by the null hypothesis.* These permutation distributions are obtained by conditioning on the observed values of sufficient statistics for unconstrained parameters. This computationally intensive method is now feasible and widely applied, although computations remain prohibitive for some problems. In a few cases at the other end of the spectrum, minimal computation is required because the conditional distribution employed is highly discrete, and can be so discrete as to provide little information about the parameters of interest. The technique is not a general cure for the "few subjects, many predictors" problem (*see* **Exact Inference for Categorical Data**; **Randomization Tests**).

Weighted Least-squares (WLS) Functional Models

Because they focus on modeling conditional expectations of individual observations on a single variable, as in logistic regression, or on cell counts determined by patterns of explanatory variables, as in loglinear models, GLMs provide an excellent framework for study of conditional probabilities and association structures. However, they are awkward for analyses of integrated data summaries such as marginal

distributions, survival rates, reliability measures, and association measures other than odds ratios, where the individual cell expectations are nuisance parameters for estimating the specific parametric functions of interest. WLS provides a convenient and powerful alternative approach to such analyses, through use of one-step WLS to obtain Neyman's minimum χ^2_N estimates and Wald Q_W statistics.

The WLS algorithm is based on the functional model $\boldsymbol{F}(\boldsymbol{m}) = \boldsymbol{X}\boldsymbol{\beta}$, with $\boldsymbol{F}(\boldsymbol{m}) = (F_1(m), \ldots, F_u(m))'$. The $F_k(\cdot)$ are second-order differentiable in the π_{ij} and $\boldsymbol{X}$ is a full-rank model matrix. The computation is performed on $\widehat{\boldsymbol{F}} = \boldsymbol{F}(\boldsymbol{n})$, an unrestricted consistent estimator of $\boldsymbol{F}(\boldsymbol{m})$, weighting using a consistent estimate of its asymptotic covariance matrix. The estimate is obtained as $\widehat{\boldsymbol{V}}_{\widehat{F}} = \widehat{\mathrm{cov}}_A(\boldsymbol{F}(\boldsymbol{n})) = \boldsymbol{H}(\boldsymbol{n})[\widehat{\mathrm{cov}}_A(\boldsymbol{n})]\boldsymbol{H}'(\boldsymbol{n})$, with $\boldsymbol{H}(\boldsymbol{n}) = [\partial F_k/\partial m_l]|_{\boldsymbol{m}=\boldsymbol{n}}$, by the delta method for "propagation of variances" introduced earlier in connection with confidence intervals for association measures in 2×2 tables. Here, $\widehat{\mathrm{cov}}_A(\boldsymbol{n})$ is the unrestricted MLE of the covariance matrix appropriate to the assumed distribution (e.g. $\boldsymbol{D}_{\boldsymbol{n}}$ for product-Poisson, and block diagonal with diagonal blocks $(\boldsymbol{D}_{\boldsymbol{n}_i} - (\boldsymbol{1}'\boldsymbol{n}_i)^{-1}\boldsymbol{n}_i\boldsymbol{n}_i')$ for product-multinomial data.

The estimator $\widetilde{\boldsymbol{\beta}} = (\boldsymbol{X}'\widehat{\boldsymbol{V}}_{\widehat{F}}^{-1}\boldsymbol{X})^{-1}\boldsymbol{X}'\widehat{\boldsymbol{V}}_{\widehat{F}}^{-1}\boldsymbol{n}$ minimizes the quadratic form $(\widehat{\boldsymbol{F}} - \boldsymbol{X}\boldsymbol{\beta})'\widehat{\boldsymbol{V}}_{\widehat{F}}^{-1}(\widehat{\boldsymbol{F}} - \boldsymbol{X}\boldsymbol{\beta})$, and is asymptotically multivariate Gaussian. Letting $\boldsymbol{V}_{\widehat{F}} = \boldsymbol{H}(\boldsymbol{m})[\mathrm{cov}_A(\boldsymbol{n})]\boldsymbol{H}'(\boldsymbol{m})$, the covariance matrix of the estimator is $\mathrm{cov}_A(\widetilde{\boldsymbol{\beta}}) = (\boldsymbol{X}'\boldsymbol{V}_{\widehat{F}}^{-1}\boldsymbol{X})^{-1}$. Its estimate, $\widehat{\mathrm{cov}}_A(\widetilde{\boldsymbol{\beta}}) = (\boldsymbol{X}'\widehat{\boldsymbol{V}}_{\widehat{F}}^{-1}\boldsymbol{X})^{-1}$, may be used to form confidence regions and Wald test statistics for $\boldsymbol{\beta}$. When the F_k are explicit algebraic functions, $\boldsymbol{F}$ and $\boldsymbol{H}(\boldsymbol{n})$ can be expressed as compositions of matrix premultiplications and elementwise logarithmic and exponential transformations on n, simplifying the development of general software.

Validity of a WLS analysis depends on sample sizes large enough to ensure that $\boldsymbol{F}(\boldsymbol{n})$ is approximately multivariate Gaussian, so requirements vary with $\boldsymbol{F}$. WLS may be suitable for analysis of marginal mean scores of an ordinal variable in a panel survey from a high-dimensional and sparsely populated contingency table, but unsuitable for analysis of probabilities or log odds from a small table with few cells and larger sample size, if any cells are not observed or have very low expected values under a model. Slower convergence in distribution of Wald/Neyman chi-squares relative to score and likelihood ratio statistics has now been noted in a variety of categorical data situations through study of exact distributions and simulations. Consequently, greater caution is indicated than was once appreciated when using this method in moderate sample sizes, especially as the computational simplicity of closed-form parameter estimation becomes progressively less of an advantage over other methods.

However, for analysis of grouped data from sufficiently large samples, the flexibility of WLS allows simple handling of some problems that are quite awkward to address from other perspectives. WLS has been particularly important in the analysis of repeated measures contingency table data, in modeling of arbitrary measures of association from grouped data, and in modeling estimates from **sample surveys**, each of which may be a complex but explicit algebraic function of counts observed at the final level of a **multistage sampling** design. As WLS is a purely second-moment based approach, like quasi-likelihood, specification of the underlying probability model for counts is not required provided a consistent estimate of $\mathrm{cov}_A(\widehat{\boldsymbol{F}})$ is available. For survey data, such an estimate is sometimes obtained by some form of pseudoreplication rather than by the delta method.

Generalized Estimating Equations (GEE)

WLS methodology requires approximately Gaussian functions of counts prior to modeling, and so cannot accommodate covariates observed at the level of the individual observation. GLMs and quasi-likelihood analyses, which naturally accommodate individual level covariates, are overparameterized for many purposes, particularly when marginal rather than conditional distributions are of most interest. Both approaches attain asymptotic efficiency through consistent estimation of the optimal weight matrix at each stage of a WLS iteration. Suboptimal weighting in WLS or IWLS, nevertheless, yields a consistent estimator of β. **Generalized estimating equation** analysis is an IWLS approach that extends the quasi-likelihood estimating equations, seeking to combine advantages of GLM and WLS by accepting suboptimal weighting and some loss of asymptotic efficiency in order to gain flexibility and **robustness**. More specifically, if some efficiency loss can be tolerated, the information matrix may be modeled only approximately, without fully accounting for nuisance association parameters from the underlying probability

distribution. This is particularly advantageous for the analysis of correlated categorical responses, such as occur in repeated measures experiments or in repeated observations over time, in those instances when the association structure itself is largely a nuisance in relation to the objectives of data analysis (*see* **Correlated Binary Data**).

For $a_i(\phi) = \phi$, the GLM estimating equations may be written as

$$\sum_{i=1}^{n} \left(\frac{\partial \mu_i}{\partial \beta_k}\right)\left(\frac{y_i - \mu_i}{\mathrm{var}(Y_i)}\right) = 0, \quad k = 1, \ldots, u, \tag{18}$$

and interpreted as quasi-likelihood equations when the distribution is unknown but $\mathrm{var}(Y_i)$ can be written as $V(\mu_i)$. Let $\boldsymbol{Y}_i$ by the random vector and $\boldsymbol{y}_i$ be the corresponding vector of observations for the i^{th} individual or other observational unit. The generalized estimating equations are a straightforward multivariate extension of (18),

$$\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \boldsymbol{S}_i = \sum_{i=1}^{n} \left(\frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}\right) \boldsymbol{V}_i^{-1}(\boldsymbol{\mu}_i, \boldsymbol{\alpha})(\boldsymbol{y}_i - \boldsymbol{\mu}_i(\boldsymbol{\beta})) = \boldsymbol{0}. \tag{19}$$

In this extension, $\boldsymbol{\mathcal{D}}_i$ is the matrix of derivatives of means of the elements of $\boldsymbol{Y}_i$ relative to those of $\boldsymbol{\beta}$ and $\boldsymbol{S}_i$ is the deviation vector $\boldsymbol{y}_i - \boldsymbol{\mu}_i$, directly generalizing $\partial \mu_i / \partial \beta_k$ and $(y_i - \mu_i)$. However, the true $\mathrm{Var}(Y_i)$ in the univariate case is replaced in the multivariate generalized estimating equations by a working model $\boldsymbol{V}_i(\boldsymbol{\mu}_i, \boldsymbol{\alpha}) = \boldsymbol{A}_i(\boldsymbol{\mu}_i)^{1/2} \boldsymbol{R}_i(\boldsymbol{\alpha}) \boldsymbol{A}_i(\boldsymbol{\mu}_i)^{1/2}$ for $\mathrm{cov}(\boldsymbol{Y}_i)$ with $\boldsymbol{R}_i(\boldsymbol{\alpha})$ a correlation matrix dependent on a vector $\boldsymbol{\alpha}$ of association parameters, and $\boldsymbol{A}_i(\boldsymbol{\mu}_i)$ a diagonal matrix of variances. If the dimension of $\boldsymbol{\alpha}$ is low, a parsimonious model thus replaces the more complex covariance structure of the underlying product-multinomial or other distribution. In the simplest implementation, known as "GEE1," (19) is solved by repeated cycles of IWLS estimation of $\boldsymbol{\beta}$ given $\boldsymbol{\alpha}$ from the previous step, and moment-based estimation of $\boldsymbol{\alpha}$ using the Pearson residuals $(y_{ij} - \mu_{ij})/\sqrt{([\boldsymbol{V}_i(\boldsymbol{\mu}_i, \boldsymbol{\alpha})]_{jj})}$ based on current values of the parameters. The resulting $\overline{\boldsymbol{\beta}}$ is asymptotically multivariate Gaussian with mean $\boldsymbol{\beta}$, whatever the working covariance structure employed. The asymptotic covariance matrix $\mathrm{cov}_A(\overline{\boldsymbol{\beta}})$ does depend on the working covariance structure, but a consistent "sandwich estimator" is

$$\left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right)^{-1} \left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \mathrm{cov}(\boldsymbol{Y}_i) \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right) \times \left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right)^{-1} \tag{20}$$

evaluated at $\overline{\boldsymbol{\beta}}$, $\overline{\boldsymbol{\alpha}}$, and $\overline{\phi}$.

The general covariance estimator (20) is employed in two ways, with the appropriate choice depending on sample size and presumed adequacy of the covariance model. When the working covariance structure is based on a highly plausible underlying distributional model and/or reflects well the empirical covariance structure, then it is reasonable to substitute $\boldsymbol{V}_i$ for $\mathrm{cov}(\boldsymbol{Y}_i)$ in (20). This yields the model-based covariance estimator

$$\left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right)^{-1}. \tag{21}$$

When the working covariance structure is correct, this estimator, evaluated at the fitted parameters $\overline{\boldsymbol{\beta}}$, $\overline{\boldsymbol{\alpha}}$, and $\overline{\phi}$, is consistent for the true covariance and gains efficiency from the information in the assumed covariance pattern. However, this covariance estimator is inconsistent if the working covariance structure is substantially incorrect, and invalid inferences can result. An alternative choice is to substitute the empirical estimator $\boldsymbol{S}_i \boldsymbol{S}_i'$ for $\mathrm{cov}(\boldsymbol{Y}_i)$. This yields the "robust" sandwich covariance estimator

$$\left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right)^{-1} \left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} (\boldsymbol{S}_i \boldsymbol{S}_i') \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right) \times \left(\sum_{i=1}^{n} \boldsymbol{\mathcal{D}}_i' \boldsymbol{V}_i^{-1} \boldsymbol{\mathcal{D}}_i\right)^{-1}, \tag{22}$$

also evaluated at the estimated parameters. "Robust" is used in this instance specifically to refer to consistency of this estimator for $\mathrm{cov}_A(\overline{\boldsymbol{\beta}})$ when the working covariance structure is misspecified, rather than in any more general sense of resistance to contamination. Large-sample confidence intervals and test statistics may be formed in the usual ways from (21) or (22). The robust sandwich estimator provides

great flexibility to the GEE method by providing reliable inferences in large samples with complex nuisance covariance structures. However, its convergence is not rapid even in standard Gaussian situations. Like other methods based on empirical variability estimates, such as Wald-based inference for some models, performance in small samples can be unacceptable in the sense that actual test levels can be noticeably higher, and confidence interval coverages noticeably lower, than their nominal specifications.

An alternative GEE implementation augments the estimating equations for the marginal mean structure with additional estimating equations for the second-moment structure. The estimates of $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$ are thus obtained from a simultaneous fit of the multivariate GLM and the residual variances and covariances or odds ratios. Alternative estimation methods for both GEE1 and this "GEE2" modification apply a Gauss–Newton algorithm to somewhat different versions of the estimating equations.

GEE methods have been successfully used for marginal modeling of **longitudinal** categorical data with covariates. In such analyses, net shifts in category distributions over time are of primary interest rather than the transition trajectories of individuals. If a dichotomous variable is studied at five time points, 26 association parameters may be needed to represent the association structure of the 2^5 table of response counts. A GEE analysis might crudely approximate this association structure using a patterned covariance matrix with $\boldsymbol{\alpha}$ of only one to three elements, say from a simple **time series** model. Accumulating evidence suggests that reasonable but simplified covariance models often sacrifice little efficiency. Modifications of GEE in the presence of **random effects**, and for **generalized additive models**, have also been developed (*see* **Marginal Models**; **Generalized Linear Models for Longitudinal Data**).

Generalized Linear Mixed Models (GLMMs)

Generalized linear mixed models (GLMMs) are GLMs in which the linear predictor $\boldsymbol{X\beta}$ is offset by additive contributions of random effects. The GLM $\boldsymbol{g(\mu) = \eta = X\beta}$ is thus generalized to $\boldsymbol{g(\mu_{(C)}) = \eta_{(C)} = X\beta_{(C)} + Z\zeta}$ with $\boldsymbol{\mu_{(C)}} = \mathrm{E}(\boldsymbol{Y}|\boldsymbol{\zeta})$, $\boldsymbol{X}$ and $\boldsymbol{Z}$ known model matrices, $\boldsymbol{\beta_{(C)}}$ fixed and unknown, and $\boldsymbol{\zeta}$ random with a specified, usually Gaussian, cdf. The subscript "(C)" is used to indicate that GLMM fixed effect parameters represent conditional effects given particular values of the random effects.

The random effects produce mixture distributions that account for extra-Poisson or extra-binomial/multinomial variability due to sample heterogeneity (*see* **Overdispersion**). They also allow description of associations among multiple categorical observations more parsimoniously than by a full multinomial representation or a loglinear model. With Gaussian random effects, association is modeled by the variances of underlying random effects distributions, that is, the usual **variance components** in the mixed model for Gaussian dependent variables. The variance components in a GLMM thus serve, in part, the same purpose as $\boldsymbol{\alpha}$ in GEE analyses. Beyond this, however, the random effects in $\boldsymbol{\zeta}$ can be estimated and the estimates used to characterize a correlated cluster of observations, such as sequential measurements on an individual over time, and to predict additional observations from the observational unit underlying the cluster. Two important special cases are the classical linear mixed model and the mixed logistic regression model, that is, the binomial GLM with canonical logit link and Gaussian random effects.

We emphasize that unless the GLMM link is the identity, which is rarely the case in categorical data analysis, the addition of random effects to the GLM *changes the meaning of the fixed effects* $\boldsymbol{\beta}$. While in the GLMM, as noted above, these are parameters $\boldsymbol{\beta_{(C)}}$ of the conditional distribution of the Y_i for given $\boldsymbol{\zeta}$, in the GLM they are parameters $\boldsymbol{\beta = \beta_{(U)}}$ of the unconditional distribution of the Y_i, that is, of the joint distribution of random $\boldsymbol{Y}$ and random $\boldsymbol{\zeta}$ integrated over $\boldsymbol{\zeta}$. Since this unconditional distribution is a marginal of the joint distribution, obtained by integrating out a mixing distribution that differentiates collections of correlated observations, the terms "marginal" and "population-averaged" are often substituted for unconditional in the GLMM literature; similarly, "subject-specific" is sometimes used in place of conditional.

The relationship of $\boldsymbol{\beta_{(U)}}$ to $\boldsymbol{\beta_{(C)}}$ can sometimes be approximated. For the mixed logistic regression model, the population-averaged parameters $\boldsymbol{\beta_{(U)}}$ are invariably attenuated in relation to the subject-specific parameters $\boldsymbol{\beta_{(C)}}$. An example of a practical interpretation of the attenuation is that odds ratios from analytic epidemiologic studies of smoking and lung cancer understate the biological impact

of an individual's decision to smoke or refrain from smoking.

Under a GLMM, estimation of either $\boldsymbol{\beta}_{(C)}$ or $\boldsymbol{\beta}_{(U)}$ is preferably performed by maximum likelihood, quasi-likelihood, or **restricted maximum likelihood** (REML) estimation from the marginal likelihood. This task is straightforward in principle but exceptionally challenging in practice. In addition to the nontrivial optimization problems posed by linear mixed models, for which the marginal likelihood is available analytically, estimation for the GLMM requires that the marginal likelihood be obtained numerically before it can be optimized. Methods currently available for doing this, by numerically integrating $\boldsymbol{\zeta}$ out of the likelihood or quasi-likelihood function using Gaussian quadrature or otherwise, or by generating observations from the marginal distribution using **Markov Chain Monte Carlo** (MCMC), have not been consistently successful for models with more than a few random effects or nested variance components. At the time of this writing, most analysis is performed using methods that maximize an approximate likelihood or that solve approximate quasi-likelihood or generalized estimating equations. Various approximations using Taylor series and Laplace expansions with differing simplifying assumptions have been implemented, sometimes using **profile likelihoods**. The approximate methods appear to work well in many circumstances, but not with small numbers of observations per random effect. Active research continues on the properties of each method and possible further improvements (*see* **Generalized Linear Models for Longitudinal Data**).

Bayes and Empirical Bayes (EB) Methods

GLMMs introduce additive random effects into the linear predictor of a GLM. This can be formally identical, for example, in a "random intercepts" model, to sampling subject-specific GLM fixed effects from a prior distribution. A substantial Bayes and EB literature employs prior distributions for contingency table probabilities, logits, or loglinear model parameters. Such methods can model heterogeneity, and smooth naive estimates from small samples or sparse tables towards more substantively reasonable values by "shrinking" them towards parsimonious model structures (*see* **Shrinkage**). Applications include removal of zero probability estimates from tables with random empty cells (*see* **Structural and Sampling Zeros**); the Agresti–Coull confidence interval for a single proportion π centered around a Bayesian point estimate using a **Beta**(2, 2) prior for π; adjustment of local standardized mortality rates by smoothing local geographical variation (*see* **Geographic Patterns of Disease**); and identification of suspect adverse drug effects from a large cross-classification, by drug and type of event, of spontaneous reports to the US Food and Drug Administration (*see* **Pharmacoepidemiology, Overview**).

The Beta distributions are the conjugate family for binomials, and the Dirichlet generalizations of Beta distributions form the conjugate family to multinomials. Both noninformative and Dirichlet priors have been applied directly to expected counts and cell probabilities. The Dirichlet priors may embody simple underlying structure, for example, a low-order loglinear model, as in the correction to the Wald confidence interval for a difference in two proportions that was mentioned above (*see* **Loglinear Model**).

A Bayesian precursor to the logit-Gaussian GLMM uses a Gaussian $N(\mu, \sigma^2)$ prior for logits from an $r \times 2$ table, a noninformative prior for μ, and a χ^2_ν prior for $\nu\lambda/\sigma^2$. Such independent prior formulations have also been used for row, column, and interaction effects in the saturated loglinear model for an $r \times c$ table. An EB approach to such tables uses flat priors for main effects and a Gaussian prior with estimated variance for interactions. Other EB applications employ Beta and **lognormal** priors for ratios of cell probabilities to expectations under independence, gamma and lognormal priors for relative risks in geographic epidemiology, and log-logistic priors for mortality proportions.

A particularly interesting area of Bayesian application, and a subject of intense current research, is the study of geographic variation and temporal-spatial modeling of counts, for instance, of animal populations and incident disease cases. Beyond recognition of its broad importance for ecological and epidemiological research, this field has received stimulus from the urgency associated with recent concerns pertaining to emerging infectious diseases and to bioterrorism. Poisson regression models may be employed in GLMMs with various spatial correlation structures, including local association implied by the reciprocal conditional distributions of a Markov random field. Empirical Bayes and full Bayes treatments of various models with priors on parameters of the random

effect distributions are under investigation (*See* **Geographic Epidemiology**).

Recent advances in computational algorithms for Bayesian inference are greatly assisting development and application of Bayesian methods, and of other methods when Bayes, frequentist, and likelihood approaches have common computational problems. For instance, a practical estimation algorithm for the probit-Gaussian GLMM embeds a Gibbs sampling step into the **EM algorithm** (*see* **Bayesian Methods for Contingency Tables**).

Software

We close with remarks on **software**, which abounds in widely available commercial packages and is available for newer methods in less polished shareware. Comments that follow reflect the authors' experience, are not product endorsements, are by no means exhaustive, and will inevitably be somewhat outdated when this is read. For the more advanced procedures that are implemented in multiple packages, the specifics of each implementation often vary substantially in computational approach, default approaches, and in the extent of analytic, algorithmic, and reporting customization available to the user.

Basic chi-square statistics, measures of association for contingency tables, and generalized linear models are available in virtually all major statistical packages, for example, $SAS^{®}$ (Version 9), $S-Plus^{®}$ (Version 6) and R (Version 1.8.1), $STATA^{®}$ (Version 8), and $SPSS^{®}$ (Version 12). General ordinal association models for $r \times c$ and higher-dimensional tables are not commonly preprogrammed, although specific models are often available depending upon the customer base of a particular product. However, cumulative logit (proportional odds) analysis is widely available, and ordinal loglinear models may readily be implemented using packages that allow arbitrary model matrices $\boldsymbol{X}$, which include all of the above and the GLM package GLIM (Version 4). (Note that caution is indicated in reading software brochures. Some use GLM to designate only the Gaussian generalized linear model with identity link function, that is, the "general" rather than "generalized" linear model.)

The most general prepackaged implementations of CMH and WLS methods are in *SAS*® PROC FREQ and PROC CATMOD, respectively, but these analyses involve simple quadratic forms and are easily incorporated into packages that allow matrix manipulation and user programming. Any unconditional logistic regression software may be used to perform conditional logistic regression analyses of paired data, while software for proportional hazards survival regression models may be used for such analyses of general matched data.

In two areas, (i) exact analyses and (ii) WLS or GEE-based methods for modelling data from sample surveys and other clustered research designs, there is increasing overlap between specialty software and general purpose statistical packages such as those above. *StatXact*® (Version 6) implements rapid algorithms for many exact analyses of two- and three-way contingency tables (*see* **StatXact**). *LogXact*® (Version 5) performs exact logistic regression analyses. Each of these packages has incorporated broader capabilities with recent releases. However, exact logistic regression is now available as an option of *SAS*® PROC LOGISTIC, a core of the most common analyses pioneered in *StatXact*® are similarly available as options in *SAS*® PROC FREQ, and the full *StatXact*® package with *SAS*® connectivity is available as a *SAS*® add-on. The *SPSS*® add-on *SPSS*® Exact Tests™ has similar capabilities.

Similarly, the *SUDAAN*® package has pioneered powerful adjustment capabilities for correlated data from stratified multistage cluster designs, with particular attention to the analyses of complex national surveys, but initially was restricted to descriptive analyses and a limited set of models. *SUDAAN*® 8.0, the release as of this writing, now implements an array of continuous, univariate and multinomial logistic, loglinear, and discrete and continuous semiparametric proportional hazards models, using GEE. The survey analysis package *WESVAR*® employs jackknife or balanced repeated replication variance estimation to fit a less extensive class of models, including logistic and multinomial logistic models. However, *STATA*® and *SAS*® now include core survey modeling capabilities that, particularly for *STATA*®, accommodate a substantial proportion – though by no means all – of data analyses for which *SUDAAN*®, *WESVAR*®, or similar specialty software would previously have been required. An *SPSS*® add-on, *SPSS*® Complex Samples™, offers similar capabilities for descriptive analyses and basic hypothesis tests. There is hope that the wider availability of convenient methods for proper variance estimation from clustered survey designs will overcome the reluctance of many

researchers to account for clustering in their analyses (*see* **Software for Sample Survey Data, Misuse of Standard Packages**).

GEE implementations are routinely available in *SAS*® (GENMOD AND NLMIXED procedures), *STATA*® (xtgee and other xt... commands), and *S − Plus*® (gee function in correlated data research library, and other functions in private libraries). *SAS*® (NLMIXED, %GLIMMIX macro) and *S − Plus*® (glme and xglm functions in correlated data research library) provide both approximate and exact approaches to fitting GLMMs. *STATA*® (xt... procedures) fits them using quadrature to obtain the true likelihood. BUGS (Bayesian analysis Using Gibbs Sampling, with Windows implementation WinBugs), a general platform for hierarchical Bayesian modeling, allows GLMM fitting based on the true likelihood through MCMC.

EPIINFO™ and *EGRET*® are packages particularly oriented to epidemiologists, the first relatively basic and the second more comprehensive and advanced but less user-friendly. *EGRET*® includes some capabilities of *StatXact*® for two-dimensional contingency tables, and for stratification-based adjustment of such tables for confounding, (*see* **Software, Epidemiological**).

Categorizing Continuous Variables

It is common, especially in medical research, for continuous variables to be converted into categorical variables by grouping values into two or more categories (*see* **Grouped Data**). Some reasons for this preference are statistical, notably the avoidance of certain assumptions about the nature of the data, but there are other less well-defined reasons. There seems to be a general preference in many clinical areas to categorize individuals, and this seems to carry over to the analysis and interpretation of continuous data. While there may be clinical value in such classifications, there is no statistical reason why all continuous variables should be treated this way. Furthermore, while creating categories may avoid certain statistical problems, it leads to new ones.

The use of grouping for descriptive purposes may allow a simpler presentation and is not especially problematic. When the approach is carried forward to data analysis, however, more serious problems may arise. Grouping may be seen as introducing an extreme form of measurement error, with an inevitable loss of power. It is questionable whether trading power for simplicity is a wise bargain. Nevertheless, there may be good reasons to categorize, so it is valuable to consider how this might be done. We consider the issues in relation to categorization of **explanatory variables** in **regression** models, but similar considerations apply more widely.

Effect of Categorizing

Converting a continuous variable into a categorical one will result in some loss of information; but it can be, and often is, argued that with three or more categories the loss is small and is offset by a gain in simplicity and the avoidance of assumptions. Connor [3] quantified the loss of information when categorizing a **normally distributed** variable which is linearly related to the outcome variable (also normally distributed) using the relative efficiency, which is based on the ratio of the expected variances of the estimated regression coefficients under the two models. For 2, 3, 4, or 5 groups, the efficiency relative to an ungrouped analysis is 65%, 81%, 88%, and 92% respectively (and is almost identical for an **exponentially distributed** variable).

Given the decision to categorize, it is not at all obvious how many groups to create. In practice the sample size should be one factor that influences the decision, as it is undesirable to have sparsely populated groups. The placing of the cutpoints may also not be obvious. Using optimally placed intervals, as derived by Connor [3] following Cox [5], is little different, in terms of efficiency, from using equally spaced intervals when the variable is normally distributed, but when the variable has an exponential distribution there is reduced efficiency with equiprobable intervals [9]. This result is important, as it is common to categorize in such situations, and equiprobable intervals are the norm. Morgan & Elashoff [11] examined the effect of categorizing a continuous covariate when comparing **survival** times. Here too, unequal groupings give increased efficiency.

Two Groups

Forcing all individuals into two groups simplifies the statistical analysis and may lead to easier interpretation of results. A **binary** split leads to a comparison of groups of individuals with high or low values of the measurement, or a comparison of proportions and a simple estimate of the difference between the groups (with its confidence interval). However, this simplicity is gained at the expense of throwing away a lot of information, as noted above. Cohen [4] observed that dichotomizing is equivalent to throwing a third of the data away. It thus leads to a loss of power to detect real relationships [15]. Patients are divided into just two categories, so that considerable variability may be subsumed. Using such binary variables in regression models may lead to **biased** estimates [15].

The choice of cutpoint to create the two groups may not be straightforward, and several approaches are possible. It is highly desirable for the choice of cutpoint not to be influenced by the actual data values. For a few variables there are recognized cutpoints which can be used (e.g. for body mass index). For some variables, such as age, it is usual to take a "round number" – an elusive concept, which in this context usually means a multiple of ten. Another possibility sometimes used is to use the upper limit of a normal range (reference interval). In the absence of any prior idea of a suitable cutoff, the most

common approach is to take the sample median. This gives two equal groups and is probably the best approach. However, using the median means that different studies will take different cutpoints, so that their results cannot easily be compared or combined. (Note that moving the cutpoint to a higher value leads to higher mean values in *both* groups.)

The arbitrariness of the choice of cutpoint may lead to the idea of trying more than one value and choosing that which, in some sense, gives the most satisfactory result. The temptation to perform multiple analyses should be strongly resisted. Taken to extremes, this approach leads to trying every possible cutpoint and choosing the value which minimizes the P value. Because of the multiple testing the overall false positive rate will be very high, being around 40% rather than the nominal 5% [2]. Also, the cutpoint chosen will have a wide confidence interval and will not be clinically meaningful and, crucially, the difference between the two groups will be overestimated. Although it is possible to correct the P value for multiple testing [2], the bias cannot currently be corrected for. Regrettably, this unacceptable strategy has become common in the cancer literature, especially in breast cancer [1, 2]. A similar proposal has appeared in the epidemiologic literature [17].

If the dependent variable is also a dichotomized continuous variable, the above effects are exaggerated. There is greater information loss [4], and there are two cutpoints to choose. The simple analysis of a **two-by-two table** can be via a **chi-square test** or an **odds ratio**. However, this is a drastic reduction of information. Maxwell & Delaney [10] studied the effect of dichotomizing two explanatory variables.

Several Groups

The simple approach of dichotomizing the explanatory variable may hide important complexities. The advantage of having several groups is that one can get a feel for the shape of a relation between the outcome variable and the explanatory variable without the need to specify the shape of that relation. Use of three or four categories is common, especially in epidemiology. It is rare for more than five groups to be used. With fewer groups there is an increased risk of pooling data for individuals with different risks. Occasionally, there may be a U-shaped relation between a variable and outcome. For example, Sather [13] showed such a relation between age and survival in children with acute lymphoblastic leukemia. With several groups such an effect can be seen clearly. With only two groups not only would this information be missed, but there could be a failure to detect any relation at all. When the true risk increases (or decreases) monotonically with the level of the variable of interest, the apparent spread of risk will increase with the number of groups used. It is thus possible to manipulate the message from the data, by choice of the number of groups.

It is most usual to divide the data into equal groups, for example using tertiles, quartiles or quintiles (*see* **Quantiles**) to divide the data values into three, four, or five groups respectively. Optimal groupings, as described above, are very rarely used. The only other reasonable approach is to split at round numbers, usually leading to groups of equal width rather than equal size, but not necessarily. The use of round numbers is esthetically pleasing, and will increase the likelihood of providing data comparable with those in other studies. It would be valuable to have standard groups for common variables, such as serum cholesterol or blood pressure. Data could still be analyzed in the authors' favored manner, but with results also presented using standard groups. This practice would considerably aid those carrying out meta-analyses.

After creation of groups, there are several options for the method of analysis. Because the groups are ordered it is desirable to use a method that specifically looks for a trend across the groups (*see* **Ordered Categorical Data**). An exception would be in the fairly rare case in which one had an a priori hypothesis of a "U-shaped" relation.

With k categories it is common to create $k - 1$ binary indicator variables (or **dummy variables**). These are entered into the **multiple regression** model. In order to test the effect of the explanatory variable X, all $k - 1$ dummy variables can be assessed at once using a single test with $k - 1$ degrees of freedom. This approach is lacking in power against a monotonic relation between the response variable Y and X. An alternative is to use $k - 1$ tests to examine each indicator variable separately, which may be done as part of a stepwise procedure. Without allowance for multiple comparisons, however, this method will lead to a increased risk of a false positive result. This method can lead to models which are hard to interpret. Walter et al. [16] recommend a different way

of creating dummy variables, where each represents whether or not an individual is in a particular group or a higher one. Here stepwise selection cannot lead to a nonsensical model, as each dummy variable represents a meaningful comparison. This approach is more sensible, but it does not seem to be much used. The problem of multiple testing remains, however.

A different strategy is to give each of the k groups a **score** (or rank) from 1 to k, and then to treat these scores as a continuous variable, say S. The regression coefficient for S then estimates the change in Y between adjacent groups. A closely similar approach involves using the mean of X within each category in place of group scores. This is a good general method, but it does impose some assumptions regarding the nature of the relation between the explanatory variable and outcome.

Creating Risk Groups

Rather than group according to the distribution of observed values of a variable, a preferable general approach is to base any grouping on outcome. This can be done either when there is a single variable of interest, or when several variables are considered simultaneously in a multiple regression model. The fitted values from the chosen model are obtained as a weighted sum of the variables in the model, where the regression coefficients are the weights. The weighted sum is often called a *prognostic index* (PI) (*see* **Prognosis**). If there are no continuous variables the PI will have as many possible values as there are distinct covariate patterns. The PI will be a continuous score if the model includes at least one continuous variable. Creating meaningful groups is often desirable for clinical reasons. As an example, the Nottingham breast cancer index [7], based on three variables, yields three risk groups. Such an approach is quite common in cancer. The advantage of keeping any grouping to the end of the analysis is that, while some categorization may be applied to some variables at an early stage, it is not required.

For grouping the PI, similar considerations apply as have been discussed. There are no easy answers, though. When creating two risk groups, the situation closely resembles the problem of finding an appropriate cutpoint for a continuous measurement or score for diagnostic purposes. Here too, a data-derived cutpoint can be obtained with a minimum P value – and again the P value but not the estimate can be adjusted for multiple comparisons [14].

Discussion

Categorization of continuous data is not necessary, and indeed is not a natural way of analyzing continuous data for most statisticians. Grouping is often used because of concern about the risks associated with mismodeling the relationship. Several strategies can be applied to assess whether the relation may in fact be curved and to model such relationships [6]. A second possibility is to use results obtained after categorization to guide the choice of an appropriate model [18] (*see* **Model, Choice of**). It is important to note that the use of categories does not remove assumptions about the nature of the relationship, as the above comments on analysis indicate.

Given the widespread practice of categorizing continuous variables, it is remarkable how little attention has been given to the way in which this should best be done. Several textbooks on statistics and epidemiology make no apparent mention of the topic, even though they present data that have been categorized. Among those that do mention the issue there is disagreement. Kramer [8, p. 179] says, with respect to creating categories, that "It is essential that these boundaries be decided a priori ... so that the investigator is not at liberty to pick a cutoff point that optimizes his chances for demonstrating statistical significance". (He considered only the case of a single cutpoint.) By contrast, Rothman [12] states that "it is often preferable to define the final categories after reviewing the data, notwithstanding the common advice that it is somehow more 'objective' to do so in ignorance of the distribution of observations in hand". These remarks indicate that, despite wide familiarity, this area of application would benefit from further research into desirable strategies.

Cauchy Distribution

S.D. Poisson discovered the Cauchy distribution in 1824, long before its first mention by A.L. Cauchy [12]. Early interest in the distribution focused on its value as a counter-example which demonstrated the need for regularity conditions in order to prove important limit theorems [12] (*see* **Large-sample Theory**). The Cauchy distribution arises naturally as the ratio of two independent **standard normal** random variables (i.e. **Student's *t* distribution** with one **degree of freedom** is a Cauchy distribution). Also, if θ is **uniformly distributed** on $(-\pi/2, \pi/2)$, then $\tan\theta$ has a Cauchy distribution. The Cauchy distribution also arises as a mixture of normals: if Y follows the **chi-square distribution** with one degree of freedom, and, given $Y = y$, X is normal with mean 0 and variance y^{-1}, then X has a Cauchy distribution. This derivation of the Cauchy distribution as a mixture motivates its use for **robust regression** analysis of data sets in which the errors have longer than normal tails [9]. Another application of the Cauchy distribution is as a useful alternative to a normal **prior distribution** in the situation where a thicker tail than the normal distribution is reasonable [4].

The Cauchy distribution has density

$$f(x) = \frac{\beta}{\{\pi[\beta^2 + (x-\alpha)^2]\}}, \quad \text{where } \beta > 0,$$

and cumulative distribution function

$$F(x) = \frac{\left\{\arctan\left[\frac{(x-\alpha)}{\beta}\right] + \frac{\pi}{2}\right\}}{\pi}.$$

The distribution is symmetric about its median α, and has first and third quartiles $\alpha - \beta$ and $\alpha + \beta$, respectively (*see* **Quantiles**). The standard Cauchy distribution has $\alpha = 0$ and $\beta = 1$.

The **characteristic function** of the Cauchy distribution is

$$\phi(t) = \exp(it\alpha - \beta|t|).$$

From this it follows that the distribution does not have finite **moments** of any order. Linear combinations of independent Cauchy random variables also follow the Cauchy distribution. In particular, if X_1 and X_2 have independent Cauchy distributions with medians α_1 and α_2 and scale parameters β_1 and β_2, respectively, then $a_1X_1 + a_2X_2$ also has a Cauchy distribution with parameters $a_1\alpha_1 + a_2\alpha_2$ and $|a_1|\beta_1 + |a_2|\beta_2$, respectively.

The mean of n independent and identically distributed Cauchy random variables with median α and scale β also has a Cauchy distribution with median α and scale β. Hence, the sample mean is not a **consistent estimator** of the median α and, in fact, it offers no increase in accuracy compared with any single value [8]. Convenient estimators of α and β are available using the **order statistics** [3, 7, 11]. For example, the median is an **unbiased** estimator of α with 81% **asymptotic relative efficiency** [2]. For **maximum likelihood** estimates, care must be taken because the **likelihood** equations can have multiple roots. Haas et al. [5] have provided tables of critical values necessary to construct confidence intervals for estimates of α and β.

While the ratio of two independent normal random variables follows the Cauchy distribution, Cauchy distributions can also arise as the ratio of other, possibly dependent, random variables [1]. For additional characterizations and applications of the Cauchy distribution, see [6] and [10].

ROBERT J. GLYNN

Causal Direction, Determination

Causality analysis studies the cause–effect relationships among several variables (*see* **Causation**). There are several definitions of causality. Here we restate one that is in terms of probability [2]: C is a candidate cause of E if $\Pr(E|C) > \Pr(E|\overline{C})$. But the role of a potential **confounder**; B say, should be taken into account. It is possible that C leads to B and then B leads to E. Formally, C is a spurious cause if $\Pr(E|C \cap B) = \Pr(E|\overline{C} \cap B)$ which means that the real cause of E is B rather than C. Therefore, conditional on B, E is not affected by C. However, there may be a large number of potential confounders and some of them are unobserved, so that testing for $\Pr(E|C \cap B) = \Pr(E|\overline{C} \cap B)$ may be difficult. Causal relationship can be represented by a path diagram (*see* **Path Analysis**), on which the relationships between variables can be shown by arrows. For example $C \to E$ means that C is the cause of E; that is, B is the direct cause of E. Determining causal direction includes determining paths and their directions. A traditional causal analysis method is the **structural equation model**, in which the causes appear in the model as independent **explanatory variables** and the effects as dependent **response variables**. Bentler & Newcomb [1] proposed the following approach: (i) Form a path diagram. (ii) Form a **multivariate multiple regression** model with one equation for each effect, and all of its causes as regressors of this effect. The correlations between independent variables are represented by correlation matrices. (iii) Parameters are estimated and tested by model fitting. Special programs for this purpose are available (e.g. EQS) [4]. For an introduction to graphic models for several kinds of outcomes, see [3]. Although the above approaches are straightforward, the asymmetry between causes and effects may not be determined by the model and available data alone. Additional information such as temporal ordering or subjective knowledge may have to be used. Recently, acyclic graphic models have been used in causal analysis [6]. However, several assumptions are made which may not be realistic in practice and large sample sizes are needed to determine the causal relationship.

In **longitudinal** studies, repeated measurements are available. However, the structural equation models do not take the time order into account. An extension of these models for longitudinal data is the dynamic regression model which imposes cause–effect relationships on a multivariate time series [5] (*see* **Multiple Time Series**). For time series models, Granger's causality [8] is defined in terms of *predictability according to a law*. For example, suppose that X_t and Y_t, $t = 1, 2, \ldots, T$, are two time series. If adding the history of $Y_t(Y_1, \ldots, Y_{t-1})$ leads to a better prediction of X_t than using the history of X_t alone, then Y causes X.

A general form for time series causality models is [5]

$$x_t = \sum_{s=1}^{p} E_s x_{t-s} + \sum_{s=1}^{q} F_s y_{t-s} + u_{1t}, \qquad (1)$$

$$y_t = \sum_{s=1}^{r} G_s y_{t-s} + \sum_{s=1}^{v} H_s x_{t-s} + u_{2t}, \qquad (2)$$

where $\mathrm{var}(u_{1t}) = \mathbf{\Sigma}_1$ and $\mathrm{var}(u_{2t}) = \mathbf{\Sigma}_2$. Causal direction can be determined by testing $F_s = 0, s = 1, \ldots, q$, and $H_s = 0, s = 1, \ldots, v$. The computer package EQS [4] can also be used for the analysis of longitudinal data, particularly to determine causal directions. Recently, combined graphic and linear dynamic models [7] have been proposed for use in the analysis of time series models with complicated structures.

Causation

The concepts of cause and effect are central to most areas of scientific research, so it is not surprising that the literature on them could fill a small library. What may be surprising, given their importance, is that consensus about basic definitions and methods for causal **inference** is (at best) limited, despite some three centuries of debate. A brief review cannot do justice to the history and details of this debate, nor to all the schools of thought on causation. This article will, therefore, focus on a few major themes that have affected modern biostatistical practice. Of necessity, some aspects of the discussion are simplified relative to the literature, and the references should be consulted for more thorough descriptions. Entries on related topics are given in the final section.

Counterfactual Causation

At least as far back as the early eighteenth century, philosophers noted serious deficiencies in ordinary definitions of causation (e.g. see Hume [8]). For example, *Webster's New Twentieth Century Dictionary* [12] offers "that which produces an effect or result" as a definition of "cause". The circularity of this definition becomes apparent when one discovers "to cause" among the definitions of "produces". In early scientific treatises, an event (or set of events) A was said to cause a later event B if there was "constant conjunction" or "regularity" of the events, in that A (the cause) was inevitably followed by B ("the effect"). Mill [13] pointed out that such "constant conjunction" could always be the effect of a third event C preceding A and B; in other words, the regularity of B following A might only be due to **confounding**[4]. Informal definitions of "effect" suffer from the same problems, because "effect" as a verb is merely a synonym for "cause", while "effect" as a noun is defined as a "result", which is, in turn, defined as an "effect" in causal contexts.

Hume [7], however, offered in passing another view of causation that pointed a way out of circularity or confounding in the definition (even if confounding might be inevitable in the observation). In the present terminology, Hume proposed that A caused B if failure of A to occur would have been sufficient for failure of B to occur (see Lewis [10]). That is, by focusing on specific instances of causation, we could say that a specific event A caused a specific event B if occurrence of A was necessary for B under the observed background circumstances. Essentially, the same concept of causation can be found in [2] and [13] (both quoted in [22]).

Of course, the preceding definition falls short of the formalism necessary for rigorous logical analysis. Such analysis first appeared in the statistics literature in [14]. The basic idea is as follows: Suppose N units indexed by $i = 1, \ldots, N$ are to be observed in an experiment that will assign each unit to one of K treatments $x_1, \ldots, x_K$. For each unit, the outcome of interest is the value of a response variable Y_i. It is assumed that Y_i will equal y_{ik} if unit i is assigned treatment x_k. Suppose that one treatment level, say x_1, is designated the reference treatment against which other treatments are to be evaluated (typically, x_1 is "no treatment", placebo, or standard treatment). We may then define the causal *effect* of $x_k (k > 1)$ on Y_i relative to x_1 (the reference) to be $y_{ik} - y_{i1}$. Alternatively, if the response is restricted to positive values (such as blood pressure), we may define the causal effect as y_{ik}/y_{i1} or $\log y_{ik} - \log y_{i1}$.

This definition of effect leads naturally to a precise usage for the word "cause". Prior to treatment, we say y_k would cause a change of $y_{ik} - y_{i1}$ in Y_i; if $y_{ik} - y_{i1} = 0$, we say x_k would cause no change in Y_i. After the experiment, if unit i had received treatment k, then we say that x_k caused a change of $y_{ik} - y_{i1}$ in Y_i; otherwise, we say that x_k would have caused a change of $y_{ik} - y_{i1}$ in Y_i.

There are four crucial restrictions that the preceding formalism places on the notion of effect (and, hence, cause). First, effects are defined only within comparisons of treatment levels. To say that "drinking two glasses of wine a day lengthened Smith's life by four years" is meaningless by itself. A reference level must be at least implicit to make sense of the statement. Smith might have lived even longer had she consumed one rather than two glasses per day. As given, the statement could refer to no wine or four glasses per day or any other possibility.

Secondly, more subtly and profoundly, the formalism assumes that y_{ik}, the response of unit i under treatment k, remains well defined even if unit i is *not* given treatment k. In the philosophy literature, this assumption and the problems attendant with it

are recognized as problems of *counterfactual* analysis [10, 11, 24] (see also the discussion of Holland [6]). The statement "if x_k had been administered, then the response Y_i of unit i would have been y_{ik}" is called a *counterfactual conditional*: it asserts that Y_i would equal y_{ik} if, *contrary to fact*, x_k had been administered to unit i. Consider again Smith's drinking. Suppose she would contract cancer at age 70 if she drank two glasses of wine a day, but would instead die of a stroke at age 68 if she drank no wine. If Y_i is her time to cancer and she drank two glasses per day, how could we define her counterfactual time to cancer given no wine? Without this definition, the effect of two glasses of wine vs. none would be undefined.

The preceding problem is common in survival analysis when **competing risks** are present. The problem is not solved by attempting to condition on "absence of competing risks": such hypothetical absence is itself not a well-defined counterfactual state, even though standard probability calculations (as used in product-limit estimates) make it appear otherwise (see Kalbfleisch & Prentice [9, p. 166], and Prentice & Kalbfleisch [18], for further discussion). Rather, the definition of the response must be amended to include the competing risks if the counterfactual definition is to be applied. For example, Y_i could become the pair comprising time of cancer or competing risk and an indicator marking the event at that time.

Thirdly, the effects captured by the counterfactual definition are *net effects*, in that they include all indirect effects and **interactions** not specifically excluded by the treatment definition. For example, Smith's consumption of two glasses of wine per day rather than none may have given her four extra years of life solely because one night at a formal dinner it made her feel unsteady and she had a friend drive her home; had she not drunk, she would have driven herself and been hit and killed by a drunk driver. This sort of indirect effect is not one we would wish to capture when studying biological effects of wine use. It is, nonetheless, included in our measure of effect (as well as any estimate) unless we amend our treatment definition to include holding constant all "risky" activities that take place during Smith's life. Such amendment is sometimes (simplistically) subsumed under the clause of "all other things being equal (apart from treatment)", but can be a serious source of ambiguity when the intervention that enforces the amendment is not well defined.

A fourth restriction, which may be considered an aspect of the third, is that the formalism assumes that treatments not applied to a unit could have been applied. Suppose Smith would not, and could not, stop daily wine consumption unless forced physically to do so. The effect of her actual two-glass-a-day consumption vs. the counterfactual "no wine" would now be undefined without amending the treatment definition to include forcing Smith to drink no wine, e.g. by forcibly injecting Smith with antabuse each day of her life. Such amendment would be of little interest, not just because of its wild impracticality, but because of the side effects it would introduce.

The preceding restriction is sometimes accounted for by requiring that the counterfactual definition of "effect" applies only to "treatment variables". The latter are defined informally as variables subject to manipulation of their levels; an additional restriction is made that each possible level (treatment) for the treatment variable has nonzero probability of occurrence (e.g. see Holland [6]). One may sense here an echo of the circularity in ordinary definitions of cause, for this notion of manipulation embodies having an effect on treatment levels. Nonetheless, it has been argued that one strength of the counterfactual approach is its explication of the ambiguities inherent in defining cause and effect [10, 22].

One model of causation that has enjoyed some popularity in epidemiology is the sufficient-component cause (SCC) model introduced by Rothman [20, 21, Ch. 2]. This model presents causal mechanisms via schematic "pie charts" composed of slices representing necessary causal components of mechanisms. It can be shown that this model can be mapped into the general counterfactual framework, although it involves certain nonidentifiable elaborations [21, Ch. 18].

Probabilistic Causation

A number of authors have attempted to formalize causation through axioms governing the evolution of probabilities over time (e.g. see Suppes [25] and Eells [1]). Such systems have attracted little attention in biostatistics. Other approaches include probabilistic extensions of the counterfactual approach. One is based on the distribution of fixed potential

responses; that is, the joint distribution $F(y_1, \ldots, y_K)$ of $y_{i1}, \ldots, y_{iK}$ in a population of units. We may also consider conditional distributions in subpopulations defined by **covariates** such as age, sex, and received treatment. Population effects can be defined as averages of individual effects over populations; statistical procedures for inferences about these effects follow from assumptions about sampling and treatment assignment mechanisms. The basic ideas were present in Fisher [4] and Neyman [14], and have been elaborated more generally since [23].

Another extension considers potential responses that are distributional parameters specific to units. For example, we could consider the probability that a given atom emits a photon in the second following absorption of a photon ("treatment 2") minus the probability of emission in the same second if no photon had been absorbed ("treatment 1"). This probability difference is the effect of photon absorption on the atom relative to no absorption. In quantum mechanics, this difference (effect) is well defined *whether or not a photon is actually emitted*. In fact, under the standard quantum model, the emission indicator ($Y_i = 1$ if the atom emits a photon in the second, 0 if not) is *not* well defined under counterfactual alternatives to the actual history of the atom. Fortunately, the latter ambiguity appears to have no practical implications for the gross phenomena studied in biostatistics. It does, however, illustrate the possibility of considering probabilities and expectations (rather than events) as responses in the counterfactual definition, even for macrophenomena.

Causal Inference

Of causal inference there may be even more written and less agreed than for the basic definitions of cause and effect. A discussion of this literature is beyond the scope of the present article. Issues of **bias**, validity, and generalizability in causal inference are discussed elsewhere (*see* **Bias in Case–Control Studies**; **Bias in Observational Studies**; **Confounding**; **Validity and Generalizability in Epidemiologic Studies**). A discussion of criteria for causal inference [5] may be found in **Hill's Criteria for Causality** and in chapter 2 of Rothman and Greenland [21]; most of these criteria are informal, and there are many objections to their use [21, Ch. 2].

Formalisms for causal inference in biostatistics have thus far been restricted to counterfactual-based procedures, as in [1, 14, 23], and to methods based on path diagrams or directed graphs. Starting with Wright [26], path diagrams (*see* **Path Analysis**) (more recently called causal diagrams) have been used to display assumptions about the absence of particular effects and to provide a basis for algorithms useful in determining whether effects are identifiable from a given observational process (e.g. Robins [19], Pearl [16], and Pearl & Robins [17]; *see* **Identifiability**). Most of these approaches take the notion of cause as a primitive; a few define effects in a manner formally equivalent to the counterfactual definition extended to probabilistic domains [15]. The counterfactual approaches emphasize the importance of **randomization** in assuring identifiability of causal effects [3, 4, 19, 23].

SANDER GREENLAND

Cause of Death, Automatic Coding

Accurate selection and coding of the underlying cause of death based on death certificates using the **International Classification of Diseases (ICD)** is a labor-intensive task requiring special training and knowledge. Persons without a medical background must learn basic anatomy and physiology as a prerequisite to cause of death coding training, but even trained nurses and physicians must learn the detailed procedures and rules embodied in the ICD. **Vital statistics** offices have had a continuing burden to maintain a well-trained and experienced mortality coding staff. However, it was not until there was a heightened interest in coding not only the underlying cause of death but the other causes on the death certificate as well, that efforts to utilize computer technology to code death certificates began in earnest (*see* **Cause of Death, Underlying and Multiple**). The dual coding burden of the different procedures required to produce the two kinds of mortality data was prohibitive for most, if not all, countries interested in producing enhanced mortality statistics.

There were several independent approaches to automation of the international selection and modification rules, most notably in England and Wales and in the United States (US). Responsible government authorities in these two countries kept in close touch with each other's progress, but resource constraints in the former left the US **National Center for Health Statistics** as the single remaining major investor in research and development of an automated mortality coding system.

Originally designed for a large mainframe computer, the US system consisted of two subsystems, MICAR (Medical Information, Classification, and Retrieval) and ACME (Automated Classification of Medical Entities). MICAR required an ICD code or a standardized diagnostic abbreviation to be assigned by a coder to each condition reported, along with a location code indicating where the condition was written in relation to the other conditions entered on the death certificate (*see* **Death Certification**). This information was entered into the computer. The MICAR software searched its internal dictionary until the condition was found and then it assigned a dictionary reference number to each such term. The reference numbers and their death certificate location codes (i.e. MICAR output) formed the input to the ACME module which then, through a series of logical decision tables, applied the international selection and modification rules to arrive at the underlying cause of death. The MICAR output data could then also be used to produce multiple cause of death tabulations by applying additional computer procedures designed for that purpose.

The original versions of both MICAR and ACME have undergone many iterations since their early development in the late 1960s. The current versions are designed to run on a personal computer and are based on the latest revision of the ICD. The MICAR module, now known as SuperMICAR, accepts English language diagnostic text as well as standard disease abbreviations as input while earlier versions required a coder to assign code numbers to each diagnostic term. This allows the data to be entered by persons who can operate a keyboard but who have no need for familiarity with the ICD.

The main features of the MICAR/ACME approach are as follows:

1. The coding of death certificates can be done by coders with less training and knowledge than is required of underlying cause of death coders, although the total number of individual codes to be assigned is greater.
2. The ACME decision tables residing in the computer are logical reflections of the steps an underlying cause of death coder is trained to follow in the application of the international selection and modification rules and therefore result in underlying cause codes with a very high degree of agreement with those resulting from the work of highly experienced human coders.
3. The same original coding of death certificates can be used to produce both underlying cause of death statistics and multiple cause of death statistics.
4. There is a higher degree of consistency in the results, since variation due to differences in interpretation of the rules by coders is eliminated.
5. Changes in the ICD, its rules, or their interpretation can be implemented at any time by modifying the appropriate decision table(s) and reprocessing the records that have been processed prior to the change.

A number of countries plan to implement this automated system when they begin using the Tenth Revision of the ICD. Because of this widespread interest, there will be increased international involvement with the content and possible future modification of the decision tables and in the way multiple cause of death data are manipulated and presented. Countries planning to use this automated system have participated in planning meetings with the system designers and, in the case of the UK, have assisted in some of the research for the latest version. In addition, a few other automated systems in languages other than English have been developed using, in part, the ACME decision table logic. This broader involvement of many countries in the same or highly similar automated programs is expected to contribute to greater uniformity and comparability of international mortality data.

ROBERT A. ISRAEL

Cause of Death, Underlying and Multiple

The underlying cause of death is defined by the **World Health Organization (WHO)** as "(a) the disease or injury which initiated the train of morbid events leading directly to death, or (b) the circumstances of the accident or violence which produced the fatal injury" [5]. This definition recognizes the importance of the public health principle of prevention. By having information on the sequence of conditions leading to death, from the initial disease or condition, through diseases arising as consequences of the initial disease, on to the final or terminal condition, it is believed that interventions can be found to break the train of events and reduce mortality from selected causes of death.

The concept of attributing to each death a single cause for statistical tabulation and analytic purposes is rooted in the early development of disease classifications. From the outset and through the first part of the twentieth century, disease classifications were focused primarily on the causes of mortality, and it was the principal cause of death – not symptoms, other concurrent conditions, nor modes of dying – that was of primary interest. At the First International Revision Conference for the **International Classification of Diseases (ICD)**, convened in 1900, Bertillon proposed a set of rules for selecting the single cause of death to be used for statistical purposes when more than one condition was reported [4]. In subsequent years, however, there was little uniformity in practice among countries for the selection of a single cause of death and it was not until 1938, at the Fifth Decennial Revision Conference, that formal recognition at the international level was given to the statistical problem of selecting a single cause of death where more than one cause was given on the death certificate (joint causes of death). This question had been under study in the United States (US), and the Conference requested the US government to continue its investigations in this regard. Accordingly, the US government established the US Committee on Joint Causes of Death, comprised of members from the US, Canada, the UK, and representatives in an advisory capacity from the Interim Commission of the WHO [2]. In recognition of the work of this committee and the recommendations of the WHO Expert Committee for the Preparation of the Sixth Revision of the International Lists of Diseases and Causes of Death, the Sixth Decennial Revision Conference, at its meeting in 1948, not only adopted the Sixth Revision of the International Lists but also an International Form of Medical Certificate of Cause of Death, a formal definition of underlying cause of death, and a standardized set of selection rules for arriving at an underlying cause of death when more than one condition is reported (*see* **Death Certification**). The recommendations of the Conference were accepted by the World Health Assembly in 1948 and incorporated into Regulations No. 1 under Article 21(b) of the WHO Constitution. The regulations serve as guidelines to Member States for the compilation of morbidity and mortality statistics in accordance with the ICD [3]. This acceptance of a standard form for certifying causes of death, the definition of the underlying cause, and the rules for selecting it from more than one reported cause was a major step in the quest for international comparability of mortality data.

While the underlying cause of death continues to form the basis for mortality data for countries with medically certified deaths, some have observed that there is a loss of potentially useful information when several diseases or conditions are reported on a death certificate but only one is used for statistical reporting and analysis. With the decline in importance, especially in developed countries, of infectious diseases and a concomitant rise in **life expectancy**, the number of death certificates listing several conditions, particularly chronic illnesses, has risen noticeably. In those cases in which more than one disease is reported, all of the diagnostic entries on the death certificate are known collectively as "multiple causes of death". From the group of multiple causes on a death certificate, an underlying cause is chosen in accordance with the standard definition and procedures, but unless additional steps are taken, the remainder of the entries on the medical certification of cause of death contribute nothing to the statistical collection of mortality data. Recognizing this, several countries, particularly England and Wales, France, Sweden, and the US, began experimenting in the 1960s and subsequent years with ways to capture the additional information and analyze and present the findings [1]. At the international level, the WHO convened several meetings of interested countries, the first in London in 1969, to review multiple cause of death coding

procedures and to compare findings. At those international meetings it was generally agreed that there was not enough similarity of approach, nor a clearly superior methodology, to recommend a single international procedure. However, the growing number of interested countries were encouraged to continue to develop and use their own methodologies and to continue to keep each other informed of results. Furthermore, it was emphasized that some form of multiple cause of death analysis and data presentation was an important adjunct to the traditional underlying cause approach. Late in the 1990s, with a growing number of countries beginning to rely on a common automated computer coding scheme (*see* **Cause of Death, Automatic Coding**), there appeared to be more likelihood that several countries would mutually agree to a uniform procedure for multiple cause of death coding and analysis. This, when realized, would form an important step toward international comparability of multiple cause data to enhance the traditional underlying cause of death statistics.

Cell Cycle Models

The proliferation of cells is fundamental to the study of the growth of tissues and organs in development, as well as the growth of colonies of bacteria (*see* **Bacterial Growth, Division, and Mutation**), yeast, and tumors. Specifically, the cell cycle refers to the identifiable stages in the division cycle of a cell based on its DNA content which is duplicated (except in meiosis) before cells can divide to produce progeny. There are four basic phases of the cell cycle: G_1 (gap one), S (DNA synthesis), G_2 (gap two), and M (mitosis). The time spent in these four phases, from birth to the division of a cell is called the *cell-cycle time*.

Numerous mathematical models have been proposed for the study of the variation in the cell-cycle time and phase durations during the last few decades. Cell-cycle modeling encompasses three major areas. The oldest of these areas is the study of cell population growth. These studies focus on predicting the time-dependent dynamics of a cell population or the time-independent distribution of cells within various cell-cycle phases. Both deterministic and stochastic models based on age-dependent progression have been used to estimate the transit times of different cell-cycle phases. The second area, cell-cycle analysis, is related to cytometric studies, and is based on characterizing cells on the basis of their DNA content or other proliferative markers, indicating the position in the cell cycle. The third and most recent area is based on detailed kinetics of growth regulation within an individual cell. The models in this area are deterministic and use nonlinear multivariable ordinary differential equations. The models in the first two areas, considered as macroscopic models, have quantitative experimental results for validation. However, the models in the third area, the microscopic models, still can be compared only with observed qualitative behavior of the relevant variables. These three types of cell cycle models are discussed below.

Macroscopic Models

Cell Population Models

The experimental observations that cells could be labeled in the S-phase with radioactive thymidine, and that the labeled cells could be identified in mitosis by autoradiography, gave rise to cell-cycle models based on the fraction of labeled mitosis (FLM) curves. These models considered the variation in phase and cycle duration by introducing multivariable and/or time delay equations to express the temporal distribution of the population with the uncertainties expressed by stochastic terms. **Regression** analysis was used to estimate the coefficients of those models. Birth rate, death rate, cell-cycle time, and population doubling time are a few of the widely used parameters in these models. Typically, the assumptions such as (i) the variability of these parameters from one cell to another, (ii) the correlations of these parameters from one generation to another, or (iii) correlation of a cellular property such as the cell size to these variables, have been tested. Although many of these models could predict the population density for a short period of time (related to experiments) none can predict adequately the long-term behavior. This difficulty is due to the environmental changes, cell-to-cell communications, and intracellular signals of the cell population. Hence, the control of cell proliferation gives rise to differences in the parameters of these models. Since the number of contributions discussing such cell-cycle models is extremely large, we suggest to interested researchers the review papers by Swan [15], Rubinow [13], Eisen [6], White [24], Cooper [5] and Arino [1], and strictly for deterministic models the work by Webb [23], Tucker & Zimmerman [19], and Arino & Kimmel [2]. These mathematical models for cell population studies overlap with other types of mathematical modeling such as **branching** models, compartmental models, **Markov processes**, discrete models, and fluid flow models. Although they fall under different subcategories, they all incorporate the same basic physical principle: mass balancing. Related models are used in other biological studies, such as **tumor growth**, cell population analysis of tissues (e.g. regeneration of epithelial cells after irradiation), and hematopoiesis.

Cell-Cycle Analysis (Measurement of DNA Content)

While the original cell-cycle models owe their genesis to the FLM experiment, a second class of models has been developed based on the recognition that DNA content can be used to identify the position of cells within the cell cycle ranging from diploid DNA

content in G_1, increasing throughout the S-phase, and being at twice diploid in $G_2 + M$ preparatory to division. The development of appropriate DNA stains and equipment such as flow cytometers has made it possible to characterize populations of cells rapidly on the basis of differing subpopulations and to infer changes in the total population on the basis of the changes in the fractions of cells within each cell-cycle phase. While it is possible to define different DNA amounts and, hence, differing amounts of progression within the S-phase, in both G_1 and $G_2 + M$, cells appear indistinguishable on the basis of DNA content, so that finer structures of cell-cycle progression are obscured. Because a histogram of the DNA distribution of a population of cells typically appears with all G_1 cells appearing in a single region and $G_2 + M$ cells appearing in a second region with cells in the S-phase at all points in between, a wide variety of procedures have arisen for deconvolving the total distribution into separate parts to obtain estimates of the fractions of cells in each phase. A discussion of these procedures may be found in flow cytometry textbooks such as Shapiro [14] and Watson [22].

More recently it has become possible to measure other markers of cell proliferation such as Ki67, PCNA, various cyclins and markers of cell death within populations of cells, and to refine the location of a subpopulation within the division cycle. These methods generally use multi-parameter measurements leading to large data sets (e.g. 50 000 cells with six parameters on each) and are currently under study.

While these macroscopic models are still studied, especially for understanding bacterial growth or cell growth *in vitro*, modern research has revealed considerable details about the intracellular kinetics of the biochemical events that drive a cell through the cell cycle. This information, which is accumulating rapidly, has opened a new aspect of cell-cycle modeling: the development of microscopic models.

Microscopic Models

Macroscopic studies of cell populations have demonstrated the need for further studies to elucidate the cause of the variability in the cell-cycle time of two daughter cells. Technological advances in biochemistry have enabled scientists to identify the biochemical changes within a cell, which permits the simulation of mechanistic models. This section gives a more detailed account of the mathematical modeling of the microscopic view of the cell cycle.

A large body of experimental work focuses on understanding the regulation of the cell cycle in eukaryotes. Studies of cell-cycle progression have led to the elucidation of a variety of proteins which are required for appropriate entry and exit from the S-phase (DNA synthesizing), entry and exit from the M-phase (mitosis and cell division), cell death, cell rest (quiescence), and permanent cell arrest (differentiation). These proteins include cyclins, and their associated kinases, which together form complexes required for progression through the cell cycle. The activation and deactivation of these kinases are controlled by other proteins called activators and inhibitors, respectively. Biochemically, phosphorylation, dephosphorylation, and proteolysis are the main mechanisms of control of these kinases at specific phases of the cell cycle. Mathematically, the kinetics of these proteins are represented by a nonlinear multivariable, first-order dynamic system. It is assumed that the oscillatory solutions of this system will mimic continuous cell proliferation. While very early contributions by Hyver & Le Guyader [8], Norel & Agur [9], and Goldbeter [7] modeled the M-phase regulation by two to three variable systems, Tyson [20] proposed a model for the regulation of the same phase by a six-variable system. All these authors established necessary criteria for obtaining stable oscillatory solutions and discussed the bifurcational properties of reduced systems. The papers by Thron [16], Obeyesekere et al. [11], and Busenberg & Tang [4] discussed further mathematical aspects of these models. A very detailed model for the same phase kinetics, which introduces a ten-variable system, was published by Tyson & Novak [21]. Experimental work continued to elucidate proteins that regulate other phases, namely the S- and G_1-phases; models for these phases have been proposed by Obeyesekere et al. [10, 12]. The kinetics or the mechanisms necessary for a cell to enter the S-phase (i.e. pass a restriction point) has been an important biological question. Some of Thron's mathematical models address this issue [17, 18]. While many authors have contributed towards cell cycle regulation, some have validated their models with qualitative experimental results. For example, see [3] for such a contribution.

Presently, the search for proteins affecting the cell cycle is ongoing. Our understanding of the number

and types of proteins that control cell-cycle regulation is growing rapidly; however, knowledge of their interactions and the rate constants is still sketchy. Thus, the results of these models have been restricted to qualitative analysis. Future cell-cycle modeling should integrate experimental results with the models developed to date, or, in other words, incorporate the microscopic models into the macroscopic models via the parameters of the latter. Our ability to do this will result in significantly more realistic cell-cycle models.

MANDRI N. OBEYESEKERE

Censored Data

In classical statistics, the observations are frequently assumed to include *independent* random variables $X_1, \ldots, X_n$, with X_i having the density function

$$f_i^\theta(x) = \alpha_i^\theta(x) S_i^\theta(x),$$

where $\alpha_i^\theta(x)$ is the hazard function, $S_i^\theta(x)$ is the survival function, and θ is a vector of unknown parameters (*see* **Survival Distributions and Their Characteristics**). Then inference on θ may be based on the **likelihood** function,

$$L(\theta) = \prod_i f_i^\theta(X_i),$$

in the usual way. In survival analysis, however, one can rarely avoid various kinds of incomplete observation. The most common form of this is *right-censoring* where the observations are

$$(\tilde{X}_i, D_i), \quad i = 1, \ldots, n, \tag{1}$$

where D_i is the indicator $I\{\tilde{X}_i = X_i\}$, and $\tilde{X}_i = X_i$, the true survival time, if the observation of the lifetime of i is uncensored and $\tilde{X}_i = U_i$, the time of right-censoring, otherwise. Thus, $D_i = 1$ indicates an uncensored observation, $D_i = 0$ corresponds to a right-censored observation. Other kinds of incomplete observation will be discussed below.

Survival analysis, then, deals with ways in which inference on θ may be performed based on the censored sample (1). We would like to use the function

$$\begin{aligned} L^c(\theta) &= \prod_i \alpha_i^\theta(\tilde{X}_i)^{D_i} S_i^\theta(\tilde{X}_i) \\ &= \prod_i f_i^\theta(\tilde{X}_i)^{D_i} S_i^\theta(\tilde{X}_i)^{1-D_i} \end{aligned} \tag{2}$$

for inference, but there are two basic problems:

1. The presence of censoring may alter the hazard function of the lifetime X_i, i.e. the conditional distribution of X_i, given that i is alive at t ($X_i \geq t$) *and uncensored at* t ($U_i \geq t$), may be different from what it was in the uncensored case, i.e. just given $X_i \geq t$ (*dependent censoring*).
2. The observed right-censoring times, U_i, may contain information on θ (*informative censoring*).

An example of a dependent censoring scheme would be if, in a clinical trial with survival times as the outcome variables, one removed patients from the study while still alive and when they appeared to be particularly ill (or particularly well), so that patients remaining at risk are not representative of the group that would have been observed in the absence of censoring. In other words, dependent censoring represents a dynamic version of what in an epidemiologic context would be termed a **selection bias**. An example is provided below (Example 1). Mathematical formulations of independent censoring (conditions on the joint distribution of X_i and U_i) may be given, and it may be shown that several frequently used models for the generation of the times of right-censoring satisfy these conditions. The difficulty in a given practical context lies in the fact that the conditions may be impossible to verify, since they refer to quite hypothetical situations.

The second concept mentioned, noninformative censoring, is simpler and relates to the fact that if censoring is informative, then a more efficient inference on θ may be obtained than the one based on (2); see below.

Independent Censoring

The general definition of independent censoring given by Andersen et al. [2], Section III.2.2 for multivariate counting processes has the following interpretation for the special case of survival analysis with time-fixed **covariates**. The basic (uncensored) model is that conditional on covariates $\mathbf{Z} = (\mathbf{Z}_1, \ldots, \mathbf{Z}_n)$ the lifetimes $X_1, \ldots, X_n$ are independent, X_i having the hazard function

$$\alpha_i^\theta(t|\mathbf{Z}_i) \approx P^{\theta\phi}(X_i \in I_{\mathrm{d}t} | X_i \geq t, \mathbf{Z}) / \mathrm{d}t. \tag{3}$$

Here, $I_{\mathrm{d}t}$ is the interval $[t, t + \mathrm{d}t)$ and $P^{\theta\phi}$ is the joint distribution of $X_1, \ldots, X_n, \mathbf{Z}$ *and* the censoring times. Note that the hazard function only depends on θ, i.e. ϕ is a nuisance parameter. Because of the conditional independence of X_i it follows that

$$P^{\theta\phi}(X_i \in I_{\mathrm{d}t} | \mathcal{F}_{t-}) \approx \alpha_i^\theta(t|\mathbf{Z}_i) I\{X_i \geq t\} \, \mathrm{d}t,$$

where the *history* $\mathcal{F}_{t-}$ contains $\mathbf{Z}$ and all information on $X_1, \ldots, X_n$ from the interval $[0, t)$, i.e. values of X_i for i with $X_i < t$ and the information that $X_j \geq t$

for j with $X_j \geq t$. Let there now be given right-censoring times $U_1, \ldots, U_n$ and define the enlarged history $\mathcal{G}_t$ as the one containing $\mathcal{F}_t$ *and* all information on $U_1, \ldots, U_n$ from the interval $[0, t]$, i.e. values of $U_i \leq t$ and the information that $U_j \geq t$ for those j where $U_j \geq t$. The condition for independent censoring is then that

$$P^{\theta\phi}(X_i \in I_{\mathrm{d}t} | \mathcal{F}_{t-}) = P^{\theta\phi}(X_i \in I_{\mathrm{d}t} | \mathcal{G}_{t-}). \qquad (4)$$

It follows that *simple type I* censoring, where all U_i are equal to a *fixed* time, u_0, and *simple type II* censoring, where all U_i are equal to the kth smallest lifetime $X_{(k)}$ for some k between 1 and n, are both independent, since the right-censoring times in these cases give rise to no extra randomness in the model; that is, $\mathcal{F}_t = \mathcal{G}_t$.

In some models, $U_1, \ldots, U_n$ are assumed to be independent given $\mathbf{Z}$ and $\mathbf{Z}_1, \ldots, \mathbf{Z}_n$ are independent identically distributed (iid). Then the assumption (4) reduces to

$$\alpha_i^{\theta}(t|\mathbf{Z}_i) \approx P^{\theta\phi}(X_i \in I_{\mathrm{d}t} | X_i \geq t, U_i \geq t, \mathbf{Z})/\,\mathrm{d}t \qquad (5)$$

and it is fulfilled, e.g. if U_i and X_i are independent given Z_i. This is, for instance, the case in the *simple random* censorship model where $U_1, \ldots, U_n$ are iid and independent of $X_1, \ldots, X_n$.

Some authors take the condition (5) (which is less restrictive than (4)) as the definition of independent censoring; see, for example, [6], p. 128. However, (4) may be generalized to other models based on counting processes and both (4) and (5) cover the most frequently used mathematical models for the right-censoring mechanisms. These include both the models already mentioned, i.e. simple type I, type II and random censorship and various generalizations of these (e.g. progressive type I censorship (cf. Example 2, below), general random censorship, and randomized progressive type II censorship; see, [2, Section III.2.2]). Earlier contributions to the definition and discussion of independent censoring are the monographs by Kalbfleisch & Prentice [13], p. 120 and Gill [7], Theorem 3.1.1 and the papers by Cox [5], Williams & Lagakos [16], Kalbfleisch & MacKay [12] and Arjas & Haara [3], all of whom give definitions that are close or equivalent to (5). Another condition for independent censoring, stronger than (5) but different from (4), is discussed by Jacobsen [11].

From (4) and (5) it is seen that censoring is allowed to depend on covariates as long as these are included in the model for the hazard function of the lifetime distribution in (3). Thus, an example of a *dependent* censoring scheme is one where the distribution of U_i depends on some covariates that are not included there. This is illustrated in the following example.

Example 1: Censoring Depending on Covariates

Suppose that iid binary covariates, $Z_1, \ldots, Z_n$, have

$$P^{\theta\phi}(Z_i = 1) = 1 - P^{\theta\phi}(Z_i = 0) = \phi,$$

and that $X_1, \ldots, X_n$ are iid with survival function $S(t)$. The **Kaplan–Meier estimator** $\widehat{S(t)}$ based on the X_i then provides a consistent estimate of $\theta = S(\cdot)$, the marginal distribution of X_i. This may be written as

$$S(t) = \phi S_1(t) + (1 - \phi) S_0(t),$$

where $S_j(t)$, for $j = 0, 1$, is the conditional distribution given $Z_i = j$. Note that these may be different, e.g. $S_1(t) < S_0(t)$ if individuals with $Z_i = 1$ are at higher risk than those with $Z_i = 0$. Define now the right-censoring times U_i by

$$U_i = u_0, \text{ if } Z_i = 1, \qquad U_i = +\infty, \text{ if } Z_i = 0.$$

Then, for $t < u_0$ the Kaplan–Meier estimator will still consistently estimate $S(t)$, while for $t > u_0$, $\widehat{S(t)}/\widehat{S(u_0)}$ will estimate $S_0(t)/S_0(u_0)$. If, however, the covariate is included in the model for the distribution of X_i, i.e. $\theta = [S_0(\cdot), S_1(\cdot)]$, then $\widehat{S_j(t)}$, the Kaplan–Meier estimator based on individuals with $Z_i = j$, $j = 0, 1$, will consistently estimate the corresponding $S_j(t)$, also based on the right-censored sample (though, of course, no information will be provided about $S_1(t)$ for $t > u_0$).

It is seen that censoring is allowed to depend on the *past* and on external (in the sense of conditionally independent) random variation. This means that if, in a lifetime study, sex and age are included as covariates, then a right-censoring scheme, where, say, every year, one out of the two oldest women still alive and uncensored is randomly (e.g. by flipping a coin) chosen to be censored, is independent. However, a right-censoring scheme depending on the *future* is dependent. This is illustrated in the following example.

Example 2: Censoring Depending on the Future

Suppose that, in a clinical trial, patients are accrued at calendar times $T_1, \ldots, T_n$ and that they have iid lifetimes $X_1, \ldots, X_n$ (since entry) independent of the entry times. The study is terminated at calendar time t_0 and the entry times are included in the observed history, i.e. $Z_i = T_i$ in the above notation. If, at t_0, all patients are traced and those still alive are censored (at times $U_i = t_0 - T_i$) and, for those who have died, their respective lifetimes, X_i, are recorded, then this right-censoring is independent (being *deterministic*, given the entry times, so-called progressive type I censoring).

Consider now, instead, the situation where patients are only seen, for instance, every year, i.e. at times $T_i + 1, \ldots, T_i + k_i \leq t_0$ and suppose that if a patient does not show up at a scheduled follow-up time, then this is because he or she has died since last follow-up and the survival time is obtained. Suppose, further, that for the patients who are alive at the time, $T_i + k_i$, of their last scheduled follow-up, and who die before time t_0, there is a certain probability, ϕ, of obtaining information on the failure, whereas for those who survive past t_0 nothing new is learnt. If these extra survival times are included in the analysis and if everyone else is censored at k_i, then the right-censoring scheme is dependent. This is because the fact that patient i is censored at k_i tells the investigator that this patient is likely not to die before t_0 and the right-censoring, therefore, depends on the future. To be precise, if the average probability of surviving past t_0, given survival until the last scheduled follow-up time is $1 - \pi$, then the probability of surviving past t_0, given censoring at the time of the last scheduled follow-up, is $(1 - \pi)/[\pi(1 - \phi) + 1 - \pi]$, which is 1 if $\phi = 1, 1 - \pi$ if $\phi = 0$, and between $1 - \pi$ and 1, otherwise.

If, alternatively, everyone still alive at time $T_i + k_i$ were censored at k_i, then the censoring would be independent (again being deterministic given the entry times).

Another censoring scheme that may depend on the future relative to "time on study", but not relative to calendar time, occurs in connection with testing with replacement, see, for example, [8].

Let us finally in this section discuss the relation between independent right-censoring and **competing risks**. A competing risks model with two causes of failure, d and c, is an inhomogeneous **Markov process** $W(\cdot)$ with a transient state 0 ("alive"), two absorbing states d and c and two cause-specific hazard functions $\alpha_{0d}(t)$ and $\alpha_{0c}(t)$, e.g. Andersen et al. [1]. This generates two random variables:

$$X = \inf[t : W(t) = d]$$

and

$$U = \inf[t : W(t) = c],$$

which are incompletely observed since the observations consist of the transition time $\widetilde{X} = X \wedge U$ and the state $W(\widetilde{X}) = d$ or c reached at that time. The elusive concept of "independent competing risks" (e.g. [13, Section 7.2]) now states that in a population where the risk c is not operating, the hazard function for d is still given by $\alpha_{0d}(t)$. This condition is seen to be equivalent to censoring by U being independent. However, since the population where a given cause of failure is eliminated is usually completely hypothetical in a biological context, this formal equivalence between the two concepts is of little help in a practical situation and, as is well known from the competing risks literature (e.g. [4, 15], and [13, Chapter 7]), statistical independence of the random variables X and U cannot be tested from the incomplete observations $[\widetilde{X}, W(\widetilde{X})]$. What can be said about the inference on the parameter $\theta = \alpha_{0d}(\cdot)$ based on these data is that consistent estimation of θ may be obtained by formally treating failures from cause c as right-censorings, but that this parameter has no interpretation as the d failure rate one would have had in the hypothetical situation where the cause c did not operate.

For the concept of independent censoring to make sense, the "uncensored experiment" described in the beginning of this section should, therefore, be meaningful.

Likelihoods: Noninformative Censoring

The right-censored data will usually consist of

$$(\widetilde{X}_i, D_i, \mathbf{Z}_i; i = 1, \ldots, n)$$

and, under independent censoring, the likelihood can then be written using **product-integral** notation

$$L(\theta,\phi) = P^{\theta\phi}(\mathbf{Z}) \prod_i \prod_{t>0} \alpha_i^{\theta}(t)^{D_i(\mathrm{d}t)} [1 - \alpha_i^{\theta}(t)\mathrm{d}t]^{1 - D_i(\mathrm{d}t)} \times \gamma_i^{\theta\phi}(t)^{C_i(\mathrm{d}t)} [1 - \gamma_i^{\theta\phi}(t)\,\mathrm{d}t]^{1 - C_i(\mathrm{d}t)}. \quad (6)$$

Here, $D_i(\mathrm{d}t) = I\{X_i \in I_{\mathrm{d}t}\}$, $C_i(\mathrm{d}t) = I\{U_i \in I_{\mathrm{d}t}\}$, and $\alpha_i^\theta(t)$ and $\gamma_i^{\theta\phi}(t)$ are the conditional hazards of failure and censoring, respectively, given the past up until t- (including covariates). The likelihood (6) may be written as

$$L(\theta, \phi) = L^c(\theta)L^*(\theta, \phi),$$

with $L^c(\theta)$ given by (2) and where the contributions from censoring and covariates are collected in $L^*(\theta, \phi)$. Thus, the function (2), which is usually taken as the standard censored data likelihood, is, under independent censoring, a **partial likelihood** on which a valid inference on θ may be based. It is only the full likelihood for θ if $L^*(\theta, \phi)$ does not depend on θ, which is the case if censoring (and covariates) are *noninformative*. Thus, noninformative censoring is a statistical concept (while the concept of independent censoring is *probabilistic*) and means that the conditional hazard of censoring $\gamma_i^{\theta\phi}(t)$ does, in fact, not depend on θ, the parameter of interest.

An example of an informative right-censoring scheme could be in a study with two competing causes of failure and where only one of the two cause-specific failure rates is of interest; if the two cause-specific failure rates are *proportional* (as in the so-called Koziol–Green model for random censoring, [14]), then the failures from the second cause (the censorings) will carry information on the shape of the hazard function for the failure type of interest. It is, however, important to notice that even if the censoring is informative, then inference based on (2) will still be valid (though not fully efficient) and as it is usually preferable to make as few assumptions as possible about the distribution of the right-censoring times, the (partial) likelihood (2) is often the proper function to use for inference.

Other Kinds of Incomplete Observation

When observation of a survival time, X, is right-censored, then the value of X is only known to belong to an interval of the form $[U, +\infty)$. This is by far the most important kind of censoring for survival data, but not the only one. Thus, the observation of X is **interval-censored** if the value of X is only known to belong to an interval $[U, V)$ and it is said to be *left-censored* if $U = 0$.

It was seen above that under independent right-censoring a right-censored observation, U_i, contributed to the partial likelihood function with a factor $S^\theta(U_i)$, which was also the contribution to the *full* likelihood under noninformative censoring. Similarly, concepts of independent and noninformative interval-censoring may be defined as leading to a contribution of $S^\theta(U_i) - S^\theta(V_i)$ to, respectively, the partial and the full likelihood. These concepts have received relatively little attention in the literature; however, this way of viewing censoring is closely related to the concept of **coarsening at random**.

Formally, **grouped data**, where for each individual the lifetime is known only to belong to one of a fixed set of intervals $[u_{k-1}, u_k)$ with $0 = u_0 < u_1 < \cdots < u_m = +\infty$, are also interval-censored. However, the fact that the intervals are the same for everyone simplifies the likelihood to a binomial-type likelihood with parameters $p_k^\theta = S^\theta(u_{k-1}) - S^\theta(u_k)$, $k = 1, \ldots, m$.

Let us finally remark that while, following Hald [9; 10, p. 144], *censoring* occurs when we are able to sample a complete population but individual values of observations above (or below) a given value are not specified, truncation corresponds to sampling from an incomplete population, i.e. from a conditional distribution (*see* **Truncated Survival Times**). Left-truncated samples, where an individual is included only if his or her lifetime exceeds some given lower limit, also occur frequently in the analysis of survival data, especially in epidemiologic studies where hazard rates are often modeled as a function of age and where individuals are followed only from age at diagnosis of a given disease or from age at employment in a given factory.

Censuses

According to a United Nations Population and Housing Census manual, "The fundamental purpose of the population census is to provide the facts essential to governmental policy-making, planning and administration" [3]. The manual goes on to state that "Population census results are also used in policy development and in management of national evaluation for programmes in such fields as ... maternal and child health, ... and welfare." Thus, the content of population censuses is designed primarily to serve official administrative functions of government, such as taxation, political representation, conscription, and revenue and resource allocation. While censuses may also provide invaluable information for planning and evaluation of social, health, and welfare programs, and description and monitoring of population composition and trends, crucial both to practical problem solving and for pure research, these applications are of secondary priority in determining census content.

To meet its basic objectives, national population censuses contain a "minimum data set" of demographic variables, which invariably includes age, sex, marital status, and geographic residence. While specific content varies widely from country to country, most national population censuses also include data on socioeconomic status, education, occupation, industry, economic activity, housing conditions, and, less frequently, health and/or disability status. Censuses in some countries may also include "cultural status" measures – for example, race, ethnicity, religion, language, or national origin.

The principal use of population censuses in epidemiologic research is in the construction of measures of **risk**. Risk is one of the most basic concepts in the study of epidemiology and is central to the study of the distribution, incidence, prevalence (*see* **Descriptive Epidemiology**), or transmission of disease, adverse health conditions, or outcomes. The risks of becoming ill, being injured, disabled, or of dying are typical examples. Formally, risk is defined as the probability that an event will occur within a specified period of time, as measured either by the calendar or by biological age [2]. Mathematically, risk is calculated as the number of events, or outcomes, occurring in the specified time period divided by the number of persons at risk at the *beginning* of that period. A widely used proxy measure of risk relates the same events to the number of **person-years at risk** among the risk group during the specified time interval. A typical example is the age-specific mortality rate, defined as the ratio of deaths to a specified age group in a specified time period, to the midyear population of that age. In turn, a midyear population of the time interval in question has been shown to be a rather accurate estimate of the person-years lived in the interval (*see* **Vital Statistics, Overview**). Various models have been developed by statisticians and demographers to link directly the true probability rate (risk) to the mortality rate. The approach is also applied to other health outcomes or status changes.

Not all members of a population are equally exposed to or are susceptible to disease, accident, death, or other changes in health status. To understand the epidemiology of adverse health conditions, or outcomes, or to design effective and efficient public health intervention programs, it is useful to identify and focus on those subsets of the population at elevated risk. For example, to study **maternal mortality**, the risk group (denominator) would not be the population at large, but would be narrowed to *females of child-bearing age*. Similarly, the study of prostate cancer mortality or morbidity would use *males at middle and old age*, perhaps separated into five-year age groups as the denominator in calculating risk. Studies of morbidity and mortality risk due to natural disasters – earthquakes, hurricanes, etc. – would limit the risk group to geographic localities in which such events are most likely to occur.

Data for risk numerators, i.e. the events, health outcomes, or health status changes, may be obtained from vital statistics (birth and death records), from special **disease registers** (cancer and congenital malformation registries), **surveillance** reports (notifications of "reportable diseases"), or from special surveys (national health surveys) (*see* **Surveys, Health and Morbidity**). In epidemiologic studies of national populations (as opposed to clinical studies), population censuses are most often the source of data for risk denominators.

As valuable as these variables from population censuses may be in differentiating risk categories in the population, decennial censuses by themselves are of limited value due to the relatively long intercensal periods. That is, any one census provides risk denominator data only every 10 years (or five years, as the case may be). Typically, censuses are

conducted every 10 years in years ending in "0", although nations of the British Commonwealth and some former colonies conduct their censuses in years ending in "1". Also, a small number of countries conduct their censuses every five years. Four methods have been developed to provide data between two adjacent censuses (already completed) or from the last census and until the next census results become available.

The first approach, to provide information between two completed censuses, involves some form of interpolation. In its simplest form the size of various population aggregates in intercensal years are assumed to change linearly between censuses, and annual estimates are calculated accordingly. More sophisticated patterns of change (logarithmic, for example) may be used in lieu of the linear assumption. However sophisticated the assumption of the pattern of intercensal change in the population risk groups, a serious limitation of this approach is that it cannot replicate irregular patterns, such as those occasioned by abrupt changes in natality or mortality patterns, in migration, or results of some sudden economic changes. Another limitation of interpolation methods is that estimates of the subpopulations generally do not add up to the totals in the overall population.

A second approach utilizing vital statistics, which are events recorded on an ongoing basis, may be used to refine intercensal interpolations and postcensal extrapolations, at least as far as irregular patterns of natality, mortality, or marriage and divorce are concerned. While vital statistics are useful in refining the denominator information, they cannot account for irregular population shifts due to changing migration patterns, or to social and economic conditions affecting the characteristics of the population.

Because of these limitations in the interpolation and extrapolation methods, some countries have instituted annual "mini" censuses – annual probability sample surveys of the total population. These surveys typically include basic demographic variables and a limited collection of socioeconomic variables. The "Current Population Survey" in the US is one such example [4].

An alternative to the intercensal sample population surveys is to use information from national population registers, such as those in use in Scandinavia, Japan, and elsewhere. These registers are, in fact, dynamic censuses in which changes in vitality, marital status, residence, and socioeconomic condition are recorded as they occur to each individual in the population. In practice, however, there are relatively few such systems of sufficient quality to warrant widespread use for epidemiologic research.

Population censuses provide an extremely important source of information identifying risk groups in a general population. While they may contain limited, or even no, specific health information, the basic demographic variables they do contain can be used very effectively to differentiate levels of risk. Age, sex, marital status, socioeconomic level, and place of residence are obvious examples generally strongly associated with risk levels. Census population data cross-classified by these variables provide direct estimates of the risk denominators, either the person-years lived or the bases for reconstructing the population initially at risk.

Other applications of censuses for epidemiologic research include censuses of housing and the preparation of special linkage studies. In many countries, a census of housing is conducted in conjunction with the census of population. This provides the opportunity to use housing, residential neighborhood, and related information to focus more precisely on populations at elevated health risks due to their living conditions and/or locations. The other approach is to link vital events, or other health-related events obtained from registers or special surveys, directly to individuals or households enumerated in the population census. While this approach may provide a particularly rich source of data for detailed epidemiologic study, it is expensive to carry out, technically difficult to accomplish in a rigorous and accurate manner, and may conflict with laws concerning privacy and **confidentiality** of personal information. Perhaps the classic example of this technique is the British linkage study utilizing the 1961 census [1] (*see* **Record Linkage**).

Thus, the population census is an invaluable tool for epidemiologists and biostatisticians. In spite of limitations in the coverage of variables, periodicity, and other problems cited above, census data are almost universally available and are easily adapted to identify a large number of highly differentiated population subgroups at elevated exposure and susceptibility to disease, injury, or death.

Centers for Disease Control and Prevention (CDC)

The Centers for Disease Control and Prevention (CDC) celebrated its 50th anniversary on July 1, 1996. The CDC evolved from a small mosquito-eradication effort in World War II to being the USA's primary agency in the promotion of health and the prevention of disease. This agency, the Malaria Control in War Areas (MCWA), was established in 1942 and was a national effort to keep military bases and essential war industry-related establishments in the southern US free from malaria. In 1946, MCWA became the Communicable Disease Center and was the agency of the US Public Health Service that directed efforts to prevent diseases such as malaria, polio, smallpox, toxic shock syndrome, Legionnaires' disease, and more recently, **AIDS**, Ebola virus, Hantavirus, monkeypox, and SARS. In the early days most efforts focused on prevention and control of unnecessary morbidity and mortality from infectious diseases of public health importance. Over the years these responsibilities have expanded to include contemporary threats to health, such as lead-paint poisoning, environmental and occupational hazards (e.g. pesticides, chemical warfare agents or hazards in the workplace), (*see* **Environmental Epidemiology**; **Occupational Epidemiology**); behavioral risks (smoking); the prevention of chronic diseases and injuries; and the promotion of healthy behavior, prenatal care, immunizations, and upgrading state and local public health agencies' readiness to infectious disease outbreaks and bioterrorism threats [41, 43]. As it expanded its responsibilities it has also changed its name. In 1967 it became the National Communicable Disease Center; in 1970, the Center for Disease Control; in 1980, the Centers of Disease Control; and in 1993, the Centers for Disease Control and Prevention. In 2003, CDC's sister agency, The Agency for Toxic Substances and Disease Registry (ATSDR) and CDC's National Center for Environmental Health merged and CDC's environmental health activities include ATSDR [41].

Today the CDC's mission is to promote health and **quality of life** by preventing and controlling disease, injury, and disability [40, 41, 43]. To accomplish this mission the CDC works with others throughout the US and world to monitor health; detect and investigate health problems; conduct research to enhance disease prevention; develop and advocate sound public health policies; implement prevention strategies; promote healthy behaviors; foster safe and healthy environments; and provide leadership and training. The CDC works in partnership with other agencies within the Department of Health and Human Services and other agencies in the US government, with state and local health departments, academic institutions, professional, voluntary, and community organizations, philanthropic foundations, school systems, churches, and other local institutions, industry, and labor [8, 40, 41]. In 2003, it had an annual budget of seven billion dollars and 9400 employees in 170 occupations and more that 5000 contractors in many locations, including field stations, states, and countries [41]. While the line between the responsibilities of the CDC and the **National Institutes of Health** (NIH) is not clearly defined, it was initially agreed that the NIH would focus more on basic research and the CDC would help the states recognize and control communicable diseases.

Statisticians have played an important role at the CDC. In the 1950s there were two groups of statisticians at the CDC, one in the Epidemiology Branch and the other in the Venereal Disease Branch. Later, in 1960, a third group in the Tuberculosis Branch located in Washington, D.C, moved to Atlanta [30]. Robert Serfling and Ida Sherman developed and used morbidity and mortality systems to monitor disease trends and to estimate excess mortality in influenza epidemics [30, 38]. These systems, and many other surveillance systems, have been developed and are being used to monitor diseases, behavioral risk factors, and traumatic occupational fatalities (*see* **Surveillance of Diseases**). Serfling and others modified and used **quota sampling** methods to study the distributions of polio cases [36, 37]. These studies showed that the highest proportion of paralytic cases were concentrated among young children living in depressed conditions. In some cities the central sections of cities with large, overcrowded black populations had the most cases. In some cases the populations were mostly white but the paralytic cases were concentrated among very poor young children. Based on these results of the surveys it was clear that the low levels of vaccination were a problem, providing the necessary justification and stimulus to pursue a much needed and vigorous vaccination program.

In the area of Venereal Diseases, Lida Usilton established a mechanical system for surveillance of venereal disease cases, their treatment progress, and follow-up and treatment of contacts [41]. **Life table** methodology was used to evaluate rapid antisyphilitic therapy and work was done to evaluate the effectiveness of syphilis contact investigations [19]. By the 1970s, mathematical modeling (*see* **Model, Choice of**), vaccine (*see* **Vaccine Studies**) and other **clinical trials**, **program evaluations**, cost–effectiveness and cost–benefit analyses (*see* **Health Economics**) and **time series** models were carried out in the Divisions of Sexually Transmitted Diseases and Tuberculosis [15, 22, 27, 29, 31–33]. Evaluations were done to compare the effectiveness of different gonorrhea control strategies. In the area of hospital-acquired infections, statisticians played a major role. The Study on the Efficacy of Nosocomial Infection Control (SENIC), a nationwide study of the effectiveness of programs to control hospital-acquired infections, was a large and sophisticated medical survey [14–17, 27, 28, 44]. Agent Orange and injury control were other areas where statisticians have worked to identify high-risk groups [3–7, 9, 23, 25]. Statisticians have played a major role in AIDS and sexually transmitted diseases (STDs) research [12, 13, 18, 20, 23, 24, 34]. In surveillance of diseases and in trend analysis, statisticians have made continuing contributions [2, 21, 26, 35, 39, 45]. In the Agency for Toxic Substances and Disease Registry, a National Exposure Registry (a listing of persons with documented environmental exposures) has been established [1, 10, 11] (*see* **Disease Registers**). The rate of reporting of adverse health outcomes in this registry is compared with national norms to assess impact of exposure.

The CDC now has statistics branches (or statisticians) in most areas of disease control and prevention working in the areas of environmental exposure and health, occupational safety and health, cancer, heart disease, sexually transmitted diseases, AIDS, tuberculosis, diabetes, hospital infections, birth defects, reproductive health, infectious diseases, bacterial and mycotic diseases, hospital infections, environmental exposures and hazards, immunizations, injury, genetics, prevention research, and so on. The statistical techniques used to analyze such data are varied, for example, **multivariate analysis**, **sequential analysis**, **categorical data analysis**, **stochastic processes**, **survival analysis**, time series analysis, **generalized linear models**, **decision analysis**, sample surveys, and estimation of **sensitivity** and **specificity** of **screening** and **diagnostic tests**.

Perhaps the biggest stimulus to increased use of data in monitoring morbidity, mortality, risk factors, costs of health care, quality of life, and other statistical information to guide policies to improve the health of the American people was when the **National Center for Health Statistics (NCHS)** became a part of the CDC in 1987. The NCHS is the principal health statistics agency of the US.

The CDC has developed and recommended many prevention and intervention strategies. Evaluation of the efficacy of these public health programs is essential before implementing prevention or intervention strategies on a broad basis. It is almost always more difficult to assess the long-term health effects of environmental and occupational hazards, or to determine the long-term effects of smoking (*see* **Smoking and Health**), lack of exercise, stress, or workplace hazards (often requiring years of study), than to design and implement programs testing drug or vaccine effectiveness. The demonstration of the efficacy of these prevention or intervention strategies is complex and often confounded by many uncontrollable, external factors, but this demonstration is essential before implementing them on a broad basis.

There are usually two levels of evaluation which require different study designs and analyses. The first level addresses control or prevention of disease in individuals, while the second concerns prevention or control in the general population. At the first level we may need a **clinical trial** to determine the efficacy of a drug, vaccine, or other intervention at the individual level. The second level is to show that we can control or prevent disease, alcohol and other drug misuse, or other risk behavior in a community.

This second stage of evaluation is both more complex and costly. It requires:

1. attention to sampling methodology and the possible **biases** introduced by the method of sampling, e.g. **telephone sampling**;
2. attention to the evaluation of diagnostic procedures and tests, i.e. that the tests are both sensitive and specific and that the evaluations are properly evaluated in different subgroups of the population;
3. that the intervention does not affect the surveillance system artifactually;

4. assurance that the surveillance system is impartial and **unbiased** in reaching different subgroups of the population;
5. knowledge of those intervention or prevention strategies appropriate for different subgroups at risk;
6. surveillance measures culturally appropriate to the subgroups of the population at risk;
7. that the community that receives the intervention must trust those who deliver the intervention; and
8. that the community must be involved in all phases of the intervention/prevention effort.

These phases include needs assessments of the community, setting objectives, developing, planning and implementing the intervention, including deciding what and how questions are asked (*see* **Questionnaire Design**) collecting and managing data (*see* **Data Management and Coordination**), and analysis and interpretation of results.

Thus, the different areas of disease control and prevention have provided statisticians with many opportunities for innovative statistical application and development to many different public health programs at CDC. For more information about CDC, visit the Web site [43].

GLADYS H. REYNOLDS

Central Limit Theory

Central limit theory asserts that the sum of a large number of none too large independent **random variables** is approximately normally distributed (*see* **Large-sample Theory**). Results such as these are important to statistical theory, because they provide general conditions under which the distribution of a **mean** is well approximated by the **normal distribution**. Central limit theory allows us to use the normal distribution in creating **confidence intervals, hypothesis testing**, and in many other statistical procedures.

The most basic central limit theorem (CLT) is for sums of independent, identically distributed (iid) random variables. See [2] and [5] for a general introduction to central limit theory.

IID CLT

Suppose $X_1, \ldots, X_n$ are iid random variables with finite mean μ and finite, nonzero variance σ^2. Then for $S_n = X_1 + \cdots + X_n$, the rescaled and centered sum,

$$\frac{S_n - n\mu}{n^{1/2}\sigma}, \tag{1}$$

converges in distribution to the normal law as n increases. That is, for all t,

$$\Pr\left[\frac{S_n - n\mu}{n^{1/2}\sigma} \leq t\right] \to \Phi(t), \tag{2}$$

where Φ is the cumulative distribution function for the standard normal.

There are many statistical applications that build on this CLT, but which are not themselves sums of iid random variables. These include **rank** statistics, ***U*-statistics**, and M-estimators (*see* **Robustness**). We present three examples here.

The Sample Median

Suppose $X_1, \ldots, X_n$ form an independent sample from a distribution with median 0 and positive density γ at 0. The sample **median**, M_n, is approximately normally distributed for large n. That is, the series $n^{1/2}2\gamma M_n$ converges in distribution to the standard normal. The sample median does not appear to be a sum of random variables, but notice that, for odd n,

$$\Pr(n^{1/2}M_n \leq t) = \Pr[\text{at least } (n+1)/2 \text{ observations are } \leq t/n^{1/2}], \tag{3}$$

and the problem reduces to one involving convergence in distribution of a sequence of **binomials**, which are sums of iid random variables.

The Sample Variance

In this example, let $X_1, \ldots, X_n$ be iid with mean μ, finite variance σ^2 and finite fourth central **moment** μ_4. The sample variance,

$$s_n^2 = (n-1)^{-1}\sum (X_i - \overline{X})^2, \tag{4}$$

is a U-statistic with kernel of degree 2. This can be more easily seen by rewriting s_n^2 as follows:

$$\frac{1}{n(n-1)} \sum_{1 \leq i \neq j \leq n} \tfrac{1}{2}(X_i - X_j)^2. \tag{5}$$

Using the Hoeffding decomposition, s_n^2 can be written as $n^{-1}\sum (X_i - \mu)^2$ plus negligible terms, and it can be shown that $n^{1/2}(s_n^2 - \sigma^2)$ is normally distributed, in the limit, with mean 0 and variance $\mu_4 - \sigma^4$.

Maximum Likelihood Estimator

Again we take $X_1, \ldots, X_n$ to be iid. Now we assume that the distribution of the Xs has density $f(x, \boldsymbol{\theta}_0)$, where $f(x, \boldsymbol{\theta}_0)$ belongs to a k-parameter **exponential family**, i.e. for $\boldsymbol{\theta} \in \boldsymbol{\Theta} \subset R^k$,

$$f(x, \boldsymbol{\theta}) = \exp[\boldsymbol{\theta}'\mathbf{T}(x) - B(\boldsymbol{\theta})]. \tag{6}$$

The **maximum likelihood** estimator $\hat{\boldsymbol{\theta}}_n$ of $\boldsymbol{\theta}_0$ is that $\boldsymbol{\theta}$ which maximizes the log **likelihood**,

$$\frac{1}{n}\sum \boldsymbol{\theta}'\mathbf{T}(X_i) - B(\boldsymbol{\theta}). \tag{7}$$

A multivariate CLT for the iid sum of the $\mathbf{T}(X_i)$ leads us to a central limit theorem for $\hat{\boldsymbol{\theta}}_n$. Under suitable conditions [4], $n^{1/2}(\hat{\boldsymbol{\theta}}_n - \boldsymbol{\theta}_0)$ converges in distribution to a **multivariate normal** with variance–**covariance matrix** $\{\text{var}[\mathbf{T}(X)]\}^{-1}$.

Multivariate central limit theory for sums of iid random vectors follows from the CLT for iid random variables. Convergence in distribution of a sequence

of random variables is equivalent to pointwise convergence of the corresponding **characteristic functions**, providing the limit is continuous at the origin [2]. Characteristic functions are especially useful in establishing CLTs for sums of independent random variables because of their multiplicative properties. From this approach, we can show that convergence in the distribution of random vectors is equivalent to convergence in the distribution of all linear functions of the random vectors.

Multivariate CLT

If $\mathbf{X}_1, \ldots, \mathbf{X}_n$ are iid random vectors in $\mathbf{R}^k$ with mean $\mathbf{0}$ and variance–covariance matrix $\mathbf{V}$, then $n^{-1/2}/\mathbf{S}_n$ converges in distribution to the multivariate normal with mean $\mathbf{0}$ and variance–covariance matrix $\mathbf{V}$.

History

A. De Moivre proved the first central limit theorem in 1733 [10]. It covers the classic example of counting the number of successes in a large number of independent Bernoulli trials (*see* **Binary Data**), each with probability p. Basically it says that, as the number of trials increases, the distribution of the number of successes, when properly standardized, approximately follows the normal distribution. **P.S. Laplace** established similar results in 1812 [18]. More formally, the De Moivre–Laplace central limit theorem is for a sequence of n independent Bernoulli trials that are 1 with probability p and 0 with probability $q = 1 - p$. The sum of the trials, S_n, follows the binomial distribution with parameters n and p. As n grows, the distribution of the sum approaches the normal distribution. By this we mean that, for large n, the chance that S_n is at most k is well approximated by the normal probability,

$$\Phi[(npq)^{-1/2}(k + \tfrac{1}{2} - np)]. \tag{8}$$

De Moivre–Laplace CLT

For β_n and α_n such that $(\beta_n - np)^3/n^2 \to 0$ and $(\alpha_n - np)^3/n^2 \to 0$, as $n \to \infty$,

$$\Pr(\alpha_n \le S_n \le \beta_n) \sim \Phi[(npq)^{-1/2}(\beta_n + \tfrac{1}{2} - np)] - \Phi[(npq)^{-1/2}(\alpha_n + \tfrac{1}{2} - np)], \tag{9}$$

where $\sim$ denotes asymptotic equivalence.

See [7] for a proof of this central limit theorem.

In the second half of the nineteenth century, P.L. Chebyshev developed limit theorems for sums of arbitrarily distributed random variables. His results are based on the **method of moments**. Liapounoff, in 1900 and 1901, derived more general central limit theorems using characteristic functions. The most classical central limit theorem is due to J.W. Lindeberg in 1922. Lindeberg's result holds for independent random variables that are not necessarily identically distributed. We consider the triangular array of random variables, where for each n, $X_{n1}, \ldots, X_{nk(n)}$ is a sequence of $k(n)$ independent random variables with mean 0 and variances $\sigma_{n1}^2, \ldots, \sigma_{nk(n)}^2$. If we let

$$b_n^2 = \sum_{j=1}^{k(n)} \sigma_{nj}^2, \tag{10}$$

then the Lindeberg condition is

$$\frac{1}{b_n^2} \sum_{j=1}^{k(n)} \mathrm{E} X_{nj}^2 \mathrm{I}(|X_{nj}| \ge \varepsilon b_n) \to 0, \quad \text{for every } \varepsilon > 0, \tag{11}$$

where $\mathrm{I}(\cdot)$ denotes an indicator function (*see* **Dummy Variables**).

Provided the Lindeberg condition is met, S_n/b_n converges in distribution to the normal law. The Lindeberg condition is almost both necessary and sufficient. Feller showed in 1935 that if each of the random variables in the sum is small, then the Lindeberg condition is both necessary and sufficient. This result is called the Lindeberg–Feller central limit theorem.

Lindeberg–Feller CLT

The rescaled sum S_n/b_n converges in distribution to the normal law and $\max_j \sigma_{nj}/b_n \to 0$ if and only if the Lindeberg condition holds.

Notice that the iid central limit theorem is a special case of the Lindeberg–Feller result. There, $k(n) = n$, $X_{nj} = (X_j - \mu)/n^{1/2}\sigma$, $b_n = 1$, and the Lindeberg condition holds by dominated convergence.

There are many generalizations of the Lindeberg–Feller result. They include bounds on the rates of convergence, convergence in the distribution of random functions, and convergence of sums of dependent random variables. In addition, limit laws can be

obtained for sums of random variables with infinite variance, and limit laws other than the normal have been studied. We briefly discuss these generalizations here.

Rates of Convergence

One well-known result on the rate of convergence to normality in the CLT was arrived at independently by Berry & Esseen.

Berry–Esseen

Suppose $X_1, \ldots, X_n$ are iid random variables with mean 0, variance σ^2, and $\mathrm{E}|X_i|^3 = \rho < \infty$. Let $S_n = X_1 + \cdots + X_n$. Then, for all n and t,

$$|\Pr(S_n < tn^{1/2}\sigma) - \Phi(t)| \leq \frac{3\rho\sigma^{-3}}{\sqrt{n}}. \qquad (12)$$

For other rate results see Petrov [15].

Functional CLT

One of the simplest examples of a random function arises from an iid sample $X_1, \ldots, X_n$ from the **uniform distribution** on (0,1). The standardized empirical cumulative distribution function,

$$U_n(t) = n^{-1/2} \sum [\mathrm{I}(X_i \leq t) - t], \quad \text{for } 0 \leq t \leq 1, \qquad (13)$$

is a random function in the space $D[0, 1]$ of all real-valued functions that are right continuous at each point of [0,1) with left limits existing at each point of (0,1].

For each fixed t, $U_n(t)$ converges in distribution to the normal law with mean 0 and variance $t(1-t)$. The multivariate CLT says that, for each k-vector $(t_1, \ldots, t_k)'$, the random vector $[U_n(t_1), \ldots, U_n(t_k)]'$ converges in distribution to a multivariate normal with $\mathrm{cov}[U_n(t_i), U_n(t_j)] = \min(t_i, t_j) - t_i t_j$. A functional CLT says that U_n converges in distribution to the **Brownian** Bridge. Of particular interest is the limiting distribution of functionals of U_n such as the **Kolmogorov–Smirnov** statistic $\sup_t |U_n(t)|$ and the Cramér–Von Mises statistic $\int_0^1 U_n(t)^2 \mathrm{dt}$ (*see* **Kolmogorov–Smirnov and Cramer–Von Mises Tests in Survival Analysis**). See [1] for functional CLTs for these and related **stochastic processes**. See [8], [12], and [16] for functional CLTs for empirical processes on spaces of functions.

Dependence

There are many CLTs for sums of random variables that are not independent. One example is the CLT for martingale difference arrays [11].

Martingale CLT

Suppose $X_{n1}, \ldots, X_{nn}$ form a martingale difference array with respect to the sigma-fields $\mathcal{F}_{n0}, \mathcal{F}_{n1}, \ldots, \mathcal{F}_{nn}$. Then, provided

$$\sum_{j=1}^{n} \mathrm{E}(X_{nj}^2 | \mathcal{F}_{n,j-1}) \to \sigma^2 \qquad (14)$$

in probability, with σ^2 a positive constant, and

$$\sum_{j=1}^{n} \mathrm{E}[X_{nj} \mathrm{I}(|X_{nj}| > \varepsilon) | \mathcal{F}_{n,j-1}] \to 0 \qquad (15)$$

in probability for every ε, then the sum $\sigma^{-1} S_n$ converges in distribution to the standard normal law.

Other CLTs for martingales can be found in [14] and [17]. CLTs for sums of dependent random variables where the dependence satisfies a mixing condition can be found in [6].

More General CLTs

Central limit theorems can hold under very general conditions. The random variables need not have finite variance. For example, take $X_1, \ldots, X_n$ to be iid from a symmetric distribution where $\Pr(|X_1| > x) = x^{-2}$, for $x \geq 1$. Then, despite the fact that the X_is have infinite variance, $(n \log n)^{-1/2} S_n$ converges in distribution to the standard normal. This is established by a truncation argument, where new random variables Y_{nj} are created such that $Y_{nj} = X_j$ provided $|X_{nj}| \leq \sqrt{n}$ log log n, and $Y_{nj} = 0$ otherwise. These truncated variables have finite variances that are roughly of size log n, and their sum differs very little from the sum of the original random variables.

This result for random variables with infinite variance leads to the question of what conditions are

needed for a sum of iid random variables to have a normal limit (*see* **Limit Theorems**).

IID CLT

Suppose $X_1, \ldots, X_n$ are iid random variables. In order that there exist constants a_n and $b_n > 0$ such that $(S_n - a_n)/b_n$ converges in distribution to the normal law, it is necessary and sufficient that, as $x \to \infty$,

$$\frac{x^2 \Pr(|X_1| > x)}{\mathrm{E}\left[|X_1|^2 \mathrm{I}(|X_1| \le x)\right]} \to 0. \tag{16}$$

Sums of independent random variables can have limit laws other than the normal. For example, the sum of iid **Cauchy** random variables, when properly normalized, has a limiting Cauchy distribution. The set of possible limit laws for sums of iid random variables are the stable laws. See [3] and [9] for these and other results.

Sums based on triangular arrays of random variables can also have limit laws other than the normal. (The iid sequence is a special case of the triangular array, as noted above.) For example, suppose the X_{nj} are independent Bernoulli random variables with probability p_{nj}, $j = 1, \ldots, n$. If $p_{n1} + \cdots + p_{nn} \to \lambda$ and $\max p_{nj} \to 0$, then S_n converges in distribution to a Poisson law with parameter λ.

In general, we consider the triangular array of independent random variables $X_{n1}, \ldots, X_{nk(n)}$ for $k(n) \to \infty$. The summands are said to be uniformly asymptotically negligible (uan) if the X_{nj} converge uniformly to 0 in probability. For uan independent summands, the family of limit laws of the sequence $\sum X_{nj}$ coincides with the family of infinitely divisible distributions, which includes the stable laws. Examples of infinitely divisible distributions are the normal, Poisson, **gamma**, and **geometric**. See [2] and [13] for a more detailed treatment of this material.

DEBORAH NOLAN

Centroid Method

The centroid method is a factoring procedure in **factor analysis**. Before the advent of high-speed computers, this was a very popular factoring method. The initial work on the centroid method was presented by Burt [1] in 1917 and it was fully developed by Thurstone [3] in 1931. The centroid method relies on the idea that if the original variables are represented as a set of vectors, then the common factor can be interpreted as a vector which passes through the centroid of the terminal points for this set of vectors.

To compute the m centroid factors for a set of p variables ($m < p$), we first calculate the **correlation** matrix for the p variables. We denote this $p \times p$ matrix as $\mathbf{R}$ and the element at the ith row and jth column of $\mathbf{R}$ as r_{ij}. Next we sum the columns of the correlation matrix, including the diagonal element or **communality** estimate. If there are negative column sums, then we should reflect the negative sums by changing their signs. We then add all the column sums to yield a grand total. The first centroid **factor loadings** are now obtained by dividing each column sum by the square root of the grand total. In symbols, the first centroid factor loading $\mathbf{a} = (\mathrm{a}_1, \mathrm{a}_2, \ldots, \mathrm{a}_p) = (\sum r_{i_1} / \sum\sum r_{ij}, \sum r_{i2} / \sum\sum r_{ij}, \ldots, \sum r_{ip} / \sum\sum r_{ij})$. These factor loadings are not final until we undo the earlier reflections that are applied to some of the negative column sums. There are two ways we can undo the change. One is to reverse the names of the variables that had the signs of their sums changed earlier and keep the loadings as they are. The alternative is to reflect the loadings of these variables and retain the original names of the variables. For the first factor loadings, we usually take the approach of reversing the names of the variables, because keeping all the loadings of this first factor positive will facilitate the rotation step that follows and also will simplify the subsequent interpretation of the rotated factor.

To determine the loadings on the second factor, we form the first residual correlation matrix. The elements of this residual matrix are denoted by $\{r_{ij \cdot a}\}$ which are equal to $r_{ij} - a_i a_j$. To obtain the second factor, **b**, we factor this residual matrix using the same computational procedure as was applied to the original correlation matrix, $\mathbf{R}$. To compute the third factor, **c**, we apply the same factoring procedure on the second residual matrix obtained from subtracting the second factor from the first residual correlation matrix. We obtain the elements of this second residual matrix $\{r_{ij \cdot b}\}$ as $r_{ij \cdot a} - b_i b_j$. Successive application of this procedure to the corresponding residual correlation matrix will give the complete centroid factor matrix.

The centroid method was originally derived as a mathematical approximation to the more difficult principal-axes procedure when computers were not generally available. Even though the centroid solution yields the same complexity of variables and factors, and also has the same variance contributions of the factors as the principal-axes procedure, it does not share the other important mathematical properties of the principal-axes solution, which include uniqueness and orthogonality. A treatment of the centroid method in factor analysis is given in Cureton & D'Agostino [2, Chapter 2].

Chain Binomial Model

Let time be discrete and indexed $t = 0, 1, \ldots$. Let S_t be the number of individuals at risk for the event of interest (e.g. infection or death) at the beginning of time interval t, and let I_t be the number that experienced the event of interest at the beginning of time interval t. The event has a duration of at least one time interval. We let $p_t = 1 - q_t = f(t, \boldsymbol{\theta}, I_t)$ be the probability that an at-risk individual has a new event at the beginning of time interval time $t + 1$, with parameter $\boldsymbol{\theta}$. As shown, this probability can be a function, $f(\cdot)$, of t and I_t. We usually start with a closed population of $n = S_0 + I_0$ individuals. Then I_{t+1} is a **binomial** random variable that follows the conditional probability mass function

$$\begin{aligned}&\Pr(I_{t+1} = i_{t+1} | S_t = s_t, p_t)\\ &\quad = \binom{s_t}{i_{t+1}} p_t^{i_{t+1}} q_t^{s_t - i_{t+1}}, \quad s_t \geq i_{t+1}. \end{aligned} \tag{1}$$

In many cases, S_t is updated via the relationship

$$S_{t+1} = S_t - I_{t+1}, \tag{2}$$

although other relationships are possible (see below). The conditional expectation and variance of I_{t+1}, respectively, are

$$\mathrm{E}(I_{t+1} | s_t, p_t) = s_t p_t, \tag{3}$$

$$\mathrm{var}(I_{t+1} | s_t, p_t) = s_t p_t q_t. \tag{4}$$

Eqs (1) and (2) form the classical chain binomial model. Formal mathematical treatment of the model involves formulation of the discrete, two-dimensional **Markov chain** $\{S_t, I_t\}_{t=0,1,\ldots}$. I_t is the (binomial) random variable of interest, and S_t is updated using (2). The probability of a particular chain, $\{i_0, i_1, i_2, \ldots, i_r\}$, is given by the product of conditional binomial probabilities from (1) as

$$\begin{aligned}&\Pr(I_1 = i_1 | S_0 = s_0, p_0) \Pr(I_2 = i_2 | S_1 = s_1, p_1)\\ &\quad \times \cdots \Pr(I_r = i_r | S_{r-1} = s_{r-1}, p_{r-1})\\ &\quad = \prod_{t=0}^{r-1} \binom{s_t}{i_{t+1}} p_t^{i_{t+1}} q_t^{s_t - i_{t+1}}. \end{aligned} \tag{5}$$

The conditional expected value of I_{t+1} from (3) suggests the deterministic system of first-order difference equations

$$i_{t+1} = s_t p_t, \qquad s_{t+1} = s_t - i_{t+1}, \tag{6}$$

which can be analyzed as an approximation to the mean of the sample paths of the **stochastic process** $\{S_t, I_t\}_{t=0,1,\ldots}$. This system reduces to

$$s_t = s_{t-1} q_{t-1} = s_0 \prod_{l=0}^{t-1} q_l, \tag{7}$$

which is analyzed using methods from discrete mathematics (see, for example, [7] and [11]).

The Reed–Frost Model

History

The probabilistic form of the Reed–Frost epidemic model was introduced by the biostatistician Lowell J. Reed and the epidemiologist Wade Hampton Frost around 1930, as a teaching tool at Johns Hopkins University. It was developed as a mechanical model consisting of colored balls and wooden shoots. Although Reed and Frost never published their results, the work is described in articles and books by others (see [1, Chapters 14 and 18] and [2, Chapters 2 and 3]). An excellent description of the early Reed–Frost model is given by Fine [6]. The deterministic version of the Reed–Frost model has been traced back to the Russian epidemiologist P.D. En'ko, who used the model to analyze epidemic data in the 1880s (see [5]). The Reed–Frost version of the chain binomial and its extensions is used to study the dynamics of epidemics in small populations, such as families or day care centers, and to estimate transmission probabilities from epidemic data.

Formulation

In this case, S_t is the number of susceptible persons at the beginning of time interval t, and I_t is the number of persons who were newly infected at the beginning of time interval t. An infected person is infectious for exactly one time interval and then is removed; that is, becomes immune. Thus, a person infected at the beginning of time interval t will be infectious to others until the beginning of time interval $t + 1$. We let R_t be the number of removed persons at the beginning of time interval t, and then, by definition,

$$R_{t+1} = R_t + I_t = R_0 + \sum_{r=0}^{t} I_r. \tag{8}$$

Since the population is closed, we have $S_t + I_t + R_t = n$ for all t. We let $p = 1 - q$ be the probability that any two specified people make sufficient contact in order to transmit the infection, if one is susceptible and the other infected, during one time interval. We note that p is a form of the **secondary attack rate**. We assume **random mixing**. Then, if during time interval t there are I_t infectives, the probability that a susceptible will escape being infected over the time interval is q^{I_t}, and the probability that they will become a new case at the beginning of time interval $t + 1$ is $1 - q^{I_t}$. Thus $q_t = q^{I_t}$, and substituting into (1) yields

$$\Pr(I_{t+1} = i_{t+1} | S_t = s_t, I_t = i_t) = \binom{s_t}{i_{t+1}} (1 - q^{i_t})^{i_{t+1}} q^{i_t(s_t - i_{t+1})}, \quad s_t \geq i_{t+1}. \tag{9}$$

The epidemic process starts with $I_0 > 0$, and terminates at stopping time T, where

$$T = \inf_{t \geq 0} \{t : S_t I_t = 0\}. \tag{10}$$

The possible chains for a population of size 4 with one initial infective – that is, $S_0 = 3$, $I_0 = 1$ – are shown in Table 1.

The probability of no epidemic is defined as the probability that there will be no further cases beyond the initial cases. This probability is

$$\Pr(I_1 = 0 | S_0 = s_0, p_0) = q^{i_0 s_0}. \tag{11}$$

For example, if $S_0 = 10$, $I_0 = 1$, and $p = 0.05$, then the probability of no further cases beyond the initial case is 0.599. From (3), the conditional expected number of new cases in time interval t is $\mathrm{E}(I_{t+1} | s_t, p_t) = s_t(1 - q^{i_t})$. On the average, the epidemic process will not progress very far if the expected number of cases in the first generation is less than or equal to one; that is, $\mathrm{E}(I_1 | s_0, p_0) = s_0(1 - q^{i_0}) \leq 1$. In many cases, $i_0 = 1$, so that there will be few secondary cases if $s_0 p \leq 1$. Then, for example, if $S_0 = 10$, $I_0 = 1$, there will be few secondary cases if $p \leq 0.1$.

Table 1 Possible individual chains when $S_0 = 3$, $I_0 = 1$

Chain	Probability	Final size
$\{i_0, i_1, i_2, \ldots, i_T\}$		R_T
$\{1\}$	q^3	1
$\{1, 1\}$	$3pq^4$	2
$\{1, 1, 1\}$	$6p^2q^4$	3
$\{1, 2\}$	$3p^2q^3$	3
$\{1, 1, 1, 1\}$	$6p^3q^3$	4
$\{1, 1, 2\}$	$3p^3q^2$	4
$\{1, 2, 1\}$	$3p^3q(1 + q)$	4
$\{1, 3\}$	p^3	4

From (7), the deterministic counterpart of the Reed–Frost model is

$$s_t = s_0 q^{\sum_{l=0}^{t-1} i_l}, \tag{12}$$

which has been thoroughly analyzed (see, for example [7] and [11]).

In some cases, the distribution of the total number of cases, R_T, is the random variable of interest. We let J be the random variable for the total number of cases in addition to the initial cases, so that $R_T = J + I_0$. If we let $S_0 = k$ and $I_0 = i$, then the probability of interest is

$$\Pr(J = j | S_0 = k, I_0 = i) = m_{ijk}, \tag{13}$$

where $\sum_{j=0}^{k} m_{ijk} = 1$. Then, based on probability arguments (see, for example, [1]), we have the recursive expression

$$m_{ijk} = \binom{k}{j} m_{ijj} q^{(i+j)(k-j)}, \quad j < k, \tag{14}$$

and

$$m_{ikk} = 1 - \sum_{j=0}^{k-1} m_{ijk}. \tag{15}$$

The Reed–Frost model has several extensions and special cases. If it is hypothesized that the probability that a susceptible becomes infected does not depend on the number of infectives that he or she is exposed to, then

$$p_t = \begin{cases} p, & \text{if } I_t > 0, \\ 0, & \text{if } I_t = 0. \end{cases} \tag{16}$$

This model is known as the Greenwood model [8].

Longini & Koopman [12] modified the Reed–Frost model for the common case in which there is a constant source of infection from outside the population that does not depend on the number of infected persons in the population. We let $a_t = 1 - b_t$ be the probability that a susceptible person is infected during interval t due to contacts with infected persons outside the population, where

$$a_t > 0, \quad \text{if } t \leq T,$$

$$a_t = 0, \quad \text{if } t > T,$$

and T is a stopping time. Then $p_t = 1 - b_t q^{I_t}$. If we let $B = \prod_{t=0}^{T} b_t$, then B is the probability that a person escapes infection from sources outside of the population over the entire period $[0, T]$. We then define CPI $= 1 - B$ as the community probability of infection. Longini & Koopman derive the probability mass function

$$m_{ijk} = \binom{k}{j} m_{ijj} B^{(k-j)} q^{(i+j)(k-j)}, \quad j < k. \quad (17)$$

Usually, $i = 0$ for this model. This model reduces to (14) when $B = 1$.

Another extension of the Reed–Frost model is for infectious diseases that do not confer immunity following infection. In this case, there is no removed state, so that $S_t + I_t = n$. Then, since $S_{t+1} = n - I_{t+1}$, the model is a discrete, one-dimensional Markov chain $\{I_t\}_{t=0,1,\ldots}$. The transition probabilities for this process are

$$\begin{aligned} &\Pr(I_{t+1} = i_{t+1} | I_t = i_t) \\ &\quad = \binom{n - i_t}{i_{t+1}} (1 - q^{i_t})^{i_{t+1}} q^{i_t(n - i_t - i_{t+1})}, \\ &\quad i_t + i_{t+1} \le n. \end{aligned} \quad (18)$$

In this case, the disease in question can become "endemic". An interesting analytic question involves the study of the mean stopping time for the endemic process. From (6), the deterministic counterpart of this model is

$$i_{t+1} = (n - i_t)(1 - q^{i_t}), \quad (19)$$

which is a form of the discrete logistic function. The stochastic behavior of (18) has been analyzed by Longini [10], and the dynamics of (19) have been analyzed by Cooke et al. [4].

There are many other extensions of the Reed–Frost model depending on the particular infectious disease being analyzed, but a further key extension is to allow the infectious period to extend over several time intervals. In this case $p_t = f(t, \boldsymbol{\theta}, I_0, I_1, \ldots, I_t)$, and $\{S_t, I_t\}_{t=0,1,\ldots}$ is not a Markov chain. Special methods are used to analyze this model [14].

Inference

Data are usually in the form of observed chains, $\{i_0, i_1, \ldots, i_r\}$, for one or more populations, or final sizes, R_T, for more than one population. With respect to the former data form, suppose that we have N populations and let $\{i_{k0}, i_{k1}, \ldots, i_{kr}\}$ be the observed chain for the kth population. Then, from (5), the **likelihood** function for estimating $p = 1 - q$ is

$$L(p) = \prod_{k=1}^{N} \prod_{t=0}^{r-1} \binom{s_{kt}}{i_{kt+1}} (1 - q^{i_{kt}})^{i_{kt+1}} q^{i_{kt}(s_{kt} - i_{kt+1})}. \quad (20)$$

For final value data, let a_{ijk} be the observed frequencies of the m_{ijk}, from (17); $i = 1, \ldots, I$, $k = 1, \ldots, K$, and $j = 1, \ldots, k$. Then the likelihood function for estimating p and B is

$$L(p, B) = \prod_{i=1}^{I} \prod_{k=1}^{K} \prod_{j=0}^{k} m_{ijk}^{a_{ijk}}. \quad (21)$$

The logarithms of (20) and (21) are maximized using standard scoring routines (see, for example, Bailey [1], Becker [2], and Longini et al. [12, 13]) (*see* **Optimization and Nonlinear Equations**) or the corresponding **generalized linear model** (see Becker [2] and Haber et al. [9]). Extensions involve making both p and the CPI functions of covariates, such as age, level of susceptibility, or vaccination status (*see* **Vaccine Studies**). Bailey [1, Section 14.3] gives an example in which (20) is used to estimate $\hat{p} = 0.789 \pm 0.015$ (estimate ± 1 standard error) for the household spread of measles among children. In the case of the household spread of influenza, Longini et al. [13] use (21) to estimate $\hat{p} = 0.260 \pm 0.030$ for persons with no prior immunity and $\hat{p} = 0.021 \pm 0.026$ for persons with some prior immunity. In addition, they estimate $\widehat{CPI} = 0.164 \pm 0.015$ and $\widehat{CPI} = 0.092 \pm 0.013$ for persons with no and some prior immunity, respectively.

Life Tables

The chain binomial model forms the statistical underpinnings of the **life table** (see Chiang [3, Chapter 10]). In this case, p_t simply depends on the time interval. Then S_t is the random variable of interest, which is formulated in terms of the interval survival probabilities $q_t = 1 - p_t$. Many important life table indices are functions of q_t. For example, the probability that an individual who starts in the cohort at time zero, is still alive at the end of time interval r, denoted q_{0r}, is $q_{0r} = \prod_{t=0}^{r} q_t$. The expected

number alive at the beginning of time interval $r+1$ is $\mathrm{E}(S_{r+1}) = s_0 q_{0r}$. This model is a discrete, one-dimensional Markov chain $\{S_t\}_{t=0,1,\ldots}$. From (1) we see that the chain binomial model for S_t is simply

$$\Pr(S_{t+1} = s_{t+1} | S_t = s_t) = \binom{s_t}{s_{t+1}} q_t^{s_{t+1}} p_t^{s_t - s_{t+1}}, \quad s_t \geq s_{t+1}. \tag{22}$$

From (5), the probability of a particular chain $\{s_0, s_1, s_2, \ldots, s_r\}$ is

$$\begin{aligned} &\Pr(S_1 = s_1 | S_0 = s_0) \Pr(S_2 = s_2 | S_1 = s_1) \\ &\qquad \times \cdots \Pr(S_r = s_r | S_{r-1} = s_{r-1}) \\ &\quad = \prod_{t=0}^{r-1} \binom{s_t}{s_{t+1}} q_t^{s_{t+1}} p_t^{s_t - s_{t+1}}. \end{aligned} \tag{23}$$

For an observed chain $\{s_0, s_1, s_2, \ldots, s_r\}$, (23) is the likelihood function for estimating $\{q_0, q_1, \ldots, q_r\}$. The maximum likelihood estimators are

$$\hat{q}_t = s_{t+1}/s_t, \tag{24}$$

while the approximate variances, for large S_0, are

$$\mathrm{var}(\hat{q}_t) \approx p_t q_t / \mathrm{E}(S_t). \tag{25}$$

In addition, the $\hat{q}_t$ are unique, unbiased estimates of the q_t, and $\mathrm{cov}(\hat{q}_t, \hat{q}_l) = 0, t \neq l$. Estimators of most of the life table functions are based on the estimators $\hat{q}_t$.

IRA M. LONGINI, JR

Chalmers, Thomas Clark

Born: December 17, 1917, in Forest Hills, New York.
Died: December 27, 1995, in Hanover, New Hampshire.

Thomas C. Chalmers, M.D., a leader in the design, conduct, and evaluation of **clinical trials**, was born in Forest Hills, New York, where his father was a physician in private practice. Following a tradition set by his father and grandfather, he graduated in 1943 from Columbia University College of Physicians and Surgeons. After additional training in medical research in New York and at the Thorndike Memorial Laboratories of Boston City Hospital, he entered private practice in Cambridge, Massachusetts, in 1947. He soon became concerned over the lack of knowledge on the efficacy of accepted medical therapies. Having learned about **randomization** from **Sir Austin Bradford Hill**, he applied this principle to a study of the treatment of infectious hepatitis among American soldiers in Japan during the Korean War. This study, a 2×2 randomized factorial study of diet and bed rest (*see* **Factorial Designs in Clinical Trials**), designed in 1951, included estimates of the required number of patients and an evaluation of ineligible patients, withdrawals, and **compliance**.

Deciding to devote his career to research and education, he was Chief of Medical Services at the Lemuel Shattuck Hospital in Boston (1955–1968), Assistant Director for Research and Education for the Veterans' Administration in Washington (1968–1970), Director of the Clinical Center at the National Institutes of Health in Bethesda (1970–1973), and President and Dean of the Mount Sinai Medical Center and School of Medicine in New York City (1973–1983).

Dr Chalmers returned to Boston in 1983. Over the next 10 years he was on the faculty of the Harvard School of Public Health and Tufts University School of Medicine, was appointed a Distinguished Professor at the Boston Veterans' Administration Medical Center, and was a member and Chairman of the Board of Trustees of the Dartmouth Hitchcock Medical Center. In 1992, at age 75, he cofounded Meta-Works, Inc., a **meta-analysis** consulting company and moved to Lebanon, New Hampshire. He continued to teach in both Boston and New York and was actively involved in numerous meta-analytic studies.

Throughout his career he was a fervent advocate of randomized controlled trials in all areas of medicine and the education of students and physicians in the skills needed to evaluate these trials. His belief in the ethical need for randomization [6] (*see* **Ethics of Randomized Trials**) led to his recommendation to "begin randomization with the first patient" [1]. A corollary was the belief that developing trends should not be known by investigators during the conduct of the trial, but should be monitored by an independent policy advisory committee (*see* **Data Monitoring Committees**). In subsequent years he was a member (and frequently chairman) of Policy or Data Safety and Monitoring Boards for numerous multicenter clinical trials.

Dr Chalmers moved to Mount Sinai in 1973 because he wanted to influence the education of medical students, and to make both students and faculty aware of the need for properly conducted clinical trials. He became concerned that clinical trials were being conducted with insufficient sample sizes and in a review published in the *New England Journal of Medicine* [3] he sought to educate physicians concerning the importance of both type II errors (*see* **Hypothesis Testing**) and sample size calculations in the planning and evaluation of clinical trials (*see* **Sample Size Determination for Clinical Trials**). His method for assessing the quality of randomized controlled trials became a standard for the evaluation of published reports of clinical trials [2]. He was one of 12 founding members of the Society for Clinical Trials and established a student scholarship to encourage the involvement of students in clinical research.

Upon returning to Boston in 1983, Dr Chalmers continued to be interested in the combination of data from multiple clinical trials and introduced the readers of the *New England Journal of Medicine* to the meta-analysis of randomized controlled trials [5]. He educated numerous students in this method of analysis and continued to work with them on manuscripts up to within weeks of his death in 1995 from prostate cancer. An obituary and tributes to Chalmers have been given in a recent issue of **Controlled Clinical Trials** [4].

Change-point Problem

The general form of the change-point problem is to determine the unknown location τ, based on an ordered sequence of observations $x_1, \ldots, x_n$, such that the two groups of observations $x_1, \ldots, x_\tau$ and $x_{\tau+1}, \ldots, x_n$ follow distinct models. The index of ordering frequently refers to time, but in general it can be associated with any variable. The simplest example is a level-change model, where $x_1, \ldots, x_\tau$ are i.i.d $N(\mu_1, \sigma^2)$ and $x_{\tau+1}, \ldots, x_n$ are iid $N(\mu_2, \sigma^2)$ with $\mu_1 \neq \mu_2$. Another example is a two-phase **regression** or a linear regression switching model [6, 10], where $x_1, \ldots, x_\tau$ follow a model $\beta_{01} + \beta_{11}t$, for some predictor variable t, and $x_{\tau+1}, \ldots, x_n$ follow another model $\beta_{02} + \beta_{12}t$.

Figure 1 shows the breast cancer incidence rate in Sweden in 1990 for women between the age of 40 and 50. There is a dramatic change in slope around the age of 46, presumably because of hormonal changes that come with the onset of menopause. It is of interest to know the age when the change occurs.

The observed number of breast cancers are given in the following. Each age group is one-tenth of a year, and the age varies from 40.2 to 50, giving a total of 99 age groups.

6	1	4	6	2	2	4	3	6	5	1	3	2	5	5	4	6	5	4	5	2	5	2	6	5
9	8	7	6	7	6	3	5	10	11	4	4	4	10	6	4	7	7	7	6	10	11	8	10	8
11	3	12	8	13	9	5	7	11	10	12	8	11	11	6	11	13	7	9	12	12	7	11	10	8
10	8	8	10	10	8	7	14	6	8	11	6	5	7	14	6	8	5	9	7	10	11	8	4	

The associated number of person-years are the following. Rate is computed as the incidence divided by the person-years.

Page [16, 17] seems to be the earliest reference for this problem. Many authors, for example, [2, 5, 7, 11, 14], have considered extensions in various different directions and settings including **time series** data, multivariate observations, discrete observations, **Poisson process**, hazard or failure rate regressions (*see* **Survival Analysis, Overview**), **quality control** or surveillance problems, **sequential** applications and multiple change-point problems. The general techniques used are nonlinear **least-squares**, **maximum likelihood** [9, 19, 21], **nonparametric**/rank-based [3] and **Bayesian methods** [1]. Techniques may also be categorized as sequential or nonsequential. In sequential applications, the data x_i's are typically available one (or several) at a time and the objective is a quick detection of a change as soon as it occurs; the cumulative sum technique is the main tool in this area (*see* **Quality Control in Laboratory Medicine**). See [18] for a bibliography up to 1980 and a more recent review is given in [13].

A change-point problem may be viewed simply as a **nonlinear regression** problem, but from a theoretical point of view, the problem is rather nonstandard or nonregular. For example, even in the simplest example of a level-change model above, the likelihood function is not differentiable with respect to the parameter τ, so the standard theory does not apply. Strong simplifying assumptions are generally needed, for example, the existence of at most one change point, to derive theoretical results of the following types: consistency and asymptotic normality of the change-point estimate [4, 10, 13], and the asymptotic distribution of a maximum statistic [9, 19, 21] to decide if there is a change and, if so, where the

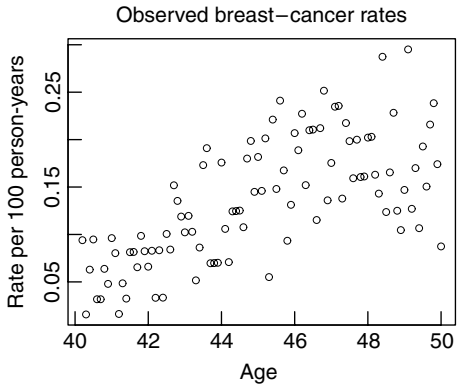

Figure 1 Breast cancer incidence for women between the age of 40 to 50 in Sweden in 1990

change is. Recent results are, for example, on the consistent estimation of the number and location of jumps [13].

From an application point of view, the nonlinear least-squares technique is the most straightforward for generating the estimate and this can be implemented easily using any statistical package that has a nonlinear least-squares routine. However, there does not seem to be a simple general result for the distribution theory of the change-point estimate; see [13]. Users may have to resort to **computer-intensive techniques** such as the **bootstrap method** to obtain a **confidence interval** [12].

We will review the nonlinear least-squares technique and express it in the language of quasi-likelihood so it naturally covers the **generalized linear model** setting [15]. It is common to start with the assumption of one change point and proceed by sequential splitting in the case of multiple change points [20]. Thus, let x_i, for $i = 1, \ldots, n$, be independent outcomes with mean and variance functions given by

$$Ex_i = \mu(t_i), \tag{1}$$

$$\text{Var } x_i = \phi v_i(\mu(t_i)), \tag{2}$$

where ϕ is a scale parameter; for example, for **normal** (Gaussian) outcomes, we might use $\phi = \sigma^2$ and $v_i(\mu) = 1$, and for **Poisson** outcomes $\phi = 1$ and $v_i(\mu) = \mu$. The mean function $\mu(t)$ is piecewise continuous function of the index variable t, which is not necessarily a time variable, with unknown regression parameters $\beta = (\beta_1, \beta_2)$ and the change-point τ according to

$$\mu(t) = \begin{cases} \mu_1(t, \beta_1) & \text{for } t < \tau \\ \mu_2(t, \beta_2) & \text{for } t \geq \tau. \end{cases} \tag{3}$$

Note that other **covariates** may also enter the regression function and the formulation would allow multivariate outcomes, but the change point is generally limited to one index variable. Denote by $\hat{\beta}$ and $\hat{\tau}$ the maximum **quasi-likelihood** estimates. Various quasi-likelihood models are now available for different types of outcome variables [15]. The standard estimation procedure alternates between τ and β in the following way. First, fix τ and estimate β using the standard (iterative-reweighted) least-squares [15] algorithm, which solves the estimating equation

$$\sum_i \frac{\partial \mu(t_i)}{\partial \beta} v_i^{-1}(\mu(t_i))\{x_i - \mu(t_i)\} = 0. \tag{4}$$

In cases where there is a jump discontinuity between the two functions μ_1 and μ_2, we can simply fit two separate regressions for $t < \tau$ and $t \geq \tau$, and estimate the scale parameter ϕ jointly. Denote by $\hat{\beta}(\tau)$ the estimate we obtain at this step.

To estimate τ, we compute the **profile** (quasi-)likelihood for τ by substituting $\hat{\beta}(\tau)$ in the quasi-likelihood function. Or, as a general approximation, we can use the Pearson's χ^2 statistic (*see* **Chi-square Tests**) as the objective function

$$Q(\tau) = \sum_i v_i^{-1}(\hat{\mu}(t_i))\{x_i - \hat{\mu}(t_i)\}^2, \tag{5}$$

where $\hat{\mu}(t)$ is evaluated at $\hat{\beta}(\tau)$. Thus, $\hat{\tau} \equiv \text{argmin}_\tau Q(\tau)$, which is a simple one-dimensional minimization problem, and $\hat{\beta} \equiv \hat{\beta}(\hat{\tau})$.

Several inferential issues are unresolved in general. One is the distribution of $Q(\hat{\tau})$, which is necessary to decide if the change at $\hat{\tau}$ is real. Theoretically, this is available under normal or **binomial** assumptions for a simple level-change model [9, 11, 13, 19, 21]. Secondly, there is no simple distribution theory for $\hat{\tau}$. Standard **large-sample theory** does not apply since the parameter is not regular. For both of these problems, we might use the permutation test (*see* **Randomization Tests**) or the bootstrap. Gibbs sampling has also been used for the Bayesian approach [1] (*see* **Markov Chain Monte Carlo**). With regards to the inference on $\hat{\beta}$, it is common to make it conditional on the observed value of $\hat{\tau}$,

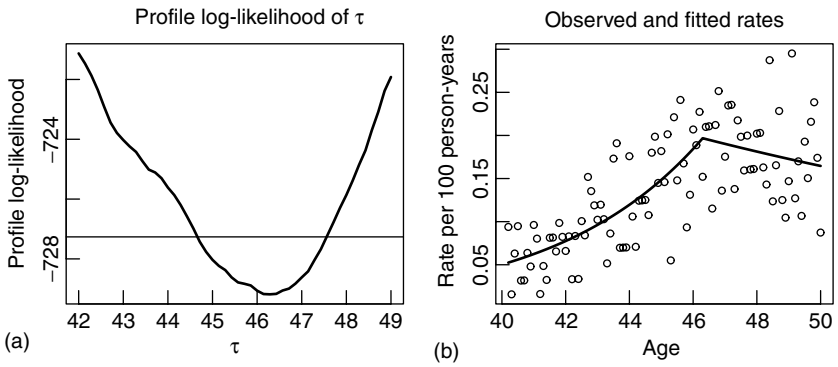

Figure 2 (a) Profile log-likelihood of the change parameter τ; (b) The observed and fitted values of breast cancer incidence

though it ignores the extra variability in the estimation of the change point.

In our example, we will assume that the observed number of breast cancer at each age group $y(t)$ is Poisson with mean $\mu(t) = N(t)\lambda(t)$, where $N(t)$ is the number of **person-years** at age t, and the rate parameter is given by

$$\log \lambda(t) = \begin{cases} \beta_{01} + \beta_{11}(t - 40) & \text{for } t < \tau \\ \beta_{02} + \beta_{12}(t - \tau) & \text{for } t \geq \tau. \end{cases} \quad (6)$$

Because we want $\lambda(t)$ to be continuous, we must have

$$\beta_{02} = \beta_{01} + \beta_{11}(\tau - 40). \quad (7)$$

Figure 2(a) shows the profile log-likelihood of τ, with a minimum at $\hat{\tau} = 46.3$ (the nominal likelihood-based 95% confidence interval is $44.7 < \tau < 47.6$.) The estimated parameters are

$$\begin{aligned} \hat{\beta}_{01} &= -7.60(\text{se} = 0.12) \\ \hat{\beta}_{11} &= 0.22(\text{se} = 0.025) \\ \hat{\beta}_{12} &= -0.05(\text{se} = 0.039). \end{aligned} \quad (8)$$

The estimated dispersion parameter is

$$\hat{\phi} = \frac{1}{99 - 4} \sum_t \frac{(y(t) - \hat{\mu}(t))^2}{\hat{\mu}(t)} = 0.76, \quad (9)$$

showing some underdispersion.

As a concluding remark, we note that there is a strong similarity between the most general change-point problems, involving, say, a continuous change and piecewise continuous functions, and general **nonparametric regression problems** for nonsmooth functions [8]. Recent advances in the latter, using, for example, the wavelet techniques, will produce natural competitors against the current nonsequential change-point analysis.

YUDI PAWITAN

Chaos Theory

Chaos derives from the Greek word $\chi\alpha o\varsigma$, from which one also obtains the English word "gas". Various probabilistic models have been proposed for the motion of gas molecules, such as the Ehrenfest **Markov chain** model for the diffusion of gas through a membrane [10]. However, in idealized situations – and even some practical ones – to which such models are applied, all motion is strictly deterministic. Hence, if one knew complete information about the momentum, energy, fields, etc. of the system in question, then, in principle, one could predict perfectly the state of the system at any future instant. However, in practice, this cannot be achieved. Now the motion of gas particles is not necessarily chaotic, in the strict sense of the word, but it provides a useful analogy. In loose terms, a system is chaotic if it is governed by a set of deterministic equations, but displays erratic, apparently random, behavior. Whilst one can attempt to provide a stochastic model for a chaotic system, one invariably obtains more substantive detail by considering the deterministic component and its contribution to the erratic nature of the observations.

Historically, the theory of chaos has been developed in the deterministic scenario, with Poincaré accredited with much of the foundation work [19], although recent statistical applications have endeavored to merge stochastic variation, or noise, into this setting. Consider first strictly deterministic chaos.

The phenomenon of chaos is produced by a function, possibly multivariable, either in discrete time, where the function comprises one or more linked difference equations, or in continuous time, where it comprises linked differential equations. Chaos is the erratic nature of the trajectories produced in the former case by iteration of the function, and in the latter by evolution of the differential equations. Chaos in continuous time must comprise at least three state variables, for otherwise trajectories would intersect and would thus not provide a unique solution at the point of intersection; however, discrete time chaos can exist in any Euclidean dimension.

There is not absolute agreement on a strict mathematical definition of chaos, although the following, reported fairly loosely, encapsulates most ideas. It follows the exposition given by Falconer [11]. Consider a function f defined on a domain D with an m-fold iterate (composition) denoted $f^{(m)}$. With this notation one can identify special kinds of points $x \in D$; for example, if $f(x) = x$, then x is a fixed point of f, and if $f^{(m)}(x) = x$ for the least $m > 1$, then x is a periodic point of order m. An attractor for f is the minimal compact set $A \subseteq D$ such that, for each $x \in D$, the set of all $f^{(m)}(x)$ which come arbitrarily close to A is nonnull. The chaotic nature, or otherwise, of f is characterized in terms of its attractor. In particular, the attractor must be such that (i) some point in the attractor produces a trajectory under f which is dense ("filling") in the attractor; (ii) the periodic points of the attractor are dense; and (iii) given any point on the attractor, one can find another arbitrarily close point on the attractor such that the two associated trajectories diverge sufficiently fast [22]. Respectively, these properties are (i) that the attractor is nondecomposable; (ii) that the attractor has some semblance of regularity; and (iii) that there is sensitive dependence upon initial conditions. In practical terms it is usually only possible to check condition (iii). Sensitive dependence upon initial conditions can be identified in many areas, from weather forecasting to tossing a coin: in the latter, the greater the angular spin and upward thrust on the coin the more difficult it is to predict the face it will show. Sensitive dependence upon initial conditions can be quantified in terms of an invariant of a dynamic system known as the Lyapunov exponent(s). Under an eigendecomposition, there is one such exponent for each Euclidean direction in which the map evolves, and, by invoking Taylor expansions, one can demonstrate that the Lyapunov exponent is the exponential rate of separation of initially nearby trajectories in the short term. (Since a chaotic map evolves in a bounded space, the separation of trajectories cannot continue indefinitely.)

If a map is chaotic, then often its attractor will be fractal-like: its fine, complex structure is not always "filling" in each Euclidean direction, and hence its dimension is not always an integer. Estimates of fractional dimension are obtained using box counting methods, amongst others. The analysis of fractal surfaces and the estimation of fractional dimension comprise research and applications which are closely allied with the study of chaos; see, for instance, Davies & Hall [9]. These topics are beyond the scope of this article.

Deterministic chaos possesses features that have stochastic interpretations. One can define a probability measure, ν, on the set D upon which the chaotic map f is defined by denoting the measure of a subset $C \subseteq D$ as the limiting proportion of time spent by an arbitrary trajectory in C (continuous time) or the proportion of its iterates therein (discrete time); that is, $\nu(C) = \lim_{m\to\infty} m^{-1}\#\{f^{(j)}(X_0) \in C; 1 \leq j \leq m\}$, where "#" denotes the cardinality of a set. Here X_0 is an arbitrarily chosen initial condition. For a wide class of dynamical systems (called "Axiom A" systems), ν does not depend on the choice of X_0; that is to say, the invariant measure is a "generic" feature of a dynamic system (which is the analog for the phrase "almost sure" in a probabilistic setting). The existence of an absolutely continuous invariant measure is known only for certain classes of maps (essentially, those that are one-dimensional and whose piecewise derivatives exceed unity in absolute value). If the dynamics of the system do not change as time evolves, then one has the equivalent of a strictly **stationary** time series. If one regarded the output of a chaotic dynamical system as a stochastic **time series**, then one could obtain its **autocorrelation function**, amongst other features. Whilst the deterministic interpretation of the variables would lead one to think that the variables are highly correlated, via the relationship induced by the map f, sensitive dependence upon initial conditions actually produces autocorrelation functions which can be zero at virtually all nonzero lags (within the stochastic interpretation of the series). Hence a chaotic series, produced by a strong deterministic relationship, can behave like an apparently purely random time series. It is for this reason, among other more technical ones, that random number generators in computers are based on chaotic maps (*see* **Pseudo-random Number Generator**).

One could point to papers in 1990, such as by Bartlett [3] and Wolff [27], which were among the first formal statistical treatments of chaos in the statistical literature, and to papers in 1992, e.g. [26], and [5], and [7], which were the first fruits of the initial activity. Of course, the scientific community more widely has known about chaos for much longer, and even statisticians, such as Tong & Lim [25], made observations of it before the 1990s. Such observations were in the context of **nonlinear time series** models, which progressively came to the fore from the 1970s [16], and which identified the relationship between modes of behavior of various models for different parameter values, charting the steady state, monotonic, periodic, limit cycle or chaotic behavior of realizations of the model; again see, for example, Tong & Lim [25]. Tong [24] draws together the theory of nonlinear time series and statistical aspects of dynamic systems, which also appears in an as yet unpublished book by K.S. Chan & H. Tong.

It is at this juncture that one is able to pose a more realistic setting for chaos by incorporating stochastic noise into the map (*see* **Noise and White Noise**). Just as time domain models for time series usually comprise a deterministic component and a stochastic component, one can formulate nonlinear autoregressions, for instance where the deterministic component is a chaotic map and noise is added into the system. $X \to f(X) + \varepsilon$, where ε represents an independent and identically distributed sequence of **random variables**. Many other formulations with noise are possible. Under this representation, the generic properties of the deterministic map f are unlikely to be related to the corresponding ones of the noisy chaotic map (for example, computations of Lyapunov exponents, fractal dimensions, and invariant measures). Moreover, interpretation of those quantities in the noisy case is difficult; for in the deterministic case there exists a geometric interpretation for them which does not make sense when noise infects the deterministic dynamics.

Parametric modeling of chaotic systems is almost impossible. Since a chaotic map cannot be linear, the family of possible maps for chaos is vast and unchartable. Unless one has considerable substantive information about the map, such as intimate knowledge of the physics governing the system, then parametric modeling usually is out of the question. However, in such cases where it is possible there has been some progress. Geweke [12] considers a realization of a deterministic chaotic map in which the series is "blurred" with an independent noise sequence. A method of parameter estimation using **maximum likelihood** in the presence of an extremely irregular **likelihood** function is demonstrated. The more realistic case of system noise is considered by Berliner [4], as described in the previous paragraph, who sets out a **Bayesian** approach to parametric model fitting. Assuming parametric knowledge of the map, one may adapt nonparametric kernel **density estimation** techniques to obtain the density

of the invariant measure of a given map, assuming that it exists and is absolutely continuous, as investigated by Hall & Wolff [15]. That technique further validates the block **bootstrap** for chaotic time series.

In fact, nonparametric modeling is where the best progress has been made. Yao & Tong [30, 31] adapt the idea of Lyapunov exponents to the stochastic setting by replacing it with a probability that trajectories will diverge exponentially fast. They call estimates of that probability a *sensitivity measure*. In an earlier paper they draw on the Taylor expansion formulation of the Lyapunov exponent to produce forecasts of a dynamic system and to bound those forecasts in terms of the Lyapunov exponent. Further in the endeavor of forecasting, they adapt a **Kullback–Leibler** statistic to identify local regions from which accurate k-step-ahead forecasts can be made and regions from which sufficient accuracy of forecasts does not exist. This is related to an adaptation of Lyapunov exponents to find local regions of relatively large or small exponential divergence of trajectories [28], which has also been studied in a local-time sense [18].

Estimates of dimension for noisy chaos [21] and interpretations of fractal properties for general time series models [8] have also been presented.

Adaptations have been made of devices used in the study of dynamic systems, such as the application of the correlation integral, used for estimating fractional dimension and, more generally, for determining the presence of chaos, as established by Grassberger & Procaccia [13], and also as a test statistic for independence in a time series, such as in Brock et al. [6] and Wolff [29]. Thus the epiphany of chaos in statistical realms has done much to complement the Box–Jenkins methodology.

Direct applications in human biology are few, although consideration of dynamic aspects have led to novel approaches in modeling. Three particular applications have received prominence in recent years. Of course, the classical discussion of chaos in biological systems *per se* is that of May [17], where simple one-dimensional maps governing biological populations were found mathematically and in reality to exhibit chaos. For various plain biological and social reasons, human population series would not be expected to display such behavior.

Earlier works on measles epidemics, such as those of Bartlett [3] and Schaffer [20], were scrutinized by Grenfell [14] and others of his co-workers subsequently in regard to chaotic dynamics in measles epidemics. Sugihara & May [23] exhibited a **cross-validation** device to distinguish between chaotic behavior (claimed to exist in measles epidemics and thought to be governed by a six-dimensional map) and purely stochastic behavior (claimed to exist in mumps and chicken-pox epidemics). It is initially plausible that childhood diseases might be chaotic. Consider a pendulum with a metallic weight: given a small displacement it will follow regular simple harmonic motion, but if it is placed near an object of the same magnetic polarity it can trace out a chaotic trajectory. This kind of forced oscillation, causing chaos, is present in childhood diseases, in that school terms and holidays "force" large numbers of potentially infectious children together and apart, respectively, and that forcing is superimposed on the natural oscillation of the epidemic. Subsequent scrutiny of epidemiologic time series raised issues about large amounts of noise present in the series, and the greater likelihood of limit cycles rather than chaotic behavior lying at the center of the dynamics (*see* **Epidemic Models, Deterministic**; **Epidemic Models, Stochastic**; **Infectious Disease Models**).

Babloyantz [1, 2], among many others, has examined physiologic dynamics and found evidence of chaos. Along the lines of the above discussion, the forced oscillations of the heart were studied, and it was found that a healthy heart is chaotic! In its usual beating mode the differenced series of times between corresponding parts of the heart cycle shows evidence of low-dimensional chaos. What is more, at the onset of myocardial infarction (heart attack), chaos gives way to limit cycle patterns. There is a large research industry into this topic, as well as in infant respiration and analysis of electroencephalograms, to name but two others in the realm of physiological dynamics (*see* **Mathematical Biology, Overview**; **Clinical Signals**).

Characteristic Function

The characteristic function has several important theoretical applications. It is used to derive distributions for sums and other linear combinations of independent **random variables**. It is also used to determine limiting distributions of statistics as sample sizes become infinitely large (*see* **Large-sample Theory**). The resulting asymptotic distributions often provide useful approximations for making inferences from finite samples when the exact finite sample distributions are too complicated to be conveniently evaluated. The characteristic function can also be used to derive **moments** of distributions.

The characteristic function of a (real-valued) random variable X with distribution function $F(x)$ is a complex-valued function defined as

$$\phi(t) = \mathrm{E}[\exp(itX)] = \int_{-\infty}^{\infty} \exp(itx)\,\mathrm{d}F(x), \quad (1)$$

where $i \equiv \sqrt{-1}$ and t is any real number. For a continuous distribution with density function $f(x)$,

$$\phi(t) = \int_{-\infty}^{\infty} \exp(itx) f(x)\,\mathrm{d}x,$$

and for a discrete distribution on the nonnegative integers,

$$\phi(t) = \sum_{k=0}^{\infty} \exp(ikt)\Pr(x = k).$$

Introductory textbooks on statistical theory often use the **moment generating function** instead of the characteristic function to avoid the introduction of complex arithmetic. They have many of the same uses, but the characteristic function provides more general results because it exists for any distribution. It is absolutely continuous on the real line and satisfies (i) $\phi(0) = 1$, (ii) $|\phi(t)| \leq 1$, and (iii) $\phi(-t)$ is the complex conjugate of $\phi(t)$.

We may obtain the rth moment of X about zero from $\phi^{(r)}(0)$, the rth derivative of $\phi(t)$ evaluated at $t = 0$. In particular, if X has finite moments up to some order n, then $\phi(t)$ has continuous derivatives up to order n and

$$\mu_r = \mathrm{E}(X^r) = i^r \phi^{(r)}(0), \quad r = 1, \ldots, n. \quad (2)$$

Equivalently, μ_r is the coefficient of the rth term in the expansion

$$\phi(t) = 1 + \sum_{r=1}^{\infty} \mu_r \frac{(it)^r}{r!}. \quad (3)$$

The rth *cumulant* of X, denoted by κ_r, is the coefficient of the rth term in the corresponding expansion of the natural logarithm of the characteristic function, i.e.

$$\ln[\phi(t)] = \sum_{r=1}^{\infty} \kappa_r \frac{(it)^r}{r!}. \quad (4)$$

Moments of X about zero are obtained from cumulants as

$$\begin{aligned}
\mu_1 &= \kappa_1, \\
\mu_2 &= \kappa_2 + \kappa_1^2, \\
\mu_3 &= \kappa_3 + 3\kappa_2\kappa_1 + \kappa_1^3, \\
\mu_4 &= \kappa_4 + 3\kappa_2^2 + 4\kappa_1\kappa_3 + 6\kappa_1^2\kappa_2 + \kappa_1^4.
\end{aligned}$$

Cumulants are also called *semi-invariants* because adding a constant to X does not affect the value of κ_r for $r \geq 2$. The term "cumulant" is motivated by the property that the rth cumulant of the sum of independent random variables is equal to the sum of the corresponding cumulants of the individual random variables for any $r \geq 1$ for which the cumulants exist. Stuart & Ord [7] provide more information on the computation and uses of cumulants and additional formulas relating cumulants to various types of moments.

Inversion formulas allow us to recover density functions and discrete probability distributions from characteristic functions. If $\phi(t)$ is absolutely integrable, i.e. $\int_{-\infty}^{\infty} |\phi(t)|\,\mathrm{d}t$ is finite, then $\phi(t)$ uniquely determines an absolutely continuous distribution with a bounded and uniformly continuous density function given by the formula

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(-itx)\phi(t)\,\mathrm{d}t. \quad (5)$$

For discrete distributions on the nonnegative integers, we have

$$\Pr(X = k) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(-itk)\phi(t)\,\mathrm{d}t. \quad (6)$$

Characteristic functions have important applications in the determination of distributions for linear combinations of independent random variables. For example, if $X_1, X_2, \ldots, X_n$ are independent random variables with respective characteristic functions $\phi_1(t), \phi_2(t), \ldots, \phi_n(t)$, then the characteristic function of $X_1 + X_2 + \cdots + X_n$ is the product

$$\phi(t) = \phi_1(t)\phi_2(t)\ldots\phi_n(t). \tag{7}$$

We complete the task by applying an inversion formula to $\phi(t)$ or simply recognizing the distribution function uniquely determined by $\phi(t)$. The characteristic function for $X_1 - X_2$ is

$$\phi(t) = \phi_1(t)\phi_2(-t). \tag{8}$$

Characteristic functions were originally introduced as a mechanism for deriving limiting distributions of sequences of random variables (*see* **Convergence in Distribution and in Probability**). Important applications include the derivation of **central limit theorems** for establishing the limiting **normal** (Gaussian) distributions of sample means or estimators of model parameters as sample sizes are increased, and the derivation of **chi-square distributions** for sums of squares and **goodness-of-fit** tests. The basic result is that if $\{X_n\}$ is a sequence of random variables such that X_n has distribution function $F_n(x)$ and characteristic function $\phi_n(t)$, then the pointwise convergence of $\phi_n(t)$ to a function $\phi(t)$ that is continuous at $t = 0$ implies that $F_n(x)$ converges to $F(x)$, the unique distribution function determined by $\phi(t)$, at all continuity points of $F(x)$. The converse of this result is also true, i.e. the convergence of the sequence $\{F_n(x)\}$ to a continuous distribution function $F(x)$ implies uniform convergence of $\{\phi_n(t)\}$ to $\phi(t)$ in any finite interval of t values as $n \to \infty$.

As an illustration, consider the limiting behavior of a sequence of Bernoulli random variables. Let X_n denote the number of successful outcomes in a series of n independent and identical trials where each trial has probability p of producing a successful outcome. Then, X_n has a **binomial distribution** with probability function

$$\Pr(X = k) = \binom{n}{k} p^r (1-p)^{n-r}, \quad \text{for } k = 0, 1, \ldots, n.$$

The characteristic function for the binomial distribution is

$$\begin{aligned}\phi(t) &= \sum_{k=0}^{n} \exp(itk) \binom{n}{k} p^k (1-p)^{n-k} \\ &= [1 - p + p\exp(it)]^n \\ &= \{1 + p[\exp(it) - 1]\}^n.\end{aligned}$$

Now consider a sequence of binomial random variables $\{X_n, n = 1, 2, \ldots\}$, where X_n is the number of successful outcomes in n independent trials with probability of success $p = \lambda/n$ on any single trial. In this scenario the probability of success on a single trial becomes smaller as the number of trials increases in such a way that the expected number of successes,

$$\mathrm{E}(X_n) = np = \lambda,$$

remains constant. Then, the characteristic function for X_n is

$$\phi_n(t) = \left[1 + \frac{\lambda[\exp(it) - 1]}{n}\right]^n,$$

and using the result that $(1 + a/n)^n \to \mathrm{e}^a$ as $n \to \infty$, it is easily seen that as $n \to \infty$,

$$\phi_n(t) \to \exp\{\lambda[\exp(it) - 1]\}$$

which is the characteristic function of a **Poisson** random variable with expectation λ. This shows that as the number of trials becomes large and the probability of success on any single trial becomes small, the binomial distribution for the number of successful outcomes approaches a Poisson distribution with the same mean.

When p remains constant as the number of trials is increased, X_n increases without bound and has no limiting distribution, but a central limit theorem can be used to show that the standardized count,

$$Z_n = \frac{X_n - np}{[np(1-p)]^{1/2}},$$

has a limiting standard normal (Gaussian) distribution. The characteristic function for the standard normal distribution is

$$\begin{aligned}\phi(t) &= \int_{-\infty}^{\infty} \exp(itx) \frac{1}{(2\pi)^{1/2}} \exp[-(1/2)x^2]\,\mathrm{d}x \\ &= \exp[-(1/2)t^2]. \end{aligned} \tag{9}$$

Consequently, the characteristic function for Z_n,

$$\phi_n(t) = \exp\{-itnp/[np(1-p)]^{1/2}\} \times [1 - p + p\exp\{it/[np(1-p)]^{1/2}\}]^n,$$

must converge to (9) for all t in any finite interval. Note that the effect on $\phi_n(t)$ of transforming X_n to $(X_n - \mu)/\sigma$ is to replace t by t/σ and multiply the result by $\exp(-it\mu/\sigma)$.

Stuart & Ord [7] provide a good introduction to the derivation and uses of characteristic functions. Additional properties of characteristic functions are reviewed by Laha [1]. For proofs and more precise mathematical statements of these results and additional developments, see Lukács [3, 4], Laha & Rohatgi [2], and Ramachandran [6]. Applications are discussed by Lukács & Laha [5] and Laha & Rohatgi [2].

KENNETH KOEHLER

Chemometrics

Chemometrics is usually defined as the application of mathematical and statistical methods to problems in chemistry. Although most such applications involve simple statistical techniques, it is the use of multivariate statistical methods that is popularly associated with the term chemometrics (*see* **Multivariate Analysis, Overview**). These multivariate methods include some that will be familiar to many biostatisticians, such as **principal components analysis** and **discriminant analysis**, as well as some others that will not. The text by Massart et al. [5] gives a good coverage of chemometrics in its wider sense. Here we concentrate on the multivariate aspects.

One important area of application is to multivariate **calibration** problems [1, 4]. Here we wish to calibrate a rapid, usually indirect, measurement of some quantity against measurement by a reference method y. The basic measurement x produced by the indirect method is multivariate, possibly highly so. For example, the rapid method may be spectroscopic, in which case it is not untypical to have as x a spectrum measured at 100 or even 1000 wavelengths. Typically, one is faced with estimating a calibration equation $y = f(x)$ from around 50 training samples on which both x and y are measured, with **multiple regression** ruled out by the dimensionality of x and great care needed to avoid overfitting the limited data. Spectroscopic examples in clinical and pharmaceutical chemistry are common. A 1995 conference [2] included a dozen papers in this area, with the rapid spectroscopic measurement of blood parameters as one popular theme.

Methods that construct a prediction equation by linear regression of y on the scores of the training samples on a number of factors derived from the original predictor variables are widely used in such problems (*see* **Reduced Rank Regression**). In principal component regression we carry out a preliminary **principal components analysis** of the original predictor variables, retaining only a small number of components that explain most of the variance in x. The second step is to regress y on the principal component scores for these components, which are linear combinations of the original measurements. In partial least squares regression (PLSR, or just PLS) we also construct new predictor variables as linear combinations of the original ones, but now we choose the combinations to maximize the covariance between the constructed variables and y. **Cross-validation** is commonly used with both of these methods to select the appropriate number of factors to include in the equation. Frank & Friedman [3] discuss these techniques and compare them with other **shrinkage** methods such as **ridge regression**.

Another application with importance in the field of medicine is the study of quantitative structure–activity relationships, universally referred to by its acronym QSAR. The idea of QSAR is to try to relate quantitative physical and chemical descriptions of molecules to their biological activity. Examples of descriptors range from simple ones such as the solubility of the molecule in water, to complex and high-dimensional ones from computational chemistry, based for example on the molecule's electrostatic potential calculated on a lattice of points surrounding it. Given a database of molecules in which some desired biological activity – such as being an effective drug or pesticide – is present to a greater or lesser extent, the general problem is to relate this activity to descriptors of the molecules. Such a relationship would guide the drug designer in synthesizing new molecules or deciding, on the basis of relatively easily measured descriptors, which existing molecules to subject to expensive biological testing. When high-dimensional descriptors are used the statistical problems are similar to those in the multivariate calibration problem, and many of the same chemometric tools used in multivariate calibration have also been applied to QSAR. Stone & Jonathan [6, 7] review statistical aspects of QSAR and provide a thoughtful commentary on the use of these tools in general.

TOM FEARN

Chi-square Distribution; Properties

This article complements the introductory article on the **chi-square distribution** by presenting proofs of its derivation as the distribution of the sum of squares of standard normal deviates. Various properties of the distribution are derived. The second section of the article deals with the noncentral chi-square distribution, which arises when the component normal deviates, whose squares are summed, have nonzero means. This is an important result as it defines the **power** of standard chi-square tests.

The Central Chi-Square Distribution

Theorem 1. Let $X_1, X_2, \ldots, X_n$ be independent with the **standard normal** $\mathcal{N}(0, 1)$ density

$$f_{X_k}(x_k) = \frac{\mathrm{e}^{-x_k^2/2}}{\sqrt{2\pi}}, \quad -\infty < x_k < \infty,$$
$$k = 1, 2, \ldots, n.$$

Then

$$U_n = \sum_{k=1}^{n} X_k^2$$

has the central chi-square distribution $\chi_n^2(0)$ with density

$$f_{U_n}(s) = \frac{s^{(n/2)-1}\mathrm{e}^{-s/2}}{\Gamma(n/2)2^{n/2}}.$$

for $0 < s < \infty$, and 0 elsewhere.

Proof. For $\alpha > 0$, $\Gamma(\alpha + 1) = \alpha\Gamma(\alpha)$, $\Gamma(1/2) = \sqrt{(\pi)}$, and $\Gamma(m + 1) = m!$ for integer $m \geq 0$.

We use complete induction on n and write $U_n = U_{(n-1)} + U_1$, where $U_1 = X_1^2$ and $U_{(n-1)} = \sum_{k=2}^{n} X_k^2$. Then forming the convolution using independence of U_1 and $U_{(n-1)}$

$$\begin{aligned} f_{U_n}(s) &= \int_0^s f_{U_{(n-1)}}(s - y) f_{U_1}(y)\,\mathrm{d}y \\ &= \int_0^s \frac{(s-y)^{(n-1)/2-1}\mathrm{e}^{-(s-y)/2}}{\Gamma((n-1)/2)2^{(n-1)/2}} \\ &\quad \times \frac{y^{1/2-1}\mathrm{e}^{-y/2}}{\Gamma(1/2)2^{1/2}}\,\mathrm{d}y \\ &= \frac{s^{n/2-1}\mathrm{e}^{-s/2}}{\Gamma(n/2)2^{n/2}} \\ &\quad \times \int_0^s \frac{\Gamma(n/2)(s-y)^{(n-1)/2-1}y^{1/2-1}}{\Gamma((n-1)/2)\Gamma(1/2)s^{n/2-1}}\,\mathrm{d}y \end{aligned}$$

Substituting $v = y/s$, we get

$$\frac{s^{n/2-1}\mathrm{e}^{-s/2}}{\Gamma(n/2)2^{n/2}} \int_0^1 \frac{\Gamma(n/2)v^{(n-1)/2-1}(1-v)^{1/2-1}}{\Gamma((n-1)/2)\Gamma(1/2)}\,\mathrm{d}v = \frac{s^{n/2-1}\mathrm{e}^{-s/2}}{\Gamma(n/2)2^{n/2}} \times 1$$

using the **beta**$((n-1)/2, 1/2)$ density integrates to 1. The parameter n of the $\chi_n^2(0)$ density is called the **degrees of freedom** parameter.

A proof using moment **generating functions** is as follows:

$$\begin{aligned} m_{X_k^2}(t) &= \mathrm{E}(\mathrm{e}^{tX_k^2}) = \int_{-\infty}^{\infty} \mathrm{e}^{tx^2}\frac{\mathrm{e}^{-x^2/2}}{\sqrt{2\pi}}\,\mathrm{d}x \\ &= (1-2t)^{-1/2}. \\ m_{U_n}(t) &= \prod_{k=1}^{n} m_{X_k}(t) = (1-2t)^{-n/2} \\ &= \int_0^{\infty} \mathrm{e}^{ts}\frac{s^{(n/2)-1}\mathrm{e}^{-s/2}}{\Gamma(n/2)2^{n/2}}\,\mathrm{d}s = \mathrm{E}(\mathrm{e}^{tU_n}) \end{aligned}$$

and we use the uniqueness of the moment generating function. The proof is similar using the uniqueness of the complex **characteristic function**,

$$\begin{aligned} \phi_{X_k^2}(t) &= \mathrm{E}(\mathrm{e}^{itX_k^2}) = \int_{-\infty}^{\infty} \mathrm{e}^{itx^2}\frac{\mathrm{e}^{-x^2/2}}{\sqrt{2\pi}}\,\mathrm{d}x \\ &= (1-2it)^{-1/2}. \\ \phi_{U_n}(t) &= \prod_{k=1}^{n} \phi_{X_k^2}(t) = (1-2it)^{-n/2} \\ &= \int_0^{\infty} \mathrm{e}^{its}\frac{s^{(n/2)-1}\mathrm{e}^{-s/2}}{\Gamma(n/2)2^{n/2}}\,\mathrm{d}s = \mathrm{E}(\mathrm{e}^{itU_n}), \end{aligned}$$

where $i = \sqrt{(-1)}$.

The chi-square distribution is a special case ($\alpha = n/2$, $\beta = 2$) of the **gamma** (α, β) distribution, which has density

$$f(x) = \frac{x^{\alpha-1}\mathrm{e}^{-x/\beta}}{\Gamma(\alpha)\beta^{\alpha}} \quad \text{for } 0 < x < \infty,$$

and 0 elsewhere.

The incomplete gamma distribution function can be calculated from

$$G(x,a) = \int_0^\infty \frac{u^{a-1}\mathrm{e}^{-u}}{\Gamma(a)}\,\mathrm{d}u = \begin{cases} \dfrac{x^a\mathrm{e}^{-x}}{\Gamma(a)} \displaystyle\sum_{k=0}^{\infty} \frac{x^k}{(a+k)_{k+1}} & \text{for small } x \\ 1 - \dfrac{x^a\mathrm{e}^{-x}}{\Gamma(a)} c(x) & \text{for large } x \end{cases}$$

with $(a+k)_{k+1} = \prod_{j=0}^{k}(a+j)$ and the continued fraction

$$c(x) = 1/(x + a_0/(1 + a_1/(x + a_2/(1 + a_3/(x + \cdots/(x + a_{2k}/(1 + a_{2k+1}/(x + \cdots,$$

where $a_{2k} = k + 1 - a$, $a_{2k+1} = k + 1$ for $k = 0, 1, 2\ldots$ (see for example Abramowitz and Stegun [1, p. 263, 6.5.29, 6.5.31]). The gamma function $\Gamma(a)$ can be calculated accurately using Stirling's formula with the Binet function error term evaluated using the continued fraction of Jones and Thron [2, p. 350].

The cumulative distribution function (cdf) for the central $\chi_n^2(0)$ distribution is then

$$F_{U_n}(x) = P(U_n \le x) = G\left(\frac{x}{2}, \frac{n}{2}\right).$$

The cdf for the **Poisson**(λ) distribution can be determined from that of the chi-square cdf

$$\sum_{k=0}^{x} \frac{\lambda^k\mathrm{e}^{-\lambda}}{k!} = 1 - F_{U_m}(2\lambda),$$

where $m = 2(x+1)$ for $x = 0, 1, \ldots$.

The Noncentral Chi-square Distribution

Theorem 2. Let X_k be independent normal $\mathcal{N}(\mu_k, 1)$ for $k = 1, 2, \ldots, n$ with densities

$$f_{X_k}(x_k) = \frac{\mathrm{e}^{-(x_k-\mu_k)^2/2}}{\sqrt{2\pi}}, \quad -\infty < x_k < \infty.$$

The distribution of

$$U_n = \sum_{k=1}^{n} X_k^2$$

is the noncentral chi-square distribution $\chi_n^2(\delta_n^2)$, where $\delta_n^2 = \sum_{k=1}^{n} \mu_k^2$, with density

$$f_{U_n}(u) = \sum_{j=0}^{\infty} \mathrm{e}^{-\delta_n^2/2} \frac{(\delta_n^2/2)^j}{j!} \frac{u^{(2j+n)/2-1}\mathrm{e}^{-u/2}}{\Gamma((2j+n)/2)2^{(2j+n)/2}}$$

for $0 < u < \infty$, and 0 elsewhere.

Proof. Make the transformation

$$\mathbf{Z} = \begin{pmatrix} Z_1 \\ Z_2 \\ Z_3 \\ \vdots \\ Z_n \end{pmatrix} = \begin{pmatrix} \frac{\mu_1}{\delta_n} & \frac{\mu_2}{\delta_n} & \frac{\mu_3}{\delta_n} & \cdots & \frac{\mu_n}{\delta_n} \\ \frac{\mu_2\mu_1}{\delta_2\delta_1} & \frac{-\delta_1^2}{\delta_2\delta_1} & 0 & \cdots & 0 \\ \frac{\mu_3\mu_1}{\delta_3\delta_2} & \frac{\mu_3\mu_2}{\delta_3\delta_2} & \frac{-\delta_2^2}{\delta_3\delta_2} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \frac{\mu_n\mu_1}{\delta_n\delta_{(n-1)}} & \frac{\mu_n\mu_2}{\delta_n\delta_{(n-1)}} & \frac{\mu_n\mu_3}{\delta_n\delta_{(n-1)}} & \cdots & \frac{-\delta_{(n-1)}^2}{\delta_n\delta_{(n-1)}} \end{pmatrix} \times \begin{pmatrix} X_1 \\ X_2 \\ X_3 \\ \vdots \\ X_n \end{pmatrix}.$$

In **matrix** notation $\mathbf{Z = AX}$, where $\mathbf{A}$ is the **orthogonal** $n \times n$ matrix above that satisfies $\mathbf{AA^T = A^TA = I_n}$, where $\mathbf{I_n}$ is the $n \times n$ identity matrix. It follows from the **multivariate normal distribution** for $\mathbf{X} : \mathcal{N}_n(\boldsymbol{\mu}, \mathbf{I_n})$, where $\boldsymbol{\mu} = (\mu_1, \mu_2, \ldots, \mu_n)^T$ that $\mathbf{Z} : \mathcal{N}_n(\boldsymbol{\eta}, \mathbf{I_n})$ with $\boldsymbol{\eta} = \mathbf{A}\boldsymbol{\mu} = (\delta_n, 0, 0, \ldots, 0)^T$. Thus, $Z_1 : \mathcal{N}(\delta_n, 1)$, $Z_k : \mathcal{N}(0, 1)$ for $k = 2, 3, \ldots, n$ and they are independent. Also,

$$\sum_{i=1}^{n} Z_i^2 = \mathbf{Z^TZ} = \mathbf{X^TA^TAX} = \mathbf{X^TX} = \sum_{i=1}^{n} X_i^2 = U_n.$$

The density

$$\begin{aligned} f_{Z_1^2}(u_1) &= f_{Z_1}(\sqrt{u_1}) \left| \frac{\mathrm{d}\sqrt{u_1}}{\mathrm{d}u_1} \right| \\ &\quad + f_{Z_1}(-\sqrt{u_1}) \left| \frac{\mathrm{d}(-\sqrt{u_1})}{\mathrm{d}u_1} \right| \\ &= \frac{\frac{1}{2}u_1^{-1/2}\mathrm{e}^{(\sqrt{u_1}-\delta_n)^2/2}}{\sqrt{2\pi}} + \frac{\frac{1}{2}u_1^{-1/2}\mathrm{e}^{(-\sqrt{u_1}-\delta_n)^2/2}}{\sqrt{2\pi}} \\ &= \frac{u_1^{1/2-1}\mathrm{e}^{-u_1/2}}{\Gamma(1/2)2^{1/2}}\mathrm{e}^{-\delta_n^2/2}\left(\frac{\mathrm{e}^{\delta_n\sqrt{u_1}}+\mathrm{e}^{-\delta_n\sqrt{u_1}}}{2}\right) \\ &= \sum_{j=0}^{\infty} \mathrm{e}^{-\delta_n^2/2}\frac{(\delta_n^2/2)^j}{j!}\frac{u_1^{(2j+1)/2-1}\mathrm{e}^{-u_1/2}}{\Gamma((2j+1)/2)2^{(2j+1)/2}}. \end{aligned}$$

Forming the convolution $Z_1^2 + \sum_{k=2}^{n} Z_k^2$ term by term and using the convolution of $\chi^2_{(2j+1)}(0)$ and $\chi^2_{(n-1)}(0)$ is $\chi^2_{(n+2j)}(0)$ gives

$$f_{U_n}(u) = \sum_{j=0}^{\infty} \mathrm{e}^{-\frac{\delta_n^2}{2}} \frac{\left(\frac{\delta_n^2}{2}\right)^j}{j!} \frac{u^{(n+2j)/2-1}\mathrm{e}^{-u/2}}{\Gamma((n+2j)/2)2^{(n+2j)/2}}.$$

Thus, the noncentral $\chi_n^2(\delta_n^2)$ density is a Poisson$(\delta_n^2/2)$ probability mixture of central $\chi^2_{(n+2j)}(0)$ densities for $j = 0, 1, 2 \ldots, \infty$. If $\delta_n = 0$, then the distribution has the central chi-square $\chi_n^2(0)$ density.

For an alternate proof using moment generating functions, consider

$$\begin{aligned} m_{X_k^2}(t) = \mathrm{E}(\mathrm{e}^{tX_k^2}) &= \int_{-\infty}^{\infty} \mathrm{e}^{tx_k^2} \frac{\mathrm{e}^{-(x_k-\mu_k)^2/2}}{\sqrt{2\pi}}\,\mathrm{d}x_k \\ &= \mathrm{e}^{-\mu_k^2/2}\frac{\mathrm{e}^{\mu_k^2/(2(1-2t))}}{\sqrt{1-2t}}. \end{aligned}$$

Then

$$\begin{aligned} m_{U_n}(t) &= \prod_{k=1}^{n} m_{X_k^2}(t) = \mathrm{e}^{-\delta_n^2/2}\frac{\mathrm{e}^{\delta_n^2/(2(1-2t))}}{(1-2t)^{n/2}} \\ &= \sum_{j=0}^{\infty} \frac{\mathrm{e}^{-\delta_n^2/2}(\delta_n^2/2)^j}{j!}(1-2t)^{-(n+2j)/2} \\ &= \sum_{j=0}^{\infty} \frac{\mathrm{e}^{-\delta_n^2/2}(\delta_n^2/2)^j}{j!} m_{\chi^2_{(n+2j)}(0)}(t). \end{aligned}$$

The parameter δ_n^2 is called the *noncentrality* parameter and n is the *degrees of freedom* parameter.

The characteristic function is

$$\phi_{U_n}(t) = \mathrm{e}^{-\delta_n^2/2}\frac{\mathrm{e}^{\delta_n^2/(2(1-2it))}}{(1-2it)^{n/2}},$$

where again $i = \sqrt{(-1)}$.

The cdf can be calculated from the incomplete gamma function as

$$\begin{aligned} F_{U_n}(x) = P(U_n \le x) &= \sum_{j=0}^{\infty} \frac{\mathrm{e}^{-\delta_n^2/2}(\delta_n^2/2)^j}{j!} \\ &\quad \times G\left(\frac{x}{2}, \frac{n+2j}{2}\right). \end{aligned}$$

We can calculate the moments of the noncentral chi-square random variable recursively. Let U_n be distributed as $\chi_n^2(\delta^2)$. Then for integer $r \ge 0$, we have

$$\begin{aligned} \mathrm{E}(U_n^r) &= \sum_{j=0}^{\infty} \frac{(\delta^2/2)^j\mathrm{e}^{-\delta^2/2}}{j!} \\ &\quad \times \int_0^{\infty} s^r \frac{s^{(n+2j)/2-1}\mathrm{e}^{-s/2}}{\Gamma((n+2j)/2)2^{(n+2j)/2}}\,\mathrm{d}s \\ &= \sum_{j=0}^{\infty} \frac{(\delta^2/2)^j\mathrm{e}^{-\delta^2/2}}{j!}\prod_{k=0}^{r-1}(n+2j+2k) \\ &= \sum_{j=0}^{\infty} \frac{(\delta^2/2)^j\mathrm{e}^{-\delta^2/2}}{j!}(n+2j)\prod_{k=0}^{r-2}(n+2+2j+2k) \\ &= n\mathrm{E}(U_{n+2}^{r-1}) + \delta^2\mathrm{E}(U_{n+4}^{r-1}), \end{aligned}$$

where U_m for $m = (n+2)$, $(n+4)$ have noncentral chi-square $\chi_m^2(\delta^2)$ distributions with the same parameter δ^2.

From this it follows by induction on integer $r = 1, 2, \ldots$ that

$$\mathrm{E}(U_n^r) = \sum_{k=0}^{r}\binom{r}{k}\delta^{2k}2^{r-k}\frac{\Gamma((n+2r)/2)}{\Gamma((n+2k)/2)}.$$

In particular, $\mathrm{E}(U_n) = n + \delta^2$, $\mathrm{Var}(U_n) = 2n + 4\delta^2$ and

$$\begin{aligned}
\mathrm{E}(U_n^2) &= n(n+2) + 2\delta^2(n+2) + \delta^4 \\
\mathrm{E}(U_n^3) &= n(n+2)(n+4) + 3\delta^2(n+2)(n+4) \\
&\quad + 3\delta^4(n+4) + \delta^6 \\
\mathrm{E}(U_n^4) &= n(n+2)(n+4)(n+6) + 4\delta^2(n+2) \\
&\quad \times (n+4)(n+6) + 6\delta^4(n+4)(n+6) \\
&\quad + 4\delta^6(n+6) + \delta^8.
\end{aligned}$$

For the central chi-square case with $\delta^2 = 0$, we have $\mathrm{E}(U_n) = n$, $\mathrm{Var}(U_n) = 2n$ and for integer $r \geq 0$,

$$\begin{aligned}
\mathrm{E}(U_n)^r &= 2^r \frac{\Gamma(r + (n/2))}{\Gamma(n/2)} \\
&= \begin{cases} 1 & \text{for } r = 0 \\ \prod_{k=0}^{r-1}(n+2k) & \text{for } r = 1, 2, \ldots \end{cases}.
\end{aligned}$$

If the $m \times 1$ random vector $\mathbf{X}$ has a multivariate normal distribution $\mathcal{N}_m(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ for

$$\boldsymbol{\mu} = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \vdots \\ \mu_m \end{pmatrix},$$

$$\text{and} \quad \boldsymbol{\Sigma} = \begin{pmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1m} \\ \sigma_{21} & \sigma_{22} & \cdots & \sigma_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{m1} & \sigma_{m2} & \cdots & \sigma_{mm} \end{pmatrix}$$

with $\boldsymbol{\Sigma}$ symmetric, positive semidefinite ($\boldsymbol{\Sigma} = \boldsymbol{\Sigma}^{\mathrm{T}}$ and $\mathbf{v}^{\mathrm{T}}\boldsymbol{\Sigma}\mathbf{v} \geq 0$ for all $\mathbf{v}$), then the quadratic form

$$\mathbf{X}^{\mathbf{T}}\boldsymbol{\Sigma}^{-}\mathbf{X} : \chi_r^2(\delta^2) \tag{1}$$

has the noncentral chi-square distribution where $\delta^2 = \boldsymbol{\mu}^{\mathbf{T}}\boldsymbol{\Sigma}^{-}\boldsymbol{\mu}$, the matrix $\boldsymbol{\Sigma}^{-}$ is a generalized inverse of $\boldsymbol{\Sigma}$ that satisfies $\boldsymbol{\Sigma}\boldsymbol{\Sigma}^{-}\boldsymbol{\Sigma} = \boldsymbol{\Sigma}$, and r is the rank of $\boldsymbol{\Sigma}$. If $\boldsymbol{\Sigma}$ is positive definite ($\mathbf{v}^{\mathrm{T}}\boldsymbol{\Sigma}\mathbf{v} > 0$ for all $\mathbf{v} \neq (0, 0, \ldots, 0)^{\mathrm{T}}$), then $\boldsymbol{\Sigma}^{-} = \boldsymbol{\Sigma}^{-1}$ is the inverse and we have full rank $r = m$.

The chi-square distribution lends its name to the chi-square statistic of Karl **Pearson** [4] (*see* **Chi-square Tests**). Let $X_1, X_2, \ldots, X_K$ have a multinomial joint distribution $\mathcal{M}(n, (p_1, p_2, \ldots, p_K))$ given by

$$\begin{aligned}
&P(X_1 = x_1, X_2 = x_2, \ldots, X_K = x_K) \\
&\quad = \frac{n!}{x_1! x_2! \cdots x_K!} p_1^{x_1} p_2^{x_2} \cdots p_K^{x_K},
\end{aligned}$$

where $\sum_{k=1}^K p_k = 1$, $\sum_{k=1}^K x_k = n$, and $x_k \in \{0, 1, \ldots, n\}$. Then for testing the hypothesis

$$\begin{aligned}
H: \mathbf{p} &= (p_1, p_2, \ldots, p_K) = (p_{10}, p_{20}, \ldots, p_{K0}) \\
&= \mathbf{p_0},
\end{aligned}$$

where $\mathbf{p_0}$ is known, against the **alternative** $A: \mathbf{p} \neq \mathbf{p_0}$, we can reject for large values of the chi-square statistic

$$V_n = \sum_{k=1}^K \frac{(X_k - np_{k0})^2}{np_{k0}}.$$

(*see* **Hypothesis Testing**). For *near by* alternatives $p_k = p_{k0} + \eta_k/\sqrt{(n)}$, where $\sum_{k=1}^K \eta_k = 0$, it has a limiting noncentral chi-square distribution

$$V_n \xrightarrow{d} V : \chi_{K-1}^2(\delta^2)$$

as $n \to \infty$, where

$$\delta^2 = \lim_n \sum_{k=1}^K \frac{n(p_k - p_{k0})^2}{p_{k0}} = \sum_{k=1}^K \frac{\eta_k^2}{p_{k0}}.$$

This result uses the multivariate **central limit theorem** that the normalized random variables converge to a multivariate normal as $n \to \infty$:

$$\begin{aligned}
\mathbf{Z}_n^{\mathrm{T}} &= \left(\frac{X_1 - np_{10}}{\sqrt{n}}, \frac{X_2 - np_{20}}{\sqrt{n}}, \ldots, \frac{X_K - np_{K0}}{\sqrt{n}} \right) \\
&\xrightarrow{d} \mathbf{Z}^{\mathrm{T}} : \mathcal{N}_K((\eta_1, \eta_2, \ldots, \eta_K), \boldsymbol{\Sigma}_0),
\end{aligned}$$

where the variance–**covariance matrix** of rank $r = K - 1$ is

$$\begin{aligned}
\boldsymbol{\Sigma}_0 &= \begin{pmatrix} p_{10} & 0 & \ldots & 0 \\ 0 & p_{20} & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & p_{K0} \end{pmatrix} - \begin{pmatrix} p_{10} \\ p_{20} \\ \vdots \\ p_{K0} \end{pmatrix} \\
&\quad \times (p_{10}, p_{20}, \ldots, p_{K0}).
\end{aligned}$$

Using the above quadratic form result (1) with $m = K$ and the generalized inverse

$$\boldsymbol{\Sigma}_0^- = \begin{pmatrix} 1/p_{10} & 0 & \dots & 0 \\ 0 & 1/p_{20} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1/p_{K0} \end{pmatrix},$$

$$\boldsymbol{\Sigma}_0 \boldsymbol{\Sigma}_0^- \boldsymbol{\Sigma}_0 = \boldsymbol{\Sigma}_0,$$

we have

$$V_n = \mathbf{Z}_n^{\mathrm{T}} \boldsymbol{\Sigma}_0^- \mathbf{Z}_n \xrightarrow{d} V = \mathbf{Z}^{\mathrm{T}} \boldsymbol{\Sigma}_0^- \mathbf{Z} : \chi^2_{K-1}(\delta^2),$$

where

$$\delta^2 = (\eta_1, \eta_2, \dots, \eta_K) \boldsymbol{\Sigma}_0^- \begin{pmatrix} \eta_1 \\ \eta_2 \\ \vdots \\ \eta_K \end{pmatrix} = \sum_{k=1}^{K} \frac{\eta_k^2}{p_{k0}}.$$

Setting $\eta_k = 0$ for the hypothesis, we have a limiting central $\chi^2_{K-1}(0)$ null distribution for V_n as $n \to \infty$.

Similar chi-square approximations hold for chi-square statistics in more complicated problems as well as for the generalized **likelihood ratio** statistic $-2\log_e(\lambda)$ of Wilks [6, 7].

Chi-square Distribution

If a random variable Z has a **standard normal** distribution [written $Z \sim \mathrm{N}(0, 1)$], then $W = Z^2$ is said to have a χ^2 distribution with one degree of freedom ($W \sim \chi^2(1)$). If $Z_1, Z_2, \ldots, Z_k$ are independent N (0, 1) random variables, then $W_k = Z_1^2 + Z_2^2 + \cdots + Z_k^2$ is said to have a χ^2 distribution with k degrees of freedom ($W_k \sim \chi^2(k)$). This representation of a χ^2 random variable gives it an additive property important in applications: if U and V are independent random variables, and $U \sim \chi^2(r)$ and $V \sim \chi^2(s)$, then $U + V \sim \chi^2(r + s)$. This enables independent testing procedures of the same hypothesis to be combined.

The importance of the χ^2 distribution in statistical **hypothesis testing** initially derives from the following observation. If a large number n of binomial trials is performed with probability of success p in each trial, and X is the random variable recording the number of successes observed, then the normal approximation to the **binomial distribution** of the random variable X implies that if we write

$$W = \frac{(X - np)^2}{npq} \equiv \frac{(X - np)^2}{np} + \frac{(Y - nq)^2}{nq}, \quad (1)$$

then $W \sim \chi^2(1)$ approximately, where $q = 1 - p$ is the failure probability, and $Y = n - X$ is the number of failures. This generalizes to considering a situation in which on each trial k kinds of outcome can occur (rather than just success or failure), to read:

$$\sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}}$$

has approximately a $\chi^2(k - 1)$ distribution if n is large, with summation $\sum$ over the k classes. This generalization was introduced by Karl Pearson in 1900. It can be applied to test the hypothesis that the probabilities of outcomes corresponding to each of the k classes each have specified values. This is the celebrated **goodness-of-fit** test of Karl Pearson. It extends to testing hypotheses where the probabilities are assumed to have a general structure, as in testing for independence of attributes in a two-way **contingency table**.

Such tests are instances of a general theory of hypothesis tests based on the **likelihood ratio**, which uses chi-square as the large-sample distribution of a test statistic under a null hypothesis (*see* **Likelihood Ratio Tests**).

The probability distribution of a chi-square random variable is described by a **gamma** density, as was already shown in 1852 by the French statistician Irenée-Jules Bienaymé (1796–1878).

Historical detail and an extensive exposition of the theory and applications may be found in [1].

Chi-square Tests

Karl Pearson [34] originated the chi-square test as a goodness of fit test to determine if observed data are consistent with a proposed probability model. To use this test, we must partition the set of possible outcomes into a set of r mutually exclusive categories and count the number of observations falling into each category. The Pearson statistic

$$X^2 = \sum_{i=1}^{r} \frac{(N_i - m_i)^2}{m_i} \tag{1}$$

is an index of discrepancy between a set of observed counts $N_1, N_2, \ldots, N_r$ in the r categories and the corresponding set of expected counts $m_1, m_2, \ldots, m_r$ for the hypothesized probability model. Pearson showed that, as the expected counts increase, the distribution of X^2 approaches a central **chi-square distribution** with $r - 1$ **degrees of freedom** when the null hypothesis is true. Hence, the hypothesized model is rejected when the observed value of X^2 exceeds $\chi^2_{r-1,\alpha}$, the upper α percentile of the central chi-square distribution with $r - 1$ degrees of freedom, for some specified significance level α.

In many situations the expected counts $m_1, m_2, \ldots, m_r$ are functions of unknown parameters that must be estimated from the data. This would occur, for example, in testing the fit of the **normal distribution** with unspecified mean and variance, testing the fit of the **Poisson distribution** with an unspecified mean, or testing the independence hypothesis in a two-way **contingency table**. To achieve an asymptotic chi-square distribution for X^2, the unknown parameters must be estimated in an efficient manner from the observed category counts $N_1, N_2, \ldots, N_r$, and the degrees of freedom of the limiting chi-square distribution must be adjusted for the effective number of estimated parameters. This was pointed out by Fisher [10], who made adjustments to the degrees of freedom in applications to contingency tables. Later, Fisher [11] provided the first proof of the asymptotic chi-square distribution of X^2 in the general case where parameters are estimated from the data. We refer the reader to [6, 23], and [35] for more information on the early development of chi-square tests.

Tests with asymptotic chi-square distributions may also be derived from **likelihood ratio tests**. For testing a composite null hypothesis against a general alternative with data consisting of Poisson, binomial, or **multinomial** counts, the natural logarithm of the likelihood ratio multiplied by -2 has the form

$$G^2 = 2 \sum_{i=1}^{r} N_i \ln\left(\frac{N_i}{\hat{m}_i}\right), \tag{2}$$

where $\hat{m}_1, \hat{m}_2, \ldots, \hat{m}_r$ are **maximum likelihood** estimates of the expected counts for the model corresponding to the null hypothesis. This statistic is often referred to as the *deviance*. The Pearson statistic for a composite null hypothesis has the formula

$$X^2 = \sum_{i=1}^{r} \frac{(n_i - \hat{m}_i)^2}{\hat{m}_i}. \tag{3}$$

Both tests are members of the larger family of power divergence statistics identified by Cressie & Read [7]. Each member of this family of test statistics has the same asymptotic chi-square distribution when the null hypothesis is true, but different members have somewhat different **power** for detecting different types of departures from the null hypothesis in finite samples.

Applications to the analysis of contingency tables include chi-square tests of homogeneity for two or more **binomial distributions** (*see* **Two-by-Two Table**), or tests of homogeneity of two or more multinomial distributions, which are used, for example, to ascertain if different treatments are equally successful for treating a certain health problem. In higher-dimensional contingency tables chi-square tests are used to test hypotheses about various types of conditional independence and to assess the relative fit of members of nested sets of models.

Accurate use of the asymptotic chi-square distributions for these tests requires large values for the expected counts. This is an issue of practical concern as it limits the number of factor levels as well as the number of factors that can be used to cross-classify data in a contingency table. It also limits the number of categories that can be used to test the fit of a continuous distribution. Decisions must be made about both the number of intervals and either interval boundaries or the interval probabilities (*see* **Categorizing Continuous Variables**; **Grouped Data**). The power of the tests to detect deviations from the null hypothesis is also affected by these choices.

Standard formulas for chi-square tests such as (2) and (3) are derived from the assumption that the

observed counts are distributed as either independent Poisson counts, a single multinomial distribution, or a set of two or more independent multinomial or binomial distributions. The use of multinomial or binomial distributions for counts can often be justified through the use of **simple random sampling**. Large international, national, or multicenter health studies, however, often employ more complex sampling schemes which violate these standard assumptions and invalidate the use of some tests (*see* **Surveys, Health and Morbidity**). After reviewing standard applications of chi-square tests, we briefly consider some approaches to developing reliable chi-square tests for complex survey data.

Simple Goodness-of-Fit Tests

We first consider the use of a chi-square test as a goodness-of-fit test for a hypothesized distribution containing no unknown parameters. This is called a test of a simple null hypothesis. To test the simple null hypothesis that a set of observations $X_1, X_2, \ldots, X_n$ is a random sample from a population with continuous distribution function $F(x) = \Pr(X \le x)$, we partition the set of possible values that could be observed into r nonoverlapping intervals, say $(a_0, a_1], (a_1, a_2], \ldots, (a_{r-1}, a_r]$. When the null hypothesis is true, the probability that any single observation X_j falls into the ith interval is

$$\pi_i = \Pr(X_j \text{ falls in } (a_{i-1}, a_i]) = \int_{a_{i-1}}^{a_i} \mathrm{d}F(x), \quad (4)$$

and the expected count for the ith interval is $m_i = n\pi_i$. The null hypothesis is rejected if

$$X^2 = \sum_{i=1}^{r} \frac{(N_i - m_i)^2}{m_i} \ge \chi^2_{r-1,\alpha}.$$

The limiting chi-square distribution has $r - 1$ degrees of freedom because the r counts must satisfy a single constraint,

$$n = \sum_{i=1}^{r} N_i.$$

The interval probabilities and expected counts satisfy corresponding constraints,

$$1 = \sum_{i=1}^{r} \pi_i \quad \text{and} \quad n = \sum_{i=1}^{r} m_i.$$

We illustrate this application of the Pearson statistic with an analysis of the distribution of survival times for male residents of a total care facility.

Example 1

We want to test the null hypothesis that the number of months that male residents of a total care facility survive beyond age 65 has an **exponential** distribution with mean 180 months. Survival times beyond age 65 were recorded for a sample of 48 male residents, and the sorted times are shown in Table 1.

First, we partition the positive part of the real line into four adjacent intervals with probabilities $\pi_1 = \pi_2 = \pi_3 = \pi_4 = 0.25$. The boundaries of the intervals are $a_0 = 0$, $a_1 = -180\ln(0.75) = 51.8$, $a_2 = -180\ln(0.5) = 125.8$, $a_3 = -180\ln(0.25) = 249.5$, and $a_4 = \infty$. The observed counts in these four intervals are (5, 8, 21, 14), the expected counts are $m_1 = m_2 = m_3 = m_4 = 12$, and the value of the Pearson statistic is

$$X^2 = \frac{(5-12)^2}{12} + \frac{(8-12)^2}{12} + \frac{(21-12)^2}{12} + \frac{(14-12)^2}{12} = 12.5.$$

The null hypothesis is rejected at the $\alpha = 0.01$ level of significance because $12.5 > 11.34 = \chi^2_{3,0.01}$. Consequently, the observed data are deemed to be inconsistent with a random sample of 48 survival times from an exponential distribution with mean 180 months.

Other Tests with Limiting Chi-Square Distributions

As previously noted, tests with limiting chi-square distributions are also obtained from likelihood ratio tests. The result that the natural logarithm of a

Table 1 Ordered survival times for male residents (months)

1	89	118	165	203	232	256	295
3	92	127	168	209	233	263	300

52	114	152	191	229	255	280	359

ratio of likelihoods multiplied by -2 has a limiting central chi-square distribution as the sample size becomes large, when the null hypothesis is true, was established under fairly general conditions by Wilks [54] and Wald [53]. For the simple goodness-of-fit test described in the previous section, the test statistic has the form

$$G^2 = 2\sum_{i=1}^{r} N_i \ln\left(\frac{N_i}{m_i}\right). \tag{5}$$

Two other statistics that have received some attention are the Freeman–Tukey [12] statistic

$$\mathrm{FT}^2 = 4\sum_{i=1}^{r}\left(\sqrt{N_i} - \sqrt{m_i}\right)^2 \tag{6}$$

and the Neyman [33] modified chi-square statistic

$$X_m^2 = \sum_{i=1}^{r}\frac{(N_i - m_i)^2}{N_i}. \tag{7}$$

These statistics are all members of the larger class of power divergence statistics identified by Cressie & Read [7]. Using

$$\mathbf{p} = (p_1, p_2, \ldots, p_r)' = \left(\frac{N_i}{n}, \frac{N_2}{n}, \ldots, \frac{N_r}{n}\right)'$$

to denote the vector of observed proportions, and

$$\pi = (\pi_1, \pi_2, \ldots, \pi_r)'$$

to denote the corresponding vector of true probabilities for the hypothesized distribution, the directed divergence of order λ of $\mathbf{p}$ from π is

$$I^{\lambda}(\mathbf{p}, \pi) = \frac{1}{\lambda(\lambda+1)}\sum_{i=1}^{r} p_i\left[\left(\frac{p_i}{\pi_i}\right)^{\lambda} - 1\right].$$

Although this quantity is a metric only for $\lambda = -1/2$, it provides a useful generalized **information** measure of the "distance" between $\mathbf{p}$ and π for any real number λ. For a test of a simple hypothesis, the divergence statistic

$$-2nI^{\lambda}(\mathbf{p}, \pi) = \frac{1}{\lambda(\lambda+1)}\sum_{i=1}^{r} N_i\left[\left(\frac{N_i}{m_i}\right)^{\lambda} - 1\right] \tag{8}$$

has an asymptotic chi-square distribution with $r-1$ degrees of freedom as $n \to \infty$. The Pearson statistic is obtained from (8) when $\lambda = 1$, the deviance is the limit as $\lambda \to 0$, the Freeman–Tukey statistic corresponds to $\lambda = -1/2$, and the Neyman statistic is the limit as $\lambda \to -1$.

For large samples, all members of the power divergence family have distributions that approach the same limiting chi-square distribution when the null hypothesis is correct, but different members may have different power for detecting different kinds of alternatives to the null hypothesis in small and moderate samples. No single member of this family dominates the other members with respect to power against all alternatives. Read & Cressie [43] suggest that values of λ between $\frac{1}{3}$ and $\frac{4}{5}$ provide a good compromise between relatively good power against most alternatives and the ability of the limiting chi-square distribution to approximate the distribution of the test statistic in small samples when the null hypothesis is true. This includes the Pearson statistic but excludes the deviance, Freeman–Tukey, and Neyman statistics. Read & Cressie recommend the power divergence test with $\lambda = \frac{2}{3}$, but we prefer the Pearson statistic because it exhibits very similar properties, it is well known and widely used, and it is commonly available in statistical software packages.

Wald Tests

To provide a broader view of the construction and uses of chi-square tests we consider a general approach for constructing chi-square tests from quadratic forms called Wald statistics (*see* **Likelihood**). The Pearson statistic can be derived as a Wald statistic, but this approach can be used to construct chi-square tests in many situations where the Pearson statistic does not have a limiting chi-square distribution.

To construct a Wald statistic, we must first select an r-dimensional random vector $\mathbf{Y}_n = (Y_{1n}, Y_{2n}, \ldots, Y_{rn})'$ that summarizes how results from a set of n observations deviate from what is expected to occur when the null hypothesis is true. A Wald statistic is a quadratic form,

$$\mathbf{Y}_n'\mathbf{C}\mathbf{Y}_n = \sum_{i=1}^{r}\sum_{j=1}^{r} c_{ij}Y_{in}Y_{jn}, \tag{9}$$

where $\mathbf{C}$ is an appropriate $r \times r$ symmetric matrix, and c_{ij} is the value in the ith row and jth column

of $\mathbf{C}$. To obtain a test statistic with a limiting central chi-square distribution, we must select $\mathbf{Y}_n$ so that it has a limiting multivariate normal distribution with mean vector $\mathbf{0} = (0, 0, \ldots, 0)'$ as $n \to \infty$ when the null hypothesis is true. Finally, the matrix $\mathbf{C}$ must satisfy the condition

$$\mathbf{\Sigma C \Sigma} = \mathbf{\Sigma}, \tag{10}$$

where $\mathbf{\Sigma}$ is the **covariance matrix** for the limiting distribution of $\mathbf{Y}_n$. The number of degrees of freedom for the limiting chi-square distribution of (9) is the trace of the matrix $\mathbf{C\Sigma}$.

If $\mathbf{\Sigma}^{-1}$ exists, then $\mathbf{C} = \mathbf{\Sigma}^{-1}$ is the unique solution to the condition of Eq. (10). It follows that the quadratic form

$$\mathbf{Y}_n' \mathbf{\Sigma}^{-1} \mathbf{Y}_n \tag{11}$$

provides a large sample chi-square test with r degrees of freedom as $n \to \infty$. On the other hand, if $\mathbf{\Sigma}$ does not have an inverse, then there will be an infinite number of choices for $\mathbf{C}$ that satisfy (10). Each of these choices will yield exactly the same value for (9), however, so it does not matter which one is used. In such cases, the degrees of freedom for the chi-square test, given by the trace of $\mathbf{C\Sigma}$, will be less than r. The inverse of $\mathbf{\Sigma}$ will not exist when the components of $\mathbf{Y}_n$ exactly satisfy one or more linear constraints. Then, individual components of $\mathbf{Y}_n$ have perfect **correlation** with linear combinations of other elements of $\mathbf{Y}_n$, so some components of $\mathbf{Y}_n$ are redundant. Another way to deal with this situation is to reduce the dimension of $\mathbf{Y}_n$ by deleting the minimum number of components required to break all of the linear constraints. There are many choices for the subset of components that can be deleted. Each choice corresponds to choosing a different $\mathbf{C}$ to satisfy (10) and results in the same value for the test statistic. Subtracting the number of deleted components from r gives the degrees of freedom for the chi-square test.

We will illustrate this recipe for constructing chi-square tests by using it to construct a simple goodness-of-fit test. In this application the set of possible outcomes is partitioned into a set of r nonoverlapping intervals. We use π_i to denote the probability that a random observation falls into the ith interval when the hypothesized distribution is correct. These probabilities are collected into the vector

$$\boldsymbol{\pi} = (\pi_1, \pi_2, \ldots, \pi_r)'.$$

For a simple random sample of n observations, $X_1, X_2, \ldots, X_n$, the vector of observed counts for the r intervals, $\mathbf{N} = (N_1, N_2, \ldots, N_r)'$, has a multinomial distribution with sample size n and probability vector π when the hypothesized distribution is correct. Using

$$\mathbf{p} = (p_1, p_2, \ldots, p_r)' = \left(\frac{N_1}{n}, \frac{N_2}{n}, \ldots, \frac{N_r}{n}\right)'$$

to denote the vector of observed proportions, we consider the vector of scaled differences

$$\mathbf{Y}_n = n^{1/2}(\mathbf{p} - \boldsymbol{\pi}).$$

When the null hypothesis is true, $\mathbf{Y}_n$ has a limiting normal distribution where the means are all zero and the covariance matrix is $\mathbf{\Sigma} = (\mathbf{\Delta}_{\boldsymbol{\pi}} - \boldsymbol{\pi}\boldsymbol{\pi}')$. Here $\mathbf{\Delta}_{\boldsymbol{\pi}}$ denotes a diagonal matrix with the elements of $\boldsymbol{\pi}$ on the main diagonal. It is easy to verify that $\mathbf{C} = \mathbf{\Delta}_{\boldsymbol{\pi}}^{-1}$ satisfies the condition of (10). Consequently, a large sample chi-square test is given by the quadratic form

$$\begin{aligned}\mathbf{Y}_n' \mathbf{\Delta}_{\boldsymbol{\pi}}^{-1} \mathbf{Y}_n &= n(\mathbf{p} - \boldsymbol{\pi})' \mathbf{\Delta}_{\boldsymbol{\pi}}^{-1} (\mathbf{p} - \boldsymbol{\pi}) \\ &= (\mathbf{N} - \mathbf{m})' \mathbf{\Delta}_{\mathbf{m}}^{-1} (\mathbf{N} - \mathbf{m}),\end{aligned}$$

which is a matrix expression for the Pearson statistic in (1). Here, $\mathbf{m} = n\boldsymbol{\pi}$.

In this case, the Wald statistic is equivalent to the Pearson statistic, but this is not always true. For a simple goodness-of-fit test, appropriate use of the Pearson statistic as a chi-square test depends on $\mathbf{\Sigma}$, the covariance matrix for the limiting normal distribution of $\mathbf{Y}_n = n^{1/2}(\mathbf{p} - \boldsymbol{\pi})$. If $\mathbf{\Delta}_{\boldsymbol{\pi}}$ does not satisfy the condition of (10) for the given $\mathbf{\Sigma}$, then the Pearson statistic is not equivalent to a Wald test and neither the Pearson statistic nor any other member of the family of power divergence statistics has a limiting chi-square distribution.

There are many other uses for Wald tests. For example, $\mathbf{Y}_n$ could be the difference between a vector of parameter estimates and a vector of hypothesized values for those parameters. Then the Wald test is used to simultaneously test that all the hypothesized parameter values are correct. Wald tests also provide a convenient way to obtain large sample chi-square tests for complex survey data.

Theoretical results for asymptotic chi-square distributions of quadratic forms are presented by Serfling [48, pp. 128–130] and Moore & Spruill [31]. Moore [29] provides straight forward extensions

to situations where $\boldsymbol{\Sigma}$ depends on the values of parameters that must be estimated from the data.

Goodness-of-Fit Tests for Composite Hypotheses

Suppose we want to test the composite null hypothesis that observations $X_1, X_2, \ldots, X_n$ were randomly sampled from a population distribution function in some family of distribution functions denoted by $F(x;\boldsymbol{\theta})$, where members of the family are distinguished by a vector of parameters $\boldsymbol{\theta} = (\theta_1, \theta_2, \ldots, \theta_k)'$. For example, we may wish to test the hypothesis that the observed data were randomly sampled from a normal distribution with unknown mean and variance. The construction of a chi-square test for a composite null hypothesis requires estimation of $\boldsymbol{\theta}$ as well as the selection of a partition of the real line into nonoverlapping intervals.

The formula for the test statistic and the related degrees of freedom will depend on the manner in which parameters are estimated and boundaries of the intervals are determined. There are two basic approaches. In the first approach the interval boundaries $-\infty = a_0 < a_1 < \cdots < a_r = \infty$ are selected before the data are observed. Then, the expected counts are functions of unknown parameters that must be estimated from the observed data. The form of the chi-square test and the resulting degrees of freedom will vary depending on whether the original observations, $X_1, X_2, \ldots, X_n$, or the interval counts, $N_1, N_2, \ldots, N_r$, are used to estimate $\boldsymbol{\theta}$. In the second approach, interval probabilities $\boldsymbol{\pi} = (\pi_1, \pi_2, \ldots, \pi_r)'$ are specified. This fixes the values of the expected counts, but the interval boundaries depend on $\boldsymbol{\theta}$ and must be estimated from the observed data before the interval counts can be computed. The first approach is said to use fixed intervals and the second approach is said to use random intervals.

Chi-Square Tests with Fixed Intervals

Without considering the observed data, specify boundaries $-\infty = a_0 < a_2 < \cdots < a_r = \infty$ for r nonoverlapping intervals. Let $\mathbf{N} = (N_1, N_2, \ldots, N_r)'$ denote the corresponding vector of observed counts obtained by classifying the observations, $X_1, X_2, \ldots, X_n$, into the r intervals. The expected count for the jth interval is $m_j(\boldsymbol{\theta}) = n\pi_j(\boldsymbol{\theta})$, where

$$\pi_j(\boldsymbol{\theta}) = \Pr(a_{j-1} < X_i \le a_j) = \int_{a_{j-1}}^{a_j} \mathrm{d}F(x;\boldsymbol{\theta}). \tag{12}$$

The null hypothesis is tested by comparing the observed counts to the estimates of the expected counts obtained by substituting an appropriate estimate of $\boldsymbol{\theta}$ into (12).

The Pearson statistic, or any other member of the power divergence family, provides a test with an asymptotic central chi-square distribution if $\boldsymbol{\theta}$ is estimated from the observed counts $(N_1, N_2, \ldots, N_r)$ instead of the original observations $X_1, X_2, \ldots, X_n$. Typically, the maximum likelihood estimator (mle) of $\boldsymbol{\theta}$ for the multinomial distribution of $(N_1, N_2, \ldots, N_r)$ is used, but any other asymptotically equivalent estimator could also be used.

Example 2

As an illustration, we use the Pearson statistic to test the composite null hypothesis that the data in Table 1 were randomly sampled from an exponential distribution with unknown mean θ. The distribution function is $F(x;\theta) = 1 - \exp(-x/\theta)$ and the density function is $f(x;\theta) = \theta^{-1}\exp(-x/\theta)$ for $x > 0$ and $\theta > 0$. Using the $r = 4$ intervals, (0, 51.8], (51.8, 125.8], (125.8, 249.5], (249.5, ∞], considered in Example 1, the observed counts are $(N_1, N_2, N_3, N_4) = (5, 8, 21, 14)$.

From (12) the probability that a randomly selected observation from the hypothesized distribution falls into the jth interval is

$$\begin{aligned}\pi_j(\theta) &= \int_{a_{j-1}}^{a_j} \theta^{-1}\exp\left(\frac{-x}{\theta}\right)\mathrm{d}x \\ &= \exp\left(\frac{-a_{j-1}}{\theta}\right) - \exp\left(\frac{-a_j}{\theta}\right)\end{aligned} \tag{13}$$

and the expected counts are $m_j(\theta) = n\pi_j(\theta)$, for $j = 1, 2, 3, 4$. An estimate of θ is obtained by maximizing the log **likelihood** function

$$\begin{aligned}l(\theta; N_1, N_2, \ldots, N_r) &= \ln(n!) - \sum_{j=1}^{r}\ln(N_j!) \\ &+ \sum_{j=1}^{r} N_j \ln\left[\exp\left(\frac{-a_{j-1}}{\theta}\right) - \exp\left(\frac{-a_j}{\theta}\right)\right]\end{aligned}$$

for the multinomial distribution of the observed counts. The first derivative of the log likelihood function with respect to θ is

$$S_{\mathbf{N}}(\theta) = \sum_{j=1}^{r} \frac{N_j \partial \pi_j(\theta)}{\pi_j(\theta) \partial \theta} \tag{14}$$

$$= \frac{1}{\theta^2} \sum_{j=1}^{r} \frac{N_j}{\pi_j(\theta)} \left[a_{j-1} \exp\left(\frac{-a_{j-1}}{\theta}\right) - a_j \times \exp\left(\frac{-a_j}{\theta}\right) \right]. \tag{15}$$

This is called the score function. The mle for θ is obtained by setting the score function equal to zero and solving the resulting equation for θ. In this case the solution cannot be expressed as a simple function of the observed counts, but a numerical solution can be obtained. The resulting mle is $\hat{\theta}_{\mathbf{N}} = 239.48$. This estimator is given the subscript **N** to indicate that it is the mle for θ computed from the interval counts.

Substituting $\hat{\theta}_{\mathbf{N}}$ for θ in (13), we obtain estimates of expected counts

$$m_1(\hat{\theta}_{\mathbf{N}}) = 9.34, \qquad m_2(\hat{\theta}_{\mathbf{N}}) = 10.28,$$
$$m_3(\hat{\theta}_{\mathbf{N}}) = 11.45, \qquad n_4(\hat{\theta}_{\mathbf{N}}) = 16.93,$$

and the value of the Pearson statistic is

$$X^2 = \sum_{j=1}^{r} \frac{[N_j - m_j(\hat{\theta}_{\mathbf{N}})]^2}{m_j(\hat{\theta}_{\mathbf{N}})} = 10.99. \tag{16}$$

This test has $r - k - 1 = 4 - 1 - 1 = 2$ degrees of freedom. Since $X^2 = 10.99$ exceeds $\chi^2_{2,0.01} = 9.21$, the hypothesis that the data were sampled from an exponential distribution is rejected at the 0.01 level.

Alternatively, the original observations, $X_1, X_2, \ldots, X_n$, could be used to estimate unknown parameters in the hypothesized family of distributions. This avoids loss of information encountered in using interval counts. When an mle $\hat{\boldsymbol{\theta}}_{\mathbf{X}}$ is computed from the original observations; however, neither the Pearson statistic, nor any other member of the power divergence family of tests, has a limiting chi-square distribution when the null hypothesis is correct. Chernoff & Lehmann [5] showed that the Pearson statistic has a limiting distribution, corresponding to a linear combination of independent chi-square random variables in this case.

Greenwood & Nikulin [14] show that a Wald statistic with a limiting chi-square distribution can be written as the sum of a Pearson statistic and a correction term. In this version of the Pearson statistic, estimates of the expected counts are evaluated using $\hat{\boldsymbol{\theta}}_{\mathbf{X}}$ instead of $\hat{\boldsymbol{\theta}}_{\mathbf{N}}$. The formula for the test statistic is

$$X^2_{\mathrm{NR}} = \sum_{j=1}^{r} \frac{[N_j - m_j(\hat{\boldsymbol{\theta}}_{\mathbf{X}})]^2}{m_j(\hat{\boldsymbol{\theta}}_{\mathbf{X}})} + \mathbf{S}_{\mathbf{N}}(\hat{\boldsymbol{\theta}}_{\mathbf{X}})' [\mathbf{J}_{\mathbf{X}}(\hat{\boldsymbol{\theta}}_{\mathbf{X}}) - \mathbf{J}_{\mathbf{N}}(\hat{\boldsymbol{\theta}}_{\mathbf{X}})]^{-1} \mathbf{S}_{\mathbf{N}}(\hat{\boldsymbol{\theta}}_{\mathbf{X}}), \tag{17}$$

where the $k \times 1$ vector $\mathbf{S}_{\mathbf{N}}(\hat{\boldsymbol{\theta}}_{\mathbf{X}})$ is the score function of the multinomial likelihood for the interval counts $(N_1, N_2, \ldots, N_r)$ evaluated at $\hat{\boldsymbol{\theta}}_{\mathbf{X}}$, $\mathbf{J}_{\mathbf{N}}(\hat{\boldsymbol{\theta}}_{\mathbf{X}})$ is the Fisher **information matrix** for the multinomial likelihood function of the interval counts evaluated at $\hat{\boldsymbol{\theta}}_{\mathbf{X}}$, and $\mathbf{J}_{\mathbf{X}}(\hat{\boldsymbol{\theta}}_X)$ is the Fisher information matrix for the likelihood function of the original observations evaluated at $\hat{\boldsymbol{\theta}}_{\mathbf{X}}$. The large sample chi-square distribution for X^2_{NR} has $r - 1$ degrees of freedom when r intervals are used.

Example 3

As in Example 2, we test the composite null hypothesis that the data in Example 1 were randomly sampled from an exponential distribution with unknown mean θ. We use the same class intervals, but the mle for the hypothesized exponential distribution of $X_1, X_2, \ldots, X_n$ will be used to estimate θ in the evaluation of the expected counts.

The log likelihood function for the hypothesized exponential distribution is

$$l(\theta; \mathbf{X}) = -n \ln(\theta) - \theta^{-1} \sum_{i=1}^{n} X_i.$$

Setting $\partial l(\theta; \mathbf{X})/\partial\theta$ equal to zero and solving the resulting equation yields the sample mean,

$$\hat{\theta}_{\mathbf{X}} = n^{-1} \sum_{i=1}^{n} X_i = 186,$$

as the mle for θ. Substituting $\hat{\theta}_{\mathbf{X}}$ for θ in (13) yields estimates of expected counts

$$m_1(\hat{\theta}_{\mathbf{X}}) = 11.67, \qquad m_2(\hat{\theta}_{\mathbf{X}}) = 12.93,$$
$$m_3(\hat{\theta}_{\mathbf{X}}) = 11.86, \qquad m_4(\hat{\theta}_{\mathbf{X}}) = 12.55,$$

and the resulting value of the Pearson statistic is

$$X^2 = \sum_{j=1}^{r} \frac{[N_j - m_j(\hat{\theta}_{\mathbf{X}})]^2}{m_j(\hat{\theta}_{\mathbf{X}})} = 12.32.$$

To obtain the correction term, we evaluate the multinomial score function given by (15) at $\hat{\theta}_{\mathbf{X}} = 186$ to obtain $S_{\mathbf{N}}(\hat{\theta}_{\mathbf{X}}) = 0.0514814$. Since there is only one parameter, the Fisher information matrix for the multinomial distribution of the interval counts contains a single element

$$J_{\mathbf{N}}(\theta) = \mathrm{E}\left(-\frac{\delta^2 l(\theta;\mathbf{N})}{\delta\theta^2}\right) = \frac{n}{\theta^4}\sum_{j=1}^{r}\frac{1}{\pi_j(\theta)} \times\left[a_{j-1}\exp\left(\frac{-a_{j-1}}{\theta}\right) - a_j\exp\left(\frac{-a_j}{\theta}\right)\right]^2. \tag{18}$$

The Fisher information matrix for the hypothesized exponential distribution of the original observations is

$$J_{\mathbf{X}}(\theta) = \frac{n}{\theta^2}. \tag{19}$$

Evaluating (18) and (19) at $\hat{\theta}_{\mathbf{X}} = 186$ yields $J_{\mathbf{N}}(\hat{\theta}_{\mathbf{X}}) = 0.0010056$, $J_{\mathbf{X}}(\hat{\theta}_{\mathbf{X}}) = 0.0013874$ and a correction of 6.94 to the Pearson statistic. Then, the value of the test statistic is

$$X^2_{\mathrm{NR}} = 12.32 + 6.94 = 19.26.$$

This exceeds $\chi^2_{3,0.001} = 11.34$, and the null hypothesis is rejected at the 0.001 level.

Chi-Square Tests with Random Intervals

In this approach the interval probabilities $\pi_1, \pi_2, \ldots, \pi_k$ are specified and the interval boundaries must be estimated before the counts can be evaluated. For a hypothesized distribution function $F(x;\boldsymbol{\theta})$, the interval boundaries are defined as

$$a_j(\boldsymbol{\theta}) = F^{-1}(\pi_1 + \pi_2 + \cdots + \pi_j;\boldsymbol{\theta}), \tag{20}$$

for $j = 1, 2, \ldots, k$, where $F^{-1}(c;\boldsymbol{\theta}) \equiv \inf[x\colon F(x;\boldsymbol{\theta}) \geq c]$. The boundaries are estimated by replacing $\boldsymbol{\theta}$ in (20) with $\hat{\boldsymbol{\theta}}_X$, the maximum likelihood estimator (mle) computed from the original observations $X_1, X_2, \ldots, X_n$. The count for the jth interval, denoted by N_j^*, is the number of observations falling in the random interval $(a_{j-1}(\hat{\boldsymbol{\theta}}_{\mathbf{X}}), a_j(\hat{\boldsymbol{\theta}}_{\mathbf{X}})]$.

A Wald test with a limiting chi-square distribution when $F(x;\boldsymbol{\theta})$ is the correct distribution function was developed by Rao & Robson [37]. This test statistic can also be written as a Pearson statistic plus a correction term,

$$X^2_{\mathrm{RR}} = \sum_{j=1}^{r}\frac{(N_j^* - n\pi_j)^2}{n\pi_j} + \mathbf{D}(\hat{\boldsymbol{\theta}}_{\mathbf{x}})'[\mathbf{J}_{\mathbf{x}}(\hat{\boldsymbol{\theta}}_{\mathbf{x}}) - n\mathbf{W}(\hat{\boldsymbol{\theta}}_{\mathbf{x}})\boldsymbol{\Delta}_{\boldsymbol{\pi}}^{-1}\mathbf{W}(\hat{\boldsymbol{\theta}}_{\mathbf{x}})]^{-1}\mathbf{D}(\hat{\boldsymbol{\theta}}_{\mathbf{x}}), \tag{21}$$

where $\boldsymbol{\Delta}_{\boldsymbol{\pi}}$ is a diagonal matrix with the elements of $(\pi_1, \pi_2, \ldots, \pi_k)$ on the main diagonal, $\mathbf{W}(\hat{\boldsymbol{\theta}}_{\mathbf{X}})$ is a $k \times r$ matrix with (i, j) element

$$w_{ij} = f[a_{j-1}(\theta);\theta]\frac{\partial a_{j-1}(\theta)}{\partial\theta_i} - f[a_j(\theta);\theta]\frac{\partial a_j(\theta)}{\partial\theta_i},$$

and $\mathbf{D}(\hat{\boldsymbol{\theta}}_{\mathbf{X}})$ is a $k \times 1$ vector where the ith element is

$$d_i = \sum_{j=1}^{r} w_{ij}\frac{N_j^*}{\pi_j}.$$

Here $f(x;\boldsymbol{\theta})$ is the density function for the hypothesized distribution.

Example 4

We test the composite null hypothesis that the data in Table 1 are a random sample from an exponential distribution with unknown mean θ. From Example 3, $\hat{\theta}_{\mathbf{X}} = 186$, and taking $\pi_1 = \pi_2 = \pi_3 = \pi_4 = 0.25$, the interval boundaries are estimated as

$$a_j(\hat{\theta}_{\mathbf{X}}) = -\hat{\theta}_{\mathbf{X}}\ln\left(\frac{1-j}{r}\right).$$

Consequently, the intervals are (0, 53.51], (53.51, 128.93], (128.93, 257.85], (257.85, ∞], the observed counts are $(N_1^*, N_2^*, N_3^*, N_4^*)$ = (6,8,23,11), and

$$X^2 = \sum_{j=1}^{r}\frac{(N_j^* - n/r)^2}{n/r} = 14.5.$$

The correction term is evaluated with

$$\frac{\partial a_j(\theta)}{\partial\theta_i} = -\ln\left(\frac{1-j}{r}\right)$$

and

$$w_{ij} = \hat{\theta}_{\mathbf{X}}^{-1}\left\{\ln\left(\frac{1-j}{r}\right)\exp\left[-a_j\frac{\hat{\theta}_{\mathbf{X}}}{\hat{\theta}_{\mathbf{X}}}\right] - \ln\left[1 - \frac{j-1}{r}\right]\exp\left[-a_{j-1}\frac{\hat{\theta}_{\mathbf{X}}}{\hat{\theta}_{\mathbf{X}}}\right]\right\}.$$

Then,

$$\mathbf{W}(\hat{\theta}_{\mathbf{X}}) = [-0.001160, -0.000703, 0, 0.001863],$$

$\mathbf{D}(\hat{\theta}_{\mathbf{X}}) = 0.031639$, and

$$X^2_{\mathrm{RR}} = 14.5 + 2.72 = 17.22,$$

with $r - 1 = 3$ degrees of freedom. This test also rejects the null hypothesis that the observations were sampled from an exponential distribution at the 0.001 level.

Greenwood & Nikulin [14] provide a thorough review of chi-square tests with fixed and random intervals that includes proofs of the asymptotic chi-square distributions. Special formulas are presented for testing the fit of the normal distribution, **location-scale families** of continuous distributions, and both discrete and continuous members of the **exponential family** of distributions. They also review the literature on selection of intervals and the small sample behavior of these tests.

Selection of the number of intervals and either the interval boundaries or the interval probabilities affects both the power of a test to detect deviations from the hypothesized distribution and the accuracy of the chi-square distribution as an approximation of its finite sample distribution when the hypothesized distribution is correct. Generally, r equiprobable intervals are recommended when nothing is assumed about likely alternatives to the hypothesized distribution. Since accurate use of the asymptotic chi-square approximation requires large expected counts, r should not be taken to be too large. Choosing a value for r that is either too large or too small may reduce the power of the test against many alternatives. For a sequence of tests with $r = 2, 3, 4, \ldots$ equiprobable intervals, power against most alternatives initially increases, reaches a maximum at some value of r, and then declines as more intervals are used. Based on a large-sample approximation derived by Mann & Wald [26] and later refined by Schorr [47], Moore [30] recommends using roughly $r = 2n^{2/5}$ equiprobable intervals for a sample of n observations. Simulation results reported by Koehler & Gan [21] suggest that using fewer intervals, say $r = n^{2/5}$, provides better power against many alternatives. Greenwood & Nikulin [14] recommend $r \leq \min[\alpha^{-1}, \ln(n)]$, where α is the significance **level of the test**.

Simulation result reported by Kallenberg [18] indicate that appreciable gains in power can sometimes be achieved by using nonequiprobable intervals. Power for detecting heavy tailed alternatives, for example, may be improved by using more intervals with smaller probabilities in the tails of the distribution. A greater gain in power against a specific class of alternatives can often be achieved, however, by using a test that more directly focuses on the specific class of alternatives than the omnibus chi-square tests considered in (16), (17), and (21).

In testing the fit of a continuous distribution, the conversion of the original observations $X_1, X_2, \ldots, X_n$ into interval counts generally results in some loss of information. When the values of $X_1, X_2, \ldots, X_n$ are available, more powerful goodness-of-fit tests can be obtained from methods based on empirical distribution functions or probability plots. A variety of such tests are reviewed by Stephens [49, 50]. Unlike the chi-square tests considered in (16), (17), and (21), these tests typically do not have convenient asymptotic distributions. Limiting distributions generally depend on the hypothesized distribution and they are often intractable. Tables of finite sample percentiles (*see* **Quantiles**) exist for testing the fit of a few distributions, but use of these tests may require **Monte Carlo simulation** of finite sample critical values.

Finally, tests with asymptotic chi-square distributions that use the original observations and do not require the classification of observations into intervals can be derived from the asymptotic normality of the score function for the hypothesized distribution. Such tests are called score tests. Further power can be gained by restricting attention to classes of alternative distributions with density functions that deviate in a smooth manner from the density for the hypothesized distribution. These are called smooth tests of goodness of fit. Derivations and applications of score tests and smooth tests are reviewed by Rayner & Best [41], who recommend the use of smooth tests for testing the fit of continuous distributions and the use of the Pearson statistic for discrete distributions.

Applications to Categorical Data

Chi-square tests provide the primary method for making inferences from categorical response data. This

Table 2 A two-way contingency table

Row factor	Column factor $j=1$	$j=2$	...	$j=J$	Row totals
$i=1$	N_{11}	N_{12}	...	N_{15}	N_{1+}
$i=2$	N_{21}	N_{22}	...	N_{25}	N_{2+}
$i=I$	N_{I1}	N_{I2}	...	N_{IJ}	N_{I+}
Column totals	N_{+1}	N_{+2}	...	N_{+J}	N_{++}

includes tests of independence and homogeneity in contingency tables and tests of significance about parameters in **logistic regression** models and other **generalized linear models**. We restrict out attention to tests of independence or homogeneity in two-way contingency tables. Additional applications can be found in any book on logistic regression analysis, generalized linear models, or **categorical data analysis**. These include the pioneering work on **loglinear models** by Bishop et al. [3] and the more recent overview of categorical data analysis by Agresti [2]. Fienberg [9] provides a good introduction to both the asymptotic theory for chi-square tests and their use in categorical data analysis.

In the construction of a two-way contingency table, each observed response is classified with respect to a finite set of exhaustive and nonoverlapping categories for each of two factors. The form of the table is shown in Table 2, where N_{ij} is the number of responses achieving both the ith level of the row factor and the jth level of the column factor. The Pearson statistic for testing the null hypothesis of independence (or no association) between the row and column factors is

$$X^2 = \sum_{i=1}^{I}\sum_{j=1}^{J} \frac{(N_{ij} - \hat{m}_{ij})^2}{\hat{m}_{ij}}, \tag{22}$$

where $\hat{m}_{ij}$ is the maximum likelihood estimate of the expected count given by the formula

$$\hat{m}_{ij} = \frac{(\text{row total}) \times (\text{column total})}{(\text{total for entire table})} = \frac{N_{i+}N_{+j}}{N_{++}}. \tag{23}$$

The deviance, or likelihood ratio test statistic, is

$$G^2 = 2\sum_{i=1}^{I}\sum_{j=1}^{J} N_{ij} \ln\left(\frac{N_{ij}}{\hat{m}_{ij}}\right). \tag{24}$$

When the independence hypothesis is true, both X^2 and G^2, as well as any other member of the power divergence family, have asymptotic chi-square distributions with $(I-1)(J-1)$ degrees of freedom if the counts are independent Poisson counts, or the entire table of counts has a multinomial distribution, or the rows of the table correspond to independent multinomial or binomial distributions, or the columns of the table correspond to independent multinomial or binomial distributions.

Example 5

As part of a survey of attitudes toward primary health care education and practice, independent random samples of first-year medical students, fourth-year medical students and postgraduate residents were taken from national databases of the American Medical Association and the Association of American Medical Colleges [4]. Table 3 summarizes the specialty orientation of the respondents. Each column in this table corresponds to an independent multinomial distribution with four response categories.

In this case, the test of the hypothesis of independence of intended specialty and academic status is a test of homogeneity of the distributions across intended specialties for the three groups. Table 4 shows the estimates of the expected counts obtained from (23). The values of the Pearson statistic and the deviance are $X^2 = 14.50$ and $G^2 = 14.64$, respectively, both with $(4-1)(3-1) = 6$ degrees of freedom. The independence hypothesis is rejected at the 0.025 level of significance. Further inspection of data reveals a slightly lower percentage of first-year students orientated toward specialist careers, a lower percentage of fourth-year students interested in internal medicine, and a slightly lower percentage of residents orientated toward mixed and primary care practice.

Table 3 Specialty orientation of respondents

Specialty	Academic status Year 1	Year 4	Residents	Totals
Specialists	127	174	366	667
Internal medicine	29	19	72	120
Mixed	24	19	32	75
Primary care	71	95	175	341
Totals	251	307	645	1203

Table 4 Expected counts for Table 3

Specialty	Academic status			Totals
	Year 1	Year 4	Residents	
Specialists	139.17	170.21	357.62	667
Internal medicine	25.04	30.62	64.34	120
Mixed	15.65	19.14	40.21	75
Primary care	71.15	87.02	182.83	341
Totals	251	307	645	1203

This example illustrates the most basic application of a chi-square test to the analysis of a contingency table. For details on applications to more complex hypotheses, see **Categorical Data Analysis**, **Contingency Table**, and **Loglinear Model**.

It is important to realize that the X^2 and G^2 tests used in the previous example are not appropriate for all tables of counts. When entries in a contingency table do not correspond to either independent Poisson counts, or a single multinomial distribution, or several independent multinomial (binomial) distributions, then neither the Pearson statistic, nor the deviance, nor other members of the power divergence family will have limiting chi-square distributions. Such tables of counts arise from the use of complex sampling schemes involving various levels of **stratification** and **cluster sampling**. They can also arise in the analysis of **longitudinal** studies and repeated measures studies, where several responses are obtained from each respondent. Some care must be exercised in constructing the table of counts and selecting the test statistic.

As a simple illustration of a repeated measures study, we consider the much analyzed vision data for 7477 women, aged 30–39, employed in Royal Ordnance factories in Britain. These data were analyzed by Stuart [51], Grizzle et al. [15], and Bishop et al. [3], among others. Each woman received two classifications: one for quality of vision in the left eye and the other for quality of vision in the right eye. To test if the distributions across the four vision categories are the same for right and left eyes, one might consider computing the Pearson statistic for the counts in Table 5. The large sample chi-square approximation to the distribution of the Pearson statistic is inappropriate in this situation because it incorrectly treats the rows of Table 5 as two independent multinomial distributions. The rows of Table 5 are not independent multinomial distributions because vision quality in the right eye has a positive correlation with vision quality in the left eye of individual women.

Example 6

To obtain a Wald statistic with a limiting chi-square distribution, we must create a table of counts showing both the left and right eye results for each woman in the study. This is done in Table 6, where each woman appears in exactly one cell of the table. A multinomial distribution with 16 categories is appropriate for the counts in this table. We want to test the hypothesis that the distribution of the row totals is the same as the distribution of the column totals. This is called a test of marginal homogeneity.

To derive a Wald statistic, we use $\mathbf{N}_L = (1907, 2222, 2507)'$ to denote the column vector of counts in the three highest categories for left eye quality. Similarly, we use $\mathbf{N}_R = (1976, 2256, 2456)'$ to denote a column vector of counts in the three highest categories for right eye quality. Corresponding vectors of proportions are $\mathbf{P}_L = \mathbf{N}_L/n$ and $\mathbf{P}_R = \mathbf{N}_R/n$, and we can express the marginal homogeneity hypothesis as $E(\mathbf{P}_L - \mathbf{P}_R) = \mathbf{0}$. The proportions for the fourth vision category are not needed because proportions are constrained to sum to one across the four categories for both the right and left eyes.

Table 5 Vision quality for women employed in Royal Ordnance factories

Eye	Vision category				Totals
	Highest	Second	Third	Lowest	
Left	1907	2222	2507	841	7477
Right	1976	2256	2456	789	7477
Totals	3883	4478	4963	1630	14 954

Table 6 Vision quality for women employed in Royal Ordnance factories

Right eye category	Left eye vision category				Totals
	Highest	Second	Third	Lowest	
Highest	1520	266	124	66	1976
Second	234	1512	432	78	2256
Third	117	362	1772	205	2456
Lowest	36	82	179	492	789
Totals	1907	2222	2507	841	7477

Then, an appropriate Wald statistic is

$$X^2_{\mathrm{MH}} = n(\mathbf{P}_{\mathrm{L}} - \mathbf{P}_{\mathrm{R}})'\mathbf{V}^{-1}(\mathbf{P}_{\mathrm{L}} - \mathbf{P}_{\mathrm{R}}), \qquad (25)$$

where $\boldsymbol{V}$ is a consistent estimate of the covariance matrix for $\sqrt{n}(\mathbf{P}_{\mathrm{L}} - \mathbf{P}_{\mathrm{R}})$. A formula for $\boldsymbol{V}$ is derived from the multinomial distribution for the counts in Table 6 by noting that $\mathbf{P}_{\mathrm{L}} - \mathbf{P}_{\mathrm{R}} = \mathbf{AP}$, where $\mathbf{P} = n^{-1}(N_{11}N_{12}N_{13}N_{14}N_{21}\ldots N_{44})'$ denotes the sample proportions from Table 6 arranged as a 16×1 column vector and

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 1 & 1 & -1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & -1 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 0 & -1 & 0 & 1 & 1 & 0 & 1 & 0 & 0 & -1 & 0 \end{bmatrix}$$

Since $\mathbf{P}$ is a consistent estimate of the probability vector for 16 joint vision categories, it follows that

$$\mathbf{V} = \mathbf{A}(\boldsymbol{\Delta}_{\mathbf{P}} - \mathbf{PP}')\mathbf{A}$$

is a consistent estimator for the covariance matrix of $\sqrt{n}(\mathbf{P}_{\mathrm{L}} - \mathbf{P}_{\mathrm{R}})$.

Evaluating $\boldsymbol{V}$, $\mathbf{P}_{\mathrm{L}}$, and $\mathbf{P}_{\mathrm{R}}$ from the data in Table 6, $X^2_{\mathrm{MH}} = 11.96$ with three degrees of freedom and the P value = 0.0075. The quality of vision is not the same for both eyes, and further inspection of the data reveals that quality of vision tends to be higher in the right eye for this population of women.

For additional details and illustrations, see **Square Contingency Table** and **Matched Pairs With Categorical Data**.

Randomization and Conditional Tests

The large-sample chi-square distribution for the Pearson statistic is also justified through randomly assigning subjects to treatment groups. When the treatments are equally effective, the randomization distribution of the possible values of X^2 corresponding to the possible random allocations of subjects to treatment groups will approximately have a chi-square distribution (*see* **Randomization Tests**). The chi-square approximation becomes more accurate as the number of subjects increases.

We could compute an exact P value for a randomization test searching through all possible tables of counts with the same row and column totals as the observed table of counts to determine the number of tables with larger X^2 values than the X^2 value for the observed table (*see* **Fisher's Exact Test**). Development of high-speed computers and efficient algorithms, like the Mehta & Patel [28] algorithm, which is able to avoid searching large blocks of tables with small X^2 values, have made it possible to apply this approach to moderately large tables. When the row and column totals are sufficiently large or the number of cells in the table is sufficiently large, even the most efficient search can overwhelm any computer. One alternative to searching through all the possible random allocations is to approximate the exact P value from the results of a sample from the possible random allocations. Agresti [1] provides an extensive review of randomization tests for contingency tables that includes a discussion of the controversy over the use of tests that condition on observed marginal counts.

Small Samples and Sparse Tables

The central chi-square distribution is a limiting distribution for X^2, G^2, and other members of the power divergence family as expected counts become infinitely large. It may not provide an accurate approximation to the distribution of these statistics if too many of the expected counts are too small. The point at which the chi-square approximation begins seriously to deteriorate depends on many factors, including the number of cells in the table, the total sample size, the relative sizes of the expected counts, and the formula for the test statistic.

A commonly used rule of thumb is that no expected count should be smaller than 1 and at least 80% of the expected counts should be no less than 5. This was part of the recommendations made in Cochran's extremely influential paper [6] on chi-square tests. While this rule of thumb guarantees accurate use of the chi-square distribution in computing P values for the Pearson statistic, simulation studies by Roscoe & Byars [45], Radlow & Alf [36], Larntz [24], Koehler & Larntz [22], and Read [42], among others, have shown that it can be relaxed for some members of the power divergence family. Larntz [24] found that the chi-square approximation for X^2 was reasonably accurate when expected counts were all larger than 1. Koehler & Larntz [22] found that the chi-square approximation for G^2 deteriorates sooner, leading to inflated type I error levels when many expected counts are between

1 and 5 and to deflated type I error levels and substantial loss of power when many expected counts were smaller than 1. Read [42] found that in sparse tables the chi-square distribution provided the most accurate approximation to exact P values for members of the power divergence family with λ in the interval [1/3, 3/2]. This includes X^2, but excludes G^2 and the Freeman–Tukey tests. This conclusion is supported by results reported by Kallenberg et al. [19], Rudas [46], Margolin & Light [27], and Hosmane [17]. Read & Cressie [43] recommend the power divergence statistic with $\lambda = 2/3$, but the Pearson statistic exhibits nearly the same behavior.

All members of the power divergence family of test statistics have discrete distributions, and finding a continuous distribution that provides a good general approximation for sparse tables is difficult. When a few, say k, of the r cells in a table of counts have very small expected counts, X^2 essentially behaves as if the table only had the $r - k$ cells with the large expected counts, with the exception of small probabilities at extreme values in the right tail of the distribution. The $C(m)$ distribution proposed by Cochran [6] and further studied by Yarnold [55] and Lawal & Upton [25] provides a good approximation to the distribution of X^2 in such situations. The $C(m)$ distribution is the distribution of a chi-square random variable with reduced degrees of freedom added to a weighted sum of squares involving independent Poisson random variables with small means. Although this approximation is useful for understanding the behavior of X^2 in the presence of small expected counts, it has limited practical value because percentiles of the $C(m)$ distribution depend on the number and values of the small expected counts in the table.

Given the current availability of high-speed computers, attractive alternatives to approximating the distribution of X^2, or some other member of the power divergence family, for sparse tables involve simulating the exact distribution of the statistic or computing P values from an exact conditional distribution of the test statistic. The randomization test of independence in a two-way contingency table discussed earlier is an example of an exact conditional test.

We have focused this discussion on tests of a null hypothesis against a completely general or unrestricted set of alternatives. Chi-square approximations for the distributions of X^2 and G^2 can provide reliable inferences in sparse tables of counts if the null hypothesis is tested against a suitably restricted alternative. For example, Haberman [16] showed that chi-square tests can be used to compare the fit of two nested loglinear models to sparse contingency tables (*see* **Hierarchical Models**). The basic criteria are that the number of parameters in the larger model and the difference in the number of parameters in the two models both must be small relative to the total sample size and number of cells in the table.

Correlated Responses and Complex Surveys

When a table of counts is obtained by adding across clusters and strata in a complex survey, neither the Pearson statistic nor other members of the power divergence family have asymptotic chi-square distributions when the null hypothesis is true. Rao & Scott [38] give a detailed account of the impact of survey design on the distribution of X^2 and G^2. Unless some adjustment is made to the standard chi-square approximation, positive correlations among responses within clusters lead to inflated type I error levels for both X^2 or G^2. Computing cell counts in a contingency table by combining results from different strata can have the opposite effect. If data from individual respondents are available, a Wald statistic with an asymptotic chi-square distribution can be constructed as described by Koch et al. [20]. Simulated comparisons of type I error levels and power for sparse tables, reported by Thomas & Rao [52], show that Wald tests can become unstable for cluster sampling when there are few clusters relative to the number of cells in the table, often resulting in inflated type I error levels. A **jackknife method** proposed by Fay [8] was shown to have better properties over a wide range of conditions.

Sometimes complete data for the individual respondents are not readily available and results from complex surveys are summarized as a table of counts with accompanying information of the survey **design effects**. In these situations there is not enough information to either evaluate a Wald statistic or use Fay's jackknife method. Rao & Scott [39] showed how to create approximate chi-square tests by using the information in the survey design effects to make simple adjustments to X^2 and G^2. The Thomas &

Rao [52] study also showed that these adjusted tests provide relatively accurate P values.

Roberts et al. [44] and Rao et al. [40] use similar adjustments for survey design effect to make inferences about parameters in logistic regression models fit to data from complex surveys. Morel [32] developed Wald tests for logistic regression. Gleser & Moore [13] review the literature regarding the application of goodness-of-fit tests to counts obtained from serially dependent observations and show that positive **serial correlation** also inflates type I error levels of chi-square tests.

KENNETH KOEHLER

Chi-square, Partition of

If ν is a positive integer, then the χ^2 random variable $\chi^2(\nu)$ with ν df is the sum of ν squared mutually independent standard normal random variables (*see* **Chi-square Distribution**). Thus the χ^2 variable has the additive property that, for positive integers ν and ν_j, $1 \le j \le k$, $k \ge 2$, a χ^2 variable with ν df decomposes into a sum of k mutually independent χ^2 variables, $\chi^2(\nu_j)$, with respective ν_j df, $1 \le j \le k$, if $\nu = \Sigma_{j=1}^{k} \nu_j$.

In the case of quadratic functions of normal variables, the Fisher–Cochran theorem (Cochran [1], Rao [30, p. 185]) provides a necessary and sufficient condition for a sum of squares to be decomposed into independent components with χ^2 distributions. Let Y_i, $1 \le i \le \nu$, be ν independent standard normal variables, and let $\mathbf{Y}$ be the n-dimensional column vector with coordinates Y_i for $1 \le i \le n$. For $1 \le j \le k$, let $\mathbf{A}_j$ be a symmetric $n \times n$ matrix with rank ν_j. Let

$$\mathbf{Y}'\mathbf{Y} = \sum_{j=1}^{k} \mathbf{Y}'\mathbf{A}_j\mathbf{Y}.$$

Then the $\mathbf{Y}'\mathbf{A}_j\mathbf{Y}$, $1 \le j \le k$, are independent $\chi^2(\nu_j)$ variables if and only if $\nu = \sum_{j=1}^{k} \nu_j$.

Such additive properties can be used in statistical inferential procedures. A χ^2 statistic suitable for testing a primary hypothesis of interest can be partitioned into components such that each component is a test statistic for a corresponding secondary hypothesis. Under certain conditions, such partitioning can lead to an insightful analysis of the problem under study.

Chi-Square Partitioning into Chi-Square Components

One of the earliest uses of a partition of a χ^2 statistic is found in Fisher [4, Chapter 9], who applies a χ^2 decomposition to study linkage in self-fertilized heterozygote corn plants. A general description of this approach is found in Cochran [2]. An additional early application appears in Haldane [20]. This approach is analogous to decompositions of treatment sums of squares in one-way **analysis of variance**. Let n_i, $1 \le i \le I$, be frequencies with a **multinomial distribution** with sample size N and with respective probabilities p_i. Consider the simple hypothesis that $p_i = q_i$, $1 \le i \le I$, where the probabilities q_i are positive and have sum 1. Let $m_i = Nq_i$ be the expectation of n_i under the null hypothesis. The classical Pearson χ^2 statistic is then

$$X^2 = \sum_{i=1}^{I} (n_i - m_i)^2/m_i$$

(*see* **Chi-square Tests**). As is well known, under the null hypothesis, X^2 has an asymptotic $\chi^2(I - 1)$ distribution. Fisher suggests use of fixed scores x_{ij}, $1 \le i \le I$, $1 \le j \le I - 1$, such that

$$\sum_{i=1}^{I} q_i x_{ij} = 0, \quad 1 \le j \le I - 1,$$

$$\sum_{i=1}^{I} q_i x_{ij} x_{ik} = 0, \quad 1 \le j < k \le I - 1,$$

and

$$d_j = \sum_{i=1}^{I} q_i x_{ij}^2 > 0, \quad 1 \le j \le I - 1.$$

If

$$Y_j = \left[\sum_{i=1}^{k} x_{ij} n_i\right]^2 \Big/ (nd_j^2), \quad 1 \le j \le I - 1,$$

then

$$X^2 = \sum_{j=1}^{I-1} Y_j.$$

Under the null hypothesis the Y_j, $1 \le j \le I - 1$, are asymptotically mutually independent random variables with χ^2 (1) distributions. This decomposition is particularly useful if the linear combinations $\sum_{i=1}^{I} p_i x_{ij}$, $1 \le j \le I - 1$, are meaningful in the problem under study.

Chi-square partitions have been considered for the χ^2 test of independence of two polytomous variables. Consider an $I \times J$ **contingency table** with frequencies n_{ij}, $1 \le i \le I$, $1 \le j \le J$. Let the frequencies have a multinomial distribution with sample size N and respective positive probabilities p_{ij}. Let

$$n_{i\cdot} = \sum_{j=1}^{J} n_{ij}$$

and

$$n_{\cdot j} = \sum_{i=1}^{I} n_{ij}.$$

Let $\hat{m}_{ij} = n_{i\cdot} n_{\cdot j}/N$. The customary Pearson χ^2 test statistic,

$$X^2 = \sum_{i=1}^{I} \sum_{j=1}^{J} (n_{ij} - \hat{m}_{ij})^2/\hat{m}_{ij},$$

and the customary **likelihood ratio test** statistic,

$$L^2 = 2 \sum_{i=1}^{I} \sum_{j=1}^{J} n_{ij} \log(n_{ij}/\hat{m}_{ij}),$$

both have asymptotic $\chi^2_{(I-1)(J-1)}$ distributions under the null hypothesis of independence of row and column variables. An early suggestion of a partition appears in Pearson [28], who suggests the decomposition

$$X^2 = \sum_{i=1}^{I} X_i^2,$$

where

$$X_i^2 = \sum_{j=1}^{J} (n_{ij} - \hat{m}_{ij})^2/\hat{m}_{ij}.$$

This decomposition is exact, but the components do not have asymptotic χ^2 distributions. As in Lancaster [26] and Williams [31], an exact partition of X^2 may be based on the approach of Fisher [4]. Conditional on the observed marginal totals $n_{i\cdot}$ and $n_{\cdot j}$, select scores $x_{ii'}, 1 \le i \le I, 1 \le i' \le I-1$ and $y_{jj'}, 1 \le j \le J, 1 \le j' \le J-1$, so that

$$\sum_{i=1}^{I} n_{i\cdot} x_{ii'} = 0, \quad 1 \le i' \le I-1,$$

$$\sum_{i=1}^{I} n_{i\cdot} x_{ii'} x_{ii''} = 0, \quad 1 \le i' < i'' \le I-1,$$

$$c_i = \sum_{i=1}^{I} n_{i\cdot} x_{ii'}^2 > 0, \quad 1 \le i' \le I-1,$$

$$\sum_{j=1}^{J} n_{\cdot j} y_{jj'} = 0, \quad 1 \le j' \le J-1,$$

$$\sum_{j=1}^{J} n_{\cdot j} y_{jj'} y_{jj''} = 0, \quad 1 \le j' < j'' \le J-1,$$

$$d_j = \sum_{j=1}^{J} n_{\cdot j} y_{jj'} > 0, \quad 1 \le j' \le J-1.$$

Let

$$X^2_{i'j'} = \frac{N \left(\sum_{i=1}^{I} \sum_{j=1}^{J} n_{ij} x_{ii'} y_{jj'} \right)^2}{c_{i'} d_{j'}},$$

$$1 \le i' \le I, 1 \le j' \le J.$$

Then

$$X^2 = \sum_{i'=1}^{I-1} \sum_{j'=1}^{J-1} X^2_{i'j'}. \tag{1}$$

Under the null hypothesis, the $X^2_{i'j'}$ are asymptotically mutually independent $\chi^2_{(1)}$ random variables. Cochran [3] provides a number of analyses which exploit this decomposition technique for applications such as testing for a linear trend in binomial proportions across levels of a quantitative covariate (*see* **Trend Test for Counts and Proportions**) and testing conditional independence between two binary variables while controlling for a third variable.

Lancaster [26] uses a special case of (1) to suggest an approximate partition of X^2 based on conventional χ^2 tests of independence for two-by-two contingency tables formed from the original table. This approximate partition is considered in Cochran [2], Kimball [24], and Kastenbaum [23], among others.

Kullback [25, pp. 173–174] and Gabriel [5] use L^2 to obtain decompositions based on tests of independence of subtables and tests of independence of collapsed tables. Let U be a partition of the integers 1 to I into p nonempty disjoint sets, and let V be a partition of the integers 1 to J in q nonempty disjoint sets. For a nonempty subset A of the integers 1 to I and a nonempty subset B of the integers 1 to J, let

$$n_{AB} = \sum_{i \in A} \sum_{j \in B} n_{ij}, \qquad n_{A\cdot} = \sum_{i \in A} n_{i\cdot},$$

$$n_{\cdot B} = \sum_{j \in B} n_{\cdot j}, \qquad n_{Aj} = \sum_{i \in A} n_{ij}, \quad 1 \le j \le J,$$

and

$$n_{iB} = \sum_{j \in B} n_{ij}, \quad 1 \le i \le I.$$

Let

$$L^2_{\cdot\cdot} = 2\sum_{A\in U}\sum_{B\in V} n_{AB}\log\left(\frac{Nn_{AB}}{n_{A\cdot}n_{\cdot B}}\right)$$

be the *generalized likelihood ratio* χ^2 statistic for testing the hypothesis $H_{\cdot\cdot}$ of independence for the collapsed $p \times q$ table with elements n_{AB} for A in U and B in V, let

$$L^2_{A\cdot} = 2\sum_{i\in A}\sum_{B\in V} n_{iB}\log\left(\frac{n_{iB}n_{A\cdot}}{n_{i\cdot}n_{\cdot B}}\right), \quad A \in U,$$

be the likelihood ratio χ^2 statistic for testing the hypothesis $H_{A\cdot}$ of independence for the column-collapsed subtable with elements n_{iB} for i in A and B in V, let

$$L^2_{\cdot B} = 2\sum_{A\in U}\sum_{j\in B} n_{Aj}\log\left(\frac{n_{Aj}n_{\cdot B}}{n_{A\cdot}n_{\cdot j}}\right), \quad B \in V,$$

be the likelihood ratio χ^2 statistic for testing the hypothesis $H_{\cdot B}$ of independence for the row-collapsed subtable with elements n_{Aj} for A in U and j in B, and let

$$L^2_{AB} = 2\sum_{i\in A}\sum_{B\in V} n_{iB}\log\left(\frac{n_{iB}n_{A\cdot}}{n_{i\cdot}n_{\cdot B}}\right), \quad A \in U, B \in V,$$

be the likelihood ratio χ^2 statistic for testing the hypothesis H_{AB} of independence for the subtable with elements n_{ij} for i in A and j in B.

Independence of the row and column variables of the original table holds if and only if $H_{\cdot\cdot}$ holds, $H_{A\cdot}$ holds for all A in U, $H_{\cdot B}$ holds for all B in V, and H_{AB} holds for all A in U and B in V. Thus

$$L^2 = L^2_{\cdot\cdot} + \sum_{A\in U} L^2_{A\cdot} + \sum_{B\in V} L^2_{\cdot B} + \sum_{A\in U}\sum_{B\in V} L^2_{AB}.$$

This decomposition may help to explain the dependence in the original table in terms of dependence in selected subtables and collapsed tables.

Let $f(A)$ denote the number of elements in a set A. Let

$$\nu_{\cdot\cdot} = (p-1)(q-1), \qquad \nu_{A\cdot} = [f(A)-1](q-1),$$

$$\nu_{\cdot B} = (p-1)[f(B)-1],$$

and

$$\nu_{AB} = [f(A)-1][f(B)-1],$$

so that

$$(I-1)(J-1) = \nu_{\cdot\cdot} + \sum_{A\in U}\nu_{A\cdot} + \sum_{B\in V}\nu_{\cdot B} + \sum_{A\in U}\sum_{B\in V}\nu_{AB}.$$

Adopt the convention that a χ^2 variable with zero degrees of freedom is a random variable which is always zero. The components in this decomposition are asymptotically independent under the null hypothesis and have asymptotic χ^2 distributions. Under the null hypothesis, the following asymptotic approximations apply:

$$L^2_{\cdot\cdot} \sim \chi^2(\nu_{\cdot\cdot}), \qquad L^2_{A\cdot} \sim \chi^2(\nu_{A\cdot}), \qquad L^2_{\cdot B} \sim \chi^2(\nu_{\cdot B}),$$

and

$$L^2_{AB} \sim \chi^2(\nu_{AB}).$$

Iverson [22] provides examples of repeated application of this decomposition. Replacement of likelihood ratio χ^2 statistics with Pearson χ^2 statistics leads to an approximate partition of χ^2 that includes Lancaster's decomposition as a special case. Gilula & Krieger [9, 10] derive a different yet analogous way of partitioning χ^2 which is exact for both L^2 and X^2.

Decompositions of the Pearson χ^2 have been much less successful in the case of multiway contingency tables, with the notable exception of Cochran's [3] decomposition of the Pearson χ^2 for conditional independence. An early attempt by Lancaster [27] was shown by Plackett [29] to be unsatisfactory. Useful χ^2 decompositions for multiway tables appear in Kullback [25, pp. 159–171], Goodman [11–14] and Haberman [18, Chapter 4]. These decompositions are based on likelihood ratio tests.

The likelihood ratio χ^2 provides a very general source of partitions of χ^2. In a typical example, a d-dimensional parameter $\boldsymbol{\theta}$ with coordinates θ_j, $1 \le j \le d$, is used to specify the distribution of some n-dimensional random vector $\mathbf{Y}$. The parameter $\boldsymbol{\theta}$ is in the interior of a d-dimensional parameter space Θ. Associated with the observation $\mathbf{Y}$ is a likelihood function L on Θ. Let $\boldsymbol{\gamma}$ be a member of the interior of Θ, and let γ_i be the ith coordinate of $\boldsymbol{\gamma}$. For each integer q from 0 to d, consider the hypothesis H_q that $\theta_i = \gamma_i$, $q < i \le d$. Let M_q be the maximum value of the likelihood $L(\hat{\boldsymbol{\theta}}_q)$ under the condition that $\hat{\boldsymbol{\theta}}_q$ is in Θ and has ith coordinate equal to γ_i

for $i > q$. Let $q(j), 1 \le j \le k, k > 1$, be integers such that $0 \le q(1), q(k) \le d$, and $q(j) < q(j+1)$ for $1 \le j < k$. Let

$$L^2(q, r) = 2\log(M_r/M_q)$$

be the likelihood ratio χ^2 for the null hypothesis that H_q and the alternative hypothesis H_r for $0 \le q < r \le d$. Integers q and r are given such that $r < q < d$. For any $q(j), 1 \le j \le k, k \ge 2$, such that $0 \le q(1), q(k) \le d$, and $q(j) < q(j+1), 1 \le j < k$, one obtains the decomposition

$$L^2[q(1), q(k)] = \sum_{j=1}^{k-1} L^2[q(j), q(j+1)].$$

Under common regularity conditions, $L^2[q(1), q(k)]$ and $L^2[q(j), q(j+1)]$ have asymptotic χ^2 distributions under $H_{q(1)}$, and the $L^2[q(j), q(j+1)]$ are asymptotically independent.

Of particular interest is the decomposition of χ^2 in Goodman [12] for a three-way contingency table. Let n_{ijk} be an $I \times J \times K$ contingency table which represents a cross classification of the polytomous variables A, B, and C, respectively, so that n_{ijk} is the number of observations with $A = i$, $B = j$, and $C = k$. In the proposed decomposition, H_1 is the hypothesis that A, B, and C are mutually independent, H_2 is the hypothesis that A and B are jointly independent of C, H_3 is the hypothesis that A and C are conditionally independent given B, H_4 is the hypothesis that A, B, and C are related by a model of no three-factor interaction, and H_5 is the saturated model that makes no assumptions about the relationships among A, B, and C. One obtains the decomposition

$$L^2(1,5) = L^2(1,2) + L^2(2,3) + L^2(3,4) + L^2(4,5).$$

In this decomposition, $L^2(1,2)$ is the conventional likelihood ratio χ^2 for a test of marginal independence of A and B, $L^2(2,3)$ is the conventional likelihood ratio χ^2 for a test of independence of B and C, $L^2(3,4)$ is the test of interaction of A and C given validity of the model of no three-factor interaction, and $L^2(4,5)$ is the test of validity of the model of no three-factor interaction. The statistic $L^2(1,5)$ is a test of validity for the model of mutual independence of A, B, and C. For generalizations to more complex tables, see [13] and [14].

Partitioning of χ^2 can also be used in contexts different from contingency tables and categorical data (e.g. [6]).

Chi-Square Partitioning into Non-Chi-Square Components

Hirschfeld [21] provides an alternative decomposition of the Pearson χ^2 based on canonical correlations. This decomposition forms the basis of **correspondence analysis** [17]. Consider the two-way table with frequencies $n_{ij}, 1 \le i \le I, 1 \le j \le J$, sample size N, and cell probabilities p_{ij}. Let

$$p_{i\cdot} = \sum_{j=1}^{J} p_{ij}, \quad 1 \le i \le I,$$

and

$$p_{\cdot j} = \sum_{i=1}^{I} p_{ij}, \quad 1 \le j \le J,$$

denote the row and column marginal probabilities, respectively. Let $K = \min(I-1, J-1)$. Then the canonical decomposition of p_{ij} is

$$p_{ij} = p_{i\cdot}p_{\cdot j}\left(1 + \sum_{k=1}^{K} \rho_k t_{ik} u_{jk}\right), \tag{2}$$

where ρ_k is nonincreasing in k,

$$\sum_{i=1}^{I} p_{i\cdot} t_{ik} = \sum_{j=1}^{J} p_{\cdot j} u_{jk} = 0, \quad 1 \le k \le K,$$

and

$$\sum_{i=1}^{I} p_{i\cdot} t_{ik} t_{ik'} = \sum_{j=1}^{J} p_{\cdot j} u_{jk} u_{jk'} = \begin{cases} 1, & k = k', \\ 0, & k \ne k'. \end{cases}$$

The canonical decomposition of n_{ij} is

$$n_{ij} = \hat{m}_{ij}\left(1 + \sum_{k=1}^{K} r_k \hat{t}_{ik} \hat{u}_{jk}\right), \tag{3}$$

where $|r_k|$ is nonincreasing in k,

$$\sum_{i=1}^{I} n_{i\cdot} \hat{t}_{ik} = \sum_{j=1}^{J} n_{\cdot j} \hat{u}_{jk} = 0, \quad 1 \le k \le K,$$

and

$$\sum_{i=1}^{I} n_{i\cdot}\hat{t}_{ik}\hat{t}_{ik'} = \sum_{j=1}^{J} n_{\cdot j}\hat{u}_{jk}\hat{u}_{jk'} = \begin{cases} N, & k = k', \\ 0, & k \neq k'. \end{cases}$$

With this decomposition, the Pearson χ^2 statistic X^2 for testing independence of row and column variables satisfies

$$X^2 = N\sum_{k=1}^{K} r_k^2 = \sum_{k=1}^{K} W_k^2,$$

where

$$W_k^2 = N^{-1}\left(\sum_{i=1}^{I}\sum_{j=1}^{J} n_{ij}\hat{t}_{ik}\hat{u}_{jk}\right)^2.$$

Unless $K = 1$, this decomposition does not lead to components with χ^2 distributions, as shown in Haberman [19]. Nonetheless, the size of the W_k^2 does provide an indication as to which ρ_k may be zero. Goodman [15, 16] and Gilula & Haberman [7, 8], among others, consider models in which, for some integer q from 0 to K, it is assumed that $\rho_k = 0$ for $k > q$.

Choi–Williams Distribution

The Choi–Williams distribution is a transform that represents the **spectral** content of nonstationary signal with a bidimensional time–frequency map. How well a time-frequency distribution represents a nonstationary signal depends on how fast the changes in the frequency content of the signal are. When they are relatively slow, the standard method of representation is the spectrogram, that is, the calculation of the Fourier (*see* **Fast Fourier Transform (FFT)**) spectrum over a short-time running window. When the spectral characteristics change more rapidly, a higher resolution in time and frequency is needed, and methods like the **Wigner–Ville Distribution** are preferred. A large class of time–frequency distributions of a signal $s(t)$ can be defined as

$$P(t,\omega) = \frac{1}{4\pi^2}\iiint s^*\left(t-\frac{1}{2}\tau\right)s\left(t+\frac{1}{2}\tau\right) \times e^{-j\theta t - j\omega\tau + j\theta u}\phi(\theta,\tau)\,\mathrm{d}u \times \mathrm{d}\tau \times \mathrm{d}\theta \quad (1)$$

where $s^*(t)$ is the complex conjugate of $s(t)$, ω is the angular frequency $2\pi f$, and $\phi(\theta,\tau)$ is a kernel that defines the type of distribution. For

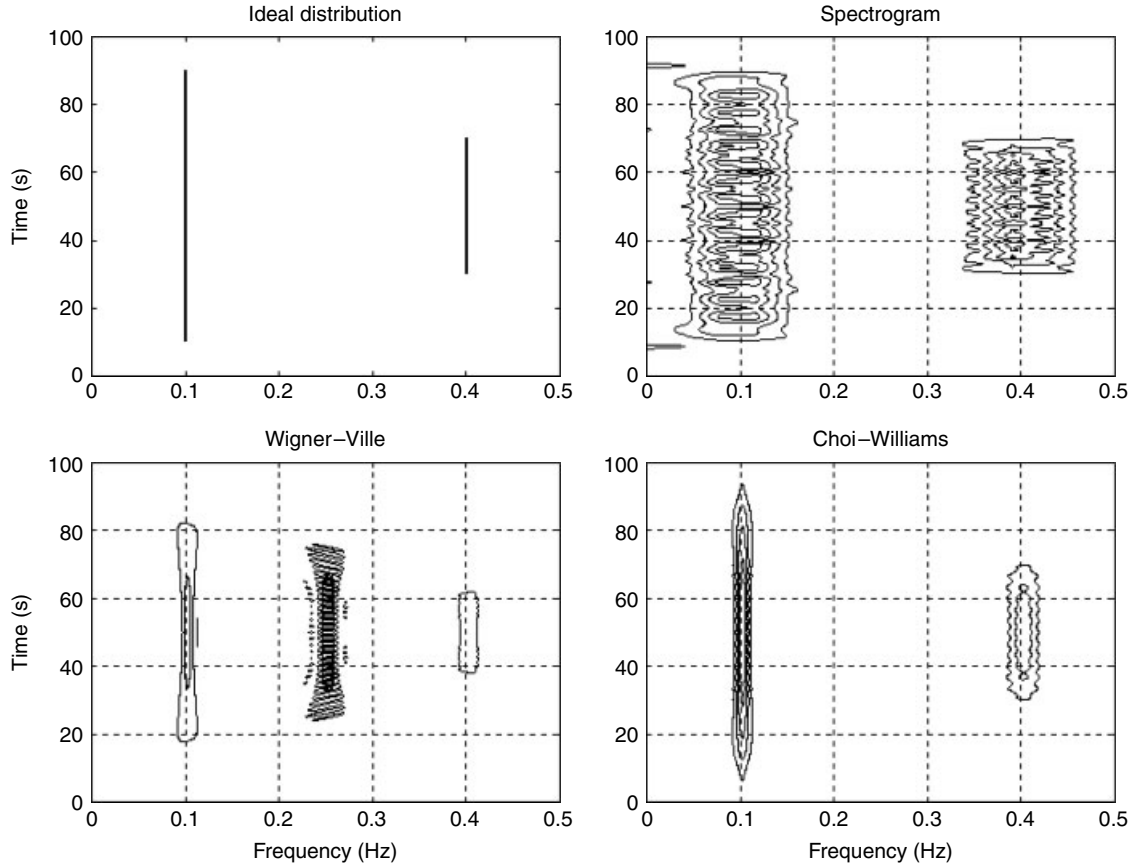

Figure 1 Comparison of time–frequency distributions for a multicomponent signal $s(t) = s_1(t) + s_2(t)$, where $s_1(t)$ is a 0.1-Hz sinusoid defined between 10 and 90 s and $s_2(t)$ is a 0.4-Hz sinusoid defined between 30 and 70 s. One expects an "ideal" distribution to show just two components, one at 0.1 Hz and one at 0.4 Hz, within the time periods 10–90 s and 30–70 s respectively. The spectrogram is a low-resolution approximation of the ideal distribution; the Wigner–Ville distribution shows a better resolution but also significant interferences; the Choi–Williams distribution provides a large suppression of interference terms with only a little loss in resolution

instance, (1) defines the Wigner–Ville distribution when $\phi(\theta, \tau) = 1$ and a spectrogram with running window $h(t)$ when $\phi(\theta, \tau) = \int h^*(u - \frac{1}{2}\tau)h(u + \frac{1}{2}\tau)e^{-j\theta u}\,\mathrm{d}u$ [4].

Choi and Williams started from (1) to address one of the main problems of the Wigner–Ville distribution: the presence of interference terms. These are spurious values indicating powers in regions of the time–frequency plane where one would expect zero values, and they are particularly prevalent in multicomponent signals. Their approach was to find the kernel $\phi(\theta, \tau)$ that minimizes the interference terms while still retaining the desirable properties of the Wigner–Ville distribution. They proposed the kernel

$$\phi(\theta, \tau) = e^{-\theta^2\tau^2/\sigma} \tag{2}$$

where σ is a parameter controlling the attenuation of interference terms [3]; the smaller σ is, the more the interferences are suppressed. Unfortunately, increased attenuation also leads to a loss of resolution in the time–frequency plane. By properly tuning σ, one can minimize the interferences and retain a sufficient time–frequency resolution.

Figure 1 compares the Choi–Williams distribution of a multicomponent signal with the spectrogram and the Wigner–Ville distribution. The Choi–Williams representation of the signal can largely suppress interference terms while still preserving a high resolution.

Choi–Williams distributions were used to describe the changes in the frequency content of several biological signals (*see* **Clinical Signals**), like the sounds produced by muscles [1] or the structure of heart-rate signals during changes in the autonomic tone [2].

PAOLO CASTIGLIONI

Chronic Disease Models

Modeling chronic disease in human populations requires different substantive and technical principles than in modeling acute infectious and epidemic disease (e.g. [5, 54]). One is that the natural history of a chronic disease is a significant portion of the life span, e.g. atherosclerosis may start by ages 10–15 – autopsy studies of accident victims showed well developed atheromas in males aged 20–25 [74]. Lung tumors may initiate 10–50 years before clinical expression [55] (*see* **Latent Period**). Evidence is mounting that infectious agents can increase chronic disease risks. *Helicobacter pylori* (discovered in 1983) is a causative factor, not only in gastritis, but also in gastric ulcers [35], cancer [28, 73], lymphoma, and liver cancer [69]. Antibodies to *Chlamydia pneumoniae*, a pathogen causing pneumonia, bronchitis, pharyngitis, and sinusitis, have been isolated from atheromas [31]. Some models of long-term changes in circulatory disease risk (and certain cancers) implicate livestock viral infections as well as chronic infection with CMV or Epstein–Barr virus (e.g. [64]).

Because of the long natural history of chronic disease, there is more potential to interact with other diseases (e.g. diabetes and atherosclerosis), risk factor exposures (e.g. cigarette **smoking**; obesity), and age-related declines in physiology (e.g. senescent amyloid changes in the myocardium [38, 43], and temporally accumulated ischemic damage [46]). At late ages (e.g. 95+ years), distinguishing between chronic diseases and age-related losses of physiological function is difficult without biologically informed dynamic models (*see* **Mathematical Biology, Overview**) (e.g. [38, 47]), because multiple age-dependent interactions exist between chronic diseases processes – interactions perturbed by exogenous factors. Thus, it is necessary to model disease behavior as a multidimensional stochastic system evolving according to internally programmed age dynamics [91] and influenced by environmentally induced damage [98].

Chronic disease model applications encounter statistical problems such as (i) estimating parameters for high dimensional processes from partial, cross-temporal data measured with error, and (ii) the interdependence of mortality and state dynamic processes. **Longitudinal** studies of human chronic diseases do not provide sufficiently fine grained and lengthy **time series** data on physiological changes to construct models without extensive theory or ancillary data [79]. This is because the measurement burden on subjects in practice limits the number of time points sampled on chronic disease processes (e.g. every 1, 2, or 5 years) compared with the usual density of samples of processes in time series analyses (e.g. [2]). Additionally, missing data [71] problems arise as a result of left and right **censoring**.

Consequently, it is necessary to combine temporally sparse observations made of a disease with other empirical and theoretical information in a global **likelihood** function (e.g. [53]). This allows data sets with different observational strengths and measurement characteristics to be combined in a model of a complex system subject to chronic functional loss on multiple dimensions, and multiple functionally dependent modes of failure. Combined correctly, the complementary strengths of data sets can improve parameter estimates (e.g. [51]). Model-based data combining is different than in **meta-analysis of clinical trials** (e.g. [19, 20, 34]) in that instead of increasing statistical **power** about a hypothesis (e.g. the effects of chemotherapy on breast cancer survival) by "pooling" cases from observationally equivalent studies, the precision of the parameters in a highly structured process model are improved using data sets covering *heterogeneous* age/time and substantive domains. This is akin to the use of stochastic compartment models in **pharmacokinetics** (e.g. [39]), and complex biological systems (e.g. [61]), to make estimates of transitions through intermediate, unobserved states from the correlation of the temporal scheduling of multiple system inputs and outputs. In such models the focus is on "temporal" homogeneity, i.e. observations of individuals in different stages of a process but following similar trajectories. Thus, all individuals do not have identically the same parameter values, or exist in the same stage of the process; rather, processes are assumed to be described by the same systems of partial differential equations.

Because of these, and other, statistical issues modeling chronic disease requires specialized analytic and data-collection procedures. In what follows we discuss several data sets and the chronic disease features they describe. We then discuss data use in chronic disease modeling.

Observation Plans for Chronic Disease Processes

We review the properties of four observational plans.

Longitudinal Cohort Studies

The classic longitudinal **cohort study** of chronic disease and risk factors is the **Framingham Heart Study**, begun in 1949–1950 [16], of a cohort of 2336 males and 2873 females initially aged 29–62 years, where multiple risk factors (e.g. blood glucose, blood pressure, cholesterol, cigarette smoking, hematocrit, vital capacity, BMI) were assessed biennially. In addition, the times to health events (some clinically determined, e.g. by EKG) or death are recorded. The exams now constitute a long time series, covering a large portion of the adult life span, on changes of multiple risk factors. Biennial assessments allowed frequent updating of risk factor–disease relationships (e.g. [41]). Biennial data have also been used to update risk factor–disease relationships by using concurrent values at each wave and, assuming conditional (on measured risk factor values) independence of events in subsequent biennial periods, treating each interval as an observation on the process [96]. Though improving **logistic regression** estimates, this does not use data on risk factor changes – and their cross-temporal covariances – to estimate the age trajectories of measured risk factors, or latent state variables [14]. Feskens et al. [25, 26] showed how longitudinal data could be used to infer the parameters of the individual's physiological dynamics.

Over time, the Framingham study changed. Risk factors were added (e.g. assessments of cholesterol components such as high and low density lipoproteins) and some dropped (e.g. uric acid about wave 4). Ancillary samples (e.g. Framingham offspring) were generated. Other risk factors [e.g. Lp(a) [15, 83] and homocysteinemia [7]; fibrinogen and hyperhomocysteinemia interactions [90]] were less completely assessed so that hazard estimates may be affected by unobserved or incompletely observed risk factors.

Other longitudinal studies were started in the 1960s, often with similar risk factors (e.g. blood pressure, smoking, cholesterol, weight and height), but with longer intervals between measurements. Follow-up periods of five to 10 years were used in the Seven Country [45] and Charleston Heart Studies [44]. Longer intervals make models describing risk factor and disease dynamics for incompletely observed processes more important.

Additionally, focus shifted from examining circulatory disease risks in middle-aged (generally male) populations, to studying a range of diseases, and total mortality, in elderly male and female populations. This was because early goals were reached (i.e. significant associations of risk factors with circulatory diseases, such as cholesterol with CHD, were demonstrated) and because many studies were initiated during a period (1954–1968) when US male mortality *increased* 0.2% per year – and shortly after the 1930s and 1940s when male CHD risk increased in the US and the UK [42]. Indeed, US life expectancy was thought as possibly having reached biological limits in the 1960s [67]. Limits were built into the 1974 Social Security Trust Fund projections [66]. Social epidemiologists theorized that chronic disease risks were intrinsic to industrial societies (e.g. [18] and [70]).

In fact, female mortality declined 0.8% per annum from 1954 to 1968. Adult male CHD mortality began declining after 1968. From 1950 to 1991, age standardized US heart disease mortality declined 53%; stroke mortality 70% [68]. However, the causes of such declines could not be identified with existing data [88]. Early CVD risk factor interventions often did not reduce total mortality [65], sometimes due to adverse effects on other chronic diseases (e.g. diuretics initially used to lower blood pressure adversely affected mortality in diabetics, [92]), making it necessary to jointly examine multiple causes of death and multiple health outcomes (e.g., JAMA estrogen and program study, July 17, 2002). As **life expectancy** above age 65 (and 85) increased in the US and other developed countries (e.g. Japan, France, Sweden [60]), the need to extend existing cohort studies to describe risk factor–disease relationships to late ages became evident (*see* **Gerontology and Geriatric Medicine**). Rapid physiological change, the multiplicity of interacting chronic disease *and* disability processes, and the high levels of mortality at ages 80+ emphasized the need for biologically motivated, gender-specific models [56].

Sequential and Parallel Cross-Sectional Studies

If the nature of chronic disease–risk factor relationships were established in cohort studies, other studies

were needed to assess risk factor variation across populations. The WHO "MONICA" (Monitoring of trends and determinants in cardiovascular disease) studies assessed age and gender-specific trends in CVD risk factors in developing and developed countries (*see* **Surveillance of Diseases**). These studies, started 1985–1987, monitored mortality and risk factor changes in men and women aged 25–64 for 10 years. Forty-one centers in 27 countries used standardized protocols to monitor 118 populations containing 15 million persons aged 25–64. Two null hypotheses were examined. First that there was no relationship between 10-year trends in cholesterol, blood pressure, and smoking and CVD. Some centers examined HDL and LDL cholesterol and physical activity. The second was that there was no relationship between 10-year trends in 28 day case fatality rates and acute coronary care.

To evaluate the first hypothesis risk factor surveys were to be done at the beginning and end of the study period by drawing independent gender-specific **random samples** of at least 200 cases for each 10 years of age category from 25 to 64 from target populations. Survey data collection was standardized for demographic variables, smoking status, hypertension (and medications), blood pressure, cholesterol, serum thiocyanate, height, and weight. Ten-year risk factor trends were evaluated from distributional (means and variances) changes between the two independent samples.

Evaluation of the second hypothesis required sufficient events to have an 80% power for detecting a 2% per annum change in CVD incidence over 10 years, significant at a 5% level using a two-tailed test (*see* **Sample Size Determination**). Thus, each study had to generate a minimum of 240 morbid events per year for ages 25–64. Depending on local CVD rates this required populations of about 300 000. Standardized procedures were used to monitor disease events, and acute coronary care [89]. Morbid events were monitored using **death certificates** and by identifying heart attack and other CVD events from hospital records with either "hot" (i.e. screening admissions) or "cold" (i.e. abstracting discharge records) pursuit. Results on myocardial infarctions and coronary deaths reported for 38 populations in 21 countries refute the suggestion that high CHD rates are associated with high **case fatality** rates [89]. This study design has the problem that independent sampling of the continuous risk factor distribution at 0 and 10 years provides little power to distinguish risk factor changes due to period vs. cohort effects (*see* **Age–Period–Cohort Analysis**).

Measurement and Modeling. If models of risk factor and mortality processes are not used to analyze disease–risk dynamics, then additional measurement issues arise. Law et al. [49] examined the relationship between cholesterol and IHD mortality in 21 535 men followed from 1975 to 1982. Cholesterol was measured twice over three years on 5696 men with LDL cholesterol assessed in the second examination. Although cholesterol is "stable" (in contrast, say, to systolic blood pressure) it exhibited significant **regression to the mean**, i.e. the cholesterol–IHD relationship was underestimated by 41% (equivalent to the ratio of total, to between person, variance of cholesterol). Surrogate dilution bias arose by measuring total cholesterol instead of LDL (*see* **Measurement Error in Epidemiologic Studies**). Total cholesterol represents the net effect of trends in HDL ("good") and LDL ("bad") cholesterol. Surrogate dilution bias reduced the estimated effect of cholesterol on mortality by 14%. Bias was found at all ages examined. In a **stochastic process** model, regression to the mean would be represented as the balance of autoregressive (*see* **ARMA and ARIMA Models**) and diffusive forces and surrogate dilution bias by influential unmeasured variables [1]. The short study period suggests mortality selection bias would be small.

Law et al. [48] examined lags between cholesterol and IHD risk, reductions using incidence and cholesterol data from 10 prospective (cohort) studies, three international studies in multiple communities, and 28 randomized controlled trials. Estimates of regression to the mean, and surrogate dilution, bias were used to adjust observational study results. In cohort studies a 10% decrease in cholesterol was associated with a 27% decline in IHD (adjusted for blood pressure and smoking). This relationship held to at least age 80 (where the IHD reduction was 19%). In randomized trials, after five years, IHD risk reduction was 25%, or 92.6% of the total effect in cohort studies. Thus, not only was atherosclerosis reversible (e.g. [8] and [72]), but reversal could occur rapidly – even before the structural regression of atheromas [3, 6]. This suggests that the rate of progression of the physiological dynamics of IHD can be changed sufficiently in five years to prevent

pathological processes from passing a clinical threshold. Also, it suggested that atherosclerotic disease affected acute (e.g. within four months) physiological changes (e.g. vasodilation and vasoconstriction due to neuroendocrine factors [6]) interacting with chronic processes.

National Longitudinal Surveys

Risk factor–chronic disease relationships can be statically modeled using nationally representative surveys (*see* **Surveys, Health and Morbidity**). The US National Health and Nutrition Examination Surveys were done four times 1960–1962 to 1990–1994. The first, the National Health Examination Survey (NHESI; $N = 7710$ adults age 18–79; response rate 86.5%) measured chronic disease prevalence and risk factors including blood pressure and cholesterol. A nutrition component was added to create the 1971–1974 National Health and Nutrition Examination Survey (NHANESI; $N = 28\,048$ noninstitutionalized persons age 1–74; the response rate was 96%; 78% were examined). NHANES-II was conducted from 1976 to 1980 for a sample of 27 801 noninstitutionalized persons aged 6 months to 74 years, 73.1% of whom were examined. NHANES-III was done over six years, 1988–1994, in two phases. In Phase I, 20 277 persons were sampled; 77% were examined. Results from Phase I show that certain year 2000 goals of the 1988 National Cholesterol Education Program were achieved by 1991 [40, 84]. Comparisons of cholesterol, hypertension, and smoking across the four surveys show that they declined from 1960 to 1990 for persons aged 65–74 [68]. Phase II of NHANES-III (1991–1994) involved sampling another 20 000 persons. Risk factors were followed with new emphasis on studying the natural history of chronic diseases. In addition, longitudinal follow-ups of health outcomes for 10+ years were done for the second and third surveys (e.g., National Health and Examination Follow-Up Survey 1971–1984; NHEFS-I [24]).

Combined Select Population and Registry Data

A fourth observation plan combines "select" and "registered" population data (e.g. [22]). Studies were done of mesothelioma and cancer risks in asbestos exposed occupational groups (*see* **Occupational Epidemiology**) as well as disease risks in populations with healthy life styles (e.g. Seventh Day Adventists [50] and Mormon High Priests in California [21]). NCI's Surveillance of Epidemiology and End Results (SEER) program of population-based tumor registries does data base of occupational studies of ionizing radiation [11] (*see* **Disease Registers**), and geographic monitoring of cancer mortality rates using vital statistics (*see* **Geographic Epidemiology**), put select population results into a national context.

For example, the absolute risk of lung cancer mortality among former smokers was examined in the American Cancer Society, Cancer Prevention Study II (CPS-II), a prospective cohort study of 1.2 million voluntary participants, begun in 1982, and analyzed after six years of follow-up. Roughly 900 000 persons were analyzed after excluding persons below age 40, above 80, or with smoking cessation before age 30, or after 75.

A "person-time" logistic regression model, where each subject had a separate entry for each year in the study, was used. A quadratic function of age provided a good fit to the risk of lung cancer death with gender, education, and smoking as covariates. **Spline** terms were added for each five years of age cohorts of former smokers. To fit risks for quit smokers, quadratic and cubic functions of time elapsed after cessation were used. **Goodness of fit** was tested using a statistic due to Hosmer & Lemeshow [36].

The study showed that smoking cessation produced benefits at all ages, e.g. the risk of smokers quitting in their early 60s was 45% of continuing smokers. The analyses did not explicitly use a **multistage model of carcinogenesis** [33] so the polynominals used to describe the health effects of quitting smoking are difficult to interpret biologically.

Innovations in Measurements of Chronic Disease Processes

Measurement of Disease Risk at the Cellular Level. Refinements in measurement were made possible by new **assays** [e.g. polymerase chain replication (PCR) and enzyme-linked immunosorbent assay (ELISA)] of nuclear and mitochrondrial DNA. This stimulated the development of **molecular epidemiology** where biomarkers of risk factor exposures are examined [76]. Biomarkers may be genetic damage caused by carcinogens forming

nuclear DNA adducts, or changes in oncogene or tumor suppressor gene (e.g. P-53) expression that can trigger, or block, tumor initiation. Other biomarkers are acquired traits affecting carcinogen metabolism (e.g. metabolizing enzyme production stimulated by exposure), or DNA damage and repair (e.g. DNA repair methyltransferase [82]). Assays of cellular DNA have also proved useful in determining the effects of viruses on cancer and other chronic diseases (e.g. the role of viruses, or immunological response to viruses, in CVD [64]).

In molecular epidemiology, biomarkers are used in **cross-sectional**, **retrospective**, prospective, or **case–control studies**. By analyzing biomarkers, disease processes can be identified early, thereby increasing the likelihood of developing preventative strategies and reducing the time necessary to identify the emergence of disease in exposed organisms.

In a study of 40 persons having smoked at least one pack per day for one year, blood samples were drawn while smoking, and at 2.5, 8 and 14 months after cessation. Smoking abstinence was monitored by measuring plasma cotinine. PAH–(polycyclic aromatic hydrocarbons, e.g. benzo [α] pyrene [32]) DNA adducts in white blood cells was twofold higher while smoking than after eight months of abstinence. A regression model of log transformed biomarkers, adjusted for background, suggested a half-life of 23.4 weeks for PAH–DNA adducts. The coefficient of variation for PAH–DNA adducts was 106%, suggesting a high degree of intraindividual variability in response to exposure. These and other data suggest a higher degree of female physiological lung cancer susceptibility to smoking products [63, 78, 100].

In a second study, lung tissue was taken from persons undergoing surgery for lung cancer ($n = 54$) or noncancer pulmonary disease ($n = 20$). Phase-I cytochrome P-450 enzymes responsible for metabolizing smoking chemical constituents into carcinogens were increased by the stimulus of smoking varying from 11-fold to 440-fold between individuals. Certain Phase-II cytochrome P-450 enzymes responsible for detoxifying activated carcinogens [e.g. glutathione S-transferase (GST)] were decreased and varied 17-fold over individuals. Thus, smoking increased cancer risks by differentially affecting Phase I and II enzymes in the cytochrome P-450 system [30] with large interindividual variation in activity [77]. Another study suggested that vitamins C and E significantly reduced PAH–DNA adducts *only* in persons with a null GSTM1 (a **genotype** which may be 50% prevalent [32]). Thus, the antitumor effects of micronutrients may strongly interact with the genotype.

These studies directly examine the biochemistry of physiological processes leading to disease initiation. This detects pathological changes early, and perhaps better identifies genetic risk. It has the difficulty that, by isolating specific disease components, producing a model of the natural history of the disease in an individual, or of a disease's effect on a population (especially given high variability in individual enzyme levels), is made difficult and makes greater demands on theory, e.g. using a parametric **Weibull** hazard for the multistage model of carginogesis [99].

Modeling Shared and Correlated Frailty. To study chronic disease risk in related individuals, one needs to control (i) the **correlation** of phenotypic traits, (ii) differences in phenotypic correlations between biologically related individuals (*see* **Familial Correlations**), (iii) **censoring**, (iv) the effects of observed **covariates**, and (v) **gene–environment interactions**. These problems can be examined with "shared" and "correlated" **frailty** models [99].

For frailty "shared" between related individuals (e.g. twins), the **hazard**, where u_i are covariate values (with effect parameters β) for the ith member of a group with shared genetic traits (e.g. for twins; $i = 1, 2$), x_i is the individual's age (the same for twins) and Z_i, a latent shared frailty variable, is,

$$\mu(x_i, Z_i, u_i) = Z_i \lambda_0(x_i) \exp(\beta u_i) \qquad (1)$$

The univariate form of (1) is identifiable for shared frailty variables with a finite mean (e.g. the **gamma** distribution). Parameters of univariate and bivariate shared frailty models are consistent only if the correlation of Z_i for related individuals is 1.0.

In correlated frailty models it is assumed that, conditional on Z_i the life span T_i is independent, with the risk μ_i for each related individual modeled as a proportional hazard, i.e. $\mu(Z_i, x_i) = Z_i \mu(x_i)$. The marginal survival distribution, when the Z_i are gamma distributed (with, for two related individuals $i = 1, 2$, the variances and correlation $\rho_{z_1 z_2}$), is

$$S(x_1, x_2) = \left[S_1(x_1)^{1-(\sigma_1/\sigma_2)\rho_{z_1 z_2}} \times S_2(x_2)^{1-(\sigma_2/\sigma_1)\rho_{z_1 z_2}}\right] \left[S_1(x_1)^{-\sigma_1^2}\right.$$

$$+ S_2(x_2)^{-\sigma_2^2} - 1\Big]^{-\rho_{z_1z_2}/\sigma_1\sigma_2}, \qquad (2)$$

where $S_i(x_i)$ are univariate survival functions, with the correlation of Z_i in the range,

$$0 \le \rho_{z_1z_2} \le \min\left(\frac{\sigma_1}{\sigma_2}, \frac{\sigma_2}{\sigma_1}\right). \qquad (3)$$

For same-sex monozygotic (MZ) and dyzygotic (DZ) twins it is assumed that $\sigma_1^2 = \sigma_2^2 = \sigma^2$ and that $S_1(x) = S_2(x)$. If covariate data, u_i, are available for a correlated frailty model, then assessing the individual hazard in (1) requires the following bivariate survival function:

$$\begin{aligned} S(x_1, x_2|u_1, u_2) &= S_1(x_1|u_1)^{1-(\sigma_2/\sigma_1)\rho_{z_1z_2}} \\ &\times S_2(x_2|u_2)^{1-(\sigma_1/\sigma_2)\rho_{z_1z_2}} \Big(S_1(x_1|u_1)^{-\sigma_1^2} \\ &+ S_2(x_2|u_2)^{-\sigma_2^2} - 1\Big)^{-\rho_{z_1z_2}/\sigma_1\sigma_2}, \end{aligned} \qquad (4)$$

where S_i is related to the integrated hazard, H:

$$S_i(x|u_i) = [1 + \sigma_1^2 \exp(\beta u_1) H(x)]^{-1/\sigma_i^2}. \qquad (5)$$

Estimation of the model with covariates is complicated because Z_i are no longer gamma distributed conditional on u_i. The **EM algorithm** may be modified for this case [37].

Longitudinal Surveys Linked to Administrative Record Systems. A third innovation is longitudinal surveys of the health of elderly populations linked to administrative records (*see* **Administrative Databases**). The 1982, 1984, 1989, 1994 and 1999 National Long Term Care Surveys (NLTCS [52]) used computerized Medicare data in two ways. First, the NLTCS samples were drawn from those records. Thus, 100% of the sample can be tracked to the end of the study, or time of death. Secondly, although NLTCS response rates were near 95%, nonrespondents were, in part, more seriously ill [58] (*see* **Bias from Nonresponse**). Health information in the Medicare files can be used to (i) adjust for health biases in nonresponse, and (ii) reduce right censoring by providing continuous time information on health changes up to the time of death.

In molecular epidemiologic studies diseases were decomposed into select physiological processes for small, intensively evaluated populations. The NLTCS examines the integrated effects of those processes on the dynamics of multiple dimensions of function in elderly persons in large, nationally representative, longitudinally followed samples. Studies show that functional changes reflect both the effects of chronic diseases (e.g. the effects of Alzheimer's disease on function) and those of risk states in elderly persons for subsequent chronic disease and decline (e.g. physical activity and stroke [85]). Thus, by following multiple functional measures over time, latent state variables for individuals, and their change with age/time, can be modeled as a multivariate stochastic process (e.g. [59]).

The NLTCS design is outlined in Figure 1. The US population is assessed five times (1982, 1984, 1989, 1994, 1999). Interviews at each date were conducted over four months, during which age-related functional loss is assumed in equilibrium with age and functional status-specific mortality.

Linked to interviews are Medicare records for persons age 65+ for 1982–2000 containing (i) continuous histories of health service use, and (ii) birth and death dates. For each NLTCS, a sample of 5000 persons passing age 65 between interviews is drawn to keep the sample representative of the US elderly population and to maintain a size of roughly 20 000 persons. Over five waves, 42 000 individuals were followed with 22 000 deaths observed from 1982 to 2000. Since functional loss is low below age 65, left-censoring bias is small. Over time, persons are right censored by mortality, though health service data are available to the time of death.

To model this multidimensional, cross-temporally sparse data set requires assumptions about the trajectory of functional changes for persons between surveys (e.g. A and B), persons dying between surveys (e.g. C) or persons newly entering the sample (E). Given the multiple functions assessed, multivariate procedures are used to identify the underlying state variables. Assumptions made about functional dynamics [e.g. does a person's state "jump" when assessed (trajectory $A_1 \to A_2$) or change linearly (trajectory $B_1 \to B_2$) between assessments?] and their interaction with the observational plan (i.e. the overlay of survey assessment intervals on illustrative trajectories A, B, C or E), can affect estimates of process stochasticity (e.g. the different propagation of uncertainty; dashed and continuous lines), and trajectories of the average level of function and mortality, at late ages.

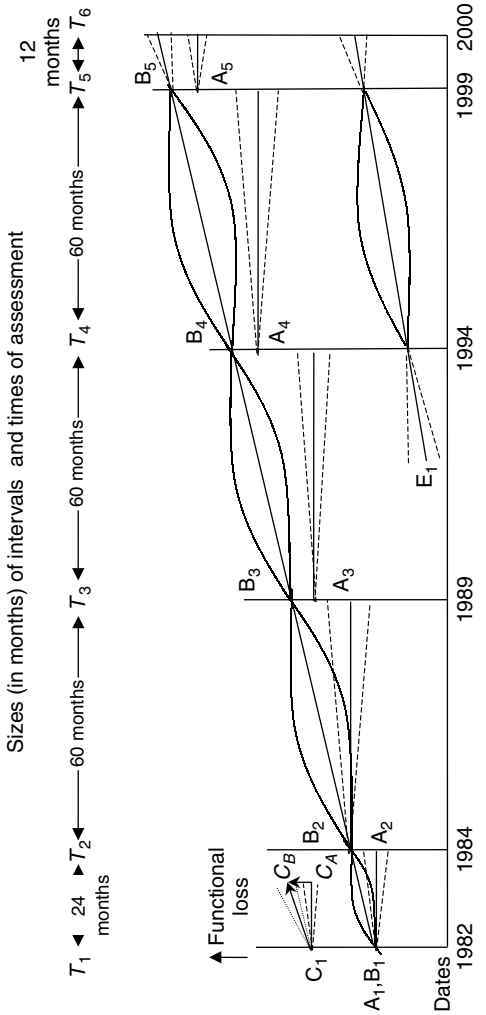

Figure 1 Temporal organization of the 1982, 1984, 1989, 1994 1999 NLTCS Longitudinal Observational Plan and illustrative trajectories of functional loss with time, and changes in the range of uncertainty about the level of functional loss relative to the time position between assessments

Hazard and Stochastic Process Models of Chronic Disease

In chronic disease models there are several types of time-related variation which can be exploited in different ways using ancillary data and theory.

Parametric Hazard Models Estimated from Failure Times

If only a few risk factors (e.g. age, sex, birth cohort/date, race, occupation, smoking) are measured, then a parametric function of age must be chosen to adjust for age increases in the physiological risk of disease (e.g. cancer) due to unobserved processes (*see* **Aging Models**).

Gompertz Hazard. A commonly used hazard is the Gompertz [29]:

$$\mu(a_{\text{it}}) = \alpha \exp(\theta a_{it}), \tag{6}$$

where θ represents the percent age increase in mortality risk μ, per unit time and a_{it} is person's i age at time t. This model describes the age dependence of mortality in many human [94] and animal [27] adult populations. Thus, θ has been interpreted as the intrinsic rate of aging (e.g. [80]). Risk factors may be represented by stratifying (6) into J discrete risk "groups" with scale parameters α_j. A stratified Gompertz, with the population in each strata known, describes the population age trajectory of disease risk as a weighted mixture of J Gompertz functions.

If membership in risk factor strata is not known, but the risk factor can be assumed continuously distributed according to a parametric (e.g. a gamma or **inverse Gaussian**) form with special properties relating to parameter changes under systematic mortality selection, a continuously mixed Gompertz hazard can be estimated by inferring the parameters of the mixing distribution from the deviation of observed and Gompertz predicted mortality rates (see below; Manton et al. [57]). The advantages of (6) are that the doubling time of risk is constant over age, and that it is an **extreme value** distribution, i.e. the progression of individual failure processes generates failure times with the same distribution in the population.

Weibull Hazard. The **Weibull** hazard [93] is used to analyze cancer risk [4],

$$\mu(a_{it}) = \beta(a_{it})^{m-1}, \tag{7}$$

where m is the number of genetic changes in a cell before a tumor initiates. In cancer, the changes are mutations in nuclear DNA that allow growth control to be lost. This function is consistent with observations of the age dependence of cancer mortality rates in populations (e.g. stomach cancer in England and Wales [87]). As carcinogenesis is studied using the techniques of molecular epidemiology, the biological validity of (7) as a model of cancer has been confirmed. For example, mutations in the p53 and p21 genes regulating cell growth and division – and possibly apoptosis in cells with DNA mutations – cause many cancers. Fearon & Vogelstein [23] found five mutations necessary for colon cancer initiation.

The Weibull is also an extreme value failure distribution where the doubling time for risk is *not* constant over age, but the probability of each mutation is. Thus, the mechanism of failure in the individual involves cells in a given tissue gradually accumulating DNA errors until the mth error occurs and a tumor initiates. This "multistage" model of carcinogenesis [4] requires that mutations be described by probabilities, i.e. each is sufficiently rare that the proportion of cells experiencing a mutation does not affect the risk of subsequent mutations. The time to the occurrence of the first cell, of N cells in a tissue, achieving m errors has the same distribution as the time to tumor initiation in a population.

Mixed Hazards. The Weibull does not fit increases in cancer risks after, say, age 75 [12]. This may be due to specific mutations occurring too rapidly to be modeled as a probability [62]. Modeling each by a hazard rate produces an overall hazard function (based on a series expansion) with additional terms slowing the age increase in risk as late events in the failure process become constrained by high transition rates for events earlier in the process. Such models produce estimates of m too large (e.g. 20–25) to be biologically plausible.

An alternative explanation for the slowing of the age increase of the Weibull is that the hazard applies to individuals. Unobserved risk factors are assumed to affect the probability of mutations, so individuals have different cancer risks. Thus, unobserved exogenous factors do not affect the number, m, of mutations needed for tumor initiation – only the m probabilities – whose effect is summarized by the individual's scale parameter, β_i. The effects of unobserved variables are represented by assuming that β_i

is distributed over individuals, according to a mixing distribution whose parameters have special properties under mortality selection. Mixed hazard functions can be examined using [17].

$$\overline{\mu}(a, \beta_i, \gamma, m) = \frac{\overline{\beta} a^{m-1}}{\left(1 + n\gamma \int_0^a \overline{\beta} u^{m-1}\, \mathrm{d}u\right)^{1/n}}, \quad (8)$$

where $\gamma = \mathrm{var}(\beta_i)/\mathrm{E}^2(\beta_i)$ is the squared coefficient of variation (CV) of the β_i, $\overline{\beta}$ is the mean of the distribution of β_i, and n determines the mixing distribution. For general n, the cumulative Weibull hazard is

$$H^{(n)}(a) = \int_0^a \frac{\overline{\beta} u^{m-1}}{\left(1 + (n\gamma\overline{\beta} u^m)/2\right)^{1/n}}\, \mathrm{d}u. \quad (9)$$

For $n = 1$ (the gamma distribution) this is

$$H^{(1)}(a) = \frac{1}{\gamma} \ln\left(1 + \frac{\gamma\overline{\beta} a^m}{m}\right) \quad (10)$$

and, for $n = 2$ (the inverse Gaussian distribution):

$$H^{(2)}(a) = \frac{1}{\gamma}\left[(1 + 2\gamma\overline{\beta} a^m)^{1/2} - 1\right]. \quad (11)$$

The gamma distribution implies a constant CV for β_i; the inverse Gaussian a decreasing CV. This model can be generalized to allow mixing across K observed risk factor strata, even if only the marginal risk factor distribution is observed [53]. The Gompertz is similarly generalized.

Semi-Parametric Hazard Models

For multiple risk factors measured over time, a more general model (*see* **Cox Regression Model**) is [13]

$$\mu(\mathbf{x}_i; t) = \lambda(t) \cdot \exp(\mathbf{x}_i^{\mathrm{T}} \boldsymbol{\beta}), \quad (12)$$

where $\lambda(t)$, the baseline hazard, is an unknown function of time, $\mathbf{x}_i$ is a J-element vector of risk factors, and $\boldsymbol{\beta}$ is a vector of coefficients. To make (12) depend on age it can be included in $\mathbf{x}_i$, and assuming $\lambda(t)$ is constant, λ_0, producing

$$\mu(\mathbf{x}_{it}; a_{it}) = \lambda_0 \exp(\theta a_{it} + \mathbf{x}_{it}^{\mathrm{T}} \boldsymbol{\beta}), \quad (13)$$

where a_{it} is current age. Eq. (13) implicitly represents multiplicative interactions between risk factors because effects are additive in the logs of risk factors. Specifically, the second-order partial derivatives of (13) are [75]

$$\frac{\partial \mu(x_{it}, a_{it})}{\partial x_{ijt} \partial x_{ikt}} = \lambda_0 \beta_j \beta_k \exp(\theta a_{it}) \exp(\mathbf{x}_{it}^{\mathrm{T}} \boldsymbol{\beta}). \quad (14)$$

The rate of change of $\mu(x_{it}, a_{it})$ in (14), relative to values of x_{ijt} and x_{ikt}, is a function of a proportionality factor, $\lambda_0 \beta_j \beta_k$, age, $\exp(\theta a_{it})$, and risk factors, $\exp(\mathbf{x}_{it}^{\mathrm{T}} \boldsymbol{\beta})$. Thus, age and risk factor values interact so that comparisons of risk factor effects across populations, where different risk factors are measured, or moments of the risk factor distribution differ, is difficult. A decomposition of (12) by cause has the problem that summing such functions produces a different distribution for total mortality (i.e. the sum of exponentials).

Combining Risk Factor Dynamics and Mortality

If the vector, $\mathbf{x}_{it}$ represents the physiological state of person i at t, then a model is needed to describe the joint evolution of $\mathbf{x}_{it}$, and disease risk. Generating a model requires assumptions about the temporal information in $\mathbf{x}_{it}$. Longitudinal studies provide only partial information on the individual's state, i.e. $\mathbf{x}_{it}$ is incomplete. For a model using incomplete data to have external and internal validity it needs to be:

1. consistent with biological theory,
2. decomposable by modes of failure, and
3. logically consistent in portraying risk factor dynamics and their interaction with mortality.

Many models do not have one or more of these properties. The exponential form of the Cox model has effects that depend on risk factor levels and is not decomposable by failure modes. Models appropriate to describe such data developed from modeling human aging as a multidimensional, stochastic process (e.g. [81] and [88]). Early models did not represent heterogeneity in individual risks. A model due to Woodbury & Manton [95] has the properties associated with conditional Gaussian distributions used to describe stochastic processes [97]. It describes chronic disease by two processes. One describes changes in $\mathbf{x}_{it}$ as J stochastic functions of their past values,

$$\mathbf{x}_{it} = \mathbf{u}_0 + \mathbf{u} a_{ijt-1} + R\mathbf{x}_{ijt-1} + \mathbf{e}_{it}, \quad (15)$$

where $\mathbf{x}_i$ are functions, possibly time dependent [i.e. R may be $R(t)$], of the prior state of the individual ($\mathbf{x}_{it-1}$), age (a_{ijt-1}), and stochastic errors $\mathbf{e}_{it-1}$, generated by "diffusion". If the $\mathbf{e}_{it-1}$ values are independent of the $\mathbf{x}_{it}$, then the diffusion process might be Gaussian (*see* **Brownian Motion and Diffusion Processes**). If the magnitude of $\mathbf{e}_{it-1}$ depends on values in $\mathbf{x}_{it}$, then the diffusion process is more complicated. Which coefficients can be estimated for (15) depends on the heterogeneity represented in the data.

The second process describes mortality as a quadratic function of risk factor values, i.e.

$$\mu(\mathbf{x}_{it}; a_{it}) = \left(\mu_0 + \mathbf{x}_{it}^{\mathrm{T}}\mathbf{b} + \tfrac{1}{2}\mathbf{x}_{it}^{\mathrm{T}}\mathbf{B}\mathbf{x}_{it}\right)\exp(\theta a_{it}), \tag{16}$$

where μ_0 is the constant force of mortality, $\mathbf{b}$ are linear coefficients adjusting for changes in the location of the hazard in the state space, $\mathbf{B}$ is a matrix of coefficients representing the quadratic and second-order interactions of the $\mathbf{x}_{it}$, and $\exp(\theta a_{it})$ represents the average effects of age related unobserved variables. Each coefficient in (16) can be made a function of age by multiplying it by $\exp(\theta a_{it})$. To relate (16) to (12) we add quadratic terms to (13) to produce, using a Taylor series expansion,

$$\mu(\mathbf{x}_{it}; a_{it}) = \lambda_0\left[1 + \mathbf{x}_{it}^{\mathrm{T}}\boldsymbol{\beta} + \tfrac{1}{2}\mathbf{x}_{it}^{\mathrm{T}}(\boldsymbol{\beta}\boldsymbol{\beta}^{\mathrm{T}})\mathbf{x}_{it} + O\left(\mathbf{x}_{it}^3\right)\right]\exp(\theta a_{it}), \tag{17a}$$

which can be expressed as

$$\mu(\mathbf{x}_{it}; a_{it}) = \left[\mu_0 + \mathbf{x}_{it}^{\mathrm{T}}\mathbf{b} + \tfrac{1}{2}\mathbf{x}_{it}^{\mathrm{T}}\mathbf{B}\mathbf{x}_{it} + O\left(\mathbf{x}_{it}^3\right)\right] \times \exp(\theta a_{it}). \tag{17b}$$

The difference between (17b) and (16) is the higher order interaction terms $O(\mathbf{x}_{it}^3)$. If these terms are negligible, then (17b) reduces to (16). The function in (16) has simpler second-order partial derivatives [75]:

$$\frac{\partial^2 \mu(\mathbf{x}_{it}; a_{it})}{\partial x_{ijt}\partial x_{ikt}} = \lambda_0\beta_j\beta_k\exp(\theta a_{it}), \tag{18}$$

which can be written

$$= \beta_{jk}\exp(\theta a_{it}).$$

Thus, quadratic hazard age and risk factor effects do not change over risk factor levels. The hazard in (16) has a number of useful properties. First, for L causes of death with the same θ (i.e. the same unobserved, age-related variables affect each cause) the quadratic forms are additive. Thus, total mortality can be consistently decomposed. Secondly, the failure mechanism represented by (16) is natural for multidimensional, biological systems where homeostatic forces keep trajectories of $\mathbf{x}_{it}$ close to a "central" region of the state space where mortality is a minimum. This is often empirically justifiable for chronic diseases (e.g. blood pressure at late ages). It may also be justified from assumptions about the dynamic response of complex biological systems to stress. Specifically, the principle of "hormesis" suggests that homeostatic (or homeorhetic) feedback mechanisms cause complex organisms to "over-control" in response to low-level environmental stress because there are time delays in responding to environmental insults due to the need for communication (e.g. by hormonal responses) between organ systems [86]. Thus, given a lag in responding, adjustments to environmental stress must be in "quanta" which, on average, overcompensate in responding to stress because an absolutely continuously graded response exactly matching the stress is not possible given the system's latency. Thus, low-level stresses "strengthen" the organism, i.e. the minimum mortality level occurs for a small but nonzero exposure. "Quanta" responses are common in humans. Without low-level exposure to pathogens, the immune system will not develop humoral responses. Alternately, the cytochrome P-450 enzyme system, although genetically programmed, may not produce a detoxifying enzyme except when stimulated by chemical stress. Thus, the quadratic hazard is the inverse of a biologically complex organism's fitness "response" to environmental stress.

Not only is the hormetic "dose–response" function reflective of a peak in an organism's "fitness" at a nonzero stress level [10], but the variability of responses is increased by structural heterogeneity in populations of responding organisms. This may be why "aged" organisms express "chronic" diseases. Models of genetic selection suggest that organisms evolve to use energy to maximize survival only to the end of the reproductive life span. This does not explain why organisms, like humans, survive long past the end of the reproductive life span and suffer chronic, degenerative diseases. Hormesis

suggests that this is a necessary response to environmental stresses, i.e. chronic diseases may be "over" responses to environmental insults. Neoplasia are tissue healing responses out of genetic (p53) control; similar arguments might be made for atheromas. Neurological diseases may be due to oxidative processes that have a function in meeting environmental stresses (e.g. the "glutamic" cascade of cell death in stroke) or in producing immunological responses.

Finally, the chronic diseases now recognized may not represent the physiological mechanisms that generate a particular pathology. Angiogenesis (i.e. the creation of new vasculature) may allow cancers to metastasize but may also permit the development of collateral circulation in a heart damaged by atherosclerosis. Many tumors develop because of the failure of the p53 gene to induce apoptosis due to mutation. Thus, is the "cancer" associated with the dysfunction of a specific organ the chronic disease, or mutations in the p53 gene that occur in many tissue types? Not only are there (i) intrinsic features of dynamic feedback systems in human organisms that dictate that the hazard is a U- or J-shaped function of exposure to environmental stress, but also (ii) a crucial problem in modeling chronic diseases is to redefine chronic disease as the understanding of disease dynamics on a molecular level improves.

Age changes in quadratic hazards with different θs are illustrated in Figure 2. Linear terms (b) describe the location of the minimum, x_{jt}^0, of the hazard relative to risk factors – a minimum that may be a function of age [i.e. $\mathbf{b}(t) = \mathbf{b}\exp(\theta a_{it})$]. The matrix of quadratic coefficients, $\mathbf{B}$, represents the age-dependent $\mathbf{B}(t) = \mathbf{B}\exp(\theta a_{it})$ curvature of the hazard relative to risk factor levels.

The **likelihood** for estimating the parameters of the two processes from a longitudinal study, where individual risk factor values are assessed at fixed time intervals, and the time of occurrence of specific lethal (or morbid) events are observed, can be written as [55] (i) the initial distribution, $\mathbf{x}_{i0}$, (ii) the regression (15) of $\mathbf{x}_{it}$ on past values in persons surviving a study interval, and (iii) the quadratic mortality function (16).

With estimates of (15) and (16) one can model the trajectory of mortality and risk factors in a cohort by using those parameters in systems of differential equations (e.g. [56]). Those differential equations describe not only the probability of survival to age a

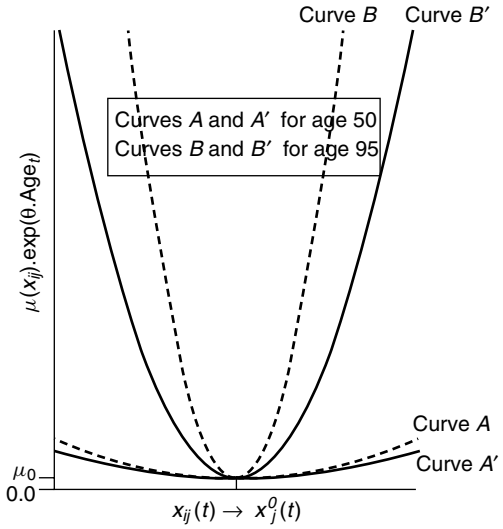

Figure 2 Changes in shape of the age-specific quadratic hazard functions at ages 50 and 95 due to the effects of unobserved variables represented by two values of the parameter θ describing the rate of aging (7.70 and 3.85%)

(conditional on changes in risk factors to a) but also the distribution of the $\mathbf{x}_{it}$ among survivors to age a.

A crucial model feature is how diffusion and risk factor heterogeneity interact with mortality over time. If the difference in the form of the partial differential equations is assumed to be updated (i) monthly or (ii) annually, then one obtains different survival patterns, or risk factor trajectories, at late age (Table 1).

In Table 1 three conditions are presented. The first assumes that, between assessments, the $\mathbf{x}_{it}$ are constant (i.e. person A in Figure 1). This produces, at age 95, a life expectancy of 5 years with an average of 46.2% of physical function preserved. Secondly, the $\mathbf{x}_{it}$ are assumed to change linearly between assessments (i.e. person B in Figure 1). Life expectancy at 95 increases to 5.4 years. The proportion of function maintained increases to 52.3%. Thirdly, state variables can be assumed to change linearly between assessments, but with mortality interacting with state variable changes every 12 months (instead of monthly). Life expectancy at age 95 is only 4.4 years and the proportion of function maintained is only 33.2%. Thus, conditions 1 and 2 represent different assumptions about $\mathbf{x}_{it}$ trajectories between assessments. Conditions 2 and 3 contrast the effect of the

Table 1 Life table models, constructed under three assumptions about state dynamics estimated from time varying covariates for females in the US NLTCS followed 1982 to 1991

	Condition 1. "Jump"processes with monthly mortality state variable interactions		Condition 2. Linear state variable dynamics with monthly mortality state variable interactions		Condition 3. Linear state variables dynamics with annual mortality state variable interaction	
Age (in years)	Life expectancy at age *a*	Average proportion of 27 functions maintained at age *a*	Life expectancy at age *a*	Average proportion of 27 functions maintained at age *a*	Life expectancy at age *a*	Average proportion of 27 functions maintained at age *a*
65	20.9	0.923	20.8	0.926	20.1	0.917
75	14.1	0.838	14.1	0.832	13.3	0.799
85	8.5	0.643	8.7	0.647	7.6	0.544
95	5.0	0.462	5.4	0.523	4.4	0.332
105	3.8	0.473	4.0	0.573	3.3	0.375

frequency at which mortality and dynamic processes interact in a model. In all three conditions the proportion of function maintained increases at late ages because, for elderly, impaired persons mortality rates eventually surpass the age rate of functional loss. Thus, the interactions of heterogeneity and mortality, and the dynamic balance of autoregression and diffusion, control the age trajectory of mortality and chronic disease processes at late ages. Thus, the model produced complex, nonlinear risk factor and mortality population trajectories at late ages. Multivariate stochastic process models are required to examine nonlinearities in risk factor dynamics and mortality at late ages.

Discussion

We have examined models of chronic disease. Techniques appropriate to modeling chronic disease change as information increases. At the least informed level we search for patterns of association between risk factors and disease risk. As information increases, measures of association may not fully exploit the available information. Thus, different models are needed for the different amounts of information generated by different observational plans.

One strategy uses improved measurement techniques to focus on increasingly detailed features of the chronic disease processes. Instead of modeling the relationship between cholesterol and CHD risk, one has to recognize that there are (i) different lipoproteins, some beneficial (e.g. HDL) and some not (LDL), and (ii) that there are multiple stages in atherogenesis, such as plaque initiation, plaque elaboration (involving lipid levels, oxidation of LDL, recruitment of macrophages having ingested oxidized LDL into plaques as "foam" cells; stimulation of arterial endothelial growth due to inflammatory responses and stimulation of local growth factor production [9]), plaque disruption, and thrombus formation. Each stage involves different risk factors and risk factor interactions. As measurement of the process improves, static models may describe process components operating over short time scales.

However, as longitudinal information accumulates, models that integrate stages of the disease process are needed to represent (i) the evolution of a multistage stochastic process, and (ii) the effects of those processes on the population distribution of outcomes. In these models the temporal organization of the stages of the chronic disease process is crucial, especially in developing interventions. Thus, the selection of models to analyze chronic disease has to be based on assessments of both the information generated by observational plans and the nature of the processes modeled.

KENNETH G. MANTON

Chronomedicine

Definitions and Aims

Chronobiology (from *chronos*, time; *bios*, life; and *logos*, science) investigates the mechanisms underlying variability in the otherwise unassessed physiological range, including rhythms found in us, resonating with cycles around us. Broad time structures (chronomes) consisting of deterministic chaos and trends organized by rhythms are found in organisms and in their environments. They are mapped by chronomics as the reference values for both an applied chronomedicine and a basic chronobiology. Chronomics quantify health, identifying new disease risks, diagnosing predisease and overt illness, enabling timely and timed treatment (R_x), and validating the short- and long-term efficacy of a given R_x on an inferential statistical individualized (as well as population) basis. Chronomics-based mapping includes the cartography of rhythms in us and around us and of their associations, with **hypothesis testing** and parameter **estimation** yielding ***P*-values** and 95% **confidence intervals** for the everyday preventive as well as curative self- or professional care of a given patient, rather than only for research on groups.

Introduction

About-daily **circadian** and about-yearly (circannual) rhythms, popularly biological clocks and calendars are part of broader biological time structures, chronomes. So are many more features of intermodulating rhythms with widely differing frequencies including those of the action potentials in the human brain and heart at the high-frequency end. Also in the circulation, notably of neonates and the elderly, are oscillations with periods of about a week, month, half-year, and year, including cisyears and transyears with periods shorter or longer than one year. Near the other end of the rhythm spectrum are about 11-year and multidecadal cycles, not only outside us, but also within us, influencing other components such as circadians. Rhythms, **chaos**, and (e.g. age-related) trends are chronome components interacting as feed-sidewards, multifrequency time-specified intermodulations requiring inferential statistical quantification, replacing time-unqualified feedbacks and feedforwards.

Historical Development

Confusing variability in blood eosinophil cells was resolved by averaging and stacking data over the 24-hour day. Time plots (chronograms) revealed to the naked eye large amplitude rhythms dependent upon the adrenal cortex as a cyclic mechanism preparatory for daily activity. The temporal placement of this and other rhythms could be manipulated by shifts, among others, of lighting or feeding regimens and was altered by magnetic storms. Experiments in continuous light or darkness at constant temperature and humidity or studies of humans in isolation from society documented endogenous features of "circa" rhythms that persisted with a period slightly but statistically significantly different from their exact societal daily, weekly, yearly, or decadal counterpart. These studies led to the coinage of "circadian" and other "circa" rhythms. A circadian system was extended to hormones influencing these cells and other endocrines, to the nervous and other systems, and eventually to nucleic acid formation, as well as to the effects of drugs, magnetic storms, and other physical agents such as noise or radiation. A genetic basis of biological circadian rhythms is now documented, *inter alia*, by studies on human twins reared apart (*see* **Twin Analysis**) and by chemical mutagenesis (*see* **Mutagenicity Study**) and gene transfer in fruit flies. The prefix "circa" (about) conveys the desynchronized feature and the fact that rhythm characteristics can only be defined with some statistical uncertainty.

In isolation from society, nearly identical frequencies were found for cardiovascular and geomagnetic rhythms, the latter gauged by the planetary disturbance index, K_p. What is more conclusive, "subtraction" to the point of disappearance and reamplification of environmental cycles' amplitudes was associated with dampened and amplified biological rhythms with corresponding frequency, respectively. Without causal implications, such findings provide strong hints of associations, rendering it essential to examine and compare the frequencies and phases of biological and environmental rhythms. A desynchronization as a free-run of biological rhythms must be documented not only from societal and other artificial, for example, lighting schedules but also from magnetic or other terrestrial, atmospheric, solar and galactic, for example, cosmic ray and/or other near-matching environmental cycles. The latter may pull

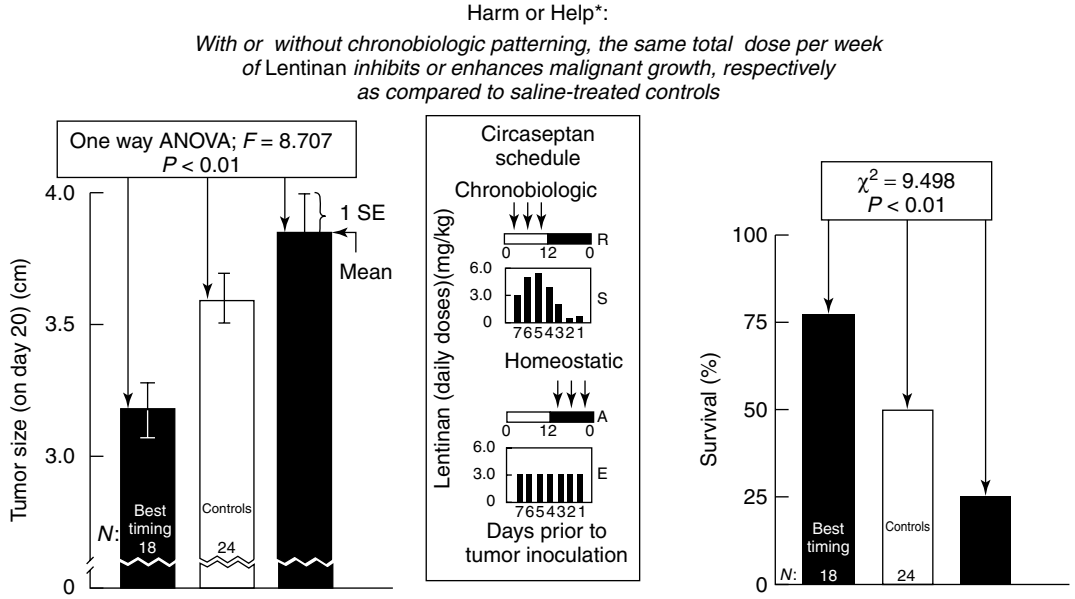
and amplify a biological rhythm without necessarily synchronizing it.

Different Types of Study

For **longitudinal** nearly "womb-to-tomb" monitoring in the laboratory, sensors are available for the telemetry of many vital functions. Transverse or **cross-sectional** studies are often linked systematically into a hybrid (linked cross-sectional) design with repeated measures for spans of days, weeks, years, or decades on different variables of human subjects or groups being compared (*see* **Longitudinal Data Analysis, Overview**).

Landmark Studies

Nonrandom patterns of morbidity and mortality from different causes stem largely from the times (e.g. hours) of changing resistance. Ubiquitous rhythms account for the difference between life and death, as a function only of timing, when in the experimental laboratory the same stimulus – noise, *X*-irradiation, an endotoxin, or a drug – is applied with the same dose or intensity under the same conditions to similar groups of inbred animals at different rhythm stages (e.g. 4 hours apart covering 24 hours). Fundamental life processes, RNA and DNA synthesis, exhibit reproducible rhythms underlying a circadian cell cycle, with important applications in cancer chronotherapy with chemicals or radiation. When anticancer drugs act at a specific stage of the cell cycle, it is important to time their administration in such a way as to optimize tumor cell kill. The concurrent aim is to minimize the damage to target organs, when pertinent rhythms are in near antiphase. Alternatively, when the time of greatest effectiveness does not coincide with that of least toxicity, one can



* Key: treatment during active (A) or rest (R) span with sinusoidal weekly pattern (S) or equal daily doses (E); $P < 0.01$. Difference in size corresponds to 50% difference in survival time; $N = N$ of animals. Therapeutic optimization by timing drug administration according to biologic week and day. Halberg E and Halberg F: Chronobiologia 7:95-120,1980.

Figure 1(a) The administration pattern of an immunomodulating drug accounts for the difference between the inhibition and stimulation of a subsequently implanted malignant growth. The conventional fixed daily dose pattern shortens survival time rather than lengthening it, as does a sinusoidally varying pattern adjusted to the body's rhythms, the *raison d'être* of chronotherapy. What remains to be proved in humans is that by resolving a time structure in both circadian and circaseptan aspects, clinical chronotherapy benefits from multifrequency timing, as it does from the use of circadian rhythmicity. See Figure 1b. Reproduced from Chronobiologia by permission of Franz Halberg

try to obtain this situation by manipulating before treatment the timing of host and cancer rhythms as much as possible, for example, by manipulating mealtimes. Findings on the critical importance of the circadian system have led to the fields of chronopharmacology and chronotherapy. Rhythms with other-than-circadian frequencies also matter: pretreatment with a sinusoidally patterned daily (and hourly) administration of the same total weekly dose of the immunomodulator lentinan can inhibit a subsequently implanted immunocytoma growth, when pretreatment with conventional equal daily doses enhances the same malignant growth in rats (Figure 1(a)). The use of tumor temperature as a marker rhythm to guide perioral cancer radiotherapy, as compared to the usual time-unspecified treatment, has doubled the two-year disease-free survival rate (Figure 1(b)). Further optimization involves about-yearly, about-weekly and circadian considerations, the latter two in keeping with Figure 1(a).

Other Clinical Uses of Chronomics

Chronome mapping leads to: (i) a positive definition of health in the light of reference standards for new endpoints (see Figure 2); (ii) a better understanding of mechanisms underlying changes of chronomes in healthy development (Figure 3) and against this reference standard, an earlier recognition of any disease process; (iii) the detection of chronome alterations before changes outside the physiological range occur, detecting predisease longitudinally in the stroke-prone, spontaneously hypertensive rat and in humans; and (iv) the opportunity to act preventively and rationally rather than after the fact of overt disease (Figure 4). A chronomic interpretation of serial data yields a location index (the MESOR (**m**idline **e**stimating **s**tatistic **o**f **r**hythm)) usually more accurate and more precise than the arithmetic **mean** (being associated with a smaller bias owing to the temporal placement of measurements and with a smaller **standard error** once other deterministic variation is accounted for) (Figure 5). This improved average, of great merit in itself, is only a dividend from the major merit of chronomics, namely, the provision of intuitively meaningful endpoints of dynamic changes (such as amplitudes, phases, waveforms and fundamental frequencies of rhythms), which convey useful information in their own right (Figure 2).

The rhythm characteristics (some shown in Figures 2 and 5) are confounded when dealing with

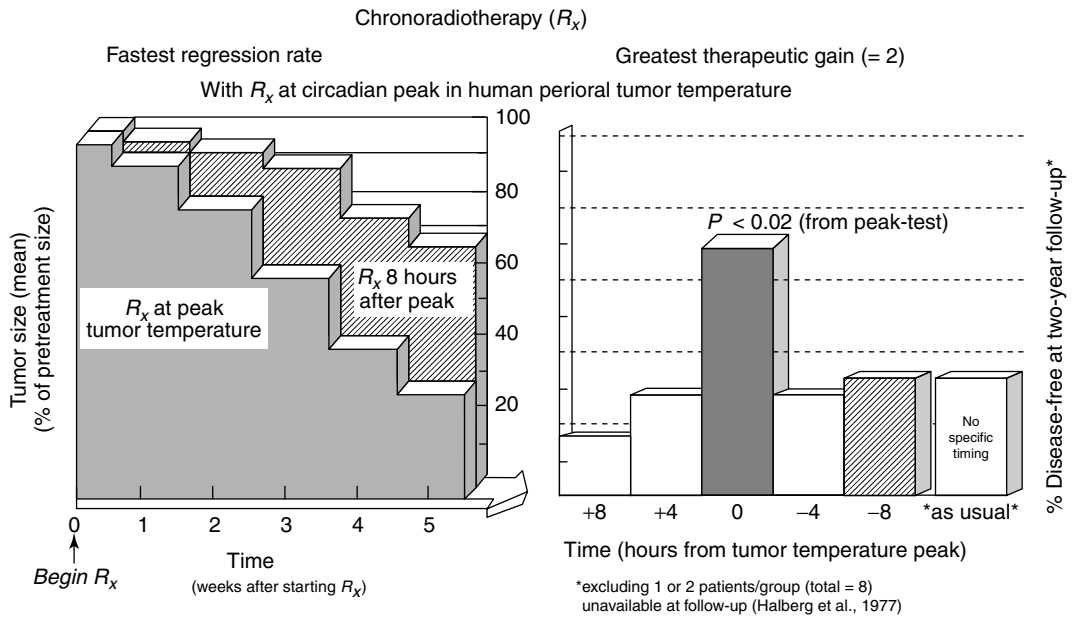


Figure 1(b) Doubling of two-year disease-free survival by radiotherapy administered at the circadian peak of tumor temperature. Reproduced from Chronobiologia by permission of Franz Halberg

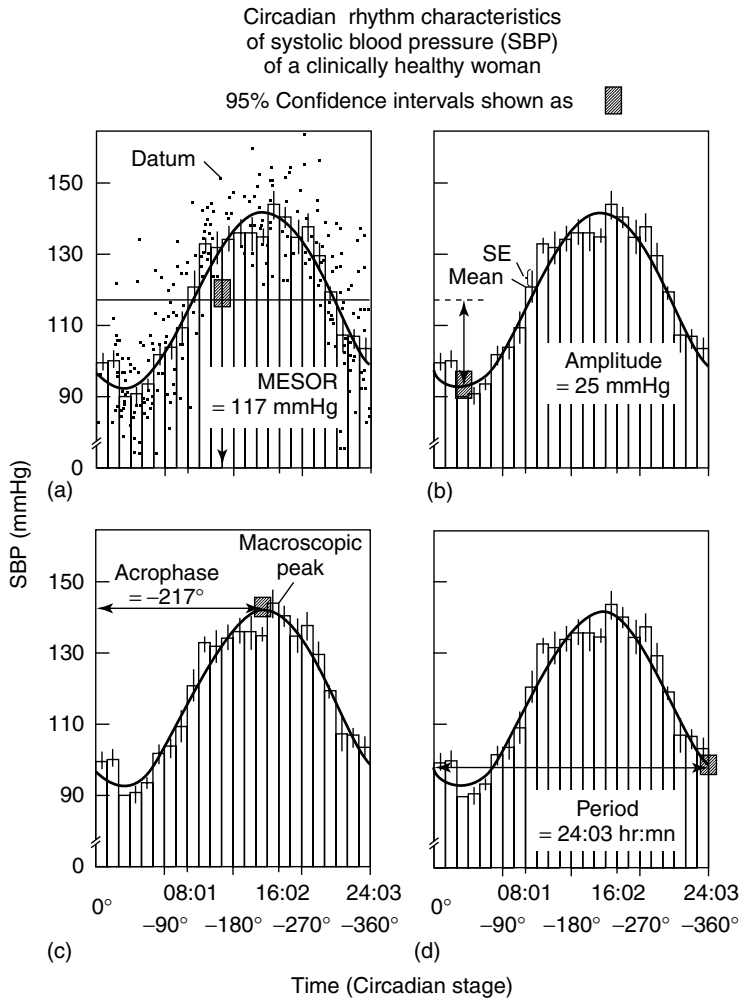

Figure 2 Illustration of circadian rhythm characteristics of systolic blood pressure of a clinically healthy woman estimated by linear–nonlinear least squares. Although the data (dots; (a)) were collected during a 9-day span and were analyzed as a longitudinal time series, the results are displayed after the data have been stacked over an idealized cycle with a period that was estimated before stacking to be 24.03 hours (d). The 95% confidence interval for the period estimate is much less than 1 hour, as can be seen from the rectangle at the tip of the arrow (d). Point-and-interval estimates are also shown for the MESOR, a rhythm-adjusted mean (a), for the amplitude, a measure of half the extent of predictable change within a cycle (b), and for the acrophase, a measure of the timing of overall high values recurring in each cycle (c). (see also abstract Figure 5.) The results also serve to indicate the large variability in systolic blood pressure, which is predictable to a large extent. These and other results, e.g., in Figure 4, also question the reliability, validity, and pertinence of single measurements used today for screening, diagnosis, and treatment of blood pressure disorders. Reproduced from Chronobiologia by permission of Franz Halberg

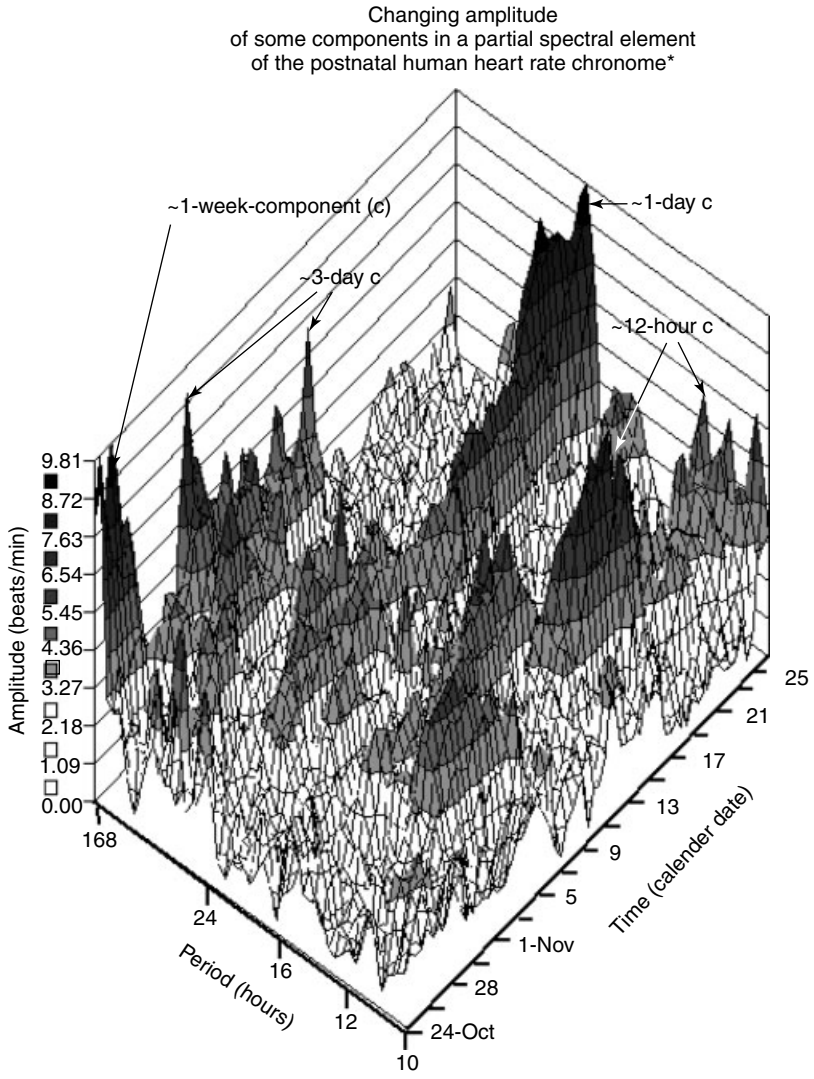
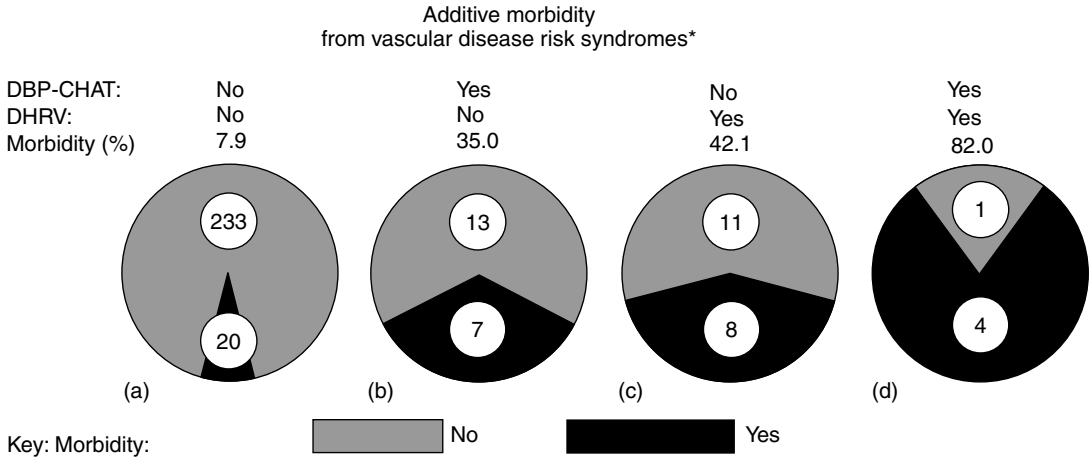
day–night ratios, for instance to classify patients as "dippers", "non-dippers", "reverse dippers", or "extreme dippers". A quantification of each parameter is then not available and consideration for the waveform is lost, as is all information on any extra-circadian components (there are many of them, and they can be important). Parameter estimation complemented by a nonparametric assessment of data stacked over an idealized day for comparison with time-specified reference values offers a readily



* in a healthy boy, born 19.10.1992, whose heart rate was measured at mostly 30-minute intervals from 20.10 for the ensuing 40 days, and analyzed as a moving spectrum in separate weekly intervals, displaced in 12-hour increments through the data set. An initially greater prominence of infradians (see ~1-week-component (c), left), shown by height and shading, corresponding to a larger amplitude, contrasts with the prominence of circadians and circasemidians in later weeks of life, while any ultradians with still higher frequencies and any trends and chaos, two other chronome elements, are unassessed in this gliding spectral window.

Figure 3 Early infradian over circadian prominence of human heart rate after birth. The oblique age scale ascends from the bottom middle to the right, giving the midpoints of 7-day intervals analyzed; trial periods are shown along a scale that ascends from the bottom middle to the left. Along the vertical scale of amplitudes initially no circadian peak, only an infradian (about-weekly) component is seen. The circadian and circasemidian components become noticeable by peaking several weeks later. Reproduced from Chronobiologia by permission of Franz Halberg



* DBP-CHAT: Diastolic circadian hyper-amplitude-tension.
DHRV: Deficient heart rate variability.
Morbidity: Cerebral ischemia, myocardial infarction, nephropathy and/or retinopathy during 6 years, without (a), with single (b, c) or both (d) disease risks.

7-day / 24-hour monitoring can detect in the neglected normal range abnormality in variabilities of blood pressure and heart rate that make the difference between <8 and 80% morbidity.

Figure 4 Pie charts compare the incidence of morbid vascular events among four groups of patients: (a) Those with an acceptable circadian blood pressure and heart rate variability; patients diagnosed with either (b). an excessive (above-threshold) circadian amplitude of diastolic blood pressure (DBP-CHAT), or (c) a decreased (below-threshold) circadian heart rate variability (DHRV), alone, and (d) patients diagnosed with both conditions. Results from a 6-year prospective study on 297 (121 MESOR-normotensive and 176 treated MESOR-hypertensive) patients, who each contributed a 48-hour record of blood pressure and heart rate measurements at 15-minute intervals at the start of study. The incidence of morbid events was checked at 6-month intervals for 6 years. Each patient's circadian characteristics of blood pressure and heart rate was interpreted in the light of reference standards obtained from independent studies of presumably clinically healthy subjects, matched by gender and age. CHAT (**c**ircadian **h**yper-**a**mplitude-**t**ension) was defined as a circadian amplitude of blood pressure above the upper (95% prediction) limit of acceptability and DHRV as a 48-hour standard deviation of heart rate below the lower limit of acceptability. Findings of Kuniaki Otsuka, in keeping with earlier studies of the spontaneously hypertensive stroke-prone Okamoto rat, and in keeping with human studies in Minnesota, Taiwan, Japan, Italy, and Germany, where outcomes are available with a 28-year perspective. Reproduced from Chronobiologia by permission of Franz Halberg

understood diagnosis, summarized on a form called a "sphygmochron" shown in Figure 6. Biostatistics should be made as simple as possible but not simpler, to paraphrase Einstein.

Examples of diagnoses are the disease risks: chronome alterations of heart rate variability, CAHRV, such as a **d**ecreased (under-threshold) **h**eart **r**ate **v**ariability (DHRV), and an excessive (over-threshold) variability of blood pressure (circadian hyper-amplitude-tension, CHAT). CHAT describes a blood pressure profile with a circadian amplitude above the upper 95% prediction limit of healthy peers matched by gender and age. CHAT can be a response during only a few days to stimuli such as conflict or grief (transient CHAT). CHAT beyond a week-long monitoring should prompt further monitoring and the initiation of non-drug treatment, e.g., by relaxation procedures. Patients with diastolic CHAT, whether MESOR-normotensive or MESOR-hypertensive, have a 720% increase in the risk of cerebral ischemic events. The diagnosis of CHAT requires both that data be collected around the clock and that the circadian amplitude be estimated and compared with available reference values. DHRV (decreased **h**eart **r**ate **v**ariability) is a deficient heart rate jitter (defined as a 24-hour standard deviation of heart rate below the lower 5% prediction limit of healthy peers), which carries a

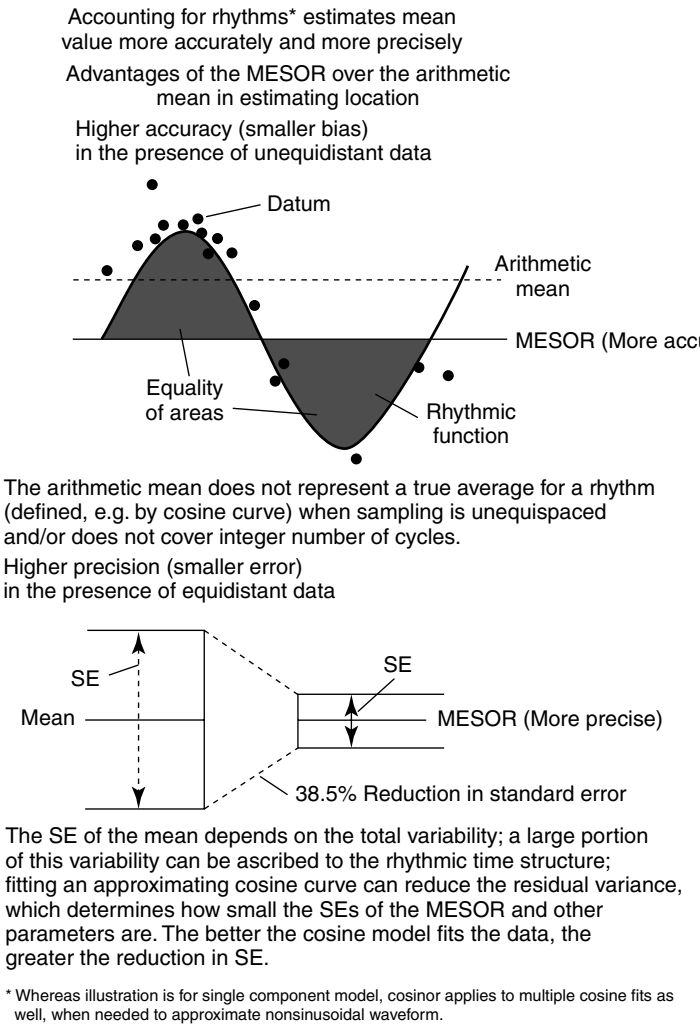


Figure 5 In the presence of periodicities, the use of statistics to resolve the time structure (chronome) usually yields a more accurate (top) and more precise (bottom) estimate of location (the MESOR, a rhythm-adjusted mean) than the arithmetic average. Reproduced from Chronobiologia by permission of Franz Halberg

550% increase in the risk of coronary artery disease and can be determined along with a check for CHAT by ambulatory monitoring without electrodes. When both CHAT and DHRV coexist, there is a doubling of the risk of vascular diseases (Figure 4). An above-threshold circadian pulse pressure (around-the-clock average difference between systolic and diastolic pressure, when the heart contracts and relaxes) further increases vascular disease risk, as may do an odd circadian timing, circadian ecphasia.

Statistical Concepts, Problems, and Solutions

Periodograms, Power Spectra, and Single (Usually Multiple-component) Linear-nonlinear Cosinors

In the precomputer era, periodograms (*see* **Spectral Analysis**) used at first necessitated equidistant data over several integer cycles of the components characterizing the data. The computations

1) Unusually long standing or lying-down during waking: unusual activity, such as exercise, emotional loads, or schedule changes, e.g., shiftwork, etc.: 2) Salt, calories, kind and amount, other, etc. Please enter this information into a separate diary along with daily times of getting up and retiring for sleep.

Figure 6 Sphygmochron, a computer-generated form used to summarize results from the combined parametric and nonparametric assessment of a blood pressure and heart rate profile. Results from both approaches are compared with reference values specified by gender and age, given in boxes next to the given subject's estimates of his/her rhythm characteristics. Reproduced by permission of Franz Halberg

were time-consuming and data could not always be obtained at regular intervals. Self-measurements of blood pressure or heart rate, for example, are not possible while sleeping. An alarm clock used to prompt a self-measurement leads to disturbance, which may affect the measurements and hence may prevent the rigorous assessment of spontaneous variation. Undue caution at the beginning of the computer era led to very conservative power spectra, with a great deal of smoothing. As the ubiquity of circadians was documented, **least-squares** procedures offered themselves for the test of anticipated rhythms in unequidistant data such as those collected in isolation from society in caves, or rooms without a clock. Thus, the single cosinor was developed. Here *single* refers to the analysis of a single series by the fit of one or, usually, of several components when the density and length of the data allow it. The addition of harmonic terms in the model quantifies the waveform when it is nonsinusoidal. The results are displayed along both rectangular and polar coordinates as point estimates and 95% confidence intervals. For time series spanning more than one or a few cycles, a chronobiologic serial section can be used, wherein the single cosinor is applied to successive consecutive or partly overlapping intervals to examine how the characteristics of a rhythm with a given frequency vary as a function of time. For long series involving components of several frequencies, chronobiologic serial sections of several orders can be applied to the original data or to the parameters obtained in a previous pass.

Least-squares procedures are well suited to the situation where anticipated rhythmic components have known approximate periods (τ_i). The least-squares fit of a model such as

$$Y(t) = \sum_{j=0}^{q} a_j t^j + \sum_{i=1}^{p} A_i \cos\left(\frac{2\pi t}{\tau_i} + \phi_i\right) + \varepsilon(t)$$

detects a rhythm with period τ_i by the zero-amplitude test ($H_0 : A_i = 0$). Confidence and/or prediction limits are derived for the parameters of all rhythmic components, whether they represent several physiologically different (multifrequency) rhythms and/or harmonics quantifying a nonsinusoidal waveform. In addition, any superimposed trend is detected by nonzero **polynomial** coefficients (a_j). Least-squares techniques to assess rhythms in short and sparse series led to several important developments.

1. Parameter comparisons: these can check for changes occurring on an individual basis, for example, to determine whether a given antihypertensive drug has lowered the circadian blood pressure amplitude of a patient with CHAT, or whether it is preferable to administer such a treatment at one versus another circadian stage.
2. Gliding spectral windows in combination with cumulative sums (CUSUM, Figure 7) (*see* **Quality Control in Laboratory Medicine**) ascertain that an effect of treatment occurs and persists with statistical significance in the given patient, when his/her blood pressure, in response to antihypertensive treatment, leaves the decision interval.
3. Phase zero trials: the parsimonious single cosinor method relying on prior information (such as the critical importance of circadian stage in relation to treatment efficacy) accounts for powerful chronobiologic pilots that are always useful but are named "phase zero trials" since usually they should precede the customary Phase I–III **clinical trials**, which then could be carried out at the "right time" determined in the phase zero trial.

For different signal-to-noise ratios and a relatively small number of subjects (≤ 20), in a hardly ever random (but rather somewhat periodic) world, the power of the single cosinor method exceeds that of a one-way analysis of variance (*see* **Experimental Design**), assuming that the (usually considered six) test times are equidistributed within one (e.g. circadian) cycle. The dangers of relying on a two-timepoint approach need to be stressed whenever the precise phase information is lacking and/or the individual's rhythm may be desynchronized in phase or period. This comment applies equally to the selection of only two time-spans, as discussed above in relation to blood pressure regarding the preference of assessing circadian characteristics over merely computing a day–night ratio. The merit of a six-timepoint design at the outset is its amenability to cost-effectively determine the optimal time and the likely gain to be derived from timing. For instance, in a six-subject, six-timepoint pilot study, the particular tested anticlotting properties of treatment with daily low doses of aspirin were optimal when the drug was administered shortly after awakening (Figure 8).

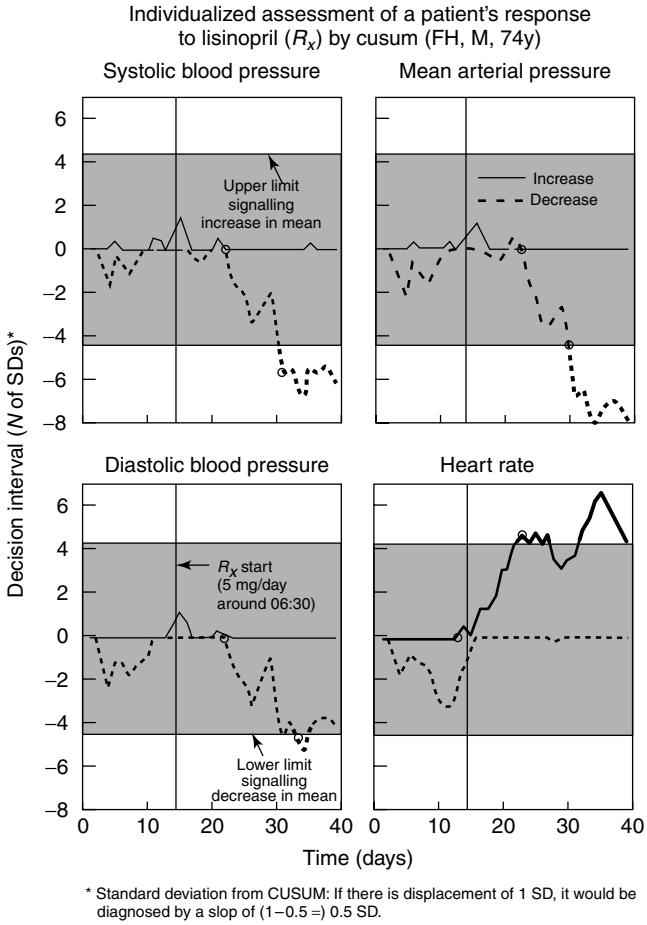

Figure 7 Control charts of daily mean values of blood pressure and heart rate data collected at 15-minute intervals around the clock. While the series of daily means is proceeding "in control" (i.e. at the pretreatment mean value), the CUSUM comprises two line graphs, signaling an increase or decrease in mean, respectively, that generally stay within the shaded "decision interval", plotted here as the horizontal lines at 4.4 and -4.4 standard deviations (SD). When the dashed curve breaks out downward of the decision interval boundary, it provides the validation of a decrease in daily blood pressure mean. The time at which the mean changed is estimated by tracking the line segment leading to the breakout back to the last occasion on which it lay on the horizontal axis. Thus, in the case of systolic blood pressure, the breakout occurs on day 30 (16 days after the start of treatment with the drug lisinopril) and the shift in pressure is estimated to have occurred on day 22 (8 days after lisinopril treatment started). An upward breakout for heart rate shows the desirability of continued monitoring to see whether a breakout is transient or sustained. In the case of blood pressure, a return into the decision interval can occur after several months of successful intervention, when an event led to the treatment's failure latter on (not shown). Indications for Linear–Nonlinear Least-squares Cosinors, Spectra, and Cross-spectra

The time structure of a variable is usually synchronized by the environment. Transient changes are associated with the expression of partly endogenous variations when an organism is studied under conditions rendered as constant as possible in terms of illumination, temperature, humidity, access to food and water, and so on. Persisting rhythms assume periods, which usually remain close to their environmental match, yet differ with statistical significance, albeit slightly, from the period of the environmental cycle with which they had been synchronized earlier.

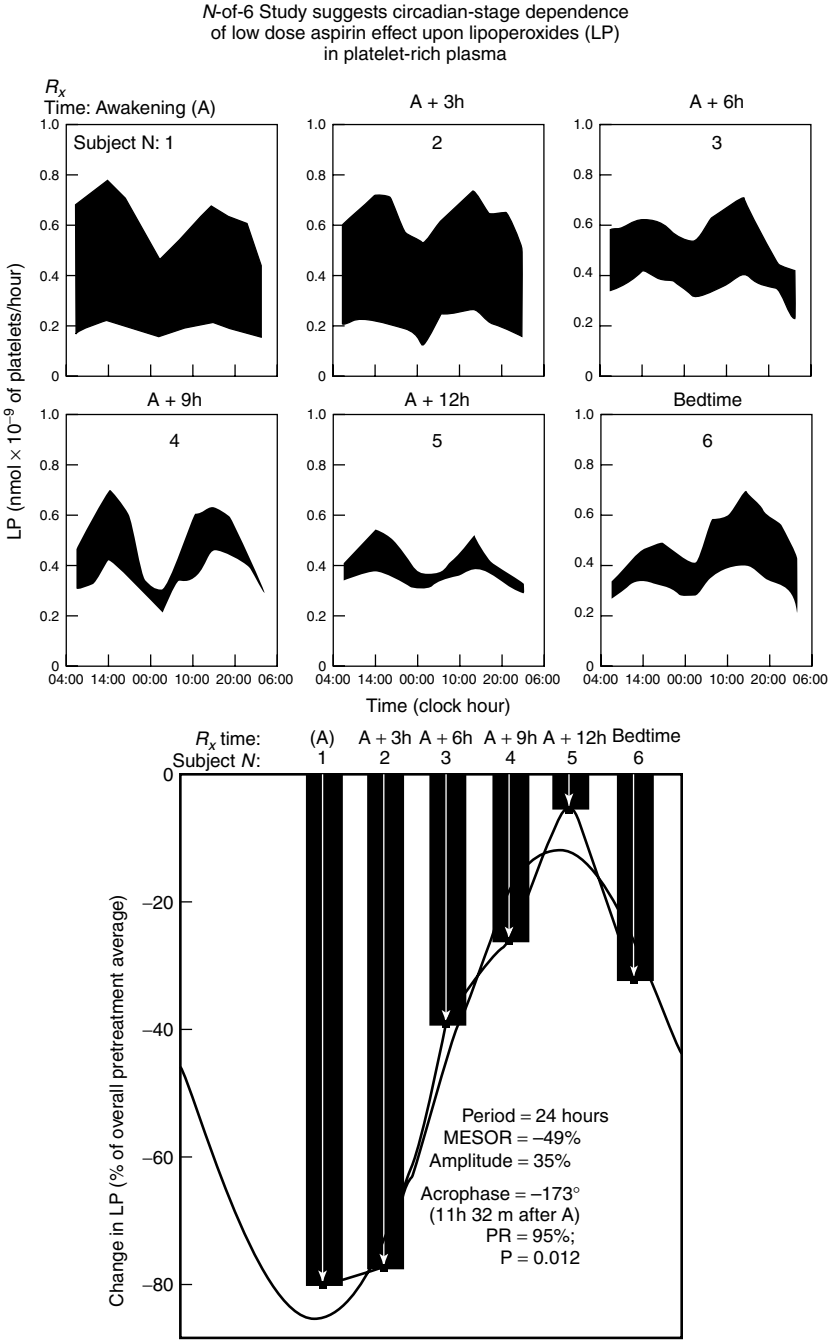

Figure 8 Power of "phase zero" chronobiologic pilots: by randomly assigning similar subjects to six different circadian stages, each to receive 100 mg/day of aspirin for one week, a large amplitude response rhythm can be assessed indicating that the lowering of lipoperoxides (LP) in platelet-rich plasma (a desired effect to prevent myocardial infarction) is maximal when aspirin is taken shortly after awakening and that aspirin does not have this effect when it is given 12 hours later. Reproduced from Chronobiologia by permission of Franz Halberg

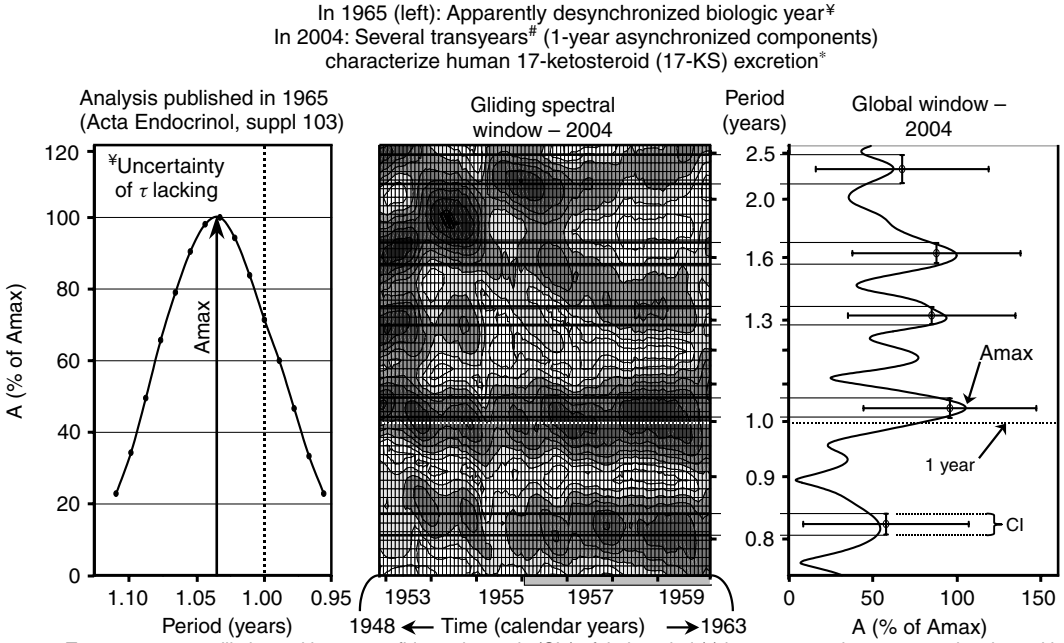
Nonlinear least-squares techniques (*see* **Nonlinear Regression**) generally serve to estimate the period(s) with other rhythm characteristics. The combination of linear and nonlinear least squares relies on guess estimates from the former to assess by the latter the persisting circadian or other rhythms, for instance in the absence of time clues. Evidence accumulates for the desynchronization from societal schedules of about-weekly (circaseptan) rhythms *in vitro* and *in vivo*, and for their frequency multiplication to about-3.5-day (circasemiseptan) rhythms after enucleation and/or mutation in unicells.

Asynchronization from the calendar year is observed further for the case of an about 1.05-year component in the daily excretion of breakdown products of steroidal hormones recorded (with gaps) for 15 years. Figure 9 shows gliding (middle) and global (right) spectral windows of these data, complementing an earlier periodogram (left) obtained without an estimate of the period's uncertainty. Percentage rhythm (R^2) values and/or ordering P values (from the zero-amplitude test) can also be displayed along with amplitudes, each in separate gliding spectra, for biological and/or physical variables for the mapping of chronomes in and around us.

Methodological Challenge in Finding Out that Stormy Weather in Space Is a Health Hazard

The combined use on existing extensive databases of spectral coherence, superposed epochs, and other remove-and-replace approaches, as in **endocrinology** (allowing nature to ablate and replace certain frequencies, e.g. of the velocity changes in the solar



Transyears are oscillations with 95% confidence intervals (CIs) of their period (τ) between 1 and 2 years, overlapping neither of these values nor one another. Cisyears are oscillations with periods between 1 and 0.5 year with CIs overlapping neither 1-year nor 0.5-year, as seen for a period of about (but not equal to) 0.8 y. * about 15-year record, daily data (with gaps) from a clinically healthy man (CH, 43 – 58 y), N = 3719. Gliding interval = 8 years (y), increment = 1 month, longest trial τ = 2.265 y, shortest τ = 0.75 y, harmonic increment = 0.05. Darker shading corresponds to larger amplitude (A). Horizontal shaded bar starting in 1956 indicates span of intermittent androgen administration; data during treatment omitted from analysis.

Figure 9 Combination of gliding (middle) and global (right) spectral windows identifies several transyears, with periods of about 1.6, 1.3, and 1.05 years, and a cisyear with a period of about 0.8 year in a 15-year record of urinary excretion of 17-ketosteroids by a healthy man. All these components are validated nonlinearly with 95% confidence intervals of their periods non-overlapping precisely 1 year. The absence of an exact calendar year by cosinor (right) had been published in 1965. Reproduced from Chronobiologia by permission of Franz Halberg

wind), has suggested that magnetic storms are consistently associated with a decreased heart rate variability. This could constitute a physiological basis for an increased localized **incidence** of myocardial infarctions and strokes also observed in association with magnetic storms. Notably in the Arctic, around-the-clock electrocardiograms covering seven days allowed the comparison of data from days with high versus low geomagnetic activity. The long-term, eventually life-long concomitant systematic monitoring of physiological variables for alignment with ongoing physical monitoring is the aim of an international chronome initiative seeking information in different geographic/geomagnetic locations as reference values for chronomedicine, while also examining questions about mechanisms of external–internal chronome interactions.

The reciprocity of cycles in us and around us led to the recent discovery of components with periods slightly longer or shorter than one year that may coexist with the circannual variation. These are the far-transyear with a period of about 1.3 years characterizing the solar wind speed, the near-transyear and cisyear with periods of about 1.05 and about 0.95 year(s), respectively, some of which can also be found in some helio- and/or geomagnetic indices. Because such components can beat with the circannual variation, circannual studies are best conducted over long enough spans to avoid obtaining controversial results corresponding to spans when the two cycles are in or out of phase. Chronomics, the mapping of broad time structures, including these newly found cycles, can serve as useful reference for designing studies with appropriate sampling recommendations.

Population-mean Cosinor

This method, based on **multivariate** statistics, was developed for drawing inferences to be generalized by checking the extent of similarity of single-cosinor estimates among individuals selected at random from a homogeneous population.

Time-specified Reference Standards: Chronodesms

This chronobiologic alternative for usual value ranges collects serial data from clinically healthy subjects to derive reference limits (such as 90% prediction intervals) that account for multifrequency rhythms, age trends (from womb to tomb), and differences as a function of gender and ethnicity, considering both changes in mean value and **variance**. These limits are for the interpretation of single values and for that of rhythm parameters (parameterdesms) and noise characteristics. This approach to the monitoring of blood pressure and heart rate identifies patients with CHAT or DHRV, among others.

Measures of Excess and Deficit and Beyond with Signal Averaging

The recognition of chronomes provides more reliable answers to the question whether and when a time series is too high or too low and detects alterations in time structure in the absence of changes in operating overall average. Chronomics in addition to comparing endpoints of anticipated periodic components with a pertinent chronodesm to determine the extent, timing, and duration of any excess (or deficit) also numerically integrates the area (under and/or over the curve) delineated by the data when they are outside time-specified limits and the limits themselves. The time when most of the excess (deficit) occurs serves for diagnosis and for timing any intervention.

Control Charts

To assess an individual's trends in mean or in other chronome characteristics, cosinor methods are applied in intervals that are progressively displaced throughout the accumulating **time series**. This chronobiologic serial section can be combined with a self-starting cumulative sum (CUSUM) to detect chronome alterations or to assess the response to a given intervention (*see* **Quality Control in Laboratory Medicine**). Such an individualized approach, first used in chronomedicine for the monitoring of epileptic seizures and for adjusting treatment, is particularly indicated in assessing blood pressure and heart rate. Hawkins' self-starting CUSUM detects a shift in mean (MESOR, circadian amplitude, and/or any other pertinent chronome endpoint or chrone) and indicates when the change may have occurred (Figure 7). Moreover, the boundaries of the decision interval can be determined even from relatively few data prior to a given intervention. Gliding spectral

windows (Figures 3 and 9) provide a view, from above or from the side, of the change in both amplitude and period.

Anticipated Developments

Some nondrug treatments or an antihypertensive drug can lower an excessive circadian blood pressure amplitude when given at the right time (rhythm stage) or raise it when given at the wrong time. For instance, an α-adrenoceptor antagonist given for benign prostatic hypertrophy in the evening raises the circadian blood pressure amplitude, but does not have this effect when given in the morning, when the circadian blood pressure amplitude is restored within acceptable limits. Further clinical trials will have to examine the degree of generality of the finding already made, that the actual incidence of adverse vascular events can be reduced by antihypertensive agents capable of lowering an excessive circadian blood pressure amplitude when given at the right time(s).

Deterministic chaos theory of heart rate variability has associated complexity, if not irregularity, with health, while regularity (periodicity) has been regarded as an index of disease, with the focus primarily on spectral components with periods of seconds or a few minutes. Results along the 24-hour scale reveal that the circadian variation is better defined in health than in the presence of heart disease. Concomitant assessment of various chronome elements reveals rhythms in endpoints of "chaos". Trends in both rhythmic and chaotic endpoints are found as a function of age and in disease versus health. For example, the correlation dimension of fractal scaling separates healthy subjects from patients with coronary artery disease at 2 A.M., but not at 10 A.M. or 2 P.M. Sampling around the clock not only reveals a circadian rhythm in the correlation dimension of cardiac interbeat intervals in health, but also a variance transposition of an endpoint of chaos from the 24-hour to the 12-hour region of the rhythm spectrum, as a new feature of CAHRV in patients with heart disease.

Chronome-specified Interactions

Chronome-specified interactions among two or more different variables have been called feed-sidewards. Those among three rhythmic entities such as the pineal–pituitary–adrenocortical interactions have been modeled *in vitro*. A rhythmic sequence of stimulation, no-effect, and inhibition by a third entity, a modulator, such as the pineal, upon the interaction of two other entities, the actor and reactor, such as the pituitary and the adrenal, is gauged by the *in vitro* production of corticosterone (see Figure 10). Another feed-sideward applies to DNA labeling in bone. An ACTH analog leads to a circadian sequence of stimulation, no-effect, and inhibition. Studies of feed-sidewards will have to be extended to multiple interactions at several (e.g. circadian and about 7-day rhythmic) chronome components, since the results can be critically important (Figure 1), as different as the stimulation versus the inhibition of a malignant growth.

Automatic Closing of the Loop Between a Chronodiagnosis and Chronotherapy

Longitudinal monitoring of vital signs for surveillance has been advocated, at least for at-risk individuals. Rather than loosing all original data except those collected just prior to an event, as done in the black box of an airplane, the data steadily accumulating over years or decades can be analyzed in relatively short spans to extract the pertinent spectral, chaotic, and trend (chronome) characteristics. Endpoints extracted from such windows are stored, thus compacting the available information as a summary for each day and then for each week or for a longer span. The information is thus progressively updated as the window is displaced and enlarged in repeated passes as-one-goes, while components with progressively lower frequencies are thus gradually resolved. This continuous examining, compacting, and recycling of information based on progressively broader windows can detect the earliest chronome alterations at one or the other frequency, which may indicate an increased disease risk and can prompt the institution of countermeasures.

Automatic monitoring devices, miniaturized for long-term ambulatory use, some implanted under the skin or in the heart, are already available for research. The windowing, compacting, and recycling of telemetered data could provide a continuous medical examination, eventually available to everybody, thus contributing a thorough objective history of vital signs, preferably retrieved in response to the push of

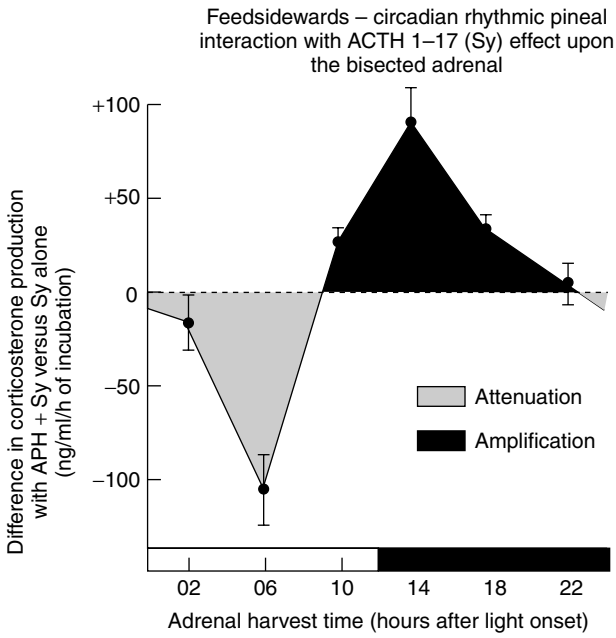


Figure 10 Much controversy can be resolved by studying the effect of the interaction by more than two entities at different rhythm stages: a third entity may modulate, in a predictable insofar as rhythmic fashion, the effect of a first entity upon a second. Predictable sequences of attenuation, no-effect and amplification can then be found. A case in point is corticosterone production by bisected adrenals stimulated by ACTH 1–17 (Sy) in the presence versus absence of pineal homogenate (APH). Such chronomodulations are part of (time-specified) feed-sidewards, for example, of rhythmic sequences of attenuation, no-effect and amplification by a modulator upon the interaction of an actor and a reactor. The figure summarizes five studies by Salvador Sanchez de la Peña with us. Reproduced from Chronobiologia by permission of Franz Halberg

a button. Eventually, the loop may be closed for automatic chronome-adjusted treatment with drug pumps and/or electrical treatment devices. Another merit of the chronome approach versus the airplane's black box may be the much more complete history of long-term antecedents to avoid the "crash" of catastrophic disease by timely and timed treatment.

GERMAINE CORNÉLISSEN & FRANZ HALBERG

Circadian Variation

Most living organisms on earth experience an annual seasonal cycle caused by the earth's revolution around the sun, and a *circadian* (Latin *circa dies*: approximately one day) day/night cycle, caused by the earth's rotation around its own axis. Other rhythms, defined by cycle length, are as shown in Table 1.

Circadian variations may arise directly from the effects of the varying levels of electromagnetic radiation from the sun at different times of the day. In addition, many living organisms have evolved internally generated rhythms that do not depend entirely on external stimuli. The *endogenous circadian rhythms* in physiological functions such as body temperature, blood pressure, and mental alertness are responsible for the normal sleep/wake cycle and for jetlag. The eventual adaptation to local time by travelers indicates that the "body clock" is sensitive by external cues known as *synchronizers, entrainers* or *Zeitgeber*. The brain centre responsible for the generation and synchronization of circadian rhythms is believed to be the *suprachiasmatic nuclei* in the anterior hypothalamus, which receives input from retinal neurones, and which regulates the production of the hormone *melatonin* by the *pineal gland*. The endogenous periodic oscillations of the suprachiasmatic nuclei may be due to certain "clock genes" which exhibit rhythmic transcription by negative feedback control [3]. Understanding the "body clock" has important implications for air travel, shift work, as well as mental disorders such as mania and depression in which sleep disturbance is an important feature.

The rhythm of a variable is characterized by its *period* (time units per cycle) or *frequency* (the number of cycles per unit time), *acrophase* and *nadir* (the times at the maximum and minimum values of the variable, respectively), *amplitude* (half the difference between the maximum and the minimum values of the variable), and the *mesor* (the mean value of the variable over the cycle). The aim of statistical analysis in circadian rhythm research is usually to estimate these parameters in a population for the variables of interest, or to test for differences between these parameters in two or more populations. The data usually consist of measurements of subjects several times a day over one or more days.

Table 1 Rhythms

Rhythm	Length of period
Ultradian	Less than 20 h
Circadian	Between 20 and 28 h
Infradian	More than 28 h
Circaseptan	About seven days
Circatrigintan	About one month
Circaannual	About one year

In the simplest design, a group of subjects is randomized into two or more subgroups, and each subgroup is measured at a different time of the same day. For normally distributed variables, an **analysis of variance** (ANOVA) can be performed with "time of day" as a main effect, with or without other main effects (e.g. sex, disease, medication) or covariates (e.g. age), or interactions (e.g. time of day by medication). For discrete variables, **chi-square tests** or the **loglinear model** may be used. The advantage of this design is that it avoids practice effects, which may artifactually inflate the value of the variable at the second time point.

Another design that also avoids this problem is the *rolling Latin square* (*see* **Latin Square Designs**), which aims to subject the different time points to the same practice effect. An example of this design, for three time points, is shown in Table 2, where T represents a testing session.

The resulting data can be analyzed using simple ANOVA, with time of day and order (first, second or third) as main effects. This, however, ignores individual effects, and it is desirable to analyze such data with more sophisticated methods such as mixed effects models for longitudinal data, **multilevel models**, or *repeated measures models*. If the data are complicated by missing data or irregular time intervals, then the use of repeated measures models is even more desirable.

Table 2 Rolling Latin square design

	Day 1			Day 2		
	0600	0800	2200	0600	0800	2200
Group 1	T	T	T			
Group 2		T	T	T		
Group 3			T	T	T	

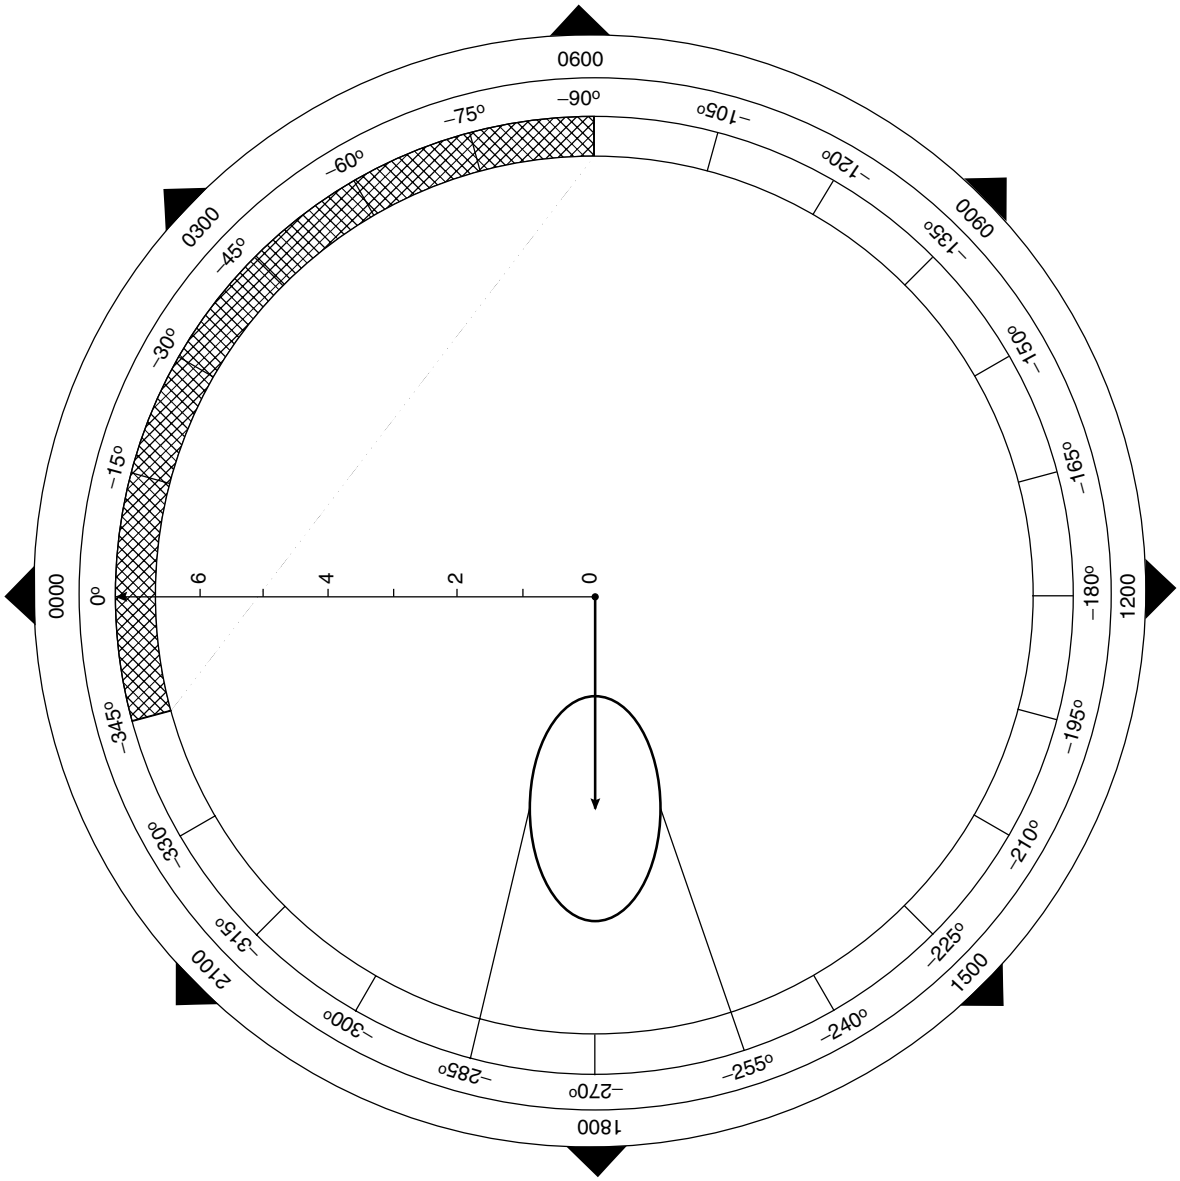

Figure 1 A cosinor display

In some studies a single subject is measured over several days and the resulting data constitute a single *time series*. Standard methods of time series analysis, such as the *correlogram* and the *spectrogram*, can then be applied. In addition, circadian rhythm researchers often use simple displays such as *Aschoff bars* and *Buys-Ballot Tables* [2].

A *sinusoid* with a period of 24 h is often fitted to data in order to estimate the amplitude and phase of the rhythm. As in *linear regression* (*see* **Linear Regression, Simple**), the significance of the fit can be tested by *F statistics*, and the *goodness of fit* between the sinusoid and the data measured by R^2, the *proportion of variance explained*. One popular extension of this approach is the *Minnesota cosinor technique* [1], which combines time series data from a number of subjects to give an overall summary of the circadian variation. The method involves estimating the phase (ϕ) and amplitude (α) of each subject, transforming these estimates to a Cartesian system ($x = \alpha \cos \phi$, $y = \alpha \sin \phi$), averaging x and y across subjects, and then back-transforming the averages to give estimates for ϕ and α of the sample. The circular confidence region for x and y gives rise to an elliptic confidence region for ϕ and α. A circadian rhythm is significant if the confidence region for ϕ and α does not include the origin (i.e. $\alpha = 0$). The result of such an analysis is usually presented in a *cosinor display*, which is a plot of ϕ and α and their confidence region in polar coordinates with time (i.e. phase) represented clockwise from 00 : 00 (north) through 06 : 00 (east), 12 : 00 (south), 18 : 00 (west) and back to 00 : 00. An illustrative example of a cosinor display is shown in Figure 1.

Circular Data Models

Circular data are data measured in the form of angles or two-dimensional orientations, and so can be represented as points on the circumference of a unit circle, or as (endpoints of) diameters of a unit circle.

Statistical models for circular data have found a particularly felicitous area of application in biology, not so much because of the range of models required (indeed, the converse is true) but because of the wealth of fascinating experiments the analysis of which requires the models and methods.

Typical of the problems of interest to biological scientists are those of bird navigation and of general orientations selected by particular creatures in response to experimental variation of their natural habitat (or of parts of themselves).

For the specific areas of medicine and the health sciences, there has been rather less use of circular models. (One of the more common applications has been to the study of **circadian variation**.) Nevertheless, there remains scope for their application. Subsequent sections of this article will review material which should be of most immediate value: modeling a single sample of circular data; **association** and **regression** involving a circular random variable; and **time series** models for circular data. The reader is referred to [4] for use of these models in statistical analysis.

Statistical Models for a Circular Population

In this section we introduce the most useful probability models for samples of circular data. However, some important points need to be made before this is done:

1. Probability distribution and density functions for *circular* data are defined differently from those for *real* (i.e. *linear*) data, with corresponding differences for the types of moments used. This issue is elaborated in the next subsection.
2. Circular data arise commonly in one of two forms:
   (i) *Vectorial* data, or data with a *sense of direction*, which can be represented as unit vectors, or as points on the circumference of a circle of unit radius; for example, arrival times (on a 24-hour clock) at out-patient clinics at a hospital.
   (ii) *Axial* data, or *undirected* data, which can be represented as oriented lines of unit length, or as (the two endpoints of) diameters of a unit circle; for example, the orientation of the principal axis of a blood cell on a plate being viewed under a microscope. If Θ is an axial random variable, then the values Θ and $\Theta + \pi$ are indistinguishable. The transformed variate $\Theta' = 2\Theta[\text{mod } 2\pi]$ is generally used for the purposes of modeling and analysis. Exceptionally, p-axial data are encountered; that is, data for which the values
   $$\Theta, \Theta + \frac{2\pi}{p}, \Theta + 2\frac{2\pi}{p}, \ldots, \Theta + (p-1)\frac{2\pi}{p}$$
   are indistinguishable. In this case the working variate becomes $\Theta' = p\Theta[\text{mod } 2\pi]$. Thus, special probability models are not required for these cases.
3. This discussion treats only univariate models: no tractable models for *multivariate* circular data have been developed, even for a case as simple as bivariate circular data. This is partly because, with the exception of the von Mises distribution, the most useful models for univariate unimodal circular data are not members of the **exponential family**, and in the case of the von Mises distribution, Mardia [7] has shown that the only bivariate distribution of exponential form with von Mises marginals is just the product of the marginal distributions.

Circular Probability Density Functions, Distribution Functions, and Trigonometric Moments

The *probability density function* (pdf) $f(\theta)$ of a continuous circular random variable Θ is a nonnegative continuous periodic function such that, for all θ,

$$f(\theta) = f(\theta + 2\pi)$$

and

$$\int_{\theta}^{\theta+2\pi} f(\phi)\, \mathrm{d}\phi = 1.$$

The *distribution function* $F(\theta)$ corresponding to $f(\theta)$ can be defined over any interval (θ_1, θ_2) by

$$F(\theta_2) - F(\theta_1) = \int_{\theta_1}^{\theta_2} f(\theta)\, \mathrm{d}\theta.$$

Corresponding to ordinary moments on the real line are trigonometric moments for Θ. The pth trigonometric moment is given by

$$\begin{aligned}\mu'_p &\equiv \rho_p \exp(\mathrm{i}\mu'_p)\\ &\equiv \alpha'_p + \mathrm{i}\beta'_p,\end{aligned}$$

where α'_p and β'_p are the pth cosine and sine moments, respectively. When $p = 1$, we simply write ρ for ρ_1, μ for μ_1; that is,

$$\mu'_1 = \rho \exp(\mathrm{i}\mu),$$

where μ is the *mean direction* and ρ the *mean resultant length*, $0 \le \rho \le 1$. If $\rho = 1$, the distribution is concentrated in a single direction (μ). However, $\rho = 0$ does *not* imply that the distribution is uniform: for example, a distribution with pdf such that $f(\theta) = f(\theta + \pi)$ will have $\rho = 0$.

The *central trigonometric moments* of Θ are obtained computed relative to the population mean direction:

$$\begin{aligned}\mu_p &\equiv \rho_p \exp(\mathrm{i}\mu_p)\\ &= \int_0^{2\pi} \exp[\mathrm{i}p(\theta - \mu)] f(\theta)\, \mathrm{d}\theta\\ &\equiv \alpha_p + \mathrm{i}\beta_p.\end{aligned}$$

When $p = 1$, we obtain $\alpha_1 = \rho$ and $\beta_1 = 0$.

Some functions of the first and second trigonometric moments are also of value. The *circular variance* of Θ is defined by

$$v = 1 - \rho, \quad 0 \le v \le 1.$$

The *circular standard deviation* is defined *not* as $\sqrt{v}$ but as

$$\sigma = \{-2\log(1 - v)\}^{1/2} \equiv \{-2\log\rho\}^{1/2}.$$

For v small (i.e. ρ near 1),

$$\sigma \simeq (2v)^{1/2} \qquad \text{or} \qquad \{2(1 - \rho)\}^{1/2},$$

the error in the approximation being less than 5% for $v < 0.18$: equivalently, $\rho > 0.82$. An associated measure of spread is the *circular dispersion*

$$\delta = \frac{(1 - \rho_2)}{2\rho^2},$$

the sample counterpart of which plays an important role in large-sample statistical inference for the mean direction.

Definitions of other quantities, such as measures of skewness and kurtosis, median and modal directions, and other measures of spread, are also available [4, Section 3.3].

Probability Distributions on the Circle: the Uniform Distribution

The **uniform distribution** plays a rather more important role in the analysis of circular data than for linear, as it provides the null model against which alternatives – unimodal or multimodal – are assessed. The pdf, df, and moments for this distribution and the other distributions described in this section are provided in Table 1.

Probability Distributions on the Circle: Unimodal Distributions

Here, we provide definitions and basic properties of the most useful probability models. The reader is referred to [6], [8], and [4] for more detailed discussion, methods of data analysis, and references to related work.

Wrapped Models

Let X be a random variable on the real line, with pdf $g(x)$ and df $G(x)$, and define $\Theta \equiv X[\mathrm{mod}\ 2\pi]$. Then Θ has a *wrapped* distribution on the circle, with pdf and df given, respectively, by

$$f(\theta) = \sum_{k=-\infty}^{\infty} g(\theta + 2k\pi)$$

and

$$F(\theta) = \sum_{k=-\infty}^{\infty} [G(\theta + 2k\pi) - G(2k\pi)].$$

Details about the properties of wrapped distributions can be found in [6, Section 3.4.8].

Two particular unimodal distributions obtained in this way, the wrapped Cauchy and the wrapped normal distributions, have found useful application in circular statistics. These are two-parameter symmetric unimodal distributions; their density and distribution functions and moments are shown in Table 1. Both have the uniform distribution as one limiting form, as the mean resultant length goes to zero. The wrapped

Table 1 Probability density functions, distribution functions, and central trigonometric moments for some standard circular distributions. $I_p(\kappa)$ denotes the modified Bessel function of order p. Note that $\beta_p = 0$, $p > 1$, as the distributions are symmetric

Distribution	Probability density function, $f(\theta)$	Distribution function, $F(\theta)$	μ	ρ	α_p, $p > 1$
Uniform	$1/2\pi$	$\theta/2\pi$	Un-defined	0	0
Wrapped Cauchy	$\frac{1}{2\pi}\frac{1-\rho^2}{1+\rho^2-2\rho\cos(\theta-\mu)}$, $0 \le \rho \le 1$	$\frac{1}{2\pi}\cos^{-1}\left[\frac{(1+\rho^2)\cos(\theta-\mu)-2\rho}{1+\rho^2-2\rho\cos(\theta-\mu)}\right]$	μ	ρ	ρ^p
Wrapped normal	$\frac{1}{2\pi}\left[1+\sum_{k=-\infty}^{\infty}\rho^{k^2}\cos k(\theta-\mu)\right]$, $0 \le \rho \le 1$	(Integral of $f(\theta)$)	μ	ρ	ρ^{ρ^2}
von Mises	$\frac{1}{2\pi I_0(\kappa)}\exp[\kappa\cos(\theta-\mu)]$, $\kappa \ge 0$	(Integral of $f(\theta)$)	μ	$\frac{I_1(\kappa)}{I_0(\kappa)}$	$\frac{I_p(\kappa)}{I_0(\kappa)}$

normal distribution behaves effectively as a normal distribution as ρ approaches unity (so that the effect of wrapping is negligible).

The wrapped Cauchy has found indirect use in algorithms for simulating data from von Mises distributions. The numerous desirable properties enjoyed by the normal distribution on the line are, on the circle, shared by the wrapped normal and von Mises distributions. For suitably chosen values of their dispersion parameters, all three distributions can be made very close to each other, so that samples from each are indistinguishable in practice, except with large data sets. As a consequence, one uses whatever is most convenient to the problem in hand.

The von Mises Distribution

Notwithstanding the preceding remarks about the closeness of the wrapped normal, wrapped Cauchy, and von Mises distributions, it is the von Mises distribution that enjoys many of the useful *inferential* properties possessed by the normal distribution on the line. As such, it is the most common model for a sample of unimodal circular data. As $\kappa \to 0$, the distribution tends to the uniform. The size of the *concentration* parameter κ is crucial for application of many parametric procedures. For $\kappa < 2$, corresponding to relatively dispersed distributions, there is significant density at the antimode (i.e. $f(\mu + \pi) >> 0$), and many of these procedures require (data-dependent) adjustment to work satisfactorily. As $\kappa \to \infty$, the von Mises distribution tends to the normal with variance $1/\kappa$.

Other Probability Models for Circular Data

Few other models for univariate circular data have found practical application. Batschelet [2] and Mardia [6] have described asymmetric models and models for discrete data, and some application has been found for mixture models, mainly mixtures of von Mises distributions.

Similarly, little is available by way of multivariate distributions involving circular random variables. Fisher [4] provides references to bivariate models in the literature.

Association and Regression Involving a Circular Random Variable

Whereas, with linear data, the topics of **association** and **regression** are sometimes presented independently of each other, this is not possible with circular data. At least for relationships involving both linear and circular variates, we need first to look one step ahead: Is the purpose of the proposed analysis to be able to predict the mean direction of Θ for a given value x of a linear variate X, or to predict the mean of X given that $\Theta = \theta$? Without answering this question it is not possible to assess the association or correlation between Θ and X. More details relating to this area can be found in [4, Chapter 6].

Some work has been done on the analysis of experiments with a circular response: see [1] for a survey of the literature.

Association Between Two Circular Random Variables

The joint distribution of two circular random variables Θ and Φ is concentrated on the surface of a torus. A simple analogue of complete linear association between real variates X and Y is so-called *T-linear association:*

$$\Theta = \Phi + \theta_0 [\text{mod } 2\pi] \qquad \text{(positive association)}$$

or

$$\Theta = -\Phi + \theta_0 [\text{mod } 2\pi] \qquad \text{(negative association).}$$

The extent to which Θ and Φ are so correlated can be measured by a simple analog of the linear correlation coefficient, namely

$$\rho_T = \frac{\mathrm{E}[\sin(\Theta_1 - \Theta_2)\sin(\Phi_1 - \Phi_2)]}{\{\mathrm{E}[\sin^2(\Theta_1 - \Theta_2)\sin^2(\Phi_1 - \Phi_2)]\}^{1/2}}$$

for variate pairs (Θ_1, Φ_1) and (Θ_2, Φ_2) distributed independently as (Θ_1, Φ_1): compare with the alternative representation of Pearson's product moment correlation coefficient as

$$\frac{\mathrm{E}[(X_1 - X_2)(Y_1 - Y_2)]}{\mathrm{E}[(X_1 - X_2)^2(Y_1 - Y_2)^2]^{1/2}}$$

(*see* **Correlation**).

Analogously to a monotone relation between X and Y, we can define a concept of complete *T-association* as one in which, when Θ moves clockwise (counterclockwise) so does Φ, with the opposite happening for negative association. Whereas, for linear variates, Kendall's τ provides a simple measure of monotone association based on two independent pairs (X_1, Y_1) and (X_2, Y_2) (*see* **Rank Correlation**), three independent pairs are required to define an analogous measure for circular variates.

Association between a Circular rv and a Linear rv

Let Θ and X be circular and linear random variables respectively, the association of which we seek to assess.

Linear–Circular Association. The simplest form of model for the conditional mean of X given Θ is provided by the periodic relationship

$$\begin{aligned} \mathrm{E}(X|\Theta = \theta) &= \alpha_0 + \beta_0 \cos(\theta - \theta_0) \\ &\equiv \alpha_0 + \alpha_1 \sin\theta + \alpha_2 \cos\theta. \end{aligned}$$

It is termed *C-linear* association. In this form, it is clear that an appropriate measure of association between X and Θ is a measure of multiple correlation between X and $(\sin\Theta, \cos\Theta)$.

By analogy with a monotone relationship between two linear random variables, C-linear association can be generalized to *C-association*:

$$\mathrm{E}(X|\Theta = \theta) = \alpha_0 + \beta_0 f[\cos(\theta - \theta_0)],$$

where $f(\cdot)$ is a monotone function of its argument. The extent of C-association can then be gauged by an analogue of Kendall's τ.

Circular–Linear Association. In the same way that modeling linear–circular association leads, at least for prediction purposes, to models relating linear variates, so the modeling of circular–linear association leads to models relating circular variates. The *circular–linear* association between Θ and X can be computed as the *circular–circular* association between Θ and $\Phi = 2\tan^{-1}(X)$.

Model for Linear–Circular Regression. From the previous discussion, it can be seen that this reduces to a standard multiple regression model.

Model for Regression with Circular Response. To model Θ as a function of a vector $\mathbf{x}$ of linear explanatory variables, suppose that the mean direction μ of Θ is related to $\mathbf{x}$ by the equation

$$\mu = \mu_0 + g(\boldsymbol{\beta}'\mathbf{x}),$$

where $\boldsymbol{\beta}$ is a vector of regression coefficients and $g(\cdot)$ is a (monotone) *link function*, which maps the real line into the circle. An example of such a link function would be $g(u) = 2\tan^{-1}(u)$. The model can be fitted quite generally, using the directional analog of least squares; however, if Θ is modeled as a von Mises variate, likelihood methods become applicable.

For suggested approaches to modeling the mean direction of Θ conditional on a circular explanatory variable ϕ, see the discussion and references in [4, Section 6.4.5].

Time Series Models for Circular Data

As noted in the discussion of probability models, there are no satisfactory models for correlated circular data, as a consequence of which modeling time series of circular data poses rather more problems than modeling time series of linear data. It is helpful to distinguish series with moderate noise from very noisy series, so two approaches are described.

Each approach utilizes link functions (cf. the preceding discussion of angular regression). Let $g(x) : (-\infty, \infty) \to (-\pi, \pi)$ be an increasing function of x such that $g(0) = 0$ and $g(-x) = -g(x)$. (One such example is the arc tan link function suggested for regression.)

For such link functions, if X is a linear random variable, then $\Theta = g(X)$ is a circular random variable; and conversely, $g^{-1}(\cdot)$ transforms a circular variate to a linear one. Now define $\{\theta_t\}$ to be a *linked ARMA(p,q) process* (*see* **ARMA and ARIMA Models**), or a *LARMA(p,q) process,* if its linked linear process $\{g^{-1}(\theta_t)\}$ is an ARMA(p,q) process.

We need to differentiate dispersed from concentrated situations. Broadly speaking, a unimodal circular variate is dispersed if its density assigns non-negligible mass to all parts of the interval $(-\pi, \pi)$: for a von Mises variate, this corresponds to a distribution with $\kappa < 2$. A distribution concentrated on a subset of $(-\pi, \pi)$ provides the opportunity to use

approximate methods based on linear-variate theory. For concentrated time series, complete LARMA(p,q) processes can be fitted. For noisier series, the only methods available at present relate to fitting autoregressive models.

For more detailed discussion of these and other methods, see [3]–[5].

Cladistic Analysis

In **association** studies, when a set of linked **markers** is available an analysis based on haplotypes is more powerful than one using only a single marker. **Haplotype analysis** does not require the discovery of every disease variant, but does assume that **linkage disequilibrium** exists between the markers and the disease variants. Moreover, the number of haplotypes can be very large when many markers are typed, thereby reducing the power to test for association. The critical challenge is to maintain precision without losing power by combining the information from different haplotypes. Templeton et al. [14–18] introduced cladistic analysis which incorporates information on the inferred evolutionary relationships of the sample haplotypes to identify disease variants. The central assumption behind this approach is that an unknown **mutation** causing a phenotypic effect occurred at some point in the evolutionary history of the population and became embedded within the historic structure represented by the cladogram. In other words, certain portions of the cladogram would display phenotypic effects different from the other portions, depending on the mutations that are shared. Thus, the cladogram defines a nested analysis that is efficient for detecting associations between measured genotypic variation and phenotypic variation at the population level. Cladistic analysis consists of two steps: constructing a cladogram of the haplotypes that reflects the evolutionary relationships; and conducting a nested analysis.

Constructing a Cladogram

Assuming we know the individual haplotypes, an evolutionary tree can be constructed by the method of maximum parsimony used for phylogeny reconstruction, as implemented in the computer program PAUP [11] or PHYLIP (software by J. Felsenstein, Version 3.57). The parsimony algorithm determines the unrooted tree that connects the observed haplotypes using the minimum number of mutations. The method of parsimony is robust and effective for reconstructing evolutionary relationships, although it does not use the frequencies of the haplotypes in the sample [12]. For example, Figure 1 shows a cladogram of 25 haplotypes found in the 13-kb alcohol dehydrogenase (ADH) (*see* **Gene**) locus in the fruit fly *Drosophila melanogaster* constructed using PHYLIP [15]. Each branch represents a single mutational change between

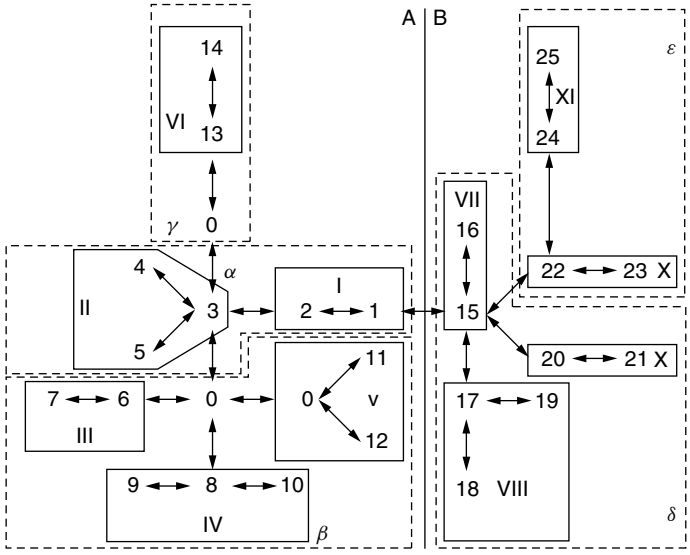

Figure 1 The cladogram defined by the nesting algorithm. The haplotypes enclosed by solid lines indicate the 1-step clades and are represented by Roman numerals. The dashed lines enclose the 2-step clades that are designated by Greek letters. A thick, solid line indicates the partitioning of the cladogram into two 3-step clades, designated by Roman letters. From Templeton et al. [1], reproduced with permission of the Genetics Society of America

haplotypes. Zeros refer to the inferred intermediate haplotypes that are not found in the sample but are necessary to connect the existing haplotypes. To summarize the evolutionary information Templeton et al. [15] developed a nesting algorithm to classify the haplotypes within clades. The nesting algorithm is as follows:

1. All the haplotypes in the cladogram are considered as 0-step clades.
2. Assume the n-step clades have been formed. Define the n-step clades with only one arrow pointing at them in the cladogram as "terminal" n-step clades, otherwise, as "internal" n-step clades.
3. Define the $n+1$ step clades as sets of all n-step clades that can be joined together by moving back one mutational step from the terminal n-step clades. After this operation, any remaining internal n-step clades that have not been incorporated into an $n+1$ step clade require further attention to be correctly classified. First, identify those remaining n-steps that are adjacent to (i.e. separated by one mutational step away from) an $n+1$-step clade that was defined in the initial operation. These n-step clades are then regarded as "terminal", and the operation is repeated. This procedure is iterated as needed until all n-step clades are members of an $n+1$-step clade.
4. Repeat step 3 until the entire cladogram can be united into a single category.

For example, haplotypes 4, 5, 7, 9, 10, 11, 12, 14, 16, 18, 19, 21, 23 and 25 in Figure 1 represent terminal 0-step clades and the remaining haplotypes are internal 0-step clades. Using the nesting algorithm, 1-step clades can be created as in Figure 1, represented by Roman numerals. To construct the 1-step clade II, for instance, the terminal 0-step clade haplotype 4 is found to be distinguished from haplotype 3 by one mutation. Similarly, haplotype 5 has one mutational difference with haplotype 3. Hence, haplotypes 3, 4 and 5 are joined into a 1-step clade. Repeating this procedure for all the terminal haplotypes leads to internal haplotypes 1 and 2 not being placed within a 1-step clade (haplotype 2 is one mutational step from the 1-step clade II; haplotype 1 is one step from the 1-step clade VII). Hence, according to step 3, both haplotypes 1 and 2 are now regarded as "terminal" and can be joined together because they are one mutational step from each other. Similarly, the 2-step clades can be defined from the 1-step clades as indicated by Greek letters, and the same procedure is applied to generate the 3-step clades, indicated as A and B in Figure 1. On the basis of these sequential operations, the algorithm thus gives a nested design.

Cladistic analysis has been recently applied in humans to study the association of angiotensin-1 converting enzyme (ACE) level with variation in the ACE gene [7, 20]. In the study of 159 randomly sampled Afro-Caribbeans by Zhu et al. [20], seven **polymorphisms** were genotyped within the ACE gene and 28 haplotypes were inferred using Clark's algorithm [1]. The positions of the seven polymorphisms are given in Figure 2. Eight common haplotypes, accounting for 83% of the total variability, were used for cladistic analysis, the remaining haplotypes being combined as R [20]. An unrooted evolutionary tree, shown in Figure 3, was first constructed from the eight haplotypes by the principle of maximum parsimony incorporated using PHYLIP. The nesting algorithm was then used to group the haplotypes. In Figure 3, haplotype 4 (note that numbers appear below the haplotypes) was grouped in clade C and haplotype 3 was grouped in clade B. Strictly, clades B and C should be considered as 2-step clades according to the above algorithm of Templeton et al. [15].

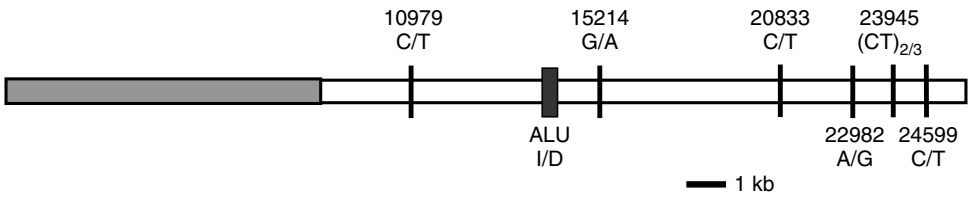

Figure 2 Polymorphic markers genotyped in ACE. From Zhu et al. [10], reproduced with permission of the University of Chicago Press

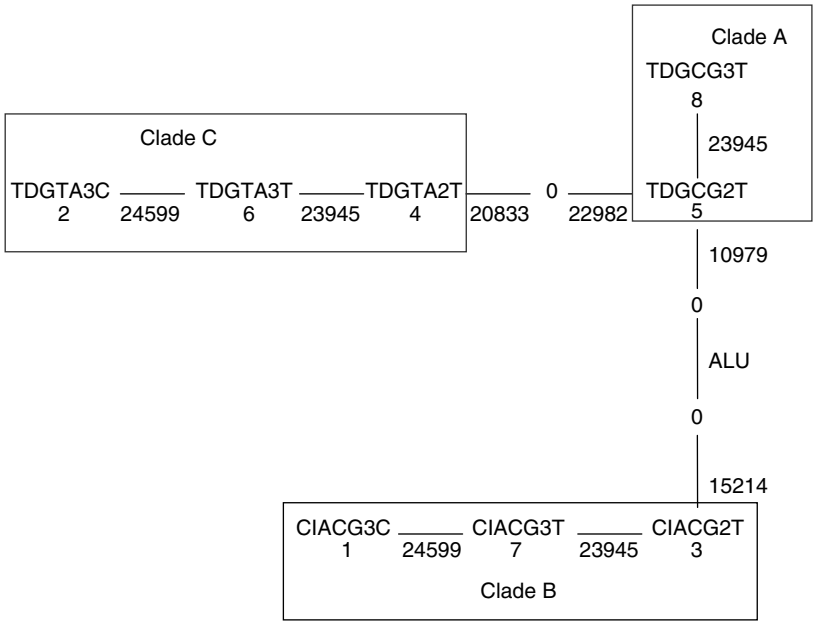

Figure 3 The eight most frequent haplotypes were used to infer a maximum parsimony tree. Haplotypes were then grouped with neighboring haplotypes into clades A, B and C. The maximum parsimony mutational connections among the haplotypes are indicated by solid lines, with the 0s representing all intermediate haplotypes that are missing from the sample. The number below the haplotypes corresponds to the haplotype, and the number below or beside the solid lines is the mutation site. The phenotypic effects attributed to these groups were tested under different model assumptions against plasma ACE activity using a measured haplotype analysis. From Zhu et al. [10], reproduced with permission of the University of Chicago Press

Nested Analysis

After defining a cladogram, there is the problem of how to carry out a nested analysis to estimate the phenotypic effects of specific haplotypes, realizing that we are dealing with the transmission of a phenotypic value from parent to offspring, and that parents pass on haplotypes, not **genotypes**, to their offspring. When homozygous genotypes are segregating in the population (i.e. each individual has two identical haplotypes), a NANOVA is an efficient method to detect and localize phenotypically important mutations for quantitative phenotypes. For example, Templeton et al. [15] performed a NANOVA of ADH level for the cladogram presented in Figure 1. The results of this NANOVA are given in Table 1. The most significant effect is associated with the transitional step between the 3-step clades A and B (Figure 1). There are also significant phenotypic effects found at the 1-step and 0-step levels. Since there are many 1-step and 0-step clades, further decomposition of variance is needed to localize the effects at these levels [15].

NANOVA will not work for populations whose members carry two different haplotypes, as in human populations. Consequently, assigning phenotypic effects to each haplotype is the core of the analysis. Fisher [5] developed two methods to measure the

phenotypic effect of a haplotype: (a) the average excess of a haplotype, defined as the average phenotypic value of the haplotype minus the overall population mean; and (b) the average effect, defined as the least-squares regression coefficient from the linear relationship between the phenotype and the number of copies of each haplotype (0, 1 or 2) an individual possesses. Under the assumption of **Hardy–Weinberg equilibrium**, the average excess is equivalent to the average effect [13]. Templeton et al. [18] proposed a random permutation procedure using average excess to test the phenotypic associations for populations containing both heterozygous and homozygous genotypes. When this procedure was used to investigate the association between the ADH locus and ADH activity in *Drosophila melanogaster*, Templeton et al. found that the result of the random permutation procedure was consistent with that from NANOVA for this homozygous population. Zhu et al. [20] modeled the relationship between ACE plasma level, sex, age, and haplotype using a **linear regression** model for the cladogram in Figure 3. Thus, the least-squares estimates of the haplotype effects are their adjusted average effects. To localize the important mutation affecting ACE level variance, a series of model comparisons can be performed. On the basis of the cladogram in Figure 3, the hypothesis was first tested that the average effect on ACE level is the same for haplotypes within each clade. This comparison can be tested by the goodness-of-fit test between model [A, B, C, R] and the full model [1, 2, 3, 4, 5, 6, 7, 8, R], which assumes that each haplotype has a different average effect on the ACE level. Table 2 shows that this comparison is not statistically significant, indicating that the average effects are similar within each of the three clades A, B and C. Next the average effects on the ACE level of clades A, B and C were compared. Because of the evolutionary relationships revealed in Figure 3, only two such comparisons were necessary, namely the average ACE level between A and B and that between A and C. As shown in Table 2, no significantly different average effects were found between clades A and B, but a significant difference was found between clades A and C, after adjusting for **multiple comparisons**. One can see from the cladogram that there are two mutational differences between clades A and C, occurring at the connected positions 20 833 and 22 982, and three mutational differences between clades A and B. However, differences of this sort can also result from an ancestral recombination that occurred between sites 15 214 and 20 833. By calculating the linkage disequilibrium between each pair of polymorphisms and testing for recombination [2], Zhu et al. found that an ancestral recombination between 15 214 and 20 833 was in fact more likely than multiple mutations. Therefore the functional variant causing ACE variation is unlikely to be located in the segment between 10 979 and 15 214. Similar arguments also exclude the segment between 23 945 and 24 599 as the location of an ACE functional variant. The 9-kb interval between 15 214 and 23 945 therefore most likely bears the functional ACE variant.

Conclusion

Cladistic analysis is a potentially powerful method for analyzing association between a set of tightly linked markers and phenotypic variation, especially for **candidate gene** studies. Since cladistic analysis uses the historical relationships between haplotypes, the necessary multiple comparisons can be conducted objectively guided by the cladogram. Consequently, the number of multiple comparisons can be reduced and the power to detect association thus improved.

Table 2 Model comparisons

	P-value obtained against model [1, 2, 3, 4, 5, 6, 7, 8, R]			
Model	Overall	Male	Female	Overall by EM
A, D, C, R (2 = 6 = 4, 5 = 8, 1 = 7 = 3, R)	0.3809	0.1028	0.1028	0.2878
A = B, C, R	0.4344	0.1508	0.9770	0.3617
A = C, B, R	0.016	0.016	0.6244[a]	0.015

[a] *P* value is 0.0636 in the test against model [A, B, C, R]. From Zhu et al. [10], reproduced with permission of the University of Chicago Press.

The method has been successfully used to localize the deoxyribonucleic acid (DNA) region affecting the ACE level in different populations [7, 20]. In an analysis of simulated data at the Genetic Analysis Workshop 12, Zhu et al. [19] also localized the Q1 functional mutation to the correct region using cladistic analysis. Although cladistic analysis was developed for quantitative phenotypes, it can also be extended to **case–control studies** of qualitative traits. Templeton [14] studied the association between haplotypes and Alzheimer's disease by performing a series of nested 2 (case and control) $\times\, n(i)$ contingency table analyses, where $n(i)$ is the number of clades in the nested category i. If the sample is small, then a permutation chi-square test can be performed using the algorithm of Roff & Bentzen [8]. **Logistic regression** and a series of goodness-of-fit tests based on the **likelihood ratio** statistic can also be adapted for nested model comparisons when we are analyzing qualitative traits.

As with all statistical methods, cladistic analysis has its limitations. The power of the method is dependent on the fidelity with which the estimated cladogram reflects the true evolutionary relationships. Several factors, such as recombination and **gene conversion**, can affect the accuracy of this estimate. To keep these sources of error to a minimum, recombination and gene conversion should be relatively rare, and this is a reasonable assumption in a candidate gene association study. If this assumption is not valid, then analyses on subdivisions of the region may be necessary [17].

Cladistic analysis requires that each individual's haplotypes be known. When samples are random, the haplotypes can be inferred with a high degree of accuracy using Clark's [1] subtracting algorithm. For family data, SIMWALK2 developed by Sobel & Lange [9], which uses simulated annealing based on a Markov process, can be used. However, uncertainty of haplotype assignment has an impact on cladistic analysis. For random samples and quantitative phenotypes, Zhu et al. [21] proposed using a two-step approach to model the relationship between the phenotype and genetic markers: (a) estimate the haplotype frequencies using the **EM algorithm** – well-developed methods are available for this purpose [3,4,6,11]; and (b) use a mixture model approach to model the association between the trait and the haplotypes. Zhu et al. [21] applied this two-step approach to the Jamaican data set described above and obtained results consistent with that using Clark's algorithm (EM results are presented in the last column of Table 2).

In summary, cladistic analysis has emerged as an important tool for detecting associations between measured genetic and phenotypic variation at the population level, although some limitations must be anticipated when the assumptions are not met. Only further practical experience will define the full contribution this analytic method can make to **genetic epidemiology**.

Classification, Overview

This article gives a general review of classification problems that occur in biometrics (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**; **Discriminant Analysis, Linear**). Confusingly, the term *classification* has two complementary meanings in the statistical literature. Firstly, it is concerned with assigning a sample to one of a set of previously recognized classes, and secondly, it is concerned with the construction and description of the classes themselves.

In classical statistical writings, classification is concerned with assigning a name to a given sample based on the values it is observed to have on some set of variables; that is, it is concerned with identification. This usage is better described as discrimination; the theory of discriminant analysis is an important part of statistics [1, 8, 15, 22, 23, 27, 30]. Basically, discrimination is concerned with labeling the sample with some name: in botany, based on the observed features of a plant, the kind of flower is identified; in medicine, based on a set of symptoms and/or biochemical tests, the disease from which a patient is suffering is identified; in banking, based on a prospective customer's financial record, the bank needs to decide whether to issue a credit card. In these examples, the assignment classes are the species of plants, the diseases to which humans are susceptible, and the populations of credit-card holders and nonholders. In the latter case there are only two possibilities (to issue or not to issue a card), and commonly assignment is to one of two classes. In the medical example, except perhaps for general expert systems for medical diagnosis, physicians would normally already have narrowed things down to a very few possibilities – perhaps merely healthy and infected with some specific disease. With plants, we may already have decided on plant genus and merely wish to decide between the relatively few species within the genus; on the other hand, we may be totally at sea and first wish to decide between the genera. Thus, when discriminating, it is fundamental first to have recognized the set of classes of interest. The values of variables may or may not overlap the classes. An example of a variable which overlaps classes is given by blood pressure, which varies in the population and with two groups of patients – one healthy and one not. It is to be expected that some healthy patients will have as high blood pressures as some with heart disease. Nonoverlapping variables are usually **categorical**, such as color, which completely separates dandelions, which are yellow, from daisies, which are white. Broadly speaking, when classes are close, with *overlap*, probabilistic methods have to be used, but when classes are distinct, assignment can be satisfactorily accomplished by using nonprobabilistic methods. When probabilistic assignment is appropriate, then it is implied that there is some probability of getting things wrong, and this encourages the development of methodology that is concerned with minimizing the probability of incorrect classification. From the probabilistic point of view, nonprobabilistic assignment is trivial, for with no overlap there is no possibility of being wrong. Nevertheless, as shown below, interesting problems arise.

All the above is concerned with assignment to classes where, as we have seen, it is assumed that relevant classes are recognized at the outset. Often, these known classes will have been described from substantive research in the field of application. Thus, medical researchers describe diseases, botanists describe plant species, and bankers know that some customers are good risks and others are bad risks. In contrast to defining classes on the basis of substantive knowledge, classes may be formed by using statistical methods. This is the second kind of problem, referred to above, where one is given an unstructured collection of what we shall provisionally term *objects*, which are not differentiated in any way. The question arises as to whether these objects might with advantage be allocated to two or more classes. This is the problem of *constructing* classifications, and it occurs very widely. It has several variants, depending on (i) whether or not the variables used to describe the objects are **random variables**, and on (ii) whether the objects represent individual samples, as is usual in the statistical literature, or whether they themselves represent previously recognized classes which one wishes to group into fewer classes at a higher level. In the most simple cases, an object may represent a class with many identical members; this is typical of classes which represent well-separated biological populations; all buttercups are yellow and all cats have claws, so in these respects, describing one buttercup or cat describes them all. Alternatively, an object may represent an entire statistical population with well-defined distributional form, very

likely a formalization of a distinct biological population, in which case replication within the population is formally possible and replicate within-population individual samples may be available. In both these cases, we shall say that the objects are *structured*, that is to say that every given object has been assigned to one of K, say, population classes. In the first case each population is represented by a single object, it being assumed that there is no variation within any population with respect to the variables with which we are concerned, or at least that variation is unimportant. With this assumption we are nearly always concerned with qualitative/categorical variables because it is inconceivable that quantitative variables do not vary in populations. In the second case, there are several, n_k, sample replicates within the kth population, and we shall be concerned mainly with quantitative variables.

In another variant of the second kind of problem, that of constructing classifications, rather than differentiated objects we may have N *undifferentiated* objects. This would be the case if we had a random sample of size N drawn from a single population. However, in the context of classification, it is common to have what looks like a random sample of size N, but we may have a strong suspicion that these N cases might be classified with advantage into a few classes. That is, we are not given any form of classification at the outset, so assignment is not relevant, but nevertheless we may wish to construct a classification. We may hypothesize that the samples come from a mixture of K populations with some specified parametric forms, and wish to decide on the number of components in the mixture and to estimate the unknown parameters. Additionally, we may indeed assign each sample to one of the newly identified component populations.

Using the terminology developed above, Table 1 lists the kinds of classification problem discussed in the remainder of this article.

Discrimination – Assignment to Classes

We first discuss the problem of assigning samples, cases, and objects to preassigned classes. As Table 1 shows, all assignment problems are concerned with structured objects. These problems may be considered either in a probabilistic framework or not. We first consider nonprobabilistic assignment.

Nonprobabilistic Assignment

The most simple method of identification, that is of assigning a name to a specimen, is to compare the properties of the specimen with the entries in a table listing the properties of every named class of relevance. Such a table is called a *diagnostic table*. It is not necessary to list all properties – only some minimal subset that is sufficient for identification purposes. Perhaps more than one diagnostic table may be needed, each listing different subsets of properties. An example would be with the identification of plants where one table might be applicable to plants in their flowering state, another to their seeds and yet another to cover the vegetative state. Diagnostic tables are practicable only when deciding among a few putative classes, and more efficient methods, such as *diagnostic keys*, have to be sought for larger problems.

Diagnostic keys have been in use for several centuries to help identify plant specimens. Nearly every flora contains a key which helps botanists name a specimen plant. More recently, the idea of a diagnostic key has found wider applications either directly, as in diagnoses based on biochemical tests,

Table 1 The main types of classification problem discussed in this article

	Objects	Assignment	Construction
Nonprobabilistic	Structured	Matching	Maximal predictive classes
		Diagnostic keys and tables	Cluster analysis: k groups
			hierarchical
			others
Probabilistic	Unstructured	(Nothing to assign to)	Mixture problems
	Structured	Discriminant analysis	Not developed (but could be)

or conceptually, as in CART (*see* **Tree-structured Statistical Methods**), the more simple expert systems (*see* **Artificial Intelligence**), or as **neural networks**. The simple botanical key operates by requiring the botanist to decide whether the specimen they wish to identify has or does not have some feature. Table 2 shows the beginnings of a key to the genera of North American orchids.

This key shows several features of interest. First, we see that the key has a hierarchical structure, with the nodes numbered on the left-hand side. In its entirety, this particular key has 55 nodes but only the first four are shown; further nodes must be added to distinguish between the various species within each genus, thus allowing the specimen to be named. On the right-hand side, the response to each question shown leads either to another node, and another question, or to an identification given in italics with a page reference where further information may be found [31]. The tree is binary with two possible outcomes at each node. Nodes need not be **binary**; indeed, node 26 of this key has three outcomes:

26: Lip directed upward; spur absent	27
Lip directed downward; spur absent	29
Lip directed downward; spur present	30

Clearly, this node could be rearranged as two binary nodes: "Lip directed upward?" and "spur absent?". Most methodologic work on keys is concerned with binary keys. A "don't know" response can be accommodated by allowing the user to use both branches, and this possibility may be allowed for when constructing the key.

We have associated the term *questions* with nodes, but it is more usual to refer to *tests* rather than questions. **Algorithms** for key construction are heuristic and are aimed at minimizing (i) the number of nodes, or (ii) the number of different tests used, or (iii) the average number of steps to identification, or, when tests have a significant cost, (iv) the average cost of identification. In the latter two cases, the relative probabilities, or frequencies, of the various outcomes may become relevant. The cost of tests may be associated with the time it takes to do them. Clearly, in some applications, waiting for the outcome of one test before deciding what test to do next can be very inefficient. This is typical of biochemical applications where tests arise from laboratory work, often automated. Then, it may be desirable to do batches of tests in parallel, requiring methods for deciding which tests should be batched together. Other refinements allow for recovery from errors that have led one down the wrong branch, reticulation that takes one across branches (so the key no longer has the form of a simple tree), and check keys which allow one to verify the correctness of an identification by including further otherwise redundant tests. Payne & Preece [25] review the methodologic literature on keys.

In all of the above it is assumed that the outcomes of tests are error-free, so that probabilistic methods are not appropriate. This is often a reasonable assumption for taxonomic keys, particularly at the genus level where, for example, all *Hexalectris* have "Lateral sepals free at base". Uncertainty has not been neglected entirely because we have mentioned the possibility of accommodating "don't knows", of recovery from an error that has led one down an incorrect branch, and of verifying the correctness of an identification. Also the probabilities of possible outcomes may be taken into account in minimizing costs and average numbers of steps to identification.

Probabilistic Assignment

While distinct groups may be separated by nonprobabilistic methods such as the diagnostic keys discussed

Table 2 The beginnings of a key to the genera of North American orchids [31]

1. Orchids terrestrial in habit	2
Orchids epiphytic in habit	40
2. Orchids saprophytic, lacking chlorophyll or green leaves	3
Orchids not saprophytic, with green leaves or green bractlike scales on a green stem	5
3. Flowers, stem, and bracts white, leaves absent	*Cephalanthera* (p. 54)
Flowers, stem, and bracts brownish, purple, or yellowish; leaves absent	4
4. Lateral sepals free at base	*Hexalectris* (pp. 110–112)
Lateral sepals united at base, forming a mentum	*Corallorhiza* (pp. 112–114)
5. . . .	

above, finer distinctions will often require probabilistic methods of the kind described below. This occurs when tests or characteristics overlap classes. Blood pressure varies widely in the human population and what may be a high blood pressure for one person, indicating heart disease, may be normal in another person. Thus, blood pressure by itself cannot distinguish between the class of healthy people and the class of diseased people; the values of blood pressure *overlap* in the two classes, or groups. Methods for assigning samples to one or more groups each characterized by its own probability distribution are among the oldest multivariate problems studied by statisticians, and under the name *discriminant analysis* have a large statistical literature (see, for example, the books by Hand [15], Lachenbruch [22], and McLachlan [23]). To many statisticians *classification* and *discrimination* are synonymous.

Barnard [1], who was advised by Fisher, and Fisher [8] introduced discriminant analysis. Fisher was concerned with discriminating between three species of iris and Barnard with discriminating between skulls from four Egyptian dynastic periods. Thus, the classes are the three irises and the four dynasties; both studies had many samples from each class. Fisher's approach was to use **linear regression**, defining a **dummy variable** as the independent variable (or **explanatory variable**) for each class. Barnard, somewhat arbitrarily, used -3, -1, 1, and 3 to characterize the four dynastics. Fisher took the irises two classes at a time characterized by a dummy variable with values -1, 1; with two classes it is immaterial what values are given to the dummy variables. There were four measurements on the four iris species – sepal length and width, and petal length and width – so a linear regression of the dummy variable on the four dependent variables was performed and used for discrimination, assigning a sample to one group when the discriminant function is positive and to the other group when it is negative. It worked very well, with few misclassifications. The calculations are easy to do and the discriminant function, being linear, is easy to use. In addition, it turns out to be quite robust to a range of distributional assumptions about the dependent variables. Consequently, the method remains popular and is much used in biometric applications, including the discrimination between diseased and healthy groups. Regression methods are well-known to carry with them certain problems; they predict much better for the sample used to fit them than for subsequent samples, and this is especially true when an optimal subset is selected from all the variables available. Naturally, these problems transfer to linear discriminators. When there is sufficient data, they are often divided into two sets: one, *the training set*, is used to compute the discriminant function, and the other is used to validate it. The error rates of the validation set give a much truer assessment of performance.

A version of two-group discrimination that owes much to Fisher's linear discriminant arises as follows. Suppose p is the probability that a sample belongs to the first group and $q = 1 - p$ is the probability that it belongs to the second group. Then we may assume that $\log(p/q)$ is a linear function of the dependent variables (*see* **Logistic Regression**). This is *logistic discrimination*; the generalization is similar to that of discriminating between **loglinear models** and linear models (*see* **Generalized Linear Model**). Logistic discrimination requires the estimation only of the regression coefficients, which usually have far fewer parameters than are required for other methods, described briefly below. Also it has certain optimal properties for a range of distributional assumptions for the two populations (see [27] for a more detailed discussion and further references).

The discrimination methods so far described only have heuristic or intuitive appeal. Since Welch [30], there has been a continuous development of theoretical underpinning. This is based on assuming that the ith group has a known density function $f_i(\mathbf{x})$, and then examining the probabilities of **misclassification error** arising from various assignment rules R, say. There are two probabilities of misclassification $p(1|2)$ and $p(2|1)$, respectively: the probability of a sample from group 2 being classified as from group 1 and the probability of a sample from group 1 being classified as from group 2. An obvious optimal classification rule is to choose R to minimize $p(1|2) + p(2|1)$. Figure 1 illustrates the geometry of errors of misclassification. The locus $f_1(\mathbf{x}) = f_2(\mathbf{x})$ defines a rule that minimizes $p(1|2) + p(2|1)$, and any other locus will give a greater total error of misclassification. Thus, we are led to a discriminant rule to assign to groups 1 and 2 according to whether $f_1(\mathbf{x}) < f_2(\mathbf{x})$ or $f_1(\mathbf{x}) > f_2(\mathbf{x})$. If, as is very unlikely, $f_1(\mathbf{x}) = f_2(\mathbf{x})$, then it is arbitrary which group is chosen, and we may toss a coin to decide. This leads to discrimination on the basis of whether or

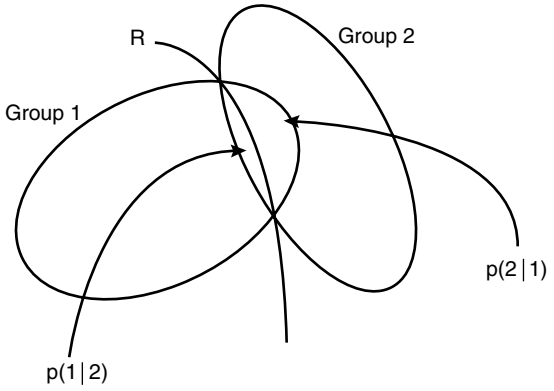

Figure 1 Illustration of the errors of misclassification for two groups. Although the elliptical shapes suggest normal distributions, they need not be so. The curve R separates space into two regions. Samples to the left of R are assigned to Group 1 and those to the right are assigned to group 2. R is supposed to show the locus of points with equal density and so passes through the intersections as shown

not the **likelihood ratio** criterion $f_1(\mathbf{x})/f_2(\mathbf{x})$ exceeds unity.

The likelihood ratio criterion is a good basis for discrimination and may be used whenever the functional forms $f_1(\mathbf{x})$ and $f_2(\mathbf{x})$ are known. When both populations are characterized by **multivariate normal distributions**, with the same dispersion matrix $\mathbf{\Sigma}$, then the likelihood ratio criterion determines R to be linear, thus justifying Fisher's linear discriminant. However, when the dispersions differ, the best discriminator turns out to be quadratic. Although quadratic discriminators are optimal, under these assumption they are not robust to departures from normality, especially when the distributions show **skewness**. Errors of misclassification are not everything, and one may wish to take into account differing costs $c(1|2), c(2|1)$ for the different types of error, and also the **prior probabilities** q_1, q_2 of the groups. This replaces the likelihood ratio criterion by the *Bayes procedure* (*see* **Bayesian Methods**) with assignment based on

$$\frac{q_1 f_1(x)}{c(1|2)} \gtrless \frac{q_2 f_2(x)}{c(2|1)}.$$

Another criterion is the **minimax** rule, which minimizes the maximum error of misclassification.

The above has been concerned with discrimination among two groups, but the ideas are easily extended to k groups. The sample space is then divided into k regions, each corresponding to assignment to a different group. Assignment then is merely a matter of deciding in which region lies the sample to be identified. By far the most popular discrimination method of this kind is *canonical variate analysis* (*see* **Discriminant Analysis, Linear**), which applies to k groups each with a multinormal distribution with the same dispersion matrix $\mathbf{\Sigma}$. It is a generalization of linear discriminant analysis applied to k groups. The distance between the groups i and j is given by the **Mahalanobis distance** D_{ij} A sample may be assigned to the group with which it has the smallest Mahalanobis distance. In the **multidimensional scaling** version of canonical variate analysis, the distances may be approximated in a few dimensions and two-dimensional approximations may be viewed visually. With an appropriate scaling, the means of each group may be surrounded by circular confidence regions. When a sample falls within one of these circles, it may be assigned to the group to which it pertains. Samples not falling within any circle do not get assigned because they may be aberrant or they may more properly belong to a previously unrecognized group. For similar reasons, the possibility of not assigning a sample should be considered in all discrimination methods.

Errors of misclassification may be calculated from a knowledge of the distributions concerned. In all the above it is assumed that the parameters of all the distributions are known. In practice they have to be estimated from data, and these estimated values plug into the exact formulas. This introduces additional uncertainties into the accuracy of quoted errors of misclassification whose analysis is a highly technical matter [23].

Appropriate multivariate distributions underlying discrimination are not necessarily known, so **nonparametric methods** are valuable. This is one reason why the Fisher linear discriminant, in its regression interpretation, and logistic discrimination are so valuable. Another approach is to use kernel **density estimators** based on the data to form empirical density functions (see [27] for a review). Recently, neural networks have been used for discrimination. These work like diagnostic keys but, at each node of the tree, branching is decided on a single variable x according to whether $x \leq c$ or $x > c$, where c is a threshold to be determined [16].

Classification: the Construction of Classes

The above has been concerned with assigning to classes. Now we turn to constructing classes. As for assignment, class-construction may be considered either in a probabilistic framework or not. As Table 1 shows, sometimes we classify structured objects and sometimes unstructured objects, so the distinction between the two becomes important in the following.

Nonprobabilistic Classification

To a computer, n unstructured objects cannot be distinguished from n structured objects, so everything which is computable for the one is also computable for the other. Sometimes this makes sense (see the discussion of mixture problems which follows closely the K-group classification discussed next), but, for example, the hierarchical classification of unstructured objects makes little sense. Initially we shall be concerned with the classification of n structured objects, each representing a separate class as described above.

k-group classification classifies n structured objects into a specified number, k, of groups, sometime, termed a *partitioning* problem. Each object is described by p variables. The basis of the classification into k groups is the optimization of one of several possible criteria, C, which is discussed below. To optimize C we start with some initial classification. One strategy is to examine the effect of transferring an object from group i to group j, say. If this transfer improves C, then we let it stand, otherwise we replace the object in group i. Transfers are examined systematically until no further improvement is possible. Then we have attained a local optimum of C which gives a putative classification into k groups. Another strategy is to examine interchanges of objects between groups i and j, or a mixture of the two strategies may be used. A different starting configuration may give a better optimum, so usually it is recommended to try several starts; several methods have been suggested for finding a "good" start. It is rare for k to be known in advance, so the groupings given by different values of k may be found and the optimal values C_k examined to suggest an acceptable value of k. If the value of C_{h+1} is not much better than for C_h, then this indicates that we should choose $k = h$. This type of heuristic algorithm is much used and its efficiency is greatly increased if we can update C, following a transfer or interchange, rather than evaluate C *ab initio* every time. Fortunately, updating is straightforward for the three main choices of C, brief descriptions of which follow. For quantitative variables and a given grouping into k classes, we consider the between/within **multivariate analysis of variance** (MANOVA), which partitions the total sum of squares into a between-groups matrix $\mathbf{B}$ and a within-groups matrix $\mathbf{W}$. Then we may define C as follows: (i) k-means grouping (or minimum within-group sums-of-squares, trace $\mathbf{W}$); (ii) minimum $\det \mathbf{W}$; and (iii) maximal predictive classification. Because the total sum of squares $\mathbf{B} + \mathbf{W}$ is constant for all possible groupings, the grouping which minimizes trace $\mathbf{W}$ also maximizes trace $\mathbf{B}$. The latter may be interpreted as maximizing the sum of the squared distances between the group centroids (or means) weighted by the group sizes. If we ignore the group sizes, then we have the k-means algorithm which maximizes the sum of the squared distances between the group means or, equivalently, the sum of the squared distances between the means and the overall mean. If we operate on $\det \mathbf{W}$, then we have the same thing in terms of Mahalanobis D^2 and the canonical variate means (*see* **Mahalanobis Distance**); as with the k-means algorithm, we may operate in weighted or unweighted mode. We shall return to the minimization of $\det \mathbf{W}$ when discussing mixture problems, below.

Many classification problems of the type discussed above may be subsumed into a single algorithm which minimizes trace $(\mathbf{X} - \mathbf{GZ})\mathbf{W}^{-1}(\mathbf{X} - \mathbf{GZ})'$ over $\mathbf{G}$ and $\mathbf{Z}$, where $\mathbf{G}$ is an $n \times k$ indicator matrix of zeros and units giving class membership and $\mathbf{Z}$ is a $k \times p$ matrix giving the coordinates of cluster centers. A **least squares** algorithm achieves the minimization by alternating between estimating $\mathbf{Z}$ for fixed $\mathbf{G}$ and estimating $\mathbf{G}$ for fixed $\mathbf{Z}$. For the problems discussed above, every row of $\mathbf{G}$ will have unit sum, indicating that each object lies in one and only one class. By taking $\mathbf{W} = \mathbf{I}$ we arrive at the k-means problem and by taking $\mathbf{W}$ to be the pooled within-group sums-of-squares matrix we minimize the squared Mahalanobis distances between groups. By removing the unit sum constraint, overlapping clusters may be formed.

Maximal predictive classification operates on binary rather than quantitative data. Thus, each variable can take only values 1 and 0, which may represent

presence/absence or two equal-status categorical levels such as male/female. For each group we may predict the level that occurs most frequently for each variable and then count the number of correct predictions in the group; this will give more correct predictions than for any other choice of predictor. The choice of the criterion is now to choose the partition into k groups that maximizes over all groups the number, C_w, of correct predictions. Alternatively, we could choose C_b to minimize the number of correct predictions averaged over the $k = 1$ predictors for the wrong groups, C_w measures the homogeneity of groups, which we want to be good (i.e. big), while C_b gives a measure of the separation between groups, which we also want to be good (i.e. small). Unlike the situation in MANOVA, where $\mathbf{W} + \mathbf{B}$ is constant for all k, $C_w + C_b$ varies with k. The difference $C_w - C_h$, which balances homogeneity within classes with separation between classes, may be used to suggest suitable values of k [14].

If now we denote by C_k the optimal value given by the k-group criterion for k classes, and the groupings of samples for C_{k+1} happen to be nested within the groupings given by C_k for $k = 1, 2, \ldots, n$, then we have a natural hierarchical classification. Natural hierarchical classifications are very rare but when absent a *best* hierarchical classifications may be desired. We could define the best hierarchical classification as that which optimizes $\sum_{k=1}^{K} C_k$, where the groupings which generate the C_ks are constrained to be nested. This gives a very general way of defining hierarchical classification with respect to any C-criterion, but it has not been studied and almost certainly leads to formidable combinatoric computational problems. The heuristic algorithms, outlined above, for optimizing k-groups, partitioning, and hierarchic interio, usually deliver a local optimum but, until recently, were the only ones practicable. Recent advances in dynamic programming (see Hubert, Arabie and Meuluran, [18]) are beginning to offer the feasibility of finding the global optimum-atleast for n < 30, say.

The desire for seeking hierarchical classifications of structured objects seems to stem partly from taxonomy, where evolutionary considerations naturally lead to hierarchical relationships between living (and fossil) organisms, but also from the importance of hierarchical systems for the organization of many things, ranging from library books to government or management of any large organization (*see* **Numerical Taxonomy**). There is an enormous literature (e.g. reviews by Cormack [4] and Gordon [10, 11, 13] on hierarchical classification and related methods. Many of the original methods for determining hierarchical classifications are heuristic **algorithms** that operate on matrices giving the (dis)similarities between all pairs of the n objects (*see* **Similarity, Dissimilarity, and Distance Measure**). A typical algorithm is that for **single-linkage** cluster analysis, which at the ith step has i groups and joins the two groups which share the smallest dissimilarity between two objects – one chosen from each group. The algorithm starts with each object in a separate group and ends up with all objects in a single group; such algorithms are said to be *agglomerative*. *Divisive* algorithms work in the opposite way, starting with the n objects in a single group and subdividing existing groups at each stage until each object is in a separate group. It turns out that both agglomerative and divisive algorithms can be found for single linkage clusters, but this is not so for most other methods. The successive divisions of the groups in a hierarchical classification can be shown as in Figure 2.

This is an artificial example which shows that objects A and B join at a level of dissimilarity of 0.1 and are joined by object C at a level of dissimilarity of 0.2; objects D and E join at level 0.3 and combine with the other three objects at level 0.4. Such a diagram, with an associated scale of dissimilarities, is known as a dendrogram. A set of fitted dissimilarities may be calculated from any dendrogram and the fitted values for the dendrogram of Figure 2 are shown alongside. The fitted dissimilarity for objects i and j is obtained by finding the dissimilarity at which i and j first join. Such dissimilarities satisfy the *ultrametric* inequality $d_{ij} \leq \max(d_{ik}, d_{jk})$, which is a stronger form of the usual metric inequality satisfied by the

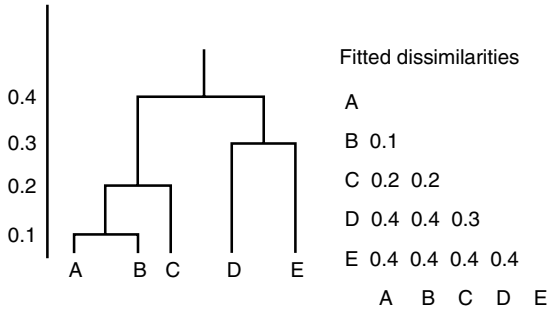

Figure 2 A dendrogram representation of a hierarchical classification with fitted ultrametric dissimilarities

sides of a triangle $d_{ij} \leq (d_{ik} + d_{jk})$. Not only does every dendrogram define dissimilarities that satisfy the ultrametric inequality, but also the converse is true [17, 19, 21]. It follows that the best hierarchical tree may be defined as the tree which minimizes

$$\sum_{i=1}^{n} (d_{ij} - \delta_{ij})^2, \tag{1}$$

where (d_{ij}) is the matrix of observed dissimilarities and (δ_{ij}) is the matrix of fitted ultrametrics. Unfortunately, such criteria are hard to minimize numerically, and existing algorithms are not very efficient. Therefore, heuristic algorithms remain popular (see, for example, [28]). Many of these algorithms can be unified by choosing different parameters in formulas that give the dissimilarity between any group and two merged groups as a linear combination of quantities that characterize the dissimilarities between the three groups concerned and their heights in the dendrogram. The most simple general-purpose formula giving the dissimilarity between group k and the amalgamation of groups i and j is

$$d_{k(i,j)} = \alpha_i d_{ki} + \alpha_j d_{kj} + \beta d_{ij} + \gamma |d_{ki} - d_{kj}|,$$

where the Greek letters are adjustable parameters which may be chosen to give different agglomerative algorithms. Unifications of these kinds, and there are several of them, facilitate programming general-purpose software for hierarchical classification encompassing many methods, but writing tailor-made programs for some of the special cases can be more efficient.

As well as characterizing trees by ultrametric distances, they may also be characterized by additive distances. Figure 3 illustrates the concepts concerned.

Now, rather than an accompanying scale of dissimilarities as in a dendrogram, the length of each branch is given. The resulting trees are termed *additive trees* because the fitted values are determined by the length of the shortest path between two endpoints, which is obtained by adding up the component parts of the path, as is shown in the table alongside the tree of Figure 3. Thus, the distance from A to C is $0.2 + 0.1 + 0.2 = 0.5$. For all quadruples i, j, k, l these fitted dissimilarities satisfy the four-point metric,

$$\delta_{ij} + \delta_{kl} \leq \delta_{il} + \delta_{jk} = \delta_{ik} + \delta_{jl},$$

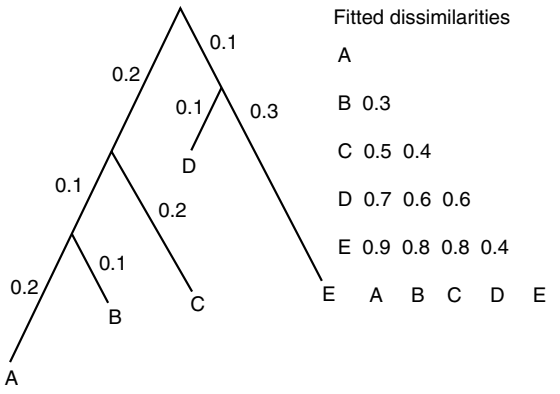

Figure 3 An additive tree representation of a hierarchical classification with fitted four-point metric dissimilarities

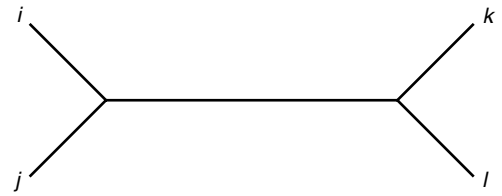

Figure 4

where the two longest sums are equal. This is often drawn as in Figure 4.

By setting $k = l$, so that $\delta_{kl} = 0$, it follows that the four-point inequality also satisfies the metric inequality for all triplets. Now (1) may be fitted by constraining the δ_{ij} to satisfy the four-point inequality, but efficient algorithms are available only for small problems. Instead, efficient heuristics are used which ensure iteratively that the four-point property is satisfied locally, e.g. by finding the best least-squares approximation to every set of four points (see [9] for an algorithm of this kind and a summary of related work). An alternative approach depends on a property of additive trees that they may be expressed as a sum of an ultrametric tree and a star tree, i.e. an additive tree with just one node. This may be written as

$$a_{ij} = u_{ij} + a_j + a_i, \quad i, j = 1, 2, \ldots, n,$$

where a_{ij} denotes the additive distance between classes i and j, a_i are additive constants, and u_{ij} denotes corresponding ultrametric distances. Thus, in the example of Figure 3, we may set $a_1 = 0.2$, $a_2 = 0.1$, $a_3 = 0.1$, $a_4 = 0.1$, and $a_5 = 0.1$, and verify that

the elements $u_{ij} = a_{ij} - a_j - a_i$ satisfy the ultrametric inequalities. The reader may check that the quantities a_i differ only by a constant, chosen to ensure that the u_{ij} are nonnegative, from the lengths of the branches of Figure 3 from the root node. Provided one has an algorithm for fitting ultrametric trees, this result allows one to construct a least squares algorithm for fitting additive trees by alternating between fitting the ultrametrics and the additive constants.

The previous result may be considered as part of the family of so-called *hybrid* models:

$$d_{ij} = u_{ij} + c_{ij}, \qquad d_{ij} = u_{ij} + a_i + a_j + c_{ij},$$

$$d_{ij} = \sum_{r=1}^{R} u_{ijr} + e_{ij}, \quad d_{ij} = u_{ij} + f_{ij} + e_{ij},$$

which place hierarchical classification problems in the wider context of statistical modeling and takes us rather far from the topic of classification under discussion.

The same objects may be given several different hierarchical classifications, either because they are based on different sets of variables or because they are based on different algorithms. The question therefore arises of deciding to what extent the classifications agree with one another. A first step is to determine an average or *consensus* classification. There are many ways to do this, the most simple of which is to fit a tree to the average (root mean square is better) of the ultrametric or additive distance matrices arising from each classification. A more popular approach is to devise combinatoric algorithms that search for objects that group together in all, or at least in many, of the separate classifications [5].

Sometimes, hierarchical classifications need to be constrained in some way. When classifying geographic, ecological and **image** data it is natural to constrain classes to be spatially contiguous so that the resulting clusters have spatial integrity. To impose constraints greatly complicates clustering algorithms, but considerable progress has been made [12].

As well as ultrametrics and additive metrics, other structures have been fitted to dissimilarity matrices. Critchley defines *ziggurats*, which are a special class of tree where the objects split off from the main tree one at a time. Diday defines pyramids which are not tree structures but are highly interlinked systematic rooted graphs. Indeed, the possibility of fitting interlinked, or overlapping, trees has been recognized for many years (see, for example, [20]). My impression is that these structures are currently mainly of research interest and have rarely been used in applications; perhaps they are more concerned with data description rather than with classification.

Probabilistic Classification

The main probabilistic method for forming classes from unstructured objects is known as the *multivariate mixture problem*. It has a long history in statistics and in its univariate form was first studied by Karl Pearson [26]. Pearson was concerned with data on several hundred shin bones from an archeological investigation. He knew that some were female and some were male, and wished to assign the bones to the two classes, after identifying and eliminating immature skeletal material. In this case, he knew that there were only two classes, but in problems where the objects are a mixture of samples from several populations, the number of classes is not necessarily known in advance. Thus, the mixture problem is to assign each of n given samples, on each of which the same p variables have been measured, to one of k classes and to determine the best value of k. Each class is assumed to be identified by a probability distribution function $f_i(x, \theta_i)$, $i = 1, 2, \ldots, k$, and a supplementary interest is to estimate the values of the parameters θ_i of these distributions. Being set up in a formal statistical context, a maximum likelihood approach can be taken. The likelihood is

$$L = \prod_{x \in C_1} f_1(x, \theta_1) \prod_{x \in C_2} f_2(x, \theta_2) \ldots \prod_{x \in C_k} f_k(x, \theta_k). \tag{2}$$

Thus, L is maximized for some permutation of the samples assigning them to the k classes, no class being empty, and the parameters θ_i, $i = 1, 2, \ldots, k$, being estimated from those samples assigned to C_i. Of course, there are an enormous number of possible permutations, so the computational problem is formidable and approximate heuristic algorithms are used. Transfer and interchange algorithms like those described above for nonprobabilistic classification are applicable, but whenever a sample is transferred from C_i to C_j the parameters θ_i and θ_j have to be reestimated which, unless a simple updating procedure is available, adds to the computational burden. An

important special case is when all the distributions have multinormal form with the same dispersion matrix. Then, the updating of the class-means and within-class dispersion matrix **W** is simple and it turns out that the permutation of the samples which maximizes the likelihood is when det **W** is minimized, thus leading back to one of the variants of the k-means problem and algorithm.

Mixture distributions may also be modeled as the distribution function

$$\sum_{i=1}^{k} p_i f_i(x, \theta_i),$$

where p_i gives the frequency of the ith population. The parameters, including the frequencies, may again be fitted by maximum likelihood. In the previous approach the frequencies may be estimated from the relative sizes of the classes C_i.

In both approaches it seems difficult to determine an optimal value of k, and I am not aware that anything better has been suggested than plotting the maximized likelihood against k and hoping to find a "dogleg" pattern in which the likelihood increases with k until a level is found where increasing k has little effect. The point where this occurs, if it does, gives a natural choice for a suitable value of k. A device which has some popularity is to add a penalty function to the likelihood (*see* **Penalized Maximum Likelihood**), so discouraging large values of k. Mixture problems have a large statistical literature, e.g. [6, 24].

Jardine & Sibson [20] suggest that classes be formed on the basis of what they term *information gain*. They use Renyi's measure of **information** to define the information in a classification and calculate the information gained from regarding the samples as belonging to a mixture of k classes rather than that all the samples belong to a single class. Similarly, information gain can be calculated when proceeding from any classification to one where the number of classes is decreased. Apart from using information gain rather than likelihood, the concepts and the computational problems are similar for the two approaches.

There is a hierarchical version of the mixture problem which seeks to classify n unstructured objects into k nested classes. Thus we seek a tree with k end points, each corresponding to a mixture component. It is rare for those who construct hierarchical classifications, even of structured objects, to be really interested in trees with n end points. Very often they will truncate the tree at some convenient level in the dendrogram. For example, in Figure 2 we might truncate at 2.5 leading to three nested classes (A, B, C), (D), and (E). Such ad hoc rules are frequently used, but I know of no direct modeling for this type of problem.

A problem that could be studied, but seems not to have been, is concerned with the classification of n objects structured into k groups. These objects may be parameterized as for discriminant analysis, and so may be represented by either n fully parameterized distribution functions or by samples from the n objects from which the parameters of the distributions may be determined. Some objects may be closer together than others, as measured, for example, by the Mahalanobis D^2, and it seems reasonable that these be classified together. In general we might wish to group the n objects into fewer homogeneous classes. In an extreme case, the objects may be characterized by point distributions so that there is no overlap and errors of misclassification are irrelevant. This suggests that some other basis for classification must be used to replace, or add to, probabilistic measures of distance between populations and between grouped populations.

Links Between Construction and Assignment to Classes

In this article I have stressed the distinction between constructing classes and assignment to classes. Yet the distinction is often blurred because one legitimate reason for constructing classes is so that future assignments to the classes should be optimal in some sense. We have seen that diagnostic keys are constructed so that identification is optimized either in terms of the number of tests that have to be done or in terms of costs. Of course, the classification is given at the outset, but if we were allowed to redefine our classes, perhaps we could reduce the number of tests required or the costs. Then we could say that the best classification is the one that minimizes these quantities. Unfortunately, there is a trivial solution with only one class, and then every specimen could immediately be assigned to that class without cost. The anomaly arises because we are not allowed to

redefine the basic classes. However, if we reallocated the species among the genera, then the key to the genera might be shorter or cheaper to use. In this way we could define a classification with optimal properties for assignment. Maximal predictive classification has such a property, as it can be shown that any object shares more properties with the class predictor for its own class than with the class predictors for all the other classes. Thus, an object may be assigned to its proper class merely by counting how many properties it shares with each class predictor. Mixtures estimated by maximum likelihood have a similar property, as can be seen from the following result, which derives from (2). Suppose (2) has been maximized and we move an object $\mathbf{x}$ from C_i to C_j. Then the likelihood becomes $L^* = Lf_j(\mathbf{x}, \theta_j)/f_i(\mathbf{x}, \theta_i) < L$. Thus, $f_j(\mathbf{x}, \theta_{ij}) \leq f_i(\mathbf{x}, \theta_i)$, showing that the boundary between objects assigned to classes C_i and C_j is precisely that given by the likelihood ratio criterion for discrimination regions. Thus, the classes obtained from the mixture model are optimal for discrimination.

Of special interest in the biometric context are problems of constructing classifications based on evolutionary concepts. Diagnostic keys and the hierarchical classifications discussed earlier are unashamedly utilitarian and, despite their hierarchical structure, make no evolutionary claims. There has been much controversy and confusion between utilitarian hierarchical classifications and classifications supposed to reflect evolutionary relationships (see, for example, [2]). This is a little surprising, because the Linnaean binomial classification of the natural world long predates Darwin and, in its original form, cannot be claimed to be based on evolutionary principles. For more than 100 years taxonomists have been extending and modifying Linnaean classifications and, for the most part, have attempted to mirror supposed evolutionary development. Similarity between organisms is likely to bear some relationship to shared genetic material but evolutionary convergence between, for example, some of the superficial features of fishes and whales shows that evolutionary classifications must be approached with care and that, although phenotypic similarity may be a satisfactory basis for constructing utilitarian classifications, it may not be for evolutionary classifications. Nevertheless, phenotypic classifications are likely to contain a substantial element of evolutionary classification, even though that is not their prime objective. Two approaches to evolutionary classification have been developed – one probabilistic and one not. The probabilistic approach is useful for constructing evolutionary trees for genetically close classes, such as different human populations, and is based on modeling genetic drift and mutation. Being a probabilistic model, in principle its parameters and the topology of the optimal tree may be estimated by maximum likelihood. The computational problems are formidable but some progress has been made (see, for example, [7]) that allow the method to be used for small problems. The nonprobabilistic approach, often termed *cladistics*, is based on the concept of *minimal evolution*, which is appropriate for categorical variables or characters. Minimal evolution requires the fitted tree to minimize the number of character changes as one moves from node to an adjacent node. There are difficulties, because with multistate characters the states have to be ordered from their presumed primitive forms to their most developed evolutionary forms. Further, the fossil record has considerable gaps and so one must allow for hypothetical missing organisms and a suitable root for the tree must be identified. When the length of a branch of a tree is defined as the number of character changes between its nodes, then the minimal evolution tree is the same as the minimal-length additive tree, in this context known as a Wagner tree. For further discussion, see [3, 29, 31].

JOHN C. GOWER

Classifications of Medical and Surgical Procedures

Many of the principles governing the construction of classifications of procedures parallel those relating to the **International Classification of Diseases (ICD)**. Like the ICD, classifications of procedures are designed to facilitate statistical analysis, with the structure and composition of categories reflecting their frequency of occurrence and surgical importance. Classifications of procedures are not intended to be surgical nomenclatures, although in common with other similar classifications they are designed to be accessed from the clinical terminology used to describe surgical and other operations.

An important additional consideration which often affects the construction of a procedure classification is an explicit definition of its scope. Although the earliest examples of such classifications were confined to those surgical operations normally carried out in operating theaters, gradually the scope of "surgery" has extended to procedures carried out in other environments. More recently there is increasing pressure for procedure classifications to include other forms of less invasive intervention, particularly those which entail the use of expensive resources.

The **World Health Organization (WHO)** considers that a Classification of Procedures should be a component of the "family" of disease and health-related classifications and indeed, for trial purposes in 1978, WHO published an International Classification of Procedures in Medicine (ICPM) [11], which was adopted by a few countries, and used as a basis for a national classification of surgical operations by a number of others. For example, a procedure classification developed in this way is an integral part of the United States International Classification of Diseases, 9th Revision Clinical Modification (ICD-9CM) [10].

Nevertheless, many countries have independently developed their own procedure classifications. Well-known examples include those from Canada [7] and the recently published Nordic Classification of Surgical Procedures [6]. This latter classification has been structured so that the listed codes form a tiny proportion (less than 0.5%) of the available space. This graphically illustrates a further particular feature of the structure of a procedure classification, in that it needs to be able to respond appropriately to the ever increasing developments in surgical techniques. The relatively poor acceptance of an international version to some extent reflects the fact that surgery is practiced differently in each country. More importantly, a procedure classification is frequently used as an important part of the billing process, or for other similar revenue purposes. In these respects, individual countries have widely disparate needs, and thus there is no uniform requirement or specification. A classification designed to meet the needs for groupings which easily aggregate on the basis of iso-resource operating theater costs would be constructed quite differently from one designed for epidemiologic purposes in order to add a proxy dimension of severity when combined with a suitable diagnostic classification such as the ICD.

In the UK, a classification of surgical operations has been available for use since 1944, when one which identified 443 categories of operation was published by the Medical Research Council [4]. The then General Register Office prepared and issued an updated version in 1950 [1], and revisions to this were subsequently issued in 1956 (first revision) [2], 1969 (second revision) [3] and 1975 (third revision) [8]. The current fourth revision (normally referred to as OPCS-4) was published by the then Office of Population Censuses and Surveys in 1990 [9].

Since 1990, the content of the tabular list categories in OPCS-4 has remained constant but the index has been regularly updated to give additional entries to these categories. Responsibility for maintenance of the classification now lies with the National Health Service Centre for Coding and Classification, but constant expansion of the frontiers of surgery presents its own particular problems. These are typified by the difficulties of fitting the recent growth in techniques of minimal access surgery within a basic classification structure not designed to accommodate them.

OPCS-4 has a wide range of national uses within the UK, including the presentation of statistics of hospital use, and as a central element in the construction of Health Care Resource Groups (HRGs) as defined by the National Casemix Office [5]. It has similar local uses, which also include a major role in the setting and monitoring of contracts. In some places it is also used in operating theater applications such as scheduling, although it was not designed for this latter purpose.

JOHN S.A. ASHLEY

Clinical Epidemiology

Clinical epidemiology involves the application of methods derived from epidemiology and other fields to the study of clinical phenomena, particularly diagnosis, treatment decisions, and outcomes. Clinical epidemiology has been characterized, somewhat immodestly but fairly accurately, as the basic science of clinical medicine. Clinical epidemiology is not a clearly delimited field. In its concern with the accuracy of diagnosis, the elements of treatment decisions, and the measurement of outcomes, clinical epidemiology overlaps substantially with clinical medicine. In its focus on physician and patient choices and the interactions between patients and physicians in clinical processes, it overlaps substantially with **health services research**. In its use of various quantitative methodologies to address questions of clinical relevance, clinical epidemiology overlaps substantially with epidemiology, economics, and other disciplines.

To facilitate an understanding of this broad field, it is helpful, if somewhat arbitrary, to consider clinical epidemiology in terms of its major areas. These include clinical measurement, diagnosis and screening, clinical decision making, measurement of treatment effects, clinical economics, and clinical study design.

Clinical Measurement

Clinical measurement, or clinimetrics, as it is sometimes called, is the foundation for all of clinical epidemiology. Sound measurements are the raw material for the various methodologies of the clinical epidemiologist. If this raw material is flawed, then it is very likely that the results and conclusions derived from it will also be flawed.

Clinical measurement involves some issues that are common to all forms of measurement and others that are almost uniquely applicable to measurement as a clinical process. The common issues for any measure include its reliability, validity, responsiveness, and generalizability. A measure is reliable if it provides consistent results when used to measure an unchanged phenomenon at different times or in different settings. A measure is valid if it truly measures the construct it is assumed to measure. A measure is responsive if it is sensitive to clinically meaningful change. A measure is generalizable if it can be usefully applied to subjects who differ by age, gender, race, diagnosis, or some other major characteristic (*see* **Validity and Generalizability in Epidemiologic Studies**).

Other issues in clinimetrics arise from the fact that clinical measurement typically involves an examiner, an examinee, and an examination technique, all of which are subject to **measurement error**. The clinical examiner may be inadequately trained or may be prone to **biased** measurement. The clinical examinee is subject to physiological variation and is prone to reporting bias. The examination methodology may be affected by a variety of factors, including calibration errors and changes in technique. The effects of the sources of measurement error can be cumulative, making clinical measurement a particularly challenging proposition.

Diagnosis and Screening

Diagnosis is a critical step in the clinical process, and the analysis of the diagnostic process is a major focus for clinical epidemiology. Diagnosis refers to the categorization of individuals who have come to a clinician with symptoms. **Screening** refers to the categorization of asymptomatic individuals in a clinical setting or in the general population.

The analysis of diagnosis in clinical epidemiology focuses on the performance of **diagnostic tests**. The key properties of a diagnostic test are its **sensitivity** and **specificity**. Sensitivity refers to the frequency with which a test is positive when it is applied to a group of individuals known to have a particular disease. Specificity refers to the frequency with which a test is negative when it is applied to a group of individuals known to be without a particular disease.

In the clinical setting, the sensitivity and specificity of a test, combined with the estimated **prevalence** of the expected diagnosis (sometimes referred to as the pretest probability of disease) determine the **predictive value** of a test. A positive predictive value estimates the probability that an individual with a positive diagnostic test result will actually have a particular disease. A negative predictive value estimates the probability that an individual with a negative test will actually be free of disease. Since pretest probability is substantially lower for screening than it is for diagnosis,

the predictive value of diagnostic tests may be substantially lower when they are used for screening.

Diagnosis in medicine is seldom based on the positive or negative result of a single test. In most diagnostic situations several diagnostic tests are available, with each providing a range of results rather than a simple positive or negative. Methods have been adopted to compare the diagnostic efficiency of different clinical tests across their range (**receiver operating characteristic (ROC) curves**) and to determine the probability of a diagnosis given the level of a diagnostic test result (**likelihood ratios**).

In many diagnostic or screening situations several tests are used in combination. In circumstances in which a diagnosis should not be missed, such as a highly treatable infectious disease, one or more diagnostic tests may be applied in parallel with any positive result leading to a diagnosis. This approach enhances the sensitivity of a diagnostic or screening strategy. In other settings, serial testing, in which a second test is done only if a first one is positive, minimizes the use of costly or dangerous second-stage tests. Serial testing lowers the sensitivity of the diagnostic or screening strategy, but it maximizes specificity and minimizes **false positive rates**.

Clinical epidemiologists also concern themselves with issues of intra- and interobserver agreement (*see* **Observer Reliability and Agreement**). In the realm of diagnosis, intraobserver agreement estimates the extent to which a clinician reproducibly categorizes subjects into diagnostic categories. Interobserver agreement estimates the extent to which two or more clinicians agree on the diagnostic categorization of subjects. Since agreement in either situation may occur by chance, **kappa** and other statistics are used as measures of agreement that adjust for chance. Clinical epidemiologists have repeatedly demonstrated that the adjusted diagnostic agreement between two trained clinicians may be surprisingly low.

Clinical Decision Making

The key methodology for the study of clinical decision making is formal **decision analysis**. Decision analysis involves the construction of detailed trees in which each decision point in a clinical treatment cascade is specified, probabilities are assigned to an exhaustive group of potential outcomes, and values are assigned to each outcome. To guide clinical practice, formal decision analysis can be quite helpful in clearly specifying the issues and potential outcomes in a given clinical decision (*see* **Decision Theory**). At the level of clinical epidemiology, formal decision analysis forms the basis for explicit cost and benefit estimates that serve to inform the choice between treatment alternatives (*see* **Health Economics**).

Measurement of Treatment Effects

A central topic in clinical epidemiology is the estimation of benefits and side-effect rates that result from clinical therapies. The estimation of benefits involves the specification and measurement of the major components of treatment outcome. Until recently, treatment outcome was usually estimated in terms of reduced mortality or improvements in the physiological manifestations of a particular disease, such as blood pressure reduction in hypertension treatment and blood sugar control in diabetes treatment.

In recent years, clinical epidemiologists, in concert with health services researchers, have expanded the measurement of treatment benefits to include the four major components of health status: physical function, psychological function, social function, and symptoms. These elements of health status are measured using a variety of methods, with an emphasis on recently developed questionnaire approaches. These questionnaires have proven to be as reliable, valid, responsive, and generalizable as more traditional clinical measures of benefit. In addition, these newer measures have more relevance for patients because they assess treatment benefits, such as functional capacity and symptom reduction, that are of particular concern to patients.

Treatment benefits may be measured using general methods that apply across diagnostic categories. The SF-36 health status questionnaire is the most widely used example of this approach. Other questionnaires are designed to measure the major elements of health status in particular categories of disease, such as arthritis or respiratory disease-specific measures (*see* **Questionnaire Design**).

Treatment benefits may also be estimated in terms of patient utilities. In this approach, such methods as **time tradeoff** and **standard gamble** are used to estimate patient-specific preferences for potential benefits. Although **utility** estimation may be methodologically difficult, it is conceptually appealing, and it provides a basis for comparing treatment benefits across different disease categories and patient groups.

There is no such thing as a treatment without costs. So in their efforts to develop an accurate and balanced assessment of medical treatments, clinical epidemiologists must measure the rate of adverse events and their severity as well as benefits. Drug toxicities, or adverse effects, may result from an overshoot in the intended effect (e.g. low blood sugar caused by a diabetes treatment), from undesirable but related physiological effects (e.g. stomach ulcers from arthritis drugs), and from apparently idiosyncratic effects (e.g. headache or skin rash from various drugs).

The study of the frequency and severity of adverse events falls into the realm of **pharmacoepidemiology**. For common treatment side-effects, follow-up of patients on medication or even data from **clinical trials** can be utilized to characterize the frequency and severity of side-effects. The rate of common side-effects can be characterized with the highest level of validity because these rates are often derived from close observations by practitioners who are actively monitoring clinical subjects for drug side-effects. For rarer adverse events, computerized clinical databases or claims databases (*see* **Administrative Databases**) are increasingly being used, for they are the best source of information on large numbers of people under treatment. Both approaches typically utilize the prescription as their measure of treatment exposure. Any side-effect of treatment that occurs outside the medical record or claims file may be difficult to capture and count. There is also an inherent problem in large-scale **observational studies** of drug use in that certain drugs may be given only to persons at high risk of certain side-effects, so that an association with those side-effects is to be expected. This **confounding** by indication has made it nearly impossible to perform pharmacoepidemiologic studies of drugs that are supposed to protect against other drug side-effects. Notwithstanding these difficulties, large-scale, computer-based pharmacoepidemiology studies offer promise in terms of identifying and quantifying the serious adverse effects of drugs.

Clinical Economics

Dollars are the other major cost of treatment, so clinical epidemiology must concern itself with the estimation of dollar costs. The first issue in doing any clinical cost study is to define the perspective from which costs are estimated. For example, a vaccination program will have different costs depending on whether costs are analyzed from the perspective of the State Health Department, the clinic providing the vaccinations, or the family whose child is vaccinated.

There are three major types of clinical cost study. The first is a descriptive study in which the costs of a treatment are measured in terms of direct medical costs (e.g. the cost of a clinic visit and the prescription), direct nonmedical costs (e.g. the cost of losing time from work to receive treatment), and indirect costs (e.g. the cost of reduced productivity caused by disease-related disability or death). Cost estimates may then be used in a cost-effectiveness study in which the costs of treatment are compared to benefits measured in terms of clinical or health status improvements. The third type of cost study is a cost–benefit study in which both the costs and benefits of treatment are measured in dollar terms. Although it is the most difficult form of cost study to carry out, the cost–benefit study has the advantage of allowing comparisons of very different treatments, such as a vaccination program for children vs. a hip replacement program for the elderly, because the benefits of each approach are measured using a single metric: dollars.

Clinical Study Design

The distinguishing characteristic of clinical studies is that they begin with subjects who have a particular diagnosis. Clinical study designs include **natural history studies**, randomized clinical trials, and N of 1 studies (*see* **Crossover Designs**). The natural history study focuses on analyzing prognosis in subjects who have a particular disease. Using the natural history design, one can evaluate the effects of treatments including important and common adverse events. One can also identify persons at high risk of experiencing a poor disease course who might be appropriate subjects for more aggressive treatment and other subjects who experience a benign disease outcome in whom aggressive treatment may not be indicated. In addition, data on prognosis can be utilized to develop "predictive models" identifying which patients might benefit from extensive, costly clinical evaluation (*see* **Predictive Modeling of Prognosis**). Thus natural

history studies of people with a particular disease provide valuable diagnostic and therapeutic information that can guide clinical decisions.

Clinical epidemiologists have identified several critical methodologic concerns in performing a natural history study. These concerns are similar to those of epidemiologic **cohort studies**, the main differences being that in natural history studies subjects already have disease. The **controls** in a natural history study are internal controls, and comparisons are made between different subsets of people with disease. Natural history studies are most accurate in so-called inception cohorts, in which patients are entered into the study just after diagnosis. If patients are entered long after diagnosis, patients who die or go into remission soon after diagnosis may be missed, thus biasing the study. Right censoring, or loss to follow-up of patients enrolled in the natural history study, must be avoided to give an accurate picture of the prognosis of disease. If dropouts tend to have poor prognosis, then the study would arrive at an inaccurately optimistic prediction of disease prognosis.

Prognostic information can be used to build prediction rules that will estimate patient prognosis based on the presence or absence of key clinical characteristics. To develop prediction rules, investigators generally study two different groups of subjects with disease. Using the first group, they develop the rule identifying those factors which affect prognosis. Using the second group, they test this prediction rule, attempting to confirm that the factors identified in the first sample generalize to the second. Such repeatability of a prediction role in two independent samples augurs well for the general applicability of this rule to yet other patient samples.

Summary

Clinical epidemiology is a heterogeneous and dynamic field in which methodologies drawn from epidemiology, economics, and psychometrics are applied to issues related to clinical measurement and clinical decision making. This applied science will undoubtedly continue to grow and become even more important as clinical scientists apply additional methodologies to the analysis of clinical problems.

Several general references on clinical epidemiology are listed in the Bibliography.

Clinical Signals

Clinical signals are obtained when human subjects are monitored, usually by measuring electrical activity in a particular part of the body. Typical signals are the electrical activity measured from the brain (EEG) and from the heart (ECG or EKG). Other signals are muscle activity (EMG), stomach (EGG), and blood pressure from an indwelling cannula. Signals not measured electronically include lung function (*see* **Pulmonary Medicine**), levels of electrolytes in the blood, and clinical symptoms measured at regular intervals such as hourly or daily.

Time series methods are applied routinely to analyze clinical signals in hospitals and they can often provide life-saving information. Many measurements vary considerably over short periods of time and it is in fact this variation that is indicative of health or sickness, and not the absolute level of the measurement. As examples, it is the variation in Peak Expiratory Flow Rate (a measure of lung function) which is diagnostic of asthma, not the absolute level and Heart Rate Variability (HRV) is used to diagnose fetal distress during labor.

The literature on the analysis of time-varying clinical signals has been dominated by engineers, who have developed their own methodology and literature in parallel with the statistical version, and sometimes the engineering methods lack an underlying statistical model, which can make dialog between the two disciplines difficult. A discussion of the different approaches taken by statisticians and engineers has been given recently [3].

Spectral Analysis

Perhaps the most common feature of the analysis of clinical signals is to look for regularly occurring features or rhythms. For humans to maintain stable bodily functions, clinical signals must be constrained to lie within certain limits and this tends to make patterns within signals recur regularly. A discussion of the role of rhythms in homeostasis has been given by Hyndman [15]. Rhythms often result from nonlinear feedback loops. A simple example will illustrate the point. To remain healthy, humans must maintain blood pressure to within certain narrow limits. Blood pressure is mediated through the baroreceptors, located in the wall of the aortic arch and in the wall of the carotid sinus. If blood pressure is too high, then signals from the baroreceptors result in vasodilation which drops the blood pressure. If pressure is too low, then vasoconstriction occurs to increase the blood pressure. The feedback mechanism is thought to be nonlinear, and incorporates a delay, and for these reasons, at rest these rhythms can occur spontaneously [16].

Spectral analysis involves decomposing a signal into individual frequency components where the amplitude of these components is proportional to the "energy" of the signal at that frequency [26]. It is a convenient method for summarizing a long time series and is a natural procedure if we believe there are rhythms in the data. Spectral analysis is the method of choice for the analysis of clinical signals.

Sampling

Some signals are essentially continuous, whereas others are discrete. For example, the heart rate is measured from surface electrodes on the chest from the ECG. Although the ECG is continuous, the heart rate is usually derived from the "R" wave in the ECG, which is a sudden spike just preceding the ventricular contraction. Thus, the heart beat signal is essentially a **point process**. Some authors have analyzed the interbeat intervals, thus arriving at a spectrum which estimates frequencies per beat, rather than per unit time. Others sample the heart rate (or RR interval) signal at regular intervals or filter the point process to produce a continuous signal which can be sampled [2, 12].

Spectral Analysis and Time-Dependent Spectra

The problem with spectral analysis is that it assumes that the signal is **stationary**. However, medical signals are not stationary in the usual sense. They contain rhythms that may come and go in the time interval, the frequencies may vary, or amplitudes of cycles at certain frequencies increase or decrease. Spectral analysis considers the entire time interval and so cycles that only occur in part of the interval will have their spectral peaks attenuated by the low power in other parts of the interval. One common solution is to assume that over a short interval the signal is stationary and so to split the time period

into nonoverlapping intervals and calculate the spectrum for each interval. These spectra can be displayed in a pseudo three-dimensional plot, with the time axis running into the page [30]. The difficulty here is that it is not realistic to think of a signal being stationary in sections. A better intuitive model is one in which the signal "evolves" slowly so that the nonstationary component is slow in comparison with the signal in which we are interested.

Priestley [25, 26] pointed out that a sine wave in which the amplitude changes over time will have Fourier components at *all* frequencies. However, it would seem sensible to consider it as having a single frequency, with a time-varying amplitude. This concept led him to define "semi-stationary" signals, which have an oscillatory form, and a method of estimating their time-dependent spectrum known as the "evolutionary spectrum". This method has not featured in applications, possibly because it is not widely known.

Many applications devise a joint function of time and frequency and obtain a distribution that will describe the intensity of a signal simultaneously in time and frequency. A method that originated in physics is the Wigner or Wigner–Ville distribution. Let $y(t)$ be a continuous signal dependent on time t. The Wigner estimate of the spectrum at frequency ω is

$$f_w(\omega) = \int_{-\infty}^{\infty} y(t - 0.5\tau)\, y(t + 0.5\tau) \exp(-i\omega\tau)\, \mathrm{d}\tau.$$

This distribution has been used extensively [7, 22]. However, in the raw form it has some undesirable properties. It lacks any physical interpretation in terms of energy and may take negative values for certain processes. If a signal contains two harmonic components, then the Wigner distribution will contain interference at frequencies between the two. Smoothing the distribution improves its properties and computationally it resembles Priestley's evolutionary spectrum, a relationship discussed by Hammond et al. [14].

A popular method of estimating time-dependent spectra is via a fitted autoregressive model (*see* **ARMA and ARIMA Models**). If we can assume that the data are generated by a finite autoregressive process of order p, then

$$y(t) + \alpha_1 y(t-1) + \cdots + \alpha_p y(t-p) = z(t),$$

where $\alpha_1, \alpha_2, \ldots, \alpha_p$ are constants and $z(t)$ is random noise with mean zero and variance σ^2.

Then the spectrum at frequency ω is given by

$$f_{\mathrm{AR}}(\omega) = \frac{\sigma^2}{\left|1 + \alpha_1 \exp(-i\omega) + \cdots + \alpha_p \exp(-i\omega p)\right|^2}.$$

Thus, a method of estimating the spectrum of a series would be to fit an AR(p) model to a section of data and insert the estimated parameters into the above equation. Contiguous sections will give successive spectra. In contrast to the usual window method of estimating the spectrum, which can be thought of as a "local smoothing" method, the AR method is a form of "global smoothing" over all frequencies [26].

One feature of sinusoidal functions is that they best model signals in which a cycle persists throughout the interval. Some clinical signals are characterized better by bursts of energy, and these can be modeled by the newly emerging technique of wavelets. A link between wavelets and evolutionary spectral analysis has been given recently by Priestley [27]. Another form of spectrum, based on regularly occurring zeros and ones rather than a sinusoidal function, is known as the *Walsh spectrum*. It has certain computational advantages over the conventional spectrum, but is difficult to interpret. It has been used as a complementary tool to conventional spectral analysis [29].

Heart Rate and Blood Pressure Variability

Three major components are to be found in a typical heart rate spectrum [2, 13, 28] and these are also present in the blood pressure spectrum. A region of activity occurs at around 0.25 Hz, which is attributable to respiration (respiratory sinus arrhythmia) and this is thought to be a marker of vagal (parasympathetic) activity. A second component at around 0.1 Hz arises from spontaneous vasomotor activity within the blood pressure control system and is mediated by vagal and sympathetic activity [13]. A third, low-frequency component at around 0.04 Hz is thought to arise from thermoregulatory activity.

Other cycles that have been detected in the heart rate include one with a wavelength of about 90 minutes [23], corresponding to rapid eye movement in

sleep, and one supposedly relating to a "perception" cycle with a wavelength of about 10 minutes [9].

Spectral analysis has a number of clinical applications. It has been suggested that heart rate variability at particular frequencies relates to mental workload [11]. It has been shown that the heart rate may become "entrained", i.e. fluctuate in phase with regularly occurring tasks and used to measure their difficulty [4].

In diabetic neuropathy, vagal denervation causes a loss of spontaneous heart rate variability. This also may cause a reduction in the frequency at which vasomotor oscillations occur, possibly due to a decrease in conduction velocity [18]. Thus spectral analysis may be used to measure the severity of denervation. For example, Bianchi et al. [1] showed that spectral analysis could discriminate 21 diabetics with neuropathy from 19 without neuropathy.

The Electroencephalogram (EEG)

The EEG is electrical activity of the brain measured by electrodes at the surface of the skull. There is an immense amount of literature devoted to the spectral analysis of EEGs. In particular, six spectral peaks can be identified [19, 29]. These peaks, with a typical range of frequencies are: delta 1 (0.5–2.0 Hz), delta 2 (2.0–4.0 Hz), theta (4.0–8.0 Hz), alpha (8.0–12.0 Hz), sigma (12.0–14.0 Hz), and beta (14.0–20.0 Hz). The peaks can be used, for example to classify different levels of sleep. Jervis et al. [17] used Walsh and Fourier transforms to show that the EEG can discriminate between subjects with Huntingdon's Chorea and normal subjects. Recently there has been interest in describing neural processes in the context of nonlinear dynamics, and in particular deterministic chaos. For example, Palus [24] has suggested that the EEG has true randomness and is not chaotic (*see* **Chaos Theory**). This is a new and fast-emerging field.

Other Surface Electrical Signals

Electrodes can be used to measure surface potentials at a number of sites, and rhythms can be detected. The electrogastrogram (EGG) refers to the surface measurement of electrical activity of the stomach. Two sorts of activity can be detected: slow waves with a frequency of about three cycles per minute and spikes with a frequency of between 0.5 Hz and 1 Hz [5, 6].

For monitoring pregnancy and parturition, the uterine electromyogram (EMG) has been proven to be an efficient tool and Duchêne et al. [10] discussed the use of an autoregressive method and a smoothed Wigner distribution for estimating the spectrum.

Hormone Levels

Hormone of various kinds, including luteinizing hormone and growth hormone, are known to be released in a pusatile fashion, and it is the pulsating levels of the hormone that cause its action rather than the absolute level [20]. Using samples of blood taken every five minutes, luteinizing hormone has been shown to have a cyclic component with a frequency of about one cycle per hour. Murdoch et al. [21] showed peaks in five out of six women ranging from 51 minutes cycle length to 120 minutes and more rapid oscillations at 20 minutes and 13.3 minutes cycle length. These were also seen, but less strongly, in four other women. This methodology has recently been extended to enable the analysis of replicated series, so that a more global analysis can be carried out [8].

Conclusion

There are a wide variety of methods in use to carry out the analysis of biomedical signals. To some extent this is inevitable; different signals have different characteristics and the methods have to adapt to these. In applications there appears little unaminity as to optimum methods, many authors deriving their own spectral smoothing windows or updating algorithms *ab initio*.

MICHAEL J. CAMPBELL

Clinical Significance Versus Statistical Significance

Study design, interpretation, and reporting often ignore the distinction between clinical significance and statistical significance. Statistical significance refers to whether or not the value of a statistical test exceeds some prespecified level. Clinical significance refers to the medical importance of a finding. The two often agree, but not always. The clearest example involves a study (either an **observational study** or an interventional study (*see* **Clinical Trials, Overview**)) that has a large number of participants. Statistical significance may be observed for small associations between exposures and disease or condition (in the case of observational studies) or differences between interventions (in the case of intervention studies). Whether or not these associations or differences are clinically significant or meaningful depends on the seriousness of the condition being studied, the prevalence of the condition, and the other benefits and risks of the intervention. An intervention effect shown in a clinical trial to be statistically significant and in the beneficial direction, but of small magnitude, may be clinically significant if the intervention is relatively nontoxic, easily administered, and useful for a condition that is of public health importance. Conversely, an intervention effect shown to be statistically significantly superior to control may not be clinically significant if the intervention has unacceptable adverse effects.

Sometimes, a combination of clinical events is used as the primary outcome of a study (*see* **Multiplicity in Clinical Trials**). The result may be statistically significant. Unless the combined outcome makes scientific or clinical sense, however, it will not be clinically relevant or significant. Clinical relevance may be achieved either because the outcome combines events that presumably reflect a common mechanism of action of an intervention or a risk factor or enables a clinician to summarize readily the effect of the intervention or risk factor.

In addition to the selection of the outcome (*see* **Outcome Measures in Clinical Trials**), clinical significance enters into the design of a trial when the expected size of the effect of the intervention and the choices of type I and type II error rates (*see* **Hypothesis Testing**) are determined. A study should be large enough to detect a clinically important difference (*see* **Sample Size Determination for Clinical Trials**). If the difference turns out not to be statistically significant, **confidence intervals** should be calculated to determine whether a clinically important difference has been excluded.

It should also be noted that the criterion for statistical significance is commonly, by convention, $P < 0.05$, though it need not be (*see* ***P*** **Value**). Clinical significance has no such convention; after the study is completed the interpretation is often individual, and will be viewed differently by different investigators, physicians, or other practitioners, and patients.

The concepts of **relative risk**, **absolute risk**, and population **attributable risk** are relevant to clinical significance. A clinical trial that yields a relative risk reduction of 30% may mean a change from a 60% event rate to 40%, or from 6% to 4%. Depending upon the size of the sample, either may be statistically significant. But also depending upon the severity of the disease and the nature and cost of the intervention, including frequency of adverse effects, the absolute reduction of 2%, from 6% to 4%, may not be clinically significant. If the condition is common and the intervention is simple, however, this 2% may be an important reduction in population attributable risk, resulting in the prevention of many clinically serious events.

The example of blood pressure reduction by nonpharmacologic means is instructive. Relatively small (3–4 mm Hg for systolic; less for diastolic), yet statistically significant, reductions in blood pressure have been obtained by means of weight or dietary sodium reductions. Although some patients will achieve greater reductions, this average reduction observed in clinical trials is frequently not seen as clinically meaningful for an individual hypertensive patient or the treating physician. However, from a public health standpoint, it is exceedingly important, as it is brought about without the need for drug treatment and translates into many thousands fewer strokes and myocardial infarctions per year in a population as large as that of the US.

Studies that are designed with appropriate **power** to detect clinically important differences in **binary** outcomes commonly also evaluate other outcomes that may be continuous variables. Examples are laboratory or physiologic measures, or quality of life

assessments. If these continuous variables are measured in all subjects, small, perhaps clinically meaningless, differences may be statistically significant. An example is a trial of a few thousand participants assessing occurrence of a clinical event as the primary outcome. Instruments measuring quality of life may be incorporated into this trial. Because quality of life is assessed in all participants, a difference of a few points on a scale that has a 40 or more point range will be statistically significant but probably not clinically significant.

Can there be clinical significance in the absence of statistical significance? Clinicians are always making judgments in the absence of optimal information. Many treatments are used, although a clinical trial may not be definitive, or may not even have been conducted, because a physician believes that the intervention is likely to be more beneficial than harmful. In addition, no clinical trial stands by itself. The results are always interpreted in light of other research (both basic and applied) findings, including other trials and observational studies. Sometimes, the totality of the information may be sufficiently persuasive, even though an individual trial may not show statistical significance, and perhaps even a **meta-analysis** may fail to do so. The judgment is made that the evidence for use is adequate, given relatively low toxicity of the intervention or the existence of a serious condition or disease. For example, the association of elevated serum cholesterol and ischemic heart disease has been well known for many years. Despite the fact that until recently there had not been evidence from clinical trials that cholesterol lowering was unambiguously beneficial, many clinicians acted as if that were the case. They may have prescribed lipid-lowering drugs only for patients at the highest risk, but recommended dietary changes for many more. This example points out that, when such judgments are made, clinicians are more comfortable employing interventions perceived to have low risk, relative to the condition being treated. Thus, dietary changes could be safely recommended even though trials of dietary intervention have not been conclusive, whereas drug therapy would await stronger evidence. Similarly, if the condition is life-threatening and there is no good standard therapy, as with some cancers, physicians often determine that a treatment merits consideration, even in the absence of statistically significant evidence.

A related issue concerns decisions based on **treatment–covariate interactions**, or subgroup findings. Overall, in a clinical trial, there may be a statistically significant beneficial finding, but even without clear evidence of interactions, clinicians may decide that the intervention should be reserved for those patients at the greatest risk. Alternatively, there may be a statistically nonsignificant trend overall in favor of an intervention, but an apparently large benefit in one or more subgroups of patients. If these results are consistent with other studies, they may be seen as evidence to use the intervention clinically in those subgroups. The reasonableness of such a course depends on the persuasiveness of the ancillary research data.

For a somewhat different view of statistical and clinical significance, see Feinstein.

Clinical Trials Audit and Quality Control

A **multicenter** randomized clinical trial is a complex undertaking, requiring cooperation among a diverse group of participants to achieve a successful result. Patients who agree to participate in a trial must be properly registered and randomized to one of the available treatments (*see* **Randomized Treatment Assignment**), and data on baseline patient characteristics, **eligibility and exclusion** requirements, adherence to treatment (*see* **Compliance Assessment in Clinical Trials**), adverse events, laboratory or other measurements, and clinical **outcome measures** must be collected and analyzed. Throughout this process, there is the possibility of errors arising in the data, ranging from honest mistakes to sloppiness or, rarely, from deliberate fraud (i.e. fabrication or falsification of data). Because of this complexity, one of the important hallmarks of a successful trial is a well-developed system for data quality control (QC) and auditing [3, 5, 6, 14].

The purpose of a data QC system is to provide reasonable assurance to the organizers of the trial as well as to the "consumers" of the results that the data on which the conclusions are based are reliable. It is unreasonable to attempt to detect and eliminate all errors in the data. A small percentage of errors will not materially affect the scientific conclusions of a well-designed and well-conducted clinical trial. Also, the data QC system itself can be a major cost component of the trial, and there is a law of diminishing returns in the attempt to lower the error rate toward zero. On the other hand, it is also unreasonable to be unconcerned with data QC. Even if the effect of a small amount of data errors on scientific conclusions is minimal, the effect of discovered errors in the data on public perception and external acceptance of the results can be profound.

Why do we do data QC at all? There are at least four reasons.

1. *Scientific validity*. It is theoretically possible that systematic or random data errors may be of a sufficient magnitude to threaten the primary scientific conclusions of the trial. Thus, a primary function of data QC procedures is to ensure that the nature and magnitude of data errors are within acceptable limits.
2. *Prevention of future errors*. Data QC procedures, applied early in a trial, can serve as an educational tool to prevent future errors in the trial. Indeed, the feedback from early detection of errors can be an extremely important aspect in ensuring high-quality data.
3. *Public confidence*. The ability of a clinical trial to affect clinical practice depends on many factors, a key one of which is public confidence in the integrity of the trial process. Unfortunately, well-publicized cases of data problems can have a major negative impact on public confidence, far beyond that justified from a purely scientific viewpoint.
4. *Product licensing*. There are expectations and requirements with respect to data quality from regulatory agencies (e.g. the **Food and Drug Administration** in the US) in those trials supporting product or device licensing applications. For such trials, the need for data QC procedures is obvious [15].

In the following sections, the clinical trials data flow process is described, the primary targets for a QC program are identified, general clinical trials QC procedures are described, useful statistical QC procedures are discussed, site monitoring and audits are described, and the costs of QC procedures are assessed.

The Clinical Trials Data Flow Process

A simplified conceptual framework for considering the data flow process in a clinical trial is given in Figure 1, where there are three steps leading from the patients to the analysis of the trial. In the first

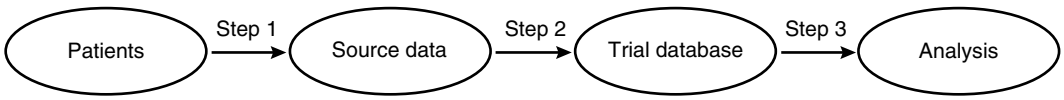

Figure 1 Data flow in a clinical trial

step, physical measurements on patients, laboratory tests, demographic data, and other patient data result in some "source data records" such as those in the official medical records or in some clinical or research laboratory database. In the second step, some subset of the source data is sent via a case report form (CRF) or in an electronic format to a centralized trial database. In some cases (e.g. questionnaire data), these two steps are combined and the data flow is directly from the patient to the trial database, and there are effectively no "source data" against which the trial database can be checked in an audit (*see* **Data Management and Coordination**). The third step in this process is the analysis step, in which various statistical procedures are applied to the trial database.

Data errors can arise at each step of the process. Thus, at step one, the source data may not reflect the "truth" of patient status or response (e.g. the birth date in the source data may not be correct if there was an error in recording it or, even, because of misrepresentation by the patient). At step two, the trial data may not be the same as the source data (in the birth date example this could be caused by an error in data entry from the CRF). At step three, there could be a programming error so that the analysis does not properly reflect the trial database. Each of these potential sources of error requires attention, but the types of QC procedures are quite different at each step. In the remainder of this article, attention will be focused primarily on step two, on data QC procedures aimed at ensuring that the trial database is an accurate reflection of the source data.

Primary Areas Targeted for QC

There are several areas that should receive special attention in any clinical trials QC plan. These are:

1. *Registration and randomization*. The process of registration and randomization of patients is of fundamental importance and must be tightly controlled.
2. **Eligibility and exclusion criteria**. The data required for assessing patient eligibility must be carefully collected and validated. For scientific reasons and for easing complexity, it is desirable to make the eligibility criteria as simple and broad as possible [7].
3. *Baseline patient characteristics*. Data available on patients at registration are often used as prognostic factors, as **stratification** factors, or for other reasons.
4. *Treatment delivery and* **compliance**. Despite the widely accepted principle of **intention-to-treat** in the statistical analysis of randomized trials, some idea of the extent of treatment delivery and compliance is desirable in interpreting the results.
5. *Response and toxicity*. Knowledge of the effect of treatments on clinical response and on the toxicity or other adverse events is essential. The clinical response is often a primary outcome measure in the trial.
6. *Laboratory values*. Laboratory data, from both clinical and research laboratories, are important in the analysis of many clinical trials [4, 18].
7. *Follow-up*. Long-term outcomes and survival are important in the analysis of most clinical trials. Indeed, in most serious chronic diseases (e.g. cancer), long-term follow-up data are the primary focus of the trial.

General QC Principles

One of the more important principles of any data QC plan is that the trial policies and procedures should be written down beforehand in a Standard Operating Procedures (SOP) document or equivalent, which should be sufficiently detailed to enable an external reader to be able to assess the data QC plan. The SOP document is also important in QC training and documentation of QC procedures at all levels. A well-trained staff following clearly articulated QC procedures provides strong protection against serious data problems. The prevention or early detection of data problems in a clinical trial is an effective way to avoid later, and very expensive, corrective measures. Indeed, some data errors cannot be corrected later.

The independence of the statistical center from the trial organizers and participants will help to ensure that QC procedures are above reproach. For example, the registration and randomization process is so important to the integrity of the trial that it must be carried out in an exemplary fashion, preferably by an independent statistical center or its equivalent.

Case report forms should be as simple as possible. There is often a temptation to include data that are not essential to the primary objectives of the trial. This temptation should be strongly resisted, since

it inevitably adds to the expenses of the trial and dilutes the QC procedures aimed at the key data. The data entry or data acquisition procedures need careful attention. For data entered into the trial database by data entry staff, one standard procedure to minimize data entry errors is independent double data entry [2]. This procedure reduces the number of data entry errors but only at increased cost. For automated data acquisition, procedures for validating the data prior to loading into the trial database are important.

Automated data editing procedures, including range and validity checks, as well as cross-field consistency checks, are an important part of any data QC program [8]. These procedures are usually deterministic checks on the data. Statistical procedures are discussed in the next Section. Range checks are of the form $a < x < b$, where a and b are prespecified constants, and x is the variable value. If x is outside the indicated interval, then a flag is raised indicating that the value x must be checked. A validity check is a test to ensure that a variable has a valid value. For example, a discrete variable must take one of a specified finite set of values. Cross-field consistency checks are checks of required relationships among two or more variables. These can be of the form $x < y$ for numerical or date variables or can simply reflect impossible configurations (e.g. females with prostate cancer).

A program of on-site monitoring and on-site auditing is important for ensuring that data in the trial database accurately reflect the source data [11]. Unfortunately, this aspect of the data QC plan is usually extremely costly, so careful thought is needed in designing this part of the plan. A separate Section below deals with monitoring and auditing in more detail.

Statistical QC Procedures

There are many traditional statistical procedures that are useful in a data QC plan [10, 12]. These are also relatively inexpensive to implement, especially compared to on-site visits to participating centers or other labor-intensive procedures, and thus should be employed extensively. Standard univariate and multivariate **outlier** detection techniques are useful (*see* **Multivariate Outliers**). The identified outliers can then be verified. Of course, unless some documented error is detected, no outlier should be deleted.

Another type of analysis that is important in multicenter studies is an analysis by center. This analysis can be as simple as an analysis of primary outcome to look for unusual discrepancies among centers. It is also important to look at bivariate plots of important data by center to spot unusual patterns. Such an analysis led to the detection of one case of scientific misconduct [1]. A more common result of this type of analysis would be to identify and correct some systematic, but unintentional, data problem at one or more centers.

Statistical random sampling schemes (*see* **Probability Sampling**) are an important part of industrial QC procedures, and these schemes can be applied profitably to data QC in clinical trials. For example, a periodic random resampling of a small percentage of records in the trial database and a check of selected fields in these records against the CRFs can ensure that the overall process is working well. Random sampling is also a key part of the auditing process described below.

On-Site Monitoring and On-Site Audits

In any multicenter clinical trial, the overall quality of the data is fundamentally dependent on the quality of data from the individual centers [9, 16]. Thus, there must be education and training of the key personnel at each center (physicians, nurses, data managers, clinical research associates, and others) and some procedure to compare the trial database with the source data from these centers. In principle, all of these activities could be conducted without visits to the individual centers, but on-site visits for these purposes are clearly preferable, although extremely expensive [17, 19]. In large simple trials, it may be impossible to visit the individual centers, whereas in some product licensing trials, extensive on-site monitoring and on-site auditing procedures at every center may be employed. Most trials fall between these extremes.

Cost–Benefit Analyses

It is a common complaint among clinical trialists that costs of data QC procedures are excessive relative to other costs of the trial and to the expected benefits. Surprisingly little has been written on this important topic [13]. As in other areas of economic analysis, there is clearly a law of diminishing returns in effect as additional QC procedures are added to reduce the

data error rate. The problem lies in deciding where to draw the line.

It seems clear from the earlier considerations that automated data editing procedures and statistical QC procedures are likely to have a large benefit for a relatively low cost. However, these procedures are largely ineffective in assuring that the trial database matches the source data. On-site monitoring and on-site auditing is almost certain to be the most expensive part of the QC procedures, but is a primary method for checking the source data.

Summary

Data quality control procedures are an important part of any well-designed and well-conducted clinical trial. Automated data editing and statistical QC procedures offer major benefits for relatively low costs. More expensive procedures such as on-site monitoring and on-site auditing may be essential to identify certain types of data errors, but their benefits relative to their costs have not been well studied.

STEPHEN L. GEORGE

Clinical Trials of Antibacterial Agents

This article focuses on comparative **clinical trials** of antibacterial agents in the treatment of acute infections caused by bacteria. Many of the issues also relate to trials of antifungal and antiviral agents, and to prophylactic trials (*see* **Prevention Trials**; **Vaccine Studies**). Specific issues of antibacterial agents in neutropenic patients are not addressed.

Clinical trials of antibacterials differ from other clinical trials in several ways. There exists a three-way **interaction** between the antibacterial agent, the patient, and the organism causing infection, and these interactions affect the approach to the design, analysis, and interpretation of results. In addition, antibacterial studies often include patients with potentially life-threatening conditions, where treatment must commence immediately. This leads to practical problems such as entry of ineligible patients and inappropriate treatment (*see* **Eligibility and Exclusion Criteria**).

Terminology

An organism causing an infection is termed a *pathogen*. Infections may be caused by more than one pathogen (a *polymicrobial infection*). The pathogen causes signs and symptoms of infection in the patient, e.g. raised temperature, and the aim of treatment is to eliminate both these clinical signs and symptoms as well as to eradicate the pathogen(s). *Susceptibility* of pathogens to treatments is an important consideration in clinical trials and is an indication of whether the pathogen is likely to be eradicated by the antibacterial drug. Susceptibility is usually measured by either minimum inhibitory concentrations (MICs) or zone sizes, and pathogens are classified as either *sensitive* or *resistant* to the antibacterial agent. It may not be possible to identify a bacterial cause for the infection before treatment commences, and patients are sometimes found to have a viral or fungal infection after entry, or even no infection at all; such patients are referred to as *misdiagnoses*.

The *clinical response* is the investigator's assessment of the patient's clinical outcome (*see* **Outcome Measures in Clinical Trials**) for the infection for which the patient entered the trial. Categories of cure and failure are used; sometimes also others, such as improvement, but categories are usually combined at the analysis stage to give a binary outcome of satisfactory or unsatisfactory. A response of indeterminate is used when a patient cannot be assessed, e.g. they are lost to follow-up. Responses are described in detail in various Guidelines [1–3].

To identify the pathogen causing infection, an appropriate sample must be taken from the patient, e.g. sputum in the case of bronchitis, cerebrospinal fluid (CSF) in the case of meningitis. Other data which should be recorded are: date of collection, source of sample, quantitative evaluation of pathogens for certain infections, e.g. urinary tract infections, and susceptibility to trial treatments. A *microbiological response* should be given for each pathogen isolated pretreatment. This will be *eradicated* if the pathogen is no longer present at the time of assessment; *persisted* if it is still present. If it is not possible to take a sample, e.g. for ethical reasons as in meningitis trials where it may not be desirable to obtain a further CSF sample, the response may be *presumed eradicated* or *presumed persisted*, on the basis of whether the patient is clinically satisfactory or not. A new organism appearing during the trial which requires treatment is called a *superinfection*. These responses are detailed in the Guidelines.

Sometimes a *"by patient" microbiological response* is given, which gives a summary of the response for pathogens within a patient; this is particularly useful in polymicrobial infections. It is derived from the pathogen microbiological response, as shown in Table 1.

Assigning responses is not always straightforward, and clear guidance must be given in the protocol of how each of the categories for each of the responses should be used.

Assessments of all three responses are made at the end of treatment and also after a suitable follow-up period to detect relapses, which are important because they may indicate that the infection was only suppressed.

Historical Development

The first set of Guidelines for the conduct of clinical trials with antibacterial agents was published by the **Food and Drug Administration (FDA)** in 1977 [5]. The British Society of Antimicrobial Chemotherapy

Table 1 "By patient" microbiological response

Pathogen response	"By patient" response	Response in analysis
All eradicated	Success	Satisfactory
All presumed eradicated	Presumed success	Satisfactory
One or more persisted	Failure	Unsatisfactory
One or more presumed persisted	Presumed failure	Unsatisfactory
Superinfection and all pretreatment Pathogens eradicated	Superinfection	Unsatisfactory

(BSAC) published guidelines in 1989 [3]. The Infectious Diseases Society of America, under a contract with the FDA, and a European Working Party produced general and disease-specific guidelines in 1992 and 1993 respectively [1, 2].

Typical Study Design

Phase III clinical studies (*see* **Clinical Trials, Overview**) of antibacterials are typically parallel group, randomized, **multicenter**, active-controlled. Placebo-controlled trials are rarely ethical because effective treatment is already available. A double-blind (*see* **Blinding or Masking**) design can be difficult for studies of intravenous or intramuscular formulations, for example some drugs effervesce. At a minimum, studies should always be assessor-blinded. Studies are relatively short; treatment rarely lasts for more than 10 days, with a 2–4 week follow-up.

The majority of studies aim to demonstrate overall **equivalence** because for most infections effective treatment is already available and it would not be ethical to conduct a trial where the expectation of success was less for one drug than for another (*see* **Ethics of Randomized Trials**). Patients who are anticipated to be at different risks of failure with the study treatments should be excluded from these trials. Hence, generally the aim is to show equivalence by proving that the new treatment is at least as good as the control treatment. The principles of equivalence trials are addressed by Jones et al. [6].

Statistical Analysis of Endpoints

No new statistical techniques have been specifically developed to analyze data from antibacterial trials. For analysis purposes, assessments are combined to give a **binary** response of satisfactory or unsatisfactory. Standard techniques for analyzing binary data are then used e.g. **odds ratio** or difference in proportions. Strata (e.g. centers) (*see* **Randomized Treatment Assignment**) and risk factors defined at the design stage may need to be explored.

Analyses are generally performed on the clinical response and on the "by patient" microbiological response. Analysis of the microbiological response for pathogens must be undertaken with care. If patients have more than one pathogen, then an analysis of all pathogens violates the assumption of independence. An analysis of each individual pathogen may be uninformative owing to the small numbers of each pathogen which are likely to be obtained, and the difficulty in predicting which types of pathogens will occur in a given study. Usually these data are only summarized and are not subjected to statistical analysis. The "by patient" microbiological response is a more useful endpoint for analysis, and can be more easily interpreted.

The analyses should be performed at the end of therapy at a minimum. At follow-up, there are often a large number of patients without a response as they are lost to follow-up, and in such situations, a statistical analysis will not be informative. A "last-value carried forward" approach, i.e. carrying forward the response at end of treatment to follow-up, can be very misleading particularly if many patients are lost to follow-up.

Response rates of zero or 100% within centers may cause complications with some methods of analysis, although exact methods are sometimes used in such situations.

Equivalence is usually defined in terms of a lower limit for the **confidence interval** for the difference between response rates, typically -10%, i.e. equivalence is demonstrated if the lower limit of the confidence interval is above -10%. This infers that for equivalence trials, the analysis should be performed

in terms of differences in proportions. This can create a dilemma for the statistician since, if other methods of analysis are used, e.g. odds ratio, this definition of equivalence cannot be applied. Often the approach taken to this problem is to present the analysis by difference in proportions, but other methods are used to check the **robustness** of this analysis.

Patient Groups for Analysis

All patients exposed to either trial drug should be included in the assessment of safety (*see* **Data and Safety Monitoring**). In the assessment of efficacy, the aim should be to analyze the comparative efficacy of the treatments whilst minimizing the potential for bias. The conventional method is to consider **intention-to-treat** (ITT) and per protocol (PP) groups. These represent all patients entering the study and all patients who meet the study criteria, respectively, although the interpretation of these can differ, as discussed below.

Efficacy analyses are usually performed on the patient groups shown in Table 2. The patients included in the bacteriological PP group will be a subset of the bacteriological ITT group, which will be a subset of the clinical ITT group. The clinical PP group will be identical to the bacteriological PP group if the clinical PP group requires patients to have microbiologically documented evidence of an infection.

In studies of antibacterial agents, some problems arise more frequently than in other types of studies; patients can be inadvertently misrandomized, they can also be randomized but not treated, and there can be misdiagnoses. There is no standard method for handling these patients in either the ITT or PP analyses, and the proposed methods should be defined in the protocol for each study. However, such patients are unlikely to affect the outcome or interpretation of an analysis unless there are significant numbers of them or the number is unbalanced between the treatment groups. In such cases the reasons should be fully explored and the interpretation of the analysis carefully considered.

Patients with an indeterminate response will be excluded from all analysis populations except ITT, where they should be classified as unsatisfactory. If there are a significant number of patients added to the ITT analysis as failures, or the number is unbalanced between the treatment groups, then the interpretation of the analysis again needs to be carefully considered.

The purest view for the PP group is to exclude all patients who do not meet the entry criteria of the trial. A more pragmatic approach is to agree which criteria are unlikely to affect the outcome of treatment and to retain such patients in the PP analysis. For patients who deviate during the trial, rules should be agreed on what constitutes a deviation serious enough to warrant exclusion. Two common problems that arise in these studies are patients given concomitant therapy to treat an infection and patients who are found to have resistant pathogens. In either case it is not always ethical to withdraw the patient from the trial if he/she appears to be responding to the trial treatment.

Table 2 Efficacy analysis groups

Name of analysis group	Response	Patient group
Clinical ITT	Clinical	All patients
Clinical PP	Clinical	All patients who meet the trial criteria. This may or may not require patients to have documented evidence of a bacterial infection
Modified ITT	"By patient" microbiological	All patients who have documented evidence of a bacterial infection
Bacteriological PP	"By patient" microbiological	All patients who meet the trial criteria and have documented evidence of a bacterial infection

ITT = intention to treat.
PP = per protocol.

Patients taking concomitant therapy are sometimes classed as clinical failures or as indeterminate; sometimes all such patients are excluded from the analyses and sometimes a more judgmental approach is taken on the basis of whether the therapy taken is expected to affect the pathogen causing the infection. Patients found to have resistant pathogens are often omitted from analyses and sometimes this is applied if the pathogen is resistant to either study treatment or only resistant to the study drug received.

There is still confusion over whether the ITT or the PP analysis should be primary. The Committee for Proprietary Medicinal Products guidelines [4] state that in studies designed to show superiority of one drug over another, the ITT analysis is usually more conservative than the PP, since the noncompliers (*see* **Compliance Assessment in Clinical Trials**) included in an ITT analysis dilute the overall treatment effect. Hence, since antibacterial studies are usually designed as equivalence studies the PP should be the primary analysis because the ITT is less conservative in showing equivalence. However, whenever possible equivalence should be demonstrated in both the ITT and PP analyses. If results differ, then this must be explained [6].

Choice of Sample Size

It is usual to base patient numbers (*see* **Sample Size Determination for Clinical Trials**) on the clinical response, although this depends on the aims of the trial and the particular infection under study. There are many methods available for calculating patient numbers using binary data, several of which are based on the normal approximation of **binomial** probability. Since the primary analysis is usually the PP analysis, patient numbers will need to be inflated based on the estimate of the proportion of patients who will contribute to the PP analysis. This will be based on previous experience in this area, or published data, and usually ranges between 65% and 95%. In studies for US registration, samples sizes may need to be sufficient to ensure sufficient numbers of particular pathogens.

Unresolved Problems

There are still a significant number of issues that remain unresolved in this area. There is no standard and accepted way to analyze the data. There is also no agreement on whether the ITT analysis or the PP analysis is primary, or whether 90% or 95% confidence limits should be used, although this partly stems from a historical lack of understanding of the principles of equivalence trials. There is no standard approach to handling patients in the PP and ITT analyses, particularly with respect to such deviations as patients taking concomitant antibacterial therapy.

Publications of antibacterial trials are generally good in their statistical content, although issues in equivalence trials are not sufficiently understood yet. Papers often lack sufficient detail in defining which patients have been included in which analyses. The approaches to handling deviations can differ widely between trials and also within trials.

Clinical Trials Protocols

A **clinical trial** protocol serves several purposes. First and foremost the protocol serves as a guideline for the conduct of the trial. It describes in a clear and detailed manner how the trial is performed so that all investigators know the procedures. This is particularly important in **multicenter trials** where it can be difficult to ensure that all centers and investigators conduct the study properly.

A second purpose of the protocol is to procure funding for the trial. Any funding source, such as government, a pharmaceutical company, or a private foundation, will generally require a protocol on which it can judge the merit of the proposal. Since funding institutions have different protocol formats, it is essential that the investigator obtains and follows the required format.

In addition to review committees of funding institutions, committees at the local institution, such as research committees or institutional review boards, need to review the trial to ensure that the trial participants' rights and safety are adequately protected, that the trial is in compliance with all of the local institution's regulations, and that the trial is feasible at the institution. The protocol serves as the basis for the review by these committees.

A fourth purpose is to provide guidelines to the groups responsible for monitoring the trial. At the local institution this may be the research committee or an institutional review board. For large studies or multicenter studies, formal data monitoring and safety committees (*see* **Data Monitoring Committees**) are also usually established. For all of these committees, the protocol provides the background information against which they determine whether the trial is progressing satisfactorily and that the investigators are complying with the intended procedures.

Finally, the protocol serves as a historical document for the trial to which trial investigators or outside investigators can refer should questions arise after its completion.

The clinical trial protocol provides broad detail about the trial and does not include the fine details of the day-to-day operations. These fine details, such as the steps to be taken at each visit, how to complete study forms, and how data will actually be processed, are usually described in a separate document, a Manual of Operations. If the trial is testing a particular technique, such as a specific surgical or a behavioral modification technique, or is using a complicated rating scale as a study variable, the fine details of the technique or administering the scale are not usually included in the protocol, but are provided in a separate document called a Training Manual.

Although each funding institution may specify its own format for a protocol, there are a number of items nearly always included. These include an abstract, the clinical background, the purpose of the trial, the methods, ethics and safety issues, organization, the budget, and copies of the proposed study forms. Some general texts discussing protocol issues are [4, 5, 7] and [8].

Abstract

A protocol usually begins with a short abstract that states the purpose and significance of the study and provides the most pertinent details, including the patient population to be studied, the treatments to be tested, the study design, the primary outcome measure(s), the number of patients, and the duration of treatment and follow-up.

Background

An in-depth summary with relevant references to published work on the study topic is included to justify the need for the trial. Any unpublished work that the investigators have done on the subject is also described. If drugs are involved, then pertinent pharmacological and toxicity data are included. In addition, if any new or nonstandard methods, such as the use of specific **surrogate endpoints**, are used in the study, then information about the method is provided.

Purpose

The purpose of the trial and its current importance are described in clear and concise terms. For purposes of funding review, this section is used to sell the importance of the trial, but it should not promise more than can actually be obtained. Reasons for

the trial might include (i) to test a new treatment regimen, (ii) to test an established treatment for a new indication, (iii) to determine the best of a number of standard treatments, and (iv) to provide additional data on the safety or efficacy of a treatment regimen for approval by a regulatory agency.

Methods

The following items are usually addressed in the methods section as appropriate for the type of trial proposed.

Hypotheses

The hypotheses that the trial is designed to test are clearly specified. Although on occasion one needs to specify more than one primary hypothesis, the number should be few so that the main aims of the trial can be kept in focus. Any secondary hypotheses that the investigators want to test are also specified. Listing the secondary hypotheses in a protocol prior to the conduct of the trial lends more credence to the results of testing such hypotheses as it shows that the results are not the product of a "fishing expedition", in which large numbers of unlikely hypotheses are tested and only those that meet some usually inappropriate criteria for statistical significance are reported (*see* **Multiplicity in Clinical Trials**). Careful consideration of secondary hypotheses in the protocol also ensures the collection of the data necessary to answer them.

Patient Population

The population of patients entered into the trial is described in detail. This is usually done by specifying criteria for inclusion and/or exclusion. Inclusion criteria are those characteristics that the patient must have to be considered for inclusion in the trial. For example, if the trial compares drug treatments in elderly male, alcoholic patients, the inclusion criteria might specify that patients be (i) men, (ii) $\geq$65 years of age, with (iii) a diagnosis of alcoholism. Exclusion criteria are the characteristics of a patient that prevent entry into a trial even though all inclusion criteria are met. For example, if the primary endpoint for the study is measured two years after entry in the trial, then patients with a life expectancy of less than two years might be excluded from participation. When defining a patient population, it should be kept in mind that, although having a large number of inclusion and exclusion criteria may ensure a more homogeneous trial population, it may also lead to results that are less generalizable and can make patient recruitment more difficult (*see* **Eligibility and Exclusion Criteria**).

Treatment Regimens

The treatments under study are described in broad detail. For drug studies, the dose administered, the dosing regimen, and the duration of dosing are given. For surgical studies, broad details about the surgical procedures are usually given; the fine details are provided in a separate training manual if needed. In trials of medical devices, the use and maintenance of the device are described. Noninvasive interventions, such as psychotherapies, require broad information such as references to the technique, how it is administered, who administers it, how the interventionist is trained, how often and how long the intervention is given, and how the intervention is monitored. Specific details on the intervention should usually be described in an appendix or separate training manual.

Trial Design

Trial design items may include the following.

1. *Randomization*. Will the treatment assignment be randomized? If so, details of the randomization method are included. Any strata identified (e.g. gender), to ensure that treatment assignments are equally distributed over important prognostic factors, are described (*see* **Randomized Treatment Assignment**).
2. *Control groups*. If a control group is used, then the protocol should define the control and justify its use. If a placebo is used rather than a standard treatment, then safety considerations for participants assigned to the placebo must be addressed.
3. *Masking (blinding)*. Knowledge of the treatment assignment can lead to bias in reporting of some outcome measures. The protocol should describe who knows the patient's treatment assignment and who is masked. Measures to maintain the

masking are also specified (*see* **Blinding or Masking**).

4. *Experimental design*. The protocol indicates the experimental design used. While most studies are two-group parallel designs in which a patient is assigned to one of two treatment groups for the entire study, other designs such as **crossover designs** and factorial designs are sometimes used (*see* **Factorial Designs in Clinical Trials**).

Pre-Study Procedures

This portion of the protocol describes the process for the recruitment and selection of trial patients as well as the pre-study evaluations and procedures that patients have before entering the trial. The data collected pre-study are described.

Treatment Phase

The clinical management of the patient over the period of treatment is described in this section. It includes items such as how often and by whom the patient is seen for treatment or monitoring, what tests or procedures are performed at each visit, and what data are collected at each visit.

Follow-Up Phase

In trials where the patient continues to be observed after treatment is completed, the follow-up procedures are described including the frequency and duration of the follow-up visits and the data collected at each visit.

Termination

Procedures for ending patients' participation in the trial, whether because they completed the planned schedule or because they need or wish to leave early, are described. Anticipated reasons for early termination are specified and methods for minimizing early terminations are described.

Study Flow Diagram

It is often desirable to include a flowchart describing how patients progress through the trial. The chart starts with patients' initial screening for recruitment and ends with their completion of the planned schedule giving pertinent highlights such as randomization, treatment assignment, treatment and follow-up visits, and possible early termination. For complicated studies, such a flowchart is useful, both to reviewers and trial investigators, as a concise reference for implementing the protocol.

Outcome Measures

The primary outcome measure(s) are those required to answer the trial's primary hypotheses. They are described in detail, including how they are collected, their validity, accuracy and reliability, the methods used to ensure that they are measured in a uniform and unbiased manner, and the methods used to minimize loss of these data in the trial. The secondary outcome measures for answering any secondary hypotheses are also listed (*see* **Outcome Measures in Clinical Trials**).

Statistical Issues

Three types of statistical issues may need to be addressed in the protocol.

1. *Sample size*. The number of patients required for the trial is determined and justified. A trial that is too small will have little chance to answer clearly the study hypotheses, while too large a trial will waste money and may subject patients needlessly to an inferior treatment. The trial sample size should be large enough to answer all of the primary hypotheses. Methods to calculate sample sizes are available for most trial designs [1, 3, 6]. The crucial issues that must be resolved usually involve estimating the expected results in the control group and determining the treatment difference to be detected (*see* **Sample Size Determination for Clinical Trials**).
2. *Statistical analysis*. The planned statistical analyses to analyze the trial data are outlined. These planned analyses are specific for each of the study hypotheses, especially for the primary hypotheses.
3. *Interim monitoring*. For trials over extended periods, the data are usually analyzed at regular intervals to determine whether a conclusion can be reached early or if there are any safety issues

that need addressing (*see* **Data and Safety Monitoring**). For such interim monitoring there are a number of statistical techniques [2] that have been developed that allow analysis of the accumulating data multiple times without affecting statistical inference at the end of the study. This section describes such interim monitoring plans.

Laboratories

If special, nonroutine laboratory tests are used in the trial, then they are described in the protocol. For multicenter studies that include central laboratories, procedures for obtaining and shipping specimens to the central laboratory are described.

Compliance

For many studies, such as those that require the administration of medication over long periods of time or that deal with difficult populations such as drug abusers, compliance with treatment regimens and with protocol procedures is a major concern. For such trials, the protocol describes how compliance is monitored (e.g. pill counts, blood serum levels, and/or missed visits) and methods used to improve compliance in noncompliant patients (*see* **Compliance Assessment in Clinical Trials**).

Ethics and Safety

One of the most important concerns of any clinical trial is the protection of the trial patients' rights and safety. These concerns are addressed in the protocol. The protocol discusses how the patient is approached for entry into the trial, how informed consent is obtained, and what safeguards are in place to ensure that the patient's participation in the trial is voluntary and confidential. Copies of the informed consent form to be used in the trial are included in an appendix. Procedures to monitor patient safety are also described, including the adverse events to be monitored, how and to whom the adverse events are reported, and a plan of action should a serious adverse event be detected during the trial (*see* **Ethics of Randomized Trials**).

Organization

The conduct of a clinical trial can be complex, particularly in **multicenter trials**. To ensure that the trial is conducted correctly, the protocol describes its organizational structure. This includes naming each investigator and describing his/her role, including his/her supervisory responsibilities, describing the roles and responsibilities of all trial support staff, and providing the composition and rules of any special committees, such as steering, endpoint adjudication, and data and safety monitoring committees, including their relationship to other components of the trial. **Data management and coordination** plans may also be described here.

Budget

The budget section lists the projected costs for the study by year of trial as well as the total budget, and provides a breakdown of costs including personnel, equipment, supplies, laboratory costs, and travel. Justification for most items in the budget is provided.

Study Forms

Many funding institutions require that the study forms be included in an appendix. This helps reviewers to determine whether the investigators are collecting the appropriate data.

Summary

Since a clinical trial protocol has many purposes and is used by so many people, it is important that it be written clearly, concisely, unambiguously, and in sufficient detail that it meets the requirements of all of its users. The protocol should provide enough detail that readers will know how the study is being conducted, but not so much detail as to overwhelm the reader. Although it is important that investigators adhere to the protocol, mechanisms should be in place for making changes if the need arises. If changes are made, then they must be well documented. In this manner, the different versions of the protocol provide a description of the evolution of the trial. In summary, the protocol acts as the main document describing the

design and conduct of a clinical trial and, as such, plays a central role in the trial.

Clinical Trials, Early Cancer and Heart Disease

Early developments in controlled **clinical trials** at the **National Institutes of Health (NIH)** took place mainly at the National Cancer Institute (NCI) and what was then the National Heart Institute (NHI) [subsequently the National Heart, Lung, and Blood Institute (NHLBI)] beginning in the 1950s. This article reviews the developments from the early 1950s to the late 1960s at both institutes, summarizing the early efforts in clinical trials, the organizations set up to conduct and monitor the clinical trials, and the developments in statistical methodology that have formed the basis for conducting many of the present day randomized controlled trials. The early history of clinical trials at these institutes has been reviewed in more detail at NCI by Gehan & Schneiderman and at NHLBI by Halperin et al. [28, 32].

Developments in Clinical Trials at the National Cancer Institute (NCI)

A major advance in the development of chemical agents for the treatment of cancer came from observations of the treatment of children with acute lymphocytic leukemia, which was a rapidly fatal disease until 1948 when Sidney Farber, in a nonrandomized study of methotrexate, observed complete remissions and longer survival among some pediatric patients [21]. However, results did not meet with uniform acceptance and questions were raised about diagnosis, selection of patients, and reporting. There was a need for a more organized approach to treatment experimentation that would lead to **unbiased** evaluations of treatments. At about the same time, animal models of the major forms of cancer – sarcomas, carcinomas, and leukemias – were developed that could be used to screen candidate materials and, if the materials were effective and not overly toxic, ultimately lead to clinical trials in humans. By 1960, there was an annual screening of approximately 25 000–30 000 materials sponsored by NCI with only about 10 – 20 new agents having sufficient effectiveness in animal systems to merit consideration for testing in humans. Peter Armitage, of the London School of Hygiene and Tropical Medicine, was a visiting scientist at NCI in the late 1950s. His background in sequential statistical procedures (*see* **Sequential Analysis**) quickly found direct application in the development of two- and three-stage screening procedures for animal tumor systems that permitted rejection of an agent at any stage but acceptance only at the final stage [3, 43]. The object was to determine quickly which new compounds should be considered for further study in man. In the late 1950s, optimism was high that this screening program would lead to a new chemotherapeutic treatment that would make large clinical trials unnecessary. Also, there was a belief that different forms of cancer were sufficiently similar so that an agent active in one form of the disease would also be active in another.

Early Efforts in Clinical Trials

Dr C. Gordon Zubrod came to NCI in 1954 at about the time that Dr James Holland departed for Roswell Park Memorial Institute in Buffalo, NY. Drs Emil Frei and E.J. Freireich arrived at NCI in 1955. Under the leadership of Zubrod, this formed the key group of clinicians who initiated the clinical trials program at NCI. When Zubrod was at Johns Hopkins University in the early 1950s, he indicated that there "were two streams of influence (relating to developments in clinical trials) – infectious disease chemotherapy and comparative studies of analgesics and hypnotic drugs" [52]. Among those playing an important role in the conduct of clinical trials at Johns Hopkins were Dr James Shannon (later Director of the National Institutes of Health), the pharmacologist E.K. Marshall, Jr and **W.G. Cochran**. About this time, the studies of streptomycin in pulmonary tuberculosis by the Medical Research Council were published and had a profound influence on the Johns Hopkins group [41] (*see* **Medical Research Council Streptomycin Trial**). The first effort at a randomized trial was a comparison of the efficacy of tetracycline and penicillin in the treatment of lobar pneumonia [5]. At the same time, the Veterans Administration began its first randomized controlled trials in tuberculosis [50].

The Organization of Trials

In 1954, the US Congress created the Cancer Chemotherapy National Service Center (CCNSC) to stimulate research in the chemotherapy of cancer. A clinical panel was formed, headed by Dr I. Ravdin, and

included among others Drs Zubrod and Holland. At an early meeting, the clinical panel reviewed a paper by Louis Lasagna, which enunciated five principles of the controlled clinical trial, including **randomization** and the statistical treatment of data [38]. Over the next several years, the clinical panel of the CCNSC oversaw the organization of cooperative clinical trials groups for the conduct of clinical trials in cancer (*see* **Cooperative Cancer Trials**). By 1960, there were 11 cooperative clinical study groups (Table 1), each comprised of a number of universities and/or V.A. Hospitals and Medical Centers and a Statistical Coordinating Center [48]. The cooperative groups were funded by the NCI through the Chairman and a Statistical Center. Zubrod recruited the chairman of each group and **Marvin Schneiderman** recruited the biostatisticians and statistical centers. One of the statisticians, W.J. Dixon, had two graduate students who were writing general statistical programs for the analysis of biomedical data. NCI awarded a contract to carry out this work that subsequently became the Biomedical Data Processing Program (BMDP) package of statistical programs (*see* **Software, Biostatistical**).

In the establishment of a clinical cooperative group, CCNSC agreed that there should be adherence to the following principles: combination of data from all institutions to accumulate rapidly the necessary number of patients; standard criteria of diagnosis, treatment, and measurement of effect; statistical design of the study, with a randomized assignment of patients to the groups to be compared; and statistical analysis and collaborative reporting of the results.

The clinical trials effort involved more types of clinical studies than randomized trials. There was a sequence of trials with differing objectives: **Phase I** – to determine the maximum tolerated dose of a regimen that can be used in looking for therapeutic effect; **Phase II** – to determine whether a particular dosage schedule of an agent is active enough to warrant further study; and Phase III – a comparative trial, usually randomized, to decide whether a new therapy is superior to a standard therapy. The primary objective of the clinical trials program was to provide a means of testing in humans new agents that had previously demonstrated effectiveness in animal tumor systems.

Some Early Trials

Following some preliminary discussions between Dr Zubrod and **Jerome Cornfield**, a leading statistician at NIH, there was agreement that childhood leukemia was an ideal disease for testing some of the new agents objectively. The first randomized cooperative clinical trial in acute leukemia was planned in 1954, begun in 1955, and reported by Frei et al. in 1958 [23]. The trial involved two regimens of combination chemotherapy – 6-mercaptopurine and either intermittent or continuous methotrexate in 65 patients. The study had the following features: a uniform protocol at the four participating institutions (*see* **Clinical Trials Protocols**); uniform criteria of response (*see* **Outcome Measures in Clinical Trials**); adherence to the principles of the controlled clinical trial, especially the randomization of patients to therapies (*see* **Randomized Treatment Assignment**); and stratification of patients by age, type of leukemia, and history of prior therapy. Statistical methods used were a comparison of

Table 1 Cooperative clinical study groups in 1960

Group	Chairman	Statistician
Acute leukemia, Group A	M. Lois Murphy	I. Bross
Acute leukemia, Group B	E. Frei	M. Schneiderman
Eastern Solid Tumor Group	C.G. Zubrod	M. Schneiderman
Southeastern Group	R.W. Rundles	B.G. Greenberg
Western Group	F. Willett	
Southwestern Group	H.G. Taylor	E. MacDonald
Prostate Group	H. Brendler	D. Mainland
Breast Group A	A. Segaloff	M. Schneiderman
Breast Group B	G. Gordon	M. Schneiderman
V.A. Groups – various malignancies	J. Wolf et al.	M. Patno
University Groups – lung, breast, stomach, ovary, colon	A. Curreri et al.	R. Stiver, G. Beebe, W. Dixon

median survival times and median duration of remissions between therapies, **confidence intervals**, and **Fisher's exact test**.

The first randomized clinical trial in solid tumors was conducted by members of the Eastern Solid Tumor Group and reported by Zubrod et al. in 1960 [53]. The trial involved a randomized comparison of two alkylating agents (thiotepa vs. nitrogen mustard) in patients with solid tumors. One objective was to "study the feasibility and usefulness of collaborative clinical research in cancer chemotherapy". The trial involved 258 randomized patients, and notable features were: blind evaluation of response by vote of clinical investigators (*see* **Blinding or Masking**); objective procedures for measurement of tumors and determination of when a response began and ended; the importance of accounting for type I and type II statistical errors (*see* **Hypothesis Testing**); appropriate sample size for detection of differences between treatments (*see* **Sample Size Determination for Clinical Trials**); and statistical analysis in the reporting of results.

A subsequent trial demonstrated the value of combination chemotherapy in acute leukemia and the independent action of drugs to increase the probability that a patient achieves complete remission [24]. Freireich et al. [25] reported a prospective, randomized, double-blind, placebo-controlled, sequential study of 6-mp vs. placebo in the maintenance of remissions in pediatric acute leukemia. This study established that 6-mp maintenance treatment leads to substantially longer remissions than placebo and was a forerunner to many adjuvant studies in other forms of cancer, such as breast cancer, in which treatments are administered when the patients are in a disease-free state [25]. This study also was a motivation for the development of an extension of the Wilcoxon test for comparing survival distributions subject to censoring [27] (*see* **Wilcoxon–Mann–Whitney Test**) and was used as an example by Cox in his, now classic, paper on regression models (*see* **Cox Regression Model**) and **life tables** [16].

Developments in Methodology

In the clinical trials program at NCI prior to 1970, there were several developments in methodology that have influenced the conduct of subsequent clinical trials. Before 1960, the clinical testing of new agents often involved as few as five patients, with the agent discarded if no positive response was obtained in at least one patient. In 1961, Gehan proposed a plan for Phase II trials that determined the minimum number of consecutive patients to study when all patients are nonresponders, before one could reject a new agent for further study, at given levels of rejection error [26]. This plan, or now more commonly Simon's modification, continues in use today in Phase II studies [46].

Several philosophical issues arose from the drug development program. The practice of human experimentation could be questioned by "Doesn't a physician have an implied duty to give his patient the best treatment? If that is the case, how can one justify having the toss of coin (i.e. randomization) decide which treatment a patient should receive?" The reply was (and is), "If the physician really knows what is the best treatment for the patient, the patient must receive that treatment and not be randomized into a trial." The question then becomes, "How and when does a physician know what is the best treatment for a specific patient?" The major ethical issue then becomes one of learning quickly (i.e. with a minimum number of patients) what is the best treatment (*see* **Ethics of Randomized Trials**). There have been several proposals for establishing what one "knows" while minimizing the number of patients who will receive the less effective treatment. Armitage proposed closed sequential procedures with paired patients on each treatment, and with the trial terminated as soon as one could establish the superiority of one of the treatments over the other [2] (*see* **Data and Safety Monitoring**). A feature of the plans was an upper limit on the number of patients one could enter. Schneiderman & Armitage later described a family of sequential procedures, called wedge plans because of the shape of the acceptance boundary, which provided a bridge between the open plans derived from **Wald's** theory and the restricted procedures of Armitage [44, 45].

In the 6-mp vs. placebo study for maintaining remissions in pediatric leukemia, patients were paired according to remission status (complete or partial), one patient receiving 6-mp and the other placebo by a random allocation, and a preference was recorded for 6-mp or placebo depending upon the therapy which resulted in the longer remission. The trial was conducted sequentially according to one of the Armitage plans [2] and a sequential boundary favoring 6-mp

was reached after 18 preferences had occurred – 15 for 6-mp and 3 for placebo. There were 12 patients still in remission at the time the study was terminated, although one could record a preference for one or the other treatment because the pair-mate had relapsed at an earlier time. It was clear that a more efficient analysis could be obtained by using the actual lengths of remission. Gehan, while working on an NCI fellowship with D.R. Cox at Birkbeck College in London, developed a generalization of the Wilcoxon test for the fixed sample size problem with each sample subject to arbitrary right **censoring** [27]. **Halperin** had previously developed a generalization of the Wilcoxon test, when all times to censoring were equal to the longest observation time [30]. Mantel noticed that one could utilize the **chi-square test** for comparison of survival data between two or more groups, assuming that one constructs a **contingency table** of deaths and survivors at each distinct failure time in the groups of patients under study. This chi-square test was appropriate when the risk of failure in one group was a constant multiple of that in the other; this test was an extension of the earlier test developed by Mantel and Haenszel which measured the statistical significance of an observed association between a disease and a factor under study in terms of an increased **relative risk** of disease [39, 40]. This test subsequently became known variously as the **Mantel–Haenszel test**, the **logrank test** or the Cox–Mantel test, and has been studied by Cox and Peto, among others [16, 42].

Another development in the 1960s was the exponential **regression** model proposed by Feigl & Zelen [22]. Dr Robert Levin of NCI was interested in studying the relationship of the survival time of leukemia patients to the concomitant variate of white blood count, separately according to the presence or absence of auer rods and/or significant granulature of leukemia cells in the bone marrow at diagnosis. Feigl & Zelen proposed a model in which an exponential **survival distribution** is postulated for each patient and the expected value of the survival time is linearly related to the patient's white blood count. A more general **loglinear model** was subsequently given by Glasser [29], and there have been numerous subsequent developments in parametric regression models with censored survival data (*see* **Parametric Models in Survival Analysis**) [17, Chapters 5 and 6, pp. 62–90].

Developments in Clinical Trials at the National Heart, Lung, and Blood Institute (NHLBI)

Prior to 1960, the National Heart Institute (NHI), subsequently to become NHLBI, had little involvement in **multicenter clinical trials**. In a trial designed in 1951, there was a comparison of ACTH, cortisone, and aspirin in the treatment of rheumatic fever and the prevention of rheumatic heart disease. A total of 497 children were enrolled in 12 centers in the UK, the US, and Canada. Felix Moore, then Chief of the Biometrics Section of NHI, was a statistical consultant. There were no differences in treatment effectiveness in the study, and no statistical or methodologic problems mentioned in the final report [8].

Subsequently, there was a multicenter observational study of lipoproteins in atherosclerosis that had substantial impact on the methodology for coordinating studies performed at several sites [47]. The Statistical Center was led by Felix Moore and Tavia Gordon at NHI. Careful quality control procedures and standardization of methods across centers were emphasized.

Early Efforts in Clinical Trials

Jerome Cornfield joined the NHI in 1960 and strongly influenced the conduct of clinical trials at NHI and statistical research on methodologic issues arising in clinical trials. In the early 1960s, intensive planning for two clinical trials was begun at NHI to reduce risk factors for coronary heart disease – The Diet Heart Feasibility Study (DHFS) and the Coronary Drug Project (CDP) [14, 20]. These studies reflected the strong interest in both dietary and drug approaches to the prevention of coronary heart disease and the recurrence of myocardial infarction. For the DHFS, the NHI Biometrics Branch served as the statistical coordinating center, first under the supervision of Joseph Schachter and later of Fred Ederer. Max Halperin rejoined the NHI in 1966 and, upon Cornfield's retirement in 1968, became Chief of the Biometrics Research Branch until his retirement in 1977. Four areas of clinical trials and methodology can be traced to these early studies and the individuals responsible for them. These areas are: organizational structure for clinical trials at NIH; methodology for the interim analysis of accumulating data (*see* **Data and Safety Monitoring**), including the **Bayesian**

approach, group sequential and stochastic curtailment methods; design and analysis of clinical trials, including the effects of patient **noncompliance** on **power** and the **intention to treat** principle; and methods for analysis of data from longitudinal clinical trials (*see* **Longitudinal Data Analysis, Overview**).

The Organization of NHLBI Trials

The "NHLBI Model" for cooperative clinical trials evolved from discussion during the planning stage of the CDP among outside medical experts and NHI medical and statistical staff. In 1967, a report by a committee appointed by the National Advisory Heart Council and chaired by **Bernard Greenberg** described this structure [35]. The report, subsequently known as the "Greenberg Report", became the basis for a structure of nearly all subsequent NHLBI trials as well as for many other trials sponsored at NIH.

The major components of the organizational structure include a Steering Committee, a Policy Advisory Board, a Data Monitoring Committee (*see* **Data Monitoring Committees**), and a Statistical or Data Coordinating Center, as well as individual clinics, central laboratories, and various other committees which served the needs of the trial. These might include committees to develop **eligibility criteria**, to assign cause of death, to define methodology and standards, or to oversee the preparation of manuscripts (for more details of organizational structure).

From the biostatistical viewpoint, the Data Monitoring Committee has the responsibility of monitoring accumulating data on a periodic basis and analyzing results for evidence of early benefit or harm. Primary and secondary outcomes measures are reviewed, along with safety data, compliance to the protocol, and subgroup analyses which may identify particular risk groups (*see* **Treatment-covariate Interaction**). The Statistical Coordinating Center and the Data Monitoring Committee work closely together in performing the appropriate data analyses needed for fulfilling the Committee's responsibilities.

The Statistical and Data Coordinating Centers for early trials at the NHLBI are given in Table 2. Personnel at these coordinating centers have played an important role in the development of clinical trials and made numerous contributions to statistical methodology.

Developments in Methodology

These are considered under three headings: data monitoring, design and analysis, and longitudinal studies.

Data Monitoring. Jerome Cornfield was involved in the planning and conduct of two clinical trials – the DHFS and the CDP. Both Cornfield and Halperin served on the Data and Safety Monitoring Committee of the CDP. At least partly motivated by his involvement in these trials, Cornfield published papers in 1966 on sequential trials, sequential analysis, and the **likelihood** principle, from a Bayesian perspective [9, 10].

In 1966, Max Halperin worked jointly with Cornfield and Samuel Greenhouse (then at the National

Institute of Mental Health) to develop an adaptive allocation procedure that would assign an increasing proportion of patients to the better of two treatments as evidence accumulated [13] (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). Their approach to the problem was Bayesian and generalized the earlier work of Anscombe and Colton [1, 7]. At around the same time, Cornfield published a general paper on the Bayesian approach that involved the use of a **prior probability distribution** with a mass of probability P at the **null hypothesis**, with a continuous density of total mass $1 - P$ over a set of **alternative hypotheses** [11]. A key feature of Cornfield's proposal was the rejection of the null hypothesis when the posterior odds (the relative betting odds or RBO) became small for H_0. The RBO was used in the CDP in the monitoring of mortality differences between the control and each of the drug treatment groups. Subsequently, Canner, of the CDP Coordinating Center, considered the determination of critical values for decision making at multiple time points during the conduct of the clinical trial from the **Neyman–Pearson** perspective [6]. Later, curtailment and stochastic curtailment methods were developed and applied to trials of the NHLBI in the 1970s and early 1980s [19, 31, 34, 37].

Statisticians working with the CDP were aware that, as the data accumulated, repeated testing for treatment differences using conventional statistical significance levels would increase the type I error (*see* **Level of a Test**) over the nominal alpha level associated with that critical value. Armitage et al. evaluated the impact of repeated testing on the type I error and demonstrated that multiple tests could increase the type I error substantially [4]. Interim analyses of clinical data are necessary for scientific and ethical reasons, but large type I errors are not acceptable. Canner developed a method for the CDP for determining the critical value at each interim analysis so that the overall type I error is close to the desired level [6]. Statisticians involved with NHLBI trials developed group sequential methods and applied them to trials starting with the CDP.

Design and Analysis. In the DHFS, it was projected that a reduction in cardiovascular risk would result from a reduction in cholesterol level. The original sample size projection was for the entry of 8000 patients into several treatment arms. Although a special review committee suggested that this sample size might be too large, Cornfield argued that there were too many inconclusive small studies already in the literature. Several aspects of the trial required consideration, including noncompliance with the treatment regimen. It was presumed that the maximum effect on risk would occur only after some period of time on treatment and that failure to adhere to the treatment regimen could mean a return to higher risk levels. Halperin et al. [33] incorporated these considerations into the design of clinical trials by proposing methods for adjusting sample size for noncompliance in the treatment group. Studies were considered with a fixed period of observation and a comparison of proportions as the main analysis. Implicit in this paper is the "**intention to treat**" principle, i.e. analysis of all randomized patients in their assigned treatment group regardless of compliance. Ultimately, the report of the CDP recognized this point [15]. Most primary and secondary **prevention trials** conducted by the NHLBI since 1970 have made use of sample size adjustments for noncompliance.

The **Framingham Heart Study** was begun in 1948 and has had an important influence on methodologic research at the NHLBI and the design of prevention trials. Over 5000 adult residents of Framingham, Massachusetts, were entered into a longitudinal study with the objective of evaluating the effects of various risk factors on the development of subsequent cardiovascular disease. The study has clarified the roles of high blood pressure, elevated total serum cholesterol, and cigarette smoking on the risk of cardiovascular disease [18, 36]. Occurrence or not of a cardiovascular event in a 2-year follow-up period is a **binary** outcome. Cornfield considered a regression approach to deal with the binary outcome variables. The problem was closely related to the discrimination problem between two samples from **multivariate normal distributions**. For a specific prior probability of belonging or not to a disease group, the posterior probability could be represented as a **logistic regression** function that was closely related to what could be obtained from a conventional **discriminant function analysis** [49]. Cornfield & Mitchell argued that one could use the logistic model to predict the impact on risk of specified changes in risk factors [12]. Subsequently, this logistic model approach was used in the design of several NHLBI prevention trials.

Longitudinal Studies. A methodology for analysis of longitudinal data was needed for the Framingham

Study which could be considered both a **cohort** and a longitudinal study. Cohorts of individuals were followed to observe patterns of morbidity and mortality, and biennial measurements of cardiovascular risk factors provided an opportunity to study patterns relating to aging. Early reports of the Framingham study used simple graphical and descriptive methods to describe patterns of aging. During the 1980s, there was much work on methodology for longitudinal studies (*see* **Longitudinal Data Analysis, Overview**) that ultimately led to NHLBI sponsorship of a workshop on methods for analysis of longitudinal and follow-up studies, whose proceedings have appeared as a special issue in ***Statistics in Medicine*** [51].

Clinical Trials, History of

Aspects of the history of **clinical trials** have been reviewed by, among others, Bull [10], Lilienfeld [49], Armitage [4], Meinert [59], and Gail [31]. In this article we survey the historical progression toward the modern clinical trial, as this method of research is practiced at the end of the twentieth century, by tracing the development of five of its requisite elements: **controls** (a comparison group), **randomization**, **blinding or masking, ethics**, and interim statistical analysis (*see* **Data and Safety Monitoring**).

Controls

The essence of the clinical trial is the control group, which provides the basis for comparing the outcomes of two or more treatments. The comparative concept of assessing therapeutic efficacy has been known from ancient times. Lilienfeld [49] cites a description of a nutritional experiment involving a control group in the Book of Daniel from the Old Testament:

> 1. In the third year of the reign of Jehoiakim king of Judah came Nebuchadnezzar king of Babylon unto Jerusalem, and besieged it. . .
> 2. And the king spoke unto Ashpenaz his chief officer, that he should bring in certain of the children of Israel, and of the seed royal, and of the nobles. . .
> 5. And the king appointed for them a daily portion of the king's food and of the wine which he drank that they should be nourished for three years. . .
> 8. But Daniel purposed in his heart that he would not defile himself with the king's food, nor with the wine which he drank; therefore he requested of the chief of the officers that he might not defile himself. . .
> 10. And, the chief of officers said unto Daniel: "I fear my lord the king who hath appointed your food and your drink; for why should he see your faces sad in comparison with the youths of your own age?". . .
> 11. Then said Daniel to the steward. . .
> 12. Try thy servants, I beseech thee, ten days; and let them give us pulse (leguminous plants) to eat and water to drink. . .
> 13. Then let our countenances be looked upon before thee, and the countenances of the youths that eat of the king's food. . .
> 14. So, he hearkened unto them and tried them in this matter, and tried them ten days. . .
> 15. And at the end of ten days their countenances appeared fairer, and they were fatter in the flesh, than all the youths that did eat of the king's food [72].

In this early example of a clinical trial, we note the presence not merely of a control group, but of a concurrent control group. These fundamental elements of clinical research did not begin to be widely practiced until the latter half of the twentieth century.

There appear to be no other recorded examples of thinking in comparative terms about the outcome of medical treatment in ancient or medieval times. Lilienfeld [49] provides an example from the fourteenth century, a letter from Petrarch to Boccaccio:

> I solemnly affirm and believe, if a hundred or a thousand of men of the same age, same temperament and habits, together with the same surroundings, were attacked at the same time by the same disease, that if one followed the prescriptions of the doctors of the variety of those practicing at the present day, and that the other half took no medicine but relied on Nature's instincts, I have no doubt as to which half would escape [78].

The Renaissance provides an example of an unplanned experiment in the treatment of battlefield wounds. The surgeon Ambroise Paré was using the standard treatment of pouring boiled oil over the wound during the battle to capture the castle of Villaine in 1537. When he ran out of oil, he resorted to the alternative of a digestive made of egg yolks, oil of roses, and turpentine. The superiority of the new treatment became evident the next day.

> I raised myself very early to visit them, when beyond my hope I found those to whom I applied the digestive medicament feeling but little pain, their wounds neither swollen nor inflamed, and having slept through the night. The others to whom I had applied the boiling oil were feverish with much pain and swelling about their wounds. Then I determined never again to burn thus so cruelly by arquebusses [63] (as cited in [10]).

An oft-cited eighteenth-century example of a planned controlled clinical trial is the ship-board experiment in which Lind found oranges and lemons to be the most effective of six dietary treatments for scurvy.

> On the 20th of *May*, 1747, I took twelve patients in the scurvy, on board the *Salisbury* at sea. Their cases were as similar as I could have them. They all in general had putrid gums, the spots and lassitude, with weakness of their knees. They lay together in one place, being a proper apartment for the sick in the fore-hold; and had one diet common to all, viz. water-gruel sweetened with sugar in the morning; fresh mutton-broth often times for dinner; at other times puddings, boiled biscuit with sugar etc. And for supper, barley and raisins, rice and currants, sago and wine, or the like. Two of these were ordered each a quart of cyder a day. Two others took twenty-five gutts of *elixir vitriol* three times a day, upon an empty stomach; using a gargle strongly acidulated with it for their mouths. Two others took two spoonfuls of vinegar three times a day, upon an empty stomach; having their gruels and their other food well acidulated with it, as also the gargle for their mouths. Two of the worst patients, with the tendons in the ham rigid (a symptom none of the rest had) were put under a course of sea-water. Of this they drank half a pint every day, and sometimes more or less as it operated, by way of gentle physic. Two others had each two oranges and one lemon given them every day. These they eat with greediness, at different times, upon an empty stomach. They continued but six days under this course, having consumed the quantity that could be spared. The two remaining patients, took the bigness of a nutmeg three times a day of an electuary recommended by a hospital-surgeon, made of garlic, mustard-feed, *rad. raphan*, balsam of *Peru*, and gum myrrh; using for common drink barley-water well acidulated with tamarinds; by a decoction of which, with the addition of *cremor tartar*, they were greatly purged three or four times during the course.
>
> The consequence was, that the most sudden and visible good effects were perceived from the use of the oranges and lemons; one of those who had taken them, being at the end of six days fit for duty. The spots were not indeed at that time quite off his body, nor his gums sound; but without any other medicine, than a gargle of *elixir vitriol*, he became quite healthy before we came into Plymouth, which was on the 16th June. The other was the best recovered of any in his condition; and being now deemed pretty well, was appointed nurse, to the rest of the sick [50] (as cited in [10, 37, 49], and [59]).

Pierre-Charles-Alexandre Louis, a nineteenth-century clinician and pathologist, introduced the "numerical method" for comparing treatments. His idea was to compare the results of treatments on groups of patients with similar degrees of disease, i.e. to compare "like with like":

> I come now to therapeutics, and suppose that you have some doubt as to the efficacy of a particular remedy: How are you to proceed?. . . You would take as many cases as possible, of as similar a description as you could find, and would count how many recovered under one mode of treatment, and how many under another; in how short a time they did so; and if the cases were in all respects alike, except in the treatment, you would have some confidence in your conclusions; and if you were fortunate enough to have a sufficient number of facts from which to deduce any general law, it would lead to your employment in practice of the method which you had seen oftenest successful [51] (as cited in [10, 49, 3], and [59]).

It remained for **Bradford Hill** more than a century later to use a formal method for creating groups of cases that were "in all respects alike, except in the treatment".

Randomization

The use of randomization as a scientific tool was a brilliant contribution by the famous statistician **Ronald A. Fisher** [22, 23]. Fisher's early applications of randomization were in agriculture. To determine which fertilizers effected the greatest crop yields, Fisher divided agricultural areas into plots, and randomly assigned the plots to experimental fertilizers. A goal of Fisher's was to obtain, through independent replications, a valid test of statistical significance (*see* **Randomization Tests**). In previous systematic designs, the fertilities of adjoining plots, to which different treatments had been applied, were not independent.

In clinical trials there were early schemes to use "**group randomization**": after dividing the patients into two groups, the treatment for each group was randomly selected. This method does not involve replication, and therefore precludes estimation of error. Armitage [3] cites a challenge based on the notion of random assignment, though not of individuals, issued as early as 1662 by the Belgian medicinal chemist van Helmont:

> Let us take out of the hospitals, out of the Camps, or from elsewhere, 200, or 500 poor People that have Fevers, Pleurisies, &c, Let us divide them into halfes, let us cast lots, that one half of them may fall to my share, and the others to yours,. . . we shall see how many funerals both of us shall have: *But* let the

> reward of the contention or wager, be 300 florens, deposited on both sides [75].

Group randomization was used by Amberson et al. in a trial of sanocrysin in the treatment of pulmonary tuberculosis published in 1931 [1].

A great step forward was the use of systematic assignment by Fibiger [21], who alternately assigned diphtheria patients to serum treatment or an untreated control group. As noted by Armitage [3], alternate assignment "would be deprecated today on the grounds that foreknowledge of the future treatment allocations may selectively bias the admission of patients into the treatment groups". Diehl et al. [18] reported in 1938 a common cold vaccine study with University of Minnesota students as subjects:

> At the beginning of each year... students were assigned at random... to a control group or an experimental group. The students in the control groups... received placebos... All students thought they were receiving vaccines... Even the physicians who saw the students... had no information as to which group they represented.

Gail [31] points out that, although on its face this appears to be the first published report of a modern randomized clinical trial, a typewritten manuscript by Diehl clarifies that this is another instance of systematic assignment:

> At the beginning of the study, students who volunteered to take these treatments were assigned alternately and without selection to control groups and experimental groups.

Hill, in the study of streptomycin in pulmonary tuberculosis [53], used random sampling numbers in assigning treatments to subjects in clinical trials, so that the subject was the unit of randomization (*see* **Medical Research Council Streptomycin Trial**). This study is now generally acknowledged to be the "first properly randomized clinical trial" [3]. It is of interest to note, as did Meier [58], that what Fisher saw important in randomization was that it made possible a valid test of significance (*see* **Hypothesis Testing**), whereas what Hill found important was the creation of comparable groups.

After the streptomycin-pulmonary tuberculosis trial, Bradford Hill and the British **Medical Research Council** continued with further randomized trials: chemotherapy of pulmonary tuberculosis in young adults [55], antihistaminic drugs in the prevention and treatment of the common cold [54], cortisone and aspirin in the treatment of early cases of rheumatoid arthritis [56, 57], and long-term anticoagulant therapy in cerebrovascular disease [39].

In the US, the **National Institutes of Health** followed the lead of the British Medical Research Council, starting in 1951 its first randomized trial [34], a National Heart Institute study of ACTH, cortisone, and aspirin in the treatment of rheumatic heart disease [68] (*see* **Clinical Trials, Early Cancer and Heart Disease**). This was followed in 1954 by a randomized trial of retrolental fibroplasia (now known as retinopathy of prematurity), sponsored by the National Institute of Neurological Diseases and Blindness [44]. In that same year, members of the US Congress asked officials of the National Cancer Institute to organize a comprehensive program for research in cancer chemotherapy, which led the next year to the development of a rapidly growing program of clinical trials under the Cancer Chemotherapy National Service Center [32]. By fiscal year 1986, the annual cost of randomized clinical trials sponsored by 10 categorical institutes of the National Institutes of Health amounted to 300 million dollars; the National Cancer Institute bore 58% of that cost [35]. During the four decades following the pioneering trials of the 1940s and 1950s, there was a large growth in the number of randomized trials not only in Britain and the US, but also in Canada and on the European continent. This growth gave impetus to the formation in the 1970s of two societies, the **International Society of Clinical Biostatistics** and the Society for Clinical Trials, and the publication of two new journals, **Controlled Clinical Trials** and **Statistics in Medicine**.

Masking

The purpose of masking, or blinding, in experiments is to prevent personal **bias** from influencing study observations. An awareness that personal bias can affect observation and judgment has existed for at least 400 years. Francis Bacon (1561–1626) noted "for what a man would like to be true, he more readily believes" [5]. Investigator bias caused a remarkable scientific delusion in the early years of the twentieth century: n-rays [76]. N-rays were "discovered" in 1902 by the eminent French physicist Blondlot, who in *Comptes rendus*, the leading French scientific journal, reported properties of

these rays that far transcended those of X-rays. According to Blondlot, n-rays were given off spontaneously by many metals, such as copper, zinc, lead, and aluminum, and when the rays fell upon the eye, they increased the eye's ability to see objects in a nearly dark room. The existence of n-rays was soon confirmed in laboratories in various parts of France, and a number of noted French scientists soon applied n-rays to research in chemistry, botany, physiology, and neurology. In 1904, *Science Abstracts* listed 77 n-ray papers. The French Academy awarded Blondlot the Lalande prize of 20 000 francs and its gold medal "for the discovery of n-rays". That same year, however, the American Physicist R.W. Wood visited Blondlot in his laboratory to test the experiments:

> He [Blondlot] first showed me a card on which some circles had been painted in luminous paint. He turned down the gas light and called my attention to their increased luminosity when the n-ray was turned on. I said that I saw no change. He said that was because my eyes were not sensitive enough, so that proved nothing. I asked him if I could move an opaque lead screen in and out of the path of the rays while he called out the fluctuations of the screen. He was almost 100 percent wrong and called out fluctuations when I made no movement at all, and that proved a lot, but I held my tongue. He then showed me the dimly lighted clock, and tried to convince me that I could see the hands when he held a large flat file just above his eyes. I asked if I could hold the file, for I had noticed a flat wooden ruler on his desk, and remembered that wood was one of the substances that *never* emitted n-rays. He agreed to this, and I felt around for the ruler and held it in front of his face. Oh, yes, he could see the hands perfectly. This also proved something [70, 76].

After Wood published his account, n-ray publications diminished in number. *Science Abstracts* listed only eight n-ray papers in 1905, and none in 1909. The French Academy changed its announced reason for the award to Blondlot "for his life work taken as a whole". According to Seabrook [70], the exposure of the blunder led to Blondlot's madness and death.

A masked experiment by the Austrian physicist Pozdena contributed to the disproof of the existence of n-rays. At haphazard intervals Pozdena's assistant soundlessly operated a shutter which in its closed position blocked the transmission of the hypothetical n-rays. During a pretest, the assistant wrote "o" for *offen* (open) and "g" for *geschlossen* (closed) while Pozdena indicated when he could detect increased luminosity. Whereas the shutter's movements were silent, the assistant's pencil scratches were not. Pozdena was able to hear the difference between an "o" and a "g". In the definitive experiment the assistant switched to a coded notation, and in 150 trials Pozdena reported increased luminosity about as often when the shutter was open as when it was closed [67].

The common cold vaccine study published by Diehl et al. [18] in 1938 cited earlier, in which University of Minnesota students were alternately assigned to vaccine or placebo, was a masked clinical trial.

> The students in the control groups . . . received placebos . . . All students thought they were receiving vaccines . . . Even the physicians who saw the students . . . had no information as to which group they represented.

Masking was used in the early Medical Research Council trials in which Bradford Hill was involved. Thus, in the first of those trials, the study of streptomycin in tuberculosis, the X-ray films were

> viewed by two radiologists and a clinician, each reading the films independently and not knowing if the films were of C [bed-rest alone] or S [streptomycin and bed-rest] cases [53].

Hill's lesson from the experience:

> If it [the clinical assessment of the patient's progress and of the severity of the illness] is to be used effectively, without fear and without reproach, the judgments must be made without any possibility of bias, without any overcompensation for any possible bias, and without any possible accusation of bias [37].

In the second trial, the antihistamine–common cold study [54], placebos ("dummies indistinguishable" from the drug under test) were used. Hill's lesson:

> . . .in [this] trial. . ., feelings may well run high in the bosom (or should I say the mucosa?) either of the recipient of the drug or the clinical observer, or indeed of both. If either were allowed to know the treatment that had been given, I believe that few of us would without qualms accept that the drug was of value – if such a result came out of the trial [37].

The terms "blind" and "double-blind" have been used commonly in clinical trials, the latter indicating

that neither the doctor nor the patient knows what treatment the patient is getting. When these terms were recognized as being awkward in trials of eye disease, the terms "masking" and "double-masking" were introduced [19].

Ethics

Medical Research Abuses

Experimentation in medicine is as old as medicine itself, and since antiquity some experiments on humans have been conducted without concern for the welfare of the subjects, who were often prisoners or disadvantaged people [52]. Thus, in the flourishing days of intellectual and scientific achievement in ancient Alexandria, anatomists used criminals for dissection alive [6]. Katz [42] provides examples of 19th century studies in Russia and Ireland of the consequences of infecting persons with syphilis and gonorrhea. During the same time, in the US,

> physicians put slaves into pit ovens to study heat stroke, and poured scalding water over them as an experimental cure for typhoid fever. One slave had two fingers amputated in a "controlled trial", one finger with anesthesia and one finger without, to test the effectiveness of anesthesia [52].

Unethical experiments on human beings have continued into the twentieth century [7, 24, 52]. In 1932 the US Public Health Service began a study in Tuskegee, Alabama, of the natural progression of untreated syphilis in 400 black men. The study continued until 1972, when a newspaper reported that the subjects were uninformed or misinformed about the purpose of the study. Participants were told that painful lumbar punctures were given as treatment, when in fact treatment for syphilis was withheld even after penicillin became available [24].

During the Nazi regime, 1933–1945, German doctors conducted sadistic medical experiments, mainly on Jews, but also on Gypsies, mentally disabled persons, Russian prisoners of war, and Polish concentration camp inmates:

> The "experiments" were quite varied. Prisoners were placed in pressure chambers and subjected to high-altitude tests until they stopped breathing. They were injected with lethal doses of typhus and jaundice. They were subjected to "freezing" experiments in icy water or exposed naked in the snow outdoors until they froze to death. Poison bullets were tried out on them as was mustard gas... [71].

Codes of Ethics, Informed Consent

The fact that in 1931, two years before the Nazis acceded to power, Germany had enacted "Richtlinien" (regulations) to control human experiments adds irony to the German doctors' cruel abuse and exploitation of human subjects.

> Issued by the Reich's Health Department, these regulations remained binding law throughout the period of the Third Reich. Consent requirements formed two of fourteen major provisions in the guidelines, one dealing with "New Therapy" and the other with "Human Experimentation". It was demanded that in both cases consent (first party or proxy consent, as appropriate) must always be given "in a clear and undebatable manner" [20].

The Nazi doctors were tried for their atrocities by the Allied Forces in 1946–1947 at Nuremberg. Three US judges at the trial promulgated the Nuremberg Code [47], the first international effort to codify ethical principles of clinical research. Principle 1 of the Nuremberg Code states:

> The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, over-reaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision [74] (cited in [47, Appendix 3]).

Other principles of the Code are that the experiment should yield results for the good of society, that unnecessary suffering and injury should be avoided, and that the subject should be free to end the experiment.

Informed consent (*see* **Ethics of Randomized Trials**) was used by Walter Reed in his studies of yellow fever at the turn of the twentieth century [6, 69]. Mosquitoes were known to be involved in the transmission of the disease, but their precise role was not clear. To clarify the mode of transmission, members of Reed's research team had themselves been bitten by mosquitoes. After a fellow worker died of yellow fever from a purposeful bite, Reed

recruited American servicemen and Spanish workers for the experiments, and drew up a contract with the Spanish workers:

> The undersigned understands perfectly well that in the case of the development of yellow fever in him, that he endangers his life to a certain extent but it being entirely impossible to avoid the infection during his stay on this island he prefers to take the chance of contracting it intentionally in the belief that he will receive... the greatest care and most skillful medical service [6, 69].

The contract specified that volunteers would each receive $100 in gold, and a $100 bonus if they contracted yellow fever. In the event 25 volunteers became ill, but none died.

In addition to Reed, other early advocates of informed consent were Charles Francis Withington and William Osler. Withington, noting in 1886 the "possible conflict between the interests of medical science and those of the individual patient", sided with "the latter's indefensible rights" [77]. Osler in 1907 insisted on informed consent in medical experiments: "For man absolute safety and full consent are the conditions which make such tests allowable" [62]. Despite this early advocacy, and despite the promulgation of the 1931 German doctors' code and the 1946–1947 Nuremberg Code, the application of informed consent to medical experiments did not take foothold during the first six decades of the twentieth century. Bradford Hill [38], based on his experience in a number of early randomized clinical trials sponsored by the Medical Research Council, believed that it was not feasible to draw up a detailed code of ethics for clinical trials that would cover the variety of ethical issues that came up in these studies, and that the patient's consent was not warranted in all clinical trials. Although the judges at Nuremberg evidently intended the Code to apply not only to the case before them, but "for the practice of human experimentation wherever it is conducted" [43], European and American clinical investigators were slow to adopt it [7]. Gradually the medical community came to recognize the need to protect the reputation and integrity of medical research. In 1955 a human experimentation code was adopted by the Public Health Council in the Netherlands [60], cited in [15], and in 1964 the World Medical Association issued the Declaration of Helsinki [47], essentially adopting the ethical principles of the Nuremberg Code, with consent "a central requirement of ethical research" [20].

Justification to Begin

The view of Bradford Hill [38] was that in starting a randomized clinical trial the doctor accepts that "he really has no knowledge that one treatment [in the trial] will be better or worse [than the other treatments]". This state of uncertainty, which has come to be known as "equipoise" [28], has remained the ethical standard for starting a randomized clinical trial. For completeness, Levine [47] has added the proviso that there must not be a treatment, other than those to be studied in the trial, that is known to be superior to the study treatments.

Peer Review

One can trace back to 1803 the notion that therapeutic innovation must be preceded by peer review:

> And no such trials [of new remedies and new methods of chirurgical treatment] should be instituted, without a previous consultation of the physicians or surgeons ... [64] (cited in [47]).

According to Levine [47], "not much more was said about peer review for about 150 years".

Research ethics committees, the US history of which is traced by McNeill [52] and Levine [48], came into being in the US in the 1950s. The 1946–1947 Nuremberg Code and the 1964 Declaration of Helsinki do not mention committee review. A requirement for such review was imposed in 1953 at the newly established Clinical Center at the National Institutes of Health, and peer review of clinical research was also practiced at some US medical schools in the 1950s. By the early 1960s, one-third of US university medical schools responding to a survey had established research ethics committees. Public outrage at highly publicized research abuses, such as those published by Beecher [7], or those committed in the Tuskegee syphilis study, gave impetus to the adoption of requirements for informed consent and peer review in research on human beings in the US [52]. In 1966 the US Public Health Service issued a policy requiring recipients of Public Health Service research grants to provide for prior committee review of studies involving human subjects to ensure that the study plans conform to ethical standards. Because the Public Health Service was then (and still is) sponsoring a large majority of medical research in the US, research ethics committees were established at

medical schools throughout the US soon after 1966. National recommendations, guidelines, or regulations for the establishment of research ethics committees in other countries soon followed: Canada in 1966, the UK in 1967, Australia in 1973, New Zealand in 1975, and Ireland in 1987 [52].

Data Monitoring by Peers

In the modern randomized clinical trial, the accumulating data are usually monitored for safety and efficacy by an independent *data monitoring committee* – also called *data and safety monitoring committee*, or **data and safety monitoring board**. In 1968 the first such committee was established, serving the Coronary Drug Project, a large multicenter trial sponsored in the United States by the National Heart Institute of the National Institutes of Health [11, 29]. The organization of the Coronary Drug Project included a policy board – a senior advisory group made up of five scientists who were not otherwise participating in the study. In 1967, after a presentation of interim outcome data by the study leadership to all participating investigators of the Coronary Drug Project, **Thomas Chalmers** addressed a letter to the policy board chairman expressing concern:

> that knowledge by the investigators of early nonstatistically significant trends in mortality, morbidity, or incidence of side effects might result in some investigators – desirous of treating their patients in the best possible manner, that is, with the drug that is ahead – pulling out of the study or unblinding the treatment groups prematurely [11].

In 1968 a data and safety monitoring committee was established for the Coronary Drug Project (apparently by the policy board) consisting of scientists who were not contributing data to the study, and thereafter the practice of sharing accumulating outcome data with the study's investigators was discontinued. The data safety and monitoring committee assumed responsibility for deciding when the accumulating data warranted changing the study treatment protocol or terminating the study (*see* **Data and Safety Monitoring**).

In 1971, for the first randomized clinical trial it sponsored, the recently established National Eye Institute of the US National Institutes of Health adopted the model of the Coronary Drug Project by including in its organization a policy board and data monitoring committee; the trial was the multicenter Diabetic Retinopathy Study [17]. In this study, as in the Coronary Drug Project, the accumulating outcome data were not shared with data-contributing investigators.

In subsequent trials sponsored by the National Heart Institute (later named National Heart, Lung, and Blood Institute) and the National Eye Institute the functions of the policy board and data and safety monitoring committee were combined in a single data monitoring committee. The example set by the Coronary Drug Project and the Diabetic Retinopathy Study established a pattern for monitoring interim clinical trials data by an independent committee that was gradually adopted by many trials in North America and Europe.

Interim Analysis

In the conduct of the modern randomized clinical trial, the ethical requirement for interim analysis of study outcomes is widely recognized, and the responsibility for such analysis is commonly delegated to an independent data monitoring committee. Bradford Hill does not mention interim analysis in his extensive writings about the clinical trials he worked on during the late 1940s and 1950s [37].

The first formal recognition of the need for interim analyses, and that such analyses affect the probability of the type I error (*see* **Hypothesis Testing**), came with the publication in the 1950s of papers on sequential clinical trials by Bross [9] and Armitage [2] (*see* **Sequential Analysis**). In sequential trials of two treatments, patients are enrolled in pairs, with members of each pair randomly assigned to one or the other treatment. The data are analyzed each time that both members of a pair reach an endpoint (e.g. treatment failure). The overall probability of the type I error is controlled at a predetermined level. The principal advantage of a sequential trial over a fixed-sample-size trial, apart from that of correcting the significance level for repeated data analyses, is that when the length of time needed to reach an endpoint is short, e.g. weeks or months, the sample size required to detect a substantial benefit from one of the treatments is less. Applications of sequential trials have been limited because when follow-up is long-term, as is required by most trials, the sequential design is less effective.

In the 1960s **Cornfield** argued that data analysis in clinical trials, because it is often marked by unforeseen developments, does not lend itself well to predetermined stopping rules [13, 16]. For the dilemma of repeated interim analyses of the accumulating data, and to address the issue of **multiplicity in clinical trials** in general, he proposed use of the **likelihood ratio**. In particular, he proposed a **Bayesian** solution in the form of "relative betting odds" [12] – a method that was applied alongside conventional frequentist methods in two trials [14, 73].

In the 1970s and 1980s frequentist solutions to interim analysis came about in the form of "group sequential trials" and "stochastic curtailment" [4, 30, 66]. In the group sequential trial, an analogue of the classical sequential trial [2, 9], the frequency of interim analysis is usually limited to a small number, say, between 3 and 6, while the overall type I error probability is controlled at a predetermined level. Pocock's boundaries use constant nominal significance levels for the individual tests; the Haybittle–Peto boundary [36, 65] uses stringent significance levels, except for the final test; in the O'Brien–Fleming boundary, stringency gradually decreases [61]; in the model by Lan & DeMets [45], the total type I error probability is gradually spent in a manner that does not require the timing of analyses be prespecified; there have also been proposals for methods of repeated **confidence intervals** [40]. Whereas group sequential designs are used to determine whether a trial should be stopped early because a treatment is efficacious, stochastic curtailment, which involves prediction of future events, is invoked when it appears that a treatment is unlikely to be shown to be efficacious even if the trial is continued to its planned conclusion [46]. Both group sequential methods and stochastic curtailment have been frequently applied to trials in the 1980s and 1990s.

Despite a renewed interest in Bayesian clinical trials since the 1980s [8, 25, 26, 33, 41], there have been few applications. Freedman et al. [27] provide an overview of Bayesian approaches to interim analysis, including a Bayesian analogue to stochastic curtailment.

FRED EDERER

Clinical Trials, Overview

Trial is from the Anglo–French *trier*, meaning *to try*. Broadly, it refers to the action or process of putting something to a test or proof. *Clinical* is from *clinic*, from the French *cliniqué* and from the Greek *klinike*, and refers to the practice of caring for the sick at the bedside. Hence, narrowly, a *clinical trial* is the action or process of putting something to a test or proof at the bedside of the sick. However, broadly it refers to any testing done on human beings for the sake of determining the value of a treatment for the sick or for preventing disease or sickness.

The broad definition of clinical trial includes definitions allowing for use of the term in references to studies involving a single treatment (e.g. as in most **phase I trials** and some **phase II drug trials**) and for studies involving use of an external **control** (e.g. studies involving historical controls) [66]. However, use herein will be in the stricter sense of usage; that is, to refer to trials involving two or more treatment groups comprised of persons enrolled, treated, and followed over the exact same time frame.

The *treatment* can be anything considered to hold promise in caring for the sick, in the prevention of disease, or in the maintenance of health. The term, in the context of a trial, refers to the experimental variable – the variable manipulated by the trialist. The variable may have just two states (e.g. as in a trial involving a single test treatment and single control treatment) or three or more states (e.g. as in a trial involving several different test treatments and one or more control treatments). The variable, in the case of drug trials, may serve to designate different drugs, different doses of the same drug, or different forms or routes of administration of the same drug. In other contexts, it may variously refer to different kinds or forms of surgery, different kinds or forms of care or management regimens, different kinds or forms of diagnostic tests, different kinds or forms of medical devices, different kinds or forms of counseling regimens to achieve some desired end, or combinations of the above.

The clinical trial, in its simplest form, involves the application of the experimental variable – treatment to a person or group of persons – and observation during or following application of the treatment to measure its effect. That measure **(outcome measure)** may be death, occurrence or recurrence of some morbid condition, or a difference indicative of change (e.g. difference in blood pressure measured for each person just prior to the start of treatment and again at some point during or after treatment).

There is no way to "test" a treatment or to "prove" its effectiveness in the absence of some absolute or relative measure of success. Trials are said to be *controlled* if the effect of a treatment is measured against a comparison treatment administered over the same time period and under similar conditions. That comparison treatment may be another test treatment or, depending on circumstances, a *control treatment* consisting of an accepted standard form of therapy, a placebo (*see* **Blinding or Masking**) or sham treatment, or observation only (no treatment).

A trial is said to be *uncontrolled* if it does not have a comparison treatment or if the enrollment to and administration of the test and comparison treatments is not concurrent (e.g. as with use of *historical controls* for evaluation of a treatment). The Book of Daniel (Chapter 1, verses 12–15) provides an account of what amounts to an uncontrolled trial involving a diet of pulse – edible seeds of certain pod-bearing plants, such as peas and beans (*see* **Clinical Trials, History of**).

> Prove thy servants, I beseech thee, ten days; and let them give us pulse to eat, and water to drink. Then let our countenances be looked upon before thee, and the countenance of the children that eat of the portion of the King's meat: and as thou seest, deal with thy servants. So he consented to them in this matter, and proved them ten days. And at the end of ten days their countenances appeared fairer and fatter in flesh than all the children which did eat the portion of the King's meat [1].

Fortuitous events can produce conditions reminiscent of the features of a trial. One such account is that given by Ambroise Paré (surgeon, 1510–1590) during the battle in 1537 for the castle of Villaine. The treatment for gunshot wounds in Paré's time was boiling oil poured over the wound. Because of the intensity of the battle, Paré ran out of oil and resorted to using an ointment made of egg yolks, oil of roses, and turpentine. The result of his "trial" is summarized by his observation the morning after the battle:

> I raised myself very early to visit them, when beyond my hope I found those to whom I had applied the digestive medicament, feeling but little pain, their wounds neither swollen nor inflamed, and having slept through the night. The others to whom I had

> applied the boiling oil were feverish with much pain and swelling about their wounds. Then I determined never again to burn thus so cruelly the poor wounded by arquebuses [72].

Many of the essential elements of the modern day *controlled trial* are contained in Lind's account of a trial performed aboard the *Salisbury* at sea in 1747:

> On the 20th of May 1747, I took twelve patients in the scurvy, on board the *Salisbury* at sea. Their cases were as similar as I could have them. They all in general had putrid gums, the spots and lassitude, with weakness of their knees. They lay together in one place, being a proper apartment for the sick in the fore-hold; and had one diet common to all, viz., watergruel sweetened with sugar in the morning; fresh mutton-broth often times for dinner; at other times puddings, boiled biscuit with sugar, etc; and for supper, barley and raisins, rice and current, sago and wine, or the like. Two of these were ordered each a quart of cyder a day. Two others took twenty-five gutts of elixir vitriol three times a day, upon an empty stomach; using a gargle strongly acidulated with it for their mouths. Two others took two spoonfuls of vinegar three times a day, upon an empty stomach; having their gruels and their other food well acidulated with it, as also the gargle for their mouth. Two of the worst patients, with the tendons in the ham rigid, (a symptom none of the rest had), were put under a course of seawater. Of this they drank half a pint every day, and sometimes more or less as it operated, by way of gentle physic. Two others had each two oranges and one lemon given them every day. These they eat with greediness, at different times, upon an empty stomach. They continued but six days under this course, having consumed the quantity that could be spared. The two remaining patients, took the bigness of a nutmeg three times a-day, of an electuary recommended by an hospital surgeon, made of garlic, mustard-seed, rad raphan, balsam of Peru, and gum myrrh; using for common drink, barley-water well acidulated with tamarinds; by a decoction of which, with the addition of cremor tartar, they were gently purged three or four times during the course. ... the most sudden and visible good effects were perceived from the use of oranges and lemons, one of those who had taken them being at the end of six days fit for duty [62].

The Treatment Protocol

The treatment protocol (the general term, *study protocol* or *trial protocol* (*see* **Clinical Trials Protocols**) has broader meaning and refers to the constellation of activities involved in conducting a trial) of the trial specifies the treatments being studied, the manner and method of usage and administration, and conditions under which other treatments are called for when needed for the well-being of those enrolled. The treatment may be administrated in one application or multiple applications. The period of treatment may be short (e.g. as in trials involving a single application of treatment such as surgery) or extended (e.g. as in trials involving the treatment of a chronic condition with drugs) over a period of weeks, months, or years. The treatment, in the case of drug trials, may involve a fixed dose administered according to some schedule or dose titration in which each person ultimately receives the amount needed to achieve a desired effect (e.g. the amount of a hypoglycemic agent needed to bring blood glucose levels to within the normal range).

Protocols for all research involving human beings are subject to review and approval by institutional review boards (IRBs) or ethics review boards (ERBs) before implementation and at periodic intervals thereafter until the research is finished (*see* **Ethics of Randomized Trials**). Therefore, investigators undertaking trials have the obligation and responsibility to obtain IRB or ERB review and approval prior to initiation of a trial, and to seek its review and approval prior to implementing amendments to the protocol of the trial. They also have a responsibility to inform IRBs and ERBs of record of any untoward events in the conduct of the trial and to report to such boards any conditions or events believed to change the risk–benefit ratio for persons enrolled into the trial or still to be enrolled.

Only patients judged eligible (as determined by specified **eligibility criteria**) may be enrolled, and among those, only those who consent to participate in the trial. Persons are under no obligation to enroll or to continue once enrolled, and must be so informed prior to being enrolled. A person must be informed, as well, of what is entailed by enrollment, of the risks and benefits that may accrue by enrollment, and of such matters and details that might cause a reasonable person to decline enrollment when so informed (e.g. that treatments are randomly assigned and that they will be administered in masked fashion).

All trials involve data collection at various time points over the course of enrollment and follow-up of persons. The amount collected per person depends on the nature of the disease or condition being treated

and on the nature of the treatment process implied by the study treatments being used. The requirement for repeated observation of a person, as a rule (except for trials done in hospital or other settings involving resident populations or in which enrollment, follow-up, and treatment is directed or managed by telephone or mail), obligates a person to a series of visits to the study site. Usually, the purpose of the first visit or series of visits will be to determine eligibility, collect necessary baseline data, obtain consent, and initiate treatment. Visits thereafter will be to fine-tune or continue treatment and to collect necessary follow-up data. The schedule of follow-up visits will be timed from the point of **randomization** or initiation of treatment and, as a rule, will be on a defined time schedule (e.g. once every week) with provisions for interim (unscheduled) visits when necessary for the care of those enrolled.

Comparison of the different treatments tested for effect is done in different ways depending on the outcome measures used to assess effect. The comparison, in the case of an event, such as death or occurrence of a morbid event, will be based on the event rate (or the raw percentage of persons experiencing the event) as seen for the different treatment groups. In the case of a continuous variable, such as weight or blood pressure, the change from entry to some defined point after enrollment will be determined for each person studied and then summarized in some fashion (e.g. by calculating a **mean** or **median**). The treatment effect will be estimated by the difference obtained by subtracting the summary measure for the comparison treatment from the indicated test treatment.

Judging the safety or efficacy of a treatment is problematic in trials not involving a designed comparison group – often the case in Phase I, II, and I/II trials (see below for definitions). The problem is compounded by the typically short duration and small size of these trials. The problem is most acute in the testing of drugs in people having a life-threatening disease when the drugs themselves carry their own morbidity and increased risk of death. Are the morbid events observed the result of the disease or the drug? Even deaths become difficult to interpret in the presence of a high background death rate from the disease. Was a death the natural outcome of the disease, or was it induced by the treatment? The issue is rarely clear until sufficient information has accumulated to cause one to discount natural causes as the likely explanation, or to allow one to recognize an unusual **clustering** of deaths and morbid events, as with the case of a trial of fialuridine (FIAU) [63].

Classes of Trials

Most clinical trials involve *parallel treatment designs*, i.e. designs where an assignment unit (usually a person) is assigned to receive only one of the treatments under study. The word *parallel* indicates that two or more groups of assignment units are proceeding through the trial side by side, with the only ostensible difference (other than baseline differences in the composition of the groups) being the treatment administered. The goal in trials with parallel treatment designs is for each person enrolled to receive the assigned treatment and to have no exposure to any of the other treatments under study in the trial (except where the requirements for proper care are overriding and make such exposure necessary).

The assignment unit (randomization unit in randomized trials), in the case of parallel treatment designs, is usually a person but can be an aggregate of persons (e.g. members of the same household) (*see* **Group-randomization Designs**) or a subpart of a person (e.g. an eye, as in the Glaucoma Laser Trial [34] (*see* **Unit of Analysis**).

The treatment design in **crossover trials** is different. In this class of designs a person or treatment unit receives two or more study treatments in a specified order. Crossover trials are classified by the number of treatments to be administered to a person or treatment unit and by whether a given person or treatment unit receives all (complete or full crossover) or just some (partial or incomplete crossover) of the study treatments. For example, a two-period crossover design is one in which each person or treatment unit receives two study treatments in some order, usually random. An n-way crossover design is one in which a person or treatment unit receives n of the treatments represented in the design.

The utility of crossover designs is limited to settings in which it is feasible to administer different treatments to the same person or treatment unit, each for a short period of time, and in which it is possible to measure the effect at the end of each treatment period. They are not useful in settings in which the outcome of interest is a clinical event that can occur at any time after enrollment.

In a trial with a parallel treatment design, assignment determines the treatment to be administered

(except to the extent that other treatments are needed for proper care) whereas, in a crossover trial, assignment determines the order of treatments to be used. Typically, each treatment is administered for a designated period of time (e.g. 4 weeks). Often the last administration of one treatment and the first administration of the next treatment are separated in time (e.g. 1 week) to allow the effect of the preceding treatment to "wear off" ("washout period") before administering the next treatment.

Imagine a trial involving three study treatments (A, B, and C) with the same (uniform) assignment probabilities and 54 people. In a trial with a parallel treatment design, 18 people would be assigned to receive treatment A, 18 would be assigned to receive treatment B, and 18 would be assigned to receive treatment C. In a trial involving a complete (full) crossover of treatments, each of the 54 people would receive treatments A,B, and C. Assuming treatments are arranged in all possible orderings, there would be six different orderings of the treatments (ABC, ACB, BAC, BCA, CAB, and CBA), and nine patients would be randomly assigned to receive a given ordering.

While the goal of the two designs is the same, to find the most effective treatment, the methodology differs. With the parallel treatment design, the treatment is evaluated in comparable groups of treatment units (usually persons), and with the crossover treatment design, the treatment effect is evaluated within the same treatment unit (usually a person).

Trials involving parallel treatment designs are of two general types with regard to sample size design – fixed or sequential. The majority are of the fixed type. That is, the sample size is specified at the outset, as determined by pragmatic considerations (e.g. by the amount of money available for the trial) or by a formal **sample size calculation**. Trials are considered to have a fixed sample size even if they do not proceed to the desired sample size, e.g. are stopped early because of a treatment difference. The sample size is fixed in the sense that the intent is to enroll and follow the specified number of assignment units unless indicated otherwise by events transpiring during the course of the trial.

In sequential trials (also of two types – open and closed), enrollment and observation continue until a stopping boundary, constructed for the outcome of primary interest (usually a **binary** "success" or "failure" type event), is crossed. Open sequential designs involve two boundaries, one indicative of superiority and the other indicative of inferiority of a test treatment relative to a comparison treatment. Enrollment continues until the observation function for the outcome measure of interest crosses one of the two boundaries. The design has the advantage of providing a test of the **null treatment hypothesis** for given type I and II error levels (*see* **Hypothesis Testing**) that, on average, requires a smaller sample size than that for a fixed sample size design.

However, the actual sample size required for a boundary crossing can be larger (in theory, sometimes much larger) than that for a fixed sample size design. The possibility of the final sample size being much larger is ruled out with the closed sequential design. That design, in addition to the two boundaries mentioned above, involves a third boundary serving to place an upper bound on enrollment. If that boundary is crossed, because neither of the other two boundaries is crossed (signifying a difference in favor of one of the treatments), then the treatments being compared are considered to be of equivalent value as measured by the outcome observation function (*see* **Sequential Analysis**).

Sequential designs have limited utility in the context of clinical trials, partly because they require rigid adherence to a stopping rule. Use is limited to instances where the "success" or "failure" of a treatment can be determined shortly after administration. They are not useful in settings involving long-term treatment and with outcome measures requiring weeks, months, or years of observation. In general, more flexible methods of monitoring trials are more appropriate (*see* **Data and Safety Monitoring**).

Drug Trials

Compounds, no matter how promising or impassioned the pleas for use, have to go through a series of tests in animals before they can be tested in humans. Those considered to lack promise after animal testing do not come to testing in humans.

Typically, the testing in humans is done in a time-ordered sequence, as suggested by the phase label affixed to trials as defined below. However, in truth, adjoining phases overlap in purpose. Hence, the label, at best, serves only as a rough indicator of the stage of testing, especially when, as is often the case, drug sponsors, at any given point in time, may have several

trials under way carrying different phase labels. The definitions of the different phase labels follow:

Phase I: Usually the first stage of testing performed in anticipation of an Investigational New Drug Application (INDA or NDA); done to generate preliminary information on the chemical action and safety of the indicated drug and to find a safe dose; usually not randomized.

Phase II: Usually the second stage of testing; generally carried out on persons having the disease or condition of interest; done to provide preliminary information on efficacy of the drug and additional information on safety; may be designed to include a control treatment and random assignment of patients to treatment.

Phase I/II: A trial having some of the features of Phase I and II trials; designed to provide preliminary information on safety and efficacy.

Phase III: Usually the third and final stage in testing, prior to submission of an NDA; concerned with assessment of dosage effects, efficacy, and safety; usually designed to include a control treatment and random assignment to treatment. When the test is completed (or nearly completed), the drug manufacturer or sponsor may request permission to market the drug for the indication covered in the testing by submission of an NDA.

Phase II/III: A trial having some of the features of phase II and III trials; designed to provide information on safety and efficacy.

Phase IV: A fourth stage of testing, sometimes carried out. Usually controlled and performed after approval of the NDA. Typically done under circumstances approximating real-world conditions; usually has a clinical event as a basis for sample-size calculation and provides for extended treatment (where appropriate) and long-term follow-up, with efficacy and safety of the drug being measured against a control treatment.

Drugs, after marketing approval, remain under surveillance for serious adverse effects. The surveillance – broadly referred to as **postmarketing surveillance** – involves the collection of reports of adverse events via systematic reporting schemes and via sample surveys and **observational studies**.

Sample size tends to increase with the phase of the trial. Phase I and II trials are likely to have sample sizes in the 10s or low 100s compared to 100s or 1000s for Phase III and IV trials.

The focus shifts with phase. The aim in the early phases of testing is to determine whether the drug is safe enough to justify further testing in human beings. The emphasis is on determining the toxicity profile of the drug and on finding a proper, therapeutically effective dose for use in subsequent testing. The first trials, as a rule, are uncontrolled (i.e. do not involve a concurrently observed, randomized, control-treated group), of short duration (i.e. the period of treatment and follow-up is short), and conducted to find a suitable dose (usually via some traditional or **Bayesian** dose escalation design) for use in subsequent phases of testing. Trials in the later phases of testing, for the most part, involve traditional parallel treatment designs, randomization of patients to study treatments, a period of treatment typical for the condition being treated, and a period of follow-up extending over the period of treatment and beyond.

Most drug trials are done under an investigational new drug application (INDA or IND) held by the sponsor of the drug. The "sponsor" in the vernacular of the **Food and Drug Administration (FDA)** is typically a drug company, but can be a person or agency without "sponsorship" interests in the drug. Regulations require investigators to report adverse events to the FDA. The general guidelines regarding consent are similar, but not identical, to those promulgated by the Office for the Protection from Research Risks (OPRR) for IRBs.

The Randomized Trial

A *randomized trial* is a trial having a parallel treatment design in which treatment assignment for persons (treatment units) enrolled is determined by a

randomization process similar to coin flips or tossings of a die (*see* **Randomized Treatment Assignment**). The trialist's purpose in randomization is to avoid **selection bias** in the formation of the treatment groups. The bias is avoided because the treatment to which a person is assigned is determined by a process not subject to control or influence of the person being enrolled or those responsible for recruiting and enrolling the person. The comparison of one group to another for treatment effect will be biased if, for whatever the reason, one group is "healthier" or "sicker" on entry than the other. Schemes in which one knows or can predict treatment assignments in advance of issue are open to such bias. Clearly, that is the case with assignment schemes posted in a clinic and open for all to see prior to issue. The bias is likely as well with systematic schemes, such as those in which every other person is assigned to the test treatment or in which persons seen on odd-numbered days receive the test treatment and those seen on even-numbered days receive the control treatment.

The goal is to create groups that provide a valid basis for comparison. To achieve that end one has to ensure that the groups are similar (within the range of chance) and to avoid bias in the assignment process. The usual method for achieving both ends is randomization.

Randomization does not guarantee comparability of the treatment groups with regard to the various entry characteristics of interest. Indeed, one can, by chance, have differences among the treatment groups. A large difference (one yielding a small ***P* value**) can arise by chance and, hence, cannot be taken as prima facie evidence of a "breakdown" (e.g. "peeking" or other purposeful acts aimed at determining assignment before issue) of the randomization process, unless supported by other evidence of a "breakdown".

The hallmarks of a sound system of randomization are: reproducible order of assignment; documentation of methods for generation and administration of assignments; release of assignments only after essential conditions satisfied (e.g. only after a person has been judged eligible and has consented to enrollment); masking of assignments to all concerned until needed; inability to predict future assignments from past assignments; clear audit trail for assignments; and the ability to detect departures from established procedures [67] (*see* **Clinical Trials Audit and Quality Control**).

The randomization may be simple (complete) or restricted. The purpose of restriction is to force the assignments to satisfy the specified assignment ratio at intervals during enrollment. Those restrictions are typically referred to as **blocking**. For example, suppose a trial involves two treatments, A and B, and the desired assignment ratio is one-to-one. A simple (unrestricted) randomization scheme would involve the equivalent of repeated flips of an unbiased coin with a head leading to assignment to treatment A and a tail to treatment B. The design would, on average, yield the desired assignment ratio, but allows for wide departures from the desired mix, depending on the "luck" of the flips.

If such departures are of concern, then the randomization scheme can be restricted by blocking so as to ensure the desired mix after a specified number of assignments. For example, imposition of a blocking requirement after every eighth assignment would have the effect of "forcing" the randomization to yield the desired mix of one-to-one after every eighth assignment. The purpose of the blocking is to ensure a near desired assignment ratio so as to protect treatment comparisons against secular trends in the mix of patients as the trial proceeds.

The randomization also may be stratified. The purpose of **stratification** is to provide treatment groups comprised of persons or treatment units having identical (within the limits of the stratification) distributions of the stratification variable. It is useful only in so far as the variable used for stratification serves to influence or moderate the outcome of interest. The stratification has the effect of "controlling" the influence of the stratification variable on outcome by ensuring the same distribution of the variable across the different treatment groups. For example, suppose one wishes to stratify on gender in the trial described above (because, perhaps, of a belief that the treatment effect will be different in women than in men). The stratification would be achieved by creating two randomizations schedules, each with a one-to-one assignment ratio and with blocking to satisfy the assignment ratio after enrollment of the 8th, 16th, 24th, etc. person in each stratum. The effect of the stratification would be to ensure the same gender mix (within the limits of the blocking) for the two treatment groups, regardless of the underlying gender mix of the population to be studied. For example, suppose 96 patients are to be enrolled from a population with a 1:2 mix of males to females. In that case, one would

expect to enroll 32 males and 64 females, and to have 16 males and 32 females in each treatment group. If the underlying mix is one-to-one, then there would be 24 males and 24 females in each of the two treatment groups.

Clearly, the number of variables that can be controlled by stratification is limited. The more variables, the more subgroups for randomization and the less useful the process is as a reliable means of **variance** control [35]. In addition, there are logistic difficulties associated with use of variables whose values have to be determined by performing laboratory tests or other diagnostic procedures during the enrollment process. Even if one stratifies on a few selected variables, other variables may well be considered to be important determinants of outcome. Hence, the experienced trialist strives to "remove" the effect of such differences via analysis procedures, e.g. by assessing the treatment effect within defined subgroups (subgroup analysis, *see* **Treatment-covariate Interaction**); or by providing estimates of treatment effect that are adjusted for differences in the distribution of important demographic or baseline variables via **regression** procedures [90].

Masking

Masking is the purposeful concealment of some fact or condition and is done to keep knowledge of that fact or condition from influencing the behavior, observation, or reporting of persons so masked. Masking, in the context of trials, is imposed to reduce the likelihood of a treatment-related bias due to knowledge of treatment assignment (*see* **Blinding or Masking**).

That bias, after a person is enrolled, occurs whenever knowledge of that person's treatment assignment serves to color the way he or she is treated, followed, or observed. One way of reducing it is by masked treatment administration. In one form of such administration (single-masked), only one member of the subject–treater pair is masked to treatment, usually the subject. Another form of masking is one in which both members of the pair are masked – double-masked treatment administration. As a rule, double-masked treatment administration means that all persons in a clinic are masked and, therefore, that those responsible for data collection and generation are masked to treatment as well.

Generally, it is not possible or prudent to mask treatment administration in trials involving treatments requiring different routes or modes of administration (e.g. as in a trial involving a medical vs. a surgical form of treatment), where knowledge of treatment assignment is part of the effect being tested (e.g. as in trials aimed at modification of one's eating habits via different modes of dietary consulting), or where the masking carries risks for those enrolled. Therefore, the opportunities for double-masked treatment administration are limited largely to trials of drugs considered safe and that are reasonably free of side-effects and that can be administered at fixed dose levels. It is usually not wise or practical to administer treatments in a double-masked fashion when treatment doses are to be titrated to achieve desired effects.

Masked treatment administration has been used as a mark of "quality" for trials. There is, therefore, a tendency to view results from masked trials as more reliable than those from unmasked trials. In truth, however, masked treatment administration is rarely 100% effective. All forms of treatment, and especially those involving drugs, produce side-effects and telltale signs that may serve to unmask treatment. Hence, the protection provided by masking can be illusory. As a result, it is better to make assessments of "quality" in terms of the risk of treatment-related bias and the likely effect of such bias, if present, on the results reported. The risk of treatment-related bias is low for "hard" outcome measures and with explicitly defined treatment protocols, even in the absence of masked treatment administration.

The second line of defense, in the absence of double-masked treatment administration, is to mask as many groups of persons involved in the trial as is possible within the limits of practicality and safety. Hence, even if it is not possible to mask patients or those who treat them, it may be possible to mask those responsible for data collection or data generation (e.g. as with an arrangement as in the Glaucoma Laser Trial [34], where intraocular pressure was measured by masked readers, or as with laboratory personnel or readers of X-rays, ECGs, or fundus photographs masked to treatment assignment).

With or without treatment masking, trialists strive for objectively defined treatment and data collection procedures and for outcome measures as free from observer or respondent bias as is humanly possible. In addition, they are inclined toward continuing effort

over the course of a trial aimed at maintaining the training and certification of study personnel in regard to required study procedures, and toward establishing and maintaining standards of performance via ongoing monitoring and quality control surveillance (*see* **Clinical Trials Audit and Quality Control**).

Analysis

The protection provided against treatment-related bias by the assignment process is futile if the analysis is **biased**. Treatment comparisons, to be valid, must be based on analyses that are consistent with the design used to generate them. In the case of the randomized trial, this means that the primary analyses of the outcomes of interest must be by assigned treatment (also known as *analysis by* **intention-to-treat**). It means, for example, that observations relating to a morbid event are counted to a patient's assigned treatment regardless of whether or not the patient was still on the assigned treatment when the event occurred.

Analyses involving arrangements of data related to treatment administered may be performed, but only as supplements to the primary analyses. They should not and cannot serve as replacements for those analyses.

Analyses by treatment assignment, as a rule, serve to underestimate the treatment effect. Usually, analyses in which the requirement is relaxed will yield a larger estimate of the treatment difference than seen when evaluated under the intention-to-treat mode of analysis (e.g. as in the case of the **University Group Diabetes Program (UGDP)** trial) [90].

Designs allowing for termination of data collection when a person can no longer receive or be maintained on the assigned treatment are open to treatment-related bias. The goals of the primary analyses cannot be met when data collection for a person ceases when that person experiences a nonfatal "endpoint" or when the person's treatment is stopped or changed. The analysis requirement implies continued follow-up of all persons enrolled into a trial to the scheduled close of follow-up regardless of their treatment or outcome status.

Monitoring Treatment Effects

The randomized trial depends on a state of equipoise – a state of legitimate doubt regarding the test treatment relative to the control treatment(s) [4, 30, 61]. It cannot be undertaken without a proper ethical climate characterized by such a state of doubt (*see* **Ethics of Randomized Trials**). It does not matter whether that state has been dispelled by observation and data, by declaration, or in other ways. For example, it would not be possible to assess the value of coronary care units for persons appearing to be having a myocardial infarction (MI), even if their value has not been demonstrated by controlled trials. They are considered to be required for good care and, hence, the window of opportunity for testing via designed randomized trials has closed. Once closed, it may remain closed, or may open again years later if people start questioning the merits of the treatment. When the oral hypoglycemic agents appeared on the scene in the early 1950s, they were widely regarded as safe and effective and, hence, became a part of the armamentarium for care of the adult-onset diabetic. However, doubts raised in the late 1950s as to their value led to a climate of doubt suitable for initiation of the UGDP trial [89].

Trials are done because of the prospect of benefit associated with a new treatment, or to test the efficacy of an existing treatment. They are not undertaken to prove a treatment to be useless or harmful. Indeed, a trialist is obligated to stop a trial prior to its scheduled completion if the accumulated data indicate that the treatment of interest is inferior to the control or comparison treatment. In fact, some argue that there is an obligation to stop if it becomes clear that the test treatment is no better than the comparison treatment, even if one is uncertain whether it is harmful. Hence, for example, investigators in the UGDP opted to stop use of tolbutamide in that trial once they were certain it was no better than the control treatment – the usual antidiabetic dietary recommendations and placebo medication.

The need for ongoing monitoring exists for any trial in which the treatments carry risk of harm, and in which it is possible to reduce that risk by timely monitoring (*see* **Data and Safety Monitoring**). That need makes it necessary for the trialist to aim for an orderly and timely flow of data from the site of generation or collection to the processing and analysis site. Clearly, the best systems in this regard are those having real-time or near-real-time flows (e.g. as with systems requiring transmission of data related to a patient visit on completion of the visit or on occurrence of an outcome of interest).

Typically, treatment effects monitoring is entrusted to a group of people that together have the necessary skills and expertise to monitor effectively (*see* **Data Monitoring Committees**) [38, 67, 70, 94]. The group is usually comprised of 5–12 people with expertise in the disease under treatment, in the design, conduct, and analysis of clinical trials, or in other specialty areas. When the group comprises a mix of people from within the trial (e.g. the officers of the trial, such as the chair and vice chair, the director of the coordinating center, etc.) and outside the trial, the votes concerning recommendations for change, generally, are vested in those outside the study. The restriction is imposed, typically, because of concerns that persons associated with the trial may have conflicts of interest that could serve to influence their votes [17].

Monitoring proceeds under different constructs, depending on the philosophy of those doing the monitoring. Some constructs require stopping rules and restrictions on the type of data that may be monitored and the number of interim "looks" that can be made in relation to the monitoring. Other groups consider such restrictions unnecessary and rely instead on the collective judgment of the monitoring group [28].

The Office for Protection from Research Risks (OPRR) (an office within the **National Institutes of Health** responsible for the promulgation and administration of regulations regarding institutional review boards) and the set of rules relating to research on human beings obligates IRBs to be satisfied that risk to subjects is minimized. As part of this assurance in regard to clinical trials, investigators must have "adequate provision for monitoring the data collected to ensure the safety of subjects" (Section 46.111) [71] and must provide participants with information on ... "significant new findings developed during the course of the research which may relate to the subject's willingness to continue participation will be provided to the subject" (Section 46.116) [71]. This requirement makes it necessary to inform patients of results during the trial that bear on their willingness to continue. This requirement pertains to information from inside or outside the study, if the information is likely to cause patients to reconsider their decision to be enrolled in the trial. Formal reconsent procedures may be required if the treatment effects monitoring committee recommends changes to the treatment protocol (e.g. as discussed in [67]).

Representativeness, Validity, and Generalizability

Representativeness, in the context of a trial, refers to the degree or extent to which those enrolled can be considered representative of the general population of persons to whom the treatment may be applied, if shown to be useful. *Validity*, in the context of a treatment difference, refers to the extent to which that difference can be reasonably attributed to treatment assignment. *Generalizability* refers to the degree to which the findings of the trial can be extended to the general population of eligible persons.

The concepts of validity and generalizability are different. Validity derives from the design of the trial and from the way it is carried out, whereas generalizability is largely a matter of judgment. A treatment comparison is valid if it is based on comparable groups of persons treated and observed in such a way so as to make treatment assignment the most likely explanation of the result observed. "Representativeness" is deduced by comparison of the demographic and other host characteristics of the study population to that of the general population of eligible persons (or by comparison with all persons screened for enrollment).

The desire for representativeness arises from the belief that conclusions from a trial will be strengthened by having a broadly "representative" study population. The drive for demographic representativeness has been propelled in recent years by the belief that women and persons of ethnic minorities have been "underrepresented" or "understudied" relative to men and the prevailing ethnic majority in trials and other areas of clinical research. Those concerns have been sufficient to cause the US Congress, in the NIH Revitalization Act of 1993, to impose requirements on trials aimed at ensuring adequate numbers of women and ethnic minorities to determine whether the treatments being studied in a trial work differently in men than in women or in an ethnic minority than in the ethnic majority [88].

There is no way to ensure "representativeness" in the absence of a **sampling frame** for the eligible **study population** and a related sampling scheme aimed at providing a representative sample of that population. However, even if one were able to develop a sampling frame (usually impossible because to do so one would have to screen the general population to identify persons eligible for study), the

population ultimately enrolled, even if selected by sampling, would, at best, be representative only of those able and willing to be enrolled, because of the requirements of consent.

Hence, trials, by nature of their design, involve select, nonrepresentative populations. Even if a treatment is found effective in a trial, one has no direct way of knowing if it would be effective for those patients not agreeing to be studied. If the issues of consent and lack of a sampling frame were overcome, then one would still be left with the fact that most clinics, for practical and ethical reasons, have to rely on those who come to them. They do not have the ability or moral authority to go and seek out suitable patients for study, especially if doing so means that those who routinely come to them would be turned away. Such a "selective" approach would be viewed as violating the principle of justice as set forth in the Belmont Report [69].

That one needs to generalize is obvious. The need arises in regard to the route of treatment, amount of treatment, type of treatment, and type of patients. For example, if a trial involved a single fixed dose of a drug and failed to find a difference (e.g. as in the UGDP trial, regarding tolbutamide) [90] does one conclude that use of the same drug, under a different, more flexible dosing scheme would produce a more favorable result? Similarly, if one compound produces a benefit, does one conclude that other sister compounds will show the same effect? Or conversely, if one member of a drug family has a bad effect (e.g. fialuridine) or fails to show a benefit (e.g. tolbutamide), does one shy away from other related compounds? Also, if a trial involves mildly diseased people and shows a beneficial effect for the test treatment, does one conclude that the test treatment will have a similar effect in sicker people?

Last, if the drug tested works for the disease or condition being treated, is it not likely that it would be useful as well for a related condition or disease? So-called "off label" use (from the fact that drugs are approved for designated indications) accounts for a large number of treatment prescriptions [12, 36, 91, 93].

Whenever one generalizes, whatever the nature or direction, one is in effect answering one or more of the above questions. If as a treater, one chooses to use a sister compound of a drug shown to be ineffective in a trial, then one is in effect saying that the result from the trial, for whatever reason, is not generalizable. Generalizations depend on judgments regarding the trials and on prior beliefs regarding the treatment in question.

A trial can provide a valid basis for comparing one treatment to another if the differences in outcomes for the treatment groups being compared can be attributed reasonably to treatment. The general "laws of science" and "principles of **parsimony**" require that one defaults to the simplest explanation – usually the one requiring the fewest assumptions. Hence, in the case of the trial in which treatments are selected by the patient or physician, one is as a rule more inclined to attribute the difference to selection factors than to the test treatment. By the same principle, one should be more inclined to attribute a treatment difference to bias on the part of the observer rather than to the treatment when the opportunity for such bias exists. The degree of "reasonableness" of such an explanation will depend on the nature of the outcomes and whether one can reasonably ascribe it to biased observation. It becomes progressively more difficult to do so, even if the observer is not masked, the "harder" the outcome measure. For example, it is not reasonable to expect that one's opinion regarding the merits of a treatment will influence one's ability to report reliably whether a person is alive or dead, but such opinion may influence how one sees or reports on a person's **quality of life**. There is a responsibility on the part of trialists to rule out other lesser explanations of results before ascribing them to treatment.

Contrary to lay perceptions, trials and comparisons of treatments within the trial are made **robust** to selection bias and the consequences of "nonrepresentative" study populations by randomization. The assessment of treatment effect is achieved by having comparable groups of patients in the different treatment groups and by having procedures for observing and following patients that are independent of treatment assignment. The comparison is valid regardless of the study population and provides information on the relative value of one treatment to another. Hence, from the perspective of the trialist, it is far more important to have comparable treatment groups than to have "representative" treatment groups.

The drive for "representativeness", while perhaps of some social value, does little to make generalizations less risky or to increase the validity of trials. There are sound practical reasons to design trials with as few exclusions to enrollment as possible.

The above list is due the efforts of Susan Tonascia, ScM, Johns Hopkins School of Public Health, Department of Epidemiology.

The fewer the restrictions the easier and faster it is to recruit. Any effort to make them more "representative" by selective recruitment and enrollment will make them more costly and will increase the time required to enroll them. The imposition of recruitment quotas to achieve a desired sample size for gender, age, and ethnic origin groups poses a far more complicated and costly recruitment effort than one involving the enrollment of all comers regardless of gender, age, or ethnic origin.

The goal of the trialist should be to strive for demographic neutrality in enrollment. That is to say, the trialist should not exclude potential participants on the basis of gender, ethnic origin, or age unless justified on scientific grounds. Scientific grounds include the knowledge or expectation of a qualitative treatment by demographic interaction (i.e. where treatment is believed to be beneficial for one demographic group and harmful for another) (*see* **Treatment-covariate Interaction**).

Another reason for exclusion is contraindication of treatment in a particular demographic group. If any one treatment is contraindicated in a trial involving multiple treatments, then the restriction has to apply to all treatments. For example, this requirement was one of the reasons why the Coronary Drug Project (CDP) involved only men. Two of the five test treatments in the trial could not have been administered to premenopausal women; thus this demographic group could not be included without making the trial much more complex [22].

As a rule, an anticipated low number in a specified demographic group is not a reason to exclude. Disease and extent of disease are much more likely to affect the response to treatment than are "demographic" characteristics. Analyses of treatment effects across the various demographic subgroups represented in a trial can help determine whether there are treatment by demographic interactions. In general, **interactions**, when noted in the context of treatment trials, are more likely to relate to disease characteristics than to demographics [32, 42, 45, 46, 65].

The mind-set regarding selection is different in **prevention trials**, where the goal is to determine whether a proposed prevention strategy works. One has to find a population suitable for testing the proposed strategy. Hence, unlike the treatment trial, risk factors predisposing to a disease and risk of an event are important. In this setting, one has to pay attention to both factors in trying to design a cost-effective trial (*see* **Health Economics**). Considerations of this sort led, for example, the designers of MRFIT [68] to exclude females from enrollment. The risk factors targeted (high blood pressure, high cholesterol, and smoking) occur less frequently in women than in men. Consequently, the effort required to find women for study would have been much greater than that required to find men. Further, for the age range studied, women have a markedly lower myocardial infarction rate (the outcome of primary interest) than do men. This lower event rate would have meant that the planned sample size with women included would have to have been considerably larger to detect the same relative difference at the power level specified for the trial. As it was, the trial required a sample size of 12 866 men (*see* **Validity and Generalizability in Epidemiologic Studies**).

Readings

The literature on the design, conduct, and analysis of clinical trials is ever-expanding. Students of trials need to monitor the literature of reported trials as they appear in medical journals and to read specialty journals, such as ***Biometrics***, ***Statistics in Medicine***, ***Controlled Clinical Trials***, *Applied Clinical Trials*, and ***Statistical Methods in Medical Research***. The list of citations given in Table 1 is but a snapshot of selected references dealing with the methods and procedures of trials.

CURTIS L. MEINERT

Clinical Trials

Clinical Trials: Journal of the Society for Clinical Trials, initiated publication in 2004, succeeding ***Controlled Clinical Trials*** (CCT) as the official journal of the **Society for Clinical Trials** (SCT, www.sctweb.org). The SCT provided editors for CCT since its initiation by Elsevier in 1980, the first editor being Curt Meinert (1980–1993), followed by Janet Wittes (1994–1998) and Jim Neaton (1999–2003). In 2004, the SCT founded a new journal, *Clinical Trials*, under the editorship of Steven Goodman. The SCT owns the copyright of its new journal, which is published by Hodder–Arnold of the United Kingdom.

The aims and scope of *Clinical Trials* mirror the makeup and interests of the sponsoring society, and are listed on the journal website, www.sctjournal.com. It is an interdisciplinary journal with coverage of virtually any method or issue related to or impacted by **clinical trials**. These include statistical methods, methods for design, conduct, monitoring (*see* **Data and Safety Monitoring**), or synthesis (*see* **Meta-analysis of Clinical Trials**) of clinical trials; research ethics (*see* **Ethics of Randomized Trials**); law, policy, and regulation (*see* **Drug Approval and Regulation**); **history of clinical trials**; impact of trials; and education and training. The journal also seeks to feature discussions of timely and important issues related to clinical trials. This will be facilitated by the SCTs initiation in 2004 of a process for producing society position papers on important methodologic or regulatory issues. In addition to articles that cover technical methods, the journal also publishes perspectives, profiles of prominent trialists, historical pieces, book reviews, and editorials. Full-length articles can be up to 7000 words, brief reports are limited to 1500 words, and research letters are 500 words or less. *Clinical Trials* publishes design articles, which describe the design and organization of particular clinical trials, focusing on how particularly interesting or challenging design issues were addressed. It will also be adding a feature popular in the first decade of CCT, a column that provides an overview of clinical trial–related articles, methodologies, and developments appearing in the wider scholarly and policy arena.

In addition to the Editor-in-Chief, the journal has a Deputy Editor, a 10-person Advisory Board, and 40 Associate Editors. The Associate Editors come from a broad array of disciplines and venues and have wide-ranging expertise: statistics, ethics, history, informatics, medicine, industry, and clinical trials. The editorial model is partially centralized, with Associate Editors making preliminary judgments about suitability of submitted manuscripts for peer review, identifying reviewers, and often handling revisions, but with their opinion being advisory to the editor. The journal is published bimonthly, although there will be supplements devoted to meeting proceedings or special topics. The journal accepts only electronic submissions (to clinicaltrials@jhmi.edu), and will be implementing the Manuscript Central online manuscript management and peer-review system in 2004. It aims to make all editorial decisions on articles not sent out for review within four weeks, and for those sent out for review within 10 weeks. Articles of particular timeliness can be fast-tracked for rapid review and publication. Articles can be made available in electronic form before the print version appears. The journal receives about 200 to 300 original manuscripts annually, of which it accepts roughly 20 to 25%.

The journal is published in both print and electronic form, with the electronic version on Ingenta (www.ingenta.com). Society members receive the journal as part of their membership fee; others can receive it either by joining the society, obtaining a nonmember individual subscription, or accessing it through an institutional subscription. Individual articles can also be downloaded by nonsubscribers for a fee.

The field of clinical trials is extremely challenging and exciting, as a field in which the unit of information is human lives or suffering, and how that information is both produced and analyzed has profound importance to medicine, patients, and society at large. *Clinical Trials* aims to be a forum where the science of statistics is advanced, as applied to this form of human research, and where the full implications and applications of these methodologies can be explored and understood by the broader scientific community with interests in this vital area.

STEVEN N. GOODMAN

Cluster Analysis of Subjects, Hierarchical Methods

Cluster analysis is concerned with investigating a set of data to discover whether or not it consists of relatively distinct groups of observations. The groups are unknown a priori so that cluster analysis is distinguished from the activity of allocating individuals to one of a set of existing groups, an activity usually referred to as *assignment* or *discrimination* (*see* **Discriminant Analysis, Linear**).

Uncovering the group structure (if any) of a set of data is clearly of considerable importance in understanding the data and using them to answer substantive subject-matter questions. In medicine, for example, separating diseases that require different treatments will often be the primary goal of any classification exercise.

A very broad division of cluster analysis techniques is into those that produce *hierarchical classifications* and those that produce *nonhierarchical classification* (*see* **Cluster Analysis of Subjects, Nonhierarchical Methods**). This article is concerned with the former and owes much to the two excellent review papers by Gordon [17, 18].

Data

The raw data to be analyzed by cluster analysis methods usually consist of a set of p variables for each of the n individuals to be clustered. Such data are commonly represented by an $n \times p$ matrix, $\mathbf{X}$, given by

$$\mathbf{X} = \begin{pmatrix} x_{11} & x_{12} & \dots & x_{1p} \\ x_{21} & x_{22} & \dots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ x_{n1} & x_{n2} & \dots & x_{np} \end{pmatrix}. \qquad (1)$$

Many clustering methods first require the raw data matrix to be transformed into an $n \times n$ matrix of pairwise similarities, dissimilarities, or distances, $\mathbf{D}$. An example of a measure frequently used in practice is the Euclidean distance, where the elements of $\mathbf{D}$, d_{ij}, are defined as follows:

$$d_{ij} = \left[\sum_{k=1}^{p} (x_{ik} - x_{jk})^2 \right]^{1/2}. \qquad (2)$$

Many other dissimilarity and distance measures can be used, however, and details are given in another entry in this Encyclopedia (*see* **Similarity, Dissimilarity, and Distance Measure**). An important problem, not considered here, is if and how the raw data should be standardized before they are converted to dissimilarity or distance measures. Details of the issues involved are discussed in Everitt [13].

(Occasionally, particularly in psychology, the matrix $\mathbf{D}$ may arise directly from, for example, asking subjects to judge the pairwise dissimilarities of stimuli of interest.)

Hierarchical Classifications and Dendrograms

In a *hierarchical* classification the data are not partitioned into a particular number of groups or clusters at a single step. Instead, the result consists of a series of partitions of the data, P_n, $P_{n-1}, \dots, P_1$. The first, P_n, consists of n single-member "clusters", the last, P_1, consists of a single group containing all n individuals. Often an investigator will not be interested in the complete hierarchy but only in a single partition of the data into a particular number of groups, say g. Deciding on an appropriate value of g from a hierarchy is a problem which will be discussed briefly later in the article.

Hierarchic classifications may be represented by a diagram known as a **dendrogram**, which can, somewhat unhelpfully, formally be defined as a *rooted terminally-labeled weighted tree* in which all terminal nodes are equally distant from the root [29]. For the purpose of the article, however, dendrograms can be characterized less formally in terms of their topology or shape, a set of labels identifying the n individuals being classified and a set of "weights" or "heights" associated with the $n - 1$ internal nodes (i.e. clusters) of the dendrogram. An example of such a diagram is given in Figure 1; others will be given later in the article. The structure of Figure 1 resembles an *evolutionary tree* (see Figure 2) and it is in biological applications that hierarchical classifications are

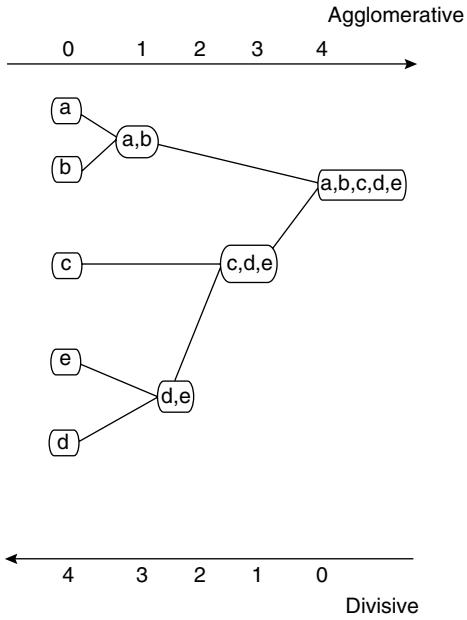

Figure 1 Example of a dendrogram

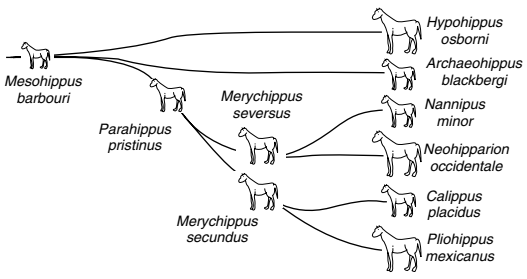

Figure 2 An evolutionary tree

perhaps most relevant. Rohlf [39], for example, suggests that a biologist, "all things being equal", aims for a system of nested clusters.

Hierarchical Clustering Methods

Many different ways have been proposed of transforming a dissimilarity or distance matrix into a dendrogram. Several of the methods, for example **single linkage** (see below), may be implemented by a variety of **algorithms**, and it is important to distinguish between algorithms and method (see [24]). Because different clustering strategies can produce different classifications of the same data set, careful appraisal of results is generally necessary, a point to which we shall return later in the article.

The two major types of algorithms that have been used to produce hierarchical classifications are *agglomerative* and *divisive*, with the former being far more commonly used in practice.

Agglomerative Algorithms

The basic operation of all such methods is similar, and is outlined in Figure 3. At each particular stage the methods fuse individuals or groups of individuals which are closest (or most similar). Differences between methods arise because of the variety of ways in which distance (or similarity) can be defined between two groups. In *single linkage clustering*, for example, intergroup distance is defined as the minimum of the interindividual values amongst pairs consisting of one individual from one group and one from the other. In *complete linkage*, the maximum value of the appropriate interindividual values is used. A method that uses more than a single interindividual distance value to define distance between groups is *group average clustering*, which uses the average of the appropriate distance values as illustrated in Figure 4. The dendrograms resulting from applying each of single linkage, complete linkage, and group average to the following small distance matrix are shown in Figure 5:

$$\mathbf{D} = \begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{array} \begin{array}{c} \begin{array}{ccccc} 1 & 2 & 3 & 4 & 5 \end{array} \\ \begin{pmatrix} 0.0 & & & & \\ 2.0 & 0.0 & & & \\ 6.0 & 5.0 & 0.0 & & \\ 10.0 & 9.0 & 4.0 & 0.0 & \\ 9.0 & 8.0 & 5.0 & 3.0 & 0.0 \end{pmatrix} \end{array}. \quad (3)$$

START: Clusters $C_1, C_2, \ldots, C_n$ each containing a single individual.

1. Find nearest pair of distinct clusters, say C_i and C_j, merge C_i and C_j,

delete C_j and decrement number of clusters by one.

If number of clusters equal one then stop, else return to 1.

Figure 3 Basic operation of hierarchical clustering procedures

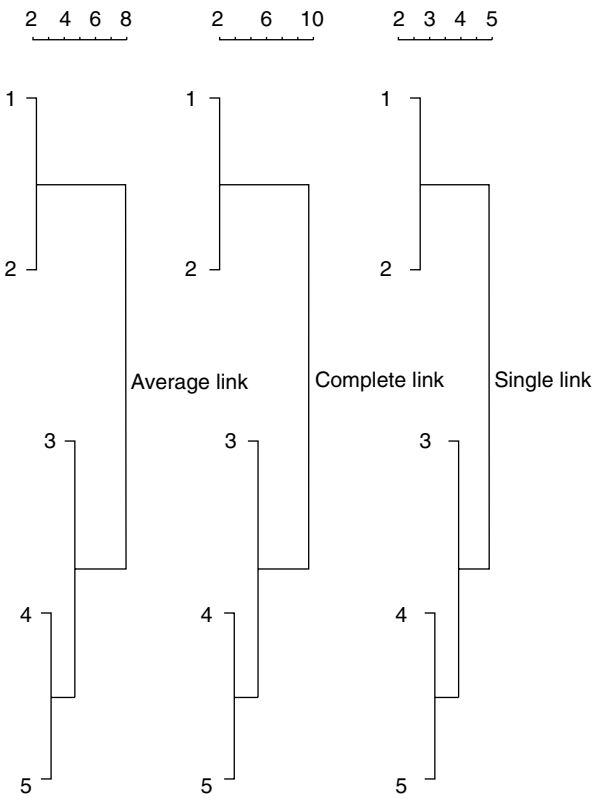

Figure 5 Single linkage, complete linkage, and group average dendrograms

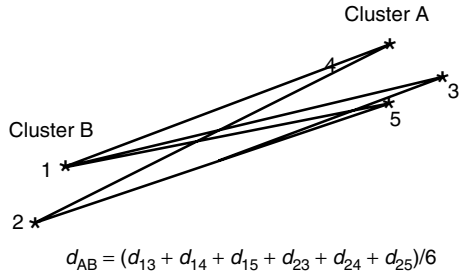

Figure 4 Group average distance

(Details of the steps in the progression from **D** to the appropriate dendrogram are given in [13].) The level at which two individuals join the same group, h_{ij}, depends on the cluster method used, but in general is different from their dissimilarity, d_{ij}. In fact, for single linkage clustering, $h_{ij} \leq d_{ij}$. The heights, h_{ij}, are always symmetric and satisfy the following ultrametric inequality:

$$h_{ij} \leq \max[h_{ik}, h_{jk}]. \tag{4}$$

The dendrograms in Figure 5 are constructed from the bottom up, but the natural way to use them is from the top down so that, for example, in the single linkage dendrogram the data are divided into two groups by "cutting" above the height value 4.

Many commonly used agglomerative algorithms are described by a general formula given originally by Lance & Williams [27, 28] and later extended by Jambu [23], in which the dissimilarity between a group (ij) formed by joining groups i and j, and some other group k is found from

$$d_{(ij)k} = \alpha_i d_{ik} + \alpha_j d_{jk} + \beta d_{ij} + \gamma |d_{ik} - d_{jk}| + \delta_i h_i + \delta_j h_j + \varepsilon h_k. \tag{5}$$

In this equation, h_i is the height in the dendrogram of group i and $\alpha_i, \alpha_j, \beta, \gamma, \delta_i, \delta_j$, and ε are parameters with particular values for particular clustering methods, as detailed in Table 1.

Methods C5 and C6 implicitly assume that the individuals are represented by points in some Euclidean space, and that the measure of pairwise dissimilarity is proportional to the squared Euclidean distance. The quantity d_{ij} has the following definitions: in the sum of squares method (C5) it is the within-group sum of squared distances of the group ij; in Ward's method (C6) it is the *increase* in the sum of squares that would be brought about by the amalgamation of groups i and j; in the centroid method (C7) it is the squared distance between the centroids of i and j; in the median method (C8) it is the squared distance between weighted centroids obtained by assigning each class the same number of individuals in evaluating the "centroid" of their union.

Direct use of the Lance–Williams–Jambu general agglomerative algorithm has $O(n^3)$ time complexity and $O(n^2)$ space complexity [47], and several authors have considered procedures for improving the efficiency of the approach. Day & Edelsbrunner [9] for example, show that by associating with each group a priority queue that orders the other groups by their distance to it, the time complexity can be reduced to $O(n^2 \log n)$. Further suggestions for improving efficiency are described in Bruynooghe [2] and Murtagh [38].

Divisive Algorithms

Divisive algorithms begin with a "group" containing all n individuals and at each succeeding stage divide an existing group into two. Algorithms that find the globally optimal divisions [12, 41] are computationally very demanding and practicable alternatives have been suggested by Macnaughton-Smith et al. [31], Vichi [44], and Hubert [22]. The only divisive algorithm that has been routinely used, however, is one applicable when the variables describing each individual are binary, and division of the data is now on the basis of the possession or otherwise of a single specified attribute, this being chosen to maximize the difference between the resulting two groups according to some particular criterion. Such procedures are known as *monothetic divisive algorithms* [7, 48]. The division criteria used are generally based on some **chi-square** type statistic – see Everitt [13] for details.

Table 1 Clustering strategies obtainable from the general agglomerative algorithm

Name	References	α_i	β	γ	δ_i	ε
C1	Single link (Florek et al. [14]; Sneath [42])	0.5	0	−0.5	0	0
C2	Complete link (McQuitty [32])	0.5	0	0.5	0	0
C3	Group average link (Sokal & Michener [43]; McQuitty [34])	$\frac{n_i}{n_i + n_j}$	0	0	0	0
C4	Weighted average link (McQuitty [33, 34])	0.5	0	0	0	0
C5	Sum of squares (Jambu [23])	$\frac{n_i + n_k}{n_+}$	$\frac{n_i + n_j}{n_+}$	0	$\frac{-n_i}{n_+}$	$\frac{-n_k}{n_+}$
C6	Incremental sum of squares (Ward [45]; Wishart [50])	$\frac{n_i + n_k}{n_+}$	$\frac{-n_k}{n_+}$	0	0	0
C7	Centroid (Sokal & Michener [43]; Gower [19])	$\frac{n_i}{n_i + n_j}$	$\frac{-n_i n_j}{(n_i + n_j)^2}$	0	0	0
C8	Median (Lance & Williams [27]; Gower [19])	0.5	−0.25	0	0	0
C9	Flexible (Lance & Williams [27])	$0.5(1 - \beta)$	$\beta(< 1)$	0	0	0

Note: n_i is the number of individuals in class C_i; $n_+ = n_i + n_j + n_k$

Properties and Problems of Hierarchical Clustering Techniques
