We can extend the two-sample logrank test to the k-sample comparison. The k-sample logrank test has a quadratic form with $(d_{1j} - E_{1j})$ replaced by the corresponding values from $k - 1$ samples and with V_{1j} replaced by the corresponding **covariance matrix**, where the hlth element is

$$\hat{\sigma}_{hl} = \frac{d_j n_{hj}}{n_j}\left(\delta_{hl} - \frac{n_{hj}}{n_j}\right)\frac{(n_j - d_j)}{(n_j - 1)}$$

and δ_{hl} is a Kronecker delta, that is, $\delta_{hl} = 1$ if $h = l$, and 0 otherwise.

Table 1

	Sample		
Failure	1	2	Total
Yes	d_{1j}	d_{2j}	d_j
No	$n_{1j} - d_{1j}$	$n_{2j} - d_{2j}$	$n_j - d_j$
Total	n_{1j}	n_{2j}	n_j

Parametric Models and Regression Analysis

In survival analysis some parametric models have been studied extensively. The common parametric distributions considered are **exponential**, **gamma**, **Weibull**, **lognormal**, and Gompertz distributions (*see* **Parametric Models in Survival Analysis**). These parametric models are often fitted to grouped data as well. The parameters are usually estimated by maximizing the full (unconditional) **likelihood** or the conditional likelihood, that is, the likelihood function for the interval $(t_{j-1}, t_j]$ conditional on surviving till t_{j-1}. Many authors have given the maximum likelihood estimator (MLE) for grouped data [12, 27, 10]. Turnbull & Weiss [38] studied a **likelihood ratio test** statistic for testing **goodness of fit** for grouped failure data with possible double censoring.

It is important to assess the effects of covariates that may be associated with lifetimes in many applications of survival analysis. The regression model

for the conditional hazard function $\lambda(t|\mathbf{z})$ of the failure time given covariate $\mathbf{z}$ could be used to examine the covariate effects. Continuous covariates are often grouped into a fixed number of strata, and the value for each stratum is approximated by the midpoint of the covariate in the stratum (*see* **Stratification**). For simplicity we consider a one-dimensional covariate case. The methods and results discussed here can be extended to multidimensional cases. Let the cells into which the data are grouped be denoted $\mathcal{C}_{rj} = \mathcal{T}_r \times \mathcal{I}_j$, where $\mathcal{T}_1, \ldots, \mathcal{T}_{L_n}$ and $\mathcal{I}_1, \ldots, \mathcal{I}_{J_n}$ are the respective calendar periods (time intervals) and covariate strata. Grouped failure time data consist of the total number of failures (occurrence) and the total time at risk (exposure) in each cell $\mathcal{C}_{rj}$, given by d_{rj} and Y_{rj}. In the literature, most early work has been done under the piecewise exponential model, that is, the hazard function is assumed to be piecewise constant within each grouping cell. The natural estimate of the unknown hazard rate λ_{rj} is $\hat{\lambda}_{rj} = d_{rj}/Y_{rj}$ (occurrence/exposure rate). Deddens & Koch [10] showed that the maximum likelihood solution is approximately equivalent to maximizing the piecewise exponential likelihood function

$$L = \prod_{r,j} \lambda_{rj}^{d_{rj}} [\exp(-\lambda_{rj} Y_{rj})].$$

The occurrence/exposure rate estimator can also be obtained by solving the equations of $\partial \log L / \partial \lambda_{rj} = 0$.

The **counting process** approach and martingale techniques are applicable in grouped failure time data analysis. We assume that the counting process N_i, where $N_i(t)$ is the number of failures of the ith individual during time period $[0, t]$, has intensity

$$\lambda_i(t) = Y_i(t)\lambda[t, Z_i(t)],$$

where $Y_i(t)$ is a predictable $(0, 1)$-valued process indicating that the ith individual is at risk with $Y_i(t) = 1$, and $Z_i(t)$ is a predictable covariance process. The occurrence and exposure in each cell $\mathcal{C}_{rj}$ can be written as

$$d_{rj} = \sum_i \int_{\mathcal{T}_r} I[Z_i(t) \in \mathcal{I}_j] \, \mathrm{d}N_i(t)$$

and

$$Y_{rj} = \sum_i \int_{\mathcal{T}_r} I[Z_i(t) \in \mathcal{I}_j] Y_i(t) \, \mathrm{d}t.$$

When the censoring processes are independent of the survival time, we can show that $M_i(t) = N_i(t) - \int_0^t \lambda_i(u) \, \mathrm{d}u$ are local martingales. Under the piecewise constant model $[\lambda(t, z) = \lambda_{rj}$, for $(t, z) \in \mathcal{C}_{rj}]$,

$$\hat{\lambda}_{rj} = \frac{d_{rj}}{Y_{rj}} = \frac{M_{rj}}{Y_{rj}} + \lambda_{rj} \frac{Y_{rj}}{Y_{rj}},$$

where

$$M_{rj} = \sum_i \int_{\mathcal{T}_r} I[Z_i(t) \in \mathcal{I}_j] \, \mathrm{d}M_i(t)$$

is the martingale part of d_{rj}. Since for each $t \in \mathcal{T}_r$, Y_{rj} is not predictable, the martingale techniques are not applicable directly. However, in the independent, identically distributed (iid) case and some mild conditions, we can show that there exists a piecewise constant function f_{rj} bounded away from zero such that $n^{-1} Y_{rj}$ **converges** to f_{rj} in probability. Then we can replace M_{rj}/Y_{rj} by M_{rj}/nf_{rj} with the difference of $o_P(1)$. It follows that

$$\hat{\lambda}_{rj} = \frac{M_{rj}}{nf_{rj}} + \lambda_{rj} + o_P(1),$$

and the predictable variation process of M_{rj}/f_{rj} is

$$\left\langle \frac{M_{rj}}{f_{rj}} \right\rangle = \frac{\lambda_{rj} Y_{rj}}{f_{rj}^2}.$$

Therefore, $\hat{\lambda}_{rj}$ is an asymptotic **unbiased** estimator and the variance can be consistently estimated by

$$\hat{\sigma}_{rj} = \widehat{\mathrm{var}}(\hat{\lambda}_{rj}) = \frac{d_{rj}}{(Y_{rj})^2}.$$

For the general nonparametric model where the hazard function is unspecified, Holford [20] noted that this estimator is inconsistent unless the grouping becomes finer as the sample size increases (*see* **Consistent Estimator**).

The useful models for many applications are the **multiplicative** and **additive hazard models**. The model equations are given by

$$\lambda_{rj} = \lambda_{r0} \exp(\boldsymbol{\beta} \mathbf{z}_j) \quad \text{and} \quad \lambda_{rj} = \lambda_{r0} + \boldsymbol{\beta} \mathbf{z}_j,$$

where λ_{r0} is the baseline hazard rate for the rth time period. The parameters λ_{r0} and $\boldsymbol{\beta}$ are readily estimated by the MLE. Berry [5] and Frome [14] provide explicit MLE for this approach. For the multiplicative risk model the hazard function can be written

as $\lambda_{rj} = \exp(\alpha_r + \boldsymbol{\beta}\mathbf{z}_j)$, which has a loglinear form. It is often called the loglinear piecewise constant model. Holford [21] derived the log likelihood for this model:

$$L = \sum_r \alpha_r d_{r\cdot} + \sum_{r,j} d_{rj}\beta z_j - \sum_{r,j} Y_{rj}\exp(\alpha_r + \boldsymbol{\beta}\mathbf{z}_j),$$

where $d_{r\cdot} = \sum_{j=1}^{J_n} d_{rj}$ is the number of failures in the rth calendar period. Taking derivatives of L with respect to α_r and $\boldsymbol{\beta}$ and setting them equal to zero, the MLE estimator of $\boldsymbol{\beta}$ is given by solving the following equation:

$$\sum_{r,j} z_j d_{rj} - \sum_r \frac{\sum_j Y_{rj} z_j \exp(\boldsymbol{\beta}\mathbf{z}_j)}{\sum_j Y_{rj}\exp(\boldsymbol{\beta}\mathbf{z}_j)} d_{r\cdot} = 0.$$

As we discuss later, this MLE estimator of $\boldsymbol{\beta}$ can also be obtained by maximizing the grouped data version of Cox's **partial likelihood**.

The more general models are: Cox's proportional hazards model [9], where $\lambda(t, z) = \lambda_0(t)\exp(\boldsymbol{\beta}\mathbf{z})$; and **Aalen's additive regression model** [1], where $\lambda(t, z) = \lambda_0(t) + \boldsymbol{\beta}(t)\mathbf{z}$.

Cox's proportional hazards model has so far been the most popular model in survival analysis. The parameter estimator $\hat{\boldsymbol{\beta}}$ is obtained by maximizing Cox's partial likelihood function. Andersen & Gill [3] provide an excellent proof that $n^{1/2}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0) \xrightarrow{P} \mathrm{N}(\mathbf{0}, \mathbf{V})$, where $\mathbf{V}^{-1}$ is consistently estimated by $-n^{-1}\partial\mathbf{U}(\hat{\boldsymbol{\beta}})/\partial\boldsymbol{\beta}$ and $\mathbf{U}$ is the partial likelihood score function $U(\boldsymbol{\beta}) = \partial \log L(\boldsymbol{\beta})/\partial\boldsymbol{\beta}$ (*see* **Likelihood**). The grouped data based estimator $\hat{\boldsymbol{\beta}}_g$ can be obtained by maximizing the following approximation to the partial likelihood:

$$L_g(\boldsymbol{\beta}) = \prod_{r,j}\left(\frac{\exp(\boldsymbol{\beta}\mathbf{z}_j)}{\sum_k Y_{rk}\exp(\boldsymbol{\beta}\mathbf{z}_k)}\right)^{d_{rj}},$$

where the product is over the grouping cells, the sum is over the covariate strata, and z_j is the midpoint of the jth covariate stratum. This estimator has been studied by Kalbfleisch & Prentice [25], Holford [20], Prentice & Gloeckler [34], Breslow [6], Hoem [19], Selmer [35], and Huet & Kaddour [22]. It can be interpreted as the maximum likelihood estimator in a **Poisson regression** model, as shown by Laird & Olivier [26]. Under slightly stronger regularity conditions proposed in Andersen & Gill [3], it can be shown that $n^{1/2}(\hat{\beta}_g - \beta_0) \xrightarrow{P} \mathrm{N}(0, V)$ when the time intervals and covariate strata shrink at some suitable rate as the sample size increases. It is important to be able to assess estimation bias caused by grouping and to correct it if necessary. In the general grouped data analysis, a **Sheppard correction** can be used to reduce the bias to a higher order of the interval width [28]. McKeague & Zhang [33] obtained a Sheppard correction for Cox's proportional hazards model, provided a consistent estimator for the Sheppard correction, and derived the optimal rate of convergence for $\hat{\beta}_g$. The grouped data based estimator of the baseline hazard function, λ_0, is

$$\hat{\lambda}_0(t) = \frac{\sum_j d_{rj}}{\sum_j Y_{rj}\exp(\hat{\boldsymbol{\beta}}_g\mathbf{z}_j)}, \qquad \text{for } t \in \mathcal{T}_r.$$

Aalen's additive risk model provides a useful and sometimes biologically more plausible alternative to the Cox proportional hazards model. For continuous data, Aalen proposed a **least squares** estimator for the cumulative hazard functions, which has been studied by Aalen [1, 2], Mau [29, 30], and McKeague [31]. McKeague [32] and Huffer & McKeague [23] fit Aalen's additive risk model to the grouped data (when the covariates are observed for each individual and are non-time-dependent), and studied asymptotic results for the grouped data version of the least squares estimator and weighted least squares estimator. The estimators can be generalized to the more general grouped data setting where the only available information is d_{rj} and Y_{rj} for each cell $\mathcal{C}_{rj}$. More work is needed.

Finally, fitting parametric and regression models to grouped failure time data is based on d_{rj} and Y_{rj}. As we discussed in the univariate case, Y_{rj} may not be observable in some applications. It is usually approximated by $Y_{rj} \approx [n_{rj} - (d_{rj} + w_{rj})/2]l_r$, where n_{rj} is the number of individuals at risk at the beginning of the time period $\mathcal{T}_r$ for the jth covariate stratum, w_{rj} is the number of individuals who withdrew in cell $\mathcal{C}_{rj}$, and l_r is the width of the time interval $\mathcal{T}_r$. This approximation is based on the assumption that, on the average, the individuals failed or withdrew at the middle of the each time period. However, in

most applications, this assumption does not hold true. The bias introduced by this approximation could be severe. Caution must be taken when grouping the data to ensure that the number of grouping cells is sufficiently large (the widths of time periods and covariate strata are relative small) and each grouping cell contains enough individuals at risk.

Group-randomization Designs

Randomized **clinical trials** compare two or more intervention or treatment strategies, using random allocation (assignment) (*see* **Randomization**) to intervention condition. Within this framework, group randomization designs (sometimes also called cluster randomization designs) randomly allocate intact groups (clusters), rather than individuals, to intervention condition. Units of group randomization include communities, small towns or villages, factories (workplaces), schools or classrooms, religious institutions, chapters of social organizations, families, and clinical practices.

Randomized trials are the recommended approach for obtaining valid comparisons of competing intervention strategies. The advantages of randomization are no less important for group-based trials than for individual-based trials [14, 15]. **Randomized treatment assignment** avoids **bias**, achieves balance (on average) of both known and unknown predictive factors between intervention and comparison groups, and provides the basis for statistical tests (see [2]).

A variety of examples can be cited to illustrate the range of group-randomized trials. A trial implemented in Indonesia randomly assigned 450 villages to participate or not to participate in vitamin A supplementation, in the form of capsules distributed to preschool children at baseline and again six months later [26]. A trial of the impact of a community-level intervention for improved treatment of sexually transmitted diseases on HIV infection in the Mwanza region of rural Tanzania randomized 12 communities (six pairs) between intervention and control [16, 17]. The Community Intervention Trial for Smoking Cessation (COMMIT) randomized 22 communities (11 pairs) in North America to test a community-based, multichannel, four-year intervention [3, 12, 15]. The Child and Adolescent Trial for Cardiovascular Health (CATCH) randomized schools to test a behaviorally oriented cardiovascular health education program [22, 27]. As a final example here, the Eating Patterns Study randomized 28 physician practices (within six primary care clinics) to evaluate the effectiveness of a self-help booklet, with physician endorsement thereof, in lowering dietary fat intake and raising dietary fiber intake in a primary-care practice setting [1]. For some other examples, see [8] and [25].

Randomization by group is less efficient statistically than randomization by individual, because individuals in a group-randomized trial will contribute less information than if individually randomized, as discussed by Cornfield [4]. There are, however, reasons why randomization by group may be chosen, some of which are illustrated by the trials referenced above. As outlined by Green et al. [15], these reasons include feasibility of delivery of the intervention, political and administrative considerations, the need to avoid contamination between individuals allocated to competing interventions, the very nature of the intervention (i.e. group-level), the existence of ready-made endpoints measured at the group level (*see* **Outcome Measures in Clinical Trials**), the desire to use site-specific resources to decrease cost, and greater generalizability.

When a group entity such as a community is investigated, two distinct types of outcome measures may be used. In one approach, we identify a cohort of individuals in each community at the beginning of the trial (at the "baseline", just before randomization) and then follow the cohort prospectively to measure changes in behavior or other outcome. Alternatively, we determine changes in the **prevalence** of some condition or behavior in each community, using independent **cross-sectional** samples at the baseline and at the end of the trial (perhaps with intermediate assessments also). Reasons for selecting one or the other approach have been given [9, 13, 15, 20]; some trials include both of these approaches.

As outlined by Green et al. [15], possible advantages of the cohort approach are: that it can target specific segments of the population (e.g. smokers in a smoking cessation trial) and measure the effect of the intervention on such individuals directly; it tends to have better statistical **power**; and it is not influenced by certain changes in the nature of the community (e.g. migration). Possible disadvantages are the problem of losses to follow-up, and the theoretical risk that repeated contact may affect either the actual success of the intervention or at least the self-reports of outcome (such as behavior change). Also, during a long trial, it can be argued that a cohort may become less representative of the community from which it was selected; at a minimum, the surviving members of the cohort will be aging while the age distribution in the community may remain

unchanged. However, this latter issue may not be of concern for trials focusing on the outcome for individuals, even though group randomization had been employed. Conversely, possible advantages of the cross-sectional approach are that it avoids the problem of losses to follow-up (although, of course, **nonresponse** to surveys remains an issue); it reduces concern about repeated assessment influencing the outcome; and it can measure overall changes in a community. Possible disadvantages are that it is less efficient statistically, and it can be influenced by in/out migration. For additional discussions of this topic, see [9], [13], and [20].

Sample size determination for group-randomized trials needs to consider the extra source of variation resulting from the inherent heterogeneity across groups; see, for example, [7], [12], [18], and [27]. Expressed another way, the outcomes of individuals within a group are generally **correlated**, as measured by the intraclass (intracluster) correlation. It is important to have an adequate number of randomized groups to account for the between-group variation. Often, in practice, it is easier to obtain a reasonably large number of individuals per group than it is to obtain a large number of groups, so the latter becomes the factor controlling (and perhaps limiting) the power of the trial. Because of this, to increase power (efficiency), we may consider **stratification** or pair-**matching** of the groups prior to randomization, and then analyzing the data accordingly. While matching could actually produce a loss in efficiency when the number of pairs is particularly small, due to loss of **degrees of freedom** in the analysis [23], gain in power can be achieved depending on how effectively the matching reduces community heterogeneity within pairs (see [11]).

As with the sample size calculations, the method of analysis must account for the correlation of individuals within a group (see [5–7]). One approach that has been used to account for cluster randomization is to adjust a standard (individual-level) analysis for the estimated **"design effect"** (i.e. the variance inflation due to clustering), which depends on the estimated intraclass correlation $\hat{\rho}$ (see, for example, [6]); for clusters of equal size n, the design effect is $[1 + (n - 1)\hat{\rho}]$. Alternatively, a variety of models can be applied to group-randomized data, to account for individual-level **covariates** as well as group variation; for example, by introducing a **random group effect** in an **analysis of variance** or **analysis of covariance**; see, for example, [24], [21], and [9]. Recently, Feng et al. [10] have compared various estimation procedures under a linear model (including **maximum likelihood** under a normal mixed model (*see* **Multilevel Models**), **generalized estimating equations**, and a **bootstrap approach**), and Klar [19] has compared model-dependent and **robust** tests using a generalized-estimating-equations extension of **logistic regression** for **binary** outcome data.

Rather than using a model-based method to account for group randomization, we may prefer a randomization-based approach. With randomization-based inference, the outcome data are analyzed many times (once for each acceptable assignment that could have been employed, according to the randomization process) and then compared with the observed result, without dependence on additional distributional or model-based assumptions. Thus, this approach is robust; **hypothesis testing** (**randomization tests** or permutation tests) and corresponding test-based **confidence intervals** can be designed for group-randomized data, based specifically on the randomization distribution [14, 15]. Such randomization tests involve permuting the assignment of groups (clusters) to intervention condition. Therefore, by definition, they account for the fact that groups (rather than individuals) were randomized. As discussed by Gail et al. [13], one can construct randomization tests that are specific for the design (e.g. unmatched or matched).

For randomization-based **inference**, although permutation is at the group level, individual-level covariates can be incorporated in the analysis (see COMMIT [3] as an example). We can use individual-level data for purposes such as imputation for missing values (*see* **Multiple Imputation Methods**), adjustment (of the intervention effect) for baseline characteristics of the individual participants (*see* **Covariate Imbalance, Adjustment for**), or performing separate analyses in subsets defined by individual-level covariates such as demographic variables [13–15]. In the latter situation, in addition to testing the main effect of intervention, we can construct randomization tests for intervention–covariate **interactions**, to test formally whether the intervention effect differs according to the value of a covariate (*see* **Treatment-covariate Interaction**).

Growth and Development

Growth and development is the process through which the fetus changes in size, shape, composition, and function to become a reproductively mature adult. Growth is generally defined as the change (or rate of change) in one or more continuous measures of size, shape or composition, usually assessed by **anthropometry**. Indeed, the term "growth" is often used as a shorthand for child anthropometry. Development reflects maturation as measured by ordinal markers of function; some markers are inherently discontinuous, while others have an underlying continuum. Menarche, the onset of menstruation, is a marker of development, while height gain is a measure of growth.

General Introduction

Growth is a process that all children undergo, and normal growth is a proxy for good health. Equally, abnormal growth is a nonspecific marker for poor health, as many childhood diseases affect growth to a greater or lesser extent. It is primarily growth that distinguishes pediatrics from adult clinical medicine.

The most obvious manifestation of growth is an increase in physical size, which, unlike many other markers of clinical status, is easily quantified. Statisticians have always been attracted by the qualities of anthropometry data: they are accessible, cheap, and reproducible; in addition, measurements are often highly correlated from one age to another.

Broadly speaking, the rate of change of anthropometry with age is fairly constant. In detail, this does not hold, of course – growth in individuals progresses in fits and starts, and some markers of development, e.g. menarche, are, by their nature, sudden in onset. However, the population assessment of growth is assumed to smooth out these discontinuities, and a requirement of smoothness is imposed commonly on summary curves relating anthropometry to age.

There are broadly two aims to the study of growth and development – **screening** individuals and screening populations. Clinically, the biostatistical challenge is to characterize normal growth and development in a way that optimizes its value as a screening tool. In public health terms, the aim is to assess the health status (*see* **Quality of Life and Health Status**) of *groups* of children, defined on the basis of, say, geography, **ethnic** make-up, or culture.

The way that individual growth is characterized depends on the available information. This may be from one or many measurement occasions, and may involve anthropometry by itself or other **covariates** as well. Ideally, as much relevant information as possible should be used in the clinical assessment.

The reference centile (*see* **Quantiles**) chart, otherwise known as a growth reference or growth standard, is the fundamental tool for assessing growth, and it is used widely throughout the world for this purpose. It summarizes the distribution of anthropometry in a known reference population at different ages through childhood by plotting selected centiles of the distribution against age.

Weight and height are the measurements most commonly expressed as growth references, although other anthropometry has also been summarized in chart form. Figure 1 shows a height centile chart for British boys in 1990, made up of nine centile curves ranging from the 0.4th to the 99.6th centile. The curves are spaced two-thirds of a **standard deviation** score (SDS) apart over the range ± 2.67 SDS, the other centiles being (approximately) the 2nd, 9th, 25th, 50th, 75th, 91st, and 98th.

Also plotted on the chart are heights for a boy measured regularly from birth to 21 years. Until the age of 12 his height stays close to the **median**, but during the adolescent growth spurt it rises to the 75th centile and then falls back to the 25th. This is a common pattern of growth, with a fairly constant centile until puberty, then a rise or fall depending on whether the growth spurt occurs relatively early or late. Thus, the chart can identify unusual growth in two ways – single measurements on a relatively large or small centile, and serial measurements that cross centiles too rapidly (up or down) over time.

The paradox of the growth chart is that even though it contains no information about velocity, being based on single measurements, it is used almost universally to assess growth. The assumption is that subjects should grow parallel to the centile curves, yet this is wrong (see below). In addition, the chart cannot flag poor growth – the degree of centile crossing corresponding to an abnormal pattern of growth is not specified.

Addressing this problem is just one of several statistical issues that arise in the assessment of growth,

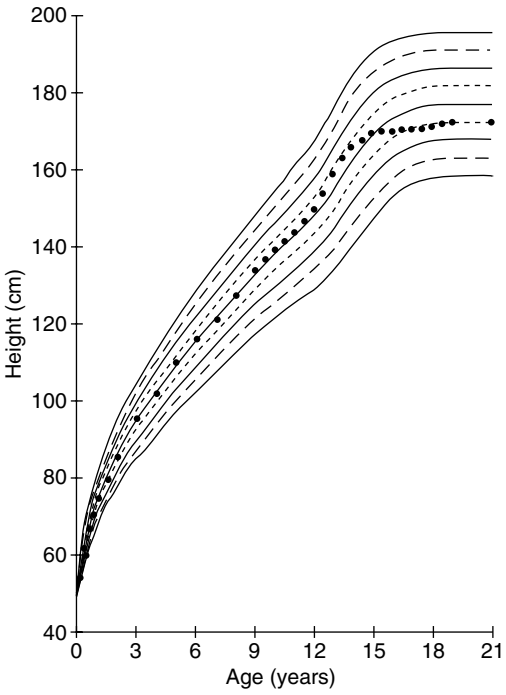

Figure 1 Height reference for British boys in 1990. The nine centiles are two-thirds of an SDS apart, at 0.4, 2.3, 9, 25, 50, 75, 91, 97.7 and 99.6. Superimposed are heights for a French boy measured from birth to 21 years

many of them directly related to the construction and use of growth charts.

Historical Development

In 1885, **Francis Galton** described centiles for summarizing the distribution of body measurements, and Bowditch later applied them to the heights of US schoolchildren. He divided the children into age groups, calculated a set of height centiles in each group, joined up the corresponding centiles across groups, and the centile chart was born.

Since then, centile charts have become very popular as a tool for monitoring growth. The statistical basis for the charts has, until recently, been simplistic – the data grouped by age, centiles for each group obtained by sorting and counting, and the centiles joined across groups with hand-smoothed or polynomially smoothed curves (*see* **Polynomial Regression**). For **normally distributed** measurements, the centiles can be estimated more efficiently using the mean and SD, each smoothed across age. For non-normal data such as weight, the centiles are often obtained assuming a **lognormal distribution**.

Two other types of chart have been developed to help assess growth over time: the velocity chart plots the rate of change in anthropometry against age, and the conditional chart plots the measurement against another covariate besides age. Where the conditional chart is based on two successive measurements, one adjusted for the other, this is a generalized form of velocity chart that has the advantage of adjusting for **regression to the mean**. The simple cross-sectional chart, by analogy to the velocity chart, is commonly called a *distance* chart.

During the 1960s and 1970s Tanner et al. [15] elevated growth chart production to something of an art form, producing hand-smoothed charts for a wide range of body measurements in British children. Since then, growth charts have continued to be developed, locally, nationally and internationally, and this interest has led over the past 10 years to a sharp increase in the statistical literature on the construction of reference centile curves and age-specific reference ranges. There has also been work on new forms of chart that are better suited to the assessment of growth over time.

Description of the Different Types of Study

Anthropometry data are collected either cross-sectionally or longitudinally. In a **cross-sectional** survey, the subjects each provide a single measurement, and the sample is chosen to be representative of some larger population. **Longitudinal** studies involve measuring the same subjects repeatedly, often at regular time intervals. The advantage of longitudinal studies is that they provide information on the distribution of growth velocity, which is not available in cross-sectional surveys.

A compromise design is the semi-longitudinal study, which combines the best features of single- and multiple-measurement designs. For the initial survey, a cross-sectional sample is drawn, then, for later surveys, a fraction of the original sample is redrawn and the balance is sampled afresh. As a simple example, efficient estimates of both height distance and annual height velocity can be obtained throughout childhood from just two surveys, one year apart.

The choice of reference sample is important. Ideally, it should be representative of the target population, obtained by random and, if necessary, by **stratified sampling**. However, there are two issues that complicate sampling for growth studies, widely debated under the titles "representative vs. healthy" and "national vs. local".

Since the chart's purpose is to identify abnormal growth, some people argue that the reference sample should be restricted to normally growing children (i.e. healthy rather than representative). The problem with this is that abnormal growth is hard to define, and it can lead to arbitrary exclusion rules. Using a representative sample avoids the arbitrariness and permits **random sampling**. The term "growth standard" implies a benchmark of healthy growth, whereas the "growth reference" is representative of the population and is neutral about its health status.

There is also concern about the appropriateness of using a nationally or internationally representative growth reference to assess individuals in areas of the world where local growth patterns are different. For instance, is it sensible to use an international reference based on North American children to assess growth in the developing world, as the **World Health Organization** (WHO) has, until recently, recommended?

The answer is that it depends. The growth chart is used in two ways – as a clinical tool and for public health purposes. Clinically, the chart should represent growth in the local **target population**, but in public health terms, international growth statistics need to be comparable – this requires the use of a common growth chart. So the question of "national vs. local" charts comes down to a question of how the chart is used.

Landmark Studies

During this century, much has been written on the statistics of growth, and it is unrealistic to mention all the relevant studies. On the construction of growth charts, Tanner et al. [15] introduced the concept of a velocity chart, and discussed the fundamentals of centile fitting in some detail. Healy [9] described the conditional **regression** chart, subsequently used by Cameron [3] and developed by Cole [5]. The fitting of centile curves became a recognized research topic in 1988, when Healy [10] and Cole [4] described separately fundamentally different methods for dealing with **skew** data. Goldstein [8] illustrated the value of **multilevel models** for analyzing data from semi-longitudinal growth studies, while Wade et al. [16] proposed a method for deriving centiles of ordinal developmental data, for example pubertal staging.

There have also been efforts over the past 60 years to model the shape of the individual human growth curve in infancy and childhood. Jenss & Bayley [11] first proposed the linear plus **exponential** model for infant growth, and other proposed models have been of the fractional polynomial family [14]. Preece & Baines [13] and Jolicoeur et al. [12] described ingenious five- and seven-parameter exponential models describing height growth during childhood.

Statistical Concepts and Techniques

Growth References

Metric for Calculation. The growth reference statistically adjusts anthropometry for age and sex, expressing it as either a centile, a fraction of the median, or a standard deviation score (SDS or Z score) (*see* **Normal Scores**). For statistical analysis, the centile is inappropriate, due to its nonlinear scale. The fraction of the median is simple to calculate and removes the age trend, but it does not adjust for age-related changes in the coefficient of variation (CV). The SDS adjusts for age trends in the mean and CV, and, in addition, it can, if the measurement is **normally distributed**, be converted to a centile. The relationship between measurement, fraction of the median and SDS is as follows:

$$\text{SDS} = \frac{(\text{measurement/median}) - 1}{\text{CV}},$$

which shows that if the CV is constant, then the fraction of the median and the SDS convey the same information.

In practice, measurements with a small CV, like height or head circumference, tend to be close to normally distributed, while other more variable measurements, like weight or skinfold thickness, are appreciably skew to the right. This nonnormality of much anthropometry has posed a problem for the construction of growth references.

Choice of Centiles. The centiles that appear on the growth chart need (i) to be symmetric about the

median, (ii) to be roughly evenly spaced across the distribution, and (iii) to provide reasonable cut-offs for screening purposes in the tails of the distribution. A common choice is the set: 3rd, 10th, 25th, 50th, 75th, 90th and 97th, approximately two-thirds of an SDS apart. Some charts prefer the 5th and 95th to the 3rd and 97th, and the WHO international reference uses whole SDSs from -3 to $+3$, reflecting the wide variation in the populations being assessed.

The scheme used in Figure 1 formalizes the two-thirds SDS spacing, and adds an extra centile in each tail to give cut-offs that screen in 4 per 1000 rather than 3% of the population. This lowers the **false positive rate**, which is desirable at a time when the costs associated with secondary referrals for growth disorder are rising steeply.

Distance Reference. The task of constructing a growth reference involves summarizing the distribution of the measurement as it changes with age. With normally distributed data, this is achieved by modeling the mean and SD (or CV) with suitable parametric or **nonparametric** functions, then calculating the required centiles. For example, if $M(t)$ and $S(t)$ are the mean and CV as functions of age t, and $C_{100\alpha}(t)$ is the 100_αth measurement centile, then

$$C_{100\alpha}(t) = M(t)[1 + S(t) \times z_\alpha],$$

where z_α is the normal equivalent deviate (NED) for tail area α. Parametric functions include fractional polynomials and nonlinear exponential functions, while nonparametric functions are the family of smoothers that includes lowess (*see* **Graphical Displays**), cubic **splines** and kernel smoothers (*see* **Density Estimation**).

Where the data are not normally distributed, they can often be **transformed**; e.g. to logarithms, to restore normality. However, this assumes that the same transformation is suitable at all ages. Where this is not the case, and the degree of nonnormality is age-related, two quite different approaches have been proposed. One is an extension of the "smoothed mean and SD" approach, where an extra parameter summarizing the third moment of the distribution is smoothed across age to give a third curve. This allows for the presence of skewness in the distribution, either as a constant or changing with age. This third parameter may be the power λ in the Box–Cox **power transformation** $g(t) = f(t)^\lambda$, or the shift c in the shifted **lognormal** $g(t) = \log[f(t) - c]$, or the shape parameter in the **gamma distribution**. The first of these alternatives, entitled the LMS method [4], has been used to construct several national growth references. The curves defining the Box–Cox power λ, the median μ, and the CV σ as functions of age t are denoted by $L(t)$, $M(t)$, and $S(t)$, respectively, and the curve for measurement centile 100α is given by

$$C_{100\alpha}(t) = M(t)[1 + L(t)S(t)z_\alpha]^{1/L(t)}.$$

The converse of this equation converts a measurement to a standard deviation score (SDS) Z:

$$Z = \frac{[\text{measurement}/M(t)]^{L(t)} - 1}{L(t)S(t)}.$$

The LMS curves are obtained either by grouping the data, estimating λ, μ and σ by group and then smoothing across groups, or, alternatively, by estimating the curves directly from ungrouped data. Cole et al. [6] have fitted reference curves for height and weight in British children using **penalized maximum likelihood**, leading to LMS curves that are cubic smoothing splines.

Estimating the third **moment** of the distribution as a function of age requires a very large sample ($n > 10^4$, ideally). There have been attempts to estimate the fourth moment in the same way, but it requires much larger samples than are currently available. The benefit is also likely to be small.

An entirely different approach, known as the Healy–Rasbash–Yang (HRY) method [10], estimates each of a set of centile curves using a form of scatterplot smoother, and models them with low-order polynomials in age. The coefficients of the polynomials are each constrained to follow a polynomial in z, the NED of the corresponding centile curves. This leads to a set of centile curves that are of similar shape, and where the spacings between centiles at each age are linked in a way analogous to a cumulative frequency distribution. The order of the polynomial in z determines the form of distribution, according to the shape of the Q–Q normality plot (*see* **Graphical Displays**). A straight line corresponds to a normal distribution, while a quadratic is similar in shape to a skew distribution and a cubic curve allows for **kurtosis**.

Velocity Reference. Distance references identify individuals whose measurement centile is extreme,

e.g. below the 4 per 1000 centile, but they give no information about *changes* in centile from one age to another. The velocity reference is designed to monitor centile change, and it provides centiles of velocity (i.e. growth per unit time) by age in the reference population. Thus, it is the direct analogy of the distance chart, and the same methods can be used to estimate distance and velocity centiles.

Velocity is calculated as $V = \Delta H/\Delta t$, where ΔH is the change in measurement H over time interval Δt. Thus, the population variance of V depends, *inter alia*, on twice the measurement error variance δ^2 of H, and Δt. For this reason, velocity charts have to be constructed for a prespecified time interval, commonly one year for height, and the centile spacings are particularly sensitive to δ, the size of the measurement error.

A relatively low velocity appears as centile crossing on the distance chart. If the distance chart is plotted on the SDS scale, so that the centile curves are horizontal straight lines, the traces of subjects growing abnormally depart from the horizontal. The advantage of working on the SDS scale is that the variability of centile change in the reference population is particularly simple to calculate: the change in SDS between two ages has a standard deviation given by

$$\mathrm{SD}(Z_2 - Z_1) = [2(1 - r)]^{1/2},$$

where Z_1 and Z_2 are the SDSs at each age and r is the correlation between them, based on the reference population.

Regression to the mean, which affects the interpretation of change over time, is not taken into account using the velocity reference. Individuals or groups below a given measurement centile can expect to become less extreme, i.e. to regress towards the mean, when measured again. This affects the velocity reference directly – subjects initially on a low centile have a greater expected velocity than those of the same age starting on a higher centile. For this reason, velocity references are intrinsically flawed, and to quantify regression to the mean, a regression-based conditional reference is needed instead.

Conditional Reference. A conditional reference adjusts (conditions) for another variable as well as age and sex (e.g. parental height or sibling weight). Healy [9] first suggested the use of a regression-based conditional reference to adjust velocity for regression to the mean by regressing the current measurement on the previous measurement:

$$H_2 = \alpha + \beta H_1 + \varepsilon.$$

Centiles for H_2 conditional on H_1 are then given by:

$$C_{100\alpha}(H_2|H_1) = \alpha + \beta H_1 + \sigma \times z_\alpha,$$

where σ is the residual standard deviation (RSD) from the regression. This regression-based reference of H_2 on H_1 then correctly predicts H_2 given H_1. Berkey et al. [2] extended the regression-based approach to two or more conditioning variables.

As with the velocity reference, the use of an SDS scale greatly simplifies the conditional reference, and the equation above becomes:

$$C_{100\alpha}(Z_2|Z_1) = rZ_1 + (1 - r^2)^{1/2} Z_\alpha.$$

This allows Z_2 to be calculated for a range of Z_1 values, which, when plotted on the SDS distance chart, define a line whose slope is the required 100αth conditional velocity centile. Several such lines can be superimposed on the SDS distance chart to provide for the simultaneous assessment of distance and velocity. The values of Z_1 and Z_2 can also be converted back and plotted on the original measurement scale. Figure 2 illustrates a combined distance and 5th centile conditional velocity chart for weight in British boys during the first year of life.

Importance of Measurement Error. The principle of growth monitoring is that individuals who cross centiles excessively are more likely to have an underlying growth disorder. The **sensitivity** and **specificity** of a **screening** test based on centile crossing, be it velocity $(Z_2 - Z_1)$ or conditional velocity $(Z_2 - rZ_1)$, depend critically on the **standard error** of the centile change, which in turn depends on the size of the **correlation** r between the measurements, which is mediated by the underlying measurement error. Unlike the distance chart, the velocity chart is highly sensitive to even a modest increase in the **measurement error**, which can increase the false positive rate dramatically. Effective growth monitoring demands high-quality measurements.

Developmental Markers. The age of occurrence of binary markers such as menarche is usually estimated

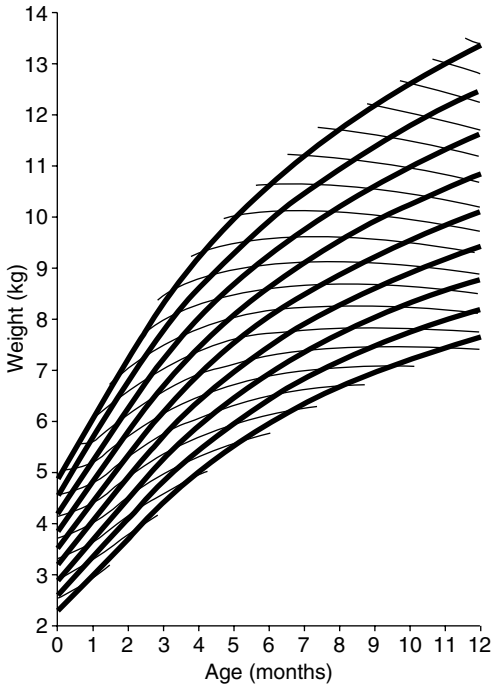

Figure 2 Conditional weight reference for British boys in 1990. The heavy lines are nine distance centiles two-thirds of an SDS apart, as in Figure 1. The slopes of the fainter lines represent the 5th centile of conditional velocity, as measured over a four-week period. The slope of an individual infant's weight curve needs to be compared with the slope of the nearest velocity line, to detect weight gain below the 5th centile

using probit or logit analysis (*see* **Quantal Response Models**), based on information from individual subjects about whether or not the event has occurred. This is a less biased estimate than the mean of the recalled age of the event, and adjusts for **censoring** in younger subjects.

Wade et al. [16] have described a method for estimating age-related centiles for ordinal data, which generalizes this approach.

Growth Curves

Growth curve analysis is a general term for the study of correlated measurements over time in individuals and groups, a topic that has been much studied over the last 30 years. It has tended to be of statistical rather than pediatric interest, and has been largely superseded in recent years by more powerful methods such as **generalized estimating equations** and **multilevel models**.

Growth Models and Adult Prediction

The shape of the human stature growth curve has always fascinated auxologists. Early attempts to model it parametrically focused on the early part of life, where the velocity decreases monotonically. Second-order fractional polynomials and the linear-exponential model both fit well over this age range [1]. However, the greater challenge has been to model height throughout childhood, including the pubertal growth spurt where the velocity rises to a peak then falls to zero. Preece & Baines [13] proposed a five-parameter exponential model, which fitted puberty well but failed to model infant growth. Subsequently, Jolicoeur et al. [12] came up with a seven-parameter model that has been found to fit well from birth to adulthood.

Gasser et al. [7] have developed nonparametric kernel-based methods to model the distance, velocity and acceleration curves of stature throughout childhood. By combining individual curves on suitably transformed age scales, they have demonstrated the existence of subtle features of the growth curve, most notably a transient peak in height velocity around age 7 (the mid-growth spurt).

Clinicians like to be able to predict adult height for children being treated for a growth disorder, using information on the height of parents or the child's stage of maturation. Statistically, the best way to do this is by **empirical Bayes**, combining the child's own measurements with information on the population child–adult growth curve. This is useful for monitoring the effect of clinical interventions (e.g. treatment with growth hormone).

Body-size Scaling

Weight and height are highly correlated with each other, and both are proxies for body size. Weight adjusted for height removes the size component, and leaves an index of shape. Shape in this context is viewed as a measure of body fatness, and the adjustment is carried out on the double logarithmic scale, leading to a power index of the form weight/height^n. When $n = 2$, the index is known as the Body Mass Index (BMI), and it is widely used as a measure of adiposity in adults and children of both sexes. The

choice of $n = 2$ gives an index that is only weakly correlated with height (ideally it should be uncorrelated), and that is also well correlated with direct measures of body fat. Like other variables measured during childhood, its distribution changes with age and needs to be adjusted accordingly.

Ratio indices like the BMI can be abused, usually when the form of the index is assumed (wrongly) to guarantee a lack of correlation between it and height. If this is of primary concern, then (log)weight should be adjusted for (log)height directly, using covariance analysis (*see* **Analysis of Covariance**). However, for clinical and epidemiologic use, the BMI is a useful tool for classifying overweight and obesity.

Guidelines On Statistical Methods in Clinical Trials

In the early 1960s, the thalidomide disaster led to a tightening of the national regulations that dictate the evidence required for authorization of a medicinal product. Forty years on, these regulations still provide the basis upon which all regulatory authorities assess medicinal products. Although the statutory basis for regulations is different in all countries (the EU is governed by EC directives and the US is governed by Federal Government Statutes), the underlying principles for assessment of medicinal products are common, i.e. the evaluation of the quality, safety and efficacy of the medicinal product given the proposed product labeling (*see* **Drug Approval and Regulation**).

As with all statutes, some interpretation of the law is required. The EC has issued its Notice to Applicants [7]. The Food and Drug Administration (FDA) regularly publishes the Code of Federal Regulations and the Japan Pharmaceutical Reference is regularly issued in Japan [12]. These elucidate some of the high level issues arising in drug authorization but do not address specific clinical trial issues. These can only be addressed in guidelines or guidance documents. Guidelines are issued by a variety of organizations, including regulatory authorities, health organizations and expert groups, and as a result of differences in health care, populations and regional traditions in clinical research around the world, the detailed technical requirements stated in these guidelines often differ between countries and expert groups.

Many guidelines focus on the appropriate design and analysis of clinical trials in different therapeutic fields and mention statistical issues, but only in a relatively limited way. In the last 15 years there has been a clearer understanding that statistical excellence in the design and analysis of clinical trials is a necessary requirement to obtain evidence that is sufficient for a marketing authorization. This realization led to the publication of national regulatory guidelines which addressed statistical methodology in clinical trials and provided guidance on reporting [1, 8, 20].

In the 1990s there was increasing pressure on pharmaceutical companies to obtain more rapid global product approvals. The most efficient way to achieve this is to perform one drug development program that is suitable for all regulatory authorities. This is difficult to achieve when guidelines for drug development differ around the world. The need for the standardization of clinical trial methodology worldwide has led to the establishment of the International Conference on Harmonization (ICH) of Technical Requirements for Registration of Pharmaceuticals for Human Use. In 1998, the ICH recommended for adoption the guideline on Statistical Principles for Clinical Trials [11], which is a consensus document covering the views of the US, Japan and the EU. This important document sets worldwide statistical standards for clinical trials.

In this article the background to the ICH process is explained. An overview of ICH E9 is presented and other important sources of guidance to statisticians working in clinical trials are discussed. The summary of ICH E9 presented here is inevitably limited in scope and perspective and cannot do justice to the carefully crafted wording of the complete document. The reader for whom the content of ICH E9 is important is strongly advised to refer to the complete guideline.

The ICH

The ICH was initiated in April 1990 to discuss scientific and technical aspects of product registration [3]. It is a joint initiative involving the regulatory authorities and pharmaceutical industry representatives from each of the three regions. The EU is represented by the European Agency for the Evaluation of Medicinal Products (EMEA) and the European Federation of Pharmaceutical Industries Associations (EFPIA). Japan is represented by the Ministry of Health and Welfare (MHW) and the Japan Pharmaceutical Manufacturers Association (JPMA) and the US is represented by the FDA and the Pharmaceutical Research and Manufacturers of America (PhRMA). There are also observers from other bodies and regions.

The purpose of the ICH is to make recommendations on the ways to achieve greater harmonization in the interpretation and application of technical guidelines and requirements for product registration in the development of new medicines. The objective of such harmonization is a more economical use of human, animal and material resources, and the elimination of unnecessary delay in the global development and availability of new medicines

whilst maintaining safeguards on quality, safety and efficacy, and regulatory obligations to protect public health. The ICH considers topics related to (preclinical) safety, quality and efficacy (including clinical safety) (*see* **Preclinical Treatment Evaluation**).

The basic principles of the ICH are to

- develop scientific consensus through discussions between regulatory and industry experts,
- provide wide consultation of the draft consensus documents through normal regulatory channels,
- produce a harmonized text, and
- gain commitment from regulatory authorities to implement the ICH harmonized texts.

Each new topic is tackled by an Expert Working Group (EWG) that includes members from the six cosponsors. The EWG then follows an extensive (five-step) process of consensus building and consultation during which comments are widely sought from all interested parties. When a final text is agreed by the EWG and accepted by the ICH Steering Committee, it is recommended for adoption by the authorities in each of the three regions.

Table 1 ICH E9 Expert Working Group

Europe – regulatory authority

Stephen Ruberg, Hoechst Marion Roussel Inc, Missouri, USA

ICH E9: Statistical Principles for Clinical Trials

In November 1995, the ICH Steering Committee decided that an ICH guideline on statistical methodology should be developed (ICH E9). The CPMP *Note for Guidance on Statistical Methodology in Clinical Trials* [1] had been completed in the previous year. It had been created as a result of considerable collaborative effort among many European statisticians from regulatory agencies, industry and academia [14, 17]. It was the most up-to-date regional guideline on statistics and so formed the basis for the new ICH guideline. However, the ICH guideline was also heavily influenced by the earlier US and Japanese statistical guidelines [8, 20].

The EWG for ICH E9 consisted of 12 statisticians: two regulatory and two industry representatives from each of the three ICH regions. Table 1 gives a list of members of the Working Group. They decided that the guideline should concentrate on principles rather than detailed procedures and that it should attempt to address a broader audience than statisticians alone. The draft document (ICH Step 2) was discussed in the worldwide statistical community so that a large number of statisticians and other scientific experts from all three regions had an influence on the final content. In February 1998 the ICH Steering Committee recommended the guideline for adoption to the regulatory bodies of the EU, Japan and the US. CPMP adopted the guideline at the end of March 1998 (and it came into operation in Europe in September 1998). In September 1998 the guideline came into operation in the US and was published by the FDA in the Federal Register. The MHW adopted the guideline in November 1998. Many therapeutic guidelines now directly reference ICH E9 and this helps to ensure that common statistical standards apply in clinical trials. It also increases the awareness of all physicians leading drug development programs that appropriate statistical input is essential for regulatory approval. Therefore, the ICH E9 guideline is essential reading for all statisticians working in the environment of clinical trials.

The full guideline is published in the statistical literature [11] with an introduction by Lewis [15] or can be obtained from the World Wide Web in English and Japanese (see Table 2).

The scope and content of the guideline are now addressed by presenting key points from each section of the guideline, using the ICH E9 section headings.

Introduction

The guideline stresses the critical role of statistical expertise in clinical research within the whole drug development program. The focus is on statistical principles in confirmatory trials. It does not prescribe specific methods or procedures.

The underlying principles of the guideline deal with minimizing bias and maximizing precision. Potential sources of bias need to be identified as completely as possible so that attempts to limit such bias may be made, otherwise the ability to draw valid conclusions from the clinical trial may be seriously compromised.

Sources of bias may arise in the design, conduct or analysis of a clinical trial. Therefore, for each clinical trial it is assumed that important details of the design, conduct and proposed statistical analysis will be specified in a trial protocol. The extent to which the procedures in the protocol are followed and the primary analysis is planned a priori will contribute to the degree of confidence in the final results and conclusions of the trial. Since bias can occur in subtle or unknown ways and its effect is not measurable directly, it is important to evaluate the robustness of the results.

Considerations for Overall Clinical Development

Trial Context. The broad aim of the process of clinical development of a new drug is to find out whether there is a dose range and schedule at which the drug can be shown to be simultaneously safe and effective, to the extent that the risk–benefit relationship is acceptable (*see* **Benefit/Risk Assessment in Prevention Trials**). The particular subjects who may benefit from the drug, and the specific indications for its use, also need to be defined.

Confirmatory trials are required to provide robust evidence in support of all key claims related to efficacy or safety. Confirmatory trials should only address a limited number of questions with a predefined primary objective, which leads to the primary hypothesis and is the basis upon which the trial is designed and analyzed. Exploratory trials may have less precise objectives, a more flexible design and involve data exploration with data-dependent choice of hypotheses. Exploratory trials cannot form the basis of formal proof of efficacy but may contribute to the total body of evidence.

Scope of Trials. Clinical trial populations range from a narrow subgroup of patients in early trials, through to a wider representation of the target population in confirmatory trials.

Clinical trials generally contain one primary variable, which should be capable of providing the most clinically relevant and convincing evidence related to the primary objective of the trial (*see* **Outcome Measures in Clinical Trials**). The use of a reliable and validated variable with which experience has been gained in earlier studies or published literature is recommended. Secondary variables, their relative importance and roles in interpretation of results, should be defined in the protocol. Issues are discussed relating to specific forms of primary and secondary variables, namely composite variables, global assessment variables, multiple primary variables, surrogate variables and categorical variables.

Design Techniques to Avoid Bias. The optimal design of studies in a marketing application is the double-blind (*see* **Blinding or Masking**), randomized controlled trial. However, it is recognized that when such trials are not feasible, single-blind or open studies may be necessary.

Blinding should be maintained throughout the conduct of the trial and only when the data are cleaned to an acceptable level should unblinding occur. Some methods to overcome difficulties in blinding are discussed (double dummy treatment, separate assessors for patient care and outcome assessment, centralized randomization).

Randomization introduces a deliberate element of chance into the treatment assignment and provides a sound basis for quantitative evaluation of the

evidence relating to the treatment effects. It tends to produce treatment groups in which the distributions of prognostic factors, known and unknown, are similar. In combination with blinding, randomization helps to avoid possible bias in the selection and allocation of subjects arising from the predictability of treatment assignments. Detailed considerations about the production of a randomization schedule are discussed, with specific guidance for crossover trials, multicenter trials, stratified randomization and dynamic allocation.

Bias can also be reduced at the design stage by specifying procedures in the **protocol** aimed at minimizing any anticipated irregularities in trial conduct that might impair a satisfactory analysis, including various types of protocol violations, withdrawals and missing values. The protocol should consider ways to reduce the frequency of such problems and to handle the problems that do occur in the analysis of data.

Trial Design Considerations

Design Configuration. The most common clinical trial design for confirmatory trials is the parallel group design in which subjects are randomized to one of two or more treatment groups. **Crossover designs** in which each subject is randomized to a sequence of two or more treatments are discussed and the importance of avoiding carryover is stressed. Issues related to **factorial designs** are also presented.

Multicenter Trials. Multicenter trials are used to facilitate the accrual of subjects within a reasonable time frame and to provide a better basis for the subsequent generalization of findings. A common protocol is needed for all centers, the manner in which the protocol is implemented should be clear, and procedures should be standardized as completely as possible. It may be advantageous to avoid excessive variation in the numbers of subjects per center if it is later found necessary to take into account the heterogeneity of the treatment effect from center to center. Rules for combining centers in the analysis should be justified and specified in the protocol or at least at the time of the blind review.

The statistical model used in the primary analysis would not normally be expected to include a term for treatment-by-center interaction (*see* **Treatment-covariate Interaction**). In some trials with very few subjects per center there may be no reason to expect centers to have an effect of clinical importance. In other situations the limited numbers of subjects per center make it impracticable to include the center effects. Consequently, it is not appropriate to include a term for center in these models and it is not necessary to stratify randomization by center.

Type of Comparison. Efficacy is most convincingly established by demonstrating superiority to placebo, or an active control, or by demonstrating a dose–response relationship. Most of the guidance given in this document relates to superiority trials.

Trials that use an active control can also be used to test the objective of equivalence (*see* **Equivalence Trials**) or noninferiority (that the efficacy of an investigational product is no worse than that of the active control). Such trials, which do not also include a placebo control or multiple doses of the new drug, have no measure of internal validity and thus make external validation necessary. These trials are not conservative in nature, so that many flaws in the design or conduct of the trial will tend to bias the results towards a conclusion of equivalence. Consequently, the design and conduct of such trials should receive special attention. This discussion has been augmented in ICH E10 (on Choice of Control Groups), which provides greater insight into the problems of demonstrating the internal and external validity of noninferiority trials.

Group Sequential Designs. Group sequential designs are most commonly applied to facilitate the conduct of interim analyses (*see* **Data and Safety Monitoring**). The statistical methods employed should be specified in advance of the availability of information on subject treatment assignments.

Sample Size. The number of subjects in a clinical trial should always be large enough to provide a reliable answer to the questions addressed (*see* **Sample Size Determination**). This number is usually determined by the primary objective of the trial. If this is not the case, then it should be made clear and justified. The method by which the sample size is calculated and the estimates of quantities used in the calculations should be stated in the protocol. The basis of the estimates should be described and the sensitivity of the sample size estimate to deviations from these assumptions should be investigated.

Data Capture and Processing. The form and content of the information collected should focus on the data necessary to implement the planned analysis and be in full accordance with the protocol and with Good Clinical Practice (ICH E6).

Trial Conduct Considerations

Trial Monitoring and Interim Analysis. Careful conduct of a clinical trial according to the protocol has a major impact on the credibility of the results (*see* **Clinical Trials Audit and Quality Control**). Careful monitoring that oversees the quality of the trial can ensure that difficulties are noticed early and their occurrence or recurrence minimized. This type of monitoring does not require access to information on comparative treatment effects, nor unblinding of the data and therefore has no impact on the Type I error.

Interim analysis is another form of "monitoring". It involves breaking the blind to make treatment comparisons and should therefore be planned in the protocol with considerations of the potential biases that may be incurred.

Changes in Inclusion and Exclusion Criteria. If changes to the inclusion and exclusion criteria (*see* **Eligibility and Exclusion Criteria**) of a trial are necessary, then they should be made without breaking the blind and should be described in a protocol amendment, which should cover any statistical consequences.

Accrual Rates. If the rate of accrual falls appreciably below the projected level, then the reasons should be identified and remedial actions taken.

Sample Size Adjustment. If the sample size is revised during the course of a trial, then the steps taken to preserve blindness and consequences, if any, for the Type I error and confidence intervals should be explained.

Interim Analysis and Early Stopping. An interim analysis is any analysis intended to compare treatment arms with respect to efficacy or safety at any time prior to the formal completion of a trial (*see* **Data and Safety Monitoring**). Since the number, methods and consequences of these comparisons affect the interpretation of the trial, all interim analyses should be carefully planned in advance and described in the protocol. Special circumstances may dictate the need for an interim analysis that was not defined at the start of a trial, in which case a protocol amendment describing the interim analysis should be completed prior to the unblinding of the data for the interim analysis.

The protocol (or an amendment before the first interim analysis) should describe the schedule of interim analyses, or at least the considerations that will govern its generation. The stopping guidelines and their properties should be clearly described in the protocol.

The execution of an interim analysis should be a completely confidential process and all investigator and sponsor staff involved in the conduct of the trial should remain blind to the results of such analyses (except for those directly involved in the execution of the interim analysis). When a sponsor performs an interim analysis, particular care should be taken to protect the integrity of the trial and limit the dissemination of results.

Any interim analysis that is not planned appropriately (with or without the consequences of stopping the trial early) may flaw the results and weaken confidence in the results. Therefore, such analyses should be avoided. The reason for an unplanned interim analysis should be explained in the study report and an assessment of the potential magnitude of bias and impact on interpretation of results discussed.

Role of an Independent Data Monitoring Committee. An Independent Data Monitoring Committee (*see* **Data Monitoring Committees**) may be established to assess the progress, safety data and critical efficacy variables of a trial, and to make recommendations about whether to continue, modify or terminate the trial. It should have written operating procedures and maintain records of all its meetings, including interim results (which should be available for regulatory review).

Data Analysis Considerations

Prespecification of the Analysis. The statistical section of the **protocol** should include all the principal features of the proposed confirmatory analysis of the primary variable(s) and the way in which anticipated analysis problems will be handled.

A separate statistical analysis plan may be written after finalizing the protocol. It gives a more technical and detailed elaboration of the analyses of primary and secondary variables, but only results from analyses envisaged in the protocol can be regarded as confirmatory. The statistical analysis plan should be reviewed and possibly updated as a result of the blind review of the data (see Evaluation and Reporting section below). It should be finalized before breaking the blind. If the blind review suggests changes to the principal features in the protocol, then these should be documented in a protocol amendment. The timing of the finalization of the statistical analysis plan and the breaking of the blind should be formally recorded.

Analysis Sets. The sets of subjects whose data are to be included in the main analyses should be defined in the statistical section of the protocol.

The intention-to-treat principle [8, 16] (*see* **Intention to Treat Analysis**) implies that all randomized subjects should be included in the primary analysis (for superiority trials). Compliance with this principle would necessitate complete follow-up of all randomized subjects for study outcomes. Since this may be difficult to achieve in a clinical trial, the term "full analysis set" is introduced to describe the analysis set which is as complete as possible and as close as possible to the intention-to-treat ideal of including all randomized subjects. A few circumstances might lead to the exclusion of randomized subjects from the full analysis set (e.g. major eligibility violation, failure to take any medication or no data post-randomization). Concerns related to all these exclusion criteria are discussed in the guideline and it is noted that no analysis is complete unless the potential biases (arising from these exclusions or any other reasons) are addressed.

The "per protocol" set of subjects is sometimes described as the "valid cases" or "efficacy" or "evaluable subjects" sample. It refers to a subset of subjects in the full analysis set who are compliant with the protocol. The precise reasons for excluding subjects from the per protocol set should be fully documented before unblinding.

It is advantageous to demonstrate a lack of sensitivity of the principal trial results to alternative choices of analysis set. In superiority trials, the full analysis set is generally used in the primary analysis, but in an equivalence or noninferiority trial use of the full analysis set is not generally conservative and its role should be considered carefully.

Missing Values and Outliers. Missing values represent a potential source of bias in a clinical trial. A trial may be regarded as valid, none the less, provided the methods for dealing with missing values are sensible. If the number of missing values is substantial, then an investigation should be made into the sensitivity of the results to the method of handling missing values. The influence of outliers can be explored in a similar manner.

Data Transformation. The decision to transform key variables prior to analysis is best made during the design of the trial on the basis of similar data from earlier clinical trials and should be specified in the protocol. The decision on whether and how to transform a variable should be influenced by the preference for a scale that facilitates clinical interpretation.

Estimation, Confidence Intervals and Hypothesis Testing. The statistical section of the protocol should specify the hypotheses to be tested and the treatment effects to be estimated. Estimates should be accompanied by confidence intervals and their method of calculation specified. The underlying statistical model (including all factors and covariates to be fitted) should be fully specified. The primary analysis of the primary variable should be clearly distinguished from supporting analyses of the primary or secondary variables.

It is important to clarify whether one- or two-sided tests will be used and to justify prospectively the use of one-sided tests. The approach of setting Type I errors for one-sided tests at half the conventional Type I error used in two-sided tests is preferable in regulatory settings.

Adjustment of Significance and Confidence Levels. In confirmatory trials, any important aspects of **multiplicity** should be identified in the protocol and adjustments to the Type I error should be implemented and explained. Alternatively, an explanation of why adjustment is not thought necessary should be provided.

Subgroups, Interactions and Covariates. Pretrial deliberations should identify the covariates and factors expected to have an important influence on the primary variable and should consider how to account for these in the analysis in order to improve precision

and to compensate for any lack of balance between treatment groups (*see* **Covariate Imbalance, Adjustment for**). Special attention should be paid to the role of baseline measurements of the primary variable. It is not advisable to adjust the main analyses for covariates measured after randomization, because they may be affected by the treatments.

The treatment effect may vary with a subgroup or covariate (*see* **Treatment-covariate Interaction**). In some cases, such interactions are of particular interest and a subgroup analysis or model including interactions is part of the planned confirmatory analysis. In most cases, however, analyses of subgroups or interactions are exploratory and should be interpreted cautiously.

Integrity of Data and Computer Software Validity. The credibility of the results depends on the quality and validity of the methods and software used for data management and statistical analysis (*see* **Data Management and Coordination; Clinical Trials Audit and Quality Control**).

Evaluation of Safety and Tolerability

Scope of Evaluation. In early phase clinical trials, the evaluation of safety is mostly exploratory. In later phases, the safety and tolerability profile of the drug can be characterized more fully. Specific comparative safety claims should be supported by relevant evidence from confirmatory trials designed to evaluate safety.

Choice of Variables and Data Collection. The safety data collected will depend on various characteristics of the drug, the type of subjects to be studied and the duration of the trial. A consistent methodology for data collection and evaluation is recommended throughout the clinical trial program.

Set of Subjects to be Evaluated and Presentation of Data. The set of subjects to be summarized for safety is usually those who received at least one dose of the investigational drug. All adverse events should be reported, whether or not they are considered to be related to treatment, but the summarization of "treatment emergent" events is also helpful to reduce the noise caused by background signs and symptoms of the disease. If treatment is long-term and a substantial proportion of treatment withdrawals or deaths are expected, then time to event analyses should be considered.

Statistical Evaluation. The previous section noted that there are a number of methods for calculating the incidence of an adverse event and that the method used should be defined in the protocol. For laboratory data, it is recommended that both the treatment means and the numbers outside certain thresholds should be evaluated.

The calculation of P values is sometimes useful as an aid to evaluating a specific difference of interest, but the general lack of sensitivity of such safety comparisons means that small but clinically important differences (*see* **Clinical Significance Versus Statistical Significance**) may be overlooked (Type II error). In addition, when P values are used as a flagging device, the multiplicity of tests makes the P values difficult to interpret in a conventional manner.

Integrated Summary. Safety information is commonly summarized across trials, but the usefulness of this summary is dependent upon the trials being adequate and well-controlled with high quality data (See ICH M4: Common Technical Document).

Reporting

Evaluation and Reporting. The reporting of statistical work is covered in the ICH E3 guideline and is therefore covered relatively briefly in ICH E9. It is however noted that statistical judgment should bear on the analysis, interpretation and presentation of results, so the statistician should be a member of the team responsible for the clinical study report.

The use of the blind review is described and it is stated that decisions made at the time of the blind review should be described in the report and should be distinguished from those decisions made after the statistician was unblinded. Many of the detailed aspects of presentation and tabulation should be finalized at the time of the blind review. It is noted that statisticians or other staff involved in the unblinded interim analysis should not participate in the blind review or in making modifications to the statistical analysis plan. Attention should be paid to any differences between the planned analysis as described in the protocol, amendments and statistical

analysis plan based on the blind review and the actual analysis.

All subjects who entered the trial should be accounted for in the report. The effect of losses of data on the main analyses should be considered carefully. Descriptive statistics should illustrate the important features of the primary and secondary variables and of key prognostic and demographic variables. The results of significance tests should be reported with precise p-values.

Summarizing the Clinical Database. An overall summary and synthesis of the evidence on safety and efficacy from all the clinical trials is required for a marketing application and may be accompanied, when appropriate, by a statistical combination of results (*see* **Benefit/Risk Assessment in Prevention Trials**). It is always valuable to present the main results of a series of similar trials in an identical form to permit comparison, usually in tables or graphs that focus on estimates and confidence intervals. To facilitate these analyses, common methods for the evaluation of primary and secondary variables and methods for handling protocol deviators are worthwhile, and essential for **meta-analysis**. Any statistical procedures used to combine data across trials should be described in detail. Attention should be paid to the possibility of bias arising from selection of trials, homogeneity of results and the proper modeling of the various sources of variation. The sensitivity of conclusions to the assumptions and selections made should be explored.

In summarizing safety data, it is important to examine the safety database thoroughly for any indications of potential toxicity, and to follow up any indications by looking for an associated supportive pattern of observations. The risks associated with identified adverse effects should be appropriately quantified to allow a proper assessment of the risk–benefit relationship.

Other ICH guidelines

By December 2003, the text of 48 ICH guidelines had been finalized and most of them had been adopted in all three regions. Fifteen of the finalized guidelines are denoted as "Efficacy"topics and include diverse topics from clinical safety to good clinical practice that would be of interest to many statisticians. In December 2003, further three ICH guidelines were issued in draft from for consultation. This demonstrates that the ICH process has slowed considerably and its major work is probably complete. However, it remains possible to propose and develop new topics and the need to revise topics must always be remembered.

Table 3

ICH topic number	Guideline title
E3	Structure and Content of Clinical Study Reports
E4	Dose Response Information to Support Drug Registration
E5	Ethnic Factors in the Acceptability of Foreign Clinical Data
E6	Good Clinical Practice
E7	Studies in Support of Special Populations: Geriatrics
E8	General Considerations for Clinical Trials
E9	Statistical Principles for Clinical Trials
E10	Choice of Control Group in Clinical Trials
E11	Clinical Investigation of Medicinal Products in the Pediatric Population
E12A	Principles for Clinical Evaluation of New Antihypertensive Drugs
M4	Common Technical Document *(format for summary documents)*

Table 3 lists those ICH guidelines that have most impact on the statistician working on clinical trials. Day and Talbot [4] provide a brief overview of ICH E3, E9 and E10. The full text of all ICH guidelines can be obtained from the ICH website (Table 2).

Other guidelines

The CPMP, FDA and MHW produce many new guidelines each year covering issues in all areas of drug development (from pharmaceutical work-up to postmarketing surveillance), and across a broad spectrum of therapeutic indications (from the use of hormone replacement therapy to treatments for cardiac failure). Current details of the US, European and Japanese guidelines can be easily accessed on the World Wide Web (Table 2).

The CPMP develops two types of guideline. A Note for Guidance is produced when there is substantial experience in a particular field (hypertension, epilepsy). A Points to Consider

document is prepared when there is limited experience, for example, acute respiratory distress syndrome. All CPMP (and FDA) guidelines are released for public consultation before they are finalized.

In 1999, the CPMP announced that it was to prepare several Points to Consider guidance documents about biostatistical/methodological issues arising from discussions on licensing applications [19]. By December 2003, five of these had been issued, on the following topics:

- Switching between superiority and noninferiority;
- Applications with: 1. meta-analyses; 2. one pivotal study;
- Missing data;
- Multiplicity issues in clinical trials;
- Adjustment for baseline covariates.

A draft Points to Consider document on "Choice of non-inferiority margin"was issued for consultation in early 2004, and "Use of statistical methods for flexible design and analysis of confirmatory clinical trials"is expected to be released for consultation later in the year. A concept paper outlining the development of guidance on "Data monitoring committees"is also expected in 2004.

The most difficult debates arise when the guidance given by the FDA and CPMP is markedly different. The most fervent statistical debate in recent years (*Journal of Biopharmaceutical Statistics*, Part 1, Volume 7, 1997) has focused on the FDA guidance for statistical approaches to establishing bioequivalence, which includes methodology for establishing population and individual bioequivalence [10]. This compares with the publication of the revised CPMP Note for Guidance on bioavailability/bioequivalence [2], which promotes "average" bioequivalence. Another FDA guideline which has a major statistical content is that on population pharmacokinetics [10] and for this topic no CPMP guidance is available at present.

All therapeutic guidelines contain important information about trial design relevant to statisticians working in that field. In many cases these therapeutic guidelines also introduce interesting statistical topics such as twofold testing strategies to achieve a primary objective (e.g. CPMP Note for Guidance on Bipolar Disorder) and designs to prove lack of disease progression (e.g. CPMP Note for Guidance on Parkinson's Disease).

This article has focused on guidelines that are issued by the regulatory authorities in the US and EU. There are many other helpful guidelines that are issued from a number of sources such as other regulatory agencies (Canada, Australia, Nordic Regions), global and local health organizations (World Health Organization, Medical Research Council) and statistical organizations (**Statisticians in the Pharmaceutical Industry**).

Discussion

The ICH E9 guideline provides a consensus view on statistical principles in clinical trials. The guideline is a useful reference to promote the importance of statistical input to all aspects of a clinical trial (design, conduct, analysis and reporting). It also provides the basis for further discussion of unresolved or contentious statistical issues and specific topics of debate are now being addressed in the literature. For example, Edwards [5] explores the circumstances under which the Type I error is influenced by the failure to prespecify the statistical model and Lin [19] discusses the weighting of centers in a multicenter trial.

Consensus on Principles Must be Accompanied by Statistical Understanding

Statisticians working within the pharmaceutical environment are used to working within a highly regulated framework. Consequently, the creation of guidelines related to statistical matters is generally welcomed and considered as a tool to facilitate consensus amongst all parties involved in the worldwide development and authorization of medicinal products. However, statisticians working in other fields of application often consider the guidelines and need for careful prespecification of analysis plans in medical statistics as a restrictive block on their statistical prowess and expertise.

Lewis [13] clearly understood this concern,

> ... Finally, let me quieten the fears that I might be advocating *standardisation* of methodology. I will fight as determinedly as the next man to prevent our statistical work from becoming in any way an automatic unthinking process. There are, of course, strong pressures in this direction in the interest of efficiency and economy. I do ask for greater efforts to reach consensus agreement on general approaches.

> I am convinced we can move a long way down this road without stifling individual freedom.

It is important to remember that regulations are statutory and enforceable by law. Guidelines, however, are based on experience to date and seek to provide a consensus across different disciplines or regions. The use of a guideline as a "cookbook" with no scientific thought will rarely result in a recipe for success. Guidelines can never address all the issues that arise in the complicated world of clinical trial experimentation, but they can provide helpful advice and a starting point for scientific input. To this must be added the expertise of those involved in the experiment, in order to obtain results that are robust and meaningful.

Professionalism of Clinical Trials Statisticians

In section 5.4.1 of ICH E6 (on Good Clinical Practice) it is stated that

> The sponsor should utilise qualified individuals, (e.g. biostatisticians, clinical pharmacologists, and physicians) as appropriate, throughout all stages of the trial process, from designing the protocols and CRFs and planning the analyses to analysing and preparing interim and final clinical trial reports.

In section 1.2 of ICH E9 it is stated that:

> ... it is assumed that the actual responsibility for all statistical work associated with clinical trials will lie with an appropriately qualified and experienced statistician, as indicated in ICH E6. The role and responsibility of the trial statistician, in collaboration with other clinical trial professionals, are to ensure that statistical principles are applied appropriately in clinical trials supporting drug development. Thus, the statistician should have a combination of education/training and experience sufficient to implement the principles articulated in this guidance.

The final sentence of this quotation has led to great debate in the statistical community questioning the level of education/training and experience that are sufficient to qualify a person as a professional clinical trials statistician [6]. This is a particularly difficult matter in Japan where very few statisticians are academically qualified [18].

Implementation and Updating of Guidelines

The ICH initiative is committed to "ensure that there is a process for updating and supplementing the current ICH guidelines, when necessary and monitoring their use, so that the benefits of harmonisation achieved so far are not lost" (ICH website).

A guideline can only be properly judged when it has been put into practice for some time and reviewed with experience from its practical application. In January 2004, it is unclear whether ICH has a specific plan to review E9, but this will be necessary if the document is to continue to have maximum value.

Guttman Scale

A Guttman scale is based on a set of items which address a one-dimensional latent variable or attribute. The response options for each of the items is of the form agree/disagree or Yes/No (*see* **Binary Data**). For example, consider an investigation in which we would like to measure a subject's physical ability. Suppose the following four items are developed: "Can you walk one city block without assistance?"; "Can you walk six city blocks without assistance?"; "Can you walk 1 mile without assistance?"; "Can you walk 2 miles without assistance?" In a Guttman scale the items are ordered hierarchically such that an affirmative response to one item implies affirmative responses to each of the items preceding it. The scale score is simply the sum of affirmative responses over the set of items. The score represents the subject's level of the attribute under investigation (in this example, the subject's physical ability).

In general terms, suppose we have k distinct items addressing the same attribute which are ordered hierarchically, i.e. ordered such that an affirmative response to one item theoretically implies affirmative responses to each of the items preceding it, and measured on each of n subjects. The data can be organized into a matrix $\mathbf{A}$ with n rows containing each subject's responses to the set of k items, which are called the subject's response profiles. For example, subject i has a response profile $\mathbf{a}_i' = (a_{i1}, a_{i2}, \ldots, a_{ik})$ with $a_{i1} \geq a_{i2} \geq \ldots \geq a_{ik}$, and $a_{ij} = 0$ or 1 representing No and Yes responses, respectively (see Figure 1). If subjects (rows of $\mathbf{A}$) are compared and sorted according to their response profiles, i.e. their scores on the set of items, a Guttman scale is said to exist if every pair of response profiles is comparable. For example, consider subjects i and j with response profiles $\mathbf{a}_i' = (a_{i1}, a_{i2}, \ldots, a_{ik})$ and $\mathbf{a}_j' = (a_{j1}, a_{j2}, \ldots, a_{jk})$, respectively. Subjects i and j are comparable if $a_{i1} \geq a_{j1}, a_{i2} \geq a_{j2}, \ldots$, and $a_{ik} \geq a_{jk}$ [1]. In this example, subject i has a higher level of the attribute under investigation than subject j since subject i scores as high or higher than subject j on every item. When every pair of response profiles is comparable, a Guttman scale is formed. The relationships among response profiles allow for subjects to be rank ordered according to their level of the attribute under investigation. Figure 1 displays the triangular relationship among response profiles in a Guttman scale (see, for example, [2]), where each item is scored as Y = Yes or N = No.

	Item					
Subject	1	2	3	.	.	k
1	Y	Y	Y	Y	Y	Y
2	Y	Y	Y	Y	Y	N
3	Y	Y	Y	Y	N	N
.	Y	Y	Y	N	N	N
.	Y	Y	N	N	N	N
n	N	N	N	N	N	N

Figure 1 Yes and No responses

Although the Guttman scale is theoretically appealing, it is highly structured and not often observed in practice [3]. In particular, Guttman scales do not work well for psychological attributes, since such attributes are generally less concrete. Guttman scaling is also known as scalogram analysis and **correspondence analysis**.

LISA M. SULLIVAN

Guy, William Augustus

Born: 1810, in Chichester, UK.
Died: September 10, 1885, in London, UK.

Guy studied medicine with **P. C. A. Louis**, qualified in Cambridge in 1837, and was appointed Professor of Forensic Medicine at King's College, London in 1838. He wrote an important appreciation of Louis's work in 1839, tinged, however, with doubt as to the applicability of statistical findings to the treatment of individual patients, and (as with Louis) a degree of scepticism about mathematical theory. He became a prolific writer on public health matters, and was a prominent member of the Statistical Society of London (later the **Royal Statistical Society**, which commemorates him with the Guy Medal).

PETER ARMITAGE

Haenszel, William M.

Born: Rochester, New York, June 19, 1910.
Died: Wheaton, Illinois, March 13, 1998.

Although William M. Haenszel is probably best known as the name to the right of the hyphen on the **Mantel–Haenszel** test and Mantel–Haenszel **odds ratio**, he has made other equally important contributions throughout a very long and productive career as a biostatistician and epidemiologist. Of particular importance is his leadership in establishing and maintaining the population-based **cancer registry** known as *SEER* (for *S*urveillance *E*pidemiology and *E*nd *R*esults); his comparative studies of cancer occurrence in foreign-born and native-born Japanese Americans; and his use and advocacy of biomarkers and pathological findings in studies of cancer etiology, especially those involving gastric and large bowel cancer. His work from the 1950s to 1970s at the National Cancer Institute (*see* **National Institutes of Health (NIH)**) was at the cutting edge of chronic disease **epidemiology** and has greatly enriched that field both substantively and methodologically.

His early life was spent in Buffalo, New York, where he went through the public elementary and high school systems, and through the University of Buffalo (now, State University of New York at Buffalo), receiving a B.A. *summa cum laude* in sociology and mathematics in 1931. A year later, he received his M.A. in statistics, also from the University of Buffalo. Shortly thereafter, he worked as a statistician at the New York State Department of Health and later, as Director of the Bureau of Vital Statistics at the Connecticut State Department of Health. His experience of nearly 20 years in health statistics and record keeping at the State level, gave him a unique expertise and perspective into registration and data collection at the "grass roots" level. This expertise became invaluable in his later work at the National Cancer Institute and at the University of Illinois at Chicago (UIC) where he collaborated extensively with State and Local Officials in his studies of cancer epidemiology. It was especially useful in the contributions that he made to establish a population-based cancer registry system that could be used for investigating **incidence** and etiology of cancers as well as survival in persons having these diseases.

In 1952, he accepted a position as Head of the Biometry Section of the newly created National Cancer Institute (NCI) and, in 1961, became Chief of the larger Biometry Branch of NCI. He stayed in this position until his retirement from NCI in 1976. During his tenure at the NCI, there was a cadre of statisticians who themselves made major contributions in biostatistics and epidemiology. Among them were **Nathan Mantel**, **Marvin Schneiderman**, **Sid Cutler**, Marvin Zelen, Ed Gehan, **David Byar**, John Gart, and John Bailar. During this period, and largely owing to Bill Haenszel's mentoring and management skills, the Biometry Branch of NCI became an internationally recognized center of excellence in the development of statistical methodology applied to **observational** and experimental health studies. He fostered a culture of productivity and achievement among statisticians at NCI and the Biometry Branch (presently under the direction of Mitchell Gail) has maintained this excellence throughout the quarter century since his retirement from NCI in 1976.

It was during his tenure at NCI, that he coauthored with Nathan Mantel his paper on what became most widely known as the Mantel–Haenszel test [4]. For many years, this was one of the most widely quoted articles in the entire scientific literature.

Although this test is now sometimes called the Cochran–Mantel–Haenszel test (or CMH test) in recognition of the test developed five years earlier by **William Cochran** [1], the two tests differ statistically, primarily in that the Mantel–Haenszel test is predicated on a **hypergeometric distribution**, whereas the Cochran test is based on a **binomial distribution**. The Mantel–Haenszel test and its associated odds ratio became, soon after its publication, a backbone of stratified analysis (*see* **Stratification**) and proved to have applications and extensions to scenarios far beyond the subject matter of the original article (e.g. tables larger than 2×2 (*see* **Contingency Table**), **survival analysis**, comparisons among adjusted rates, etc.).

There has been much discussion and speculation concerning the comparative contributions that each of the two authors made in the development of the test. Both Mantel and Haenszel, when queried individually, have always praised the contribution of the other. In a 1984 symposium at the University of Illinois at Chicago marking the 25th anniversary of the original publication, Haenszel indicated that his own major contribution was in the formulation of "how the fourfold table (*see* **Two-by-Two Table**) was entered and constructed". By this, he probably meant that, in the **case–control** scenario on which it was originally based, the appropriate inference issue is predicated upon the null distribution of exposed cases, given that the marginals for total cases, total controls, and total exposed persons are fixed. This leads to the hypergeometric formulation that is different (although generally indistinguishable numerically) from Cochran's earlier hypothesis test.

The Mantel–Haenszel test and its subsequent extensions represented major advances in statistical analysis. Its accuracy, however, as with all statistical tools, is entirely dependent on the quality of the underlying data, and it could lack generalizability if the cancer cases being studied were not representative of the universe of cancer cases with respect to the exposure being studied (*see* **Validity and Generalizability in Epidemiologic Studies**). Recognizing this, Haenszel and others in leadership roles at the NCI began efforts for establishing a registry of cancer cases that would be representative of all cancer cases in the United States. On the basis of their efforts, the population-based registry, SEER, was launched in 1973. It now contains over 30 years of data on cancer incidence and survival and remains as one of the flagship programs at the NCI.

Also, while at NCI, Haenszel launched his landmark studies comparing the high gastric cancer rates in Japan to the much lower rates in those Japanese who had migrated to Hawaii [3], and identified diet as a possible risk factor for gastric cancer (*see* **Migrant Studies**). He repeated in other ethnic groups, this model of comparing cancer rates that prevail in the parent country to those among persons of the same ethnic group who migrated to the United States as well as to those among persons of the same ethnicity who were born in the United States. This model has served as a tool for generating etiological hypotheses that can be verified in subsequent case–control or **cohort studies**.

He also began, while at NCI, his studies focusing on gastric cancer in Cali, Colombia in collaboration with Pelayo Correa, a Colombian pathologist and epidemiologist at Louisiana State University [2]. This program was innovative in that it focused on population surveys that included gastroscopic measurements, and that its major objectives were to identify **risk factors** for the known precursors of gastric cancer. By focusing on the precursors rather than the much rarer cancers themselves, they could conduct **cross-sectional**, case–control, and cohort studies that had adequate statistical **power**, whereas similar studies that focused on gastric cancer rather than the precursor would have much less statistical power. This collaboration continued for many years after Haenszel's retirement from NCI and provided a wealth of information about the epidemiology of gastric cancer, especially dietetic risk factors.

After his retirement from NCI in 1976, Haenszel relocated to the Chicago area where he took a joint position at the Illinois Cancer Council and the University of Illinois School of Public Health. Both of these Institutions were in their very early years, and Haenszel's initial plan was to help these Institutions for two years and then totally retire at age 68. The intended two years stretched out to nearly 20 and he had a truly rich career as a senior mentor and advisor to both Chicago Institutions, and as a senior consultant to many agencies engaged in cancer research and cancer control. Among these were Louisiana State University (where his collaboration with Correa and his group continued), NCI, the American Cancer Society, the Illinois Department of Public Health, and the **International Agency for Research**

in Cancer (IARC). During this period, he was a major force in the establishment in the 1980s, by the Illinois Department of Public Health of a population-based cancer registry, which has since matured into a high quality registry and a resource for investigations of cancer etiology. At the University of Illinois at Chicago School of Public Health, he was instrumental in enriching the curriculum in chronic disease epidemiology, developing and teaching a series of courses in quantitative epidemiology and in cancer epidemiology. In addition, he devoted much time in mentoring junior faculty and students, many of whom are now senior epidemiologists and biostatisticians. The Haenszel Memorial Award was established in the early 1990s and is given in his honor annually to a student in the Division of Epidemiology and Biostatistics at UIC who has performed outstanding research during his/her career as a student.

Haenszel's health began declining in the mid-1990s, and he retired for a final time in 1996, two years before his death. His legacy lives on in the continuing work of his collaborators and disciples and in the vitality of the Institutions on which he left his mark.

PAUL S. LEVY

Half-normal Distribution

The half-normal distribution will arise in sampling from a standard normal population when the signs of the negative observations are lost or not relevant. The half-normal distribution was introduced by Daniel [2] in connection with the **analysis of variance** of **factorial experiments**. An example of the use of the half-normal in biostatistics is given by Berlin et al. [1], where the outcome of interest was the difference in treatment effects between two treatments in a number of **clinical trials**. The treatment effects (and hence their differences) were assumed normally distributed, but there was no reason to assign either treatment as the first of the pair, so the sign of the difference was made to be positive.

Formally, if z is normally distributed with mean equal to zero and variance equal to one, then the half-normal distribution is the distribution of $\sigma|z|$. The probability density function (pdf) is given by

$$f(x) = \frac{1}{\sigma}\sqrt{\frac{2}{\pi}}\left\{\exp\left[\frac{-(x/\sigma)^2}{2}\right]\right\}, \quad x \geq 0. \quad (1)$$

The first four central **moments** of the half-normal are given by Elandt [3]:

$$m_1 = \sigma\sqrt{\frac{2}{\pi}}, \quad (2)$$

$$m_2 = \left(1 - \frac{2}{\pi}\right)\sigma^2, \quad (3)$$

$$m_3 = \sqrt{\frac{2}{\pi}}\left(\frac{4-\pi}{\pi}\right)\sigma^3, \quad (4)$$

$$m_4 = \left(\frac{3\pi^2 - 4\pi - 12}{\pi^2}\right)\sigma^4. \quad (5)$$

The standardized third and fourth moments (**skewness** and **kurtosis**, respectively) are

$$\sqrt{\beta}_1 = \frac{(4-\pi)\sqrt{2}}{(\pi-2)^{3/2}} = 0.995272 \quad (6)$$

and

$$\beta_2 = \frac{3\pi^2 - 4\pi - 12}{(\pi-2)^2} = 3.86918. \quad (7)$$

The parameter σ can be estimated by equating the noncentral theoretical and sample moments:

$$\hat{\sigma}^2 = \sum_{i=1}^{n} \frac{x_i^2}{n}, \quad (8)$$

where n is the sample size. According to Johnson [4], this is also the **maximum likelihood** estimator.

The half-normal distribution is a special case of the folded normal distribution, where the point of folding is at zero. The folded normal was investigated by Leone et al. [5], Elandt [3], and Johnson [4].

R.H. BYERS

Halley, Edmond

Born: November 8, 1656, in Haggerton, UK.
Died: January 14, 1742, in Greenwich, UK.

Edmond Halley was a major English astronomer, mathematician, and physicist, who was also interested in **demography**, insurance mathematics (*see* **Actuarial Methods**), geology, oceanography, geography, and navigation. Moreover, he was considered an engineer and a social statistician whose life was filled with the thrill of discovery. In 1705, he reasoned that the periodic comet – now known as Halley's comet – that appeared in 1456, 1531, 1607, and 1682, was the same comet that appears every 76 years, and accurately predicted that it would appear again in December 1758. His most notable achievements were his discoveries of the motion of stars, which were then considered fixed, and a scheme for computing the motion of comets and establishing their periodicity in elliptical orbits.

Edmond Halley, whose name was also spelled Edmund, was the eldest son of a prosperous landowner, soapmaker, and salter in London. He was tutored at home before attending St Paul's School, where he learned Latin, Greek, and mathematics, including geometry, algebra, the art of navigation, and the science of astronomy. In 1673, at the age of 17, he entered Queen's College, Oxford, and was introduced to John Flamsteed, who was appointed Astronomer Royal in 1676.

In November 1676, Edmond Halley sailed to the island of St Helena, where he cataloged the stars of the southern hemisphere, and incidentally discovered a star cluster in Centaurus, a constellation in the Southern Hemisphere. In 1677, he timed a transit of Mercury and of Venus across the sun and made rough calculations of the mean distance between Earth and the sun. In 1678, he published his results in Catalogus Stellarum Australium, was elected a fellow of The Royal Society, and received the M.A. degree from Oxford University. He married Mary Tooke in 1682, and they had three children – two daughters and one son. He established a home and small observatory center at Islington, and saw the comet of 1682.

Halley encouraged Newton to expand his studies on celestial mechanisms and contributed important editorial aid and financial support to the publication of Newton's major work, *Philosophiae Naturalis Principia Mathematica*, in 1686. From 1685 to 1696 he was assistant of the secretaries of the Royal Society, and from 1685 to 1693 he edited the *Philosophical Transactions of the Royal Society*. In 1698 he was the frequent guest of Peter the Great, who was studying British shipbuilding in England. He was the technical adviser to Queen Anne in the War of Spanish Succession, and in 1702 and 1703 she sent him on diplomatic missions to Europe to advise on the fortification of seaports.

Between 1687 and 1720 Halley published papers on mathematics, ranging from geometry to the computation of logarithms and trigonometric functions. He also published papers on the computation of the focal length of thick lenses and on the calculation of trajectories in gunnery. In 1684 he studied tidal phenomena, and in 1686 he wrote an important paper in geophysics about the trade winds and monsoons. From 1683 to 1692 he published two important papers in geophysics about terrestrial magnetism and made a chart of the variation of the compass. In 1716 he suggested that the aurora was governed by the terrestrial magnetic field.

Halley was a man of great curiosity who combined his astronomical knowledge to help in the dating of historical events. In 1691 he published a paper on the date and place of Julius Caesar's first landing in Britain, and in 1695 he published a paper on the ancient Syrian city of Palmyra. In 1695 he began an intensive study of the movement of the comets, using the hypothesis that cometary paths are nearly parabolic. In 1696 he became deputy controller of the mint at Chester. Between 1698 and 1700, Halley was appointed as a naval captain. He charted magnetic variations while crossing the Atlantic, and was the first to adopt isogonic lines to connect points of equal magnetic variation. In 1704 he was appointed Savilian Professor of Geometry at Oxford and was granted the degree of Doctor of Civil Law. In 1705 he published his cometary views in *Philosophical Transactions*, and *A Synopsis of the Astronomy of Comets*. In 1706 and 1710 he translated and published *Conics*, and *Sectio Rationis of Apollonius*. In 1712 Halley and Newton published *Historia Coelestis*, an edition of Flamsteed's observations, using material deposited at the Royal Society, and infuriated Flamsteed.

Although the major scientific interest of his life was astronomy, Halley wrote a seminal paper on **life**

tables. Since the end of the sixteenth century, registers of births and deaths by sex and age had been well kept in Breslau, Silesia. Caspar Neumann, a prominent evangelical pastor and scientist, used the data to combat some popular superstitions about the influence on health of the phases of the moon and certain ages (those divisible by seven and nine). Neumann sent his results to Leibniz, who in 1689 brought them to the attention of the Royal Society. Since the work of **Graunt** and **Petty**, members of the Royal Society were waiting to receive observations suitable for construction of a life table and sent the data to Halley for analysis. In 1693 Halley wrote the paper "An estimate of the degrees of the mortality of mankind, drawn from curious tables of the births and funerals at the City of Breslaw, with an attempt to ascertain the price of annuities upon lives." Halley assumed a constant number of births per year, mortality by age constant in time, and no migration. He did not present the data in detail, but he calculated a life table based on the number of survivors by year, including the first empirical distribution of deaths according to age. He used the life table to calculate the number of men able to bear arms from age 18 to 56, the **median** remaining lifetime for an individual of age x (*see* **Life Expectancy**), the total population size, and certain calculations relating to annuities. He found that the value of an annuity is the sum of the expectation of the payments made to the living, a concept later pursued by **Abraham de Moivre**. His expectation became the fundamental quantity in life insurance, today called the pure endowment. Having written an important paper on life tables, Halley never returned to the topic, which was far from his main interests.

In 1715 Halley published a paper on novae, and nebulae, and recorded ideas and experiences of living underwater. In 1720 Halley succeeded John Flamsteed in his appointment as Astronomer Royal. In 1729 he was elected a Foreign Member of the Academie des Sciences at Paris. By 1731 he had published a method of using lunar observations for determining longitude at sea. He also studied the question of the size of the universe and the number of stars it contained.

At his death, Edmond Halley was 86 years old and widely mourned. He was a famous and a friendly man of rare intelligence who was always ready to support young astronomers. As Joseph Laland said about Halley, he was "the greatest of English astronomers ... ranking next to Newton among the scientific Englishmen of his time".

For more complete information about Halley's life, see the following references.

LINA ASMAR

Halperin, Max

Born: November 5, 1917, in Omaha, Nebraska.
Died: February 1, 1988, in Fairfax, Virginia.

Max Halperin was a leading statistician in biostatistics for over 40 years both at the **National Institutes of Health** and at the Biostatistics Center at the George Washington University. At the time of his death he was Research Professor of Statistics and Director of the Biostatistics Center of the George Washington University.

Halperin graduated from the University of Omaha in 1940 with a B.S. degree and from the University of Iowa in 1941 with an M.S. degree, both in mathematics. He earned his Ph.D. in mathematical statistics from the University of North Carolina in 1950. From 1941 to 1946, Halperin served in the Armed Forces primarily with the US Air Force in the China–Burma–India theater of operations.

A brief review of his career begins with the year 1948–1949 when he was a research mathematician at the RAND Corporation where he worked with Alex Mood. He then spent the years 1950–1955 in the Biometrics Department of the US Air Force School of Aviation Medicine at Randolph Field, Texas. He first came to the National Institutes of Health (NIH) in 1951, joining Felix Moore in the Biometrics Research Branch of the National Heart Institute (NHLBI). From 1955 to 1958 he was Chief of the Biometrics Office of the Division of Biologic Standards, NIH. For the next eight years he held positions as statistician in private industry with the General Electric Company and with the Sperry-Rand Corporation. He returned to the NIH in 1966 as Assistant Chief and Chief of the Biometrics Research Branch, NHLBI. After retirement from the NIH in 1977, he spent the remaining years of his career as Research Professor of Statistics and Director of the Biostatistics Center of the Department of Statistics at the George Washington University.

Max Halperin entered the Statistics Department at the University of North Carolina shortly after **Harold Hotelling** became chairman of the Department. His first attempt at a dissertation had to be scrapped since a paper was published on the same topic. In 1948 he met Alex Mood who suggested that he write on the estimation of parameters in truncated samples. He successfully completed his dissertation on this theme, publishing one of the first papers on this subject in the *Annals of Mathematical Statistics* [3].

Max Halperin was widely respected and recognized for his contributions to theoretical and applied statistics and biostatistics. He took great joy in working on theoretical problems, particularly those initiated by his consultations with investigators engaged in scientific research. His theoretical work reflected his strength in **multivariate analysis** and his adeptness in deriving **large sample**, asymptotic distributions. His interests in both theoretical and applied research ranged over a broad spectrum of subjects. He contributed significantly to (i) various topics in **regression** such as inverse estimation [16], **errors in variables** [7, 13], interval estimation in **nonlinear regression** [9, 12]; (ii) interval estimation (*see* **Estimation, Interval**) of parametric nonlinear functions [11, 14, 21]; and (iii) distribution-free tests (*see* **Nonparametric Methods**) [4, 23, 25, 30]. In addition, he wrote on applied probability [5, 19], on reliability [10, 18], and on other problems in general statistical methodology [6, 8, 15, 20]. Halperin collaborated with **Cornfield** and others to write on an alternative solution for the **multiple comparison** problem [24] which turned out to be a powerful method to detect **outliers**, and to write on an adaptive procedure for sequential clinical trials (*see* **Sequential Analysis**) [1].

Halperin and his colleagues in the Biometrics Research Branch of the NHLBI were to a large extent responsible for developing the statistical foundations of the **multicenter clinical trial**. During this period,

as Chief of the Biometrics Branch in the NHLBI and later as Director of the Biostatistics Center, his interests were primarily directed to the **clinical trial**. The more he became involved in the conduct of clinical trials the more he realized that the clinical trial was much more complicated than a simple extension of a laboratory experiment into the community. He was led to consider special aspects of design [17, 31] and problems in **data and safety monitoring** [27]. His greatest effort at this time was devoted to two major topics: stochastic curtailment [28, 32] and early stopping of a clinical trial [2, 22]. His ideas and writings in these areas had a great impact on the planning and direction of clinical trials (*see* **Clinical Trials Protocols**). In addition to his personal research related to clinical trials, Max Halperin greatly influenced the design and conduct of clinical trials through his service on steering, policy advisory, or **data and safety monitoring boards** of many major clinical trials sponsored by the NHLBI.

Towards the end of his career, he was responsible for another novel idea related to multiple comparisons. Conventionally, statisticians looked for protection against making no errors – in an experiment, or family of experiments, etc. Halperin, however, relaxed the requirement by seeking protection against making at most one error, or at most two errors, etc. [29].

Halperin was a member of the Board of Directors of the **American Statistical Association** (1975–77) and served as an Associate Editor of the ***Journal of the American Statistical Association*** (1971–74) and of the *American Statistician* (1976–80). He was a member of a committee on standards for statistical symbols and notation together with H.O. Hartley and P.G. Hoel and was the senior author of the Committee's report [26]. He was Chairman of the Biometrics Section of the American Statistical Association in 1974.

Max Halperin received many honors. He was a Fellow of the American Statistical Association, the Institute of Mathematical Statistics, the American Association for the Advancement of Science, and an elected member of the **International Statistical Institute**. He received a Superior Service Award from the Department of Health, Education and Welfare (1973) and the Statistics Section Award from the **American Public Health Association** in 1985.

Max not only worked on statistical problems – he also loved to talk about statistics, especially to point out the difficulties he was running into on a specific problem. Many of these discussions would occur at lunch, which for his associates became special occasions. The problems on which he worked were primarily those motivated by his work. The sole criterion: Was it real and interesting?

Max married Mary Ann Thomas whom he met while both were working at the National Heart Institute. They have a daughter, Martha.

SAMUEL W. GREENHOUSE

Haplotype Analysis

Haplotype analysis examines and attempts to specify the genetic information descending through a pedigree, thus providing a useful visualization of the gene flow. Specifically, a haplotype for a given individual and set of loci is defined as the set of alleles inherited, one per locus, from the same parent (*see* **Gene**). Thus, for each person there are two haplotypes, one of maternal origin and the other paternal. Usually, the loci under consideration are syntenic, that is, the haplotype consists of alleles all on a single chromosome. Traditional haplotype analysis, also known as haplotype reconstruction or simply haplotyping, is the process of obtaining a "best" estimate for each of the two haplotypes for each person in a pedigree. This set of haplotypes is the inferred haplotype vector for that pedigree. For example, Figure 1 shows for a small fully typed pedigree the most likely of the 262 144 haplotype vectors consistent with the data [11, 15].

In addition to traditional haplotyping that simply specifies from which parent each child's allele is descended, there is a more complete form of haplotyping that specifies from which parental *allele* each child's allele is descended, that is, specifies grandparental source information. This more complete haplotype analysis includes sufficient information to describe completely gene flow through a pedigree. For example, consider Figure 2(a), which demonstrates a traditional haplotyping solution at a single locus, that is, everyone has been assigned an ordered **genotype**. (Here, an ordered genotype is listed with the maternal allele on the left, paternal allele on the right.) However, notice that the gene flow is not completely specified, in that the grandparental source of the "1" allele in the grandchildren cannot be determined. Grandparental source information can be displayed by using a gene flow representation. Figure 2(b) shows one of the four gene flow representations consistent with the data in Figure 2(a). Here, each individual is represented by two nodes at each locus: one for the allele of maternal origin and one for the paternal allele. The founders' nodes have specific alleles assigned to them and then arcs are drawn connecting each child node with the parental node from which it descended. This more complete form of haplotyping can be defined as the task of reproducing the complete gene flow information for a pedigree at the loci under consideration.

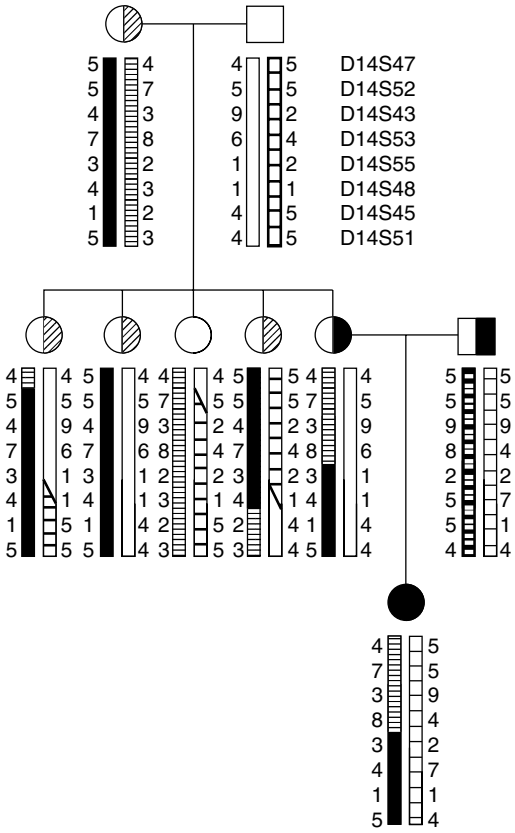

Figure 1 Example of a haplotyped pedigree in which each founder haplotype has been uniquely hatched. This is the most likely of the 262 144 haplotypes consistent with the fully typed pedigree [15]. This pedigree comes from a study of Krabbe disease: the full-black symbol indicates an affected person; half-black indicates obligate carriers; half-hatched indicates carriers identified by an enzyme assay [11] (*see* **Genetic Counseling**). Applications of Haplotype Analysis

Haplotype analysis has several common applications. An early goal of haplotyping was to make the genetic data used in **linkage analysis** more informative. A locus is defined to be informative at a mating, that is, for two parents and their child, if the observed typing information at that locus allows one to infer from which parental allele each allele in the child is inherited (*see* **Polymorphism Information Content**). To illustrate this, consider a locus at which the parents are typed as **heterozygotes** with no alleles in common, for example, a/b and c/d, then one is

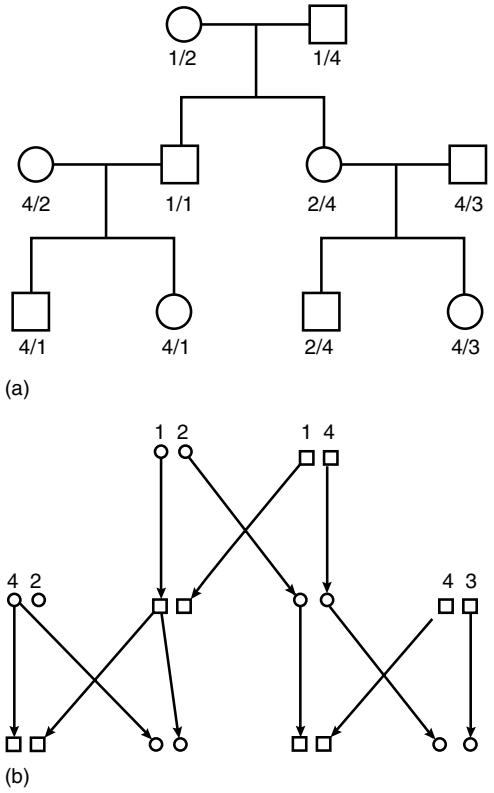

Figure 2 (a) Pedigree data set with one locus in which ordered genotypes have been inferred for each person. (Ordered genotypes are shown as maternal-allele/paternal-allele.) The grandparental origin of the "1" allele cannot be determined; (b) one of the four gene flow representations consistent with the data in (a). Reproduced from Sobel & Lange [14] by permission of the University of Chicago Press

assured an informative mating. Conversely, consider the mating in Figure 3(a) in which all three loci are individually uninformative. To increase informativeness, one may construct a single, highly polymorphic "mega-locus" from a number of less polymorphic, but closely linked, loci. (Indeed, some researchers still use the term haplotyping to refer only to this application or to the related problem of finding the population frequencies of the newly defined "mega-alleles".) The creation of a mega-locus is advantageous because each locus alone may be uninformative for many matings in the pedigree, while the combined mega-locus will often be informative at nearly all matings. For example, the mating in Figure 3(a) is uninformative at all three loci. However, if one can

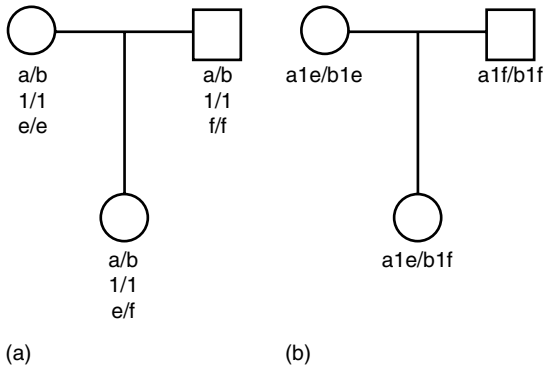

Figure 3 (a) Unordered genotypes at three loci. Each locus is uninformative in this mating; (b) shows the three loci haplotyped and combined into one "mega-locus" that is informative

create haplotypes for these three loci using the rest of the pedigree (not shown), then the newly defined mega-alleles may make the mega-locus informative. Such an informative mega-locus is seen in Figure 3(b). By treating the combined loci as a single point in the genome, the results of standard linkage analysis will often be improved. Clearly, this approach is best suited for closely linked loci, usually with no recombination between the loci.

Haplotyping is also used to identify genotyping or data-entry errors. Even relatively few mistyping errors can have a significant effect on the determination of genetic maps and gene localization [1, 8]. Haplotyping, by exhibiting the gene flow within a pedigree, permits a visual check of the data to find likely mistypings. Mistyping that results in non-Mendelian inheritance is easy to detect, for example, a 1/3 child from two 1/2 parents. (Of course, if these data stand up to retyping, then nonpaternity or non-maternity must be considered.) However, mistyping a true 2/2 child as a 1/2, when both parents are 1/2, is difficult to detect. Haplotyping across this locus may highlight the possibility that the child's typing was in error. For example, in Figure 4 haplotyping reveals a double recombination, one on either side of the questionable allele. If the distance between these flanking markers is small, then the "1" allele in the child would be a definite candidate for retyping. Several papers have discussed statistical tests (usually **likelihood ratio tests** or their approximation) that indicate which typings are most likely to be in error [1, 8].

Finally, haplotype analysis may provide a more precise localization of a putative trait locus than

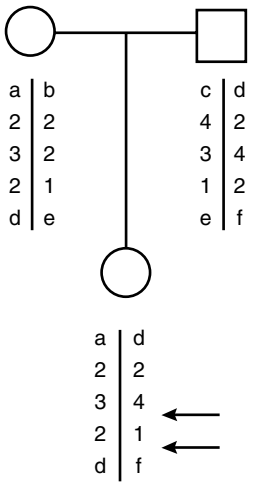

Figure 4 Haplotyping results that suggest that the child's typing may be in error at the "1" allele. The arrows indicate flanking recombination events

standard linkage analysis. The introduction of a rare trait in an isolated population, by new mutation or immigration, probably occurred in only a few ancient individuals. Many of the living affected persons will have inherited the trait from a common founder, even though it is not apparent that they are related. Haplotyping of these affected persons, over loci linked to the trait, may reveal a conserved haplotype inherited through many generations from a common founder. The conserved haplotypes will be flanked by alleles not part of the inferred ancient haplotype. These nonconserved alleles are evidence of recombination events that may have occurred in any generation since the introduction of the trait into the population. The interval contained within all such flanking recombination points is most likely to contain the trait locus. This localization technique, using conserved affected haplotypes in isolated populations, employs recombinations from the entire history of the trait's segregation within the population. Classical linkage analysis can only work with the recombination events manifested within the pedigrees observable today. Thus, it is not surprising that this use of haplotype analysis in an isolated population can often localize a trait to a smaller interval than can classical linkage analysis alone.

As an example of this use of haplotype analysis, consider the localization of the autosomal recessive disorder ataxia-telangiectasia (A-T). In early 1995, classical linkage analysis on an international consortium of 176 pedigrees generated an approximately 500 kb (kilobase) support interval for an A-T gene located on the short arm of chromosome 11 [7]. This support interval roughly spanned the region from S1819 to S1294, which contains the markers S384 and S535 (*see* **Genetic Markers**), as shown in Figure 5. No recombination events were seen in the 176 pedigrees between the A-T locus and either S384 or S535. Figure 6 shows an ancestral haplotype analysis of Costa Rican A-T affected persons and demonstrates that 20 out of the 27 seemingly unrelated affected individuals (and 34 out of the 54 haplotypes) contain a region from an identical ancestral haplotype [19]. Moreover, the boundaries of the conserved haplotypes (see individuals 26–3, 35–3, and 13–3) indicate that the trait locus must be distal to S384. (Here, distal is the direction away from the centromere and proximal is the reverse.) A similar haplotype analysis of a subpopulation of British A-T affected persons concluded that the locus must be proximal to S535 [16]. Haplotype analysis thus localized the A-T gene to the approximately 200 kb interval between S384 and S535; the approximately 100 kb A-T gene, now called ATM, was subsequently found within this interval [12].

Origins of Computational Complexity

Haplotyping is not conceptually difficult – it is simply determining the parental (and grandparental) origin of the children's alleles. What makes haplotyping

Figure 5 Map of four loci on chromosome 11 that are closely linked to the A-T gene. The 500 kb support interval is indicated for the A-T locus found using linkage analysis

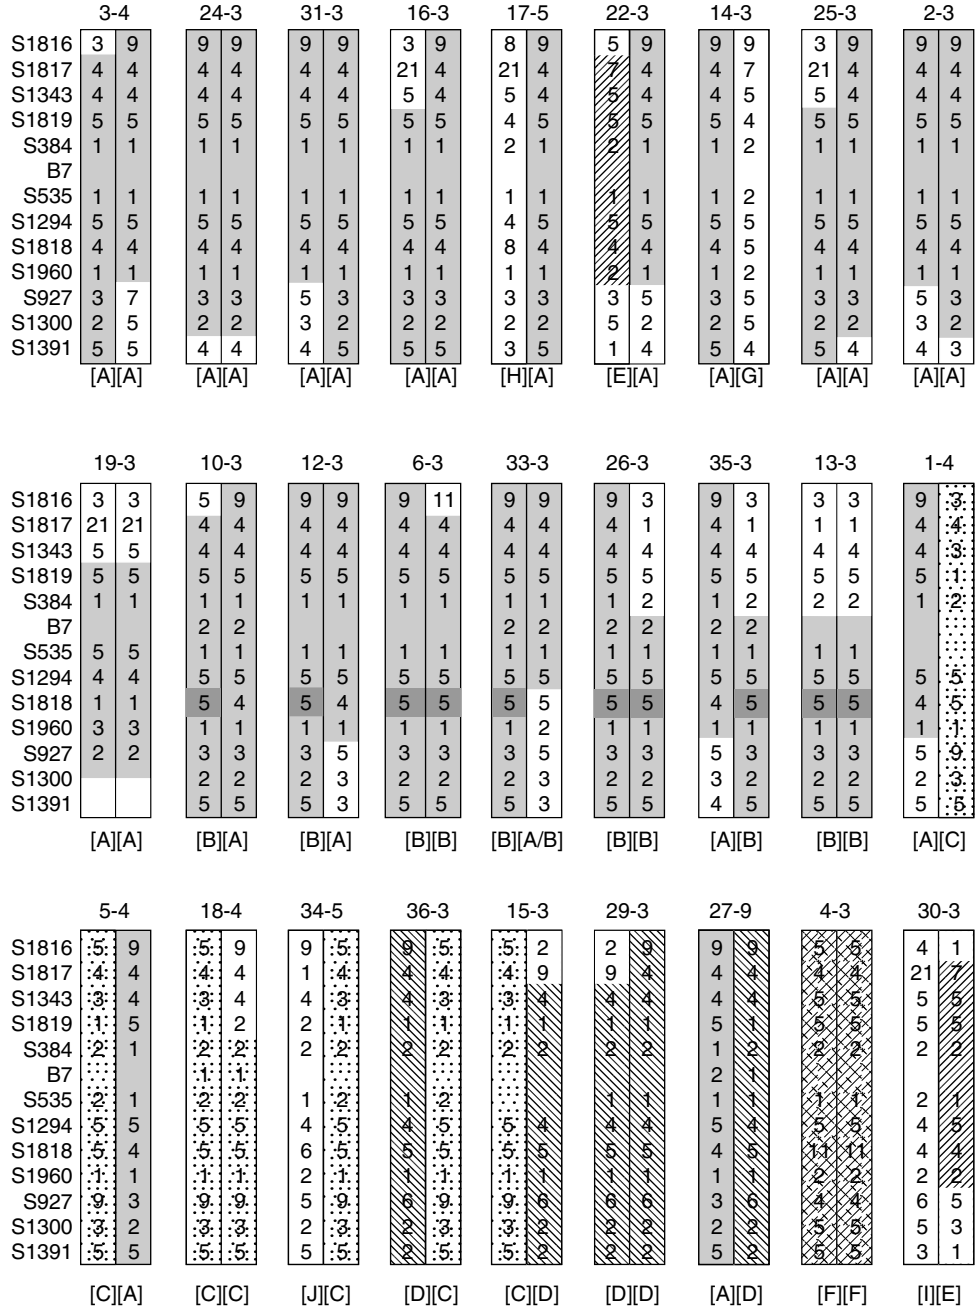

Figure 6 Haplotyping results of 27 living Costa Rican A-T affected persons. The individuals are labeled above the haplotypes; the haplotypes are labeled by bracketed capital letters. The haplotypes of common ancestral origin are similarly hatched. Unique haplotypes (G, H, I, and J) are not hatched. Reproduced from Uhrhammer et al. [19] by permission of the University of Chicago Press

exceedingly difficult in practice is the amount of missing information usually encountered in a pedigree data set. With even moderate amounts of missing data, the number of haplotype vectors that are consistent with the observed data can grow to astronomical levels. Thus, the search for the "best" haplotype vector is often a nontrivial combinatorial optimization problem.

For typical haplotyping problems, the missing data come in the following three forms: (i) Unknown typing is seen in real pedigrees because there are often some people who are simply unavailable for reliable typing at all the loci under consideration. These people may be too remote for sampling; they may decline to participate; or they may simply be deceased. (ii) Phase information for a locus at a typed individual specifies which allele is maternally inherited and which paternally. Modern genetic data, usually marker genotypes and trait phenotypes, do not specify phase. Marker loci are missing phase information because almost all are codominant loci that yield unordered genotypes. In the case of trait phenotypes, even the underlying alleles may be obscured, for example, a dominant allele will hide the value of the other allele. (iii) Grandparental source information is also required to be assured of complete knowledge of the gene flow through a pedigree (see Figure 2). However, no source information is specifically included in conventional pedigree data, although occasionally some can be directly inferred.

Much missing data of any type will result in a large number of possible haplotype vectors, each consistent with the data. For example, without phase information even a fully-typed pedigree can have an abundance of consistent haplotype vectors. Specifically, with p people fully typed over l loci there can be as many as 2^{pl} haplotype vectors consistent with the data [15]. For real fully typed pedigrees this value is usually significantly smaller, lowered by homozygosity in the founders and informativeness in the matings. The inheritance patterns in the vicinity of the people with missing data can help one infer the missing values, but the trend towards highly **polymorphic** marker loci increases the number of possible haplotypes the missing data imply. Considering the extent to which each of the three types of data is usually absent, it is not surprising that searching for the best haplotype vector is often computationally complex.

To demonstrate the size of the space that one must search to choose a best haplotype vector for a pedigree, consider the 36 person pedigree structure shown in Figure 7. This pedigree is from a study of dopa-responsive dystonia [10]. We simulated randomly complete gene flow data on the 14 linked polymorphic markers used in the linkage study. We considered then only the resulting unordered typing information for each individual, except for the six people unavailable for typing in the actual study, for whom no typing information was included. Table 1 lists for each person the number of haplotype pairs consistent with the simulated data. The number of haplotype vectors for the pedigree would be somewhat less than the product, over all people, of these numbers of haplotype pairs. Thus, an exhaustive search of the possible haplotype vectors is well beyond practical computability. (This analysis was previously reported by Sobel et al. [15].)

Algorithms for Haplotype Analysis

The algorithms that have been devised to overcome the computational complexities of haplotyping have evolved considerably with changes in technology. The trend has been away from heuristic and rule-based approaches toward more **likelihood**-based methods, while using sophisticated techniques to avoid as much as possible the computational bottleneck of calculating likelihoods for pedigrees with significant missing data. Manual haplotyping, the first

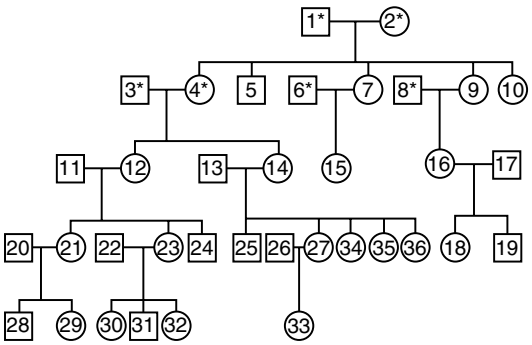

Figure 7 This 36-person pedigree structure is part of the data set used to generate Table 1. The individuals marked with an asterisk have no typing information assigned to them. Everyone else is typed at 14 polymorphic linked loci. Reproduced from Sobel et al. [15] by permission of Springer-Verlag

method used, and still used by some, is likely not to consider all the possibilities, even for moderate-sized pedigrees. Indeed, the majority of published haplotype vectors we have examined can be improved; for examples, see Sobel et al. [15]. Another problem with manual haplotyping is that it is difficult to prove that one has performed sufficient analysis to enable others to have confidence in the results. Clearly, the tedious and error-prone nature of haplotyping lends itself to computer-based approaches.

The first class of widely-used computer **algorithms** specifically designed for haplotype analysis were rule-based: PATCH by Wijsman [24] and CHROMLOOK by Haines [4]. By using logical rules to transform the available typing information into inferred underlying haplotypes these programs avoided all likelihood calculations. This approach was developed because at that time the major likelihood calculation programs were fairly limited, by computer memory and time constraints, in the size and complexity of the pedigrees they could handle. Thus, these nonnumeric rule-based algorithms are faster than any other approach. However, rule-based algorithms are by their nature somewhat *ad hoc*. Particularly in the presence of nontyping or uninformative matings, these approaches may leave portions of the haplotypes undetermined. Also, by not considering the recombination fractions between loci, which can be quite varied, these methods may miss a more likely solution.

In contrast to the qualitative rule-based methods, several quantitative algorithms have been devised. All are based on searching for the haplotype vector that maximizes a likelihood calculation. The most straightforward is the exhaustive enumeration technique. For small pedigrees with few untyped people, one can consider systematically every possible haplotype vector and rank them by exact likelihood. This brute-force approach has become feasible with the speed of modern computers and likelihood calculation programs [21]. This algorithm is guaranteed to find the **maximum likelihood** solution, but is only practical for small pedigrees.

To handle larger pedigrees it is necessary to invoke some scheme to reduce the number of possible haplotype vectors that are considered or to reduce the number of calculations required for each vector. One such strategy is not to compute exact likelihoods over the untyped and uninformative loci, which is where the calculations become complex because the number of possible configurations becomes large. This is the strategy used by the CHROMPIC option of the CRI-MAP program developed by Green et al. [2]. Again, however, nontyping may lead to significant uncertainty or even leave portions of the haplotypes undetermined.

Another implemented strategy reduces the number of configurations that need be considered by using a sequential conditional probability algorithm. Here, the haplotype pairs are assigned to people in the pedigree in a sequential fashion. Once the first $i-1$ haplotype pairs have been assigned, individual i is assigned the most probable haplotype pair given the observed data and the previously assigned haplotypes. This is the method used in the program HAPLO developed by Weeks et al. [15, 21]. This method can accommodate pedigrees with a modicum of missing data, in which case the order in which the haplotypes are assigned can affect significantly the amount of computation required.

The next strategy for surveying the space of possible haplotype vectors in reasonable time employs the combinatorial optimization technique known as simulated annealing. This technique has been shown to work on many previously intractable optimization problems in many fields [20]. However, the stochastic nature of simulated annealing implies that one is assured only of reaching a near-optimal solution and repeated applications are normally suggested for confidence. SIMCROSS, developed by Weeks et al. [15, 21], includes a particularly fast implementation of simulated annealing for haplotyping. The speed is attained by using an easily calculated **pseudo-likelihood** for the haplotypes. Specifically, for each locus interval i with recombination fraction θ_i, let $\rho_i = \theta_i$ if interval i contains a crossover, and $1-\theta_i$, otherwise; SIMCROSS uses the pseudo-likelihood $\prod_i \rho_i$. Missing data and large pedigrees can be accommodated by simulated annealing, because it visits only a small fraction of the possible configurations and can escape local maxima of the search space.

Yet another strategy for efficiently searching the space of haplotype vectors uses the gene flow representation of pedigrees as modeled in Figure 2(b). If one ignores the actual alleles assigned to the founder nodes in such a complete gene flow representation, then one is left with only the graph of inheritance paths. Two facts are notable about the space of all such graphs that are consistent with the observed typing. First, the number of these graphs is smaller than the number of possible haplotype vectors – much smaller if there is nontyping in the pedigree. Secondly, given a graph it is straightforward to find the set of founder alleles such that the complete gene flow representation (that is, the combination of the graph and the founder alleles) has maximum likelihood [14]. Thus, one can search the relatively small space of graphs and rank each graph by the maximum likelihood of all haplotype vectors consistent with the graph. Moreover, by conducting this search of the space of graphs, one is, in effect, searching the space of all possible haplotype vectors.

Two haplotyping programs use inheritance graphs, although with different techniques for searching the graph space. For pedigrees in which $2n - f \leq 16$, where n is the number of nonfounders and f the number of founders, GENEHUNTER, by Kruglyak et al. [5], uses the Viterbi algorithm over hidden **Markov chains** to search the graph space comprehensively in reasonable time. Thus, as with the exhaustive enumeration technique, GENEHUNTER is guaranteed to find the maximum likelihood solution and yet is practical for pedigrees of small to modest size, including those with missing data.

However, for large complex pedigrees even the space of inheritance graphs can become too large for deterministic analysis. Similar to SIMCROSS, SIMWALK2, by Sobel & Lange [14], also uses simulated annealing, but to survey the graph space and thus obtain an estimate of the most likely graph. The simulated annealing is performed on a **Markov process** that moves between graphs using the Metropolis criterion [9], that is, in proportion to the ratio of their exact likelihoods. Although SIMWALK2 may be somewhat slower than the above programs for simple pedigrees (except for the exhaustive enumeration approach, which is, of course, the slowest), it can provide in reasonable time a good estimate of the best haplotype vector for even the most complex pedigree data set.

Conclusions

Haplotype analysis has evolved considerably, driven by the rapid change in genetic and computer technology. This evolution has moved from an *ad hoc* qualitative methodology to quantitative estimations based on maximum likelihood considerations. Despite this progress, haplotype reconstruction can still fail to recover the true haplotype vector for a pedigree, particularly in the presence of large intervals between loci and significant amounts of nontyping. It may simply be that the true state is not the most likely state consistent with the observed data [15]. However, the

process of haplotyping may well reveal those specific regions in which more information is needed to pinpoint the true underlying haplotype vector [5].

It is interesting to note that the most recent advances in haplotyping involve techniques that are also proving useful in other branches of pedigree analysis. For example, many areas of pedigree analysis have profited from the use of the gene flow representation of genetic data (see Sobel & Lange [13] and Thompson [18] for reviews). Clearly, haplotyping to the level of complete gene flow information is equivalent to specifying all the identity by descent (IBD) characteristics in the pedigree (*see* **Identity Coefficients**). Thus, it is not surprising that the directed inheritance graphs and the Markov process techniques mentioned above have also been proposed for use in robust nonparametric IBD-based linkage statistics [3, 5, 14, 22, 23] and for **Markov chain Monte Carlo** (MCMC) **multipoint linkage analysis** [5, 6, 13, 14, 17]. These multiple applications demonstrate the importance and flexibility of the gene flow representation and the Markov process methods employed. Moreover, it shows that haplotype analysis can play a central role in the confluence of statistics and genetics that exists in the field of pedigree analysis.

Hardy–Weinberg Equilibrium

The Hardy–Weinberg Equilibrium (HWE) principle, the most fundamental rule of **population genetics**, prescribes the **genotype** frequencies at a locus in terms of its allele frequencies in a population. In the most general form, it states that in the absence of mutation, selection, migration, and random genetic drift (*see* **Population Genetics**), and with random mating in a population, the genotype frequencies at an autosomal locus in a large population will reach equilibrium in a single generation and will continue to be in proportions given by the expansion of $(p_1A_1 + p_2A_2 + \cdots + p_kA_k)^2$, where p_i, $i = 1, 2, \ldots, k$, are the frequencies of k alleles $A_1, A_2, \ldots, A_k$ at the locus in the population. In other words, the frequency of a homozygote A_iA_i becomes p_i^2 and that of a **heterozygote** A_iA_j becomes $2p_ip_j$, the rule that was independently discovered by the British mathematician G.H. Hardy [8] and the German physician Weinberg [20]. Of course, before them, Yule [22], Pearson [15], and Castle [1] noted that this rule works for the special cases of allele frequencies at a biallelic locus (see [12] and [17] for historical notes on the discovery of HWE).

Several authors attempted to pay tribute to Castle's [1] work by renaming this rule as Castle–Hardy–Weinberg's (CHW) law (see, for example, [13]). HWE, as a predictive equation for genotype frequencies in a large population in terms of the allele frequencies at a locus, has played a pivotal role for many other population genetic principles. For example, since the equilibrium is reached in a single generation, it implies that if mating is at random, then to understand the genotypic composition of a population it is not necessary to investigate the past history of the population. Also, the rule implies that random mating (with regard to the locus under study) is equivalent to random union of gametes. Furthermore, under this rule, the frequency of a rare recessive gene is about one-half of its heterozygote carrier frequency, and, for rare dominant diseases, the frequency of affected individuals in a large population is approximately twice the allele frequency.

Since the conditions (i.e. no preferential mating, no viability and/or fertility differential of alleles, no immigration or emigration, no mutation, and infinite population size) under which HWE is strictly valid are quite severe, and perhaps no real population satisfies most of these conditions, the applicability of HWE in predicting genotype frequencies is still being questioned in current work (see, for example, [11]). The early optimism of the robustness of HWE, however, has turned out to be justified, since for most loci for which the allelic effects are not physiologically meaningful (e.g. **blood groups**, enzyme-proteins, DNA markers), the rule provides a good approximation to reality. This is so, because, in nonexperimental populations, the extent of deviation from HWE is generally so small that the statistical **power** of its detection is "notoriously" small [5, 19].

While HWE can be extended to X-linked loci, to polyploid genetic systems, and even to genotype frequencies at linked loci, the critical difference is that the approach to equilibrium under these systems is gradual, instead of being reached in a single generation (see [7] for discussions on these systems). Deviations from HWE, in the presence of "nondetectable" alleles, and/or mixture of subpopulations that do not completely interbreed, are also well studied (see, for example, [2, 3, 6, 16, 18], and [21]), indicating that unless subpopulations are genetically well differentiated, or the nondetectable alleles are at high frequency in the population, the approximation of HWE is accurate relative to the usual sampling error of genotype frequency evaluation. Both of these factors cause the expected frequencies of homozygotes to be increased, with corresponding deficiencies of heterozygotes in relation to the predictions of HWE, although the deviations are small and are not generally detectable [4, 14]. In contrast, the finite size of a population is expected to cause a reduction of homozygote frequency, with heterozygote frequencies correspondingly increased by a factor of the order of the inverse of twice the breeding size of a population [7, 9, 10].

RANAJIT CHAKRABORTY

Hawkins, Francis Bisset

Born: 1796
Died: 1894

Bisset Hawkins is most widely remembered as the author of the first book on medical statistics in the English language [2]. He was the first Professor of Materia Medica at King's College, London, and was a prolific author in the fields of industrial medicine and public health. He was a founder member in 1834 of the Statistical Society of London (later the **Royal Statistical Society**), although he does not appear to have played a very active part in its later proceedings, and his death at an advanced age went unrecorded in the Society's *Journal* (*see* ***Journal of The Royal Statistical Society***).

According to **Greenwood** [1], Hawkins "was instrumental in obtaining the insertion in the first Registration Act of a column containing the names of the diseases or causes by which death was occasioned", initially on a voluntary basis. That may prove to be a more lasting claim to fame than the celebrated book.

Unfortunately, *Elements of Medical Statistics* now has only curiosity value. Hawkins adopts a purely descriptive approach, relying heavily on crude death rates, but with some appreciation of the effects of the age structure of a population on demographic measures such as the **average age at death**. His detailed comments often show a remarkable lack of critical awareness. The book contains many complimentary remarks about Manchester, which he apparently thought to have a remarkably low death rate (1 in 74, as compared with 1 in 43 for Birmingham and 1 in 40 for London). Unfortunately, he had made an arithmetic slip, and in a copy of the book owned by the Royal Statistical Society all the complimentary references to Manchester are scored out, apparently in his own hand. Again, he seems to have accepted anecdotes from classical antiquity with a degree of naivety. He refers uncritically to reports of individuals living to ages greater than 150 years; and he uses a fatality rate from acute fevers quoted by Hippocrates as a control for more favorable figures recorded in 1825.

As Greenwood remarks, Hawkins "had been diligent and brought together numerical data from all parts of the world and was certainly one of the first physicians to advocate a serious study of hospital records". The work of pioneers often shows traces of fallibility, but they deserve to be remembered for their achievements rather than their weaknesses. Hawkins lacked the mathematical abilities of the younger physicians **W.A. Guy** in England and **Jules Gavarret** in France, but he helped to ensure that medical applications played a significant part in the enormous growth of statistical activity during the first half of the nineteenth century.

PETER ARMITAGE

Hawthorne Effect

The Hawthorne effect is an effect on study participants that results from their knowing that they are being studied. For example, in a study of methods to promote smoking cessation, it might be necessary to contact study participants each year to determine smoking status. The Hawthorne effect could distort study results if this repeated annual contact affected smoking behavior or the reporting of smoking behavior.

MITCHELL H. GAIL

Hazard Models Based on First-passage Time Distributions

Introduction

Survival and **event history analysis** study the occurrence of events. It seems highly reasonable to imagine that these events depend on underlying processes that determine the occurrence. The dissolution of a marriage does not happen out of the blue; most often there is a process of deterioration prior to divorce. The occurrence of myocardial infarction, as another example, is the manifestation of a process of occlusion of coronary arteries. The reason why these underlying processes do not figure in the statistical analysis of survival data is that they are usually unobserved. Occasionally, partial information may be available through **covariates** or **marker processes**.

Although observation of the process is a problem, it might still be of interest to model survival data with the idea of an underlying process in mind. Such models will be highly idealized, but may still yield some insight. Typically, what one would do is to imagine that the process can be described roughly by some standard **stochastic process** with simple mathematical properties. It could be a **Markov** model on a finite state space, with a number of transient states and one absorbing state, such that the occurrence of the event in question corresponds to entrance into the absorbing state. Such distributions are called ***phase-type distributions***. Or the process could be modeled as a Wiener process (**Brownian motion**) with drift, such that the event occurs when the process passes a certain limit. The first-passage time in this case follows an ***inverse Gaussian distribution***. This inverse Gaussian family has interesting and useful properties and should definitely be used much more in survival analysis and other fields.

Assuming the stochastic process point of view allows for some general considerations of interest [2], we shall consider a population of individuals on the transient state space of the stochastic process (i.e. prior to absorption). In a sense, there are two forces operating on these individuals, namely, the general diffusion in the transient state space, and the attraction of the absorbing state. The rate at which absorption takes place (i.e. the **hazard rate** of the first-passage distribution) is created in a balance between these two forces. Understanding the shape of the hazard rate is in general difficult, and the present point of view might help in doing so.

A very useful concept in this context is that of an *attractor*. For many processes, the distribution of survivors (i.e. the distribution on the transient state space) moves towards an attractor, that is, a fixed distribution on the state space. The attractor is often termed a *quasi-stationary limit*. It is the limiting distribution given nonabsorption, and it is a somewhat surprising fact that such a limit often exists in spite of the continuous leaking of probability mass into the absorbing state.

A practical reason for considering the underlying processes is that many, if not most, covariates used in survival analysis are not really **risk factors**, but rather measures of how far advanced a disease is. An example is the staging measures used in cancer (*see* **Oncology**). A statistical application of this idea is given in [2].

Markov Chain with Absorption

The simplest stochastic process of use in this context, is a time-continuous **Markov chain** on a finite state space. One state is absorbing, and the idea is that the process starts out according to some distribution on the remaining (transient) state space. The first-passage time is the time to absorption, and its distribution is termed a *phase-type distribution*; see [1]. Such distributions play an important role in probability theory and there exists a lot of theory for their properties.

An example is given in Figure 1, which represents a Markov chain where an individual can move up and down in a state space before eventually being absorbed. This could model a disease where "repair" and improvement occur in various stages before the disease in the end moves into a nonreversible state. The interesting thing about this model is that it gives a nice illustration of how the shape of the hazard rate is influenced by the distance of the starting point from the absorbing state. Starting in states 1, 3, and 5 respectively and computing the hazard rates of time to absorption, one gets the result illustrated in Figure 2 (parameters equal to $\alpha = 1.5$ and $\beta = 1.0$). Hence, the three major shapes of hazard rates occurring in practice – the increasing, the decreasing, and the

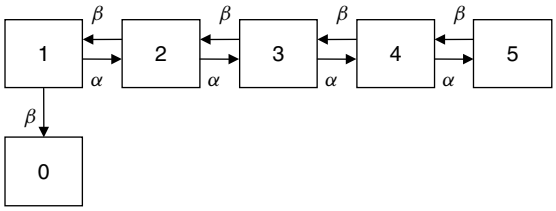

Figure 1 State space of a phase-type model. (Reprinted from Aalen and Gjessing, 2001. Reproduced by permission of the authors)

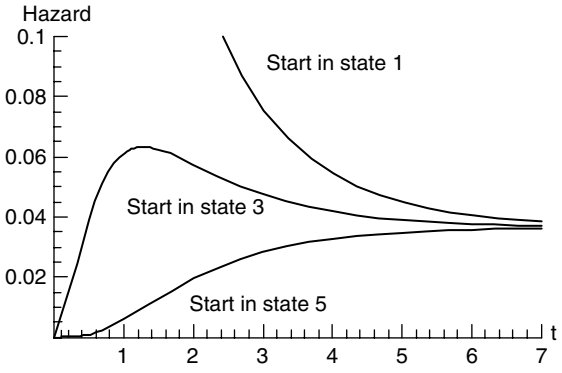

Figure 2 Hazard rates for time to absorption dependent on starting state in phase-type model. Parameters: $\alpha = 1.5$, $\beta = 1.0$. (Reprinted from Aalen and Gjessing 2001. Reproduced by permission of the authors)

unimodal one – arise naturally. This is no accident, but has to do with how the starting points relate to the quasi-stationary distribution. For the parameter values chosen here, the quasi-stationary distribution on states 1 to 5 is given as 0.037, 0.090, 0.167, 0.276, 0.430. With this starting distribution, the hazard rate of absorption is constant and equal to 0.0365. The three states 1, 3, and 5 can be considered to have, respectively, a short, medium, and long distance from the absorbing state, compared with a quasi-stationary distribution.

Sometimes, a unimodal hazard rate (increasing first and then decreasing) has been given the naive interpretation that its maximum point represents a point of "crisis". An example is the "seventh year itch" interpretation of divorce rates peaking after about seven years, the idea being that a typical marriage goes through a crisis after seven years, and then the divorce rate declines when it passes through the crisis. A more sophisticated interpretation of a declining hazard rate as a result of selection effects has been promoted within the context of ***frailty*** theory. The present interpretation of varying hazard rate shapes is yet another one. It tells us in fact that a unimodal hazard would be expected to arise quite often, as a natural phenomenon.

An extension of this theory to **semi-Markov processes** has been developed; see [6].

Wiener Process with Absorption

The Wiener process is the prototype of a continuous and completely random stochastic process. When combined with a drift term, it is an interesting model of a process that approaches some aim with a lot of random detours along the way; see [2, 4, 5] for statistical applications. We shall consider a Wiener process with drift $-\mu$ ($\mu > 0$, that is, drift towards zero) and variance coefficient σ^2, this meaning that the increments of the process over an interval of length Δt is normally distributed with mean $-\mu\Delta t$ and variance $\sigma^2\Delta t$. The process starts out in some positive state, c, and is absorbed when it hits zero at some time T. The distribution of T is the classical example of a first-passage time distribution, and is usually denoted the inverse Gaussian distribution. The density of T is given by:

$$f(t, c, \mu, \sigma) = \frac{c}{\sigma\sqrt{2\pi}}\, t^{-3/2} \exp\left[-\frac{(c-\mu t)^2}{2\sigma^2 t}\right] \tag{1}$$

In this case, there exist several quasi-stationary distributions [3], one of which is "canonical" in the following sense: starting out in a single given state with probability 1, the distribution of "survivors" will converge to the canonical one. The canonical one is given by: $(\mu^2/\sigma^4)\, x \exp(-\mu\, x/\sigma^2)$, which is a **gamma distribution**, and is illustrated in Figure 3. If the process is initiated with this distribution on the positive real line, then the hazard rate of absorption in zero is constant and given as $(\mu/\sigma)^2/2$. Note that this hazard rate *depends on the square of* μ. This means, for instance, that if the drift towards the event (i.e. absorption) doubles, then the rate at which the event occurs is multiplied by four. In practical applications of the model, such considerations may be of interest in the interpretation.

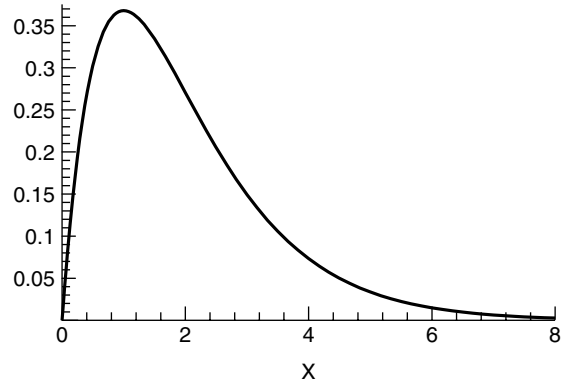

Figure 3 Quasi-stationary distribution for a Wiener process with absorption (parameters: $\mu/\sigma^2 = 1$). (Reprinted from Aalen and Gjessing 2001. Reproduced by permission of the authors)

The hazard rate of an inverse Gaussian distribution is unimodal, that is, increasing first and then decreasing. As pointed out by Aalen and Gjessing [2], when the starting point is close to the point of absorption compared to the quasi-stationary distribution, then the hazard rate is largely decreasing. When the starting point is far away, it is largely increasing. Finally, with a starting point in between, both the increasing and decreasing parts of the hazard rate will be of interest.

Hazard Plotting

Hazard plotting and **nonparametric** statistical inference for **hazard rate** (intensity) models have been vigorously studied in the mathematical framework of counting processes, as illustrated by articles, such as **Counting Process Methods in Survival Analysis**, **Nelson–Aalen Estimator**, **Kaplan–Meier Estimator**, **Aalen–Johansen Estimator**, **Repeated Events**, **Duration Dependence**, and **Goodness of Fit in Survival Analysis**. Common to these versions of the simple techniques for analysis of hazard rate models are some specific model assumptions that were not made by W. Nelson when he originally proposed what is here termed the *Nelson–Aalen estimator* of an integrated hazard.

As explained in detail in the article **Repeated Events**, the basic estimating equations (*see* **Estimating Functions**) for rate and mean functions are **unbiased** more generally than under the above model assumptions, provided that the observation intervals are independent of the process generating the events. (In particular, this means a more restrictive assumption on the **censoring** pattern.) Nelson described his approach in his monographs [1, 2].

Hazard Rate

The hazard rate at time t of an event is the limit $\lambda(t) = \text{limit}_{\Delta \downarrow 0} \Delta^{-1} \Pr(t \preceq T \prec t + \Delta | t \preceq T)$, where T is the exact time to the event. Special cases and synonyms of hazard rate, depending on the event in question, include force of mortality (where the event is death), instantaneous incidence rate, **incidence rate**, and **incidence density** (where the event is disease occurrence).

For events that can only occur once, such as death or first occurrence of an illness, the probability that the event occurs in the interval $[0, t)$ is given by $1 - \exp(-\int_0^t \lambda(u)\,\mathrm{d}u)$ (*see* **Survival Analysis, Overview**; **Survival Distributions and Their Characteristics**). The quantity $\int_0^t \lambda(u)\,\mathrm{d}u$ is known as the **cumulative hazard**.

Often, the theoretical hazard rate $\lambda(u)$ is estimated by dividing the number of events that arise in a population in a short time interval by the corresponding **person-years at risk**. The various terms, hazard rate, force of mortality, incidence density, person–years incidence rate, and incidence rate are often used to denote estimates of the corresponding theoretical hazard rate.

MITCHELL H. GAIL

Hazard Ratio Estimator

In **survival analysis**, statistical models are frequently specified via the **hazard** function $\alpha(t)$. A simple model for the relation between the hazard functions in two groups (e.g. a treatment group 1 and a control group 0) is the **proportional hazards model** where

$$\alpha_1(t) = \theta\alpha_0(t), \tag{1}$$

with θ being the treatment effect. For a parametrically specified baseline hazard, $\alpha_0(t)$, both the treatment effect and the parameters in the baseline hazard are usually estimated using **maximum likelihood**. In a semiparametric model where the baseline hazard is left unspecified, several estimators for θ are available: the maximum **partial likelihood** ("Cox") estimator, cf. [5] (*see* **Cox Regression Model**), a class of **rank** estimators, and some *ad hoc* estimators.

Assume that the available data are

$$(X_{ij}, D_{ij}; \quad i = 1, \ldots, n_j, \quad j = 0, 1),$$

where the X_{ij} are the times of observation: a failure time if the corresponding indicator D_{ij} is 1, a right-censoring time if D_{ij} is 0. The Cox estimator, $\hat{\theta}$, is then the solution to the following equation:

$$O_1 = E_1(\theta), \tag{2}$$

where, for $j = 0, 1$, $O_j = \sum_i D_{ij}$ and

$$E_1(\theta) = \sum_{ij} \frac{Y_1(X_{ij})\theta}{Y_0(X_{ij}) + Y_1(X_{ij})\theta} D_{ij}.$$

Here, $Y_j(t) = \sum_i I(X_{ij} \geq t)$ is the number at risk at time $t-$ in group j, $j = 0, 1$. Notice that (2) expresses that for $\theta = \hat{\theta}$, the observed number, O_1, of failures in group 1 should be equal to a corresponding "expected" number, $E_1(\theta)$ under the proportional hazards assumption. The Cox estimator $\hat{\theta}$ is **consistent** and asymptotically normal under mild regularity conditions when n_0 and n_1 tend to infinity (*see* **Large-sample Theory**).

A class of explicit "rank" estimators originally introduced by Crowley et al. [6] and further discussed by Andersen [1] is for a given *weight process L(t)* given by

$$\widehat{\theta_L} = \frac{\sum_{i=1}^{n_1} L(X_{i1})(D_{i1}/Y_1(X_{i1}))}{\sum_{i=1}^{n_0} L(X_{i0})(D_{i0}/Y_0(X_{i0}))}. \tag{3}$$

For $L(t) = I(t \leq t^*)$, $\widehat{\theta_L}$ is simply the ratio between the **Nelson–Aalen estimators** for the cumulative hazards in groups 1 and 0 evaluated at t^*. Under the same kind of regularity conditions as for $\hat{\theta}$, the rank estimators given by (3) are also consistent and asymptotically normal if the weight process is well behaved in large samples. It was shown in the above-mentioned papers that the Cox estimator $\hat{\theta}$ given by (2) is always less dispersed than any $\widehat{\theta_L}$ given by (3). However, for the particular choice

$$L(t) = \frac{Y_0(t)Y_1(t)}{Y_0(t) + Y_1(t)}, \tag{4}$$

$\widehat{\theta_L}$ is nearly fully **efficient** when θ is close to 1. Furthermore, a fully efficient estimator is the two-step estimator of Begun & Reid [3] that is obtained with

$$L(t) = \frac{Y_0(t)Y_1(t)/\theta^*}{Y_0(t) + Y_1(t)\theta^*},$$

where θ^* is some preliminary, consistent estimator, e.g. $\widehat{\theta_{L=1}}$.

Using an estimator $\widehat{\theta_L}$ and its estimated variance (see, for example, Andersen et al. [2, Section V.3.1]) the hypothesis $\theta = 1$ of no treatment effect may be tested. This gives all the standard linear nonparametric two-sample tests for survival data (*see* **Linear Rank Tests in Survival Analysis**) and, in particular, the weight process given by (4) gives the **logrank test**.

Another explicit *ad hoc* estimator, discussed by Breslow [4], is given by

$$\tilde{\theta} = \frac{O_1/E_1(1)}{O_0/E_0(1)},$$

with

$$E_0(\theta) = \sum_{ij} \frac{Y_0(X_{ij})}{Y_0(X_{ij}) + Y_1(X_{ij})\theta} D_{ij}.$$

The estimator $\tilde{\theta}$ is generally inconsistent when $\theta \neq 1$ but it has gained some popularity due to its simplicity

and close connection to the logrank test, which is also based on the observed, O_0 and O_1, and expected, $E_0(1)$ and $E_1(1)$, numbers of failures.

Tests for the proportional hazards assumption (1) based on $\widehat{\theta_L}$ were studied by Gill & Schumacher [7] and further developed by Lin [9] and Sengupta et al. [10]; see, for example, Andersen et al. [2, Example VII.3.5].

The estimators discussed above only make sense under the proportional hazards model (1). However, Kalbfleisch & Prentice [8] defined, for a given survival function, S, the *average hazard ratio* by $\theta_1(S)/\theta_0(S)$ where, for $j = 0, 1$,

$$\theta_j(S) = -\int_0^\infty \frac{\alpha_j(t)}{\alpha_0(t) + \alpha_1(t)}\, \mathrm{d}S(t). \qquad (5)$$

Under the model (1), the average hazard ratio reduces to θ. Particular emphasis was paid to survival functions of the form $S(t) = (S_0(t)S_1(t))^\gamma$ where, for $j = 0, 1$, $S_j(t)$ is the survival function corresponding to the hazard function $\alpha_j(t)$. In this case (5) reduces to the following quantity:

$$-\int_0^\infty S_0(t)^\gamma\, \mathrm{d}S_1(t)^\gamma,$$

which, for a given value of γ, is easily estimated by replacing the survival function $S_j(t)$ by its **Kaplan–Meier estimator**.

PER KRAGH ANDERSEN

Health Care Financing

The methods used to finance personal health care service play a major role in shaping a country's health care system. Personal health care services are those services such as hospital care, physician care, dental services, and drugs that are provided directly to individuals. The financing methods influence the terms under which people access the health care delivery system, the types of health care provided, and the mechanisms used to allocate health care services. They also influence how the costs of health care services are distributed over the population by income and by health status.

Two aspects of health care financing are the focus of this article: the sources of funds for health care services and the mechanisms used to pay individuals and institutions who provide health care services. Figure 1 presents a diagrammatic representation of these two aspects of health care financing and provides a framework for the discussion that follows.

Sources of Payments for Health Care

Overview

Individuals may simply use their own incomes to purchase health care services from health care providers (physicians, hospitals, clinics, laboratories, and other firms/individuals). In most other markets, this is the way goods and services are purchased. However, the market for health care services has evolved quite differently. In this market, other mechanisms such as private insurance plans, sickness funds, and national health insurance systems have been developed to pay for a significant proportion of personal health care services.

Nevertheless, as indicated in Figure 1, all health care is eventually paid for by individuals. It is individuals who ultimately pay the premiums to insurance companies and the taxes to governments, which in turn pay for health care services. Furthermore, even though business may be a source for collecting premiums and/or taxes, the amounts paid by businesses are passed back to individuals and households through lower wages, higher prices, or lower returns on invested capital. The total payments made for health care are sometimes referred to as the *cost* of personal health care.

The way that the funds are raised to pay for health care services affects the distribution of the cost of health care within a country. Two types of distributions of the cost of health care are frequently considered: the distribution by health status (across the healthy and the sick), and the distribution by income. Analysts classify funding sources with respect to income as progressive, regressive, or proportional. In a progressive funding system, the fraction of a person's income paid in taxes (or premiums) rises as their income rises; in a regressive funding system, the fraction of a person's income paid in taxes (or premiums) declines as their income rises; while under a proportion funding system, this fraction is constant regardless of a person's income. This section will discuss the sources of funds in some detail and comment on the distribution of the cost of health care.

Payments by Third Parties

A basic characteristic of health care systems in all developed countries is that the majority of payments for medical services flows through third parties. A third party is an entity, usually an insurance company or government agency, that pays for medical services but does not receive or provide health care services. This payer is the third party, while the patient and the health care provider are the first two parties. This distinction between the third party and the providers is becoming blurred, particularly in the United States.

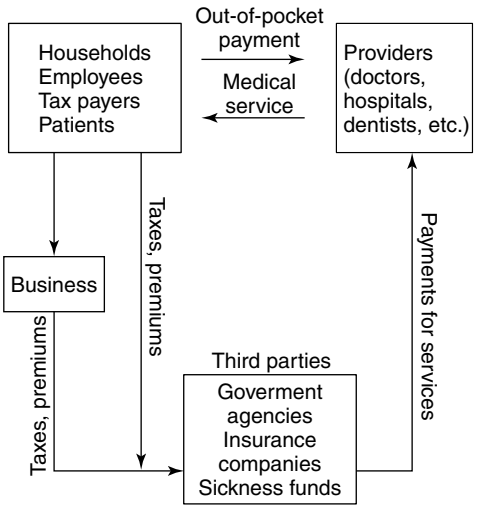

Figure 1 Health care financing. Source: adapted from [8]

In the US, groups of health care providers may assume some financial risk (thus acting as insurers) by contracting with governments, businesses, and/or individuals to provide medical care at a fixed rate per person covered. In general, third-party financing arose for two reasons: individuals wanted to insure against the large and uncertain financial costs associated with illness, and governments wanted to ensure that the population at large or certain vulnerable portions of the population had access to needed health care.

As indicated in Figure 1, there are three basic sources of third-party funds: general taxes, payroll taxes, and insurance premiums. General taxes include income taxes, value-added or consumption taxes, and other specific taxes. Payroll taxes are employment-related taxes, which are normally set as a percentage of payroll or wages. (Payroll taxes may apply to all wages, or to wages up to a certain amount.) (Additionally, governments may use other sources of revenue such as that from lotteries). Insurance premiums are the amount paid for an insurance policy – premiums vary according to the type and amount of insurance purchased as well as the characteristics of the individuals covered under the policy. Premiums are the price paid for an insurance policy. (An individual's policy may cover the individual, or the individual and other persons dependent on that individual.) Payments made by the insurance company for covered medical services used by individuals enrolled in the insurance plan are funded by the premiums. If premiums are the sole funding source for the plan, then premiums must reflect the expected cost of health care services used by the individuals covered under that plan as well as the administrative cost of running the plan.

There are two different approaches to setting the health insurance premiums: community rating and experience rating. Community rating systems use the average, expected cost of medical care for all individuals in a community and assign this premium to each individual in the community. An experience rating system groups individuals by some common characteristic (i.e. place of employment, age, whether or not they smoke) and assigns individuals of like characteristics the same premium, which is based on the average, expected cost of medical care for individuals with those characteristics (*see* **Actuarial Methods**).

Major Sources of Third-party Funds in Selected Countries

Payroll taxes are the major source of third-party funds in France and Germany. In both of these countries, employees and employers pay a certain percentage of their wages into sickness funds. In Germany, there are several sickness funds, and employees often have a wide choice of sickness funds in a region. Once an employee selects a fund, the fund has the right to collect its premiums (which vary from fund to fund) as a percent of the employee's gross wages – half the premium is paid by the employer and half by the employee. There is a limit on the amount of wages subject to premiums. In France, there is one large sickness fund (which covers about 80% of the population) and several small funds. The contributions paid by employers and employees are set by the Central Government: the employer pays about 12.6% of total wage bill and the employee pays about 6.8% of wages. In both of these countries, systems have been developed to cover individuals who are unemployed and those who are retired.

General taxes are the major source of third-party funds in the United Kingdom and Canada. The British National Health Service is a national program. The Canadian Medicare program is a decentralized program and the cost of the program is shared between the federal and provincial governments. Each Canadian province administers its own program and exercises some discretion regarding which medical services are covered. Third-party financing in the United States is fundamentally different from that in all other developed countries because of the large mix of funding methods used. Multiple types of third parties exist, including government programs such as Medicare and Medicaid, nonprofit insurance companies such as Blue Cross/Blue Shield, and numerous private insurance plans vended to employers, unions, and individuals. This variety of third-party payers results in a mix of sources of third-party funds, including premiums by individuals and businesses, general taxes, and payroll taxes.

In the United States, the majority of employed people and their dependants obtain health insurance through their employment. However, the provision of health insurance by employers is strictly voluntary (other than the State of Hawaii, which mandates that employers provide health insurance). The fact

that many employers voluntarily offer health insurance reflects the strong incentives in the current tax system for employers to provide health insurance. Under current tax codes, employer-paid premiums are considered a cost of doing business and are treated as a business expense. (Large companies frequently self-insure and hire administrators to manage their health benefits. Thus, these companies do not strictly pay premiums. Nevertheless, conceptually, one can think of expected, average health care costs as the premium.) Furthermore, these employer-paid premiums are not considered income for employees and are exempt from individuals' income taxes. Wide differences exist across firms with respect to the design of the benefit package and the proportion of the premium paid by the employer. (employers generally pay a higher proportion of the total premium for their employees than for their employees' dependants who might also be included in the health plan.). Employers sometimes offer employees a choice among health insurance plans. Active competition exists among insurance companies in the employment-offered health insurance market, and premiums are set competitively. Premiums tend to be experience rated rather than community rated, and businesses with healthy employees have lower premiums than businesses with generally sicker employees. In the United States, health insurance is also available to individuals and groups, independent of employment. Premiums are experience rated and reflect the average, expected cost of illness for individuals within the defined group covered by a particular policy. The sicker the pool of individuals covered by an insurance policy, the higher the premiums. However, a number of states have passed legislation that set limits on the range of premia.

Although the United States lacks universal health insurance, it provides public health insurance for the poor, the disabled, and the elderly through two publicly funded programs, Medicaid and Medicare. Medicaid, which is jointly funded by the Federal and State governments, provides medical services to low-income individuals who meet specific eligibility criteria. Eligibility criteria may vary slightly across states. In general, the Medicaid enrollees are medically disabled and/or poor. Medicaid contains specific benefits for low-income women and their children, and the majority of those covered by Medicaid are women and children. (The majority of payments, however, go for the disabled and the elderly to pay for long-term care services not covered under the Medicare program.) The federally funded Medicare program insures most people aged 65 and over, as well as a small subset of the general population who are medically disabled. The Medicare program is funded through a combination of payroll taxes, general tax revenues, beneficiary premiums, and direct beneficiary payments (*see* **Health Services Organization in the US**).

It should be pointed out that health insurance markets have developed in many countries to supplement government health insurance programs. For example, people in the United Kingdom may purchase private health insurance as an additional source of third-party funding that facilitates access to specialists and allows individuals to jump queues and to use private facilities not covered by government programs. Canadians may purchase supplemental health insurance policies to pay for medical services not covered under the provincial Medicare programs and to pay for nonessential amenities such as private rooms. Likewise, American Medicare beneficiaries may purchase supplemental insurance (called Medigap insurance) to cover expenses not included in the Medicare program, such as outpatient prescription drugs and extended nursing home care, as well as Medicare cost-sharing liabilities.

Direct Payments by Individuals

Individuals may also pay health care providers directly for services rendered. Direct payments to providers are often referred to as *out-of-pocket payments*. People may pay directly for health care services for several reasons: they are uninsured, or a particular service is not covered by their health insurance plan, or the health insurance coverage is not complete. For example, many insured individuals routinely make some out-of-pocket payments because their health insurance policies (including the national health insurance programs discussed above) contain explicit *cost-sharing* provisions mandating some amount of direct payment by the individual. Cost-sharing provisions take several different forms including: deductibles (a fixed amount that must be paid by the insured before any third party payment will be made); copayments such as a specific payment that the insured must pay for each service (e.g. $6.00 for each prescription filled or $5.00 for each visit to a physician); or a specific percentage of the bill (such

as the 20% copayment Medicare beneficiaries must pay for physician services). Wide variations exist across countries with respect to the level of out-of-pocket payments for health care. For example, in both Canada and in the United Kingdom there are no out-of-pocket payments for basic services covered under the respective national health insurance systems. In Germany, out-of-pocket payments are very limited, whereas France has substantial cost sharing (i.e. 20%–30%) for many health care services. In general, out-of-pocket payments in the United States are high relative to those in other developed countries for a number of reasons: a significant number of people are uninsured (no third-party payer), and private health insurance plans are not standardized with respect to the types of services covered or the level of cost-sharing provisions on covered services. Note that although the Medicare program does contain significant cost-sharing requirements, few Medicare beneficiaries actually pay much out-of-pocket for Medicare covered services. Indigent Medicare beneficiaries have their cost sharing covered under the Medicaid program, while the majority of other Medicare beneficiaries have their cost-sharing liabilities covered through employer sponsored retiree health benefits or privately purchased supplemental (Medigap) policies.

Uninsured Individuals

Among the developed countries, only the United States has a large number of people without insurance because it is the only country without a universal health insurance program. Approximately 17% of the United States nonelderly population was uninsured in 2002 [2]. The uninsured pay for services out of their own pocket. However, a large portion of the cost of medical care used by the uninsured is covered by publicly funded clinics, specifically designated charity funds, and "cost-shifting". Cost-shifting occurs when a provider charges some groups of patients higher than normal fees in order to cover the cost of services provided to other groups of patients for whom the provider receives no or inadequate payments.

Implication of Funding Sources on the Burden of Illness

In general, health insurance programs funded predominately by income taxes are the most progressive with respect to income. Individuals with the most income pay proportionately more than individuals with the lowest incomes, regardless of their use of medical services. Health insurance programs funded by premiums are the most regressive with respect to income. Payroll taxes tend to be moderately regressive because the percentage of a person's income from wages tends to decline as total income rises. Value-added or consumption taxes are also regressive with respect to income because low-income individuals tend to spend a higher proportion of their income on consumption goods than do upper-income individuals. However, the regressive nature of health insurance programs financed by consumption taxes can be reduced by excluding specific items (such as food) from taxation.

The broader and more inclusive the funding base for health insurance programs, the more the financial cost of illness is shifted from the sick to the healthy. The more out-of-pocket payments serve as the source of funds for health care, the more the burden of the financial cost of illness is borne by the sick. The more experience rating is used to set premiums, the more the relatively sick have to pay for health care. Thus, under national health insurance systems, such as those in the United Kingdom, Germany, and Canada, the *financial* cost of illness is borne socially and distributed broadly across the population. Actual expenditures (in out-of-pocket payments and premiums) made by the sick are much less than that of the total cost of their medical care. This is in contrast to the United States where a higher proportion of costs are paid out of pocket and a large number of insurance plans are experience rated.

Third-party Payments and Consumer Demand

Health insurance affects the price that a person pays for medical service, but the effect can be complicated. For example, a person who has complete insurance coverage pays a price of zero for each medical service used. A person with an insurance plan specifying a $500 deductible, 20% cost sharing, and a $3000 limit on out-of-pocket payments, pays out of pocket for the first $500 of medical services used and then pays 20% of charges for additional medical services until a total of $13 000 in medical services has been used. At that point, the person will have spent $3000 in total out-of-pocket expenses and the insurance policy will cover all additional costs. Thus, individuals covered

under the former plan may choose to use medical services differently than those covered under the second plan since they face very different prices for the same unit of medical care.

Not surprisingly, there is considerable interest in how the structure of cost sharing influences the number of health care services used, that is, in determining how responsive consumers are to out-of-pocket payments for medical services. Since the United States is the only country where direct patient payments are a significant source of funds, most research on this issue has been done in the United States using that country's data. Several different analytical structures have been employed to examine the use of services (*see* **Health Care Utilization Data**) by individuals who pay different prices for the same service including the examination of natural experiments (e.g. some exogenous event changes the price that an individual pays for health care), analyses of self-reported utilization data from large-scale surveys such as the National Medical Care Expenditure Survey (*see* **Medical Expenditure Panel Survey (MEPS)**), and analyses of claims data from different health insurance plans [7]. The need to control for nonprice factors that influence the use of health care services, as well as **selection bias** complicates this research. (Selection bias arises when people who need more services choose plans with more extensive coverage, and vice versa.) The best study examining these issues uses data from the Health Insurance Experiment, a randomized clinical trial (*see* **Clinical Trials, Overview**) conducted by the RAND corporation [6]. This experiment, conducted in the 1970s, **randomized** people from six different locations (both urban and rural) in the United States into one of 14 insurance plans, which differed by the amount of the deductible, consumer cost sharing, and maximum out-of-pocket expenses.

The research revealed that consumers generally respond to the price of health care services, and the extent to which they respond varies by the type of medical service. For example, the price of emergency services produces very little response, while people are more highly responsive to the price for elective services. The demand for mental health care services is more price responsive than that for physical health care services.

As argued above, the presence of health insurance affects an individual's behavior, relative to what it would be if he or she were not insured. This effect is sometimes referred to as *moral hazard*. Moral hazard is said to occur when insured individuals change their behavior because they have insurance. The term was first applied in the life and fire insurance markets. For instance, moral hazard is said to exist if a person burns down the house in order to collect fire insurance, or fakes death with the intent of collecting the life insurance payments. The use of the term in the life and fire insurance markets implies some immoral behavior on the part of the insured.

In the health insurance market, *moral hazard* refers to insured individuals engaging in riskier (in terms of their health) behavior because of the presence of health insurance or otherwise changing their health-related behavior, such as using more health care services or failing to seek out low-cost providers. However, most commonly the term *moral hazard* simply reflects the basic law of demand: as the out-of-pocket price of medical services decreases, people use more medical services. In this sense, moral hazard and price responsiveness (known as price elasticity of demand) are intimately related. Thus, there is nothing immoral about this type of moral hazard; it is simply a manifestation of rational human choice.

Funding Sources in the United States

As indicated above, the financing of health care services in the United States is more complex than in other countries. Table 1 presents information on the sources of funds for personal health care services in the United States; both total service and by the type of service. In 2002, expenditures on personal health care services were $1340.2 billion, of which 15.9 was paid by direct patient payments (out-of-pocket payments) and 84.1% by third parties. However, the proportion of expenditures covered by third parties ranges from 97% for hospital care to 44% for drugs and other services.

Data Sources

Information on health care expenditures is reported by the government agencies for each country. For example, the Center for Medicare and Medicare Services website has detailed information on program expenditures as well as national health care expenditures. Furthermore, both the *Health Care Financing Review and Health Affairs* annually publish detailed information on health care expenditures in the United

Table 1 Source of payment for selected personal health care 2002. Total: 1340.2 billion (US: 2002)

Type of service	Total (%)	Patient direct	Private health insurance	Other private	Federal[a]	State and local[b]
Hospital care	100	3.0	33.9	4.2	47.3	11.6

States. The Department of National Health and Welfare in Canada publishes data on Canadian health expenditures. The Organization for Economic Cooperation and Development (OECD) maintains an ongoing data collection and analyzes effort aimed at producing timely, consistent data for 24 nations in Asia, Europe, and North America. The journal *Health Affairs* periodically publishes data on the performance of health systems in OECD countries.

Paying Health Care Providers

A number of methods exist for paying health care providers (physicians, hospitals, clinics, labs, and other individuals/firms supplying health care services) for medical care services rendered to individuals. This section presents an overview of the most important of these payments methods.

Paying for Physician Services

Physicians are generally paid using one of three general methods of payment: fee-for-service, capitation, or salary. In some cases, physicians receive payments under more than one of these payment methods. The use of multiple payment methods occurs when either a given payer uses a combination of methods, or, as occurs in the United States, a physician receives payments from more than one third-party payer, each of which uses a different payment method.

Fee-for-service. Under the fee-for-service method of payment, physicians receive a fee for each service provided. The medical service rendered is the *unit of payment*, and there is a certain degree of discretion regarding how a service is defined. A service unit can be very distinct (e.g. a urinalysis) or relatively comprehensive (e.g. an appendectomy where the physician payment covers all care associated with the procedure, including the preoperative visit, the surgical procedure itself, and some follow-up care). Thus, the service on which the unit of payment is based can actually be some bundle of separate, discrete services.

Payments to physicians for medical services may be based on the fees that physicians set for their services or on a specific fee schedule. A fee schedule defines the amount or relative amount of fees for each physician service. In general, only third-party payers use fee schedules. Individuals without insurance for physicians' services are usually billed according to charges set by the physician.

In the United States, third-party payers using the fee-for-service method may pay physicians an amount based on the physician's charges, prenegotiated rates, or a fee schedule. Because different third-party payers may use different rates or schedules, physicians can receive different payment amounts for the same type of service depending upon the third party payer involved. By contrast, in most other countries using the fee-for-service method, physicians receive payment based on a single negotiated fee schedule or on regional negotiated fee schedules. The best-known fee schedule in the United States is the *Medicare fee schedule*, the fee schedule used by the Medicare program to pay physicians for services rendered to Medicare beneficiaries. The Medicare fee schedule assigns each defined unit of service a relative value quantifying the resources (such as physician time, skill, and use of support services) needed to produce the service. The Medicare fee schedule employs a conversion factor to translate the value of the resources used into a specific payment amount.

In addition to the Medicare program, some of the other third-party payers in the United States have adopted the Medicare fee schedule for use with their own resource conversion factors to set payments for physician services.

Capitation. The capitation method of payment provides physicians with a defined, periodic, per patient payment (usually monthly), regardless of the number or type of covered services the physician provides to a patient. Most commonly used to pay primary care physicians, the periodic payment reflects the expected cost of providing the covered services. The covered services and terms of the care provided under capitation vary with the actual capitation agreement. When used to pay primary care physicians, some subspecialty services provided to patients by other physicians may be charged to the primary care physician for payment out of the primary care physician's capitated fee. Likewise, some specified services provided by the primary care physician may not be included in the capitated fee and instead may be paid for on a fee-for-service basis. Again, these arrangements vary by the actual capitation agreement.

The capitation fee may be adjusted to reflect patient characteristics such as age in order to compensate physicians for variations in the expected use of services by groups of patients with similar characteristics. In the United States, managed care plans use the capitation method widely to pay primary care physicians, as does the British National Health Service.

Salary. The salary method of payment provides physicians with a fixed monthly or annual salary that does not vary with the number of patients treated or services provided. However, not all physicians are paid the same salary, which may be based on such factors as specialty, hours worked, special duties (such as administrative tasks), and years of experience. In many European countries, hospital-based physicians are paid using the salary method, while physicians working in the outpatient setting receive payment under other methods. In the United States, physicians working for government agencies, some Health Maintenance Organizations, or large group practices, often receive payment by the salary method.

It should be noted that a physician can receive payment under a single payment method, while third-party payers make payments for the physician's services using several different payment methods. For example, a physician belonging to a large group practice may receive a salary even though insurance plans pay for services rendered by physicians in the group via a capitation method.

Paying Other Professionals. For other health care professionals (physical therapists, dieticians, social workers, home care nurses, etc.), the fee-for-service and salary methods are widespread, while capitation is rarely used.

Paying Hospitals

Numerous methods are used to pay for hospital services, such as payment based on established charges, retrospective costs, per diem rates, per case rates, capitated payments, or budgets. Because there are many different third-party payers in the United States, hospitals located there frequently receive payments under a host of different methods. In contrast, hospitals in other countries tend to be paid according to a single payment method.

Charge-based Payments Method. Prevalent only in the United States, the charge-based method requires hospitals to define a price or "charge" for each service the hospital provides. This hospital-established charge (or a negotiated percent of that charge) for each service is then paid either directly by the patient or by the patient's health insurance company. If the insurance policy requires copayments, then the hospital's charge is split between the patient and the health insurance company according to the conditions of the insurance contract. The charge-based method allows the hospital to determine the price of hospital services. This method is not used by government payers.

Retrospective-cost-based Payment Method. The retrospective cost-based payment method pays hospitals on the basis of the actual costs of providing hospital services as opposed to a hospital set charge (which may not be linked to the cost of providing services). Under this method, a set of accounting rules allocates hospital costs to a group of patients. Although relatively common in the United States

from 1966 to 1983 because it was used by the Medicare program, most state Medicaid programs, and several Blue Cross plans, this method has lost importance since the mid-1980s when Medicare introduced the Prospective Payment System. When this method is used, hospital payments are typically subject to limitations – either limits on the extent to which reimbursable costs can rise from year to year and/or limits on the maximum allowable costs. Limitations on the maximum allowable costs are normally set relative to costs reported by other similar hospitals.

Per Diem Payment Method. The per diem payment method pays hospitals a set amount for each day that a patient spends in the hospital. In general, the per diem rate is independent of patient characteristics, (e.g. the same per diem rate is paid for patients undergoing heart surgery as for maternity cases). However, the per diem rate may vary by hospital. The rate is generally set via negotiations between the third-party payers and the hospital. The per diem method is relatively common in Europe. In Canada, provincial governments use the per diem method to pay hospitals located outside the province for hospital care rendered to residents of the province. These transfer payments represent only a small proportion of hospitals' budgets.

Per Case Payment Method. The per case method pays a hospital a set amount for each patient discharged from the hospital. In the most extreme form of the per case method, hospitals receive a defined amount per discharge irrespective of the patient's condition. More commonly, patients are classified into groups on the basis of the expected costs for necessary care (known as **case mix** formulations). Using a cost weight established for each group, the hospital receives a payment related to the patient's group classification. A number of patient classification systems exist, but the most frequently used systems are based on the **diagnosis related groups** (DRGs) developed at Yale University [3]; see [4, 5] for an overview of case-mix classification issues.

The *Medicare Prospective Payment System* is the best known of the case-mix-based per case payment systems. This system classifies patients into one of approximately 540 DRGs. A cost weight assigned to each group reflects the expected relative cost of treating patients within that group. For each patient discharged, the hospital receives a set payment that varies by the DRG assigned to the patient. This particular per case payment system also contains provisions for additional payments for patients whose treatment cost are exceptionally high (referred to as outlier payments) and adjustments for the higher costs of teaching hospitals.

Capitation Payment Method. The capitation payment method pays hospitals a fixed, periodic fee per patient for a defined group of patients, often referred to as a panel of patients. The capitation payment does not vary with the actual use of services. Thus, even if no hospital services are used by any patient in the hospital's panel of patients in a given period, the hospital still receives payment. Unexpectedly, high use of hospital services by the patients in the panel can result in net hospital losses for the period. This payment method shifts financial risk from the third-party payer to the hospital itself and its use is relatively rare.

Budget Payment Method. The budget payment method provides hospitals with a global budget designed to cover all services provided by the hospital over the course of the year. The global budget may be unilaterally set by some government agency; it may be established according to some generally accepted formulas, which account for inflation and changes in the size of the inpatient population; or it may be negotiated between the payer and the hospital. In some countries, global budgets involve the use of case-mix information. For example, in the Canadian provinces of Ontario and Alberta, the provincial governments use case-mix information to identify hospitals with global budgets, which may be over- or underfunded relative to other hospitals serving similar patients. Like a capitation system, a global budget system shifts financial risk from the third party to the hospital system. However, it differs from the capitation system because it is not so closely related to the number of covered lives.

Paying Other Institutional Providers. The same methods that have been developed to pay for hospitals are used to pay other institutional providers.

Data Sources

Government agencies publish reports that include the detailed specifications of their health care payments.

For example, the rules for both the Medicare Hospital Prospective Payment System and the Medicare Physician Payment system are published annually in the *Federal Register*. The former includes a listing of all DRGs, the associated costs, the relative cost weights, and other information needed to transform DRG relative costs into payment rates. The latter includes a list of physician services, associated codes, associated relative values, and the conversion factor. The Ontario Ministry of Health publishes the *Schedule of Benefits* for physician services under the Health Insurance Act. This includes the listing of services, the associated codes, and the payment amounts.

Incentives Embedded in the Payment Methods

Theoretical Effects of Provider Payment Mechanisms

The effects of these different methods of paying providers have been the focus of a large body of research (*see* **Health Services Research, Overview**). The basic approach to assessing providers' response to methods of payment is to identify those actions that either increase the providers' profits or decrease their losses. This can be done through formal theoretical modeling [1] as well as through a thoughtful consideration of the issues.

In general, analysts believe that the fee-for-service payment method creates incentives for providers to increase the number of services provided. Furthermore, the fee-for-service payment method lacks incentives for physicians to combine services in a way that minimizes the total cost of treating a patient to obtain a specific outcome. This effect, combined with a physician's desire to deliver thorough and comprehensive care, can result in too many services being provided. The capitation payment method eliminates the incentive in the fee-for-service method to increase the number of services rendered. Instead, the capitation method creates strong incentives for physicians to manage a patient's care efficiently – at least with respect to the services covered under the capitation fee. However, the capitated payment method may result in under-treatment of patients when physicians are not involved in the long-term planning of patient care. Furthermore, there may be some incentives for physicians actively to seek out or recruit relatively healthy (i.e. less costly) patients and to discourage relatively sick (i.e. more costly) patients from joining or remaining in the physician's panel of patients. This is possible because physicians can influence the nature of the interaction that they have with patients.

The salary payment method significantly reduces physician incentives to provide either too many or too few services. However, this method lacks any incentives for physicians to manage patient care efficiently. Furthermore, while the salary payment method removes the incentive for excessive use of medical services, physicians may respond by decreasing their work output. Thus, this method may necessitate productivity enhancement and monitoring measures to ensure an adequate level of work effort on the part of physicians.

Analysts examine the same factors when they consider the incentive effects embedded in the different methods used to pay hospitals. Under a charge-based payment system or a retrospective-cost-based payment system (when most of the payments are made by third parties), there are few financial incentives for hospital administrators to decrease costs or to develop systems that encourage physicians to manage care efficiently. Under a per diem payment method, financial incentives exist to manage the daily costs of hospital care but not the number of days. Therefore, as long as the per diem payment rate is higher than the marginal daily costs, incentives exist to increase the length of the hospital stay. The per case payment method creates strong incentives to manage the use of inpatient services efficiently but also creates incentives to shorten hospital stays. Hospitals may achieve shorter stays by transferring patients to other facilities. The per case payment method also contains financial incentives for hospital decision-makers to undertreat patients, to discriminate against relatively sick patients, and to encourage actively the admission of relatively healthy patients.

Empirical Research on Supply Response

Research on the supply response to payment methods has been concentrated in the United States because of the variety of payment schemes in effect there, the extensive changes in the level and structure of payments that have been made by third parties, and the accessibility of electronic databases (*see* **Administrative Databases**) suitable for testing hypotheses about supply response.

Different analytical approaches analyzing provider response to employer changes have been used. Two approaches are commonly used are before–after studies comparing the outcomes for a common set of providers before and after some specific change in payment method and **fixed effect** models analyzing the effect of payment method using categorical variables to characterize the payment method. Analysts also use a difference in the differences approach in which they analyze the relative differences across two panels of medical providers (or patients) over time where one panel has experienced a change in payment methods and the other panel has not. In general, empirical results are consistent with the incentive effects as discussed above (see [9] for a review of physician supply response).

Databases

As noted, research on supplier response has been facilitated by the existence of large, electronically available databases. For example, the Medicare program's administrative records include detailed information on all payments made under the traditional Medicare program. In the Medicare system, an electronic claim record is created for each service provided to a Medicare beneficiary by a physician or other individual medical care provider. A comprehensive electronic claim record is also created for each hospital admission for a Medicare beneficiary. Each provider of medical services (including hospitals and clinics) and each Medicare beneficiary has a unique identifier. Therefore, it is possible to develop records of episodes of care for beneficiaries and to assess the effect of payment changes for hospital care on length of stay, hospital transfers, the characteristics of hospital patients, and the use of non-hospital services. Detailed data linking providers and recipients (*see* **Record Linkage**) are also available for some state Medicaid programs and some private insurance companies and health plans. Additionally, some states require hospitals to report detailed diagnostic and charge information on all their discharges or mandate the collection of limited clinical data on all patients. These data are available from the relevant state agencies. Finally, the American Hospital Association (AHA) surveys all hospitals in the United States about the number of beds, the number of admissions, and costs. The results are reported in the *AHA Annual Guide to the Health Care Industry* as well as electronically.

Macroeconomic Concerns: A Comment

In all countries, the health care system is shaped by the general regulatory environment within which consumers make decisions about accessing the health care system, and providers make decisions about the types of treatments to provide or recommend. There are significant differences across countries with respect to the extent of centralized controls over the number and location of hospital beds, the number and specialties of physicians in training, physician licensing, practice location and mobility, and the ability of hospitals or groups of providers to establish clinics or purchase advanced technology. In addition, all health plans (government and private) define the types of services they will cover, the relative frequency with which some services (e.g. preventive services) will be paid for, and the conditions under which patients can seek specialty care. Under some plans, patients are allowed to self-refer to specialists; in others, they must obtain permission from a primary care physician to visit a specialist.

In addition to the regulatory controls, the level of control that government authorities have over aggregate health care budgets varies. In general, the more a health care system is directly budgeted, the more governmental control there is over the size of the health care system (subject of course to the give and play of the political environment). In those cases where governments or regulatory authorities control the prices of care (per service, per day, or per case), providers can influence the outcomes by altering the mix of services or the volume of care. However, it is possible to impose budgetary control in a system where prices are directly controlled. For example, the United States has imposed physician expenditure targets called Volume Performance Standards for physicians under the Medicare program. The conversion factor applied to determine the Medicare fee schedule is a function of how well physicians in the aggregate meet the volume performance standard. In the province of Ontario, the government sets income limits for individual physicians. As payments to individual physicians reach the limit, the proportion of the fee paid decreases. In general, there is much less aggregate control over the health care delivery system in the United States than there is in other countries.

The financing methods and the type of aggregate controls imposed on a country do not appear to have a major independent effect on the size of the health care sector relative to the aggregate economy. Health care expenditures per capita are highly correlated with gross domestic product per capita. In fact, a study of health care costs in countries that were members of the Organization for Economic Cooperation and Development (OECD) found that $R2$ (*see* **Correlation**) was 0.93 for a simple model in which the log of a country's per capita expenditures on health care was regressed against the log of the country's per capita domestic product [7].

Health Care Technology Assessment

What is HTA?

Health technology assessment (HTA) is the evaluation of the properties, effectiveness, and the direct and indirect impacts of health technologies. A health technology refers mainly to interventions or methods used to affect the health of an individual or populations. Thus, it includes health promotion, health care interventions to treat and rehabilitate (including drugs, devices, and procedures), and the systems for the support and delivery of care such as telemedicine and patient records. Health technology assessment (sometimes referred to as *Health Care* or *Health Service Technology Assessment*) can be considered a major component of **Health Services Research** (HSR), which is also concerned with broader issues like the financing, organization, and delivery of care. HTA is carried out in order to find out whether a technology works, for whom, at what cost and with what other intended or unintended consequences for the individuals, their families, the health service, and society in general. Therefore, it is best conducted by teams incorporating disciplines, such as statistics, epidemiology, economics, psychology, and sociology. The results are used to inform health policy and practice at a national or a local level.

Reasons for HTA

Over the last 25 or so years, health care spending in developed countries has been rising in real terms and as a percentage of gross domestic product. Much of this increased spending has been on new interventions for the prevention or management of disease. Therefore, health care funders are particular keen to ensure that this investment is worthwhile and delivers a sufficient return in the form of improved health outcomes. In addition to the cost implications of health technologies, several of them such as *in vitro* fertilization, genetic testing, organ transplantation, and life sustaining technologies raise important ethical and social concerns.

Research has also shown that there are significant geographical variations in the patterns of practice even within the same health care system [19] not explainable by variations in the underlying frequency of disease. Health care professionals and experts are not always reliable sources of information about the effects of a health technology. Clinical practice, therefore, rather than being determined purely by professional views, should be more firmly based on the research evidence. This has led to the call for "**Evidence-based Medicine**" and the standardization of health care informed by the research evidence base. HTA is the engine that provides much of the data for evidence-based health care and the evidence base for the development of clinical practice guidelines.

HTA grew out of general technology assessment that emerged in the United States in the mid-1960s in response to concern about the consequences of the rise of technology in modern life. In 1972, the US Congress established an Office for Technology Assessment (OTA) followed by the National Center for Health Care Technology and subsequent to that, the Office of Health Technology Assessment (OHTA). OHTA was a component of the National Center for Health Services Research and Health Care Technology Assessment (NCHSR), which later became the Agency for Health Care Policy and Research (AHCPR), the predecessor of the Agency for Healthcare Research and Quality (AHRQ).

OHTA's role was to advise the Healthcare Financing Administration now the Centers for Medicare & Medicaid Services, (CMS) on coverage decisions for new medical technologies under the Medicare program. The AHRQ continues its role as science advisor to CMS by providing health technology assessments to the Coverage and Analysis Group at CMS, whose coverage decisions are often followed by private health insurers. (*see* **Health Services Organization in the US**.)

Topics Addressed by HTA

Since there is no standard set of activities that can be said to form a part of all HTAs, much will depend on the aims of the HTA and the nature of the technology. However, one or more of the following elements are usually present [12].

- Assessment of the current state of development and use of the technology.
- Assessment of the technical characteristics of the technology if it is a device (*see* **Medical Devices**).
- Assessment of the effectiveness technology.

- Assessment of the safety of the technology.
- Economic evaluation of the technology to examine the resource use relative to the benefits/harms.
- Effect of the technology on the organization and delivery of services.
- Wider impact of the adoption of the technology.
- Ethical issues associated with the use of the technology.

Though HTA can encompass a wide range of topics spanning the technical to the social and ethical, in general most of them are limited to consideration of effectiveness and **cost-effectiveness** (*see also* **Pharmacoepidemiology, Adverse and Beneficial Effects**.)

Titles of some recent HTAs produced around the world include:

- Implantable Defibrillators (ICD)
- Positron Emission Tomography (PET) Imaging in Cancer Management
- Monitoring blood glucose control in diabetes: a systematic review
- Phakic Intraocular Lenses
- Systematic Review and Economic Evaluation of the Effectiveness of infliximab for the treatment of Crohn's Disease
- Evaluation of Molecular Tests for prenatal diagnosis of Chromosome Abnormalities
- Oseltamivir for the Treatment of Suspected Influenza: a clinical and economic assessment
- Sentinel Node Biopsy in Breast Cancer
- A Systematic Review of Atypical Antipsychotic Drugs in Schizophrenia
- Acupuncture: Evidence from Systematic Reviews
- Clinical and Cost-effectiveness of Routine Dental Checks: A Systematic Review and Economics Evaluation.

There is a tendency for HTA to focus on new technologies as these may represent the most pressing demands on health care budgets and so are of direct concern to health care funders. However, this can result in a bias, in which new technologies recommended as cost-effective displace older technologies that may be equally or more beneficial but which have not been assessed. Techniques have been developed to support a more rational and scientific approach to prioritizing research on technologies. Methods for estimating the payback from investments in such assessments have been developed but are quite crude, More recently, Claxton et al. [1] have developed a Bayesian decision theoretic approach (*see* **Bayesian Decision Models in Health Care**) to valuing additional information that helps funders or regulators decide whether the costs of reducing uncertainty by carrying out more research is justified by the expected value of improved information. The model helps regulators to decide if a health technology should be adopted on the basis of existing evidence or whether it is worth undertaking research to reduce uncertainty further.

Methods Used in HTA

Many HTAs consist of reviews of the results of existing research. Traditional reviews have now largely been discredited as being unreliable and often biased. It is important that reviews are systematic in order to ensure that there is an explicit, comprehensive and methodologically sound, and unbiased approach to identifying, appraising, and summarizing the research [10]. Quantitative approaches to combining the results of studies found in the review – **meta-analysis** – are now widely used [18]. This has been an important area for methodological development with different methods of handling variations between study heterogeneity and for combining evidence from different types of study designs, such as Bayesian **hierarchical models** [13]. Recently, there has been interest in methods for combining quantitative and qualitative data.

The most reliable evidence for estimating the effectiveness of a health technology (i.e. its effect on health outcomes) is a randomized controlled trial (RCT) (*see* **Clinical Trials, Overview**). If well conducted, this method reduces the susceptibility to bias and provides more reliable estimates of the effect of the health technology than other designs such as **quasi-experimental** and uncontrolled studies that often overestimate the effects. However, experimental evaluation of health technologies may be difficult if the technology is emerging, presents ethical challenges, and is very expensive to run. Questions are also raised about the degree to which the results of trials can be generalized to routine care situations. Thus, attempts are made to make trials as realistic or pragmatic as possible. Methods are also being developed for applying the results of studies to particular

patient subgroups or individuals, rather than just use average estimates.

If the technology is widespread and not applied to individuals, such as telemedicine or media health promotion campaigns, **randomization** is carried out at a higher level than the individual – cluster randomized trials (*see* **Cluster Randomization**) – which raises new methodological and statistical problems.

Assessing the benefits to patients of a technology involves deciding what endpoints or **outcome measures** should be used. Increasingly, it has been accepted that conventional clinical outcome measures such as lung function tests for people with asthma be replaced or supplemented by more patient-centered measures (which may be disease specific, dimension specific or cover the whole of health-related **quality of life**) [5]. All too often, technology assessments have based their conclusions on evaluations using **surrogate endpoints** or intermediate outcome measures, often physiological or biochemical markers that are taken to be predictive of important outcomes such as death. However, this often wrongly assumes that the predictive models are accurate and that in real life the pathway between the intermediate and eventual outcome is clear and unchanging. In addition, surrogates rarely predict harm and so a technology that looks beneficial on the basis of the performance of surrogate endpoints (e.g. reduction in cholesterol or reduction in cardiac dysrhythmias) may actually result in worse outcomes when measured by the effect on, say, total mortality [8].

Economic evaluation is often an integral part of a health technology assessment (*see* **Health Economics**). Using resources for one technology has an opportunity cost, in that the benefits derived from using those resources in some other effective intervention are forfeited. Thus, it is important to consider the resource implications associated with generating the benefits – cost-effectiveness. The standards for conducting economic evaluations have become more established over time [7] and now often employ complex statistical techniques for modeling the effectiveness and cost data [15].

Though most HTAs are predominantly quantitative in methods resulting in estimates of the costs and benefits of the technology, increasingly, qualitative approaches are being used to gain a richer understanding of the likely impact of technologies on patients and the health care system [11].

Timing

Health technologies have a life cycle with an early developmental phase, early adoption, then (if successful) rapid diffusion, and then a reduction in use as it becomes obsolete and is either displaced by newer technologies or abandoned as information about lack of effect or adverse side effects become available [3]. There is no best time to assess a health technology, the less established it is the more likely its uptake will be influenced by the assessment, for it is difficult to change practice once the use of a technology is widespread. However, it can be more difficult to assess a technology in its early phase because there are less data on effects and costs available on which the assessment can be based. Early assessments of some technologies, especially those involving technical skills, may underestimate the benefits if there is a learning effect. There is no right solution to this trade-off, which has been nicely captured as Buxton's paradox "its always too early until it is too late"! Several countries have established "horizon scanning" programs for the early identification and assessment of new and emerging technologies [17].

A good introduction to the wide range of methods used in conducting HTAs is provided by Stevens et al. [16].

Organization of HTA

Health Technology Assessment tends to be sponsored by national or regional health care funders such as the government, or by social or private insurance funds, or health care providers. In addition, there is substantial industrial HTA activity. HTA may be carried out in-house or by commissioning universities or specialist consultancy companies.

One of the earliest and sustained programs of HTA in the English-speaking world was established in 1993 as part of a national Research and Development program for the United Kingdom National Health Service (`www.ncchta.org`). It involves a national system of consultation to determine priorities for assessments reflecting areas where clinicians, health service managers or health service users felt there was sufficient uncertainty about the appropriate use of health technologies. More recently, the program also has a stream of work commissioned specifically by the National Institute for Clinical

Excellence, which was established to make recommendations to the NHS and government as to what health technologies should be publicly funded and to produce clinical practice guidelines. In most other European countries, there are well-established agencies for HTA. In Canada also, there have been various provincially funded HTA programs with a national Canadian Coordinating Office for HTA (CCOHTA: www.ccohta.ca).

HTA has had a long but more turbulent history in the United States [4] partly because of the fragmentation of the health care system (resulting in HTA being sponsored by several public and private organizations) and also because of the powerful professional and commercial interests. The congressional OTA and the federally funded OHTA were both closed down in the 1990s despite their good international reputation. Federally funded technology assessments are now conducted internally at the AHRQ or by contracting with one of their 14 Evidence-based Practice Centers (EPCs: www.ahrq.gov/clinic/epc/). One of these is the Blue Cross and Blue Shield Association Technology Evaluation Center (TEC), which provides technology assessment services to all independent Blue Cross and Blue Shield Member Plans, issuing around 20 to 25 TEC assessments per year.

Most health care systems are facing similar pressures and have to consider the appropriate use of the same technologies. Thus, an international organization was established in 1993 to promote the sharing of information from different assessments carried out across the world and to cooperate in the conduct of these assessments. Initially established by publicly funded HTA organizations, the International Network for Agencies for Health Technology Assessment (INAHTA: www.inahta.org) now has about 40 member agencies from 20 countries, stretching from North and Latin America to Europe, Australia, and New Zealand.

The conduct of HTA is also promoted by Health Technology Assessment International.(HTAi: www.htai.org), a new professional and scientific society. This society is the only professional society focusing specifically on HTAs around the world.

Dissemination of HTAs

The results of HTA are disseminated in a variety of ways including reports to the commissioner and articles in major medical journals. The specialist journal, the *International Journal of Technology Assessment in Health Care*, also serves as a forum for the wide range of professionals interested in the assessment of medical technology, its consequences for patients, and its impact on society. The Center for Reviews and Dissemination at the University of York, UK, in collaboration with the INAHTA, maintains a database of HTAs produced by a variety of agencies internationally (http://nhscrd.york.ac.uk/welcome.htm). It contains details of over 1600 HTA publications and hundreds of ongoing INAHTA projects. The National Library of Medicine also maintains a searchable collection of large full text technology assessments mainly carried out in the USA in *Health Services/Technology Assessment Text* (HSTAT: http://hstat.nlm.nih.gov). This includes the evidence reports from the AHRQ and the US Preventive Services Task Force's *Guide to Community Preventive Services*.

Impact of HTAs

HTAs are rarely undertaken as a purely academic exercise; they are carried out in order to inform policy and practice. The policy impact might be, for example, the decision of a health regulator to license a new drug or device of a health care funder to pay for a health technology and under what conditions (coverage decisions). At a clinical practice level, an HTA can feed into the production of clinical practice guidelines produced by a regulator, a health care organization or professional association. In ideal circumstances, HTA can result in the increased uptake of cost-effective technologies or lead to a reduction in the use of ineffective, unsafe technologies or those whose costs are too high, relative to any benefits. However, rarely does the evidence from an assessment lead to unambiguous policy or practice implications – the facts rarely "speak for themselves". Not only is there usually some uncertainty about the evidence, but also the way that evidence interplays with the practice, social, economic, and political context, can result in the same evidence being used to justify different recommendations. Thus, small benefits relative to cost may lead to recommendations to pay for a technology in a rich health economy such as the United States whilst a more cash limited system

such as the NHS in the United Kingdom might decide using the same evidence to restrict use or require more evidence [6].

At the level of clinical practice, many other factors will mediate the impact of an HTA, such as the mode of dissemination, and the degree to which it requires major professional change and the costs (e.g. financial, time, and skills acquisition) of adopting the recommended technology [14]. There has been little formal evaluation of the impact of HTAs on practice.

HTAs can influence decisions affecting the licensing or, more usually, the coverage of new drugs, devices and procedures, and so they have the potential to affect the sales and profits, the costs to health systems, and the clinicians' income. Health care professionals who use these technologies, and the industries that sell these are often suspicious that HTA is a device to cut costs and reduce professional control over health care.

This can make HTA reports the object of intense scrutiny by the health care, pharmaceutical and devices industries, government, and professional groups [6]. For example, the Canadian Coordinating Office of Health Technology Assessment (CCOHTA) had to use 13% of its annual budget to successfully beat a lawsuit from a pharmaceutical company seeking to prevent the release of a report on cholesterol lowering drugs (statins) [9]. In the United States, orthopedic surgeons orchestrated a campaign against the AHCPR in response to its guideline on the management of back pain, which stressed the importance of nonsurgical approaches. The backlash contributed to a cut in AHCPR's budget and the curtailment of guideline production [2]. This highly politicized environment makes it all the more important to have strong and independent procedures for the conduct of HTA.

Health Care Utilization and Behavior, Models of

Models of health care utilization behavior provide guidance for defining variables, specifying the relationships between them, and evaluating programs and policies concerned with access to and utilization of health care services (*see* **Health Care Utilization Data**; **Health Care Utilization Data, Analysis**). Diagrams (as in Figure 1) are used to categorize the relevant variables and their interrelationships.

Models may be used to guide the conduct of descriptive, analytic, or evaluative studies of the operation and performance of the health services delivery system. Descriptive studies focus on profiling the variables in the model (represented by boxes in Figure 1) for a population or subgroup. Analytical designs speculate on the hypothesized relationships between the implied predictors (independent variables) and outcomes of interest (dependent variables) (displayed by arrows). **Experimental designs** or **quasi-experimental designs** test the impact of a specific program or intervention on desired outcomes (the end-points in Figure 1).

Four major types of conceptual models have been developed and applied in specifying the interrelationships of the array of possible predictors of health care utilization behavior, and in guiding the conduct of analytic and evaluative research in this area [2]. These include (i) models of patient decision making, grounded in sociological theory and research (particularly those developed by Suchman, Kosa and Robertson, and Mechanic); (ii) the health belief model, based in social psychological theory (developed by Becker); (iii) economic models of the demand for medical care (as amplified by Grossman); and (iv) the behavioral model of health services utilization (developed by Andersen and his colleagues, displayed in Figure 1) that has guided the conduct of much **health services research** on access to and utilization of health care services [1, 5]. The first three types of models will be reviewed next and the behavioral model discussed in more detail in the section that follows.

Models of Patient Decision Making

Suchman

Suchman's framework for stages of decision making about seeking medical care is focused on episodes of illness. In Suchman's paradigm, the sequence of seeking medical care for illness is divided into five stages: (i) experience of the symptom; (ii) assumption of the sick role; (iii) medical care contact; (iv) dependent patient role; and (v) recovery or rehabilitation. A group with more parochial or traditional, in contrast to more cosmopolitan, affiliations and a popular,

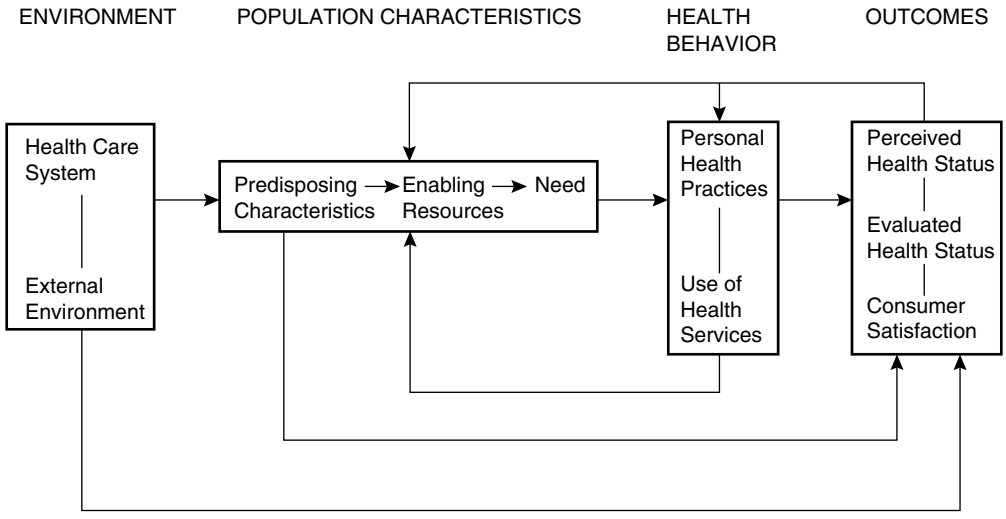

Figure 1 An emerging model – phase 4. Reprinted from [3] by permission of the publisher

rather than more scientific, orientation toward medical care would, he suggests, be more likely to delay in recognizing symptoms, linger longer in the stage of using home remedies, be suspicious of medical providers and perhaps shop around more, fail to adhere to prescribed therapies, and relinquish the sick role as soon as possible.

Kosa and Robertson

Whereas Suchman's model tended to offer more sociological or structural explanations for why individuals might respond differently at different stages of an illness episode, a model developed by Kosa and Robertson focused more on psychological explanations. Behavior is motivated by the individual's psychological need to reduce the anxiety aroused by the threat of illness. The Kosa and Robertson model also assumes stages of individual decision making in response to illness: (i) an assessment of a disturbance in usual functioning; (ii) anxiety arousal based on the perception of the symptoms; (iii) the application of one's medical knowledge to address the problem; and (iv) the performance of activities to alleviate the anxiety. Activities may be of two kinds: therapeutic interventions directed at the removal of the specific health problem, or interventions aimed at relieving the anxiety of satisfying other needs (e.g. fear) without addressing the health problem directly.

Each stage of decision making is influenced by these psychological dynamics as well as the culture and social groups (e.g. family) of which they are a part or with whom they come in contact (e.g. professional medical providers).

Mechanic

Mechanic's model catalogues an array of social and psychological factors that might influence the likely impact of symptoms on individuals care-seeking. These include: (i) perception of symptoms (e.g. salience, seriousness, disruptiveness, frequency); (ii) characteristics of individuals (e.g. tolerance of discomfort, knowledge of illness, competing needs); and (iii) accessibility of care causing disruption in the treatment process (e.g. inconvenient location or hours of service, out-of-pocket costs). However, the need for care from the point of view of the patient (self-defined illness) may not always agree with the need for care as defined by the provider (other-defined illness), which may have significant consequences for patient compliance and continuity [1].

Health Belief Model

The health belief model was originally conceived to understand preventive health care (health behavior) but has subsequently been applied to explaining care-seeking in response to illness (illness behavior) and those activities required for recovery from illness (sick role behaviors). The major components of this social–psychologically oriented model are as follows: (i) an individual's subjective state of readiness to take action, based on the individual's perceived likelihood of susceptibility to the illness, as well as its seriousness; (ii) an individual's assessment of engaging in a given health care-seeking behavior, based on weighing the benefits (reducing susceptibility or seriousness) relative to the likely costs (physical, financial, etc.); (iii) the presence of cues to action to trigger the appropriate action, coming from either internal (e.g. symptoms) or external (e.g. interpersonal interactions, mass media) sources; and (iv) the role of other modifying factors, such as demographic, sociopsychological, and structural. These factors all influence the perceived threat of the disease and the subsequent likelihood of taking action [1].

Models of Consumers' Demand for Medical Care

Economic models of consumer choice stress means (e.g. health insurance or income) through which people can attain services or translate their perceived need into economic demand for medical care. An important contribution to the demand models was made by Grossman, who argued that what consumers really demand when they purchase medical care is health [5]. A number of hypotheses might be generated by this model of joint demand for health and care including: (i) as people age and their stock of health declines they will increase their consumption of medical care to offset the decline; (ii) as people's income increases, their consumption of medical care will increase because they will place increased value on healthy days; and (iii) as people's education increases, their demand for medical care will

decline because they will be more efficient in producing health [4]. The best known application of the demand for medical care model is the RAND Health Insurance Study which employed randomized trials (*see* **Clinical Trials, Overview**; **Health Care Financing**) to estimate the effects of changes in health insurance benefits on people's use of medical care and their health status [6].

Behavioral Model of Health Services Utilization

The behavioral model of health services utilization is arguably the most comprehensive and widely applied model in health services research focusing on access to and use of health care services [2, 3]. The most current adaptation of the model is displayed in Figure 1.

The original version of the model developed in the 1960s suggested that people's use of services is a function of their predisposition to use services (predisposing variables), factors which enable or impede use (enabling variables), and their need for care (need variables). Predisposing variables include demographic and social structure factors (e.g. employment, social class, occupation, race) and health beliefs. The enabling component encompasses both resources specific to individuals (e.g. income, insurance coverage, regular source of care) and attributes of the community in which they live (e.g. physician and hospital bed supply). The need for care may be based on perceptions of the individuals themselves or diagnostic assessments by providers.

The model provides an empirical approach to assessing the equity of health services utilization. Andersen and Aday (originators of the model) assume that in an equitable system, need (rather than predisposing and enabling) components will be the primary basis for accounting for subgroup variations in use. They also distinguish those components which are more mutable (alterable by the health care system) – enabling factors – vs. those that are not – demographic or social structural characteristics.

In later versions of the model (1970s) the health care system was explicitly included in the model in recognition of the important impact of organizational and financial factors on the distribution and delivery of services. The dimensions of health services use measures (type, site, purpose, and time interval for care) were elaborated, and satisfaction added as another important (subjective) indicator of individuals experience of care-seeking.

More recently (during the 1980s and 1990s) the model allowed for the growing recognition of the importance of considering the impact of health care utilization in the context of other likely predictors of health outcomes. Revisions acknowledged that the external environment (physical, political, and economic) and personal health practices (such as diet, exercise, and self-care) influence formal health services utilization and (ultimately) health outcomes. The revised model added people's perception of their health status and clinical (evaluated) measures of health status as well as patient satisfaction with service as outcomes. Finally, it incorporated feedback loops showing that health outcomes, in turn, affect subsequent predisposing factors, perceived need for services, and health behavior.

Limitations of Dominant Models and New Directions

A number of criticisms have been offered of the original and expanded behavioral model of health services utilization, which may be seen as establishing the grounding for new substantive and methodological research based on the model [2, 7]. These criticisms relate principally to the specification of the independent and dependent variables in the model, the causal pathways between and among them, and the generalizability and policy relevance of research based on the model.

Independent Variables

The criticisms of the major predictors of utilization relate primarily to the validity or accuracy of the operational definitions used to measure major study concepts; the fact that most studies in which the model is used do not fully encompass all components of the model; the need to add other dimensions to capture adequately the relevant predictors for selected types of utilization or populations; and the likelihood of significant **interactions** between subcomponents of the model.

Dependent Variables

Important extensions of the model in terms of the utilization variables themselves would be to explore

more systematically the interrelationships (or trade-offs) between different types of service use (e.g. ambulatory vs. inpatient), as well as the relationship of utilization to both patient satisfaction and health outcomes.

Relationships between Variables

Full tests of the interrelationships between and among variables entail the use of stronger analytic and evaluative research designs and the application of more sophisticated modeling techniques in empirically examining these interrelationships.

Generalizability

Major criticisms of the model have focused on the fact that most studies in which it has been utilized explain only a small amount of the variation in health services utilization. Also, the program and policy relevance of the model would be enhanced by the design of studies and analyses to relate more directly the impact of utilization on patient satisfaction, health outcomes, and costs.

Summary

In summary, various factors may account for those who ultimately seek health care. Substantial progress has been made in specifying and measuring the relationships among these factors. The conceptual models reviewed here provide integrative frameworks for considering many of these factors and their interrelationships. However, health services research can provide continued guidance in refining these models, designing and implementing empirical studies to test and evaluate them, and shaping the formulation and interpretation of the policy relevance of research guided by such models.

Health Care Utilization Data, Analysis

Data on health care utilization are used to address important questions about what is done for whom, and can shed light on why and with what outcome, in the large segment of economic life that "delivers" health care services to populations. We discuss the kinds of utilization studies and analytic issues that commonly arise. **Multivariable modeling** techniques are used to identify differences in use and possible reasons for these differences, although the available data often limit the questions that can be successfully addressed (*see* **Health Care Utilization Data**).

Important concerns when studying utilization are (a) identifying all instances of use, (b) identifying the at-risk population, (c) accounting for differential risk of individuals, and (d) distinguishing real differences from random noise. These issues are explored in more detail in this article, and in the articles on **health care utilization data** and **risk adjustment**.

An influential class of **small area variation** studies has established that people in different parts of the country and in different communities within the same region receive very different care, for example, **population-based rates** of tonsillectomy, hysterectomy, or hospitalization vary tremendously. Additional research has tried to understand these differences, for example, asking if areas with high hospitalization rates also have high rates of inappropriate hospital admissions (*see* **Health Care Utilization and Behavior, Models of**). Geographic variation in patterns of use may reflect lack of agreement within the medical community about treatment options, and help identify opportunities for improving care through standardization to better treatment protocols.

Disparities studies that explore variations in treatment by patient race or sex may reflect societal prejudice in allocating expensive resources. Variations by payer class, such as Medicaid versus private insurance, or payment method, such as **fee-for-service** versus **capitation**, may point to inequities or inefficiencies related to financing.

Other studies seek to estimate the effect of various factors on utilization during an instance of caregiving, such as a hospital admission. Potential predictors of utilization include patient characteristics (sociodemographic, medical), characteristics of doctors or other medical providers (sociodemographic, training, and experience), and characteristics of the conditions of practice (the particular site or its features, or the organizational/financial structures under which the care is given). Predictor variables can be heavily confounded; for example, most patients seen at high-volume hospitals may be city dwellers, making it difficult to sort out the separate effects. **Hierarchical** or **nested** models are needed to explore the influence of facility-specific factors, and may be of particular importance when the units of analysis differ from the units of inference (e.g. individual hospital admissions are studied for the purpose of comparing hospitals).

Another goal is to describe differences in **case mix**, as a guide to why providers may differ in the care they give and the outcomes achieved. Case-mix differences may serve as the basis for redistributing money among providers, so that those who treat the sickest patients receive the highest per-patient reimbursements.

Yet another goal is to provide "quality" reports, which guide patients and health care purchasers, assessing what health care providers do and what they achieve with the people they serve. An important initiative in the United States in the 1990s has been developing a protocol for comparing health plans (HEDIS) along measures such as what fraction of a plan's women of an appropriate age receive annual mammograms. However, HEDIS measures are generally not **risk-adjusted** and even when we agree that providers should encourage mammography, it is easier to achieve, say, 95% compliance with middle-class women than with a poor, transient population. Also, few HEDIS measures assess the quality of care given to the very sick, largely because this is so difficult to do.

Cost-effectiveness studies seek to relate the cost of the health care inputs used to the value of an achieved outcome. They require data on utilization and a plausible methodology for "pricing" this, as well as a numerical measure of the outcome, such as "quality-adjusted life years" (**QALYs**). Health care strategies with the highest QALY yield per dollar might be the first to be implemented (or the last to be eliminated) in a health care system with constrained dollars.

Provider profiling is used to identify individual doctors, hospitals, or health care systems with exemplary or problematic practices. Especially when providers are compared in public releases of analyzed

data, much harm can be done if good providers are "flagged" as problematic either because of random variation (small numbers and a "bad bounce") or because they care for an unusually difficult mix of patients. Appreciation of the "small numbers" problem and good **risk adjustment** is critical to useful provider profiling.

Special Features of Utilization Data that Require Analytic Attention

Skewness and Heteroscedasticity

Health care utilization variables often have a predominance of low values and long, heavy right tails. This is true when looking at numbers of office visits or hospitalizations per year, days of stay in a hospital for hip fractures, and costs of care for individual hospitalizations or during fixed periods of time. For example, in a working insured population during a one-year period, 20 to 30% of people eligible to receive health care may incur no costs, many more have low-level, nonhospital expenses, and the 5% with the most intense use may account for around 50% of all expenses; the standard deviation for expenditures is generally several times larger than the mean, and in a system with average costs of about $2000 per year, the most expensive cases exceed a million dollars. A few large outliers can substantially distort analyses, even in data sets that contain hundreds of thousands of cases, and decisions about whether to truncate or remove these extreme cases can affect study findings. For many purposes, top-coding (e.g. making the dependent variable equal to the smaller of $50 000 and actual cost) can effectively control the undue influence of extremely large observations.

A technique for addressing the concentration of zero values is to use a two-part model [2], in which one equation predicts the probability of any use (in the whole population) and a second equation predicts the level of use among users. The expected level of use for an individual is then calculated by multiplying these two estimates together. This framework has been extended to a four-part model in which the probability of hospital use is estimated for users, and then the costs for users without hospitalization and for those hospitalized are separately estimated [2].

To address skewness, many authors transform the utilization variable, for example, by modeling log (1 + dollars). (We add 1 because log(0) equals negative infinity). This may help in identifying factors that affect use because it makes the p-values on the significance of individual predictors more credible, but usually does not help predict actual levels of use (dollars, that is, not log dollars). Log transforms are especially problematic when the data contain both small observations and large ones, because the same multiplicative change has so different a meaning when, say, applying a 20% increase to a $10 versus a $1000 expense. When retransforming a log-transformed variable into its original scale, a smearing estimate [2] can be used to address bias, but the smearing only works under the assumption of constant variance, which is unlikely when the observations vary widely in magnitude. A simple way to put retransformed estimates on the "right scale" is to multiply all estimates by the number needed to make the average prediction equal to the average actual outcome (i.e. multiplying by $k =$ mean actual/mean predicted). Typically, R^2 values are higher for models in a log scale, although retransformed estimates fit the actual outcomes less well than models constructed on untransformed data. **General linear modeling** provides an attractive framework for simultaneously addressing the problems of skewness and nonconstant variance of the outcome variable, while predicting it in its original, untransformed scale. For example, the function that "links" costs to predictors can be specified as the log function and variances can be specified as proportional to means.

Lack of Independence

When studying hospital admissions, multiple hospitalizations for the same patient cannot necessarily be identified. Thus, the data may not be able to answer questions such as "now that patients are being discharged from hospitals earlier, have readmission rates increased?" Furthermore, random variation is greater when rehospitalizations are common than when single hospitalizations are the norm. When clustered data are analyzed as if independent, chance variability can be misinterpreted as evidence of systematic differences [1].

When examining the role of a site-specific characteristic such as "do hospitals which see lots of AIDS cases do better with them?" or "do major teaching hospitals see sicker patients?", analysis should account for the fact that patients are nested in hospitals, which are in turn nested within hospital type.

Otherwise, effects attributed to hospital "characteristics" can easily be determined by the experience of a few large facilities.

Death

Patients who die shortly after entering the hospital often use the least resources, while those who remain alive a few days but eventually die are among the most expensive. Some authors propose treating utilization (a nonnegative variable) as the outcome in a **survival analysis**, with death as the censoring variable. The resources that a patient would have used had he or she not died are then estimated, which may or may not be a useful concept. In addition, death is an "informative" reason for censoring, which may muddle the interpretation of findings. In general, it is unclear how and whether to use information about death in predicting utilization.

Study Scope

The Study Population

For many purposes, the "full" or "fully eligible" population, such as people who reside in a particular area, persons theoretically eligible to receive care from the Veteran's Administration, or enrollees in an HMO, is the right study frame. However, many people entitled to receive care in a system do not use it, perhaps because they require no care or because they receive it elsewhere. Sometimes the relevant study population is "all users", such as people who have received care at a particular VA center, or who use a particular physician as their primary care doctor.

To learn how medical problems are treated and what outcomes are achieved requires problem-defined study cohorts, such as people with diabetes, with hypertension, or with low back pain. Eligibility criteria affect what we see. For example, if the data from system A enable us to find all people who are even mildly diabetic, while system B data only identify hospitalized diabetics, we will probably see lower rates of diabetes, but more intensive treatment and worse outcomes per diabetic patient in system B.

Breadth of Use Within Relevant Populations

Gross measures of use (such as number of hospital admissions per thousand person-years of experience) matter to payers, but administrators need to understand where inefficiencies occur. Thus, for example, numbers of hospitalizations for respiratory problems for patients with asthma, and the prevalence of blood sugar tests and eye exams for diabetics provide more focused views of a health care delivery system. One difficulty in conducting such studies is that only some systems maintain disease registries that specifically allow the utilization of, say, diabetic patients, to be tracked.

Individual payers (such as state Medicaid programs) are principally interested in monitoring the utilization for which they pay, but the larger community has an interest in tracking the outcomes associated with all care that individuals receive.

Utilization in a Population Versus During a Period of Treatment

Some services are delivered at most once to any one person, such as hysterectomy, which is removal of the uterus. However, many services can be delivered more or less often and with variable intensity. Thus, each of the following questions may be of interest about inpatient hospital care for a population: What fraction was ever hospitalized during a given year? How many hospitalizations occurred per person-year of exposure? How many days of hospital care were incurred per person-year? How many days of intensive care unit (ICU) stay were used per person-year?

Examples of relevant measures when the hospital admission is the unit of analysis are: total length of stay, presence of any special care unit stays, number of days in special care units, number of x-rays ordered, and total cost of diagnostic testing. Comparisons are only meaningful among relatively similar cases; little insight is gained by pooling information for patients admitted for heart attacks with those admitted for hernias.

Which measure of utilization is examined depends upon the policy purpose. For example, when utilization is examined for quality-monitoring purposes the most relevant measure may be whether an appropriate medication or service was delivered, such as beta blockers for heart attack patients, rather than how often; with hospice programs that provide supportive care for people thought to be near death, per-person utilization, rather than services per month of enrollment, may be most relevant.

What is the Unit of Analysis?

When summing total hospital costs over a group of admissions, it does not matter whether an expense relates to a single admission, to several admissions for the same individual, or to one admission for each of several people. Such distinctions are important, however, to explore whether low costs per admission are due to frequent readmission for people discharged "early". "Unbundling" and "cost shifting" may also produce apparent shifts in utilization that are not real. (Are hospital costs lower simply because of separate billing for procedures that might have been subsumed in a global hospital bill, or because some services have been shifted to the outpatient setting?)

Episodes of Care and Calendar-based Time Frames

Utilization per "episode of care", ranging from first problem identification, through active treatment and follow-up can be used to compare providers on the efficiency with which they handle a defined medical problem, such as "stomach pain, due to an ulcer". Episodes can only be studied when care offered to the same person in different settings can be linked. Other potential difficulties arise in defining when one episode ends and a second one begins; the concept may not even make sense for chronic conditions. Also, when the same person has more than one medical problem, it is not obvious which services should be assigned to which episode.

When a medical event has a readily identifiable starting point, but no clear endpoint, it often makes sense to examine utilization within a fixed window of observation long enough for most follow-up care to occur. For example, we may study all stress tests that occur within 30 days following a hospital admission for heart attack, whether or not they are done in the hospital; or, all respiratory-related tests and services offered within the first six months after a breathing problem is identified.

Even costs per "episode" may not capture efficiencies associated with preventive care, since the number and/or severity of episodes may be affected by the presence and quality of preventive services. A yet more global way to examine utilization is through the lens of total use per person-year of coverage.

Health Care Utilization Data

Many important questions about the fairness, efficacy or efficiency of health care delivery systems require utilization data. Ideally, we would like to have information on the nature, timing, cost, and setting of each person's utilization, and the ability to link that information with personal demographics, health status characteristics, and health outcomes, including declines in **functional status** and death.

Health services research works best when there is a complete list of persons whose care is being tracked and longitudinal records of the medical problems addressed, all care given, and health outcomes. Such records, maintained by the Centers for Medicare and Medicaid Services (CMS) for its Medicare program (which covers over 40 million people, including almost all US citizens over the age of 65) are a uniquely powerful resource for health services research (*see* **Medicare Data**). Unfortunately, loss of data, due to the failure to acquire "encounter records" (dummy bills) from managed care programs, is of growing concern in the Medicare program and elsewhere.

Another important source of health utilization data is the Veteran's Health Administration (VHA), with over 4 million users (mostly military veterans) annually. The main weakness of these data lies in the difficulty of identifying the set of people who, were they sick, would seek their care in this system. On the other hand, the VHA, as the nation's largest integrated health care delivery system, supports well-integrated, research quality, administrative and clinical data systems through the Veterans Affairs Information Resource Center (VIREC) [2].

In contrast to the completeness and continuity of Medicare data, and to the sophistication of the VHA's nationally integrated data system, is the fragmented information available for low-income persons with Medicaid health coverage. Each state administers its own Medicaid program, eligibility requirements constantly change, people move on and off the system as their incomes and other circumstances that affect eligibility change, and the same person can appear under different identification numbers.

Data from privately insured populations have intermediate-level quality, with most people remaining enrolled through the same employer year after year, although they may switch health plans during annual, open-enrollment periods. Other problems arise because coverage is usually offered to "families" of employees; thus, marriage, divorce, alternative coverage that becomes available (or is lost) to a spouse or child, job loss, and geographical movement can all disrupt the continuity of the data. Typically, employer-based coverage systems do not record why someone disenrolls; they may not even have an explicit record ("positive enrollment") of each person entitled to receive care in their "family" contracts.

Several government surveys address these gaps in US health care utilization data. One is CMS's Medicare Current Beneficiary Survey that seeks to capture all health care utilization (not just Medicare-covered utilization) from randomly selected program beneficiaries (*see* **Medicare Data**). Another is the National Health Interview Survey (NHIS) conducted, since 1957, by the National Center for Health Statistics (NCHS). Although NHIS data focuses on the health (rather than the health care utilization) of the US civilian, noninstitutionalized, household population, it contains some important utilization information, notably on child immunizations [3]. The Medical Expenditure Panel Survey (**MEPS**) contains extensive additional data on a subset of the NHIS sample, focusing on the nature, frequency, cost, and financing of health care utilization [4].

Only some health records are computer accessible and fewer can be reliably tracked at the patient level. This limits the questions that population-based studies can address. For example, many statewide databases capture in a uniform format and make available for research, a file with one record for each inpatient admission. Available variables include the age, sex, zip-code of residence of the patient, the principal problem that caused the admission and other medical problems present (using the International Classification of Diseases diagnostic coding system), major procedures (such as surgeries) received, dates of admission and discharge, discharge disposition (e.g. in-hospital death, transfer to another facility, discharge home), days of stay in special care units (e.g. ICUs), and hospital billing information, including "payer". These data capture very much the same information that Medicare requires for hospitalizations, in very much the same format, but for all persons, not just those in the Medicare program; see [1, Chapter 5] on administrative data. However,

despite the richness of these data, a great deal of important medical information is missing, some of which can (with time and effort) be captured by retrospectively abstracting information that is usually recorded in patients' medical charts; see [1, Chapter 6] on medical record data.

Another way to improve the completeness of available information is through prospective data collection, which assures that the desired elements will be present by collecting them while care is being administered. In certain health care systems, various additional computerized information, such as laboratory findings as well as tests ordered, drugs prescribed, and amounts dispensed, can round out the picture of what medical problems were being seen and what resources were used.

Patient surveys can capture "outside" utilization, such as purchases of nonprescription drugs and use of alternative or uncovered services like chiropractic or acupuncture, as well as provide insight into patients' views of their own health or of the care they receive. Although self-report is not an ideal way to capture health care utilization, it may be important when more reliable information is not available. Surveys can be very helpful in targeting people who might benefit from case management; see [1, Chapter 7] on survey data.

Measuring Utilization

Utilization studies may focus on a particular kind of use or on a summary measure of total utilization or "cost". Kinds of uses include hospital admissions, specific surgeries such as hysterectomies and tonsillectomies, ambulatory care (such as doctor's office visits and outpatient surgeries), readmissions to hospital (within, say, two weeks of an earlier discharge), diagnostic tests, referrals for specialist care, and intensive care unit stays. "Cost" measures can be constructed as weighted averages of different factors, where the weights reflect the intensity of resource consumption and not necessarily the dollars exchanged.

Average annual costs per person is a natural summary measure of health care expenses. In the case of a purchaser of medical care, such as CMS's Medicare program, "cost" is most commonly defined as the sum of all dollars that the purchaser pays for covered services; "cost" can also include overhead (the administrative costs associated with running the program). "Total" health care costs are larger than this, however, including at least the "out-of-pocket" expenses of health care consumers for covered services (copayments and deductibles) and consumers' expenditures for noncovered goods and services, such as over-the-counter medicines and devices, dental, psychiatric or long-term care, and visits to "nonorthodox" practitioners such as acupuncturists or chiropractors. Some calculations also attempt to capture costs ancillary to the receipt of care, such as the price of transportation to providers or the value of time lost in care seeking, as well as costs ancillary to being sick (lost productivity).

Most health care providers do not know the cost of particular instances of caregiving. If average (rather than marginal) costs are sought, the accounting system used to allocate fixed overhead expenses to particular cases matters, as does the universe of cases over which the average is computed (e.g. all admissions at the same hospital, admissions to the same administrative unit, pneumonia cases, admissions paid for from a single source). On the other hand, marginal costs, such as the cost of drawing and testing one additional blood sample in a fully equipped and staffed laboratory, may seriously understate the resources needed to provide services.

The "charges" that appear on many billing records often bear little relationship to either what payers actually pay or what expenses were actually incurred. Charge comparisons are suspect, especially when pooling or comparing cases from institutions with different accounting systems. Health services researchers sometimes use the method of "cost-to-charge ratios" to convert charges to a more credible estimate of costs.

Another way to summarize utilization is by "pricing" and counting each unit of care; a "synthetic" total cost is calculated by summing the imputed costs associated with the care given. The price of a service may be generated internally (e.g. as the average charge associated with it in the data) or externally, as a "book rate". The technique is credible so long as most relevant services are likely to be captured in the data and the relative prices, at least, form a believable weighting system. Any summary cost figure is essentially a weighted sum of inputs.

When comparing utilization across different delivery systems, it is important to recognize that some data-capture systems are substantially more complete than others. As a rule, records are most complete

and accurate when payments are linked to individual services through bills; "what was done" often cannot be tracked when capitated, and "lump sum" payment systems are used.

Health Economics

The principal foundations of health economics are based in microeconomic theory and welfare economics [17]. Essentially, this field of specialization within the discipline of economics addresses the allocation of resources directed to health improvement and the organization, delivery, and financing of health services. Under this broad purview, practitioners in the field of health economics have tackled such questions as:

1. How does the uncertainty of health outcomes influence the optimal forms of organizing and paying for medical care [1]?
2. What mix of cost-sharing between patients, health plans (insurers), and health care providers (e.g. hospitals and physicians) will produce optimal outcomes in terms of the most improved health for the least incremental cost [9, 10]?
3. Under what conditions would increased competition among providers of health services be likely to produce improvements in health status and efficiency relative to existing market arrangements for health care [29]?
4. What are the economic costs to society of prevailing patterns of illness [32, 33]?
5. How does one measure the cost and benefit of programs directed toward the improvement of health [21, 27]?
6. What are the aggregate results of health care, when measured as increased **life expectancy** for given levels of health care expenditure [3]?
7. What are the differences in performance (e.g. in the quality and efficiency of services) between not-for-profit and for-profit organizations in health care [14]?
8. What contractual arrangements provide the greatest protection for health plans, providers, and patients from the "agency problems" inherent in the sometimes-conflicting interests of those parties [25]?

These questions illustrate, but of course do not fully characterize, the range of issues subsumed in health economics. A common theme cutting across theory and empirical work in health economics is to discover which forms of market structure, industrial organization, and individual behavior lead to efficient and equitable outcomes. Potential market structures range from the one extreme of "perfect competition", in which large numbers of consumers and providers interact in an environment of perfect information, to monopoly, with one large firm controlling the market. Virtually no health care services are provided in a market structure that is close to the perfectly competitive or monopoly model.

Indeed, health care is distinguished from other economic markets by specialized information, principal–agent relationships, a relatively small number of providers in any given local area (an "oligopoly"), an inherently intimate and highly personalized service, and the dominance of third-party insurance. Arrow [1] highlights the special nature of health care from the perspective of the economist as uncertain medical consequences resulting in demand for treatments determined by physicians with payment emanating from third-party insurance carriers. Thus, the consumer is unable to predict the illness, not responsible for selecting the services he will receive, and will not – for the most part – pay the bill. This peculiarity of medical care markets challenges the traditional theoretic paradigms.

Accordingly, health economists have approached market structure from a different tack: What kinds of economic incentives and countervailing power would induce consumers and concentrated provider oligopolies, characterized by few, large firms producing highly differentiated services for a wide array of consumers, to behave efficiently and to achieve equitable outcomes?

In attempting to answer such questions, the economist's attention inevitably turns to the related issue of how health care providers are organized; in terms of "vertical" integration among the suppliers of inputs (e.g. pharmaceutical manufacturers) and the "output" providers (e.g. hospitals and medical groups), and the "horizontal" integration in local markets of providers of similar services (e.g. hospital mergers and consolidations of medical groups) (*see* **Health Services Organization in the US**). Moreover, while market structure and industrial organization exert a strong influence on health services outcomes, the factors governing the individual behavior of consumers and providers are equally pivotal in the study of health economics (*see* **Health Care Utilization and Behavior, Models of**). Seminal studies of the role of coinsurance and deductibles (patient "cost-sharing") in encouraging the efficient use of services [30] have

contributed greatly to our understanding of health care, as has the theoretic and empirical research on different modes of provider payment [16, 17] (*see* **Health Care Financing**).

Ever since Kenneth Arrow's pioneering work on the role of uncertainty in shaping health economics [1], economists have investigated the importance of payment and organizational arrangements in determining health outcomes. In the past decade, economics has made great strides in addressing these issues through the lens of "agency theory" [7, 25]. This theory illuminates how the form of ownership, organizational rules, methods of paying health care providers, and the level of payment to providers interact to induce persons and organizations (the "agents") to act in conformance with the objectives of parties (the "principals") who delegate discretion and authority to those agents to act on their behalf. Health economic research has focused on health plan benefit design, experience rating of health plans, and risk adjustment–among other contract features–as mechanisms for ameliorating agency problems.

Defining "Efficiency"

In defining efficiency, the economist has in mind two distinct and quite specific types:

1. Technical efficiency refers to the production of a given amount of services ("output") for the least amount of resources ("cost"). This can be imagined as minimizing average cost per unit of output, or – equivalently – minimizing the total cost of producing a predetermined level of output.
2. Economic, or "allocative", efficiency examines "trade-offs" in the allocation of resources. An arrangement is allocatively efficient when the incremental benefits of services provided are equal to the incremental costs of those services. Thus, allocative efficiency is measured "at the margin": Is the change in total cost (marginal cost) of services matched by an equal change in patient health benefit (marginal benefit) from those services?

Following these definitions then, the search for efficient arrangements follows the so-called Pareto criterion: social welfare is optimized when no arrangement can be devised under which some individual(s) could be made better off without others being made worse off. This criterion effectively requires both technical and allocative efficiency. Either failure to produce at least cost or failure to deliver the correct output (aligning marginal benefit with marginal cost) would violate the Pareto principle.

Kaldor [20] and Hicks [15] refined the Pareto rule into a potential compensation criterion. Assuming that the gains to the "winner(s)" under some new arrangement could be measured, a situation was optimal if and only if no change could be effected that would leave winners with sufficient gains to compensate fully the losers. The use of a standard of "potential", rather than actual compensation, reflects the existence of real world costs of information and exchange (so-called "transaction costs") that impede actual exchange of compensation.

In recognition of the centrality of efficiency within economics, a set of methodologies for economic evaluation has been developed. Those methods can be broadly categorized as follows:

1. cost–benefit analysis;
2. cost–effectiveness analysis;
3. cost–utility analysis.

Over the past 20 years or so, a substantial literature has developed in the applied area of health economic evaluation [8]. Each of these techniques is grounded in economic theory, and their application to health services problems is illustrated in what follows.

Cost–Benefit Analysis

Cost–benefit analysis translates all costs and benefits into monetary units. The opportunity cost concept underlies the logic and implementation of all three economic evaluation methodologies. Opportunity cost is defined as the value of the resources used up in a given activity, measured as the value that those resources would have produced in their next best alternate use. Hence the value of opportunities foregone constitutes the opportunity cost of a given employment of resources. Even if no money changes hands – for example, in the case of time and assets donated for a particular activity – the resources do

have this opportunity cost, which includes both direct, observable monetary costs and implicit opportunities forgone.

The time value of resources, captured in normal financial dealings through the rate of interest, is another crucial element in cost–benefit analysis. Looking forward from today, a cost incurred a year from now is somewhat less onerous than the same monetary cost incurred today. Similarly, a benefit realized one year from now is perceived as less valuable than a benefit of equivalent magnitude delivered today.

This rate of time preference is reflected in the practice of "discounting" costs and benefits through the use of a discount rate – analogous to the interest rate or rate of return required in financial transactions. The use of a discount rate in valuing costs and benefits implies that those consequences are long-lived, or spread over a period of time. Thus the discounting approach is appropriate for health programs that take the form of investments, which involve commitment of resources over time in return for future benefits.

Whereas persons considering *financial* investments generally accept the logic of requiring *interest* (some additional amount above what they invested originally) as compensation for having to wait to receive returns in the future, a thought experiment may be useful for the reader seeking to convince himself or herself that this approach can be applied appropriately to investments the direct payoffs of which are in terms of *health*, not dollars. Suppose that investing in a new positron emission tomography (PET) scanner costs $1.2 million today, and is expected to produce health benefits starting three months from now and lasting for the useful life of the scanner (estimated to be 10 years, for example). Furthermore, assume that those health benefits are expressed as earlier detection of, and more rapid recovery from, a variety of acute health problems. For purposes of the hypothetical, let the incremental (specific) costs of caring for those health problems *if not* detected earlier by PET scanning, be valued cumulatively at $200 000 per year (say, 20 cases per year at $10 000 costs saved per case).

The use of costs of caring avoided as the value of the scanner's *health benefit* simplifies the illustration that benefits can be converted into monetary equivalents. Then, to complete the reasoning, if one assumes that health investments "compete" with financial investments for scarce resources, it makes sense that the expected rate of return on the next best alternate financial investment of comparable risk should become the rate of return required for a given health investment. Thus, a discount rate equal to the foregone financial return should be used to convert the future stream of benefits into its (time zero) present value equivalents.

Now let the required return on investments of comparable risk be 20%. In this case, if the initial costs of the scanner were subtracted from the discounted present value of the future health benefits (in a technique described in the next section), using 20% as the discount rate, one would calculate the scanner's net benefit valued as of now to be a negative $361 506. The reason is that, given that the benefits accrue over the future 10 years, they are not sufficiently large to offset the time costs of waiting (the 20% rate of return foregone) to recover the initial investment cost of $1.2 million.

Inflation would not affect these comparisons, because the health benefit values and the discount rate both would simply be increased by the same proportionate amount to reflect the rising cost of living. Thus, one can think of these examples as valuing costs and benefits in "real terms" (i.e. having abstracted from inflation).

Not only does the discount rate capture the time value of resources, but also the risk involved in the costs and payoffs from different programs. In reality, since health programs often do not adopt the language of owners, investors, and return on investment, the notions of business risk, financial risk, and systematic risk – so central to mainstream economic analysis of investments – have only infrequently been applied in health program applications of cost–benefit analysis. Nonetheless, to the extent that the benefits and costs of health programs are stochastic, not deterministic, it is appropriate to increase the discount rate from the level appropriate for a "riskless" investment, to compensate for the riskiness of the project.

To convince oneself of the appropriateness of building a positive "risk premium" into the discount rate for health investments, let us revisit the earlier thought experiment of the PET scanner. Suppose in that case that the benefits of the scanner were risky, in the sense that the estimated savings in cost of caring were dependent on alternate treatments available and environmental conditions affecting personal and public health for the kinds of health problems detected by the scanner. Then

it seems reasonable that to a risk-averse decision maker the health benefits per year would be worth something less than the stated amount of $200 000. Put differently, the decision maker would accept a "certainty equivalent" amount of something less than $200 000 per year *for sure* in exchange for the current risky "claim" to an *expected* value of $200 000 per year.

Modern finance theory allows one to calculate the size of the premium to be built into the discount rate (or to value the certainty equivalent amount per year) for a given level of riskiness. The risk premium to be added to the discount rate might, for example, be calculated from the capital asset pricing model (CAPM) developed by William Sharpe, Jan Mossin, and John Lintner [5]. The CAPM model assumes that: (i) the capital market is perfectly competitive; (ii) transaction costs are zero; (iii) investors have homogeneous beliefs about the risk and return on assets in the economy; and (iv) investors hold well-diversified portfolios (assumptions that, while not strictly true, seem to generate patterns of asset returns generally consistent with empirical experience in the security markets, although the CAPM's specific validity has come under recent challenge [11]. If these assumptions hold true, the required return on a particular investment – "health" or "financial" – is given by the following equation: $r_i = r_F + \beta_i(r_M - r_F)$, where r_i is the expected (required) return on a risky investment i, r_F is the return on a riskless investment (say, in 10 year Treasury bonds), r_M is the expected return on the "market portfolio" of economy-wide assets, and β_i is the systematic, or "market", risk of investment i. This systematic risk, or "beta", is measured by the **regression** coefficient (**covariance** of returns on i with returns on M, divided by the **variance** of the market portfolio's returns), and represents the notion that only such systematic risk will be "priced" in required returns. Nonsystematic risk, the unique variability associated with each asset's returns, will be averaged out ("diversified away", in the finance lexicon) by holding a large number of assets not perfectly correlated with each other in one's portfolio. Or one might find, equivalently under the CAPM, that all the risk in the payoffs from the scanner investment had been diversified away by the decision maker's holding of a well-diversified portfolio of health *and* financial investments. That is, suppose the risk was all "diversifiable"; in other words, the returns on the scanner investment had zero covariance with broader activity in the market. In this case, no "risk premium" would be built into the discount rate. For the purposes of the preceding example, assume that this "risk premium" accounts for, say, 10%, or half of the 20% required return. That implies that, if the health benefits were known with certainty, the appropriate discount rate would be a smaller amount, 10%. Then the net benefit in present value would change to +$28 913, and the scanner investment would be worth undertaking, on balance. The trick in factoring risk into health investments is to determine this risk premium, which in theory should reflect the extent to which the health payoffs (and costs) covary with returns on assets reflecting the larger economy (the "market portfolio"). In practice, this is extremely difficult to do, and analysts instead generally perform **sensitivity analyses** of the impact of different discount rate assumptions on estimated net benefits.

The analyst's perspective is crucial in implementing a specific cost–benefit analysis. Alternative points of view include the following:

1. society's – for example, in the case of public programs, in which the costs and benefits are broadly diffused among a large population (a publicly funded mobile coronary care unit for emergencies represents such an investment);
2. third-party payers' – for example, if a private health plan were structuring a new covered benefit (say, bone marrow transplantation), and wished to evaluate whether the long-term benefits in terms of market share (additional premium revenues) would offset the expected costs of the additional coverage;
3. health care providers' – for example, if a hospital or medical group were implementing a new information system and wished to compare the capital and operating costs of the investment with the future benefits of improved patient care and enhanced clinical efficiency over the long run; and
4. patients' – for example, in the case of a consumer cooperative organized for the health care of its members, the decision to develop a specialized home care unit (say, for persons with chronic obstructive pulmonary disease), with the costs to be fully funded through a surcharge to member premiums and with caregiver support to be provided by member volunteers.

Each one of these points of view suggests a potentially different perspective on costs and benefits. For example, the nature of the publicly funded mobile coronary care unit implies that a social opportunity cost viewpoint be used to assess that program. A full accounting of the direct monetary costs and implicit opportunity costs of the investment would be appropriate, as would a broad conception of population benefit. In contrast, the third-party payer might not incorporate the value of volunteer resources (e.g. donated time) in its calculation of program cost and would likely value benefit more narrowly in terms of gains in premium earned net of health care costs incurred for subscribers only. Similarly, providers and patients will view costs and benefits in narrower terms, based on the inflows and outflows of resources internalized by them.

Another important consideration in cost–benefit analysis is the methodology used to measure program benefits. Two basic approaches exist: (i) the human capital approach [32, 41], which measures program benefits as the sum of direct treatment costs (for illness) saved plus the value of increased production (in the work-for-pay labor force) attributable to the program; and (ii) "**willingness to pay** (WTP)", which values program benefits according to what prospective program "beneficiaries" would be willing to pay in return for receiving those benefits. The WTP technique has certain conceptual advantages relative to the human capital methodology, in that it includes the perceived value of leisure and nonmarket production as well as the **quality of life** and other indirect benefits of health program investments [18, 34].

These advantages come at a practical price, however. Measures of willingness to pay generally require either that careful population-based **surveys** be performed to collect sample estimates of benefit, or that intended beneficiaries' preferences be inferred by examining their choices in real-life situations in which health and money are "traded off". The "revealed preference" approach is exemplified in surveys of airline passengers, regarding their willingness to pay for improved airline travel safety [19] and for improved air quality [39]. Examples of the "revealed preference" approach include the classic work by Viscusi [38], which inferred the implicit value of human life by comparing the wage premium demanded for jobs at different levels of occupational health risk. Similar safety choices that have been analyzed include the use of automobile safety belts [4] and the decision to purchase new cars with improved safety features [2].

The Cost–Benefit Analysis Algorithm: A Geometrical and Numerical Example

The logic of cost–benefit analysis is displayed graphically in Figure 1. Consider the case of a small local health plan deciding whether to contract with an independent information systems company for its information technology support of its patient care arrangements with hospitals and physicians. The contract is for one year, and the present (year 0) value of the plan's total assets is \$2 million. The plan expects additional net revenues (revenues minus costs) next year of \$1 080 000 from the additional transaction processing efficiencies estimated from this one-year contract.

The curve BDE, labeled "project opportunity set", depicts the set of all projects available to the plan for investment. The "capital market line", drawn as CDF, reflects the tradeoffs for borrowing and lending (rates of return and interest rates) available for investing in comparably risky projects. The revenues and costs are quite risky for this project, in light of the control given up by "outsourcing" this traditional insurance function, so the plan assigns a 20% discount rate to the contract.

The project will require \$400 000 in initial investment (represented as a movement from point B to point A, drawing down plan assets from \$2 million to \$1.6 million), to cover the costs of canceling existing contracts for this information systems support function and the incremental costs of hiring staff to monitor the new arrangement. As shown in Figure 1, this proposed project would add an

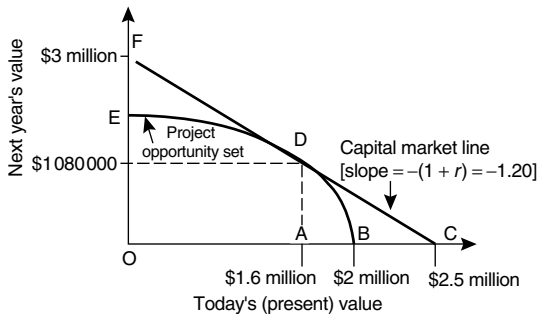

Figure 1 The logic of cost–benefit analysis

estimated \$500 000 to the net value of the health plan's assets. This is represented by the horizontal distance between the plan's original position (point B, pre-investment) of \$2 million and the ending position (point C) of \$2.5 million. This amount equals the net present value (NPV) of benefits less costs. Put another way, based on the plan's estimates, the company's next year value would be \$3 million, or \$600 000 more in year one terms than would have been the case if the plan's assets were simply invested in the capital markets for a 20% rate of return [\$3 million − 1.2(\$2 million) = \$0.6 million]. This \$600 000 in increased "future (year 1) value" is equivalent to receiving \$500 000 (\$600 000/1.2) in increased value today (year 0).

Next, consider the example of a local community not-for-profit hospital deciding whether or not to acquire 49% ownership interest in a large multispecialty medical group that is preeminent in its service area (*see* **Hospital Market Area**). The hospital's total assets are presently worth \$400 million. Acquisition of the group practice would not compromise the hospital's not-for-profit status, but would require an investment of \$60 million cash by the hospital and lease arrangements with the medical group for use of imaging and laboratory technology. The hospital estimates that the proposed lease contract represents a subsidy to the medical group (hospital costs greater than revenues recouped by the hospital) of \$20 million, for a total net investment of \$80 million in present value. The expected rate of return to the hospital on comparably risky investments is 15%, which the hospital's chief financial officer chooses as the discount rate for the costs and benefits of the hospital's investment in the medical group.

The hospital takes the "provider's" perspective in this cost–benefit analysis. The future revenues (benefits) are estimated at \$20 million per year for 25 years (the expected "economic life" of this investment), and annual costs to the hospital of supporting the medical group (e.g. with information systems, health plan contracting support, billing services) are estimated as \$5 million. Thus, the "net benefit" of this project, measured as total benefits minus total costs discounted to their present value, is represented as

$$\text{net present value benefit} = \sum_{t=0,1,\ldots,n} \frac{\text{benefits in year } t \text{ minus costs in year } t}{1/(1+\text{annual discount rate})^t},$$

summed over years $t = 0$ (now), $1, 2, \ldots, n$,

where n is the terminal year of the project. (1)

In this case the estimated net present value (NPV) is

$$\text{NPV (in \$millions)} = \left\{ \frac{\sum t = 1, \ldots, 25(20-5)}{(1.15)^t} \right\} - 80(\text{the time "0" net investment})$$

$$= 15(6.4641) - 80 = \$16\,962\,236. \quad (2)$$

Thus, based on this cost–benefit analysis, the investment should be undertaken because the present value of the net benefits of the project is positive. The figure of 6.4641 is termed the "annuity factor", and it represents the value today (time zero) of \$1 paid in each of n years (= 25 years in this case) invested at a rate of return r (= 0.15 in this case). The formula for calculating this factor is $\{(1/r)[1 - (1/(1+r)^n)]\}$.

In the case of publicly funded programs with widely dispersed beneficiaries and many implicit (rather than direct monetary) costs, it is likely to be more difficult to isolate the annual stream of costs, benefits, risk, correct discount rate, and the "economic life" of the program, but the principles remain the same.

Cost–Effectiveness Analysis

Cost–effectiveness analysis compares the incremental medical costs and health outcomes of alternate health care programs. In contrast to cost–benefit analysis, the denominator of the cost–effectiveness ratio represents health effects expressed in natural units (e.g. life-years gained (*see* **Person-years of Life Lost**), days free of symptoms, cases avoided) rather than monetary units. Valuation of outcome using monetary units favors those with greater income, to the extent that health outcomes are a "normal good", the value of which increases with income [28]. The cost–effectiveness approach to economic evaluation avoids the somewhat controversial monetary valuation of improved health outcomes such as lives saved. However, it should be noted that – in effect – even cost–effectiveness analysis requires an *implicit*

monetary value of health outcomes; otherwise, the decision maker would not know at what level to set the cost–effectiveness threshold for minimally acceptable projects. Under most conditions, results from cost–benefit and cost–effectiveness methods lead to similar conclusions [31]. The interest in the cost–effectiveness model currently stems from its broader acceptance within the health care field and, perhaps, from a working assumption that health decision makers generally operate under externally imposed budget constraints that effectively *fix* the threshold for minimally acceptable projects [23].

A maximization hypothesis underlies the method of cost–effectiveness analysis. Health outcomes are maximized for a given level of medical resource input [12]. The analytic perspective for cost–effectiveness analysis should be that of the health care decision maker, as it is the decision maker who seeks to maximize aggregate health benefits given a budget constraint. This perspective, however, has been criticized as inconsistent with the theoretic axioms of welfare economics, and not in the interest of society [13, 18]. Whereas cost–benefit analysis is strictly based upon a compensation test such as Kaldor–Hicks, cost–effectiveness analyses do not always result in a desirable reallocation from gainers to losers, unless the threshold for minimally acceptable investments is set according to the net benefit maximization rule [12].

The types of questions appropriate for cost–effectiveness analysis include the following:

1. Which of two drug products is most cost-effective for the treatment of major depression [35]?
2. Is heart transplantation a cost-effective strategy [37]?
3. Are work-site intervention programs for hypertension cost-effective [24]?

At the heart of the cost–effectiveness method is the determination of the average and marginal ratios of costs and effectiveness [40]. The average cost–effectiveness ratio is the net cost of each program divided by its measure of effectiveness, resulting in an estimate of the cost of the intervention per unit of outcome gained (e.g. cost per case avoided, or cost per life-year gained). The marginal cost–effectiveness ratio shows the costs and effectiveness of one program in relation to the alternate program.

Specifically, the marginal cost–effectiveness ratio is defined as the difference in medical care costs (net costs) over the difference in program effectiveness (net effectiveness) when comparing at least two alternatives. The marginal cost–effectiveness ratio can be expressed as

$$\frac{TC_a - TC_b}{O_a - O_b},$$

where TC is the total direct medical care costs associated with the intervention, O is the health outcome associated with the intervention, a is program a (new), and b is program b (existing level of care).

Cost–effectiveness analysis is most useful when there are multiple health programs with a common measure of effectiveness, thus allowing direct comparison between alternative programs. This is not always possible, for most medical interventions lack a common outcome measure. For example, medical interventions for hypertension involve an outcome measured in blood pressure units, while antibiotic treatments are assessed in terms of cases resolved.

Selection of the comparator is important, as the marginal cost–effectiveness ratio reflects a direct comparison of the new intervention compared to a base case. The cost–effectiveness ratio can vary dramatically depending upon the characteristics (cost and effectiveness) of the base case comparator.

The analytic horizon of a cost–effectiveness study should correspond to the expected period over which program costs and outcomes will be realized. For acute conditions such as treatment for infection, a less than one-year horizon is appropriate. However, programs for treatment of chronic disease (e.g. hypertension, diabetes, or asthma) and strategies for primary prevention (e.g. vaccination or disease screening) require a longer time frame. In those instances in which costs and outcomes extend beyond one year, discounting to adjust for time preference of the cost stream as a consequence of the program is recommended. Discounting nonmonetary clinical benefits is less widely accepted. Current recommendations for the selection of discount rates for economic evaluations of health care interventions range from 3% to 5% in the US and Canada [22].

Discounting health care costs and benefits has intended and unintended consequences. Time preference adjustment, also known as net present value calculation, of cost streams from comparator programs that accrue at different rates and at different time

periods allows for a standardized valuation of the numerator of the cost–effectiveness ratio. One potential down side to discounting is that public health prevention programs (e.g. immunization or health promotion interventions) often have relatively high up-front costs. Monetary savings that offset these costs may not be realized until much later. Thus, some programs may be judged as not cost-effective simply because of the discount factor.

For resource allocation purposes, the cost–effectiveness ratio can suggest that a new program: (i) improves allocative efficiency (same or better outcome at lower costs); (ii) reduces allocative efficiency (same or worse outcome at higher costs); or (iii) is potentially cost-effective (better outcome at higher cost) relative to the comparator. The latter result requires some interpretation by the decision maker as to the amount of additional resources that they are willing to allocate from other sources in order to realize the incremental gain in health outcome [6].

Cost–Utility Analysis

Cost–utility analysis is a special form of the cost–effectiveness model in which the lack of a common outcome measure is overcome by estimation of some composite metric such as the quality-adjusted life year (QALY) (*see* **Quality of Life and Health Status**). This single outcome measure incorporates the effect of the program or treatment on the quality and quantity of life and allows for comparison of a wide array of interventions [36]. The quality adjustment is derived from preference weights or health utility scores. Several direct and indirect approaches have been developed to measure health utilities or preferences for various outcomes (*see* **Health Status Instruments, Measurement Properties of**; **Outcomes Research**).

The QALY is not the only outcome measure used for cost–utility analysis. The healthy-year equivalent (HYE) has been proposed as an alternative to the QALY, in part because of the restrictive assumptions about preference measurement [26]. The acceptance of the HYE for cost–utility analysis remains controversial.

The primary application of cost–utility analysis is in cases in which programs or treatments generally impact the health status of individuals rather than improve survival or some other clinical outcome measure. Most importantly, cost–utility ratios can be used to compare programs and treatments across different disease states.

A Cost–Utility Analysis Example

Suppose that three different medical options are available for the treatment of inoperable stage 3 to 4 nonsmall cell lung cancer. Option 1 is supportive care without the use of chemotherapy agents. Option 2 is a chemotherapy regimen that consists of two concurrently administered agents. Option 3 is a chemotherapy regimen that consists of three concurrently administered agents. Patient survival, preference weights (utility scores), and cost data are depicted in Table 1. These data show that option 2 is more effective than either option 1 or option 3 from the standpoint of **median** survival. However, best supportive care without chemotherapy (option 1) provides better quality of life for patients. Options 2 and 3 are more expensive, owing in part to the additional cost of the chemotherapy agents, than option 1.

When comparing option 2 to a baseline of option 1, the incremental cost–utility ratio is $[(9985 - 4639/214 - 112) \times 365]$, or \$19 130 per QALY gained. Option 3 compared to option 1 yields an incremental cost–utility ratio of $[(6606 - 4639/165 - 112) \times 365]$, \$13 546 per QALY gained.

Table 1 A cost–utility example

	Treatment options		
Parameter	Option 1, best supportive care	Option 2, two-drug regimen	Option 3, three-drug regimen
Median survival (days)	112	214	165
Preference weight	0.61(±0.22)	0.34(±0.30)	0.34(±0.30)
QALY	0.187	0.199	0.154
Cost (\$)	4639	9985	6606

The Use of Cost–Effectiveness and Cost–Utility Studies by Decision Makers

How are cost–effectiveness and cost–utility analyses used to augment resource allocation decisions? The possible outcomes of a cost–effectiveness or cost–utility study comparing program or treatment A to program or treatment B are illustrated in Table 2. When the overall cost of A is less than B and the health outcomes associated with A are greater than for B, then A is considered to be "dominant", and should be adopted by providers and purchasers as they improve efficiency in the delivery of care. On the other hand, if A is more costly and provides reduced health benefits when compared to B, the new technology should be rejected. Most new programs or treatments are not consistent with the previous two examples. The third row of Table 2 shows the cost–outcome relationship of most new medical technology or programs. Health benefits are improved at some incremental cost for program A compared to program B. Clinicians, patients, and payors must decide whether the improvement in health outcome is "worth" the additional costs. Tradeoffs or substitutions must be made in order to finance and make available treatment A. The final possible result of a cost–effectiveness study is one in which A is less costly when compared to B and also is less effective. Again, if a health system or insurance plan were to adopt such a treatment (e.g. some population **screening** strategies), then tradeoffs would have to be made in terms of foregone benefit.

How attractive does a new treatment have to be to warrant adoption and reimbursement? At what level of cost per health outcome gained would decision makers choose to accept and use new medical innovations? Currently, a cutoff point for cost–effectiveness determination remains uncertain. The value of \$100 000 per QALY has been discussed by policy makers as the level below which a new program would be described as cost-effective and, therefore, worth the investment.

Table 2 Results of cost–effectiveness and cost–utility analyses for resource allocation decisions

Cost difference	Outcome difference	Implication
Cost (A) < Cost(B)	$O(A) > O(B)$	Accept A
Cost (A) > Cost(B)	$O(A) < O(B)$	Reject A
Cost (A) > Cost(B)	$O(A) > O(B)$	Tradeoff
Cost (A) < Cost(B)	$O(A) < O(B)$	Tradeoff

Summary

Health economics is a field of specialization within the discipline of economics that addresses the allocation of resources directed to health improvement and the organization (*see* **Health Services Organization in the US**), delivery, and financing of health services (*see* **Health Care Financing**). In recognition of the centrality of efficiency within economics, a set of methodologies for economic evaluation of health care programs and interventions has been developed. These methods include cost–benefit, cost–effectiveness, and cost–utility analysis. The application of these tools to health economic problems, and particularly to resource allocation decisions, is an area of intense interest. For analysts considering the use of these methods, a complete understanding of the role and limitations of each is necessary.

Health Services Organization in the US

This article describes several of the key features and components of the health care system in the US.

Integrated Health Systems

The medical care system in the US has many separate components including physicians' offices, nursing homes, hospitals, drug stores, laboratories, and insurance companies. Historically, the US has operated primarily under the fee-for-service system, whereby a physician or other practitioner bills the patient for each encounter or service rendered (*see* **Health Care Financing**). Under this system, the components of the medical care system have usually operated independently.

When various elements of the delivery system necessary for the provision of care are formally interrelated, they are referred to as an *integrated health system*. An integrated health system may own all the components of the system, or it may own some components and contract for the others to achieve a complete system. The degree of integration can vary greatly. Some integrated systems include a direct insurance function, offering packaged insurance benefits to an enrolled population, with all services delivered through the integrated system. Alternatively, an employer or insurer may contract with the integrated system to use the delivery mechanism only.

One early US example of a long-standing, highly integrated health care system is the Kaiser Health Plan of California, which has its own salaried doctors who are usually required to treat patients in Kaiser's outpatient facilities. In Europe, an example is the British National Health Service, which pioneered integration and coordination with the control of resources.

The rapid increase in the cost of medical care has accelerated interest in, and prompted increased development of, integrated health care systems. It is believed that integrated systems promote more efficient and effective health care, in part because comprehensive management information systems permit administrators to monitor the use of services, the referrals to specialists, and access to specific, and especially expensive, services. A large system can obtain discounts on supplies and drugs.

Numerous organizational arrangements exist for structuring the components of an organized system. The essential features of an integrated delivery system are the degree of coordination in its network and its potential for controlling physician and patient behavior.

The best-known structure for an integrated system in the US is the *Health Maintenance Organization (HMO)*. It is so called because each patient pays a premium amount prospectively for all covered services, independent of which services were actually provided, which gives a physician or system an incentive to maintain the patient's health. There are several variants of the HMO model. In a *Closed-Panel HMO*, the HMO owns the outpatient and inpatient facilities and owns or contracts for most other services, is paid a fixed amount for each patient covered (*capitation*), and pays the doctors (the panel) a salary or other predetermined compensation. This model allows a great degree of control over both physicians and patients.

Another common HMO structure is the *Independent Practice Association (IPA)*, which contracts with some or all community-based physicians, hospitals, and other providers for services provided to enrolled clients. More structure is offered by the organizational form termed "group practice without walls" in which community-based physicians form a single legal entity while practicing independently with common office management services and shared contracting.

Another category of integrated system is based on legal and organizational relations between hospitals and physicians. These include *Physician Hospital Organizations (PHOs)* and *Management Service Organizations (MSOs)*. PHOs are usually initiated by hospitals for the development of partially integrated systems of care that can contract with insurance companies and employers. PHOs may work with a restricted universe of physicians or may be more broadly based. The MSO tends to be more physician-oriented than the PHO, is sometimes initiated by physicians, and provides greater practice support services for the physicians who are participating.

Health services research is easier to perform within an integrated health care system than in independent facilities, because there are enrolled populations and often a unified information system. Considerable research has been done to determine whether one organizational system yields higher **quality of care**, higher satisfaction, or lower cost

than other systems. The impact of such systems and differences between for-profit and not-for-profit systems will need a further evaluation as they evolve, although the evidence thus far is generally positive. For a further description of integrated health systems, see Brown [1].

Hospital and Health Systems

Hospitals were first termed "almshouses" or "poor houses" and provided care primarily to the homeless poor and chronically disabled. Wealthier people received care in their own residences. As medicine advanced, particularly after the turn of the century, and most notably after World War II, the hospital's role as a source of biomedical expertise and knowledge grew dramatically. In the US, the development of professional **nursing** and specialized technology and the increasing ability of physicians to intervene in disease and illness spurred on the growth of the nation's hospitals in the first half of the 1900s. The growth of private health insurance and government entitlement programs, and further advances in medical technology and the professional development of physicians in the years prior to and after World War II, gave a further thrust to hospital growth and development. In the US, health services are increasingly provided in an ambulatory setting, causing hospitals to become more a source of highly specialized services.

Hospitals and health systems may be organized and owned as government entities or as private for-profit or nonprofit entities. Hospital ownership and hospital management may be differentiated in that in some instances a hospital may be publicly owned, or owned by a nonprofit entity, but managed under contract by a for-profit corporation. Government hospitals may be owned by federal, state, or local entities. A for-profit hospital is typically part of a larger corporation, as may be the case also for a nonprofit entity. Publicly held, for-profit companies that own and operate or manage hospitals under contract are typically large corporations whose stock is traded on national stock exchanges.

In recent years, the for-profit hospital sector has experienced a high degree of turmoil with, most recently, increasing consolidation. Some controversy exists as to the extent to which for-profit hospitals are run more efficiently and have lower personnel-to-patient ratios. Economic pressures, however, are forcing all hospitals to improve their economic efficiency and management expertise and to focus on parameters of performance.

The traditional organizational structure of hospitals in the US includes three sources of power and authority. The governing board is ultimately responsible for all of the operations of the hospital. Hospital administration is delegated responsibility for the day-to-day management of the facility. The hospital medical staff is typically separately organized with delegated responsibility from the board for clinical matters, including the credentialing of physicians and assessing and assuring the quality of health services provided. Hospitals that are part of larger health systems, however, typically lose managerial and governance autonomy.

Hospitals and health systems in the US are facing increasing competition and cost pressures. Managed care requires an assumption of risk and participation in various new forms of reimbursement that have a variety of controls associated with them. Increasing vertical integration is occurring throughout the US in the hospital industry. Concerns over quality of care, malpractice litigation, excess bed capacity, and provision of care to the medically underserved are also common in most communities throughout the US.

Research needs to focus on issues of efficiency, outcomes, and costs of care in the hospital and health systems. Also relevant are issues associated with the integration of the hospital with other services and with systems of care.

Further information on the organization of hospitals in the US can be found in [13].

Ambulatory Care Services

Ambulatory (outpatient) care encompasses those services provided to a noninstitutional patient, as opposed to inpatient services, which are provided to a patient who has been admitted, at least overnight, to a hospital or other health care facility. Ambulatory services include a wide range of settings, professionals, and specific health care clinical services. Technological advances and financial pressures are increasingly leading to a shift of services from inpatient to outpatient care.

The typical US citizen has approximately six physician contacts per year. The most common setting for ambulatory care services is the physician's

office, incorporating solo practitioners, group practices, and hospital outpatient departments. Ambulatory services are also provided in a variety of other settings, including, most notably, ambulatory surgery centers, which have grown tremendously in importance and are now the setting for 70% of all surgery performed in the US, emergency rooms, and hospital clinics. Governmentally sponsored ambulatory care services include those in institutional settings such as Department of Veterans Affairs facilities and prisons, as well as military services and the Indian Health Service.

Ambulatory care plays an important role, particularly in managed care plans, in the coordination, organization, and control of all health care. Ambulatory care is usually less expensive than inpatient care.

Research has begun to address key issues such as the role of the gatekeeper in ambulatory care, appropriate use of services, coordination and access, and clinical practices and outcomes (*see* **Outcomes Research**).

Further details on ambulatory care services may be found in [12].

Group Practice

A group practice is a formal organizational arrangement for the affiliation of three or more health care professionals characterized by the sharing of income, expenses, medical records, staff, facilities, and other resources. The first physician group practice in the US was the Mayo Clinic in Rochester, Minnesota. Historically, most physicians were solo practitioners. With the advent of increasing specialization and administrative complexity, and, more recently, of insurance and prepayment, group practice has grown explosively, with approximately 40% of all physicians in the US practicing in a group.

Group practice provides professional management and shared financial and patient care responsibility. Group practice also limits a practitioner's clinical and financial freedom, requiring that practitioners conform to group norms and standards. Personal autonomy is exchanged for greater financial flexibility and contracting advantages.

Group practices may be organized as professional corporations, foundations, partnerships, and other legal forms. Other complex legal entities and contracting arrangements are used in groups that are involved in managed care. Some larger groups own their own hospitals, and most groups own ambulatory surgery, laboratory, and other specialized facilities. Under managed care, group practice assumes a particularly important role in managing physician resources and in controlling patient access to services.

Havlicek [5] provides further description of group practice.

Primary Care

Primary care is the provision of ongoing, day-to-day health care services, encompassing preventive services (*see* **Preventive Medicine**) as well as relatively routine and patient- and provider-initiated services. Primary care typically requires less intensive resources than more specialized care and can often be provided during a brief office visit. Primary care also includes follow-up and continuing care for chronic diseases.

Primary care is typically provided by a physician in the physician's office, but is also provided by other health professionals, such as nurse practitioners, especially in specialties such as pediatrics. Primary care is also available in hospital facilities and the patient's home.

Primary care provides an important entry into the health care system. It is the best setting for ongoing monitoring and coordination of care, and a reliable source of advice and guidance. It is the coordinating and controlling aspect of primary care, combined with increased reliance on primary care providers (i.e. general internists, family practitioners (*see* **General Practice**), pediatricians, and sometimes obstetrician/gynecologists), that is a key defining principle of many forms of managed care.

Wenzel [16] elaborates on the characteristics of primary care in the US.

Long-Term Care

Long-term care includes a broad array of physical health, mental health, and social services provided to individuals with significant, often permanent, illness and disability. In some instances, the need for long-term care may be only temporary, with eventual recovery. Long-term care services, in contrast to acute or short-term care, typically involve a broader array of social, and residential, services, as well as health services. The involvement of social and other

services may present financial difficulties for many individuals due to lack of external subsidies such as health insurance.

Long-term care services include skilled nursing facilities, such as nursing homes; inpatient hospital services, including medical, surgical, psychiatric, and rehabilitation facilities; ambulatory care services, and mental health facilities; alcohol and drug abuse programs; adult day care; home health services; hospice care; and social services, including meals on wheels, homemaker and personal care services; transportation, communication, health promotion activity programs, and recreational activities; and, finally, housing programs, including congregate care, retirement communities, assisted living facilities, and other living arrangements.

Long-term care services are primarily devoted to individuals with chronic physical or mental disability. An important component of long-term care is the rehabilitation service, particularly for individuals suffering from chronic disease, trauma, and accidents. The older population of long-term care users typically have multiple physical and/or mental health problems, as well as various social and financial constraints. A growing population of individuals in both the long-term and mental health systems is characterized by mental and/or physical disability attributable to various forms of dementia, such as Alzheimer's disease.

Nursing homes are an important component of long-term care. Nursing homes that are Medicare-certified are eligible to accept patients covered under the Medicare program. Medicare coverage of long-term care services is extremely limited, and most patients are required to spend-down most of their personal financial resources before becoming eligible for Medicaid program coverage. The nursing home resident is typically aged 85 and above with multiple health, and often mental health, problems and with a variety of dependency requirements.

Hospice is a form of organizing services for individuals with terminal illness. Hospice may be provided in specifically designated facilities or in the patient's home and involves a coordinated, multidisciplinary approach to addressing the patient's needs as well as those of the family.

Home health services is another growth area in long-term care. Technological advances allow a wider range of services, such as infusion therapy, to be provided in patients' homes, thereby decreasing the need for inpatient care. Increasing coverage under Medicare and insurance plans has spurred the growth of home health care in the US.

Long-term care services are often fragmented and need integration to match services to patient needs. Coordination requires integrated information systems (*see* **Administrative Databases**), care coordination, particularly by case managers, and integrated financing mechanisms. Current long-term care financing arrangements in the US limit this type of integration. Social services, in particular, are often inadequately coordinated with physical health and mental health needs. For further reading, see Evashwick [4].

Public Health and Preventive Services

Public health and preventive services are the front line of protection against injury, disease, and illness. Primary prevention and many public health services are population-based, such as the protection of food, water, and milk supplies, and the monitoring of disease (*see* **Surveillance of Diseases**) and disposal of wastes. Preventive services delivered to individuals with the purpose of avoiding illness include vaccinations and immunizations, physician examinations, and screening (*see* **Screening, Overview**). Of increasing importance in recent years is work site accident avoidance (*see* **Occupational Health and Medicine**).

Public health services are provided through state and local public health agencies. The core functions of public health agencies at all levels of government (see [7]), are: assessment, development, and assurance of public health services. State agencies have responsibility for the entire population in a state. Local agencies provide direct services, such as restaurant inspections and monitoring of food and water supplies. Provision of personal services such as immunization, venereal disease screening, and family planning clinics is a local function. State agencies intervene when local agencies do not perform adequately legally required public health services. In the US, federal agencies with responsibility for public health include the federal **Centers for Disease Control** and Prevention, which provides laboratory, epidemiologic, and advisory expertise. Federal grant support for selected priorities is provided to state and local agencies. Responsibility for protecting the nation's health is ultimately shared by

governmental agencies with front-line providers and by every citizen as well. Research needs in this area include cost/benefit analysis of screening (*see* **Screening Benefit, Evaluation of**) and routine personal preventive services. There is controversy about the appropriateness and frequency of most preventive measures. Further discussion on this topic appears in [7] and [14].

Mental Health Services

Mental health services involve services provided for psychiatric and neurological disease and illness pertaining to the brain and its function, as well as to emotional and behavioral deviance (*see* **Psychiatry**; **Neurology**).

Until the second half of the twentieth century, mental illness and dysfunctional behavior were treated by institutionalization and isolation as well as persecution. Developmental and experiential origins for behavior, codified by Freud and others, led to the establishment of psychiatry and psychoanalysis to diagnose and treat mental illness. Biomedical research is now vastly improving the identification and treatment of such illnesses as depression, schizophrenia, obsessive–compulsive behavior, and addictions.

Increasingly, physiologic etiologies are being identified for many forms of mental illness and aberrant behavior, leading to enhanced pharmacologic intervention. The introduction of psychotropic drugs in the 1950s, along with community-based outpatient services, led to the deinstitutionalization of mental health patients in the US. However, inadequate resources and lack of an integrated and comprehensive delivery system have also caused increases in the homeless population in many cities, multiple hospitalization episodes, and increased criminal activity by and against those with mental illness.

The US has both public and private mental health systems. The public system is the provider of last resort and is characterized by governmental facilities, while the private system cares for individuals with insurance, the ability to self-pay, or coverage under entitlement programs. The private system is characterized by private psychiatric hospitals and a greater role for psychiatrists as opposed to psychologists, who are more prevalent in the public system. Mental health services tend to be limited under private health insurance. Where physiologic origins for mental disorders are identified, prospects for enhanced coverage are brighter, as are the social advantages. However, problems such as developmental disabilities and severe organic brain disorders, dementia, including Alzheimer's disease, substance abuse, and criminal activity remain complex challenges. Mental health problems also raise numerous complex legal, ethical, and moral issues regarding individuals' rights to privacy, to treatment, and to involvement in society, as well as issues of access to care, appropriateness of various professional providers, and avenues for financing.

Research needs include continued epidemiologic investigations of the nature of illness and determination of cost-effective interventions (*see* **Health Economics**), as well as determination of the most appropriate sites for care, best practitioners to utilize, and financing arrangements.

The reader is referred to [6] and [11] for more detailed description of mental health services in the US.

Health Care Personnel

Approximately 8% of US, civilian employment is involved in the health care system as providers of care or in organizing or managing the system. Physicians are the key clinical decision-makers in the health care system. In the US, federal and state government initiatives in the mid-1960s led to substantial increases in the number of medical schools, as well as medical school graduates from existing schools. In addition, during the late 1960s and 1970s, federal policy allowed for an influx of substantial numbers of foreign medical school graduates. The result of these policy actions is a substantial increase in the number of physicians in training and in practice. Geographic dispersion of physician supply has also improved greatly over the past 30 years. Significant attention has been directed toward specialty distribution, to focus recently on increasing the supply of primary care practitioners at the expense of many surgical subspecialities. Managed care has endorsed this shift with an emphasis on providing care through primary care practitioners wherever possible.

There are over 2 000 000 registered nurses in the US. In recent years, there has been a dramatic shift in the education of individuals eligible to become registered nurses from hospital-based diploma programs

to baccalaureate and associate degree programs based in colleges and universities. The nursing field also includes many other roles, including various forms of nursing assistants and licensed practical nurses, as well as more heavily credentialed nurses, such as nurse practitioners.

Numerous other specialty professionals contribute to health services. For example, improvements in oral health combined with greater efficiency in dental practice have impacted demand for dental services and education; the number of dental schools and graduating dentists has begun to decline. However, dental services are still inequitably distributed due to financial constraints.

Research issues for the future are complex and include the increasing role of specialists in many areas, competition between different practitioners for employment and clinical roles, credentialing and licensure of professionals, and matching availability of personnel to the need for such individuals in an increasingly fiscally constrained environment. Issues of quality, cost, and appropriateness of utilization, will also need to be addressed in the future (*see* **Health Workforce Modeling**).

For further information on health care personnel in the US, see [2, 3], and [8].

Managed Care

Managed care is a general term representing the realignment of health care services and reimbursement in such a manner as to shift the risk, both financially and in other forms, from insurers to providers and consumers. Managed care is the more current form of what was previously termed prepaid health care. Although managed care is in a state of flux, some specific organizational structures are beginning to evolve.

Managed care plans are designed to reduce utilization, particularly of inpatient services, and at the same time often to provide a broader benefit structure with some degree of emphasis on preventive services in view of their potential long-term cost benefits. One important feature of managed care plans is the establishment of contractual arrangements with providers to allow the plan and its management to impose various forms of oversight and control over providers. Provider risk-sharing through contractual arrangements that provide incentive compensation is also common. Reduced consumer administrative burdens are typical of many forms of managed care, although various barriers are also introduced to reduce consumer incentives for utilization as well.

Managed care provides services in a more financially constrained framework, whereby both providers and consumers have greater incentive to control use of services and hence costs. Substitution of lower-cost clinical alternatives, rationing of services, coordination of care, reduction of duplication of services, and managerial efficiencies are among the approaches utilized in implementing managed care systems. Use of quantitative databases to monitor and evaluate clinical patterns of care, financial experience, and quality and utilization is an important component of managed care, which drives the need for a structured information system (*see* **Administrative Databases**) and for statistical evaluation methods for assessing use and patterns of care.

Managed care often incorporates various forms of HMOs. The percentage of the population enrolled in managed care plans has increased dramatically in the past decade. In the US, entitlement programs such as Medicare and Medicaid increasingly incorporate managed care principles and contractors to instill efficiencies and cost savings.

Managed care plans, through contractual arrangements with providers, establish networks of individual and institutional care sources. Less restrictive plans, such as Preferred Provider Organizations and Point-of-Service HMO plans use networks but allow out-of-plan use at higher cost. More restrictive forms of managed care, such as Closed-Panel HMOs often do not allow out-of-plan use of services. Other incentives and controls affecting consumers include copayments and deductibles, case management, benefit limitations and exclusions, and access barriers in various forms.

An increasingly popular mechanism for controlling utilization by consumers in managed care plans, particularly HMOs is the gatekeeper. The gatekeeper is a primary care physician who must either provide or approve referrals for any services within the plan. The gatekeeper concept has assigned much greater responsibility to the primary care physician and has reduced direct access to specialists by consumers.

In managed care plans, financial incentives for providers are often designed to provide rewards for the careful management of dollars. Various forms of incentives, such as bonuses and profit-sharing pools,

are used to encourage physicians to control carefully the use of services, particularly expensive inpatient and specialty care. Reimbursement of physicians has also shifted in many plans from traditional fee-for-service payment to salary and capitation, whereby incentives are much more clearly focused on rationing and control of utilization.

Further research is needed to test many of the principles of managed care and their long-term effects on cost, quality, and patient and provider satisfaction. Possible underutilization, lack of access, and adverse effects of financial incentives for physicians are other research issues.

Kongstvedt [9, 10] provides a good source for further reading regarding managed care.

Regulation and Controls

Regulatory mechanisms to control health care services may be imposed by governmental entities or by payers under contractual arrangements. Government intervention is usually designed to protect health and safety or to influence the health care market when the market fails to achieve those social goals desired by political forces.

Examples of US governmental regulations pertaining to health and safety include fire, health, and safety codes imposed by state and local governments. State regulation of health care personnel includes licensure of physicians, nurses, and other categories of professionals. Payers may also implement limited regulation of this nature, such as evaluation of participating physicians' qualifications and credentials.

Marketplace regulations in the US, particularly by government, date back to the Hill–Burton legislation, which allocated federal funds for hospital construction and renovation after World War II on the basis of simple health planning computations. The more recent era of government intervention dates to the Great Society in the mid-1960s. Numerous interventions attempted to influence costs and allocation of resources. Examples include subsidies aimed at individuals and institutions, such as grant and loan program tax exemptions. Entitlement programs such as Medicare and Medicaid represent large-scale, subsidy-type interventions. Restrictions on entry into professional fields through licensure requirements and facility licensure and capital expenditure controls are additional examples of interventions. Regulation through payment mechanisms includes requirements under the Medicare and Medicaid programs, rate-setting commissions, wage and price controls, payment restrictions under insurance programs, including contractual arrangements under managed care, and the determination of fee schedules.

Controls to assure the **quality of care** are also common in health services. These are usually associated with entitlement programs or with contractual obligations under insurance plans, particularly under managed care. These mechanisms have included professional review organizations, utilization review, preadmission authorization, second opinions for surgery, and other programs to assess quantitatively various aspects of the quality and utilization of services, and the control of use of services by providers and patients.

Numerous other regulatory mechanisms have been utilized in the past or are currently in place. These include: financial controls on consumers, including benefit limitations, deductibles, coinsurance exclusions, and other provisions of insurance plans; limitations on the supply of services through rationing, queues, and other restrictions on access; reviews of provider services, including claims reviews, medical audits, institutional reviews; and legal, regulatory, and practice-influencing effects from medical malpractice litigation.

Regulation and control of health services has historically had a focus on either affecting utilization and costs or influencing perceived inadequacies and misallocations of resources within the health care system. Although many regulatory efforts in the past have failed to provide adequate results or have simply not been cost-effective, marketplace mechanisms continue to be the primary focus at the present time with an emphasis on reduction in cost increases, on influencing patient expectations of behavior, and on affecting physician practice patterns and use of resources. Regulatory control mechanisms are increasingly focusing on economic considerations with some added focus on monitoring various aspects of the quality of care provided. Evaluation of consumers and providers by managed care organizations and self-evaluation of such managed care organizations themselves and by external organizations have grown substantially in recent years. Under the pro-competitive market approach in the US of recent years, the federal government's

direct role in the regulation and control of health services has focused primarily on costs, access, and quality issues in government entitlement programs with a less substantive contribution to the assessment of various aspects of the larger system.

The reader is referred to [17] for more details regarding regulating and controlling health services in the US.

Technology Assessment

Advances in technology can improve the diagnosis, treatment, and cure of disease and illness. However, important issues related to the diffusion and evaluation of technology impinge on policy-making regarding the role of technology in health services.

The evaluation of technology involves complex considerations including costs and benefits, regulation, efficacy, and clinical effectiveness. Diffusion of new technology is driven by financial considerations. Under fee-for-service reimbursement, technological advances have a tendency to be utilized as quickly as regulatory approval is achieved, while in a managed care environment the potential for some hesitation exists.

The principal federal agency responsible for technology assessment in the US is the **Food and Drug Administration (FDA)**. Drugs and medical devices must be demonstrated to be safe and efficacious to achieve FDA approval for clinical application. This complex and controversial process requires considerable time and financial resources.

Clinical research studies are usually necessary to determine the appropriate clinical situations when each technology should be utilized. Technologies that lead to overall cost reductions in health services due to their substitution for more expensive therapies are of particular research interest. Managed care organizations are interested in the appropriateness of various technologies and their associated costs. Controversy is building over the potential restriction of some technologies under insurance and entitlement programs due to costs and limited benefits. Ultimately, rationing of resources necessitates making judgments as to whether particular technologies are warranted in individual cases.

Further details may be found in Skorup [15].

Health Services Data Sources in Canada

The system is referred to as "national" because plans are linked by the federal government's Canada Health Act principles.

Similarly, the provinces and territories have separate health information systems to serve their particular purposes. These are a complex assortment of components operating in different places and at different levels, often quite independently. However, through agreements, the provinces and territories, federal government departments, and other organizations have instituted national health information databases and registries, maintained according to national standards. These databases do not yet form a coherent whole, but they are accessible to decision makers, planners, epidemiologists, researchers, and others to improve health services, and ultimately the health of Canadians (*see* **Administrative Databases**).

In 1989, the Conference of Deputy Ministers of Health, concerned about the limited and fragmented nature of health information, approved the establishment of the National Health Information Council (NHIC). In 1990, a National Task Force on Health Information was created to assist the NHIC with identifying health information needs. In addition, the Task Force was asked to develop priorities and organizational structures to bring about improvements and changes. Following consultations, the Task Force recommended establishing a Canadian coordinating council for health information.

These are available from the CIHI, two federal government departments – Statistics Canada (STC) and Health Canada (HC) – and a smaller but important special purpose agency, the Canadian Centre for Occupational Health and Safety (CCOHS). Each of these agencies is described briefly in the section "National Health Information Organizations in Canada". There are other data sources in the provinces/territories but national series and comparisons are mostly available through the national agencies.

Framework for Health Information

The evolution of health information has mirrored paradigm shifts in the view of health care – largely in-patient acute care and physician administrative data at first, and over time moving towards information across the continuum of care and on a broader definition of health. Canadian health care information consists mainly of information from government and hospital sources. Canada has standardized and comprehensive national databases, and these have the potential for much further development. Currently, the availability of data is most complete in the areas of hospitals, identifiable diseases or conditions, and utilization and costing. Surveys such as NPHS and CCHS are being used to explore nonmedical determinants of health. For convenience in identifying current data sources and development activities for the future, Canadian health information is categorized into three main areas.

1. *Health determinants*. The factors that influence or determine health. They include the environment, human biology, lifestyles, behaviors and risk factors, demographics, occupation, and socioeconomic factors. Examples are satisfaction with job, cigarettes smoked, proportion of aged, elderly below low income cutoffs, and labor force participation, or lack of it.
2. *Health services*. Services, interventions, and systems (whether public or private sector) allocated for restoring, maintaining, or improving health. These are subdivided into morbidity, health human resources, environmental and **occupational health**, and financial and operational data areas. Examples include mortality rates, readmission rates as well as physician to population ratios, numbers of health care facility beds and financial indicators. (*see* **Health Services Research, Overview**).
3. *Health status/population health*. Objective and subjective measures – including morbidity, disability, **life expectancy**, and **vital statistics** – of the health and well-being of populations as diagnosed by health care professionals or reported through self-assessment. Examples are life expectancy and **infant mortality**.

The remainder of the article discusses these broad areas of health information, listing major data holdings and indicating specific examples of information that may be derived from the sources. In addition, a sample of Canadian initiatives underway to widen the scope and fill the gaps in current information are described.

Health Determinants

Data for health determinants are mainly derived from general or special purpose population surveys, both periodic and occasional (*see* **Surveys, Health and Morbidity**). After the one-time Canada Health Survey in 1978, there was a gap until the mid-1980s when a number of federal and provincial surveys were initiated. These include surveys to provide information on current issues such as **AIDS**, tobacco control, and fitness. Other surveys have health-related components for population subgroups, including aboriginal Canadians, children and youth, disabled persons, seniors, and women. There have also been large provincial population sample surveys in Ontario and Quebec. Many of these activities are continuing.

A major ongoing survey is the biennial National Population Health Survey (NPHS) (1994–95, 1996–97, etc.). It includes a set of core population health status measures, longitudinal data on health determinants, and in its first three cycles, special, periodic **cross-sectional** information. This survey of 17 000 households is conducted by Statistics Canada. The self-reported information helps to monitor the health objectives of the provinces and territories, focusing on conditions responsive to prevention, treatment or intervention and examining the states of good health – not just illness. Specific survey categories are **health status**, use of health services (*see* **Health Care Utilization Data**), determinants of health, and demographic and economic information. The survey also allows the possibility of linking to the national health databases (*see* **Record Linkage**).

In 2000, Statistics Canada began conducting Canadian Community Health Survey (CCHS) as part of the Health Information Roadmap Initiative (see Further Initiatives). The CCHS, provides the basis for producing cross-sectional estimates to address priority health data gaps at national, provincial, and health region levels. The CCHS is composed of two cross-sectional components conducted over a two-year cycle. The first component is a health region-level survey has a sample of more than 130 000 with content adapted to health region needs while the second is a province-level survey in the second year with a specific, in-depth theme. With the introduction of the CCHS, the NPHS has now become a strictly longitudinal survey.

Other surveys which provide information either directly or indirectly on health determinants include: consumer income and expenditure; general social surveys; labor force surveys; the international literacy survey; environmental surveys, etc. These may either originate from or be conducted by Statistics Canada for another client (i.e. other government departments such as Industry Canada).

Examples of health determinants available from population surveys include:

1. Alcohol consumption (Statistics Canada – STC; Health Canada – HC).
2. Exercise frequency (STC, HC).
3. Measures taken to improve health (STC, HC).
4. Nutrition (HC).
5. Risk factors (lifestyle) (STC, HC).
6. Smoking/tobacco control and use (STC, HC).

Health Services

Health services data sources contain data elements on health-related curative, preventive, or promotional services provided to patients or to the general public. Many of these data have personal and/or institutional identifiers, so privacy, **confidentiality**, and security standards must be maintained. The major subcategories of data are morbidity, health human resources, environmental and occupational health, and financial and operational areas.

Morbidity

Morbidity databases include data from services provided in hospitals and those provided by physicians and other health practitioners. The Hospital Discharge Abstract Database (DAD) and its companion Hospital Morbidity Database at CIHI are major service event databases. DAD contains over 85% of all Canadian hospital patient discharges (about 4.3 million records annually). It provides data collection and processing services, reports to facilities, and carries out comparative reporting.

Major health care services data sources include:

1. Canadian Organ Replacement Register (Canadian Institute for Health Information – CIHI).
2. Hospital Discharge Abstract Database and Hospital Morbidity Database (CIHI, STC) – (i) most responsible diagnosis leading to hospital

length of stay; (ii) interventions; and (iii) relative resource use by grouping of cases.

CIHI is responsible for many databases and registries that capture information across the continuum of health care services in Canada. This information supports research and analysis for planning and policy making purposes. A detailed statement of purpose is included in the full description of each data holding. All CIHI's data holdings are subject to strict privacy and confidentially principles set out in *CIHI Principles and Policies for the Protection of Health Information* (PDF) 437 KB. Click on any of the links below for further information on the database, related publications, availability of data, and contact information.

Canadian Joint Replacement Register (CJRR) – captures information on hip and joint replacements performed in Canada and follows joint replacement patient time.

Continuing Care Reporting System (CCRS) – contains demographic, administrative and clinical data for residents in facility-based continuing care in Canada.

Hospital Mental Health Database (HMHDB) – contains demographic and medical diagnosis information for inpatient hospital stays for mental health disorders in Canada.

National Ambulatory Care Reporting System (NACRS) – includes data for all home-based and community-based ambulatory care: day surgery, outpatient clinics emergency departments. Currently contains Ontario emergency data only.

National Rehabilitation Reporting System (NRS) – A national health information system for adult inpatient rehabilitation services.

National Trauma Registry (NTR) – contains demographic, diagnostic and procedure information on all admissions to acute care hospitals in Canada due to injury.

Ontario Chronic Care Patient System (OCCPS) – contains demographic, administrative and clinical data for patients in designated chronic care beds in Ontario Hospital. Beginning in April 2003, these facilities will submit data to the national database (CCRS) and historical data will be converted.

Ontario Trauma Registry (OTR) – contains demographic, diagnostic and procedural data on all admissions to acute care hospitals in Ontario due to injury, plus detailed data on major trauma, and data on all deaths in Ontario due to injury.

Therapeutic Abortions Database (TADB) – contains basic demographic and medical information related to Canadian patients obtaining therapeutic abortions in Canada.

3. Health Promotion Surveys (HC).

Health Human Resources

Health human resources databases (*see* **Health Workforce Modeling**) track data elements related to medical and health practitioners, including numbers graduating and practicing, geographical distribution, services provided, and remuneration. The National Physician Database is a major source of information on the quantity of physician services, their costs, and limited patient information. It receives about 16 million records annually from the provincial/territorial health insurance (Medicare) system.

Major health human resources data sources include:

1. National Physician Database (CIHI).
2. Southam Medical Database (physician demographics) (CIHI).
3. Registered Nurses Database (CIHI).

Environment and Occupational Health

Environmental health databases (*see* **Environmental Epidemiology**) from Health Canada and Statistics Canada track chemical, biological, and physical hazards (*see* **Risk Assessment for Environmental Chemicals**), product safety, medical devices, **radiation** protection, and tobacco control (*see* **Smoking and Health**). Occupational health and safety databases, mainly from CCOHS also provincial departments of labour and worker compensation boards, include practical health and safety information on chemical and other contaminants and hazards, regulations, standards, and guidelines.

Major environmental health data sources include:

1. Environmental monitoring and analysis databases (STC).
2. Environmental health databases (HC).
3. Occupational health and safety databases and information (CCOHS).

Financial and Operational Areas

Financial and Operational databases contain details on both governmental and nongovernmental areas, in particular sectors (including hospitals and residential care facilities) or geographic areas (provinces and territories) or at the national level. The main database is National Health Expenditures which contains data from 1960 to the present by spending category and source of funding. The data originate from diverse public documents, including public accounts and annual reports, and private sector sources.

Major health expenditures data sources include:

1. National Health Expenditures Database (CIHI) – actual, real, and per capita expenditures by sector and category.
2. Annual Hospital Survey (CIHI) – beds per 1000 population by type of care.

Health Status/Population Health

Health status includes demographic information, general health status, health status of population subgroups, and illnesses or conditions by geographic or population groups.

The major sources of demographic information are the **census** (held every five years) and the regular reporting of vital statistics (historically – births, deaths, marriages, and divorces). These programs are managed by Statistics Canada. Vital statistics measures are traditional, if indirect, health status measures and may include such items as the age-specific fertility rate, births by **birthweight**, and age of mother (such as teenage births).

Health status data are derived from mandatory disease reporting systems (*see* **Disease Registers**), from general or special purpose population surveys (i.e. the National Population Health Survey), or from hospital or self-reported morbidity and general mortality databases (see details under the section "Health Determinants" above). Under the leadership of Health Canada, national **surveillance** networks are in place to create a picture of health risks, patterns, and trends across Canada. New early warning systems have been set up to detect **communicable diseases** of public health importance. These new surveillance networks represent combined laboratory and epidemiologic efforts. New surveillance systems are also in place to detect trends and risk factors in noncommunicable diseases. These include: acute coronary syndrome; myocardial infarction; childhood asthma; diabetes; congenital anomalies; breast, cervical, prostate, and brain cancer; perinatal health; and childhood injuries.

Selected data available include:

1. Demographic – birth rates (STC); fertility rates (STC); population size and distribution (STC).
2. General health status – health expectancy (STC); life expectancy (STC); health indicators (STC).
3. Health status of population subgroups – aboriginal health (HC, STC); immigrant health (STC) children's health (HC, STC); seniors' health (HC, STC); women's health (HC, STC).
4. Illnesses and conditions – accidents and injuries/trauma (CIHI, HC); AIDS (HC, also in STC health indicators); cancer (STC, HC); cardiovascular disease (STC, HC); chronic diseases (HC); communicable diseases (HC, also in STC health indicators); congenital abnormalities (HC); disability (STC); hospital mental health (CIHI, STC); hospital morbidity (CIHI, STC); mortality/causes of death (STC); notifiable diseases (HC, also in STC health indicators); therapeutic abortions (CIHI/STC); tropical diseases (HC).

Further Initiatives

In 1999, the Government of Canada launched the Health Information Roadmap initiative, a significant investment to enhance the gathering and sharing of information on the health of Canadians and the health of their health care system. The objective was to ensure the regular dissemination of timely and relevant information needed to enhance the public understanding and debate about issues of health and health care and to provide support to those responsible for developing policies, designing and managing programs and evaluating the health care system.

Health Indicator Conceptual Framework

In order to guide the identification of specific indicators that are primarily intended to support regional health authorities in monitoring progress in improving and maintaining the health of the population

Table 1 Health indicators conceptual framework

	Health status		
Well-being	Health conditions	Human function	Deaths
	Nonmedical determinants of health		
Health behaviors	Living and working conditions	Personal resources	Environmental factors
	Health system performance		
Acceptability	Accessibility	Appropriateness	Competence
Continuity	Effectiveness	Efficiency	safety
	Community and health system characteristics		
	Resources	Population	Health system

and the functioning of the health care system for which they are responsible, CIHI developed a health indicator conceptual framework (Table 1). In addition, the indicators should assist with reporting to governing bodies, the public, and health professional groups. The initial set of indicators was selected through a consultative process involving over 500 individuals including health administrators, researchers, caregivers, government officials, health advocacy groups, and consumers. Ongoing consultation with representatives from across the country ensures that existing indicators meet the needs of stakeholders, and that new indicators are added as new needs emerge and new data become available.

This framework is based on a population health, or determinants of health model. This framework reflects the principle, based on the supporting scientific evidence, that health is determined by a complex interaction of factors, including the social and physical environments, well-being, prosperity, health care, as well as genetic endowment and individual behavioral and biological response.

About these indicators. In September 2000, First Ministers issued a CommuniquØ on Health in which they agreed to provide clear accountability reporting to Canadians, beginning in September 2002. Over the past two years, health ministries from all provinces, territories, and the federal government have been working to select and to report on a set of comparable health indicators to the public.

As part (which map back to the conceptual framework) of their agreement in September 2000, First Ministers identified 14 areas for comparable health status and health system performance indicators reporting:

Health status

1. Life expectancy
2. Infant mortality
3. Low birth rate
4. Self-reported health

Health outcomes

5. Change in life expectancy
6. Improved quality of life
7. Reduced burden of disease, illness, and injury

Quality of service

8. Waiting times for key diagnostic and treatment services
9. Patient satisfaction
10. Hospital re-admission for selected conditions
11. Access to 24/7 first contact health services
12. Home and community care services
13. Public health surveillance and protection
14. Health promotion and disease prevention

National Health Information Organizations in Canada

Canadian Institute for Health Information (CIHI)

CIHI's mandate is twofold. It is mandated to be a national coordinator for the development and maintenance of an integrated health information system in Canada. Also, it provides accurate and timely information needed to: establish sound health policies, effectively manage the Canadian health care system, and generate awareness of factors affecting good health. The Institute was established in 1993 as a nongovernmental, nonprofit agency. CIHI is responsible

for data collection, processing, and analysis in wide areas of health, human resources, health care, and health expenditures. It also develops, promotes, and applies national standards to improve the accuracy and comparability of health statistics. Products and services are described in the Canadian Institute for Health Information *Catalogue of Products and Services* (2002) and on the CIHI Web site (www.cihi.ca)
Canadian Institute for Health Information. 377 Dalhousie Street, Suite 200, Ottawa, Ontario, Canada K1N 9N8. Tel. (613) 241-7860; fax. (613) 241-8120; internet: `www.cihi.ca.`

Statistics Canada (STC)

STC is recognized internationally for its expertise in statistics for all aspects of Canadian life. In health, it is responsible, mainly through its Health Statistics Division, for data in the areas of determinants of health, vital statistics, and health surveys to provide accurate and timely statistical information and analyses about the health of Canadians. Statistics Canada provides information on the health status of the population and other specialized information to diverse clients, including life insurance companies, health care associations, pharmaceutical companies, local health units, federal and provincial policy and program areas, and the general public. Products and services are described in the Statistics Canada web site (www.statcan.ea).
Statistics Canada. Director, Health Statistics Division, Statistics Canada, Main Bldg., Tunney's Pasture, Ottawa, Ontario, Canada K1A 0T6. Tel. (613) 951-1746; fax. (613) 951-0792; email: hd.ds@statcan.ca

Health Canada

Health Canada is the federal department responsible for helping the people of Canada maintain and improve their health. In partnership with provincial and territorial governments, Health Canada provides national leadership to develop health policy, enforce health regulations, promote disease prevention, and enhance healthy living for all Canadians. Health Canada ensures that health services are available and accessible to First Nations and Inuit communities. It also works closely with other federal departments, agencies, and health stakeholders to reduce health and safety risks to Canadians.

The Population and Public Health Branch (PPHB) collects the information on health determinants, diseases, and health services related to national programs on health promotion. Their role is to identify, investigate, prevent, and control disease on a national basis. The Healthy Environments and Consumer Safety Branch promotes safe living, working and recreational environments, and collects information on the environment in relation to human health. The Health Products and Food Safety Branch manages the risks and benefits to health products and food and collects information in this area. The first Nations and Inuit Health Branch collects data and information on Aboriginal Peoples.

The information collected through Health Canada and its multijurisdictional network is used by the department and other agencies and government jurisdictions for prevention, control, and policy formulation.

Health Canada. Internet: www.hc-sc.gc.ca

The Canadian Integrated Public Health Surveillance (CIPHS) program is one of several projects that are part of the Network for Health Surveillance in Canada. CIPHS' mandate is to bring standards-based management of public health data and to develop software applications that will allow for a convergence of the information in existing and new systems so that crucial public health information will be available to health professionals and decision-makers at the local, provincial, territorial, and national levels. CIPHS brings together a strategic alliance of public health and information technology professionals working collaboratively to build an integrated suite of computer and databases tools specifically for use by front-line Canadian public health professionals. These front-line public health workers will be able to more effectively undertake public health action through improved management of information and access to key data elements.

Canadian Centre for Occupational Health and Safety (CCOHS)

CCOHS is a federal government agency under the Department of Human Resources Development. It

is an internationally recognized resource in occupational health and safety and in electronic information delivery systems. It provides information and advice about occupational health and safety in order to promote safe and healthy working environments.

Health Services Data Sources in Europe

Describing half a century of development for the more than 20 health systems of Europe, each of which has followed a somewhat different path, is difficult. However, one could summarize by noting that Europe's health systems, in general: (i) experienced a virtually unbridled expansion during the third quarter of the twentieth century; (ii) underwent a process of learning to operate under relative fiscal constraints between the mid-1970s and the late 1980s; and (iii) in the 1990s are experiencing a host of reforms that aim simultaneously at consolidating high but insufficient Equity achievements, and at doing more (Effectiveness) with fewer resources (Efficiency) while involving a broader array of participants in the decision processes (Empowerment) [3].

Europe's health systems are typically described as *Bismarckian* (i.e. predominantly nationwide public schemes to protect individuals against the financial risks associated with illness, through subsidized medical care benefits largely delivered through autonomous agents) or as *Beveridgian* (i.e. medical suppliers accessible to all residents at public expense, often publicly supplied, with out-of-pocket expenses limited – generously so in the early decades). In the Central and Eastern countries – not reviewed here – the appropriate label to describe collective production of, and universal entitlement to, a basic medical package was that of a *Semashko* model. That model nominally supported more preventive interventions than in the West but a considerably small array of high-technology procedures aimed at increasing survival rates in the older age strata. A fourth mixed model with heavier reliance on private insurance for sizable population segments and safety nets for frailer segments applies in a third of the Dutch population and, in a different way, in Swiss cantons. Although there is vocal advocacy for higher private insurance participation, this approach has not been a dominant model in the pattern of Europe's **health care financing** during the second half of the twentieth century.

There are, of course, many variations in European health systems within this broad classification scheme. For example, in Bismarckian France, insurees are required to pay their bills directly and are subsequently reimbursed, whereas in Bismarckian Germany vouchers relieve patients from the necessity of most cash transactions. These differences are more than cosmetic. Faced with broadly similar structural problems, some European public authorities opt for modest doses of reform in the apparent belief that structural adjustments can be painless, whereas others such as Britain choose to restructure on a large scale. Ambitious blueprints for a different system with competition among providers and among payers with a larger role for the insurees (the Dutch Dekker Plan in the late 1980s) appear to have yielded to more modest and politically easier ways using a small measure of competition. Stepwise priority setting, which started in the Netherlands and in the Nordic countries, is gaining ground in larger countries. After several decades of a pull towards public responsibility for medical care financing, a redefinition of the private–public mix is everywhere on the agenda, with population *well-being* still a dominant driver but with a strong concern for cost-effectiveness (*see* **Health Economics**) and greater codetermination.

European *averages* – used by necessity to describe expenditure trends and health states of the population to highlight the spread of real-world dispersions among the 22 countries – are published under the auspices of OECD (Organization for Economic Cooperation and Development)-Europe. Broadly similar measurement is available only for the 22 European country members of the OECD. OECD-Europe in 1997 comprised the 15 Member States of the European Union (formerly referred to as the European Community), which are Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain, Sweden, and the UK, together with the Czech Republic, Hungary, Iceland, Norway, Poland, Switzerland, and Turkey. OECD's membership also includes Australia, Canada, Japan, Korea, Mexico, New Zealand, and the US (these non-European countries are not reviewed in this article).

In the 1990s the institutions governing the European health systems and the mix of incentives and regulations governing them have become more diverse. However, there appears to be an underlying trend towards a separation of finance and delivery. Health services in Europe involve monetary transactions, but by and large they are not an activity like all others and obey a distinct set of principles. Money increasingly follows the patient. Monolithic structures are yielding, as in

Britain, in favor of fund-holding general practitioners or, as in Italy, in favor of hospitals run as still publicly owned but autonomous enterprises. The concern for quality has become pervasive, thereby generating closer monitoring and a growing demand for evaluation. External constraints (mainly of a financing nature, but also strained labor relations or ideologic debates as well as the time required to generate micromanagement models) slow down the transformation process of the multifaceted European health systems. An underlying converging current is, however, greatly facilitated by common external constraints (the need to abide by the discipline of a common currency unit, for instance, prompted Belgium, France, Italy, Spain, and others to accelerate reform proceedings) and by shared ethical principles, notably with respect to children, to ethnic minorities, and to underprivileged segments of the population. The OECD *Health Policy Studies* series (notably volumes 2, 5, 6, and 7) and the CD-ROM statistical compendium *OECD HEALTH DATA 97* embrace in a reasonably comprehensive way the health systems trends in the 22 countries referred to here.

In 1996 the European nations' *measured* effort to finance the range of medical goods and services varied by a 2 to 1 ratio (Germany, at 10.5% of GDP, leading Switzerland and France at the top; Poland and Turkey, at under 5% of GDP, at the bottom, with a sizable concentration at around 8% of GDP). Higher spending in some countries (about $2400 at purchasing power parity – a level of living exchange rate – in Switzerland, $2000 in Germany, and $2000 in France) primarily reflects higher per capita incomes but also higher costs of in-patient care episodes, physician contacts, and medicines. Poland and Turkey, whose *measured* expenditure on medical goods and services is closer to $300 per capita, are OECD-Europe's lowest real income countries. The elasticity of health expenditure to total domestic demand – which translates to a relative citizen and consumer preference for medical goods and services over all goods and services – has been well above unity during the second half of the twentieth century, although financing pressures have slowed this proclivity in most countries. Sizable public deficits and public debts have constrained the management of Europe's health systems in the 1990s while at the same time providing them with an opportunity to restructure.

The main driver of Europe's health systems is not simply a finance engine, but one which also has concerns for quantity and **quality of life**. Gains in **life expectancy** at birth have been greater than three months per year since the 1950s in Europe, with somewhat faster gains for disability-free life expectancy. Potential life years lost – a measure of avoidable mortality below 70 years of age – has shrunk by two-thirds, and morbidity from a number of causes has declined, even though the accelerating demand for services and the fluctuating indicators of patient satisfaction may convey the opposite perception. **Quality of care** and **outcomes** remain important concerns in the European health systems.

Europe's Health Systems Information

The intrinsic complexity of political and social organizations implies that – short of mammoth and virtually unmanageable integrated information systems – the data describing their features are compartmentalized and typically developed in isolated corners of the system. A catalog of data sources is required in each European country. No country releases information on inputs, on throughputs, on financing and on performance indicators, on health status and on outcome measurement, and on **population-based studies** in less than a dozen statistical collections. Multiplied by 22 (not to mention the **World Health Organization's** 50 European members), a combined catalog would reach booklet size. As **evidence-based medicine** and evidence-based health systems are only slowly maturing in most countries, the booklet would soon become a directory. A printout of the *OECD HEALTH DATA* sources and methods facility in hypertext – which ties to the 700–800 **time series** on 29 health systems contained in the software – exceeds 200 normal pages, but even that represents a considerable shortcut for a policy analyst in need of simultaneous access to information on several industrialized countries. Forerunners of the hypertext file have been published in conventional paper format [1, 2].

In particular, *OECD HEALTH DATA* covers macrohealth data pertaining to:

1. **Health status** (life expectancy, potential years of life lost, premature mortality, morbidity, and perceived health status)

2. Inputs and throughputs (health employment, medical education and training, high-technology medical facilities, health R&D, the pharmaceutical industry activity, and trade in medical goods)
3. Medical consumption and practice (average length of stay and admission/discharges by **case-mix** groupers or by **International Classification of Diseases (ICD)** categories, pharmaceutical deliveries by therapeutic classes, ambulatory surgical procedures, and other indicators of medical activity and their prices)
4. Lifestyle and environment (nutrition, nuisances and pollutions, behavioral parameters affecting health, and social protection arrangements)
5. Expenditure on health services and finance (*see* **Health Care Financing**) (total and public, outlays on medical functions and benefits: in-patient care, outpatient services, pharmaceuticals, therapeutic appliances; expenditure by age groups; and sources of funding)
6. Demographic and macroeconomic references related to the composition of the population and the labor force, general education, the national product, public finance, and monetary conversion rates.

A particular feature of the datafile is the inclusion of a hypertext facility that lists for every group of variables the intended content of each series, known deviations from the *standard* definition, and the sources of the data.

Other multicountry datafiles are available to the analyst. The European Office of the World Health Organization (WHO) periodically releases a *HEALTH FOR ALL* software which focuses on public health objectives set in the aftermath of the 1978 Alma Ata Conference. These include 38 targets designed to reduce substantially the toll of premature mortality and largely avoidable morbidity, resulting notably from lifestyle and environmental factors. These targets reinforce the continuous monitoring exercise of WHO in the areas of **communicable diseases** and of cancer and other chronic diseases. WHO supports a network of collaborating centers which collate information in their area of specialty, e.g. the **incidence** of **AIDS**. The total sum of these datafiles makes up a sizable amount of reasonably homogeneous data.

The Nordic Council, an informal institutional machinery set up by Denmark, Finland, Iceland, Norway, and Sweden, pioneered a harmonized development of epidemiologic as well as activity nomenclatures, notably in surgery. *Health Statistics in the Nordic Countries*, specialized publications on medicines and on social protection, and the relevant tables in the *Yearbook of Nordic Statistics* provide a limited but harmonized supply of data with detailed indications on the sources in the five countries.

The Commission of the European Union, chiefly through its Statistical Office (Eurostat), has over time developed data files dealing with policy areas pursued by the European Union or related to these pursuits. One example is a large database on congenital anomalies, Eurocat. Another is a database related to the use of case-mix (**diagnosis related groups** or related approaches) management. Many of these specific datasets are, like those developed under the auspices of the WHO collaborative work, the product of learned societies united by prospective economies of scale in pooling basic data. The European Union has an ambitious data development program on its agenda for the 5-year period 1997–2002 that expands its long-term concern for data on work accidents and occupational diseases, on the mobility of medical professionals, on trade in pharmaceuticals and medical equipment, and on selected areas of prevention, all domains in which the Treaties governing the Union provide the authority.

A few learned societies, like the European Dialysis and Transplant Association or the International Birth Defect Monitoring Association, have, over time, built sizable registries (*see* **Disease Registers**). These reasonably homogeneous datasets are similar to those generated by North American and Australasian bodies. Elsewhere, world associations, such as the International Dental Federation, which created a Working Party with participants from several continents, have instilled a world standard gradually disseminated through the national associations willing to take part in a survey of professional practice. Networks of social insurance administrators and payers and of public hospital managers etc. have instilled a culture in which their domestic reporting procedures are slowly converging.

The bulk of the data developmental effort lies, however, where the power to intervene lies: in public and in private national machineries. Health is virtually not defined anywhere; only its absence is recognized. In much the same way, the characteristics of health professionals and of delivery functions

such as hospital care and the measurement of quality of life attributes are not shared. Referring to one of the most established nomenclatures, the ICD, half a century of practice has not sufficed to erase variations in coding practices, let alone in aggregation. Medical culture is not uniform across countries, nor sometimes within countries. Since cross-national compendia are built from national time series or surveys, important attributes or characteristics may vary among individual entries. Lengthy commentaries are thus required for virtually every single component.

International agencies which cooperate in limiting the costly multiplication of nomenclatures are not immune to the risk of using similar headings for different datasets since the criteria underlying the construction of these datasets may vary. The reporting of drinking habits supplies an illustration: the *Health for All* compendium seeks comprehensiveness and identity of concepts; it borrows the basic data from a distillers' compilation which rests on identical conversion of beer, wine, and spirits into pure alcohol. *OECD Health Data*, on the other hand, seeks consistency between the hundreds of data elements it collates from each country more than cross-national comparability.

The preponderance of national datasets over international ones relates to the obvious policy relevance of the former. Companies develop datasets or purchase them from specialized service outfits because of their contribution to corporate strategy; governments develop sizable datasets to plan, implement, and evaluate incentives and regulatory interventions in their health systems. The statistical instruments developed in European countries much resemble those found in the US, comprising one-off surveys, recurrent surveys, **administrative databases**, and elaborate statistical constructs. Because the governance culture of most countries comprising OECD-Europe has been on the whole less quantitative than that prevailing in North America, and notwithstanding sociopolitical choices conducive to considerably greater involvement of public authorities in the management of health care delivery and in health systems financing, European countries have historically been providing less quantitative information on their respective health systems than what may be readily accessible in the US. The quantity and the quality of information released in Europe has been progressing at a rapid pace, however, since the oil crisis of the mid-1970s forced countries to reappraise the cost-effectiveness of public spending and since corporations operate less and less on captive markets but must live in a competitive environment. The list of these new statistical products is a long one – concerned analysts may turn to the *OECD Health Data* hypertext facility, to other international sources of quantitative information and, increasingly, to *Annual Statistical Yearbooks* or *Statistical Abstracts* of the countries in which they have a greater interest for preliminary indications of what is currently accessible. Furthermore, the stream of information is not drying up and, in several areas, new data collection activities have recently been started in Europe in support of evidence-based management systems.

JEAN-PIERRE POULLIER

Health Services Data Sources in the US

The ability of the health care system to respond to the dynamic needs of a nation, and the adequacy of that response, is governed by the availability of relevant data. The necessary information is used for purposes of planning, and to establish baselines and assess change. Sociodemographic, economic, medical utilization, health care expenditure, insurance coverage, health status, and diagnostic measures are critical health care indices that assist in the determination of the demand for health care by the health service user population. For effective administration of health services, information is also needed on manpower and facility requirements and supply, access to care, satisfaction with care, manpower shortage areas, and financial constraints [9].

In the US, federally sponsored health care **surveys** and other related data systems such as inventories of health care providers have served as the primary data sources to assess the nation's overall level of health and health care needs, and to help identify deficiencies in the health care delivery system. Resultant analytic databases (*see* **Administrative Databases**) have been used to formulate analyses with policy implications, to model the impact of proposed changes in programs, and to evaluate the impact of policies over time. Numerous health surveys have also been conducted by state and local governments to address comparable health system evaluations at the subnational level. Health services information systems have also been developed with funding from private foundations and industries, but their focus is usually quite specific in nature. A brief description of these health services data systems in the US is presented below.

Population-based Surveys: Measures of Health Care Use, Expenditures, Access, and Need

National data on the incidence of acute illness, the **prevalence** of chronic conditions and impairments, the extent of disability, and the utilization of health care services are obtained in the US through the National Health Interview Survey (NHIS). The survey is an annual **cross-sectional** survey of approximately 40 000 households selected to represent the civilian, noninstitutionalized population of the US. Sponsored by the **National Center for Health Statistics (NCHS)**, the sample data measure demographic and socioeconomic characteristics, health status, and the use of health care services. Periodic supplements in the area of utilization, behavior, and health status are used on a rotating basis to collect more detailed information.

The NHIS national core sample also serves as the sampling frame for the Medical Expenditure Panel Survey (MEPS), which replaces the periodic National Medical Expenditure Survey (NMES). The survey is cosponsored by the Agency for Health Care Policy and Research (AHCPR) and the National Center for Health Statistics. This **panel** survey collects data to provide national annual estimates of health care utilization, expenditures, insurance coverage, and sources of payment for the civilian noninstitutionalized population, and for an oversample of policy-relevant subgroups that include the poor and near poor, the elderly, individuals with functional limitations, and individuals predicted to incur high levels of medical expenditures. Data collection for the redesigned MEPS was initiated in 1996, based on a sample of households from the 1995 NHIS. The MEPS survey is conducted annually, and obtains both cross-sectional and **longitudinal data** needed to monitor health care utilization, expenditures, and health insurance coverage continuously and to examine changes over time. The survey has sample size peaks, consisting of 13 000 households at five-year intervals starting in 1997, that satisfy national precision requirements for policy-relevant population subgroups. In the off-years of the survey (e.g. 1998–2001 and 2003–2006), the sample will be reduced in scale to approximately 9000 households, but with sufficient sample for national estimation and for large policy-relevant population subgroups. The survey obtains data necessary to make annual estimates and to model individual (and family-level) health status, access to care and use, expenditures, and insurance behavior over the two-year period [5]. Furthermore, the household data on utilization and expenditures is supplemented by linkage to data from medical providers [8] (*see* **Record Linkage**).

Person-specific data comparable to those collected in the MEPS are also obtained for a sample of the

Medicare eligible population in the Medicare Current Beneficiary Survey (MCBS), sponsored by the Health Care Financing Administration (HCFA). The MCBS is an ongoing longitudinal panel survey of 12 000 individuals selected from Medicare administrative files, that collects health care data covering a three-year period. Household respondents provide data on health care utilization, expenditures, insurance coverage, and health status, which is supplemented by linkage to Medicare Claims Information.

Prevalence data for specific diseases and health conditions and measurements of the nutritional status of the US population are collected in the National Health and Nutrition Examination Survey (NHANES), which is also sponsored by NCHS [20]. Data for NHANES are collected through direct physical examinations, laboratory analyses, and interviews. In the most recent NHANES, completed in 1994, approximately 30 000 persons aged two months and older, were examined in standardized mobile examination centers to obtain a wide range of medical measurements. The measurements include dietary intake, hematologic and biochemical tests, a physical examination and a nutritional assessment. The resultant database allows for the monitoring of national trends with respect to heart disease, diabetes, lead exposure, iron deficiency, and children's growth and development in addition to the nutritional health of the nation.

National estimates of the incidence, prevalence, consequences, and patterns of substance use and abuse are obtained from the National Household Survey on Drug Abuse (NHSDA). This annual survey, sponsored by the Substance Abuse and Mental Health Services Administration (SAMHSA), consists of about 18 000 household interviews of the population aged 12 and older, using special procedures to assure privacy and anonymity.

Analytic data on the use of medical services for family planning, infertility, and prenatal care are obtained in the National Survey of Family Growth (NSFG), conducted by the National Center for Health Statistics. The survey collects information from a nationally representative sample of over 8000 women in the child-bearing ages (15–44) on fertility, factors affecting childbearing (such as contraception, sterilization, and infertility), and related aspects of maternal and infant health [15]. The survey is usually conducted approximately every five years, and the NSFG survey design is consolidated with the NHIS, which serves as the sampling frame for the study.

Another survey with a focus on children, the NCHS-sponsored annual National Immunization Survey (NIS, formerly referred to as the State and Local Immunization Coverage and Health Survey), has been designed to produce estimates of early childhood immunization rates [1]. The annual survey consists of a telephone screening interview with 800 000 households each year to identify approximately 32 000 households with children between the ages of 19–35 months of age, in order to obtain more detailed immunization data on this target population.

The **Centers for Disease Control** and Prevention (CDC) sponsors the Behavioral Risk Factor Surveillance System (BRFSS), which is designed to collect state-specific general population data on forms of behavior that are related to the leading causes of premature death. The survey is a general population telephone **surveillance** system, which obtains data of particular interest to state health departments in targeted risk reduction and disease prevention activities [29].

Another source of both national and community-specific population based data on health services utilization, access to care, insurance coverage, and consumer satisfaction will be forthcoming from the household survey component of the Community Tracking Survey (CTS). The survey is being conducted by the Center for Studying Health System Change and is funded by the Robert Wood Johnson Foundation [16]. The study is designed to track changes in the health care system and their effects on care delivery and individuals. The household survey sample consists of 36 000 households to be interviewed in 1996–1997, primarily selected in 60 communities, and includes a longitudinal component with data collection in 1998–1999.

Another set of more targeted person-specific surveys have been designed with a special emphasis on obtaining statistical information on the older population. The Longitudinal Study of Aging, sponsored by NCHS and the National Institute on Aging (NIA), was designed to measure changes in functioning and in living arrangements in a cohort of older Americans. The survey was based on a supplement on aging to the 1984 National Health Interview Survey and consisted of 7500 participants aged 70 or older, who were interviewed in 1984, 1986, 1988, and 1990 [17]. The Health and Retirement Survey,

also sponsored by the National Institute on Aging, is a national panel survey consisting of a sample of individuals who were 51–61 in 1992 and their spouses (7600 households, over 12 600 persons) that are subsequently interviewed every two years over a 12-year period. The survey obtains information on health and cognitive conditions and status, retirement plans and perspectives, health insurance and pension plans, and income and net worth, to facilitate analyses of decisions affecting retirement [14]. In addition, the Asset and Health Dynamics Among the Oldest-Old (AHEAD) Survey, sponsored by the NIA, is a panel study of 10 000 persons born in 1923 or earlier that were primarily identified in the screening of 69 000 households for the Health and Retirement Survey. The survey obtains data on physical and functional health, cognitive functioning, economic status (assets and income), out-of-pocket costs for service use (community and nursing home), and other economic resources, in order to support analyses on the interplay of resources and late life health transitions [29]. Data collected in the AHEAD survey will be linked with information from the National Death Index.

The National Center for Health Statistics collects and publishes data on births, deaths, marriages, and divorces in the US through the National Vital Statistics System. In addition to demographic information, the death certificate data include items on educational attainment, Hispanic origin, and recent improvements in the medical certification information on **cause of death** [21] (*see* **Vital Statistics, Overview**).

A number of national household surveys that have been designed with a primary emphasis on socioeconomic issues also serve as important sources of health care estimates in the US. The Current Population Survey is an annual household survey consisting of approximately 60 000 housing units, sponsored by the Bureau of Labor Statistics and the Bureau of the Census, to obtain national estimates of employment, unemployment, and other socioeconomic characteristics of the general laborforce and the overall population [28]. The survey permits national and regional estimates of health insurance coverage for the US civilian noninstitutionalized population. The Survey of Income and Program Participation is a panel survey consisting of 36 700 households, sponsored by the Census Bureau, to produce national estimates on the economic situation of households, families and persons by detailed demographic characteristics covering a four-year period. The survey has included questions on work disability, functional limitations, and health insurance coverage which allow for the derivation of national population estimates for these health-related measures [28]. National household level estimates of out-of-pocket expenditures for health care can be obtained from the Consumer Expenditure Survey, sponsored by the Bureau of Labor Statistics [30]. The survey has been designed to provide data on the buying habits of American consumers, and consists of interviews with approximately 5000 consumer units each quarter.

Surveys of Health Care Institutions and Providers, and Hospital and Medical Information Systems

Surveys of medical providers and health care institutions both complement and enhance the information on health services utilization that are obtained from household surveys and serve as the primary source of clinical information on diagnostic and therapeutic services provided to patients (*see* **Health Care Utilization Data**). Physician-specific surveys provide information on practice characteristics, perceptions regarding clinical autonomy, scope of care provided, financial incentives derived through association with managed care organizations, and the impact of managed care arrangements on the practice of medicine. Health services utilization data obtained from institutions, such as from hospital discharge records, provides essential information on surgical procedure rates to help inform whether unexplained geographic variation exists for specific conditions. Furthermore, surveys of institutions such as nursing homes provide data for national estimates of institutional health services utilization, related expenses, and sources of payment, further distinguished by characteristics of the facility, including structure, size, certification, staffing, revenues, and expenses.

The MEPS Medical Provider Survey (MPS), sponsored by the Agency for Health Care Policy and Research, reflects a design strategy to enhance data reported by households on health services utilization and related expenditures through a contact with the associated medical providers. Data from the survey will be used to reduce the **bias** in national health care expenditure estimates that would occur if solely derived from household reported data. Individuals enrolled in the Medicaid program, in which financial

transactions occur only between the provider and the state Medicaid agency, and enrollees of managed care plans are often unaware of the total amount billed or how much the provider is paid for the services they received [6]. Furthermore, detailed information on the specific types and intensity of the services provided, such as physician procedure codes (CPT-4s), diagnosis codes (ICD-9s and DSM-IVs), and classification codes for inpatient stays (DRGs), need to be obtained directly from the medical providers (*see* **International Classification of Diseases (ICD)**). To satisfy these design objectives, the annual MEPS Medical Provider Survey targets a nationally representative sample of the physicians, facilities and home health providers that were reported to provide medical care to MEPS household respondents [7].

The National Ambulatory Medical Care Survey (NAMCS), sponsored by NCHS, is a perennial source of statistical data on the ambulatory medical care provided by office-based physicians to the US population. The target population consists of office based visits to physicians engaged in the provision of direct care to ambulatory patients. The survey data collected can be used for research on the use, organization, and delivery of medical care. For the physician practices selected into the sample, information is collected on patient visits, date and duration of visit, patient characteristics, diagnostic and therapeutic services provided, and the disposition and duration of the visit [25]. For the 1992 survey a sample of 3000 physicians was selected, with data obtained from approximately 34 000 patient records.

The National Hospital Ambulatory Medical Care Survey (NHAMCS), sponsored by NCHS, is an annual survey of visits by patients to emergency departments and outpatient departments of non-Federal short-stay or general hospitals. In 1993, utilization data were collected for approximately 36 000 patient visits to emergency departments and 35 000 patient visits to outpatient departments [21]. Non-Federal short-stay general hospitals that have a 24-hour emergency room are also eligible for the Drug Abuse Warning Network (DAWN) sample. The DAWN is an ongoing drug abuse data collection system sponsored by the Substance Abuse and Mental Health Services Administration, which obtains data on drug abuse occurrences that have resulted in a medical crisis or death. The primary objective of the data system is to facilitate the monitoring of drug abuse patterns and trends [21].

National estimates of the utilization of non-Federal short-stay hospitals can be obtained from data collected through the NCHS sponsored National Hospital Discharge Survey (NHDS), from a national sample of the hospital records of discharged patients. Estimates are provided by the demographic categories of the patients discharged, geographic regions of hospitals, conditions diagnosed, and surgical and nonsurgical procedures performed. Measurements of hospital use include frequency, rate and percent of discharges, and days of care and average length of stay [11]. For the 1991 survey, 466 hospitals participated and data were abstracted from about 235 000 medical records.

The Agency for Health Care Policy and Research's Healthcare Cost and Utilization Project (HCUP-3) uses encounter-level administrative data collected by state governments and state hospital associations to create research databases. There are two HCUP-3 inpatient databases. The State Inpatient Database (SID) contains discharge abstract records for all discharges from community hospitals in 17 states, comprising half the discharges in the US. The Nationwide Inpatient Sample (NIS) is a sample of the SID and approximates a 20% sample of US community hospitals. The NIS contains all discharges from 900 hospitals. The HCUP-3 hospital inpatient databases include patient demographics, diagnoses, and procedures, length of stay, hospital charges, expected pay source, and hospital and physician identifiers. The databases are designed to support research in the following areas: variations in medical practice, diffusion in medical technology, effectiveness of medical treatments, quality of health services, hospital economic behavior, impacts of market structure, changes in delivery systems, and impact of state and federal health care reform initiatives. HCUP-3 also includes an Alternative Services Database that contains records for all hospital-based ambulatory surgeries in five states. The Alternative Services Database enables studies examining the shift of health services from inpatient to outpatient settings [10].

The US Department of Health and Human Services sponsors three distinct surveys of nursing homes: the institutional portion of the Medicare Current Beneficiary Survey (MCBS); the National Nursing Home Survey (NNHS), conducted by NCHS; and the National Nursing Home Expenditure Survey (NNHES), conducted by AHCPR. The MCBS includes an annual institutional component; the

NNHS was last conducted in 1995; and the NNHES was fielded in 1996 as part of the MEPS. To complement the 1996 MEPS Household Survey, the National Nursing Home Expenditure Survey collected data from a sample of 800 nursing homes and more than 5000 residents nationwide on the characteristics of the facilities and services offered, expenditures, and sources of payment on an individual resident level, and resident characteristics, including functional limitation, cognitive impairment, age, income, and insurance coverage for calendar year 1996. The survey also collected information on the availability and use of community-based care prior to admission to nursing homes and data on the capacity, staffing, and services provided by the institutions [5, 24]. NCHS also sponsors the annual National Home and Hospice Care Survey, which obtains facility characteristics and patient specific health service utilization information from home health agencies and hospices.

Other related nongovernment data sources of health care providers and institutions in the US include the American Medical Association's (AMA) Annual Physician Survey [4], which obtains information on practice characteristics, patient profiles, hours and weeks worked, professional income, professional expenses, and fees. The Community Tracking Survey (CTS), conducted by the Center for Studying Health System Change and funded by the Robert Wood Johnson Foundation [16], includes a physician survey to obtain data necessary to track changes in service delivery, access, and perceived ability to provide quality care. The sample design complements the CTS household survey, consisting of a sample of 12 600 physicians in 60 communities.

Health Insurance Data Systems

Coverage and Costs

In the US, the population's access to health services is influenced by the presence and generosity of their health insurance coverage (*see* **Health Care Financing**). Population-based surveys such as the MEPS and the NHIS provide critical data on the sources of insurance coverage that characterize the population. The 1997 Integrated MEPS-Insurance Component (IC), sponsored by AHCPR, will consist of interviews with approximately 9200 employers, 300 union officials, and 400 insurers, to obtain supplemental information on the health insurance held by respondents to the 1996 MEPS Household Survey. This linked survey will provide data to support analyses of individual behavior and choices made with respect to health care use and expenditures and insurance coverage (*see* **Health Care Utilization and Behavior, Models of**).

In a complementary fashion, the 1994 National Employer Health Insurance Survey (NEHIS), co-sponsored by the Agency for Health Care Policy and Research, the National Center for Health Statistics, and the Health Care Financing Administration, was designed to obtain national and state-level estimates of the number of employers offering health insurance, their costs, and the coverage and characteristics of their respective health plans. The 1997 MEPS-IC will include an establishment component that conducts interviews at more than 30 000 establishments to obtain national and regional estimates of the availability of health insurance at the workplace. The analytic objective is to derive estimates of the amount, types, and costs of health insurance provided to Americans by their employers [5, 27].

The Community Tracking Survey (CTS) also includes an employer survey to measure changes in employers' offering of insurance, the types of insurance offered, premiums, and employees' share of premiums [16]. The sample design complements the CTS household survey, consisting of a sample of approximately 10 000 employers in 60 communities.

Utilization

In addition to survey data, **administrative databases** such as data on insurance claims provide another mechanism to measure health services utilization (*see* **Health Care Utilization Data**). Claims data are generally gathered and maintained at the patient level in order to report charges and monitor the use of medical services and resources [2]. In the US there are three major sources of claims data: Medicare, Medicaid, and private insurers [19]. As of 1991, Medicare claims are available for all Medicare enrollees in the US. The Medicare claims database includes information on cost, diagnoses, and procedures. Alternately, state-specific Medicaid claims data are available as part of the Medicaid Statistical Information System

(MSIS) for 21 states, although the level of detail provided on diagnosis and procedures varies widely, given the nonmandatory reporting requirements for these data elements. Complete Medicaid diagnosis and procedure coding is available in the Tape-to-Tape Medicaid database, but is limited to four states (California, Georgia, Michigan, and Tennessee). Claims data from private insurers are generally employer-based, and vary in the level of detail provided regarding information on cost, diagnoses and procedures, and enrollment data. Insurers such as Blue Cross/Blue Shield, United Health Care, and Kaiser Permanente maintain comprehensive claims databases, as do commercial vendors such as MEDSTAT/SysteMetrics, Inc. and Shared Medical Systems, Inc. [23]. These claims data also have been used in the conduct of cost analyses of clinical practice guidelines.

Health System Inventories and Related Federal Program Data

The US Department of Health and Human Services now obtains data on the level, characteristics, and distribution of the **health workforce** and the physical capital in the health system through a number of separate inventories and surveys, with several more in the early planning stages.

The Health Resources and Services Administration (HRSA) has developed and maintained the Area Resource File System (ARFS), which is designed to be used by health professionals seeking consistent, current, and compatible information for conducting research on the nation's health care delivery system [13] (*see* **Health Services Organization in the US**). The Area Resource File System consists of four major components: (i) the Area Resource File (ARF) which is a county-specific database that consolidates many disparate data elements useful in the analysis of health professions issues and developments on a geographic basis (*see* **Small Area Estimation**); (ii) a State/National Timeseries database; (iii) a microcomputer data series containing demographic, health facilities, and health professions data extracts for use on microcomputers; and (iv) detailed hospital data files. This data system provides the necessary information to allow for research and analysis of the geographic distribution and maldistribution of health manpower, the analysis of health manpower supply, utilization, requirements and cost, and the development of long-range **forecasts** of the health profession's supply and requirements [13].

The National Health Provider Inventory was developed and is maintained by the National Center for Health Statistics to provide counts of the number of health care facilities such as nursing homes and board and care homes in the United States. It also includes an inventory of all home health agencies and hospices in the US, and has served as a **sampling frame** for more detailed surveys of these facilities and agencies [26]. The inventory was last conducted in 1991. The American Medical Association maintains a master file containing data on physician specialty and current employment status for nearly every physician in the US [4]. Hospital-level inventory information is obtained in the American Hospital Association's annual survey of all non-Federal hospitals in the US [3]. A biennial inventory of mental health organizations and general hospital mental health services (IMHO/GHMHS) is maintained by the Substance Abuse and Mental Health Services Administration.

The Health Care Financing Administration maintains the Medicare Statistical System (MSS), which provides data for examining the program's effectiveness and for tracking the eligibility of enrollees and the benefits that they use, the certification status of institutional providers, and the payments made for covered services. The MSS consists of four distinct databases: the health insurance master file, containing demographic and benefit utilization data for Medicare enrollees; the service provider file, which contains information on hospitals, home health care agencies, skilled nursing facilities, clinical laboratories, and suppliers of outpatient physical therapy services that participate in the Medicare program; the Hospital Insurance (HI) claims file, which includes information on the beneficiaries' entitlement and use of benefits for hospital, skilled nursing facility, and home health agency services; and the Supplementary Medical Insurance (SMI) payment records file, which provides information on whether the enrollee has met the deductible and on amounts paid for physician services and other SMI covered services and supplies [12, 21]. The Health Care Financing Administration also compiles estimates of health expenditures on an annual basis by type of expenditure and source of funds in their National Health Accounts [18].

Other administrative data systems with a health services focus are maintained by Federal government departments outside Health and Human Services, in order to satisfy program-specific objectives. The Department of Defense maintains several health-related data systems within the Office of the Deputy Assistant Secretary of Defense. One such system, the Defense Enrollment Eligibility Reporting System (DEERS), has information on eligibility for medical, dental, and other related benefits on approximately 13.8 million uniformed services beneficiaries [22]. The Defense Department also maintains the Defense Medical Information System (DMIS), which contains patient data with data elements comparable to those found on the Uniform Hospital Discharge Data Set or the UB-82 [2]. The clinical and administrative data in DMIS on all inpatient episodes at Defense Department facilities are obtained for the Automated Quality of Care Evaluation Support System (AQCESS).

The Department of Veterans Affairs (DVA) maintains four main health related data files: the Patient Treatment File (PTF), which includes patient-specific claims type data (admission date, diagnosis, and procedures) for care received at VA facilities; the Out Patient Care file (OPC), which includes patient specific outpatient utilization data; the Long-Term Care Patient Assessment Instrument (PAI) file, which contains patient-specific demographic, treatment, and diagnostic data for residents of DVA hospital intermediate medicine wards or nursing home units; and the Annual Patient Census (APC) file, which contains utilization data on patients in DVA hospitals at the end of the fiscal year [2].

Summary

In totality, the set of health service information systems that are available in the US are quite comprehensive in their capacity to measure the demand for health services by the US population, and to assess the ability of the health system to satisfy that demand. Future efforts at health service information system expansions at the federal level will be directed to a broader systems view that allows for characterization of the health system as a whole, the analysis of interactions between supply and demand, and the analysis of the relationship between capacity, functioning of the system, and cost. Such information will allow modeling of the impact of change in one aspect of the system on others (e.g. the interaction of the private and public health systems under various health reform scenarios). Similarly, a stronger focus on systems-wide or community perspectives will allow for analysis of the overall structure of the system in terms of regionalization, organization, and redundancy [5].

ROSS ARNETT

Health Services Research, Overview

Health services research (HSR) is the "multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being" [12]. In both basic and applied research, HSR aims to increase knowledge and understanding of the structure, processes, and effects of health services for individuals, families, organizations, institutions, communities, and populations [9, 12]. The origins of health services research can be traced to the 1920s in the US, and several experts since the 1970s have developed descriptions or definitions of the field [3, 4, 9, 13, 14, 17]. HSR has grown most prominent in the 1990s in both the US and abroad, where it is sometimes referred to as health systems research, or simply health research.

Definitional Concepts

Several important concepts set the field of health services research apart from other academic or clinical disciplines. First, HSR is multidisciplinary in that it involves a wide range of disciplines, clinical specialties, and distinct academic fields; those who work in health services research tend to be identified not by their academic training but rather by the nature of the research they conduct. Core areas generally include clinical specialties (e.g. medicine, nursing, dentistry, pharmacy, social work, and public health), economics (or **health economics**), epidemiology, statistics, and biostatistics. Depending on the research or policy question at hand, however, a considerable range of fields can play major roles in HSR, including anthropology, bioengineering, business administration, computer sciences, decision analysis, ethics and bioethics, history, law, management sciences and administration, psychology, **operations research**, and sociology.

Secondly, HSR involves investigations into basic questions of the behavior of individuals, organizations, and systems within health care; more commonly, HSR comprises applied studies concerned with practical questions of health policy, health care delivery and management, evaluation of health care interventions, and the use of information for public and private health care decision-making. Thirdly, HSR directly generates new or better knowledge about this range of topics, and it also contributes to conceptual, theoretic, and methodological structures by which empirical work can be framed, conducted, and interpreted. Fourthly, HSR is concerned with issues of health services that are broadly defined and involve populations (i.e. members of groups defined by sociodemographic characteristics, health conditions or diagnoses, cultural or ethnic factors, geography or geopolitical jurisdictions, or public or private health insurance plans); it is not focused solely on personal health care for individuals.

Finally, HSR is an expansive field that can include clinical studies (*see* **Clinical Trials, Overview**), **outcomes research**, and health technology assessment; it is sometimes characterized as boundary-crossing [2] when multiple fields, disciplines, and methods are brought to bear on a single question. HSR is distinguished, however, from basic biomedical research and clinical investigation in that it is concerned more with the effectiveness of health care interventions (what works in health care in average or day-to-day practice and health care delivery) than with their efficacy (what works and how safely in ideal settings or controlled trial circumstances). Thus, for many decisions about allocation of resources in the health care sector and day-to-day clinical practice, HSR often provides the critical information that biomedical research cannot [10].

Topics Addressed by Health Services Research

The breadth of health services research is explained by the fact that the field endeavors to understand and improve all aspects of the processes and outcomes of health care delivery and to overcome significant problems of making high-quality health care available to all members of a given society at an affordable cost to that society. The costs and the quality of health care have been the subject of study for the longest period (several decades); more recently, HSR has also been concerned with access to care, health care reform and restructuring of public- and private-sector health care systems, computer-based and electronic communications and information systems, and the size and changing roles of the health care workforce.

Costs of Health Services

The costs of health care and public (e.g. national) and private (e.g. individual) levels of expenditures on care have long been an important area of investigation in health services research (*see* **Health Care Financing**; **Health Economics**). Most basic are studies of the total expenditures on health care, often described in terms of the percentage of gross domestic product (GDP) of a country that is devoted to health care. The effects of various elements of private or public health insurance, including the impact of so-called cost-sharing (coinsurance and deductibles), have been a major area of research; the most prominent HSR investigation of these issues was the Health Insurance Experiment, conducted by the RAND Corporation in the 1970s and 1980s [15]. Related issues concern what services or benefits are included in health insurance packages, how insurance is priced, how health insurance plans reinsure themselves against catastrophic loss, and how insurance plans should be regulated. Because consumer choice of health insurance plans can significantly affect how well and how extensively health care costs are shared across healthy and sick individuals, and even undermine the basic idea of insurance, HSR has directed considerable attention to biased (i.e. adverse or favorable) selection of risk and **risk** (or **case-mix**) adjustment techniques. HSR also involves studies of who pays for what portions of the cost of different types of services (such as health care for physical ailments, as contrasted with mental or emotional disorders, or sociomedical problems such as substance abuse). Most recently, approaches to consumer-designed, individualized health insurance have been the object of HSR investigation in the US.

Organization of Health Care

Closely tied to questions of the costs of health care are issues of how health care delivery is organized and financed (*see* **Health Services Organization in the US**). Health services researchers investigate a wide range of ways in which to structure health care systems: for example, national health systems (or universal national or provincial health insurance), systems in which some portions of a population are enrolled in publicly supported health plans or insurance schemes, private-sector approaches based largely on fee-for-service reimbursement, and private-sector entities of various sorts that are characterized as health maintenance or managed care organizations. HSR illuminates how the structure of health care delivery systems affects the practices and performance of clinicians and of persons seeking or obtaining care, and it documents how different organizational structures and ways of reimbursing health care facilities or clinicians pose incentives for inducing or constraining the provision of services. It is also concerned with the effects of different attempts to control national health care spending through various regulatory controls and use of competition and free-market principles. More recently, HSR has examined aspects of "health care reform", such as the shift in the US from a fee-for-service to a prepaid, capitated, or managed care orientation, and the movement in countries with national health systems to introduce various aspects of private-sector health care delivery or insurance.

Quality of Care and Satisfaction with Care

An important component of HSR is the study of how populations and individuals can obtain efficacious, effective, appropriate, competent, and compassionate health care services – in short, high-quality health care. **Quality of care** has been defined as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" [6]. HSR aims to identify problems with quality of care, such as overuse of unnecessary or inappropriate services, underuse of needed and appropriate care, and good or poor technical and interpersonal care. It measures the structural aspects of care (e.g. professional credentials or characteristics of facilities), processes of care (e.g. what is done to and for patients and consumers), and outcomes of care (e.g. death, disease, disability, or discomfort). Investigators in this field also study patient safety (or medical errors) and patient or consumer satisfaction with health care amenities, delivery system procedures, and/or outcomes. Of particular note in the US has been the development of the "CAHPS" (Consumer Assessment of Health Plans Survey) family of surveys. HSR studies that combine issues of costs and quality are said to be concerned with the "value" of health care.

HSR also contributes to the measurement and improvement of the quality of health care by providing data collection and analysis tools for programs

of quality assurance and continuous quality improvement or total quality management. Because some of these programs rely heavily on gathering and disseminating information to patients and consumers, HSR has contributed to the design of reliable, valid, and practical means by which information can be obtained, synthesized, and made available in forms such as so-called report cards to purchasers and consumers. Such efforts typically imply comparisons among health care providers and plans, so HSR has been expected to develop techniques by which differences in patient severity of illness, presence of other health problems ("**co-morbidity**"), or other factors can be taken into account. These "**risk adjustment**" questions are considered to pose among the most difficult research questions facing the field in the late 1990s.

To provide adequate guidance on these quality-of-care issues, HSR is also deeply involved in evaluating the clinical effectiveness (e.g. expected benefit of a health care intervention under average conditions of use) of health services. Such studies typically focus on the expected benefits and harms of alternate approaches to prevent, diagnose, treat, or palliate illnesses in different patient populations; they may specifically address the cost–effectiveness of alternate health care interventions [5]. These activities may involve assessing and comparing specific health care technologies (i.e. technology assessment) or developing clinical practice guidelines ("systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances" [7]). HSR directed at these areas also targets questions of how patients (and their families) and clinicians make treatment decisions (*see* **Health Care Utilization and Behavior, Models of**), the role of shared (or informed) decision-making, and the contributions of medical informatics and decision support systems.

Access to Health Care

Health services research has for decades been concerned with the extent to which individuals can seek and successfully obtain health care when it is needed – in short, access to care, defined as the timely receipt of appropriate care [8]. Among the topics studied are the numerous financial and nonfinancial barriers that confront individuals or groups in gaining access to care. These can include costs (especially for those who have no public or private health insurance), geographic difficulties (travel distances or times to obtain care, especially for persons in rural or frontier areas), **ethnic** and racial factors, cultural and attitudinal barriers, and language or literacy impediments. Investigators study the demographic, cultural, financial, and other factors that influence people to choose among health insurance plans, to seek preventive services and health care, to follow healthy lifestyle or treatment recommendations and regimens, and to acquire information about illnesses and problems. Also of concern to HSR investigators are mechanisms for expanding access to care and the effects on access (and hence health) of the lack or loss of public or private health insurance coverage.

Information Systems, Informatics, and Clinical Decision Making

HSR depends heavily on computer-based health services information systems (*see* **Administrative Databases**). These supply health care providers and researchers with faster and easier access to better and more complete health care information on both individuals and groups than was ever possible in the past. Many different information systems are now available to clinicians and to patients and consumers, and these provide information on clinical problems, practice guidelines, and other data needed to make informed decisions about clinical care. In addition, computer-based systems often include tools to assist clinicians in real-time decision making, such as automatic alerts or reminders at the time of patient visits or when the results of laboratory tests or diagnostic procedures are obtained, and computerized physician order entry for tests or medications. How such clinical decision making tools should be developed, deployed, and evaluated in terms of costs and quality of care are questions of considerable interest to HSR (*see* **Decision Analysis in Diagnosis and Treatment Choice**).

Computer-based information and telecommunications systems also permit individuals to communicate with others about health problems of concern to them and to learn about different treatment options. "Telemedicine," "Telemonitoring," and the rapidly expanding availability of health information on the Internet are additional communications phenomena that expand interactions within the health care sector. The impact of all these resources and communications technologies on the attitudes and behavior of

clinicians and patients or consumers, and ultimately on health care systems, is another important area of HSR.

Health Care Professions and Workforce

Investigators in the HSR field track the supply of and demand for different types of health care professionals and workers, including the development of various types of models that permit educators and policy makers to predict the need for and plan for education and training of health personnel (*see* **Health Workforce Modeling**). In addition, researchers examine how individual and team education and training, professional socialization, and cultural and ethnic background affect practitioner attitudes, behavior, and performance. HSR also concerns itself with ethical and bioethical questions involving the health professions, such as how health care professionals, particularly physicians, reconcile their professional duties to act in their patients' best interests with their responsibility to society as a whole, especially when resources are scarce and economic incentives pose difficult or conflicting obligations.

Methods Used in Health Services Research

Health services research employs virtually all quantitative and qualitative methods found in statistics and biostatistics, economics (*see* **Health Economics**), sociology (*see* **Social Sciences**) and anthropology (*see* **Anthropometry**), psychology, epidemiology (*see* **Analytic Epidemiology**; **Descriptive Epidemiology**), **operations research**, **actuarial** sciences; finance, management, political science, policy analysis, and law. The types of studies done in HSR can include randomized controlled trials (*see* **Clinical Trials, Overview**), a wide array of **quasi-experimental** investigations involving simple or complex **case–control studies, observational studies** and descriptive studies, and community-based demonstrations and evaluations; the **units of analysis** can be nations; regions, states, or provinces; municipalities of all sizes, and communities or neighborhoods (*see* **Small Area Variation Analysis**); groups of individuals defined according to many different sociodemographic (*see* **Social Classifications**), cultural, or health characteristics; health care providers, specified according to type of clinician or facility, health care plan, or setting of care; and families or individuals. HSR places significant emphasis on understanding the end results of health care programs and health care delivery and on obtaining self-reported information on processes and outcomes of care from patients and consumers (*see* **Quality of Life and Health Status**; **Outcomes Research**; **Quality of Care**). The field has generated many reliable and valid instruments for obtaining such information (*see* **Health Status Instruments, Measurement Properties of**) and pursues sophisticated methods research in outcomes measurement [11]. HSR studies employ many sources of information (*see* **Health Services Data Sources in Canada**; **Health Services Data Sources in Europe**; **Health Services Data Sources in the US**), including various types of interviews and questionnaires, focus groups, **surveys** and polls, so-called **administrative data** from various types of computer-based information systems (e.g. insurance billing claims, or hospital discharge abstracts), administrative records of health care programs and plans in the private or public sector, community health information networks, and patient medical records – both paper- and computer-based. Generally, the biostatistical methods required in HSR are similar to those used in biomedical research, except that the sets of variables of interest in HSR tend to be more broadly defined, more concerned with functional and quality-of-life outcomes of interest to patients, families, consumers, and policy makers, and sometimes more difficult or costly to measure than variables of interest in biomedical or clinical investigations.

Major Funders of Health Services Research

Globally, the US funds and produces the great majority of health services research work: of this, the largest portions are supported by agencies of the US federal government. Since the late 1960s, the leading agency was the National Center for Health Services Research (variously titled over the years), a unit of the Department of Health and Human Services (DHHS, formerly the Department of Health, Education and Welfare). In 1989, the Agency for Health Care Policy and Research (AHCPR) was created from this Center; reauthorised and renamed the Agency for Healthcare Research and Quality in 1999, AHRQ continues to

this day to be the central public-sector funding source for HSR. As of 2002, AHRQ had centers focused on evidence-based practice, outcomes and effectiveness research, primary care, organization and delivery of health care, cost and financing of health care, quality of health care and patient safety.

Other DHHS agencies, notably several in the **National Institutes of Health** (especially the National Institute for Mental Health, National Institute for Drug Abuse, and the National Institute for Alcoholism and Alcohol Abuse) and the Centers for Medicare and Medicaid Services (formerly the Health Care Financing Administration) also support projects that fall within the HSR rubric. The US Department of Veterans Affairs has a formal program to support HSR, and elements of the US Department of Defense conduct activities focused on HSR issues such as prevention, quality, or efficient delivery of services. Numerous private philanthropic organizations (foundations) also support research (or demonstrations and evaluations) on HSR topics, especially in areas related to access to care, quality of care, and organization and financing of care; often their focus is on state or local, rather than national or international, issues. Internationally, some governments have programs of health systems research within their national health services (e.g. the UK) or support related efforts in health technology assessment (e.g. Sweden and Canada).

Compared with levels of spending on health care or biomedical research, the support for HSR is small. As of 2000 in the US, approximately $1.35 billion (US dollars) was spent on HSR, a figure that approached only 0.10% of the $1.3 trillion spent that year on health care in that country. Few nations, however, support HSR at these or higher levels.

Personnel Engaged In or Trained In Health Services Research

The number of professionals in the HSR workforce has always been difficult to estimate, for it consists of researchers trained to design, supervise or carry out, and report on HSR work, individuals who assist in such investigations, and users who analyze HSR information or apply HSR for management and policy purposes. A mid-1990s estimate put the number of current health services researchers at 5000, largely in the US; of these, about one-half are trained at the doctoral level and just over one-quarter (mostly physicians) have clinical degrees [9]. This workforce has been trained through many different organizations and programs supported by both public and private funds; only a small minority of these programs are formally established to train individuals at the doctoral level in health services research *per se*.

Professional Organizations and Publications

The most prominent professional organization for health services researchers is Academy Health, a private, nonprofit organization, established in 1981 (as the Association of Health Services Research) and based in Washington, DC. Related organizations include international societies focused on specific areas that HSR studies, including quality of care (International Society for Quality in Health Care) and technology assessment (International Society for Technology Assessment in Health Care). Another global effort is the **Cochrane Collaboration** with centers in Australia, Canada, Denmark, France, Italy, the Netherlands, Norway, the UK, and the US; these centers, like the evidence-based Practice Centers supported by AHRQ in the US, prepare, maintain, and disseminate systematic reviews of the effectiveness of health care, generally using information from randomized controlled trials or other reliable evidence (*see* **Meta-analysis of Clinical Trials**).

Journals available internationally that exclusively or frequently publish on HSR-related topics include *Health Care Financing Review, Health Economics, Health Services Research, Inquiry, Journal of Health Economics, Medical Care*, and *Medical Care Review*; some have been publishing since the 1960s. Newer journals include *Health Services Management Research, Journal of Evaluation in Clinical Practice, Journal of Health Services Research & Policy*, and *Quality of Life Research*. Health policy publications, which also typically feature HSR-related work, include *Health Affairs, Health Policy, International Journal of Health Services, Journal of Health Politics, Policy and Law*, and the *Milbank Quarterly*. Journals with a public health, epidemiologic, or clinical orientation that also publish HSR-related work include the *American Journal of Public Health, Annals of Internal Medicine, BMJ (British Medical Journal), Journal of the American Medical Association, Journal*

of Clinical Epidemiology, Journal of General Internal Medicine, Lancet, Medical Decisionmaking, New England Journal of Medicine, and publications of other professional and clinical societies in the United States and other nations. HSR is often at the core of material published in the journals of international societies, such as the *International Journal for Quality in Health Care* and the *International Journal of Technology Assessment in Health Care*. Several monographs published since 1990 provide substantial overviews of the primary issues that HSR has covered since that time [1, 4, 9, 16].

Health Services Resources, Scheduling

Operations Research had its origins in World War II, where speedy solutions were required for new operational problems, usually of a military kind. The underlying philosophy of innovation and simplicity was adapted after the war for application in industry, where it proved to be of considerable commercial value [8]. It was a natural extension of scope to explore the possibilities of applying it to public services and there was a spate of applications to the health services in the 1960s and 1970s [7] (*see* **Health Services Research, Overview**). Applications to specific organizational problems included the planning of appointment systems, blood bank inventories, ambulance routing, and the control of hospital bed occupancy. In practice the implementation of optimal policies was somewhat limited by political and economic constraints and the emphasis of research in the area changed to more qualitative questions and resource planning at the population level, for example in the assessment of demographic trends [12]. Important though such issues may be, the efficient solution of small-scale operational problems is a significant ingredient of efficient resource utilization. In particular, the unpredictability of demand and patient progress means that the stochastic nature of the processes involved is important at all but the macroscopic level.

It is the purpose of this article to outline one particular area, namely that of the utilization of discrete and equal units of resource, such as beds. When such units are in use we say they are occupied and describe the class of corresponding processes as "occupancy processes", though the latter expression may be applied to the utilization of resources that we would not normally describe as being occupied.

Occupancy Models

Occupancy problems and the models which may be used to study them have certain common ingredients. Generally speaking they will fall naturally into the continuous or discrete time frameworks, the former being more appropriate for activities that fit into the span of a working day, the latter for modeling longer-term activities in which resource utilization at a fixed point of the day is of interest. The mathematics of discrete time models tends to be less elegant but more tractable: rather few continuous time models of any sophistication can be handled analytically. In particular, nonhomogeneity in time is much more easily handled with discrete time models. The ability to permit variation of parameters with time is an important practical consideration; so also is the question of whether we are interested essentially in the short- or long-run properties of a process. The latter can be obtained rather more easily than the former by the derivation of a stationary distribution (*see* **Stationarity**).

The most tractable models have the first-order **Markov** property, which means, in practical terms, that the state of the process must incorporate all the information necessary for predicting its future course. This imposes a severe restriction on the situations that can be modeled simply, though a number of devices for mitigating its effect are referred to below. In the face of analytical difficulties, numerical or **simulation** methods will usually provide solutions quite feasibly, though they bring their own problems of interpretation, particularly with complex models involving many parameters. A simple analytical model, however, even if not particularly realistic in points of detail, may give insight into the structural aspects of a problem that are concealed by more complex formulations.

The models and situations we consider all have available at any given time a fixed number N of units of resource, e.g. beds, operating suites, casualty nurses. These resource units are assumed to be **exchangeable**, i.e. to be equally capable of servicing the requirements of one unit of demand, i.e. one patient in each of the latter examples. In **queuing** theory applications, these resource units would be identified with servers. The occupancy of the system is defined as the number of the units, $X(t)$, that are actually in use at time t; this would often be expressed as a percentage of N.

Arrivals to and departures from the system will typically increase or decrease the occupancy, except that, if $X(t) = N$, then arrivals may form a queue. Queuing processes put emphasis on characteristics such as the length of the queue and the **mean** queuing time. For many health service applications, however, these characteristics are less important than those of the occupancy process, $X(t)$, and its determinants, such as the nature of the arrival and departure

processes. Arrivals and departures will typically be determined by times in a continuous time model, but by counts associated with the fixed time units of the process in a discrete time model. Emergency inputs to the system will result in arrivals determined by points in a **Poisson process** (not necessarily time homogeneous) in the continuous case or by **Poisson distributed** counts in the discrete case. The Poisson process and distribution form important ingredients of all such models, both in theory and in practice.

Some Example Applications

We now consider some areas of application of the general class of models outlined. Each of these areas has been studied by a number of investigators, but not necessarily from a modeling point of view that is consonant with our discussion above.

Appointment Systems

The idea of reducing patient waiting time by providing a realistic schedule of appointments in an out-patient facility or in **general practice** has a long history [1, 2], though most contributions to the subject have been concerned with practical feasibility rather than statistical issues. Stochastic elements of the problem include the possibility of the nonarrival or lateness of scheduled patients, and also the unpredictability of the lengths of times of individual appointments. There is a conflict between the time a patient may expect to wait and the time for which a doctor might be idle; tuning the parameters of the system should achieve a balance consistent with preassigned **utilities**.

Models for the situation are typically formulated in continuous time and use results from queuing theory, although nonstandard assumptions, such as deterministic but unequally spaced arrival times, quickly lead to analytic difficulties; moreover, the stationary theory is not generally useful. Certainly, a queue is an inevitable feature of an appointment system, but interest may focus as much on the final finishing time of a clinic as on the waiting and idle times. Brahimi & Worthington [5] describe a recent application of queueing theory to appointment systems, while O'Keefe discusses practical issues and limitations of theoretic systems [10].

Operating Theater Utilization

This problem has quite a lot in common with that of appointment systems, though the inputs are typically under the complete control of the hospital and patient waiting time would normally be given little weight. Length of service time, i.e. of individual operations, would be the main stochastic element and the optimization criteria might well include the probability that a scheduled operation would need to be postponed. In practice, the exchangeability property of the general model would probably fail and it would be necessary to put particular operations in particular theaters, thus introducing a combinatorial element into the problem.

Casualty Units

Here the units of resource might be regarded as multidimensional, in the sense that waiting may be occasioned by a shortage of doctors, nurses or X-ray facilities, for example. It could well make sense, however, to model a casualty department by treating bed-spaces as the fundamental units of resource; in this case N could be regarded as effectively infinite, the phenomenon of patients waiting on trolleys being a not unfamiliar feature of busy units. A patient in the system could reasonably be assured of emergency attention by a rearrangement of priorities among those present, though the average length of stay within the unit would then be dependent on the occupancy; this would not preclude using a first-order Markov model. Continuous time would probably be a first choice for a casualty unit, though a discrete time approximation would make it easier to incorporate the time heterogeneity that could be expected. All arrivals would effectively be from Poisson processes and the total occupancy would therefore also follow a Poisson distribution under weak assumptions (see below).

In-Patient Wards

The hospital ward provides a classic example of the models we have discussed. Typically, we should expect a mixture of emergency and scheduled admissions. At one extreme an orthopedic surgical facility would have very few emergency admissions; at the other, certain medical facilities may have nearly all their admissions as emergencies – even a general medical ward would probably admit over half its cases as emergencies.

Early models of bed occupancy [14] borrowed the ideas of queuing theory, regarding beds as servers. They were consequently formulated in continuous time; we would argue, however, that discrete-time models are much more appropriate. Thus, it is the number of patients in a hospital ward overnight that is of crucial importance; during the day patients are arriving and departing in a way that gives a certain flexibility of bed use.

The models described in the section below also mostly assume that N is infinite, largely because this permits a number of analytic results of great importance that would otherwise not apply. It may at first sight seem to be an unrealistic feature of the models. However, we can argue that results from such models may provide useful approximations to the finite capacity case if a ward is not too near to full capacity. Moreover, it is often possible in practice to extend the capacity of a ward by using emergency beds or borrowing from other facilities. Such devices would entail organizational costs which can then be quantified by the predictions of the model.

Queuing theory has also been applied, rather more naturally, to the study of waiting lists [13].

Maternity Units

Before the practice of inducing births, admissions to a maternity unit would have been very close to a homogeneous Poisson process. Nowadays admissions are likely to be both of an emergency and scheduled character. In this respect, maternity units have become more like other hospital in-patient facilities, though continuous time might have advantages that do not apply in the general case.

Some Theoretic Results for Occupancy Processes

Generally speaking, occupancy models are analytically much more tractable if we make assumptions of the independent behavior of the individuals in the system. Assuming Poisson inputs, this implies a potentially infinite capacity, which clearly conflicts with reality. However, the models would give a good guide to the behavior of finite systems that are not operating at full capacity and in practice there often are, as argued above, overflow possibilities for emergencies entailing extra costs which can be quantified by the predictions of the model.

Relaxing assumptions such as the infinite capacity or nonindependent behavior of individuals in the system quickly leads to analytic intractability. More sophisticated models can still be studied straightforwardly using simulation methods. However, it is not always easy to extract useful generalizations from large-scale simulations. On the philosophy that modeling is as much concerned with providing an understanding of underlying phenomena as making precise numerical predictions, analytic methods are to be preferred. It is in this spirit that in the following section we summarize simple analytic results concerning the behavior of stochastic occupancy models.

In the following exposition we consider patients occupying beds and moving through a hospital with a number of different wards according to well-defined stochastic rules, though we emphasize that the results would apply to any system with a number of compartments providing units of resource to service the needs of individuals representing units of demand. Similarly, we will, for discrete time models, consider daily time units, though these can also be arbitrarily defined.

Random Inputs

Suppose that patients are admitted as emergencies to a single ward with infinite capacity modeled in discrete time, i.e. the numbers admitted each day are independent **random variables** with a Poisson distribution. If their lengths of stay (LOS) in the system are determined independently from an arbitrary distribution, then the distribution of the occupancy process, or number of beds occupied, also has a Poisson distribution [11]; so too does the daily number of discharges. In the steady state, the mean occupancy is equal to the mean length of stay multiplied by the mean admission rate, a result which we refer to as the mean occupancy theorem and which applies very generally. With suitable modification of the theorem, this important result remains true even when there is day-to-day variation in the mean number of patients admitted per day and in their LOS distributions [4, 9].

If a system has many wards through which patients move independently, then an analogous result applies, i.e. independent random inputs to one or more wards result in Poisson-distributed occupancies of them and, furthermore, the numbers in the different compartments are independent. The same result is obviously

true for hypothetically defined "compartments" which may be defined to represent abstract stages of a patient's progress, for example.

There is a continuous time analog of these results. Specifically, if we have a multiward system with independent inputs to one or more wards resulting from Poisson processes, and if patients move independently through the different wards, then the resulting occupancies are independently Poisson distributed. In particular, we may model a set of hypothetical compartments in each of which a patient spends a length of time, which necessarily has an **exponential distribution**, in such a way as to reproduce any total LOS distribution with a rational Laplace transform [6]. Such models may be useful for modeling flow through a maternity facility, for example, but do not permit the study of any kind of control mechanism.

Deterministic Inputs and Independent Progress

If inputs are deterministic and the lengths of stay, though having an arbitrary distribution, are determined independently of one another and of the occupancy of the process, then the **variance** of the latter is approximately proportional to the **standard deviation** of the LOS distribution [4], with a mean determined by the mean occupancy theorem. This result determines the component of variability in a system that is due to the unpredictability of the length of stay and permits the study of a system in which admissions are planned according to a predetermined pattern of bookings.

General Inputs and Independent Progress

The analysis underlying the above result provides the occupancy distribution resulting from general input distributions and general LOS distributions, which need not be time homogeneous, i.e. may differ on different weekdays, for example. The variance of the occupancy process partitions approximately into components due to the input variance and the variability in the LOS. Analytic expressions are available that completely determine the behavior of an infinite-capacity system in which patients are admitted and progress through the system independently of one another and of the state of the system [4].

Scheduled Inputs

The variance of an occupancy process can, in theory, be reduced by controlling either the admissions or the discharges, though in practice it would be unsatisfactory to determine discharge from a unit merely to control occupancy unless some transfer to an intermediate or predischarge ward were arranged. Scheduling the admissions to bring the occupancy closer to an ideal value, however, is administratively feasible, for example by admitting from a short-notice list a number of patients determined by the occupancy at a given time. The consequential non-independence in the system can be modeled using first-order **Markov chains**. The Markov requirement implies that the lengths of stay have a **geometric distribution**, but there are arguments permitting the relaxation of this rather severe assumption [3]. More seriously, the Markov assumption implies, in the first instance, that patients can be given a maximum of one time-unit of notice, typically 1 day. This restriction can also be relaxed with a non-Markovian process which is a functional of a first-order Markov process and for which the marginal distribution is easily computed [3].

Prediction of Discharge

Using only the current occupancy of a ward to schedule the number of admissions obviously wastes information about the probable short-term future of the process. Predicting the probability of the discharge of individual patients has obvious potential for improvement and can generally be expected to reduce the variance of $X(t)$. The degree of reduction obviously depends on the degree of predictability, but empirical and theoretic considerations suggest that a factor of the order of one-third may be achievable [4].

Discussion

This article has been based on the concept of occupancy, with particular emphasis on bed occupancy. It may reasonably be argued that concentration on beds ignores the demand for other resources, most of which are more expensive than the mere provision of a bed. It is indeed true that this emphasis has led to progressively shorter lengths of stay in hospital and a consequent rise in the cost per bed day. At the

same time, the availability of a bed in an emergency is certainly a key question and deployment of other resources exhibits an elasticity in practice, so that the effects on the system as a whole of an extra patient are not as hard to accommodate as the requirement for an extra bed when a facility is full.

More generally, it may be argued that concentrating on any one unit of resource is clearly to risk oversimplifying the problem, given that in practice we typically require multiple resources, any one of which may be in short supply. Moreover, resources are often interrelated in ways that make independent modeling unsatisfactory. Nevertheless, we need to start somewhere, and it is the object of modeling as much to throw light on general principles and underlying structural relationships as to provide accurate representations or predictions.

Health Statistics, History of

The field of statistics in the twentieth century (*see* **Statistics, Overview**) encompasses four major areas; (i) the **theory of probability** and mathematical statistics; (ii) the analysis of uncertainty and errors of measurement (*see* **Measurement Error in Epidemiologic Studies**); (iii) design of experiments (*see* **Experimental Design**) and sample surveys; and (iv) the collection, summarization, display, and interpretation of observational data (*see* **Observational Study**). These four areas are clearly interrelated and have evolved interactively over the centuries. The first two areas are well covered in many histories of mathematical statistics while the third area, being essentially a twentieth-century development, has not yet been adequately summarized. Although the fourth area has been going on since man first learned to think inductively, it relies on the state of the art in the first three areas. In this brief survey of health statistics during the past five centuries, emphasis will be given to the development of official health statistics systems in Europe and the US.

Early Interest in Statistics

At the end of the fifteenth century, mathematics was at a rather primitive stage and the threshold of the "scientific revolution" was still two generations away. The mathematics of the Greeks had only re-entered European thinking in the twelfth century, and although some progress had been made in practical applications in navigation and commercial arithmetic, the burgeoning of numeracy was only beginning. Mathematicians still did not recognize the number zero or know how to deal with negative numbers. Except for a few examples of probabilistic thinking such as that in the talmudic literature [10], there was scant evidence of the use of a mathematical approach to probabilities to estimate **risks** or assess the reliability of measurements until the mid-seventeenth century.

Most historians of statistics trace the origins of modern probability theory to the efforts to solve certain gambling problems [e.g. Pacioli (1494), Cardano (1539), and Forestani (1603)] which were first solved definitively by Pierre de Fermat (1601–1665) and Blaise Pascal (1623–1662). These efforts gave rise to the mathematical basis of probability theory, statistical distribution functions (*see* **Sampling Distributions**), and statistical **inference**.

The analysis of uncertainty and errors of measurement had its foundations in the field of astronomy which, from antiquity until the eighteenth century, was the dominant area for use of numerical information based on the most precise measurements that the technologies of the times permitted. The fallibility of their observations was evident to early astronomers, who took the "best" observation when several were taken, the "best" being assessed by such criteria as the quality of observational conditions, the fame of the observer, etc. But, gradually an appreciation for averaging observations developed and various techniques for fitting the observational data to **parametric models** evolved. Many of the founders of modern statistics contributed to the early development of the theory of measurement errors including **Jacob Bernoulli** (1654–1705), **Abraham De Moivre** (1667–1754), **Pierre Simon Laplace** (1749–1827), and **Carl Friedrich Gauss** (1777–1855).

A systematic approach to the collection of data and tabulating observations in a rational manner began with the teachings of Francis Bacon (1561–1626). In his influential treatise *Novum Organum* (1620), he attacked the scholastic philosophy which had developed in the Middle Ages on the basis of the methods of Aristotle. One of the first areas influenced by Bacon's approach was **demography** and **vital statistics** and the social utility of systematic observations is clearly reflected in these early efforts.

The utilitarian nature of statistics is evident in the origins of the word from the Italian *stato* (state), and the original meaning of statistics was a collection of facts of interest to a statesman. Initially such facts were not primarily numerical, but included information on geography, politics, and customs of a region. The compilers of such facts were called statists, a term which survived into the nineteenth century, when the word statistics came to be used for numerical data only, replacing the term "political arithmetic", and the word "statistician" came into vogue.

The Origins of Demography and Vital Statistics

Since ancient times, sporadic surveys of people and property were done to set tax assessments and levies for military service. But after the fall of the Roman empire, regular **censuses** covering an entire state did not occur until the eighteenth century. However, there were intermittent attempts to keep track of the births and deaths in some areas through church records of weddings, christenings, and burials. The City of London was one of the first to regularize the maintenance of such records in 1538, but only within the Church of England. Also at about this time a **surveillance** or early warning system of plague deaths was started in London. To detect the onset of a plague epidemic, parish clerks submitted weekly reports on the numbers and causes of deaths. These weekly *Bills of Mortality* were noted by the authorities who were to take actions if they detected the onset of an epidemic, and by the wealthier citizens for "an indication of when to leave the city for the fresh air of the country" [7]. The weekly bills were published regularly from 1604 until 1842 when they were superseded by reports from the Registrar General.

In 1662, **John Graunt** (1620–1674), a London tradesman who had been active in local politics and intellectual society, published his *Natural and Political Observations Made Upon the Bills of Mortality*, which historians of statistics have referred to as "a remarkable book [12]", "one of the great classics of science [6]", and "a paragon for descriptive statistical analysis of demographic data [7]". Hald summarizes Graunt's contributions to the origins of statistics thus:

> Graunt's critical appraisal of the rather unreliable data, his study of mortality by cause of death, his estimation of the same quantity by several different methods, his demonstration of the stability of statistical ratios, and his life table set up new standards for statistical reasoning. Graunt's work led to three different types of investigations: political arithmetic; testing the stability of statistical ratios; and calculation of expectations of life and survivorship probabilities [7].

At a time when denominator data on the size of the population by age were not available, Graunt used several ingenious lines of reasoning to generate the first **life table** ever published, perhaps his most famous contribution.

Owing to the widespread influence of Graunt's work, bills of mortality similar to the London bills were introduced in Paris in 1667, and soon after in other cities in Europe.

Graunt's life table was brought to the attention of Christiaan Huygens (1629–1695) and his brother Ludwig (1631–1699) who proceeded to develop a probabilistic interpretation of the life table, which was rediscovered independently by **Nicholas Bernoulli** (1687–1759). These investigations, together with the more applied techniques of **Edmond Halley** (1656–1742) based on the births and funerals in the City of Breslau (1693), and the work of Deparcieux (1703–1768) in France who used data from tontines to construct the first correct life tables, formed the foundation of the **actuarial** sciences for life insurance and annuities. These were developed further by Abraham DeMoivre (1667–1754), Thomas Simpson (1710–1761), Benjamin Gompertz (1779–1865), and William Makeham (1826–1891).

It was not until 1766 in Sweden that Per Wargentin (1717–1783) published the first mortality tables for a whole country based on enumerations of the living population as well as on deaths. These mortality tables demonstrated for the first time in a general population that the mortality rate of females was less than that of males.

Graunt's methods of statistical analysis were widely adopted by seventeenth-century statists. **William Petty** (1623–1687), who was a protégé of Graunt, and after Graunt's financial bankruptcy in 1666, his patron, coined the term "political arithmetick" and was one of the founders of the field of political economy. Gregory King (1648–1712) and Charles Davenant (1656–1714) contributed to improvements in the estimates of the population of England. Sebastien de Vauban (1633–1707) described the extent of poverty in France, for which he suffered public disgrace because of its embarrassment of the royal government. Nicholas Struyck (1678–1769) instituted town censuses in the Netherlands and improved the recording of births and deaths. The revelations of statistical data were also used to support religious positions such as the claim of John Arbuthnott (1667–1735), who was a vigorous proponent of political arithmetic, that the stability of the sex ratio "is not the effect of chance but divine providence". Somewhat later, Johann Peter

Suessmilch (1707–1767) in Germany gathered vital statistics from virtually every source then available as evidence of certain tenets of orthodox Lutheran theology. He maintained that the life span (*see* **Life Expectancy**) was constant and that little could be done to improve mortality rates. His work directly influenced the thinking of **Thomas Robert Malthus** (1766–1834). These diverse endeavors eventually led to the establishment of governmental statistical offices in the nineteenth century.

Among the developments in mathematical statistics that occurred during the eighteenth century, two had special relevance for health statistics. **Daniel Bernoulli** (1700–1782), who first developed the **normal** approximation to the **binomial distribution** and used it in studies of the stability of the sex ratio at birth, applied the methods of calculus to mortality rates by treating them as continuous functions. This enabled him to obtain a solution in 1760 to an important public health question of his day: to estimate the impact on life expectancy of eliminating smallpox through a proposed program of mandatory vaccination. His invention of the method of **competing risks**, with some improvement by d'Alembert (1761) and by Makeham (1874), still forms the basic tool for such analyses.

A second development expanded the techniques used by Vauban. Laplace proposed a nonrandom sampling method to estimate the size of the population in 1786. It was based on a notion similar to that of current **ratio estimates**, i.e. that the size of the population of a region was proportional to the annual number of births in that region and that the constant of proportionality could be determined from a purposive sample of subregions. Graunt had used a similar assumption implicitly a century earlier.

Laplace's method was severely criticized, most notably by Baron de Keverberg (1827) [11, p. 164]. These criticisms clearly reflected an appreciation that there were a multitude of factors that could influence any chosen characteristic of a population, that subgroups of the population were not homogeneous with regard to the array of factors influencing the characteristic, and, therefore, purposive samples of the population could not reflect the total population. Only complete censuses of the population would do, and these would have to amass immense amounts of information. At this time there was not yet an appreciation for the power of random sampling methods (*see* **Probability Sampling**).

Applying Statistics to Medical and Social Issues

Just as **demographic** and economic statistics began with the name of "political arithmetic" in the seventeenth century, medical statistics began with the name of "the numerical method" early in the nineteenth century. Although some of his methods were evident in the works of **Phillipe Pinel** (1745–1826) and other French physicians, **Pierre-Charles-Alexandre Louis** (1787–1872) has been described "as the first modern clinician, the man who made bedside medicine a science as well as an art, and who established the principle of learning medicine from thoughtful observation of patients [1]." His studies on the inefficacy of blood letting were the beginning of quantitative medicine and earned him the title of "father of medical statistics" [12]. Louis's hopes for his numerical method were echoed by Giacomo Tommasini (1768–1846) in Italy, and **F. Bisset Hawkins** (1796–1894) in England, who published in 1829 the first English textbook on medical statistics with the rather grand title of *Elements of Medical Statistics; Containing the Substance of the Gulstonian Lectures Delivered at the Royal College of Physicians with Numerous Additions Illustrative of the Comparative Salubrity, Longevity, Mortality, and Prevalence of Diseases in the Principal Countries and Cities of the Civilized World.* Although by later standards Louis's statistical attempts were often inadequate, suffering particularly from sparse numbers, he had a crucial influence on **William Farr** who attended his lectures during his two years in Paris, as did several American physicians who were influential in the early development of public health and epidemiology.

Louis's methods were not immediately accepted for many of the same reasons that Laplace's methods were not: the variability between cases was thought to be highly individualistic and not subject to statistical summarization. For example, **William A. Guy** (1810–1885), who contributed much to public health and occupational statistics, felt "the formulae of the mathematician have a very limited application to the results of observation" [12, p. 151].

The Belgian, **Adolphe Quetelet** (1796–1874), who dominated the field of social statistics for half a century, may have gone too far in the other direction. Impressed by the **central limit theorem** and believing that averages based on large numbers of

observations from a population had remarkable stability, he introduced the concept of the "average man" (*l'homme moyen*) which had considerable popular appeal. He was also enamored of the normal distribution and fitted it to many characteristics, marvelling at the statistical homogeneity of large bodies of data which detracted from further exploration of valid heterogeneities. However, he influenced a large number of statisticians including **Louis Adolphe Bertillon** (1821–1883), Wilhelm Lexis (1837–1914), **Francis Galton** (1822–1911), **Karl Pearson** (1857–1936), and **Ronald A. Fisher** (1890–1962) [11].

Development of Health Statistics in England

During the eighteenth century many physicians and registrars in England recognized the inadequacies of the bills of mortality. There were frequent calls for reforms but because of concerns about personal liberties, religious arguments, and beliefs that population figures were crucial state secrets, it was not until 1800 that Parliament passed a population act that set up the census of 1801. By the 1830s, as in the mid-seventeenth century (with Graunt and Petty), London "witnessed a flash of enthusiasm for vital statistics and political arithmetic" [5, p. 13]. The Statistical Society of London was founded in 1834 by the same group that had founded the statistics section (Section F) of the British Association for the Advancement of Science in 1833, and started publication of its Journal in 1838. These and other early statistical societies in England were greatly concerned with social problems, conducting several surveys to document conditions in England and continuing to push for social reforms long after the surveys proved too expensive to continue. Although they claimed scientific objectivity, these statists were superficial in their use of mathematical methods, paid little attention to the validity or accuracy of their data, but were aware that using numeric data gave credibility to political arguments [5].

A more balanced contribution was made by William Farr (1807–1883) in the area of vital statistics. Starting his career as an unsuccessful London clinician, he quickly became an acknowledged authority on vital and health statistics with a strong interest in medical and social reform. He founded his own weekly journal, *British Annals of Medicine, Pharmacy, Vital Statistics, and General Science*, which lasted only eight months, January to August 1837, but allowed him to write major articles on medical reform and vital statistics. The Births and Deaths Registration Act of 1836 had inaugurated the modern system of civil registration and led to the establishment of the General Register Office in 1837. Farr joined the staff of the General Register Office in 1839, serving forty years, first as compiler of abstracts and then as superintendent of the Statistical Department.

Farr "insisted that the statistician adopt a critical approach, investigating the accuracy of his data, questioning the appropriateness of the units used, and attempting with the help of ratios, logarithms, and the calculus of probabilities to discover relationships and regularity in order to make predictions" [5, p. 29]. Farr's philosophy had an almost immediate impact on improving British statistics. The first four censuses were fraught with many problems. The 1841 census was the first conducted under the supervision of the General Register Office and Farr was one of the key advisors. It was a great improvement over its predecessors and, together with the annual vital statistics data, enabled Farr to put together tables and analyses which placed England at the forefront of this discipline. Between 1836 and the Registration Act of 1874, Farr was largely responsible for establishing the procedures for collecting and analyzing the official mortality statistics. He introduced the standard **death certificate** in 1845 which saw almost no change until 1902. Through Farr's influence the census of 1851 introduced questions on physical disabilities and other medical items which were continued through 1911.

Farr was greatly interested in statistical nosology, introducing his first classification of diseases in 1839. The first International Statistical Congress in 1853 took up the issue, but Farr's nosology did not win the support of other European countries. It was not until 1893 that Jacques Bertillon (1851–1922) proposed a system that became the International List of Causes of Death (*see* **International Classification of Diseases (ICD)**).

Problems noted in the vital registration system in the mid-nineteenth century are still of concern at the end of the twentieth, namely accuracy of diagnoses was not reliable, selection of a single underlying cause of death (*see* **Cause of Death, Underlying and Multiple**) from among several listed

conditions, "the temptation of practitioners to obscure or falsify the cause of death to save respectable families embarrassment in certain sorts of death" [5, p. 62]. Henry Wyldbore Rumsey (1809–1876), one of the chief proponents of sound vital statistics, was vigorous in pointing out statistical fallacies and shortcomings of the existing systems that bear rereading today.

Many of Farr's statistical methods have had a lasting impact: defining mortality rates precisely and basing them on **person-years at risk**, establishing the standard expression of mortality as "deaths per thousand", using the life table and life expectancy as key instruments to assess mortality, using the method of indirect standardization (*see* **Standardization Methods**) to compare mortality rates of localities (although he seems to have made little use of the direct method first demonstrated by F.G.P. Neison in his refutation of the proposal of Edwin Chadwick (1800–1890) to use **average age at death** as a criterion for the health of communities), recommending the establishment of longitudinal **cohort studies** [9], and proposing a paradigm for the estimation of the economic value of human life at each age and social class. Farr's association with **Florence Nightingale** (1820–1910) also resulted in contributions to the use of statistical information for health policy purposes, particularly in respect to the graphic presentation of data (*see* **Graphical Displays**).

Development of Vital Statistics in the United States

As interest in statistical information burgeoned in Europe in the first third of the nineteenth century, a similar phenomenon was occurring on the other side of the Atlantic [4]. Although medicine, statistics, and science generally, in the US lagged behind that in Europe, America had actually preceded other countries in two important respects. Whereas other areas relied on church-maintained records of christenings and burials as the basis for vital statistics, the Massachusetts Bay Colony enacted a law in 1639 requiring the reporting of every birth and death within its jurisdiction, thus establishing the collection of vital statistics as a governmental function covering the entire population. The other colonies gradually adopted similar regulations but for at least the next two hundred years the quality and completeness of the reports were decidedly deficient. The second precedent was when the US became the first nation to establish by constitutional mandate a periodic census requiring complete enumeration of the entire population, conducting its first census in 1790.

At about this time death reports were being used on occasion in port cities to institute quarantine measures in efforts to control epidemics of cholera, yellow fever, and typhus. As the Benthamite social reform interests reached America and evidence for the harmful effects of poverty, industrialization, and unsanitary conditions was sought from vital statistics, the inadequacies of the city and local registration systems became evident. In 1826, Walter Channing (1786–1876) in Boston outlined some of the requirements for valid data on causes of death, including the requisite for medical certification. In 1827 Nathaniel Niles and John D. Russ published the first report on public health statistics in a comparison of mortality data from New York, Philadelphia, Baltimore, and Boston. Other analyses soon followed which became models for the quantitative health reports produced by subsequent generations of health officials which led to increasing pressures for improving the quality of the information. In 1842 Massachusetts again achieved a first by establishing a statewide vital registration system. The effort to establish similar systems in other states marked the beginning of an organized public health movement and contributed to the professionalization of statisticians in this country [2, 3].

Following on the foundation of the Statistical Society of London, statistical societies were started in New York and other American cities. Most did not last very long but the **American Statistical Association**, founded in Boston in 1839, proved to be enduring. It is significant that 14 of the original 54 local members were physicians. But it was a publisher and bookseller, Lemuel Shattuck (1793–1859), who was the Society's key "statist" for health-related issues. He consulted with, among others, Quetelet and was a prime mover for the Massachusetts Registration Act of 1842. He also played a role in the origins of national vital statistics by having mortality queries included in the 1850 census.

In 1846, the first national medical convention (which led to the founding of the American Medical Association) formed two committees relevant to health statistics: (i) a committee on registration

whose report "provided for the convention to formally petition every state government to enact effective registration legislation and to request state and local medical societies to take the lead in lobbying for such laws" [3, p. 201], and (ii) a committee on disease nomenclature which adopted a modification of Farr's classification. Neither of these recommendations was widely adopted for at least 50 years. Although there were many attempts, these efforts were often failures since "the registration movement had moved too far ahead of its base of community support" [3, p. 204]. At the end of the century, no state had a system as good as those in several European countries.

During the last two decades of the nineteenth century, the initiative for improving vital statistics shifted to the Federal government [8]. Under Dr John Shaw Billings (1838–1913), who directed vital statistics in the 1880 and 1890 US censuses, improvements were made in gathering mortality data. The **American Public Health Association** joined with the Census Bureau, which was established in 1902, in drafting a model vital statistics law and standard birth and death certificates that each state could adopt. Because of the early efforts of Cressy L. Wilbur (1865–1928), Chief Statistician for Vital Statistics from 1906 to 1914, the birth- and death-registration areas grew, reaching completeness in 1933, nearly a century after several European countries. The Division of Vital Statistics of the Bureau of the Census was transferred to the Public Health Service in 1946, becoming the National Office of Vital Statistics, with Dr Halbert L. Dunn (1896–1975) as Director. In 1960, NOVS was combined with the National Health Survey to become the **National Center for Health Statistics** with **Forrest E. Linder** (1906–1988) as its first Director.

Development of Health Surveys in the United States

The establishment of the National Health Survey in 1957 marked a milestone in health statistics. With only a few exceptions, previous data relating to health came from vital statistics or from diagnosed diseases seen in hospitals or included in various notifiable **diseases registers**. As public health concerns in the US shifted from the surveillance and control of acute **communicable diseases** to the prevention of chronic diseases, it was necessary to develop data systems that would better describe the current health status of the population (*see* **Quality of Life and Health Status**) and shed some light on health-associated behaviors and use of health care services (*see* **Health Services Organization in the US**). The National Health Survey was the first continuous nationwide survey to gather information from randomly drawn representative samples (*see* **Probability Sampling**) of the noninstitutionalized population of the country to accomplish these aims (*see* **Surveys, Health and Morbidity**). It consists of two distinct surveys: the National Health Interview Survey (NHIS) and the National Health Examination Survey, the latter subsequently expanded to the National Health and Nutrition Examination Survey (NHANES). The NHIS conducts interviews in about 1000 households each week to obtain information on acute illnesses, chronic conditions, health-related knowledge and behaviors, and use of health services. The NHANES involves detailed standardized medical examinations, including laboratory studies and special tests such as ECGs and X-rays, and extensive questionnaires on nutrition and previous health conditions. The NHANES is a periodic survey and NHANES III (actually the sixth cycle of these surveys), being carried out from 1988 to 1994, examined a sample of about 30 000 persons aged 6 months and over. Health interview surveys have now been conducted in many countries and examination surveys have been used effectively in several developing countries to assess the population's health.

These surveys would not have been feasible without the development of survey methodologies which occurred in the twentieth century. Anders N. Kiaer (1838–1919), the first director of the Norwegian Central Bureau of Statistics, reintroduced the idea of a survey sample in what he called the "representative method", in which the sample was to be selected purposively as Laplace had suggested a century earlier, rather than randomly. Arthur Lyon Bowley (1869–1957) is credited with being the first statistician to use random sampling (1906). The seminal breakthrough for sampling methodology came in 1934 when **Jerzy Neyman** (1894–1981) established the theoretical basis for **stratified sampling** with unequal inclusion probabilities. He made another major contribution when he introduced the use of cost functions into survey sampling theory (1938). In the early 1940s, Morris Hansen (1910–1990) and William Hurwitz (1908–1969) at the Bureau of

the Census perfected the methodologies for complex **multistage sampling** designs that are the basis for most modern large-scale surveys.

Conclusion

At the end of the twentieth century, most industrialized countries have effective vital statistics systems in place and many have established periodic interview surveys to assess the health status and needs of their citizens. Much remains to be done in developing countries to institute health services information systems (*see* **Administrative Databases**) that can guide public policies and programs. As the public health burden continues to shift from infectious diseases to problems of an aging population, to concerns about health promotion and disease prevention, and to assuring adequate health care for all citizens, the needs for reliable, relevant, and timely health statistics become ever greater. Fortunately, the methodologies developed over several centuries and the data systems that have been established can, if appropriate resources are provided, meet these needs.

Health Status Instruments, Measurement Properties of

Introduction

In this article, we present the key measurement properties necessary for a useful health status instrument. This article also includes a comment on the issue of respondent and administrative burden. The discussion is drawn largely from a previous publication [5]. The concepts are most relevant for measurement of health status, but apply to measurements of any human attribute or characteristic.

The Structure of Health Status Measures

Since semantic issues in health status measurement are both controversial and important, we will clarify how we shall use words in our discussion. Some measures consist of a single question which essentially asks "How would you rate the quality of your life?" [25].

This question may be asked in a simple or a very sophisticated fashion, but either way yields limited information. More commonly, health status instruments are questionnaires made up of a number of *items*, or questions. These items are added up in a number of *domains* (also sometimes called *dimensions*). A domain or dimension refers to the area of behavior or experience that we are trying to measure. Domains might include mobility and self-care, which could further be aggregated into physical function, or depression, anxiety, and well-being, which could be aggregated to form an emotional function domain. For some instruments, investigators have undertaken rigorous valuation exercises in which the importance of each item is rated in relation to the others. More often, items are equally weighted, implying an assumption that their value is equal.

What Makes a Good Health Status Instrument?

Current strategies for evaluating health status measures build on close to 100 years' work in the measurement of attributes such as intelligence and attitudes [1]. These strategies have evolved, incorporating insights from studies directly relating to health status and **quality of life** [23].

Measuring at a Moment in Time versus Measuring Change

The goals of health status measures include differentiating between people who have a better health status and those who have a worse health status (a *discriminative instrument*), and measuring how much health status has changed (an *evaluative instrument*) [16]. The construction of instruments for these two purposes can be quite different. For instance, let us take the example of thyroid disease. If we are trying to discriminate between those with and without thyroid disease, we would be unlikely to include fatigue as an item, because fatigue is too common among people who do not have thyroid disease. On the other hand, in measuring improvement in health status with treatment, fatigue, because of its importance in the day-to-day lives of people with thyroid disease, would be a key item. In the next sections, concerned with what makes a good health status instrument, we list key measurement properties separately for discriminative and evaluative instruments. The properties that make useful discriminative and evaluative instruments are presented in Table 1.

Signal and Noise

Investigators examining physiologic endpoints have long been aware that reproducibility and validity are the necessary attributes of a good test. For health status instruments, reproducibility translates into having a high ratio of signal to noise, and validity translates into whether they are really measuring what they are intended to measure. For discriminative instruments, the way of quantifying the signal-to-noise ratio is called *reliability*. If the variability in scores between subjects (the signal) is much greater than the variability within subjects (the noise), an instrument will be deemed reliable. Reliable instruments will generally demonstrate that stable subjects show more or less the same results on repeated administration. For evaluative instruments, those designed to measure changes within individuals over time, the way of determining the signal-to-noise ratio is called *responsiveness*. Responsiveness refers to an instrument's ability to

Table 1 What makes a good health status measure

Instrument property	Evaluative instruments (measuring differences within subjects over time)	Discriminative instruments (measuring differences between subjects at a moment in time)
High signal-to-noise ratio	Responsiveness	Reliability
Validity	Correlations of changes in measures over time consistent with theoretically derived predictions	Correlations between measures at a moment in time consistent with theoretically derived predictions
Interpretability	Differences within subjects over time can be interpreted as trivial, small, moderate, or large	Differences between subjects at a moment in time can be interpreted as trivial, small, moderate, or large

detect change. If a treatment results in an important difference in health status, investigators wish to be confident that they will detect that difference, even if it is small. Responsiveness will be directly related to the magnitude of the difference in score in patients who have improved or deteriorated (the signal) and the extent to which patients who have not changed obtain more or less the same scores (the noise).

Validity When There is a Gold Standard

If we have a **gold standard** or criterion standard for some aspect of health, it implies that we have endorsed a particular measurement tool as providing the underlying truth about that aspect. The concept of a reference, gold, or criterion standard is most easily applied for physiologic measures. For instance, experts may agree that the cardiac angiogram is a gold standard for measurement of various aspects of cardiac anatomy and function, and noninvasive tests should be judged in relation to this criterion.

Although there is no gold standard for health status, there are instances in which there is a specific target for a health status measure that can be treated as a criterion or gold standard. Under these circumstances, one determines whether an instrument is measuring what is intended using *criterion validity*, according to which an instrument is valid insofar as its results correspond to those of the criterion standard. For instance, criterion validity is applicable when a shorter version of an instrument (the test) is used to predict the results of the full-length index (the gold standard). Another example is using a health status instrument to predict mortality. In this instance, to the extent that variability in survival between patients (the gold standard) is explained by the questionnaire results (the test), the instrument will be valid. Self-ratings of health such as more comprehensive and lengthy measures of general health perceptions include an individual's evaluation of her or his physiologic, physical, psychologic, and social well-being. Perceived health, measured through self-ratings, is an important predictor of mortality [17].

Validity When There is No Gold Standard

Validity has to do with whether the instrument is measuring what it is intended to measure. When there is no gold or criterion standard, health status investigators have borrowed validation strategies from clinical and experimental psychologists, who have for many years been dealing with the problem of deciding whether questionnaires examining intelligence, attitudes, and emotional function are really measuring what they are supposed to measure.

The types of validity that psychologists have introduced include face, content, and construct validity.

Face validity refers to whether an instrument appears to be measuring what it is intended to measure, while *content validity* refers to the extent to which the domain of interest is comprehensively sampled by the items, or questions, in the instrument. Quantitative testing of face and content validity are rarely attempted. Feinstein [4] has reformulated these aspects of validity by suggesting criteria for what he calls the *sensibility*, including the applicability of the questionnaire, its clarity and simplicity, likelihood of **bias**, comprehensiveness, and whether redundant items have been included. Some of these criteria compete with one another: redundant items may help to ensure comprehensiveness, and reduce the likelihood of bias, while increasing the burden on respondents. Because of their specificity, Feinstein's criteria facilitate quantitative rating of an instrument's face and content validity [18].

The most rigorous approach to establishing validity is called *construct validity*. A construct is a theoretically derived notion of the domain(s) that we wish to measure. An understanding of the construct will lead to expectations about how an instrument should behave if it is valid. Construct validity therefore involves comparisons between measures, and examination of the logical relationships that should exist between a measure and characteristics of patients and patient groups. The first step in construct validation is to establish a "model" or theoretic framework that represents an understanding of what investigators are trying to measure. That theoretic framework provides a basis for understanding how the system being studied behaves, and allows hypotheses or predictions about how the instrument being tested should relate to other measures. Investigators then administer a number of instruments to a population of interest, and examine the data. Validity is strengthened or weakened according to the extent to which the results confirm or refute the hypotheses. For example, a discriminative health status instrument may be validated by comparing two groups of patients; those who have undergone a very toxic chemotherapeutic regimen and those who have undergone a much less toxic chemotherapeutic regimen. A health status instrument should distinguish between these two groups, and, if it does not, it is very likely that something has gone wrong. Alternately, **correlations** between symptoms and functional status can be examined, the expectation being that those with a greater number and severity of symptoms will have lower functional status scores on a health status instrument.

Another example is the validation of an instrument discriminating between people according to some aspect of emotional function. Results from such an instrument should show substantial correlations with existing measures of emotional function. We call construct validity that deals with measurements at one point in time *cross-sectional construct validity*. The principles of validation are identical for evaluative instruments, but their validity is demonstrated by showing that *changes* in the instrument being investigated correlate with *changes* in other related measures in the theoretically derived predicted direction and magnitude (*longitudinal construct validity*). For instance, the validity of an evaluative measure of health status for patients with chronic lung disease was supported by the finding of moderate correlations with changes in walk test scores [7].

Validation is not an all-or-nothing process. We may have varying degrees of confidence that an instrument is really measuring what it is supposed to measure. *A priori* predictions of the strength of relationship with other measures that one would expect if a new instrument is really measuring what is intended strengthen the validation process. Without such predictions, it is generally easy to rationalize whatever correlations between measures are observed.

Validation does not end when the first study with data concerning validity is published, but continues with repeated use of an instrument. The more frequently an instrument is used, and the wider the situations in which it performs as we would expect if it were really doing its job, the greater is our confidence in its validity. Perhaps, we should never conclude that a questionnaire has "been validated"; the best we can do is to suggest that strong evidence for validity has been obtained in a number of different settings and studies.

Interpretability

A final key property of a health status measure is *interpretability*. For a discriminative instrument, we could ask whether a particular score signifies that a patient is functioning normally, or has mild, moderate, or severe impairment of health status. For an evaluative instrument, we might ask whether a particular change in score represents a trivial, small but important, moderate, or large improvement or deterioration. Considerable research has focused on establishing what constitutes the minimal important difference (MID) in health status. One can define the MID as "The smallest difference in score in the outcome of interest that informed patients or informed proxies perceive as important, either beneficial or harmful, and which would lead the patient or clinician to consider a change in the management" [22]. However, any change in management will depend on the downsides, including cost, associated with that outcome and the values and preferences patients place on these outcomes.

A number of strategies are available for trying to make health status scores interpretable and describe the MID [6, 9, 11]. The first is called an anchor-based approach. Investigators have often used global ratings of change (patients classifying themselves as unchanged, or experiencing small, medium, and large improvements or deteriorations) as the independent

standard when correlations between the ratings and the instrument for which information on interpretability is sought are strong, generally greater than 0.5. Several disease-specific instruments use seven-point scales with an associated verbal descriptor for each level on the scale. For each questionnaire domain, one could divide the total score by the number of items so that domain scores can range from 1 to 7. Using this approach to framing response options, the smallest difference that patients consider important is often approximately 0.5 per question [10, 14]. A moderate difference corresponds to a change of approximately 1.0 per question, and changes of greater than 1.5 can be considered large. So, for example, in a domain with four items, patients will consider a one point change in two or more items as important. This finding seems to apply across different areas of disease, including patients with chronic airflow limitation [10]; patients with both adult [14] and child [13] asthma patients, and parents of child asthma patients [12]; and adults with rhinoconjunctivitis [15].

The approach described above relies on within-patient comparisons as the independent standard. One alternative is between-patient comparisons. In one example of this approach, groups of patients with chronic airflow limitation participating in a respiratory rehabilitation program completed the Chronic Respiratory Questionnaire [20]. The patients conversed with one another long enough to make judgments about their relative experience of fatigue in daily life. While there was a bias in their assessment (patients generally considered themselves better off than one another), their relative ratings allows estimates of what differences in the Chronic Respiratory Questionnaire score constitute small, medium, and large differences [20].

Another anchor-based approach uses HRQL instruments for which investigators have established the MID. Investigators can apply **regression** or other statistical methods to compute the changes on a new instrument that correspond to those of the instrument with the established MID [21]. Similar to the anchor-based approach using transition ratings, investigators should ensure that the strength of the correlation between the change scores of these instruments exceeds a minimum (e.g. a correlation coefficient of 0.5). Yet another approach to estimate the MID involves enrolling panels of experts or patients and qualitative research methods, such as Delphi techniques [26]. The experts establish a consensus what constitutes the MID of the CRQ. Investigators have also proposed distribution-based methods to determine interpretability of HRQL instruments. Distribution-based methods differ from anchor-based methods in that they interpret results in terms of the relation between the magnitude of effect and some measure or measures of variability in results [9]. The magnitude of effect can be the difference in an individual patient's score before and after treatment, a single group's score before or after treatment, or the difference in score between treatment and control groups. As a measure of variability, investigators may choose between-patient variability (the **standard deviation** of patients at baseline, for instance) or within-patient variability (the standard deviation of change that patients experienced during a study).

If an investigator used the distribution-based approach, the clinician would see a treatment effect reported as, for instance, 0.3 standard deviation unit. The great advantage of distribution-based methods is that the values are easy to generate for almost any HRQL instrument because there will always be one or more measures of variability available. This contrasts with the work needed to generate an anchor-based interpretation. The problem related to this methodology is that the units do not have intuitive meaning to clinicians. It is possible, however, that clinicians could gain experience with standard deviation units in the same way they learn to understand other HRQL scores. Cohen addressed this problem in a seminal work by suggesting that changes in the range of 0.2 standard deviation unit represent small changes, those in the range of 0.5 standard deviation unit represent moderate changes, and those in the range of 0.8 standard deviation unit represent large changes [3]. To further respond to this problem, investigators have attempted to provide empirical evidence about the relationship between distribution-based and anchor-based results. These studies address the question, "What is the appropriate interpretation of a particular magnitude of effect, in distribution-based units, as judged by the results of anchor-based studies?".

The **standard error** of measurement (SEM) presents another distribution based method and is defined as the variability between an individual's observed score and the true score and is computed as the baseline standard deviation multiplied by the square root of 1 minus the reliability of the

Table 2 Modes of administration of health status measures

Mode of administration	Strengths	Weaknesses
Self-administered	Minimal resources required	Greater likelihood of low response rate, missing items, or misunderstandings
	Willingness to respond to personal questions	Need modest literacy and numeracy skills
	Reduced risk of erroneous interpretation by interviewer	
	Can be computer- administered	
Interviewer-administered	Maximizes response rate	Requires considerable resources,
	Few, if any, missing items	Training of interviewers
	Minimizes errors of misunderstanding	May reduce willingness to acknowledge problems
Telephone-administered	Few, if any, missing items	Limits format of instrument
	Minimizes errors of misunderstanding	Access to phone necessary
	Less resource-intensive than interviewer-administered	
Postal-administered	Modest resources required	High likelihood of low response rate, missing items, or misunderstandings
		Interference by family members
	Willingness to respond to personal questions	Need modest literacy and numeracy skills
Surrogate responders	Reduces stress for target group (very elderly or sick)	Perceptions of surrogate may differ from those of target group
	Improves response rate (young children and those incapable of responding)	

QOL measure. In theory, a QOL measure's standard error of measurement is sample independent, whereas its component statistics, the standard deviation and the reliability estimate, are sample dependent and vary around the standard error of measurement [27]. When the between-person variability in the population increases, the standard deviation will increase (tending to raise the standard error of measurement), but the reliability will also increase (tending to lower the standard error of measurement). Thus, the standard error of measurement largely reflects within-person variability over time.

Knowing the change or difference in score that is meaningful enables the clinically useful estimation of the number of patients who need to be treated for one individual to have an additional clinically meaningful improvement [8]. (*see* **Number Needed to Treat (NNT)**)

Respondent and Administrative Burden

Alternate approaches to obtaining information from patients have different resource implications. The strengths and weaknesses of the different modes of administration are summarized in Table 2. Health status questionnaires are either administered by trained interviewers or self-administered. The former method is resource intensive, but ensures compliance and minimizes errors and missing items. The latter approach is much less expensive, but increases the number of missing patients and missing responses. A compromise between the two approaches is to have the instrument completed under supervision.

Another compromise is the telephone interview, which minimizes errors and missing data but may necessitate a relatively simple questionnaire structure unless the response options are provided to the respondent in advance. With clear instructions postal completion can provide valid data but may have a low response rate [19]. Computer administration has become a common method of questionnaire administration and yields similar responses to paper versions [2] (*see* **Computer-assisted Interviewing**).

Another issue in administrative and respondent burden is the length of the questionnaires. This may be less of an issue in research settings in which,

once one has invested the resources in setting up the interview, the incremental resource expenditure of a longer interview is relatively minor. On the other hand, it may be necessary to find a short questionnaire for clinical settings in which one needs to obtain information at regular intervals (*see* **Questionnaire Design**).

Under these circumstances, distilling the measurement of health status into a few key questions would be a dream come true. One approach to achieving this goal is to develop a long instrument, test it, and use its performance to choose key questions to include in a shorter index. This approach has been used, for example, to create shorter questionnaires based on the lengthy instruments from the Medical Outcomes Studies [24].

How would one determine if the shortened questionnaire is an adequate substitute for the full version? The issue for discriminative purposes is the extent to which people are classified similarly by the short and long forms of the questionnaire. Statistically, one would examine the extent to which **variance** or variability in scores, in the full instrument is predicted or explained by scores of the abbreviated version: the greater the extent to which the rating of people's quality of life by the shorter instrument corresponds to ratings by the longer version, the more comfortable we should be with the substitution.

For evaluative purposes, the responsiveness and validity of the shorter version should be tested against the full instrument. If both correlations of change with independent measures and instrument responsiveness were comparable, substitution of the shorter instrument would be desirable. If measurement properties deteriorated, the investigator would face a decision about trading off respondent burden with increases in sample size necessitated by a less responsive instrument. Before comparing results generated by original and shortened versions of a questionnaire, one should check that a single patient sample yields the same between-subject differences (discriminative) and within-subject changes (evaluative) with both versions.

Health Workforce Modeling

Health workforce modeling is generally concerned with projecting the future supply of and requirements for a particular type of health professional. The objective of such an effort is to assess the relative balance between supply and requirements under various assumptions and alternative future workforce policies. *Health workforce modeling* is a term that has come into usage over the last two decades as a more gender-neutral formulation of what had traditionally been called *health manpower* planning [6]. In addition, modelers have in more recent years used the more neutral term *requirements* as a generic term which may reflect, depending on the disciplinary background and/or political orientation of the modeler, the "needs", "wants", "demand", or "expected utilization" for health services of a relevant population (*see* **Health Care Utilization Data**). Health workforce modeling, when employed at a regional or national level, is directed toward alerting policy makers to current or potential future imbalances between supply and requirements or to identifying maldistributions of professionals by geographic region, specialty, or practice setting which may adversely affect access to care, **quality of care**, or health care costs. The deceptively simple goal of these analyses is to develop policies, typically affecting the supply side, to ensure that the proper number and type of health professionals will be available to deliver required services to a specified future population. In practice, the achievement of this goal is complicated by the incompleteness of data necessary to implement the models, lack of agreement on essential definitions, competing perspectives of diverse stakeholders, and lack of agreement on what constitutes the "correct" balance between supply and requirements.

Workforce modeling has become of greater interest as governments wrestle with fundamental reforms of the structure and financing of their health care systems (*see* **Health Care Financing**). The undersupply of health professionals can adversely affect the health status and economic viability of populations. Alternatively, because the education of health professionals is supported in large part by public funds, the oversupply of highly trained professionals wastes scarce societal resources that could be better employed elsewhere. The unemployment or underutilization of health professionals carries enormous personal costs as well. However, it has been persuasively argued by Reinhardt [11] that the role of governments in attempting to bring supply in line with requirements ought to be limited to making information on health professions markets freely available to all affected parties so that the market can adjust supply and demand as it does in most other professions.

Invariably, a health professions model will develop a forecast of the future supply of one or more types of personnel and a forecast of the requirements for the personnel in a future time period. Occasionally, modelers will verify their models by "backcasting" to determine if the model, under known conditions and parameter settings, would have predicted correctly a previously recorded level of supply. Some intrepid researchers have assessed the historical performance of alternate forecasts made in prior periods to actual data after they became available [1].

At the national or regional level, three categories of models have been employed:

1. Supply models which forecast the number of a particular kind of health professional expected to be practicing at some future time period (usually expressed either in full-time equivalent persons or in head count).
2. Requirements models which translate the expected utilization or need for specified health services into requirements for a particular kind of professional.
3. Integrated models which explicitly represent the interaction of supply and requirements and other exogenous factors such as disposable personal income, health insurance coverage, and managed care penetration simultaneously to develop estimates of supply and requirements.

Health Workforce Supply Models

Health professions supply models have taken several forms. Conceptually, the most simple is a model that forecasts the future stock of particular kinds of health professionals by obtaining from professional associations or licensure data a count of those practicing in one year, adding to it the expected entrants and subtracting those who leave the profession owing to retirement or death, to produce an estimate of the

active workforce in a future period. Rates of addition, separation, and labor force participation in a cohort will depend on age, gender, and geographical location, among other factors. These labor stock models are appealing for policy analysis because training program enrollments, graduation rates, class composition, and licensure or certification rates are at least partially controllable through policy interventions. As described below, the US Bureau of Health Professions has developed a set of labor stock models to estimate supply [13].

The Bureau of Labor Statistics (BLS) of the US government uses a complex econometric model to estimate the occupational employment of 507 occupations in 258 industrial groupings. The model depends in part on projections of the gross domestic product (GDP) contributions of various industry sectors, the interrelationships between sectors, demand for goods and services, personal income, and other factors. The GDP, demand, and income projections alone require the solution of 400 equations with 213 exogenous variables. Despite the complexity of the BLS models at the macro level, these techniques cannot capture the micro-level details of training program structure and career choice that are found in workforce stock models which frequently drive the production of health professionals.

Bureau of Health Professions Physician Supply Models

Because the investment by society into the training of physicians is greater than for any other health profession and because the length of the supply "pipeline" is the longest of any health profession, considerable effort has been devoted to modeling the physician supply process. At the US federal level, the Bureau of Health Professions [3] utilizes a physician supply forecasting model that consists of five submodels: three at the national level and two at the level of states and census regions. An aggregate supply model forecasts the total national supply of physicians by age, gender, and country of medical education. A specialty model allocates the total supply among 36 specialties in eight practice settings (inpatient, outpatient, long-term care, etc.) and to nonpatient care activities (administration, teaching, and research). A model of the graduate medical education process projects the distribution of residents by specialty and by year of training for future years. The results of the graduate medical education model may be influenced by changing the size, fill rates, and proportions of US and international medical graduates in residency programs. These, and the dynamics of specialty choice and specialty switching, are policy variables that can be influenced, in part, by government initiatives.

Health Workforce Requirements Models

Unlike supply models, which are relatively transparent in their assumptions, requirements modeling is influenced at least as much by the philosophical perspective taken by the model as by the analytic approach. Supply models are largely descriptive. Requirements models are either explicitly or implicitly normative in that they describe what the number and type of health care professionals should be to provide health care to a given population. The simplest (and least useful) kind of requirements model is to form a ratio of providers-to-population, e.g. dentists per 100 000 persons. These provider-to-population ratios give a gross measure of supply which can be used to compare one nation with another or one region with another but tell us nothing about what care is delivered, how it is delivered, to whom it is delivered, and in what facilities it is delivered.

A utilization-based model will forecast health services utilization for a particular population, usually in the form of office visits, inpatient episodes of care, nursing home days, etc. Each encounter type can then be described in terms of who is involved and how long a particular person or team is typically involved. Person-hours are then aggregated over all delivery venues applicable to a given health profession to determine the number of full-time equivalent providers required to deliver an assumed volume of services. In their pure form, utilization-based models forecast only what *will* be rather than what *should* be the number and types of providers required under certain utilization and task allocation assumptions. Utilization models will account for variation in utilization of services by age, gender, and geographic region and they may account for differential access owing to insurance status, provider availability, travel distance, and social and economic factors. Utilization models do not attempt to provide estimates of the number and kind of services needed by a population to maintain that population in optimum health.

Need-based models, on the other hand, start from the perspective of a population's need for a certain mix of health services as recommended by knowledgeable health professionals usually convened in consensus panels. Gaining consensus on what should be done, to whom it should be done, and by whom it should be done is not an easy process, especially when competing specialties and professions are involved. The term *adjusted need-based model* refers to an approach that tempers the requirements estimate with information about how populations actually use services based on assumptions relating price and accessibility.

In the US in the early 1980s, the Graduate Medical Education National Advisory Committee (GMENAC) [14] developed an adjusted need-based model from the work of a number of disease area expert panels representing medical or surgical specialists, primary care providers, and nonphysician providers (such as physician assistants and nurse practitioners). A modeling panel integrated the findings of the disease area panels to resolve problems with overlap and variations in assumptions.

The opportunity for enormous variation in requirements estimates exists at two points in the process. First, professionals (and clinical evidence) may not agree on what services should be provided. Secondly, the rate of service provision and the mix of professionals providing the service can be affected greatly by health system organization (*see* **Health Services Organization in the US**) and financing structures. Analysts have, for example, found variations of 25% or more in the number of physicians required, depending on whether traditional fee-for-service or aggressive managed care utilization rates and staffing ratios are assumed [12, 16]. Unless one is willing to accept wildly unrealistic estimates of the number of health professionals required, estimates must be based on supportable assumptions regarding the utilization and delivery patterns that will actually occur at the specified future time [10]. Presentation of supply and requirements estimates under alternative future scenarios is one way to illustrate the sensitivity of estimates to changes in the settings of model parameters or policy options.

Another recent development is the Bureau of Health Professions' Integrated Requirements Model for Primary Care for Physicians' Assistants (PAs), Nurse Practitioners (NPs), and Certified Nurse-Midwives (CNMs) [9]. Known as the IRM, this system has been used to forecast US requirements for physicians and other nonphysician primary care providers for the delivery of primary health care services, using a variety of assumptions (or scenarios). These assumptions can be adjusted by the users and are designed so that users can also forecast requirements under an unlimited number of scenarios by varying model inputs and parameters. At the heart of the model is the assumption that requirements will differ depending on how certain primary care tasks are allocated to the various health professions and where the boundaries of "primary care" tasks lie within the health services domain.

A Recent Application of Requirements Forecasting in an Integrated Delivery System

To determine the number and kinds of physicians required to staff the US Department of Veterans' Affairs (VA) health care delivery system, the Institute of Medicine [7] utilized three distinct but complementary approaches: (i) empirical models based on current practice in the VA; (ii) expert judgment models; and (iii) comparisons to other large integrated systems operating in the US. In practice, these three approaches interacted to a great extent, and the final recommendation was for an informed blending of alternative requirements forecasts.

The empirical models developed were of two forms: (i) production functions (PF), in which physicians were one of several factors leading to the production of patient care workload, and (ii) inverse production functions (IPF), in which the required number of physicians in a given specialty was estimated directly from workload and other staffing inputs. In the PF variant, the patient workload (measured, for example, in weighted workload units) for one of 14 patient care areas (e.g. inpatient psychiatric service) was hypothesized to be related to the number of physician FTEs by specialty allocated to the area, the number of residents by year of training, nurse FTE per physician, other support FTE per physician, and other institutional factors possibly affecting productivity.

In the IPF variant the required number of physicians in 11 specialties for a given facility was assumed to be a function of the estimated required workload in all settings (inpatient, outpatient, and long-term care), the number of residents assigned in

the specialty by year of training, support staff allocated to the specialty, and other productivity-related factors such as hospital type.

The second major approach to forecasting physician requirements was to use 11 expert panels organized around specialty (e.g. neurology, rehabilitation medicine, and radiation oncology) or multidisciplinary care area (e.g. long-term care). Rather than simply critiquing the empirically derived estimates, the panels developed independent quantitative estimates of physician requirements under a variety of alternative scenarios of care provision. The work of the panels was informed by the results of the empirical models and external norm data from other organizations.

Ultimately, estimates of requirements from the empirical models were formally reconciled with estimates from the expert judgment methods through a weighting and smoothing process. In the end, no "cook book" approach was developed. Rather, it was recommended that the empirical, expert judgment, and external norm approaches be continually enhanced and coordinated to produce demand-driven staffing requirement estimates that would guide management decisions and resource allocation. On the basis of the Institute of Medicine (IOM) experience, Lipscomb et al. [8] have developed a **Bayesian** statistical approach to combine expert panel judgments through **hierarchical models**.

Integrated Supply and Requirements Models

One currently used example of an integrative model is the Econometric Model of the Dental Sector (EMODS) developed at the US Bureau of Health Professions [1]. EMODS employs an interactive system of equations explicitly to represent the impact of population changes, disease etiology, dental insurance, cost of services, and personal income on demand for dental care. Also included on the production side is the technology of care delivery, use of auxiliaries, hours of work, and the labor content of procedures. Supply equations (exogenous to the model) include not only the stock of dentists, but also the stock of various auxiliaries as well. Prices for care affect consumption of services, which in turn affects employment of dentists. The full model contains a set of 195 equations that represent the interactions in the dental care sector. The model has been tested and **calibrated** by comparing model estimates to actual data over a period of several years (*see* **Model Checking**). Among the complex econometric models that have been formulated for various health professions, the most highly developed is the model of the dental sector, which is self-contained and relatively easy to describe. Even in dentistry, however, it is difficult to obtain adequate data to permit full utilization of econometric models. In fact, to reduce the data burdens, researchers have found that a single-equation **regression** model, while not providing the richness of insight available in the full model, does permit adequate forecasts of dental prices and expenditures [1].

Data Requirements for Workforce Modeling

Figure 1, adapted from *Data Systems to Support State Health Personnel Planning and Policy making: A Resource Guide for State Agencies* [15], outlines three different levels of sophistication in both the supply and requirements domains and identifies the kinds of data required at each level. An important feature of this approach is that it allows one to move from the simplest approaches to the more complex approaches. This is essential because one can get lost quite easily in sophisticated details of modeling and equations before one has had a chance to answer the more basic questions about supply and requirements. From a practical perspective, modeling efforts should proceed sequentially, collecting data specified in the innermost portions of Figure 1 and then proceeding outward in both the supply and requirements directions consistent with not only the required precision and planning time horizon, but also the resources available to the task.

On the supply side, these basic analyses and data include the counts of licensees in state and employment counts. Such basic data can be augmented by national and state trends in the number of practitioners, as indicated by the growth in newly licensed persons in the state or nation and trends in employment. Professional association data can be useful in understanding and projecting supply, but, because of duplication in licenses, national estimates of supply remain problematic. Such an approach, however, can be used at the state or regional level, where universal unduplicated licensure ensures that supply can be

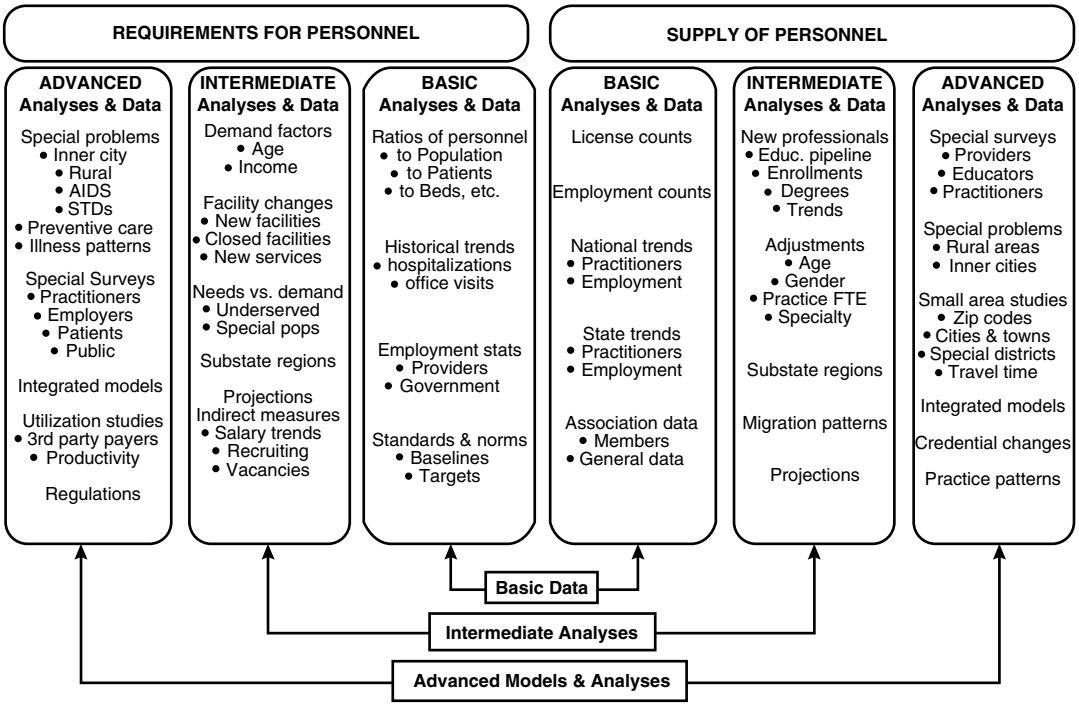

Figure 1 The health workforce data analysis hierarchy. Adapted from [4], based on [15, Figure 1]. Reproduced from *Physical Therapy* by permission of the American Physical Therapy Association

adequately measured and trends can give us a hint as to what the underlying demand might be.

A comprehensive licensure data system – such as maintained in the state of North Carolina – takes time to implement, but, with periodic resurveys, the quality of data improves. Additional items can be added to increase the usefulness of the database. Data generated in North Carolina using this model are now available on location, employment setting, and type of employment. These data provide helpful information by projecting demand as well as supply, as mobility in and out of employment sectors can be quite sensitive to economic trends.

One of the ways in which demand can be estimated from supply data is by looking at the different sectors in which health professionals are employed, and by comparing the kinds of employment for the entire workforce with those of the newly licensed individuals in a given year. For example, in North Carolina, 36.8% of the currently licensed individuals in physical therapy are working primarily in hospitals. This figure has fluctuated between 35% and 40% over the past decade, even as the total number of therapists has increased. Among newly licensed personnel in 1994, including both new graduates and immigrants to the state, the proportion employed in hospitals is 64%. This proportion suggests that hospital employment is especially attractive to new graduates and immigrants. By examining employment trends, it may be possible to determine whether this percentage increase will continue (representing an increase in employment in that particular sector) or whether it represents the employment patterns of new entrants who subsequently move to other sectors.

The methods used here to assess requirements emphasize trends rather than needs or demands. Obviously, such an approach is subject to misinterpretation, but it uses available data from supply to assess changes in different sectors to provide "reality checks" on the more idealistic need-based models and the more abstract and data-intensive demand-based models. Such an approach also provides information at the state and local levels, where decisions about expansion in the number and size of training institutions are likely to occur.

Emerging Issues

As the data requirements for both supply and demand models become more complex and sophisticated, and as various elements in national health systems are becoming decentralized and privatized, new issues are coming to the fore. Chief among these are how to resolve inherent tensions between the need for regulation and accountability expressed by central health authorities, credentialling bodies, national payment systems, and health professional educational systems, and the need for privacy and **confidentiality** expressed by individual health professionals, their associations, and health service delivery systems, which increasingly employ health professionals. As data requirements for workforce planning become more complex, they also become more onerous to individuals. Health workforce planners of the next generation will be faced with the challenge to use creative and innovative strategies to acquire data at increasingly detailed levels while preserving the confidentiality of the sources.

New information technologies also provide unprecedented opportunities for health workforce modeling. For example, the availability of various kinds of **simulation** software for microcomputers allows the development and display of simulations and **sensitivity analyses** in real time. In addition, the use of geographic information systems (GIS) allows cartographic presentation of databases containing disease patterns (*see* **Mapping Disease Patterns**) and demographic data. Overlaying the location of health professions or activity space data on such maps can provide dramatic opportunities to identify issues of distribution which might well remain opaque in the absence of such visual displays. Creatively applied, such processes can be conducted in group settings with panels of health professions, education administrators, and health policy analysts in attendance in such a way that not only engages their attention, but also serves to close the loop between planning and policy.

Conclusion

Health workforce modeling has been employed at a variety of organizational levels and has either concentrated on a single health profession or considered multiple health professions interacting to provide a spectrum of health care services. At the micro level, models have been developed to analyze one or more specific types of personnel in a specific delivery setting (e.g. physician assistants employed in the office of a generalist physician). Models have been developed to analyze various kinds of personnel in an organized delivery system (e.g. all physician specialties in an integrated health care delivery system which includes inpatient, outpatient, long-term, and home health care). Some models have covered specific kinds of personnel in a regional, state, or national framework with the purpose of forecasting future workforce structure and affecting health workforce policy (e.g. physical therapists in the US or all licensed health professions practicing within the boundaries of a given state, perhaps at a county level of disaggregation).

Although not formally workforce modeling, population-based "benchmarking" also has been applied recently in health workforce studies as a way to get at the notion of "requirements", while avoiding the question of whether "needs" or "demands" are being met. This approach compares a priori standard ratios of health professionals to populations (either normative or those extant in particular health systems) to the range of these ratios across **hospital market areas**, broad regions, or national health systems. A recent application of this approach used managed care ratios in the US to examine how variations in supply and composition of the physician workforce relate to the organization of the health care delivery system in different areas [2].

This article concentrates on applications at the health system or national levels because most of the recently published material is directed at macro-level analyses. This concentration of published material at higher levels of aggregation is a result of the recent emphasis on workforce reform as a part of health system reform proposals, and is also a consequence of single-site studies being described most frequently in less accessible internal documents of the firms in which the analyses were performed. An excellent earlier summary of **operations research** applications that spanned this entire spectrum appears in [6]. In addition, Hall & Mejia [5] provided a comprehensive monographic summary of the various approaches up to the mid-1970s, with a special focus on techniques applicable to developing countries and feasible for health workforce planning as a component of more general health and development strategies.

Healthy Worker Effect

Epidemiological studies of occupationally or environmentally exposed cohorts are useful in identifying and quantifying environmental risks, because workers are generally exposed to higher levels of toxic materials than the general population. Although higher exposures make it easier to detect and characterize modest elevations in risk, such studies are plagued by a particularly pervasive form of selection bias, referred to as the healthy worker effect (HWE). The HWE is reflected in better health status of workers relative to the general population. This bias arises because workers were healthy enough to be hired initially and those who remain at work stayed healthy enough to maintain employment, whereas general populations include persons unfit for work because of impaired health.

The HWE can be regarded as a form of *selection bias* because workers are selected preferentially on the basis of health status, either by themselves or as a result of job requirements. There are two sources of the HWE: the initial selection of healthier individuals at the time of hire and the survival of healthier individuals among the exposed workers. The latter, healthy worker survivor bias, results from less healthy workers leaving the workforce as well as less healthy workers transferring to jobs with lower exposure(s). Both forms of self-selection can distort the shape of the exposure–response relationship and lead to bias towards the null.

Identifying the Bias

The HWE was originally identified as a feature of cohort mortality studies [6]. In such time-to-event studies, the standardized mortality ratio (SMR) for all causes of death combined provides a convenient measure of the extent to which the bias is operating. By this measure, the HWE has been found to wear off with length of follow-up [8]. This same pattern of rising SMRs with increasing time since hire or length of follow-up has also been consistently observed for specific causes of death, including cardiovascular disease and nonmalignant respiratory and digestive diseases [8]. The increase in the SMR during the time period just after leaving work provides evidence that the HWE is stronger for cardiovascular disease mortality than for cancers [2]. Despite evidence that the HWE also affects cancer mortality rates, particularly in the period close to hire, the lack of consistency in this finding suggests that a weaker bias is operating.

Selection bias due to the healthy worker survivor effect also arises in cross-sectional studies of morbid outcomes and longitudinal studies of recurrent events, although it cannot be as easily identified [3]. The bias is particularly prominent in cross-sectional studies of active workers. In such studies, the undersampling of short-term workers results in a disproportionate number of survivors, i.e. workers who are more resistant to the effects of exposure. This is often found in cross-sectional studies of acute toxicity where the most responsive or sensitive workers are ‘selected out’ of exposure.

By contrast, longitudinal studies with repeated measures of exposure and response over time are frequently used to study the development of chronic conditions by observing changes in a continuous physiological parameter. Like cohort studies, longitudinal studies often involve measures of exposure that vary over time. Time-varying exposures and confounders complicate exposure–response analyses because the inter-relationships between time-dependent variables makes it more difficult to control the HWE. On the other hand, information about changes in exposure over time allows for analytical strategies to address the HWE in ways that are impossible in more limited study designs.

The hypothesis in most studies of time-varying occupational exposures is that past or current exposure affects current health status. However, causality can also move in the reverse direction, with past health status impacting subsequent exposure either via job transfer or leaving work. This reversal in the direction of a causal relationship has been referred to as *feedback*. Feedback is a key feature of the HWE, whereby current exposure and health status may both be affected by past exposure and health status as well as affect subsequent measures.

Over the past 25 years much research has focused on methods to reduce this form of selection bias. This effort has produced a large literature on the topic of the HWE, but the problem has so far proven to be easier to detect than to fix. Several strategies have been proposed to address the HWE in longitudinal studies of time-to-event or repeated measures. The empirical basis of each method and its effectiveness in reducing bias due to selective hire, leaving work,

or job transfer in studies of occupational hazards is described below.

Reducing the Bias

Using an Internal Reference Group

In its simplest form, the HWE is recognizable as a lower mortality risk among an occupational cohort compared to a national or regional reference population. Whether this is viewed as a problem of unmeasured confounding or selection bias, some of the distortion can be eliminated by the selection of a more appropriate comparison group. An unexposed group of workers is needed to avoid unmeasured confounding by health status. An internal analysis that relies on an unexposed, or less exposed, subset of the study population as the reference group will reduce the HWE. This approach will eliminate the component of the bias due to the hiring of healthier workers, since all subjects were similarly hired.

The component of the HWE due to the survival of the healthier workers in the active workforce, however, will not be corrected by the use of an internal reference group. If sicker workers systematically leave work or transfer out of the more highly exposed jobs, the HWE will persist. For example, as described in more detail below, because workers who develop asthma in jobs with high exposure are more likely to leave work or be transferred than workers in jobs with low exposure, comparisons between workers with more and less exposure may result in a negative exposure–response curve even in the presence of a hazard.

Lagging Exposure

Lagging exposure is a method used in cancer epidemiology to account for disease latency by assigning zero weight to exposures that occur in a time period just prior to the observed health event. It has also been proposed as a strategy to reduce the bias caused by selective leaving [7]. The rationale is that recent exposures should be ignored because only the healthiest survivors remain exposed. For example, lagging exposure to arsenic by 10 to 20 years increased the rate ratios for respiratory cancers in a reanalysis of Enterline's cohort study described by Arrighi and Hertz-Picciotto [1].

A similar approach involving exposure weighting was applied to address HWE due to selective job transfer in a reanalysis of a cross-sectional study of asthma with information on date of diagnosis and retrospective exposure information over time [4]. In the original unadjusted analysis, the odds ratio for asthma prevalence was estimated in a **logistic regression** model based on cumulative exposure to metalworking fluids up to the time of the cross-sectional survey. To account for the possibility that workers transfer to lower exposure jobs after developing asthma, zero weight was assigned to exposures that occurred after the reported age of onset. Using a proportional hazards model, exposure was cumulated only up to the age of onset for each case and all subjects in the risk set for that case. In contrast with the unlagged analysis, a significantly elevated incidence rate ratio was observed for synthetic fluid exposure.

Although exposure lagging has effectively reduced the HWE in several instances, this approach has limitations. Lagged exposures cannot be used in studies of acute health effects because the most recent exposures are probably the most biologically relevant. Even in studies of chronic conditions, such as cardiovascular disease, current exposures may continue to exert an effect and exposure lagging may not be a viable option.

Adjusting for Time Since Hire

The HWE, as measured by the SMR for all causes of death combined, declines with increasing time since hire (or length of follow-up) [8]. It follows, as suggested by Fox and Collier [6], that analysis restricted to the subgroup with longer follow-up will be less biased by the HWE. Alternatively, time since hire can be viewed as a simple confounder, i.e. a risk factor for the health outcome in the absence of exposure, and associated with exposure. It then follows that HWE can be addressed using either of the standard methods to control confounding: stratification or inclusion of a marker for the HWE as a covariate in a multiple regression model. The diminished HWE that occurs with increasing time since hire may even occur independent of exposure. Flanders has shown that even when there is no effect, adjusting for time since hire reduces bias [5].

By contrast, the HWE does *not* decline with increasing duration of employment. In fact, it

increases because the healthiest workers manage to remain employed longest. Steenland and Staynor suggested that an explanation for the difference is that duration of employment includes mostly active person years whereas time since hire includes an increasing proportion of inactive person time [12].

Adjusting for Employment Status

Observed mortality rates for workers after leaving employment are double the rates among active employees [12, 13]. Steenland and Staynor have suggested that employment status acts as a negative confounder under the null hypotheses [12]. In this case, the HWE might be reduced by treating employment status (on or off work) as a time-varying confounder and identifying each person year as either one in which the subject was actively working or off work. Based on combined data from 10 cohorts selected by the US National Institute for Occupational Safety and Health, adjustment for employment status reversed the negative trends between duration of exposure and all cause mortality [13].

Adjustment for employment status as a confounder will, however, itself lead to bias if subjects in more highly exposed jobs leave the workforce at a different rate than workers in jobs with less exposure. The bias will occur whether the exposure causes individuals to leave work because it seriously impairs their health (in which case leaving work is an intermediate variable on the causal pathway from exposure to disease) or simply because high-exposure jobs have a higher or lower turnover rate due either to the irritant effects of exposure (say on the eyes) or because more highly exposed jobs are often preferentially lost when economic downturns occur. Steenland et al. simulated data based on two alternative hypotheses: (a) cumulative exposure affects leaving but does not necessarily affect disease, and (b) cumulative exposure also affects disease. Results demonstrated that under either hypothesis, adjusting for confounding by controlling for employment status in the analysis results in bias [13]. Epidemiologists recognize that if a covariate is a confounder it must be controlled for in the analysis to reduce bias. However, we have argued here that when a covariate is also affected by earlier exposure (e.g. the covariate is an intermediate variable on the causal pathway from exposure to disease), controlling for that variable will, in fact, introduce bias.

None of the straightforward approaches described above can adequately address this problem: employment status is likely to act as a confounder and also be influenced by exposure. It is this aspect of HWE, which we refer to as the healthy worker survivor effect, that limits the effectiveness of all the methods reviewed to this point, and provides the motivation for the more analytically complex method of estimation known as G-estimation.

G-estimation

In studies with information on exposure and work status over time, change in work status can both depend on past exposure and affect future exposure. Since being off work is often related to health status as well as exposure, work status (active vs. inactive) can act as a confounder. If high exposure causes workers to preferentially leave work then, as noted above, bias can result whether or not one controls for work status in a standard analysis. G-estimation provides an appropriate adjustment for the effect of a time-varying exposure in the presence of a time-varying confounder, such as employment status, which is influenced by past exposure as well [9–11].

G-estimation is an example of structural equations modeling in which causal structures are integrated into observational data analysis to model causal relationships [9, 10]. The causal models are structural nested failure time models for the effect of a time-dependent exposure on a survival time outcome. The causal parameter is estimated using a semiparametric method by treating the cohort data as a sequential randomized trial in which exposure at time t is randomly assigned, conditional on past exposure and employment history and on baseline variables such as race, gender, age at hire and calendar period of hire.

G-estimation of structural nested failure time models also allows one to estimate the magnitude of the exposure effect. The exposure–response parameter has a direct interpretation as the fraction of years of life lost due to continuous exposure at a unit dose. Robins et al. show how to convert this estimate into an estimate of the causal mortality ratio comparing an always exposed to a never exposed worker population [11]. Thus the method can theoretically be used to provide unbiased estimates of the effect of the cumulative exposure variable typically used in

studies of chronic disease, even in the presence of selection bias due to the healthy worker survivor effect.

In a structural nested failure time model the causal effect of exposure is quantified by contrasting observed outcomes and exposure histories with counterfactual outcomes, e.g. the outcomes exposed subjects *would have had* in the absence of exposure. Although such counterfactual outcomes are not directly observed for exposed workers, under the sequential randomization assumption mentioned above this contrast can be unbiasedly estimated from the available data. Simply compare, at each time t, the subsequent survival experience of each subject at work at time t with other subjects also at work at time t with the same exposure and employment history prior to t but with a different exposure at t. Subjects who are off work at time t are not used in this comparison because less healthy workers preferentially leave work and thus are not comparable to subjects remaining at work. The need for exact matching on past exposure and work history can be overcome by modeling the mean exposure at time t as a function of past exposure and employment history using logistic, polytomous logistic, or least squares regression models depending on whether exposure is dichotomous, polychotomous, or continuous.

In order to apply the G-estimation algorithm, data on whether a worker was actually on or off work at each time t must be available. If, instead, one incorrectly assumes all workers were continuously employed from their date of hire until their date of last employment, when in fact long lay-off periods are common, serious bias may result, regardless of the method of analysis.

G-estimation has been used to estimate the effect of azidothymidine (AZT) on Kaposi's sarcoma, the effect of aerosolized pentamidine on survival in acquired immune deficiency syndrome (AIDS) patients, the effect of smoking cessation on heart disease mortality in the Mr Fit study, the effect of graph vs. host disease on time to recurrence in leukemic patients treated with bone marrow transplantation, and the effect of systolic hypertension on coronary artery disease in the Framingham cohort. To date, however, there has been no successfully completed application of this methodology to the analysis of occupational or environmental cohort data, although several studies are currently underway.

Hepatology

Hepatology is the study of diseases of the liver. These can be mainly classified as hepatitis, hepatocellular carcinoma (or liver cancer), and liver cirrhosis.

Hepatitis

Several distinct infections are included under the generic title of hepatitis. There are many similarities between these different forms of hepatitis, but their epidemiologies and methods of prevention and control vary. These infections are labeled as hepatitis A, B, C, D, and E. Hepatitis D is sometimes called delta hepatitis [3]. Most statistical work has been done on hepatitis A and B, with little on other forms of hepatitis.

Hepatitis A and B occur worldwide. Outbreaks of hepatitis A are patchy and tend to occur in regular cycles. For developed countries disease spreads in day-care centres for children in diapers, to household and sexual contacts of acute cases, intravenous drug users, and travelers to endemic countries. Hepatitis A is spread by the fecal–oral route. Contaminated water supplies, handling and preparation of food by infected foodhandlers, and shellfish have all been responsible for outbreaks. Hepatitis B is endemic with little seasonal variation in incidence. In developed countries such as the US, infection is most common in young adults, whereas in developing countries widespread infection occurs in infancy. Hepatitis B infection is common in certain high risk groups: intravenous drug injectors, promiscuous heterosexuals, male homosexuals, and workers in some health care and public safety occupations. It is spread by infectious blood, saliva, semen, and vaginal fluids.

Hepatitis C is transmitted by infected blood and blood products, and occurs virtually everywhere in the world. It accounts for 15%–40% of community-acquired hepatitis cases. High-risk groups include transfusion recipients, intravenous drugabusers, and dialysis patients. Hepatitis D closely resembles and is often associated with hepatitis B infection. Its mode of transmission is also very similar. Hepatitis E closely resembles hepatitis A in both its clinical symptoms and its epidemiology. The attack rate is highest amongst young adults, especially males.

Hepatitis A

Frösner et al. [8] discussed the decrease in incidence of hepatitis A infections in Germany using serological data. They used a catalytic model (*see* **Communicable Diseases**) with a sigmoidal decrease in the force of infection (*see* **Hazard Rate**). The force of infection fell from 0.04 per year in 1945 to 0.005 per year in 1965. Frösner et al. [9] and Schenzle et al. [23] discussed antibodies against hepatitis A in seven European countries. Prevalence was highest in Greece and France and lowest in Scandinavia. The force of infection had declined almost everywhere in the period leading up to 1979. Keiding [14] considered nonparametric estimation (*see* **Nonparametric Methods**) of the age-specific force of infection applied to serological hepatitis A data for Bulgaria. These data are ideal for statistical **estimation** as they were collected before the advent of mass vaccination. Keiding estimated the proportion of people of different ages who must be vaccinated to eliminate hepatitis A in Bulgaria. Greenhalgh & Dietz [10] extended this work to an age-structured model and vaccination at several different ages. They examined the effect of different mixing patterns on vaccination campaigns.

Hadeler et al. [11, 12] performed a statistical analysis of the outbreaks of hepatitis A in Maricopa County, Arizona. These studies strongly link the spread of hepatitis A in the US to very young children in day-care centres and provide a framework for designing disease control strategies. Sattenspiel [20] developed a matrix-migration model for the spread of hepatitis A in US day-care centers using these results. The theoretical results of Sattenspiel's model were applied to data on the incidence of hepatitis A in Alberquerque, New Mexico, in 1979. Analysis of the data suggested that local clusters were at higher risk for epidemics. Close social ties linked up these centers in small local clusters which helped explain the disproportionate number of cases associated with these centers. Sattenspiel [21] described two stochastic **simulation** models which supported these results. Sattenspiel & Simon [22] pushed the theoretical development of the model further.

Liu [15] considered a differential equation **epidemic model** for hepatitis A where the duration of the **latent period** depends on the number of infectious individuals. He showed that nonlinearity due to a dose-dependent latent period can cause periodicity. This model was compared with US hepatitis data.

Hepatitis B

Hepatitis B infects people worldwide. The highest rates of infection are in sub-Saharan Africa and East Asia. Early mathematical models for hepatitis B were due to Cvetanovic et al. [5] and Pasquini & Cvetanovic [19], who used a compartment model (*see* **Pharmacokinetics and Pharmacodynamics**) in which the host population was stratified clinically and epidemiologically to investigate a variety of control strategies in Mediterranean countries. Anderson & May [1] developed a differential equation model for the spread of hepatitis B. A key feature was that around 1% of infected individuals became carriers and continued to transmit the disease for the rest of their lives. These carriers are an important reservoir of infection and their presence represents a complication for immunization programs. Anderson et al. [2] described a model for the sexual transmission of hepatitis B in developed countries which included heterogeneous mixing with respect to age and sexual activity class. They used this model to assess the effects of vaccination campaigns. The first dynamic model of hepatitis B transmission in developing countries has been developed by McLean & Blumberg [18].

Edmunds et al. [7] discussed the influence of age on the development of the carrier state. A model was fitted to the data using **maximum likelihood**. Infants infected perinatally were found to have a high probability, 0.885, of becoming carriers. Over early childhood there is a sharp decrease in the proportion of infections which lead to the carrier state. By adulthood the probability of becoming a carrier was about 0.1. Implications for vaccination programs were also discussed. Edmunds et al. [6] outlined a deterministic compartmental model to describe the transmission dynamics and control of hepatitis B in the Gambia. The model included a class of carriers. They examined the impact of mass vaccination on the incidence of liver cancer (as carriers have a higher than average chance of developing liver cancer). They used age-structured serological data to estimate parameters. Two models were outlined which assumed that infection in adults was due to horizontal and sexual transmission, respectively.

Cirrhosis

Liver cirrhosis is a chronic disease of the liver, normally suffered by alcoholics, but it can also be caused by chronic hepatitis C infection. Carriers of hepatitis B also have a higher risk of developing cirrhosis [3]. Hepatocellular carcinoma occurs in 10%–25% of cirrhotic patients [17]. The prevalence of cirrhosis in the population is not known exactly. This is partly due to the fact that many cases are clinically silent. Up to 30% or even 40% of cases may be discovered at autopsy, and an unknown proportion remains clinically silent. There may be marked geographical differences in incidence from one country to another, or even between different regions in the same country [16]. Moreover, the proportion of alcoholic and nonalcoholic cirrhosis differs from one country to another, the prevalence of alcoholic cirrhosis being highest generally in wine-producing countries [17].

Hepatocellular Carcinoma

Primary hepatocellular cancer (PHC) or hepatocellular carcinoma (HCC) is recognized worldwide. It is among the most common malignant neoplasms in China, many parts of Asia, and Africa. It is relatively uncommon in the US and Europe. Chronic infection with hepatitis B virus is an important risk factor in most cases; hepatitis C may also be involved. Most patients go through a stage of liver cirrhosis before development of the tumor [3].

Berman [4] and later Higginson [13] called world attention to the extremely high incidence rate of HCC amongst the black male population in Mozambique. From the statistical data from various geographical locations it seems that the greater the incidence rate, the younger the peak age. Among Mozambican males the peak age is between 25 and 34 years, the average age in Japan is 56.8 years in males and 59.9 years in females, and it is higher in Northern Europe [17]. HCC occurs in more advanced ages in alcoholic cirrhosis.

DAVID GREENHALGH

Heritability

Before discussing what genetic heritability is, it is important to be clear about what it is not. For a binary trait, such as whether or not an individual has a disease, heritability is not the proportion of disease in the population attributable to, or caused by, genetic factors. For a continuous trait, genetic heritability is not a measure of the proportion of an individual's score attributable to genetic factors. Heritability is not about cause *per se*, but about the causes of variation in a trait across a particular population.

Definitions

Genetic heritability is defined for a quantitative trait. In general terms it is the proportion of variation attributable to genetic factors. Following a genetic and environmental variance components approach, let Y have a mean μ and variance σ^2, which can be partitioned into genetic and environmental components of variance, such as additive genetic variance σ_a^2, dominance genetic variance σ_d^2, common environmental variance σ_c^2, individual specific environmental variance σ_e^2, and so on.

Genetic heritability in the narrow sense is defined as

$$\frac{\sigma_a^2}{\sigma^2}, \tag{1}$$

while genetic heritability in the broad sense is defined as

$$\frac{\sigma_g^2}{\sigma^2}, \tag{2}$$

where σ_g^2 includes all genetic components of variance, including perhaps components due to epistasis (gene–gene interactions; *see* **Genotype**) [3]. In addition to these random genetic effects, the total genetic variation could also include that variation explained when the effects of measured **genetic markers** are modeled as a **fixed effect** on the trait mean.

The concept of genetic heritability, which is really only defined in terms of variation in a quantitative trait, has been extended to cover categorical traits by reference to a **genetic liability model**. It is assumed that there is an underlying, unmeasured continuous "liability" scale divided into categories by "thresholds". Under the additional assumption that the liability follows a **normal distribution**, genetic and environmental components of variance are estimated from the pattern of associations in categorical traits measured in relatives. The genetic heritability of the categorical trait is then often defined as the genetic heritability of the presumed liability (latent variable), according to (1) and (2).

Comments

There is no unique value of the genetic heritability of a characteristic. Heritability varies according to which factors are taken into account in specifying both the mean and the total variance of the population under consideration. That is to say, it is dependent upon modeling of the mean, and of the genetic and environmental variances and covariances (*see* **Genetic Correlations and Covariances**). Moreover, the total variance and the variance components themselves may not be constants, even in a given population. For example, even if the genetic variance actually increased with age, the genetic heritability would decrease with age if the variation in nongenetic factors increased with age more rapidly. That is to say, genetic heritability and genetic variance can give conflicting impressions of the "strength of genetic factors".

Genetic heritability will also vary from population to population. For example, even if the heritability of a characteristic in one population is high, it may be quite different in another population in which there is a different distribution of environmental influences.

Measurement error in a trait poses an upper limit on its genetic heritability. Therefore traits measured with large measurement error cannot have substantial genetic heritabilities, even if variation about the mean is completely independent of environmental factors. By the definitions above, one can increase the genetic heritability of a trait by measuring it more precisely, for example by taking repeat measurements and averaging, although strictly speaking the definition of the trait has been changed also. A trait that is measured poorly (in the sense of having low **reliability**) will inevitably have a low heritability because much of the total variance will be due to measurement error (σ_e^2). However, a trait with relatively little measurement error will have a high heritability if all the nongenetic factors are known and taken into account in the modeling of the mean.

Fisher [1] recognized these problems and noted that

> whereas ... the numerator has a simple genetic meaning, the denominator is the total variance due to errors of measurement [including] those due to uncontrolled, but potentially controllable environmental variation. It also, of course contains the genetic variance ... Obviously, the information contained in [the genetic variance] is largely jettisoned when its actual value is forgotten, and it is only reported as a ratio to this hotch-potch of a denominator.

Historically, other quantities have also been termed heritabilities, but it is not clear what parameter is being estimated, e.g. Holzinger's $H = (r_{MZ} - r_{DZ})$ (the correlation between monozygotic twins minus the correlation between dizygotic twins) (*see* **Twin Analysis**) [2], Nichol's $HR = 2(r_{MZ} - r_{DZ})/r_{MZ}$ [5], the E of Neel & Schull [4] based on twin data alone, and Vandenburg's $F = 1/[1 - \sigma_a^2/\sigma^2)]$ [6]. Furthermore, the statistical properties of these estimators do not appear to have been studied.

JOHN L. HOPPER

Heterozygosity, Loss of

Loss of tumor suppressor **gene** function has long been implicated as an important event in the onset and progression of cancer. One assay commonly used to define chromosomal regions likely to contain novel tumor suppressor genes is loss of heterozygosity (LOH). LOH compares the chromosomal organization and stability of cells from normal tissues with those from tissues derived from various stages of tumor development, thus highlighting chromosomal regions that may harbor tumor suppressor genes. To date, multiple regions of LOH have been defined for essentially all tumor types, in some situations facilitating our understanding of the function of the underlying genes. For other cancers, however, the delineation of LOH boundaries for tumor subtypes is ongoing as investigators seek to determine the molecular chain of events leading to tumor progression. As characterization of individual tumor suppressor genes progresses, LOH will become a powerful diagnostic tool for clinical assessment of tumor stage and grade.

LOH detects chromosomal deletions within tumor cell populations by comparing allele patterns from a single individual's normal and tumor cells at a set of ordered genetic **markers** referred to as a "**haplotype**." The point at which a pattern changes from two haplotypes, representing the heterozygous state of the normal cell, to a single haplotype, representing the loss of all or part of one chromosomal arm containing a putative cancer gene, is used to define the boundaries of LOH for a single tumor (Figure 1). Historically, one problem associated with precisely defining such boundaries has been a lack of reproducibility across studies. This has been due, in part, to the small numbers of tumors analyzed by many studies, as well as the heterogeneous collections of tumors used. This problem can theoretically be solved by the development of tumor banks featuring large numbers of well-characterized tissues. A bigger concern, however, has been contamination of samples from adjacent, noncancerous tissues, which reduces the quantitative potential of the technique, as well as its ability to detect subtle molecular events. The introduction of laser capture microdissection to isolate virtually pure populations of tumor cells has almost eliminated this problem [11].

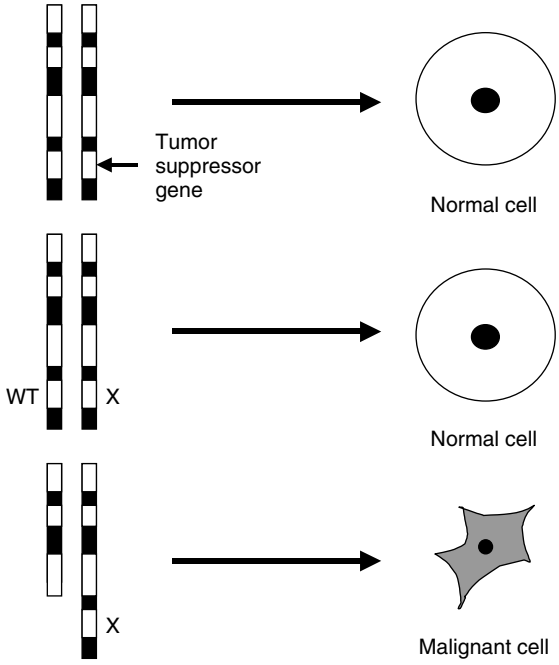

Figure 1 Normal cells require at least one functional copy of a critical tumor suppressor gene to remain noncancerous. When one inherited copy is nonfunctional because of a germ-line inactivation event and the remaining copy is lost as evidenced by LOH, malignancy results. WT: wild-type functional tumor suppressor gene. X: germ-line mutant nonfunctional tumor suppressor gene

Within any study, the utility of LOH for detecting the hierarchy of molecular events leading to disease is limited largely by the number of tumors representing the full range of pathologic stages and grades. Although stratification of data by clinical features of disease may limit overall power to detect rare events, the resulting increase in genetic homogeneity may facilitate detection of important chromosomal regions with statistical significance.

Because of the unique challenges faced in understanding the development of a tumor that is both common in the population and genetically heterogeneous (*see* **Genetic Heterogeneity**), we will consider the example of prostate cancer as we highlight the ways in which LOH can provide novel and useful information towards the identification of genes that drive the initiation, progression, and, ultimately, metastasis of cancer.

An Example: LOH and Prostate Cancer

It is estimated that nearly 198 100 men in the US will be newly diagnosed with prostate cancer, and approximately 31 500 men will die of the disease in 2001 [14]. Hence, identifying the genes responsible for the initiation and progression of the disease is of paramount interest [18]. The epidemiology of prostate cancer is consistent with a multistep process, with the premalignant lesion for most prostatic carcinomas being prostatic intraepithelial neoplasia (PIN) [2]. Autopsy results often reveal microscopic foci of well-differentiated prostate carcinoma, so-called "latent tumors". These tumors appear to be present in over 30% of men in their 60s and upwards of 70% of men in their 80s [3]. These are, in general, microscopic low-grade tumors that may never manifest clinically. The key to understanding prostate cancer, therefore, is to exploit technologies that allow us to understand the genetic differences between latent tumors and those that develop to clinically significant disease.

In the case of prostate cancer, there are several specific chromosomal regions that are frequently highlighted by LOH. One of the most comprehensive studies to date has been that of Saric et al. [20] who compared LOH profiles of 49 high-grade PIN, 22 primary prostate tumors, and 34 metastatic tumor foci using 37 microsatellite markers from 15 chromosomes. Tumor samples were microdissected from paraffin embedded tissues to greater than 75% purity. PIN was identified based on enlarged luminal secretory epithelium, frequently associated with enlarged nucleoli. Primary tumors were included if they were Gleason scores 3–8. Metastatic foci were obtained from 26 autopsies, collecting samples from lymph node, peritoneum, liver, and other tissues. Microsatellite markers were selected to span LOH regions defined by previously published studies, many of which were limited to the examination of only single chromosomes and/or included a heterogeneous mix of tumors. In the resulting analysis, significant levels of LOH were observed at only two regions (5q13–14 and 16q24.2) when considering high grade PIN, 15 regions when analyzing primary tumors, and 20 when metastatic tumors were analyzed. This concurs with results from others describing a relationship between increased genomic instability from PIN to primary cancer [26] and primary tumors to metastases [5]. Interestingly, both of these regions observed in high grade PIN were also lost in either primary or metastatic tumors, and 12 of the 15 LOH events defined in primary tumors (8p12–p21, 8p22, 8p23.1, 10q22–23, 11pter-q13, 16q22.1, 16q24.2, 16q24.3, 16q24, 17p13, 18q23, 21q22.3) were also observed in metastatic tumors.

Using LOH to Select Candidate Genes

Among the most frequently reported regions lost in studies of prostate tumor LOH are chromosomes 11 [6, 23] and 8 [8, 17, 19, 24]. Indeed, using a set of 38 microdissected samples of normal prostatic epithelium and invasive carcinoma, Dahiya and colleagues have described four distinct regions of LOH on chromosome 11, two each on the p and q arms [6]. Among the most interesting candidate genes on 11p is KAI1, which maps to 11p11.2, and has been shown to suppress metastasis when introduced into rat prostate cancer cells. In addition, expression of the gene is reduced in human cell lines derived from metastatic prostate tumors [9, 10]. Not surprisingly, levels of protein are inversely correlated with tumor grade [1]. The percentage of LOH or allelic imbalance at the KAI1 locus in metastatic tissues from autopsy cases is estimated at 70%, compared with 33% for clinically localized cases [16]. All of these studies suggest a key role for KAI1 in metastatic progression of prostate tumors and nicely illustrate the ways in which LOH can be used to map and subsequently enhance our understanding of tumor suppressor biology. Particular **candidate genes** have been investigated as a follow-up to many other regions of LOH. A comprehensive listing of such genes is included in a recent review by De Marzo et al. [7].

Most LOH studies to date have focused on a limited number of chromosomes. To best utilize the technique, high density, genome-wide scans of 300–400 markers are needed. At least one such study should include tumors derived from high-risk families of the type currently being used in genome-wide scans aimed at mapping prostate cancer susceptibility loci [13, 21, 22]. Given the apparent heterogeneity of prostate cancer, a comparison of potential germline and somatic events may prove useful for finding genes important in disease etiology. Indeed, Xu et al. have recently reported **linkage** to 8p22–23 in a set of 159 high-risk prostate cancer families [25]. Chromosome 8 is arguably the most frequently reported region of LOH for prostate

tumors [8, 17, 19, 24], with some studies reporting as many as 50% of tumors showing loss of all or part of the chromosome [17]. Joint analysis of representative data sets is clearly needed. In addition, comparing regions of frequent LOH from prostate tumors with other hormonally influenced tumors, such as breast and ovarian, may lend further insight to the existence of generalized tumor suppressor genes important in multiple hormonally regulated tissues. Several such regions have already been reported [4, 12, 15], suggesting some commonality between different tumor types.

Summary

LOH has been and continues to be one of the most important tools available for assessing genes important in cancer. The utility of the technique is limited only by characterization of the samples to which it is applied. Given the current abilities to isolate, purify, and characterize tumors, there is great potential for LOH to further inform us about tumor etiology.

HAWKINS B. DE FRANCE &
ELAINE A. OSTRANDER

Heterozygosity

Genes can exist in different allelic forms and there are several ways to quantify the degree of allelic variation in a population. One way is simply to report the frequencies of the different alleles. Other parameters are used to address specific genetic questions. Individuals with two different alleles for some gene are said to be heterozygous for that gene, whereas those with two alleles that are the same are homozygous. The continued existence of heterozygotes implies continued genetic variation, and there have been several reports of correlation between growth rate and heterozygosity (see [2]).

If a gene has alleles a_i, then the frequencies of **genotypes** $a_i a_i$ and $a_i a_j$, $j \neq i$, are written as P_{ii} and P_{ij}, and the frequency of allele a_i is written as p_i. For large random mating populations, the **Hardy–Weinberg** law states that

$$P_{ii} = p_i^2,$$
$$P_{ij} = 2p_i p_j, \quad i \neq j.$$

When it is of interest to be able to quantify H, the total frequency of heterozygotes, under the Hardy–Weinberg situation this requires only the following allele frequencies:

$$\begin{aligned} H &= \sum_i \sum_{j \neq i} P_{ij} \\ &= \sum_i \sum_{j \neq i} p_i p_j \\ &= 1 - \sum_i p_i^2. \end{aligned}$$

This last expression is often referred to as *heterozygosity*, but this is a misnomer since it provides the frequency of heterozygotes only under Hardy–Weinberg equilibrium. It is more appropriate to define "gene diversity" D by

$$D = 1 - \sum_i p_i^2.$$

For populations with an **inbreeding** coefficient of f, heterozygote frequencies are modified to

$$P_{ij} = 2p_i p_j (1 - f),$$

so that

$$H = (1 - f)D.$$

The most likely cause of a difference between H and D in human populations is population **admixture**. If a proportion α_k of the population belongs to subpopulation k, in which frequencies for alleles a_i are p_{ki}, then the frequency of $a_i a_{i'}$ heterozygotes in the whole population is

$$P_{ii'} = 2p_i p_{i'} + \sum_k \alpha_k (p_{ki} - p_i)(p_{ki'} - p_{i'}),$$

where the total allele frequencies are given by

$$p_i = \sum_k \alpha_k p_{ki}.$$

This result assumes Hardy–Weinberg frequencies within each subpopulation. There may be more or less of a particular heterozygote than expected from the Hardy–Weinberg law in the whole population, although the overall heterozygosity is diminished:

$$H = D - \sum_i \sum_k \alpha_k (p_{ki} - p_i)^2.$$

In linkage studies it is necessary to determine whether or not recombination has occurred between two loci, and this in turn puts constraints on the genotypes of individuals in successive generations. The **polymorphism information content** (PIC) characterizes the extent to which a marker gene (*see* **Genetic Markers**) is useful for linkage studies, with higher values being better. It cannot be greater than H.

Variance of Heterozygosity

If sample allele and genotype frequencies are written as $\tilde{p}_i$ and $\tilde{P}_{ij}$, the sample heterozygosity is

$$\tilde{H} = \sum_i \sum_{j \neq i} \tilde{P}_{ij}.$$

Taking expectation $\mathcal{E}$ over repeated samples of n individuals from the same population, assuming genotype counts are **multinomially distributed**, provides

$$\mathcal{E}(\tilde{H}) = H,$$

whereas the expected value of sample diversity,

$$\tilde{D} = 1 - \sum_i \tilde{p}_i^2,$$

is

$$\mathcal{E}(\tilde{D}) = \left(1 - \frac{1+f}{2n}\right) D$$

The variance over repeated samples from the same population is just the **binomial** variance for $\tilde{H}$,

$$\text{var}(\tilde{H}) = \frac{1}{n} H(1-H),$$

whereas for diversity [3],

$$\text{var}(\tilde{D}) = \frac{2(1+f)}{n}\left[\sum_i p_i^3 - \left(\sum_i p_i^2\right)^2\right].$$

If heterozygosity is averaged over loci, then the variance of the average depends on two-locus heterozygosities. If $H_{ll'}$ is the probability of an individual being heterozygous at loci l and l', then the sample single-locus heterozygosities are correlated:

$$\text{cov}(\tilde{H}_l, \tilde{H}_{l'}) = \frac{1}{n}(H_{ll'} - H_l H_{l'}),$$

so that the variance within populations of heterozygosity averaged over m loci is

$$\text{var}(\tilde{H}) = \frac{1}{nm^2}\sum_l H_l(1-H_l) + \frac{1}{nm^2}\sum_l \sum_{l' \neq l} (H_{ll'} - H_l H_{l'}).$$

Brown et al. [1] pointed out that the two-locus heterozygosity depends on **linkage disequilibrium** between the loci, and the variance of average single-locus heterozygosity therefore serves as a summary statistic for linkage disequilibrium. The same holds for average gene diversity.

Hidden Markov Models

Hidden Markov models (HMMs) are a class of stochastic models that have proven to be useful in a wide range of applications for modeling highly structured sequences of data. Some applications of HMMs include machine speech recognition [15], ion channel kinetics [9, 10], and biomolecular sequence analysis [1, 4–6, 8] (*see* **DNA Sequences**).

A hidden Markov model can be viewed as a black box that generates sequences of observations. The unobservable internal state of the box is stochastic and is determined by a finite state **Markov chain**. The observable outputs of the black box are stochastic, with distribution determined by the current state of the hidden Markov chain. In more detail, let $(s_t, t = 0, 1, 2, \ldots)$ be an unobserved Markov chain on the state space $(1, 2, \ldots, L)$ and let $(y_t, t = 0, 1, 2, \ldots)$ be an observed process that takes values in the set $(1, 2, \ldots, K)$. The restriction to discrete observations is not essential but it is adequate for the applications considered here.

There are three inference problems that arise in the development or application of hidden Markov models: **estimation** of model parameters, restoration of the hidden states, and model selection (*see* **Model, Choice of**). In this article we define an HMM as a stochastic model that generates sequences of observations, provide examples of HMMs that are used in applications, and discuss approaches to the first two inference problems.

Model Specification

An HMM with L hidden states and K observable outputs is specified by three sets of distributions. First is the *initial distribution* of the hidden Markov chain

$$\Pr(s_0 = i), \quad i \in \{1, \ldots, L\}. \tag{1}$$

Second is the *transition distribution* of the hidden Markov chain as represented by the $L \times L$ matrix $\mathbf{\Lambda} = [\lambda_{ij}]$ with elements

$$\lambda_{ij} = \Pr(s_{t+1} = j | s_t = i), \quad i \in \{1, \ldots, L\}, \quad j \in \{1, \ldots, L\}. \tag{2}$$

Third is the set of *output distributions* of the hidden states as represented by the $L \times K$ matrix $\mathbf{\Pi} = [\pi_{ij}]$ with elements

$$\pi_{ij} = \Pr(y_t = j | s_t = i), \quad i \in \{1, \ldots, L\}, j \in \{1, \ldots, K\}. \tag{3}$$

Both of the matrices $\mathbf{\Lambda}$ and $\mathbf{\Pi}$ are stochastic, i.e. they are formed by nonnegative numbers and their row sums are equal to one. Thus the parameter $\boldsymbol{\theta} \equiv (\mathbf{\Lambda}, \mathbf{\Pi})$ takes values in a compact set Θ which is a direct product of L L-dimensional and L K-dimensional simplexes.

Models with continuous output distributions can be developed by replacing the probability mass function in (3) with an appropriate density function, e.g. **normal**. With some minor modifications, the results below can be applied to continuous data.

The number of hidden states and their connectivity, i.e. the set of nonzero λ_{ij}, define the *architecture* of an HMM. The choice of an architecture is typically driven by an application for which the HMM is intended. In some cases the architecture is an attempt to model a physical system (e.g. ion channels) and in other cases the HMM is merely a convenient fiction that is useful for **classification** or **prediction** (e.g. speech recognition). The states of the hidden Markov chain may be recurrent or transient. It is worthwhile to consider two classes of architectures. First is the *recurrent* architecture in which any hidden state may be reached from any other hidden state. Second is the *left-to-right* architecture, in which the hidden states are transient. Of course, arbitrarily complex HMMs can be constructed with both recurrent and nonrecurrent components.

It is often convenient to consider transient chains and to introduce two states *begin* (B) and *end* (E) that do not produce any output. Without loss of generality we assume that the initial distribution is concentrated in the state B. Thus $\Pr(s_0 = \mathrm{B}) = 1$. The state transition matrix $\mathbf{\Lambda}$, whose dimension becomes $(L + 2) \times (L + 2)$, is modified as follows:

1. The state B is unattainable from any state including itself; $\lambda_{i\mathrm{B}} = 0$, for all i.
2. State E is absorbing, so that $\lambda_{\mathrm{EE}} = 1$ and is recurrent, so there is a stopping time $n^* = \min(k : s_k = \mathrm{E}, k \geq 0)$ such that $\Pr(n^* \leq \infty) = 1$.
3. The direct transition from state B to state E is not allowed; $\lambda_{\mathrm{BE}} = 0$.

Introduction of the absorbing state E allows us to deal with finite realizations of the HMM up to the

stopping time n^*. We put $n = n^* - 1$ and use the following notation for the sequence of hidden states and the corresponding sequence of outputs

$$\mathbf{s} \equiv s_1 s_2 \ldots s_n,$$

$$\mathbf{y} \equiv y_1 y_2 \ldots y_n.$$

The states $s_0 = \mathrm{B}$ and $s_{n+1} = \mathrm{E}$ will be suppressed in the notation, except where they are explicitly needed below.

Suppose we observe N independent realizations of an HMM and denote the set of observed outputs by

$$\mathbf{Y} \equiv \left\{ \begin{array}{l} \mathbf{y}_1 = y_{1,1} y_{1,2} \ldots, y_{1,n_1} \\ \vdots \quad \vdots \\ \mathbf{y}_N = y_{N,1} y_{N,2} \ldots, y_{N,n_N} \end{array} \right\}.$$

The sequences of paths through the hidden Markov chain that produced $\mathbf{Y}$ will be denoted by

$$\mathbf{S} \equiv \left\{ \begin{array}{l} \mathbf{s}_1 = s_{1,1} s_{1,2} \ldots, s_{1,n_1} \\ \vdots \quad \vdots \\ \mathbf{s}_N = s_{N,1} s_{N,2} \ldots, s_{N,n_N} \end{array} \right\}.$$

In this formulation there is a one-to-one correspondence between the states of the hidden Markov chain and the elements of the observed sequence. The model can be generalized to include null states (other than B and E). Null states may be visited by the hidden Markov chain but do not produce any observable output.

Hidden Markov models can have large parameter spaces because there may be many possible state transitions and because each state can have its own unique output distribution. Depending on the application, it may be desirable to allow all nonzero parameter values to vary freely. At the other extreme, we may require that some subsets of parameters take identical values. Constraints of this type are referred to as "tied" parameterizations. A less extreme form of combining information can be achieved by imposing a hierarchical model on the parameters in which sets of parameter values are assumed to be drawn from a common distribution [7, 19].

There are known **identifiability** problems with the recurrent HMM model due to the labeling of the states, and some convention for state labeling is needed. There can also be identifiability problems if the output distributions in different states are not distinct. These issues are discussed by Leroux [15]. We note that, for the two-state model, identifiability problems also arise when $\lambda + \mu = 1$. This result suggests that further investigation into the identifiability of HMMs may be worthwhile.

Examples of HMMs

Finite-State Recurrent Architecture

Consider a hidden Markov chain with two main states denoted by 0 and 1. The two-state recurrent architecture is illustrated in Figure 1. Its transition probability matrix, defined on the extended state space (B, 0, 1, E), is

$$\mathbf{\Lambda} = \begin{bmatrix} 0 & \lambda_{\mathrm{B}0} & \lambda_{\mathrm{B}1} & 0 \\ 0 & \lambda_{00} & \lambda_{01} & \lambda_{0\mathrm{E}} \\ 0 & \lambda_{10} & \lambda_{11} & \lambda_{1\mathrm{E}} \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

For the case of binary (0, 1) data sequences, the output distribution is given by

$$\mathbf{\Pi} = \begin{bmatrix} \pi_{00} & \pi_{01} \\ \pi_{10} & \pi_{11} \end{bmatrix}.$$

This HMM generates nonhomogeneous binary sequences that consist of homogeneous regions of two types, with distinct frequencies of zeros and ones. This model and the more general L-state, K-output recurrent model were applied by Churchill [4, 5] to identify regions with distinct functions in DNA sequences based on differences in local base frequencies.

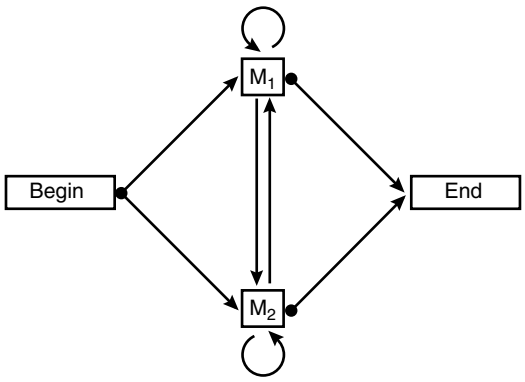

Figure 1 Two-state recurrent HMM architecture

Left-to-Right Architectures

An example of a left-to-right architecture is shown in Figure 2. Left-to-right models are used in applications to speech recognition as "word" models. Each state has an output distribution that characterizes part of the acoustic signal that defines a word. The state transitions follow the evolution of the word from left to right and allow for compression or expansion of the duration of the signal over time. Collections of word models can be nested inside a larger HMM for purposes of word classification and recognition. Further details and references on HMM applications to speech recognition can be found in [13].

Biomolecular Models

Another example of a left-to-right architecture is the mutation–deletion–insertion (MDI) model shown in Figure 3. The MDI model has become a very popular tool for the problem of aligning multiple DNA or protein sequences [1, 14]. In this model, there are three different types of states. The backbone of the model consists of *mutation* states ($M_1, M_2, \ldots, M_L$). Each mutation state M_i has a corresponding *deletion* state D_i. Following the state B there is an *insertion* state I_0, and following each of the mutation states M_i there is an insertion state I_i. There are two sets of output distributions in the MDI model. Outputs from M-states are generated according to $\Pr(j|M_i)$. These distributions will typically vary from state to state and reflect the position-specific frequencies of nucleotide or amino acid subunits as they occur along the length of a molecule. Outputs from I-states are generated according to $\Pr(j|I_i)$. These states allow for site-specific insertion of letters into the sequence. The D-states are silent and do not produce any output. These states allow specific positions (modeled by M-states) to be skipped in the generation of an output sequence. The length of an output sequence will typically be close to the number of M-states in the model, but any realization may be shorter or longer due to insertion and deletion events.

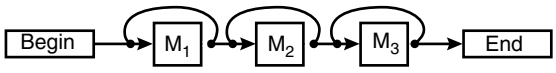

Figure 2 A simple left-to-right HMM architecture

The presence of silent states in the MDI model introduces a minor complication into our description of these HMMs. It was implicit in our earlier definition of an HMM that there is a one-to-one correspondence between outputs and hidden states. However, in the MDI model, as it is typically implemented, there may be hidden states (D-states) that are visited but have no corresponding output. Thus the length of **y** may be less than the length of the corresponding hidden state sequence **s**. We note that the output of an MDI model can be viewed as the

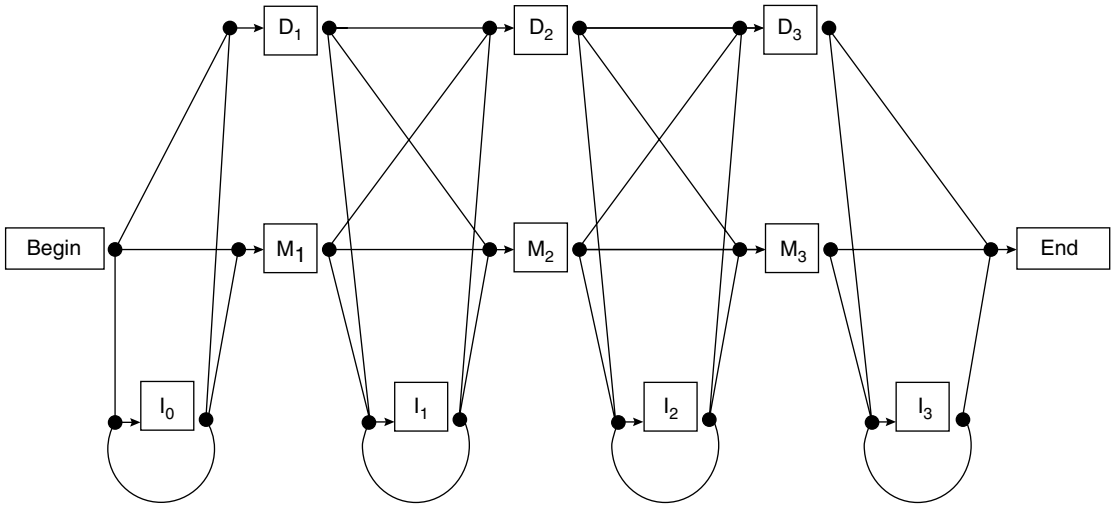

Figure 3 Mutation–deletion–insertion (MDI) architecture with three M-states

output of a standard HMM consisting of only M-states and I-states. This MI chain is embedded within the MDI chain and can be constructed by simply removing the D-states. The architecture of the MI chain includes additional transitions to replace the removed D-states. Unfortunately the additional transition parameters must be constrained in a rather complicated fashion to recover exactly the original MDI model. The output distributions of the MI model are identical to those of the MDI model. It follows that results derived for standard HMMs apply equally to MDI models.

A hidden Markov model has been developed for the problem of DNA sequence assembly [6, 7]. We consider a collection of DNA sequences (see Table 1) that are independently copied from a common *prototype* sequence, $\mathbf{r} = r_1, \ldots, r_L; r_i \in$ (A,C,G,T), by a process that introduces errors in the form of *substitutions, deletions*, and *insertions*. Each realization, $i = 1, \ldots, N$, of the MDI chain will generate a sequence $\mathbf{y}_i$ with elements $y_{ij} \in$ (A,C,G,T,N). The output character N is sometimes generated by DNA sequencing devices to represent ambiguous determination of a base. Each M-state in the MDI chain is associated with an element of the prototype sequence, i.e. M_i is associated with r_i. This association will determine the output distribution of the M-state. For example, if the state M_i is associated with $r_i = \mathrm{A}$, the most likely output of state M_i is the letter A. A substitution error occurs when the output is a letter other than A. A deletion error occurs when the state D_i is visited, thus bypassing M_i, and no letter is generated as output. An insertion error occurs when the state I_i is visited, thus generating extraneous letters in the output sequence. To summarize, a visit of the D_i-state results in a deletion of r_i in the copying process; k successive visits of the I_i-state result in an insertion of k letters after the ith position in the prototype; a visit of the M_i-state results in copying r_i, with possible substitution error.

The output from N realizations of an MDI chain will be a set of sequences of letters. The sequences will generally be similar to one another but may vary in length as well in the identity of specific letters. Often the goal of applying an MDI model to a sequence is to restore the hidden state sequence. Restoration of $\mathbf{s}_i$ establishes a correspondence between the elements of $\mathbf{y}_i$ and the states of the MDI model. Furthermore, the multiple path restoration of $\mathbf{S}$ establishes a correspondence among all elements of all the DNA sequences via their correspondence with the M-states. This correspondence is a *multiple sequence alignment* [21]. An example of an HMM-generated sequence alignment of the DNA sequences from Table 1 is shown in Figure 4.

Inference for HMMs

Likelihood

In this section, we describe an **algorithm** to compute the **likelihood** of an observed sequence $\mathbf{y}$, i.e. $\Pr(\mathbf{y}|\boldsymbol{\theta})$. In the case of multiple independent observations, the likelihood is simply the product $\Pr(\mathbf{Y}|\boldsymbol{\theta}) = \prod_{i=1}^{N} \Pr(\mathbf{y}_i|\boldsymbol{\theta})$.

We can express the likelihood as a summation over all possible hidden state sequences

$$\Pr(\mathbf{y}|\boldsymbol{\theta}) = \sum_{s} \Pr(\mathbf{y}|\mathbf{s},\boldsymbol{\Pi}) \Pr(\mathbf{s}|\boldsymbol{\Lambda}), \tag{4}$$

where

$$\Pr(\mathbf{y}|\mathbf{s},\boldsymbol{\Pi}) = \pi_{s_1,y_1} \cdot \pi_{s_2,y_2} \ldots \pi_{s_n,y_n} \tag{5}$$

and

$$\Pr(\mathbf{s}|\boldsymbol{\Lambda}) = \lambda_{\mathrm{B}s_1} \cdot \lambda_{s_1 s_2} \ldots \lambda_{s_n \mathrm{E}}. \tag{6}$$

However, this summation is generally intractable, and an alternative approach is needed to compute the likelihood.

The likelihood can also be written in the form

$$\begin{aligned} \Pr(\mathbf{y}|\boldsymbol{\theta}) &= \prod_{t=1}^{n} \Pr(y_t|\mathbf{y}^{t-1}) \\ &= \prod_{t=1}^{n} \sum_{s_t=1}^{L} \Pr(y_t|s_t) \Pr(s_t|\mathbf{y}^{t-1}), \end{aligned} \tag{7}$$

where $\mathbf{y}^{t-1} = y_1, \ldots, y_{t-1}$. We assume that the distribution of y_t depends only on s_t. The first term in (7) is the output distribution and the second term is the predictive density. The predictive density can be computed using the *forward pass algorithm*. This algorithm is the basis for a number of other computations and is presented here.

The Forward Pass Algorithm. To begin, suppose that $\Pr(s_{t-1}|\mathbf{y}^{t-1})$ is known. A prediction of the state

Figure 4 A multiple sequence alignment of the DNA sequences in Table 1. The alignment was generated using an MDI architecture with 52 M-states. Letters aligned in each column correspond to the same M-states. Insertions are shown above the main sequence and deletions are shown as dashes. An estimated consensus or prototype sequence is shown below the multiple alignment

at time t can be computed, using the law of total probability, as

$$\Pr(s_t|\mathbf{y}^{t-1}) = \sum_{s_{t-1}=1}^{L} \Pr(s_t|s_{t-1}, \mathbf{y}^{t-1}) \times \Pr(s_{t-1}|\mathbf{y}^{t-1}). \quad (8)$$

This conditional distribution is called the *predictive density*. Next, the information in the current observation is incorporated by updating the predictive density. The so-called *filtered density* is

$$\Pr(s_t|\mathbf{y}^t) = \frac{\Pr(y_t|s_t, \mathbf{y}^{t-1}) \Pr(s_t|\mathbf{y}^{t-1})}{\Pr(y_t|\mathbf{y}^{t-1})}, \quad (9)$$

by **Bayes' theorem**, where

$$\Pr(y_t|\mathbf{y}^{t-1}) = \sum_{s_t=1}^{L} \Pr(y_t|s_t, \mathbf{y}^{t-1}) \Pr(s_t|\mathbf{y}^{t-1}).$$

Restoration of the Hidden Markov Chain

The problem of restoring the hidden state sequence $\mathbf{s}$ from a given observation sequence $\mathbf{y}$ is addressed here. We assume that the model parameters $\boldsymbol{\theta}$ are given and suppress $\boldsymbol{\theta}$ in the notation of this section.

There are two general approaches to the state restoration problem. A local restoration uses the marginal conditional densities to find the most probable state at each point t. This marginal restoration is given by

$$s_{i,t}^* = \text{argmax}_{s_t} \Pr(s_t|\mathbf{y}_i).$$

A global restoration maximizes the full conditional density to find a most probable restoration. Thus,

$$\mathbf{s}_t^* = \text{argmax}_s \Pr(\mathbf{s}|\mathbf{y}_i).$$

These two approaches can result in quite different solutions. The first problem is solved using the *backward algorithm* and the second is solved using the *Viterbi algorithm* [20].

The Backward Algorithm. The backward algorithm uses the results of the forward algorithm to compute the conditional distribution of the hidden state sequence given the complete sequence of

observed data. It is sufficient to specify the distribution of pairs of adjacent states because we assume the Markov property.

The joint distribution of two adjacent states is computed recursively, starting with the last step of the forward algorithm

$$\Pr(s_t, s_{t+1}|\mathbf{y}) = \frac{\Pr(s_{t+1}|\mathbf{y}) \Pr(s_{t+1}|s_t) \Pr(s_t|\mathbf{y}^t)}{\Pr(s_{t+1}|\mathbf{y}^t)}$$

The marginal distribution can be obtained by summing the expression over s_{t+1}. Thus

$$\Pr(s_t|\mathbf{y}) = \Pr(s_t|\mathbf{y}^t) \sum_{s_{t+1}=1}^{L} \frac{\Pr(s_{t+1}|\mathbf{y}) \Pr(s_{t+1}|s_t)}{\Pr(s_{t+1}|\mathbf{y}^t)}.$$

See Rabiner [17] or Churchill [4] for more detail.

The Viterbi Algorithm. Our goal is to find the sequence of states $\mathbf{s}$ that maximizes over the space of all state sequences the conditional probability of $\mathbf{s}$ given the observation sequence $\mathbf{y}$ and known model parameters. Notice that

$$\Pr(\mathbf{s}|\mathbf{y}) = \frac{\Pr(\mathbf{s}, \mathbf{y})}{\Pr(\mathbf{y})}, \tag{10}$$

and thus it is sufficient to find the sequence of states which maximizes $\Pr(\mathbf{s}, \mathbf{y})$.

The joint probability can be factored as

$$\begin{aligned}\Pr(\mathbf{s}, \mathbf{y}) &= \prod_{t=1}^{n} \Pr(s_t, y_t|\mathbf{s}^{t-1}, \mathbf{y}^{t-1}) \\ &= \prod_{t=1}^{n} \Pr(y_t|\mathbf{s}^t, \mathbf{y}^{t-1}) \Pr(s_t|\mathbf{s}^{t-1}, \mathbf{y}^{t-1}) \\ &= \prod_{t=1}^{n} \Pr(y_t|s_t) \Pr(s_t|s_{t-1}). \end{aligned} \tag{11}$$

Let $\delta_t(i)$ denote the maximum probability up to time t over all state sequences which end at the state $s_t = i$,

$$\delta_t(i) = \max_{s^{t-1}} \Pr(\mathbf{s}^{t-1}, s_t = i, \mathbf{y}^t). \tag{12}$$

The joint probability, (11), can be maximized by the following procedure:

1. initialization,

$$\delta_1(i) = \Pr(s_1 = i) \Pr(y_1|s_1 = i), 1 \le i \le r; \tag{13}$$

2. recursion,

$$\delta_t(j) = \max_{1 \le i \le r} [\delta_{t-1}(i)\lambda_{ij}] \Pr(y_t|s_t = j); \tag{14}$$

3. termination,

$$\max_{\mathbf{s}} \Pr(\mathbf{s}, \mathbf{y}) = \max_{1 \le i \le r} \delta_n(i). \tag{15}$$

We are asking at each time point t, if the present state is $s_t = j$, which state at time $t - 1$ maximizes the joint probability over all past state sequences. Roughly, if we are in state j at time t, where did we come from at time $t - 1$?

For each state $1 \le j \le r$ at time t we wish to keep track of the state at time $t - 1$ which gives us the maximum. To do this, we define the quantity

$$\psi_t(j) = \arg \max_{1 \le i \le r} [\delta_{t-1}(i)\lambda_{ij}]. \tag{16}$$

When the process is terminated, we have computed $\delta_n(i)$ and $\psi_n(i)$ for $1 \le i \le r$. A state sequence which attains the maximal probability can be constructed by a traceback. Let

$$s_n^* = \arg \max_{1 \le i \le r} [\delta_n(i)] \tag{17}$$

be the best final state. The traceback is completed by the recursion

$$s_t^* = \psi_{t+1}(s_{t+1}^*), \ t = n - 1, \ n - 2, \ldots, 1. \tag{18}$$

Note that $\delta_t(j) \to 0$ fast. Thus computations are more easily executed on a log scale. The recursion, (13), will look like

$$\begin{aligned}\log \delta_t(j) = &\max_{1 \le i \le r} [\log \delta_{t-1}(i) + \log \lambda_{ij}] \\ &+ \log \Pr(y_t|s_t = j). \end{aligned} \tag{19}$$

Parameter Estimation

In the **maximum likelihood** approach to HMM restoration, no prior information on the parameter θ is assumed and the inference problems of parameter estimation and state restoration are addressed by first finding an estimator for $\boldsymbol{\theta}$ and then restoring $\mathbf{S}$ conditionally given the estimated value.

In general, the likelihood is intractable for direct maximization. However, given a state sequence $\mathbf{S}$, the augmented data likelihood,

$$\Pr(\mathbf{Y}, \mathbf{S}|\boldsymbol{\theta}) = \prod_{i=1}^{N} \Pr(\mathbf{y}_i, \mathbf{s}_i|\boldsymbol{\theta}) = \prod_{i=1}^{N} \Pr(\mathbf{y}_i|\mathbf{s}_i, \boldsymbol{\Pi}) \Pr(\mathbf{s}_i|\boldsymbol{\Lambda}), \quad (20)$$

is quite well behaved. The problem of maximizing the augmented data likelihood is trivial. The augmented data **sufficient statistics** for this problem are matrices $\mathbf{C}^{\boldsymbol{\Lambda}} \equiv [c_{ij}^{\boldsymbol{\Lambda}}]$ and $\mathbf{C}^{\boldsymbol{\Pi}} \equiv [c_{ij}^{\boldsymbol{\Pi}}]$, where $c_{ij}^{\boldsymbol{\Lambda}}$ is the number of transitions to the j-state from the i-state and $c_{ij}^{\boldsymbol{\Pi}}$ is the number of outputs j from state i. When some parameter values are tied, the dimensions of the sufficient statistics can be reduced.

The problem of maximizing the observed data likelihood is solved by the *Baum–Welch* algorithm [2, 3, 17]. An initial estimate $\boldsymbol{\theta}^0$ is chosen. The algorithm iterates the following steps:

1. Use the forward and backward algorithms to compute the conditional expectation of $\mathbf{C}^{\boldsymbol{\Lambda}}$ and $\mathbf{C}^{\boldsymbol{\Pi}}$ with respect to $\Pr(\mathbf{S}|\mathbf{Y}, \boldsymbol{\theta}^m)$.
2. Use the expected sufficient statistics from step 1 to obtain a new estimate $\boldsymbol{\theta}^{m+1}$. The MLEs for $\boldsymbol{\Pi}$ and $\boldsymbol{\Lambda}$ are simply the row-normalized expectations of $\mathbf{C}^{\boldsymbol{\Lambda}}$ and $\mathbf{C}^{\boldsymbol{\Pi}}$, respectively.

As $m \to \infty$ the sequence of parameter estimates $\boldsymbol{\theta}^m$ will converge to a point of maximum, not necessarily global, of the likelihood function [3, Eq. (4)]. HMM likelihoods can be multimodal, and thus it is recommended to try several starting values for the estimation algorithm.

From a computational point of view the first step can be carried out in time proportional to $N \times L^2 \times$ (average sequence length) and the estimator in step 2 can be obtained in closed form. However, the implementation can be rather tedious and in many applications a *modified* version, called the segmental k-means algorithm [12], is used. Step 1 is replaced by:

1. Obtain a most probable path $\mathbf{s}_i^{m+1} = \operatorname{argmax}_{\mathbf{s}} \Pr(\mathbf{s}|\mathbf{y}_i, \boldsymbol{\theta}^m)$ for each $i = 1, \ldots, N$.
2. Obtain a new estimate $\boldsymbol{\theta}^{m+1}$ that maximizes the augmented data likelihood $\Pr(\mathbf{Y}, \mathbf{S}^{m+1}|\boldsymbol{\theta})$.

The first step can be accomplished by dynamic programming [20], and a closed-form estimator is available for step 2. This algorithm produces an estimator $\tilde{\boldsymbol{\theta}}$ that maximizes the objective function $\max_{\mathbf{s}} \Pr(\mathbf{y}, \mathbf{s}|\boldsymbol{\theta})$. Although this is not a maximum likelihood estimator, the two estimators will generally be very similar [16].

Having obtained some parameter estimate $\boldsymbol{\theta}^*$, we can restore $\mathbf{S}$ using either of the methods in the section, "Restoration of the Hidden Markov Chain".

A Bayesian Approach

A weakness of the likelihood approach to the state restoration problem is that the final solution is based on the point estimator of $\boldsymbol{\theta}$ and fails to take into account other "reasonable" values of $\boldsymbol{\theta}$. Furthermore, it may be of interest to find not only an *optimal* multiple path but also to have access to reasonable alternative restorations. These concerns motivate a **Bayesian** approach to the state restoration problem.

We assume a **prior distribution** $P_0(\boldsymbol{\theta})$ for the parameter $\boldsymbol{\theta} \equiv (\boldsymbol{\Lambda}, \boldsymbol{\Pi})$ so that the posterior distribution of the pair $(\mathbf{S}, \boldsymbol{\theta})$ is

$$\Pr(\mathbf{S}, \boldsymbol{\theta}|\mathbf{Y}) \propto P_0(\boldsymbol{\theta}) \prod_{i=1}^{N} \Pr(\mathbf{y}_i|\mathbf{s}_i, \boldsymbol{\Pi}) \Pr(\mathbf{s}_i|\boldsymbol{\Lambda}), \quad (21)$$

where the last two terms are defined in (5) and (6), respectively. Integrating out the parameter $\boldsymbol{\theta}$ in (21) we obtain the marginal posterior $\Pr(\mathbf{S}|\mathbf{Y})$, which will be our primary interest. Similarly, summing over all multiple paths, we obtain the marginal posterior of $\Pr(\boldsymbol{\theta}|\mathbf{Y})$. These marginal posterior distributions are not practically computable, in part because of unassessable normalizing constants.

Two slightly different solutions have been proposed for this problem. Both approaches use a Gibbs sampler (e.g. [11]) to approximate the desired posterior distributions (*see* **Markov Chain Monte Carlo**). The Gibbs sampler alternately generates random samples from the full conditional distributions $\Pr(\mathbf{s}|\mathbf{y}, \boldsymbol{\theta})$ and $\Pr(\boldsymbol{\theta}|\mathbf{y}, \mathbf{s})$. In Robert et al. [18] the hidden state sequence is sampled elementwise. In Churchill & Lazareva [7], the full sequence is sampled in one step at each iteration of the Gibbs sampler. Sampling of $\boldsymbol{\theta}$ is trivial when conjugate Dirichlet or Dirichlet mixture priors are used (*see* **Loglinear Model**).

Summary

Hidden Markov models provide a powerful class of models that can be applied to analyze data that consist of sequences of dependent observations with an underlying heterogeneous structure. The inference problems of parameter estimation and state restoration can be addressed using algorithms described in this article, but many subtle and difficult issues may arise in any particular application. The widespread use and success of hidden Markov models in speech recognition and molecular sequence analysis suggest that there may be many fruitful areas of application to which these methods can be applied.

GARY A. CHURCHILL

Hierarchical Models in Genetics

A problem with the evaluation of large amounts of genomic information is the issue of **multiple comparisons**. This problem arises from performing numerous analyses on the same data without taking into consideration the increased likelihood of falsely detecting an association. Hierarchical modeling – incorporating higher-level "prior" models into a conventional analysis – offers a solution to problems of multiple inferences. Furthermore, this approach can give estimates that are more plausible and stable than conventional estimates by "borrowing information" from the similarities in one's data.

Previous work has shown that parameter estimates from hierarchical models can be more plausible and stable than estimates from conventional models [5, 9, 10, 13]. This potential improvement results from modeling similarities among parameters of interest by using a second-stage model. In addition to providing parameter estimates of effect that are more accurate and more plausible than those from conventional models, it allows one to incorporate multiple levels of information on genetic and environmental factors into a single analysis and provides a solution to problems of multiple comparisons [12]. For example, Thomas et al. [9] presented a hierarchical modeling approach for evaluating **candidate genes** and environmental factors, and applied it to simultaneously investigate the **associations** between multiple human leukocyte antigen (HLA) alleles and insulin-dependent diabetes mellitus (IDDM). Furthermore, hierarchical modeling can simultaneously address issues of population stratification [6] (*see* **Bias in Case–Control Studies**).

Hierarchical Modeling

First-stage Model

Assume that one collects data on multiple correlated exposures of interest $\mathbf{x}$ (i.e. **genotype**), and phenotype y. Further assume that one wants to use these data to estimate coefficients β for the effects of genotype on phenotype. One can estimate β from the following **generalized linear model** for the expectation of y conditional on $\mathbf{x}$:

$$g_1[\mathrm{E}(y|\mathbf{x})] = \alpha + \mathbf{x}\beta, \qquad (1)$$

where g_1 is a monotonic differentiable strictly increasing link function between the random and systematic components, and y has mean $\mathrm{E}(y|\mathbf{x})$ and **variance** σ^2. Conventional analytic approaches to estimating β using (1) include: (a) fitting a (full) model that contains all the exposures; (b) reducing a full model with a preliminary testing algorithm (e.g. stepwise); (c) constructing numerous one-at-a-time models (i.e. evaluating the multiple parameter inference problem as multiple one-parameter inference problems); and (d) estimating haplotypes from the genotype information and the effects of haplotypes on phenotype (*see* **Haplotype Analysis**). Unfortunately, none of these approaches provides entirely satisfactory estimates of β. Approach (a) is impracticable if a full model will not fit one's data; moreover, even when the model does fit, this approach can give biased and inefficient estimates. Approach (b) excludes statistically "nonsignificant" exposures from the full model regardless of their biologic importance, and produces biased point and variance estimates [5, 7, 8]. Approach (c) takes no account of correlations among the exposures. Approach (d) requires estimation of haplotypes, and assumes that effects are homogeneous across haplotypes. Finally, none of the approaches properly addresses issues of multiple comparisons [7, 10].

Second-stage Model

Instead of undertaking a conventional single-stage analysis, one can use a hierarchical model to estimate β. This approach provides a coherent framework for multiple inference problems, using shrinkage estimation to improve estimation accuracy [5, 13]. In particular, this approach uses higher level "priors" to model the parameters of interest (here β) as random variables whose joint distribution is a function of hyperparameters. Assume that in addition to the above data (i.e. $\mathbf{x}$ and y), one has information about similarities between the components of β (e.g. physical distance between genetic **markers**). One can use such additional information in a second-stage generalized linear model for the expectation of β conditional on this information:

$$g_2[\mathrm{E}(\beta|\mathbf{Z})] = \mathbf{Z}\pi, \qquad (2)$$

where g_2 is a strictly increasing link function, β has mean $\mathrm{E}(\beta|\mathbf{Z})$ and variance τ^2, and $\mathbf{Z}$ is a second-stage

design matrix expressing the similarities between the β. For example, one could assume a linear link function and define a second-stage design matrix $\mathbf{Z}$, where z_{ij} indicates a function of the physical distance between each **polymorphism** (i.e. element z_{ij} of $\mathbf{Z}$ is equal to $e^{-d_{ij}t}$, where t is a scale parameter estimated from the data, and d_{ij} is the distance between polymorphism i and polymorphism j). Thus, the coefficients for each polymorphic marker β_i would be related through a second-stage covariate (e.g. physical distance) that is thought to be relevant to the strength of the marker-specific effects (which are measured by β_i).

Hierarchical Estimates

Hierarchical (i.e. posterior) estimates are then obtained by combining results – essentially taking weighted averages – from the different level models. Weights used in combining these results reflect how well each stage was able to estimate that level's parameters. Specifically, more unstable estimates will be given smaller weight, and vice versa. Hence, if sufficient data exist to estimate adequately first-stage parameters, then adding a second-stage will have limited effect on these estimates. To fit the levels in a hierarchical model separately one can use iterative weighted least squares. Assume that one has conventional **maximum likelihood** coefficient estimates $\hat{\beta}$ from fitting a first-stage model. One can then compute hierarchical estimates $\tilde{\beta}_{\mathbf{W}}$ of the coefficients β by averaging $\hat{\beta}$ with the fitted $E(\beta)$ from the second-stage regression of $\hat{\beta}$ on $\mathbf{Z}$. In particular, one can estimate the second-stage regression coefficients π using weighted-least-squares:

$$\tilde{\pi} = (\mathbf{Z}'\mathbf{W}\mathbf{Z})^{-1}\mathbf{Z}\mathbf{W}\hat{\beta}, \tag{3}$$

where $\mathbf{W} = [\hat{\mathbf{V}} + \mathbf{diag}(\tau^2)]^{-1}$, and $\hat{\mathbf{V}}$ is inverse information for β evaluated at $\hat{\beta}$. The fitted value for β from the second-stage regression is therefore $\mathbf{Z}\tilde{\pi}$. Averaging $\mathbf{Z}\tilde{\pi}$ with the maximum likelihood estimates $\hat{\beta}$ gives the hierarchical estimate

$$\tilde{\beta}_{\mathbf{W}} = \mathbf{B}\mathbf{Z}\tilde{\pi} + (\mathbf{I} - \mathbf{B})\hat{\beta}, \tag{4}$$

with estimated covariance matrix

$$\tilde{\mathbf{C}} = \hat{\mathbf{V}}[\mathbf{I} - (\mathbf{I} - \mathbf{H})'\mathbf{B}], \tag{5}$$

where $\mathbf{B} = \mathbf{W}\hat{\mathbf{V}}$, $\mathbf{I}$ = the identity matrix, and $\mathbf{H} = \mathbf{Z}(\mathbf{Z}'\mathbf{W}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{W}$. Equation (4) shows how two-stage hierarchical modeling compromises between first- and second-stage estimates: the distance of the hierarchical estimate from either stage estimates is indirectly proportional to its stability. More specifically, the larger the elements in $\hat{\mathbf{V}}$ are, the farther $\tilde{\beta}_{\mathbf{W}}$ will be from $\hat{\beta}$. Conversely, the larger the τ^2 are, the farther $\tilde{\beta}_{\mathbf{W}}$ will be from $\mathbf{Z}\tilde{\pi}$.

Using the weighted-least-squares approach requires that enough data exist to fit a first-stage model. When a full model will not fit one's data, a penalized **likelihood** hierarchical approach can be used instead. This approach entails thinking of the second-stage design matrix $\mathbf{Z}$ as a rational basis for choosing a penalty function for penalized likelihood. Specifically, the penalty function based on (2),

$$\mathbf{P} = \tilde{\beta}'_{\mathbf{P}}(\mathbf{I} - \mathbf{H})'(\mathbf{I} - \mathbf{H})\tilde{\beta}_{\mathbf{P}}, \tag{6}$$

could be used to compute hierarchical estimates of the coefficients $\tilde{\beta}_{\mathbf{P}}$ by penalized likelihood. This corresponds to a weighted sum-of-squared-residual penalty for departures of $\tilde{\beta}_{\mathbf{P}}$ from the linear model $\mathbf{Z}\pi$. The maximum penalized likelihood estimates are obtained by maximizing $\mathbf{L} - \mathbf{P}/2\tau^2$, where $\mathbf{L}$ is the conventional log likelihood derived from (1). Hence, τ^2 is the inverse of the usual smoothing parameter in penalized likelihood [11].

When distributions are not conjugate, one can use Gibbs sampling to fit hierarchical models (*see* **Markov Chain Monte Carlo**). Gibbs sampling is a Monte Carlo method for estimating the joint and marginal posterior distributions of a set of random variables when direct calculation of these distributions is infeasible. It requires only specification of the set of conditional distributions of each random variable, given all other variables, and possibly data [3]. If the full conditional distribution does not have a simple form, one can still use Gibbs sampling by applying a derivative-free adaptive rejection sampling procedure to generate samples from the exact posterior distribution [4].

Application of Hierarchical Models

As an example of hierarchical modeling, Thomas et al. [9] presented an empirical-Bayes approach (*see* **Markov Chain Monte Carlo**) for testing associations with large numbers of candidate genes in the

presence of environmental risk factors. They investigated this approach by application to **HLA** associations in IDDM, and by a **simulation** study designed to reflect situations they have observed in family studies of IDDM. Their hierarchical approach assumed that the log **relative risks** for all alleles at a given locus are exchangeable (presuming that there is no preferential zygotic assortment and negligible recombination; *see* **Linkage Analysis, Model-based**). Furthermore, they considered modeling the covariance between two haplotypes as a function of the number of alleles they share, and the marginal strength of the effects of these alleles. Simulation results indicated that hierarchical empirical-Bayes was superior to maximum likelihood. In particular, when there were no haplotype effects, empirical-Bayes estimates were closer to the true value than maximum likelihood estimates for 75% of the alleles, and the empirical-Bayes estimates were more stable as well. When there were haplotype effects, empirical-Bayes was also superior because maximum likelihood models were often unable to fit without first using the data to select a subset of variables.

Aragaki et al. [1] used a hierarchical model to estimate NAT2 genotype-specific dietary effects on adenomatous polyps. The first stage used **logistic regression** to model the joint effects of **genotype** and diet, as well as their main effects and other **covariates**. However, using this conventional approach to estimate dietary effects within nine genotypes – with the 910 case–control subjects in the study – gave unstable results. Therefore, to improve precision they modeled the joint effect of genotype and diet as a function of initial rate of carcinogenic conversion of dietary heterocyclic amines to aryl nitrenium ions [1]. In comparison with the conventional results, the hierarchical model gave more precise and reasonable estimates.

Another potentially valuable application of hierarchical modeling arises in combining linkage results across different studies (*see* **Meta-analysis in Human Genetics**). In this situation, the fact that different studies give results for the same marker locus is exploited in an attempt to improve estimates of recombination or lod scores. Specifically, one can use hierarchical modeling to combine likelihoods [2], or corresponding lod scores and recombination fractions. For example, when estimating **confidence** (or support) **intervals** for a particular recombination fraction, one can apply a hierarchical model that "borrows strength" from all recombination fractions estimated at the marker of interest. The general concept is similar to that presented above, except that here we are interested in estimation of likelihoods instead of regression coefficients.

The potential improvement available with hierarchical approaches does require reasonable higher-level models; but, as long as this requirement is met, hierarchical modeling will generally give better estimates than (one-stage) conventional maximum likelihood. In contrast, if a higher-level model cannot provide an even remotely reasonable approximation to reality, this approach may produce invalid confidence intervals, and parameter estimates may be less accurate than those obtained with typical analyses.

Hierarchical Models in Health Service Research

Hierarchical models provide a natural framework for conceptualizing and quantifying systematic and random components of variation in **multilevel** data. For example, hierarchical nested structures are present in data describing **health care utilization**, cost (*see* **Health Economics**), and **outcomes** for patients treated in specific hospitals, which may in turn belong to particular health care systems or may be clustered by geographic or **hospital market areas** (*see* **Small Area Variation Analysis**).

The analysis of variations in health care processes and outcomes seeks to quantify and characterize variability across clusters, such as physicians, hospitals, and geographic or market areas, at each level of the hierarchical data structure. In particular, the analysis seeks to determine whether comparable patients receive similar treatment and experience similar outcomes across clusters. If differences exist, the analysis turns to the examination of how patient, hospital, or regional characteristics may be related to these differences. In addition, the analysis examines the link between measures of outcome, such as patient mortality, morbidity, and functioning and indicators of process, such as descriptors of regional or provider practice patterns. When the focus of the analysis is on comparative measures of performance of health care providers, the term *profiling* analysis is often used (*see* **Profiling Providers of Medical Care**).

A number of methodologic issues confront the investigator in the analysis of variations in health care. First, sample size can vary across clusters, resulting in substantially different precision of cluster-specific estimates. For example, the number of patients with a particular condition in each hospital may vary from a handful to several hundred in a typical analysis of hospital variations. Secondly, the analytic strategy needs to take into account the **correlation** of the responses within each cluster (*see* **Clustering**). Failure to do so may result in understating the error associated with the estimates of effects of case-specific **covariates**, such as the effect of patient characteristics on medical procedure utilization across different geographic areas. Thirdly, the analyst needs to derive reliable cluster-specific estimates, such as mortality rates for each hospital, and also to estimate the effects of cluster-level covariates, such as hospital characteristics. The usual approach of fitting a single **regression** model to the entire data set does not account for correlations and cannot accommodate both cluster-specific indicator variables and cluster-level covariates.

Hierarchical regression modeling goes a long way toward meeting these methodologic challenges. The approach enables the analyst to separate sampling variability from variability across clusters. It also allows the latter to be further partitioned into a *systematic* component (*see* **Fixed Effects**), which is linked to cluster characteristics, and a *random* component (*see* **Random Effects**). The hierarchical model accommodates within-cluster correlations and makes it possible to estimate case- and cluster-level covariate effects and **variance components** simultaneously. The model also makes it possible to pool information across clusters in order to derive more precise estimates of cluster-specific parameters and cluster-level effects.

Examples

Although hierarchical models have been extensively discussed in the statistical literature (see [4], [7], [8], and [14], and references in **Multilevel Models**), their use in **health services research** is relatively recent [1–3, 5, 6, 9, 10, 12, 13]. In a particular study, the complexity of the hierarchical model will be commensurate with the research question and the level of detail in the data. The following examples illustrate two typical scenaria.

Aggregate Responses: Hierarchical Poisson Model

Consider studies in which a **Poisson** count, Y_i, of events is observed in the ith of K clusters. For example, Y_i can be the number of patients who experience complications after undergoing a specific operation in the ith hospital during a particular year. The number of patients receiving the operation in the ith hospital is denoted by n_i. If there is no reason to suspect systematic differences across hospitals, the following hierarchical model with an **exchangeable** second-level structure can be considered:
Level I (within-hospital). $Y_i|\theta_i \sim$ Poisson $(\theta_i n_i)$.
Level II (between-hospitals). $\log(\theta_i) \sim \mathrm{N}(\mu, \sigma)$.

Fully **Bayesian** formulations of the hierarchical model include a third level, in which **priors** on the population parameters μ and σ are specified. Vague (but proper) priors are often used at this stage.

A model of this type was employed in a recently published analysis of teenage conception rates for different health boards in Scotland [5]. The model was used to derive estimates and posterior intervals of the individual health board rates (θ_i) and of the relative ranking for each health board. Similar models have been used with **binomial** outcomes in Level I and with cluster-level covariates in Level II of the hierarchy.

Case-level Responses: Hierarchical Logistic Model

The models for binomial and Poisson responses are applicable to studies in which only aggregate data are available on each cluster. If case-specific data are available, more intricate hierarchical regression models can be employed. In many studies a **binary** response, Y_{ij}, is observed on the jth case in cluster i, where $j = 1, \ldots, n_i$ and $i = 1, \ldots, N$. The available data include a K-dimensional vector of covariate values X_{ij} on the ijth case and an L-dimensional vector of covariate values Z_i on cluster i. For example, in a study of geographic patterns of utilization of coronary angiography in elderly patients who had a heart attack, the binary response of interest was the indicator of whether angiography was performed on a patient within a specific time interval after the infarction. Data on patient sociodemographics (such as age, gender, and race) and **co-morbid** conditions were represented by the vector X_{ij}, and characteristics of the geographic area (such as location, and availability of angiography in local hospitals) were represented by Z_i [2]. As a second example, in a profiling analysis of the performance of hospitals which treat heart-attack patients, the binary response of interest was the indicator of whether a patient survived past the initial 30-day period after the heart attack. Data on patient sociodemographic characteristics and severity at hospital entry were represented by the vector X_{ij} and selected hospital characteristics by the vector Z_i [12]. As a third example, in an analysis of data from the National Health Interview Survey, the binary response was an indicator of whether an individual had a physician visit in the past year. The analysis included data on characteristics of the individual and the county of the individual's residence [9].

The following hierarchical **logistic regression** model was used in the analysis of the angiography data:

Level I (within-area variability). A logistic model was assumed within each area. Specifically, if $p_{ij} = \Pr(Y_{ij} = 1)$, then

$$\text{logit}(p_{ij}) = \beta_{0i} + \beta_{1i} X_{1ij} + \beta_{2i} X_{2ij} + \cdots + \beta_{Ki} X_{Kij}.$$

Level II (between-areas variability). The variation across areas was partitioned into a systematic and a random component. The systematic component was expressed by a **multiple linear regression** model linking the within-area logistic coefficients to area-level covariates. Specifically,

$$\beta_{ki} = \gamma_{k1} Z_{1i} + \cdots + \gamma_{kL} Z_{Li} + \varepsilon_{ki}.$$

The error terms ε_{ki} were assumed to have a **multivariate normal distribution** with mean zero and covariance structure such that (i) the error terms for different units are independent, and (ii) the within-unit $(K + 1) \times (K + 1)$ **covariance matrix** D is the same for all units. Heavier-tailed distributions, such as **multivariate *t*** may also be used for modeling the variability of the β_i [1]. In a third and final level, vague proper priors can be assumed on the components of γ and on the covariance matrix D.

The above hierarchical logistic model makes it possible to combine data across geographical areas in order to derive smoothed estimates of the effects of patient characteristics, such as sociodemographics and co-morbidity, both over the entire country and within each area. Therefore, we can determine whether a specific patient characteristic (such as race) has a differential impact on practice patterns in different areas of the country. The process of combining information across areas takes into account differences in sample size and results in improved precision of estimates for areas with small sample sizes. The hierarchical model estimates of the logistic coefficients can be conceptually described (and numerically approximated) as a weighted combination of (i) the coefficients resulting from fitting the logistic model solely to the data of the particular area and (ii) average values of these coefficients across areas, as determined by the area-level characteristics. In the angiography example, the hierarchical model estimates are effectively obtained by shrinking the

coefficients from the fully stratified analysis towards a regression line determined by the area characteristics included in the vector **Z**. The degree of **shrinkage** is different for each covariate, being influenced by (i) the accuracy with which the particular covariate can be estimated via the stratified analysis (*see* **Stratification**) and (ii) by the degree to which the estimate for a particular area differs from the estimates for the other areas. Shrinkage is generally going to be higher for coefficients of areas with smaller overall sample sizes and/or small cell counts for a particular covariate.

The hierarchical model also makes it possible to derive area-specific estimates of the probability of the outcome (in this case, performance of angiography) for each stratum of patients that can be defined using the covariate vector **X**. These probabilities can be presented graphically using maps (*see* **Mapping Disease Patterns**). In addition, the model makes it possible to examine the relation between area-level covariates (**Z**) and area-specific event rates or area-specific effects of patient characteristics. In the angiography analysis, for example, it was determined that an area's rate of angiography for an average patient was positively related to an index measuring the availability of the procedure to patients in that area. It was also found that the effect of race differed across census regions in the country.

There are two simpler *fixed-effects* alternatives to the hierarchical logistic model of the analysis of variations across areas: (i) regression analysis stratified by area, and (ii) regression analysis using a single logistic model for the entire country, with indicator variables for each area and their interactions. The fully stratified analysis is close to the spirit of Level I of the hierarchical model. However, such an analysis may not be an efficient approach and may lead to highly imprecise estimates of effects, especially in areas with small sample sizes overall or in some categories of patients. The analysis via a single logistic regression model is more common in practice. However, the **standard errors** of the coefficients from this analysis do not account for the effects of clustering of patients within areas and will, therefore, need to be adjusted. This correlation is accounted for by the hierarchical analysis. In addition, the analysis via a single regression model for the entire country cannot incorporate both patient-level and area-level covariates without leading to model indeterminacy. For example, if **dummy variables** for areas are included then it is no longer possible to include variables indicating the location of the area and other area characteristics. Such area characteristics can be accommodated via the hierarchical model or via a two-stage approach in which a fully stratified analysis is first carried out and the resulting coefficients are used as the dependent variable in regression models similar to those in Level II of the hierarchical model. The two-stage analysis will generally lead to consistent estimates of the second-stage coefficients but is likely to understate the standard error of the estimates without careful adjustment.

Further Applications

Hierarchical regression modeling techniques are by now available for most response data of interest in health services and outcomes research. In particular, the response may be binary or a count as above; **polytomous**, e.g. utilization of one of several alternative treatments [1]; **ordered categorical**, e.g. appropriateness of care; or continuous. The latter may be observed completely, e.g. cost of care; or above a threshold, e.g. vulnerability to malpractice claim [3]. For each type of response the models can include cluster-level covariates, such as hospital size and teaching status. Aggregate data on patient mix can also be included in Level II of the model, but that would provide only a rudimentary method for **case-mix** adjustment. More substantial case-mix adjustment can be implemented with models such as the hierarchical logistic model above. The approach requires the use of patient-level information and can be accomplished with hierarchical models in which Level I describes the relation of the response on an individual patient to patient characteristics. However, it should be noted that the use of hierarchical modeling does not necessarily address the effects of **selection bias**, especially if such bias is related to covariates that are not represented in the database.

Further levels can be added to the above hierarchical models in order to accommodate additional structure in the data. In the Poisson example, longitudinally observed counts may be available on each cluster over several years (*see* **Longitudinal Data Analysis, Overview**). In the logistic example, primary clusters such as hospitals may be further grouped by geographic region or market area. In each case, the incorporation of further levels and corresponding covariates is straightforward. In

addition to cluster-level covariates, the hierarchical structure may also be used to model spatial dependence. Such models have already been developed and used in epidemiologic studies and can be readily adapted for health services research data.

Model Fitting and Checking

Simulating observations from the posterior distribution of the parameters is generally recognized to be the most flexible and broadly applicable approach to fitting hierarchical regression models. This fully Bayesian framework provides a more realistic account of uncertainty in the estimates without the need for rather complex adjustments. A key practical advantage of the approach is that it makes it possible to **simulate** values and derive estimates of any function of the parameters, with little additional computational burden. For example, in profiling analyses, it is generally straightforward to simulate values from the posterior distribution of any measure of hospital performance, to derive estimates and to account for the uncertainty in these estimates. The most common algorithms for generating simulated values involve **Markov chain Monte Carlo** (MCMC) methodology [4]. Although special programs may have to be developed for some of the more complex, multilevel models, a large class of problems can be analyzed using the publicly available software BUGS [11]. A number of recent authors have proposed **diagnostics** for checking the convergence of MCMC runs [4]. Some of these diagnostics are now available in BUGS and other MCMC software. A recent account of approaches to checking model fit (*see* **Model Checking**) and comparing alternative models can be found in [4].

An alternative computational approach to posterior simulation has been developed using weighted **least squares** methods and can be implemented via the software package MLn (*see* **Multilevel Models**). Some classes of hierarchical regression models can also be fitted using special SAS subroutines (*see* **Software, Biostatistical**) for mixed models as well as a plethora of more specialized software.

Hierarchical Models

This term is currently used in a variety of contexts. The most traditional one is in the sense that two statistical models are said to be hierarchical if one is a submodel of the other. A set of models, $H_1, H_2, \ldots, H_k$, is similarly called a hierarchy if

$$H_1 \subset H_2 \subset \cdots \subset H_k.$$

Hierarchical models specified by a finite set of parameters are of particular importance, because the comparison of models can be based on standard likelihood ratio tests. When models are not hierarchical, or nested, then special procedures are required (*see* **Separate Families of Hypotheses**).

The term "hierarchical" can also be used to refer to a single model, usually in the context of **regression** or **analysis of variance**. In this usage, a model is said to be hierarchical if the presence of an **interaction** term implies the inclusion of all lower-order interactions and main effects for the explanatory variables involved in the interaction. The model is hierarchical in the sense that it includes all submodels in a hierarchy as special cases. It has been argued that only such models should be considered [1], but this is not universally accepted. Significance tests for the presence of interactions are, however, best considered in the context of hierarchical models.

Another usage of the term "hierarchical models" is as a synonym for **multilevel models**. This usage derives from the hierarchical nature of data in which observations are nested within higher level classifications. For example, individuals may be nested within families, or patients may be nested within clinics. **Bayesian** hierarchical models provide another use of the term. **Markov chain Monte Carlo** methods are very important in this context.

VERN T. FAREWELL

Hill, Austin Bradford

Born: July 8, 1897, in Hampstead, London, UK.
Died: April 18, 1991, in Cumbria, UK.

Reproduced by permission of the Royal Statistical Society

Austin Bradford Hill was Professor of Medical Statistics and Director of the Medical Research Council's Statistical Research Unit at the London School of Hygiene and Tropical Medicine, 1946–61; he introduced the principle of **randomization** into the conduct of controlled trials (*see* **Clinical Trials, Overview**) in clinical medicine and established particularly clearly the role of smoking in the production of lung cancer and, subsequently, many other diseases (*see* **Smoking and Health**). As a result of the experience gained in interpreting the observed association between smoking and lung cancer, Hill drew up "guidelines" to help reach a positive conclusion about causality that have come to be used widely in epidemiology and, on occasions, in the law (*see* **Hill's Criteria for Causality**).

Career

Hill, who was always known as Bradford Hill in scientific circles and as Tony to his friends, had wanted to study medicine, but he was diverted from doing so by the outbreak of World War I. He enlisted, at the first opportunity, in 1916 and opted for a commission in the Royal Naval Air Service. After being posted to the Greek islands in support of the attack on the Dardanelles, he developed pulmonary tuberculosis and, in November 1917, was invalided out of the service and sent home. Instead of causing his death, which was the anticipated outcome, the development of pulmonary tuberculosis probably saved his life, for the expectation of life of fighter pilots in World War I was measured in weeks. The downhill progress of the disease was, however, arrested after he was given an artificial pneumothorax to rest his lung, and by 1919 he was sufficiently recovered to think again about his future. Medicine was out of the question and he decided to study economics as an external student of London University. With the aid of a correspondence course and by reading in bed, he succeeded in obtaining a second class honours degree in 1922, having attended the university itself only to take examinations.

Hill had no desire to make a career of economics and he managed to enter medicine with the help of **Major Greenwood**, a friend of his father and one of the few medical statisticians of the day. He obtained a grant from the **Medical Research Council** to investigate the reasons for the high mortality of young adults in rural areas and, whilst holding it, attended part of **Karl Pearson's** course on statistics for the London B.Sc. at University College. From then on he worked consistently with Greenwood in a variety of capacities in the conduct of epidemiologic research and, later, in the teaching of medical statistics at the London School of Hygiene and Tropical Medicine, where Greenwood had been appointed to the professorship of Medical Statistics. On the outbreak of World War II he was seconded to the Research and Experimental Department of the Ministry of Home Security and subsequently to the Medical Directorate of the Royal Air Force. In 1946 Greenwood retired and Hill was appointed to succeed him, both as professor at the School and as director of the MRC's unit.

Teaching Medical Statistics

Hill described himself as an arithmetician rather than a statistician, and it was the clarity of his exposition of simple arithmetic and statistical procedures and of the logic that justified conclusions from epidemiologic studies, combined with his sensitivity to the ethical concerns of practicing clinicians, that enabled him to

influence British academic medicine as greatly as he did. From his first appointment at the London School of Hygiene in 1933 he found himself responsible for **teaching** the elements of statistics to medical postgraduates who, as a group, had little liking or aptitude for mathematics in any form. At that time, the need for some sort of statistical analysis had been recognized in the field of public health and had begun to be appreciated in laboratory medicine, but it was hardly understood in clinical medicine at all. Hill responded, not by pressing the need for deferring to a statistical consultant, but by urging research workers in all branches of medicine to learn enough about statistical techniques to appreciate their value in both the planning of experiments (*see* **Experimental Design**) and in the interpretation of figures and so to accept the statistician as a partner in their research, while the statistician, for his part, had to steep himself in the realities of medical practice. His lectures on medical statistics proved to be so effective that he was asked to publish them in a series of articles in the *Lancet* and to republish them in book form. The book, entitled *Principles of Medical Statistics*, was published in 1937 [4] and republished and expanded in a further 10 editions, some of which were translated into Spanish, Korean, Indonesian, Polish, and Russian, before a twelfth enlarged edition appeared shortly after his death, with his son, I. D. Hill, as joint author [8]. The fact that statistical analysis is now an integral part of almost every medical publication is a result of the work of many gifted statisticians throughout the world (*see* **Statistical Review for Medical Journals, Journal's Perspective**). The fact that the medical profession awoke to its need in the middle of the century was largely due to its exposition by Hill.

The Introduction of Randomization

In the first edition of his book, Hill made no reference to randomization in the planning of controlled trials. He urged only the need for concurrent controls, obtained, for example, by giving different treatment to alternate patients, a technique that had been recommended since the end of the nineteenth century, but was still the exception rather than the rule. This method was, however, far from ideal, as practice proved that a doctor's decision to enter a patient into a trial could be **biased** if he knew what treatment he or she would receive. Hill appreciated this, but he explained, shortly before his death, that he had deliberately omitted any reference to randomization in his 1937 articles

> because I was trying to persuade doctors to come into controlled trials in the very simplest form and I might have scared them off. I think the concepts of "randomization" and "random sampling numbers" are slightly odd to the layman or, for that matter, to the lay doctor, when it comes to statistics. I thought it would be better to get doctors to walk first, before I tried to get them to run [6].

By the end of World War II, the situation had changed and Hill felt able to introduce physicians to the idea, and in 1946 he persuaded two committees of the Medical Research Council to adopt the method: first, to test the value of a pertussis vaccine to prevent whooping cough [11] and second, a few months later, to test the efficacy of streptomycin in the treatment of pulmonary tuberculosis (*see* **Medical Research Council Streptomycin Trial**) [10]. The results of the latter study were, however, published first and it is usually, but undeservedly, described as the first randomized clinical trial.

The idea of randomization in biological experiments was not new. It had been introduced by **R. A. Fisher** 20 years before as a basic principle of experimental design in agriculture; but it was unheard of in clinical medicine and was anathema on first presentation to many clinicians who thought it conflicted with their responsibility for doing the best they could for individual patients and resulted in beneficial effects being diluted by giving the new treatment to patients who were unsuitable for it. Neither objection was, of course, valid, as entry to the trial was in the clinician's own hands and required him or her not to know which was the better treatment and to exclude patients if they were thought to be unsuitable for either of the therapies under trial (*see* **Ethics of Randomized Trials**; **Medical Ethics and Statistics**). Gradually clinical opposition was overcome, largely, in the UK, as a result of Hill's emphasis on ethical considerations, which won the respect of practising clinicians, and within 10 years randomization had become the standard technique for the conduct of controlled clinical trials. Recent claims that randomization had been introduced earlier by others as, for example, in the trial of patients for the treatment of the common cold, do not bear close investigation [9].

Smoking and Lung Cancer

Of Hill's many epidemiologic studies the most outstanding are those that demonstrated the importance of cigarette smoking as a cause of lung cancer. In one, comparisons were made between the smoking habits of patients with lung cancer admitted to 20 London hospitals and the habits of other patients of the same sex and age admitted to the same hospitals with other diseases (*see* **Case–Control Study, Hospital-based**). The results showed sharp differences between the two groups and led to the conclusion that cigarette smoking was an important cause of the disease [1]. This was not the first study to have shown that patients with lung cancer tended to have smoked more than other patients, but it was the first in which a firm conclusion about causality had been reached on logical grounds and it set out clearly the basis for it. The conclusion was not, however, widely accepted, and Hill set out to test it by means of a prospective study, in which information was obtained about the smoking habits of 40 000 British doctors, who were then followed to determine the mortality rates in different groups of men and women who smoked different amounts. Within a few years, results were obtained that were almost identical to those predicted from the case–control study [2, 3] and the validity of the earlier conclusion quickly came to be accepted. Neither the case–control study nor the prospective, or **cohort study** as it has come to be called, was the first of their type to have been carried out; but they set standards of design and analysis by which subsequent similar studies have come to be assessed.

Guidelines for Determining Causality

In reaching the conclusion that the association observed between smoking habits and the development of lung cancer reflected cause and effect, Hill had first to exclude chance, bias, and **confounding** as alternative explanations. The first two were not difficult to exclude, but the third was, and positive evidence had to be sought that would justify the choice of causality. Koch's postulates that had been valuable in determining the microbiological causes of infectious disease were not appropriate for other types of disease that could have multiple causes, and Hill suggested a set of guidelines to replace them, based on his experience in interpreting the results of his studies of lung cancer [5]. Only one feature had to be present (the temporal relationship of the suspected cause and its effect), none alone was conclusive, and Hill emphasized that the guidelines were no more than a help to constructive thought and that each case had to be considered on its merits. For this purpose, they have proved to have lasting value to both scientists and lawyers.

Hill, the Man

Hill was not a prolific writer of scientific papers. Apart from his lecture series on medical statistics and the many editions of his textbook, his bibliography lists only 140 publications, including 28 letters to journals and 13 reviews or historical notes [7]. His influence on British medicine was, however, disproportionately great; not only because of the importance of some of the papers, but because of his teaching, the advice he gave personally to the many individuals who sought it, and his contribution to the work of the Medical Research Council through membership of many committees and, in 1954, membership of the Council itself. In committee, he expressed his opinion cogently and firmly, but he never imposed it and he was, in consequence, always listened to with respect and his advice was almost always taken. In public he avoided controversy and, though distressed by Sir Ronald Fisher's attacks on his interpretation of the association between smoking and the development of lung cancer, he preferred to let the facts speak for themselves rather than embark on a public dispute. He took immense trouble over his lectures, which he gave without the use of visual aids and rehearsed so often and read so well that his audience often thought that he spoke without a text. Even those whose interest flagged were kept attentive by the occasional witty aside. As a department head, he kept his door open to any junior who sought his advice and he saw his job as providing the conditions under which his university and research staff could be most productive. No one who worked in his department ever wanted to leave, and it was only with the greatest difficulty that they could be persuaded to take up more senior positions elsewhere.

Hill's Criteria for Causality

Despite philosophic criticisms of inductive **inference**, inductively oriented causal criteria have commonly been used to make such inferences. If a set of necessary and sufficient causal criteria could be used to distinguish causal from noncausal **associations** in **observational studies**, the job of the scientist would be eased considerably. With such criteria, all the concerns about the logic or lack thereof in causal inference could be forgotten: it would only be necessary to consult the checklist of criteria to see if a relation were causal. We know from philosophy that a set of sufficient criteria does not exist [3, 6]. Nevertheless, lists of causal criteria have become popular, possibly because they seem to provide a road map through complicated territory.

A commonly used set of criteria was proposed by **Sir Austin Bradford Hill** [1]; it was an expansion of a set of criteria offered previously in the landmark Surgeon General's report on Smoking and Health [11], which in turn were anticipated by the inductive canons of John Stuart Mill [5] and the rules of causal inference given by Hume [3]. Hill suggested that the following aspects of an association be considered in attempting to distinguish causal from noncausal associations: strength, consistency, specificity, temporality, biologic gradient, plausibility, coherence, experimental evidence, and analogy. The popular view that these criteria should be used for causal inference makes it necessary to examine them in detail:

Strength

Hill's argument is essentially that strong associations are more likely to be causal than weak associations because, if they could be explained by some other factor, the effect of that factor would have to be even stronger than the observed association and therefore would have become evident (*see* **Cornfield's Inequality**). Weak associations, on the other hand, are more easily explained by undetected **biases**. To some extent this is a reasonable argument, but, as Hill himself acknowledged, the fact that an association is weak does not rule out a causal connection. A commonly cited counterexample is the relation between cigarette smoking and cardiovascular disease.

Counterexamples of strong but noncausal associations are also not hard to find; any study with strong **confounding** illustrates the phenomenon. For example, consider the strong but noncausal relation between Down syndrome and birth rank, which is confounded by the relation between Down syndrome and maternal age. Of course, once the confounding factor is identified, the association is diminished by adjustment for the factor. These examples remind us that a strong association is neither necessary nor sufficient for causality, nor is weakness necessary nor sufficient for absence of causality. In addition to these counterexamples, we have to remember that neither **relative risk** nor any other measure of association is a biologically consistent feature of an association; as described by many authors [4, 7], it is a characteristic of a study population that depends on the relative **prevalence** of other causes. A strong association serves only to rule out hypotheses that the association is entirely due to one weak unmeasured **confounder** or other source of modest bias.

Consistency

Consistency refers to the repeated observation of an association in different populations under different circumstances. Lack of consistency, however, does not rule out a causal association, because some effects are produced by their causes only under unusual circumstances. More precisely, the effect of a causal agent cannot occur unless the complementary component causes act, or have already acted, to complete a sufficient cause. These conditions will not always be met. Thus, transfusions can cause HIV infection but they do not always do so: the virus must also be present. Tampon use can cause toxic shock syndrome, but only when other conditions are met, such as presence of certain bacteria. Consistency is apparent only after all the relevant details of a causal mechanism are understood, which is to say very seldom. Even studies of exactly the same phenomena can be expected to yield different results simply because they differ in their methods and **random errors**. Consistency serves only to rule out hypotheses that the association is attributable to some factor that varies across studies.

Specificity

The criterion of specificity requires that a cause leads to a single effect, not multiple effects. This argument has often been advanced to refute causal interpretations of exposures that appear to relate to myriad effects, especially by those seeking to exonerate smoking as a cause of lung cancer. The criterion is wholly invalid, however. Causes of a given effect cannot be expected to lack other effects on any logical grounds. In fact, everyday experience teaches us repeatedly that single events or conditions may have many effects. Smoking is an excellent example: it leads to many effects in the smoker. The existence of one effect does not detract from the possibility that another effect exists. Thus, specificity does not confer greater validity to any causal inference regarding the exposure effect. Hill's discussion of this criterion for inference is replete with reservations, and many authors regard this criterion as useless and misleading [8, 9].

Temporality

Temporality refers to the necessity that the cause precede the effect in time. This criterion is unarguable, insofar as any claimed observation of causation must involve the putative cause C preceding the putative effect D. It does *not*, however, follow that a reverse time order is evidence against the hypothesis that C can cause D. Rather, observations in which C followed D merely shows that C could not have caused D in these instances; they provide no evidence for or against the hypothesis that C can cause D in those instances in which it precedes D.

Biologic Gradient

Biologic gradient refers to the presence of a monotone (unidirectional) **dose–response** curve. We often expect such a monotonic relation to exist. For example, more smoking means more carcinogen exposure and more tissue damage, hence more carcinogenesis. Such an expectation is not always present, however. The somewhat controversial topic of alcohol consumption and mortality is an example. Death rates are higher among nondrinkers than among moderate drinkers, but ascend to the highest levels for heavy drinkers. Because modest alcohol consumption can have beneficial effects on serum lipid profiles, such a J-shaped dose–response curve is at least biologically plausible.

Conversely, associations that do show a monotonic trend in disease frequency with increasing levels of exposure are not necessarily causal; confounding can result in a monotonic relation between a noncausal risk factor and disease if the confounding factor itself demonstrates a biologic gradient in its relation with disease. The noncausal relation between birth rank and Down syndrome mentioned above shows a biologic gradient that merely reflects the progressive relation between maternal age and the occurrence of Down syndrome.

Thus the existence of a monotonic association is neither necessary nor sufficient for a causal relation. A nonmonotonic relation only conflicts with those causal hypotheses specific enough to predict a monotonic dose–response curve.

Plausibility

Plausibility refers to the biologic plausibility of the hypothesis, an important concern but one that is far from objective or absolute. Sartwell [9], emphasizing this point, cited the remarks of Cheever, in 1861, who was commenting on the etiology of typhus before its mode of transmission (via body lice) was known:

> It could be no more ridiculous for the stranger who passed the night in the steerage of an emigrant ship to ascribe the typhus, which he there contracted, to the vermin with which bodies of the sick might be infested. An adequate cause, one reasonable in itself, must correct the coincidences of simple experience.

What was to Cheever an implausible explanation turned out to be the correct explanation, since it was indeed the vermin that caused the typhus infection. Such is the problem with plausibility: it is too often not based on logic or data, but only on prior beliefs. This is not to say that biological knowledge should be discounted when evaluating a new hypothesis, but only to point out the difficulty in applying that knowledge.

The **Bayesian** approach to inference attempts to deal with this problem by requiring that one quantify, on a probability (0 to 1) scale, the certainty that one has in prior beliefs, as well as in new hypotheses. This quantification displays the dogmatism or open-mindedness of the analyst in a public fashion, with certainty values near 1 or 0 betraying a strong commitment of the analyst for or against a hypothesis. It

can also provide a means of testing those quantified beliefs against new evidence [2]. Nevertheless, the Bayesian approach cannot transform plausibility into an objective causal criterion.

Coherence

Taken from the Surgeon General's report on Smoking and Health [11], the term *coherence* implies that a cause and effect interpretation for an association does not conflict with what is known of the natural history and biology of the disease. The examples Hill gave for coherence, such as the histopathologic effect of smoking on bronchial epithelium (in reference to the association between smoking and lung cancer) or the difference in lung cancer incidence by sex, could reasonably be considered examples of plausibility as well as coherence; the distinction appears to be a fine one. Hill emphasized that the absence of coherent information, as distinguished, apparently, from the presence of conflicting information, should not be taken as evidence against an association being considered causal. On the other hand, presence of conflicting information may indeed undermine a hypothesis, but one must always remember that the conflicting information may be mistaken or misinterpreted [12].

Experimental Evidence

It is not clear what Hill meant by experimental evidence. It might have referred to evidence from laboratory experiments on animals, or to evidence from human experiments. Evidence from human experiments, however, is seldom available for most epidemiologic research questions, and animal evidence relates to different species and usually to levels of exposure very different from those that humans experience. From Hill's examples, it seems that what he had in mind for experimental evidence was the result of removal of some harmful exposure in an intervention or prevention program, rather than the results of laboratory experiments [10]. The lack of availability of such evidence would at least be a pragmatic difficulty in making this a criterion for inference. Logically, however, experimental evidence is not a criterion but a test of the causal hypothesis, a test that is simply unavailable in most epidemiologic circumstances.

Although experimental tests can be much stronger than other tests, they are not as decisive as often thought, because of difficulties in interpretation. For example, one can attempt to test the hypothesis that malaria is caused by swamp gas by draining swamps in some areas and not in others to see if the malaria rates among residents are affected by the draining. As predicted by the hypothesis, the rates will drop in the areas where the swamps are drained. As Popper emphasized, however, there are always many alternative explanations for the outcome of every experiment. In this example, one alternative, which happens to be correct, is that mosquitoes are responsible for malaria transmission.

Analogy

Whatever insight might be derived from analogy is handicapped by the inventive imagination of scientists who can find analogies everywhere. At best, analogy provides a source of more elaborate hypotheses about the associations under study; absence of such analogies only reflects lack of imagination or experience, not falsity of the hypothesis.

Conclusion

As is evident, the standards of epidemiologic evidence offered by Hill are saddled with reservations and exceptions. Hill himself was ambivalent about the utility of these "standards" (he did not use the word *criteria* in the paper). On the one hand he asked "in what circumstances can we pass from this observed *association* to a verdict of *causation?*" (original emphasis). Yet, despite speaking of verdicts on causation, he disagreed that any "hard-and-fast rules of evidence" existed by which to judge causation:

> None of my nine viewpoints [criteria] can bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as a *sine qua non*.

Actually, the fourth criterion, temporality, is a *sine qua non* for causality: If the putative cause did not precede the effect, that indeed is indisputable evidence that the observed association is not causal (although this evidence does not rule out causality in other situations, for in other situations the putative cause may precede the effect). Other than this one condition, however, which may be viewed as part

of the definition of causation, there is no necessary or sufficient criterion for determining whether an observed association is causal.

Historical Controls in Survival Analysis

The use of historical controls in treatment evaluation is a large and controversial topic, and a general discussion is given elsewhere (*see* **Bias from Historical Controls**). The purpose of this article is the more technical one of surveying current contributions to the centuries-old statistical tradition [4] of comparing the observed mortality of a study group with that expected under "standard" (historical) rates.

If the historical rates are derived from a specific statistical analysis, then the straightforward modern approach would usually be to formulate a general statistical model containing the current data as well as the historical information, and then simply test the hypothesis of equality of the relevant mortality rates, perhaps taking into account **covariates**. Partly because the historical information is not always available as concrete statistical estimators, but also to some extent motivated by tradition, there is considerable interest in rephrasing the question as "how would these individuals have survived had they been subject to standard (historical) conditions?" Note that the so-called Peters–Belson approach in regression analysis similarly predicts study group responses from a statistical model fitted only to a control group, and then compares observed with expected [1–3].

A separate article recalls the classical calculation of **expected number of deaths** and contrasts it with a sometimes more easily interpretable calculation called the "prospective method", which however requires knowledge of the potential **censoring** time for each individual, including those who died during the study. Another separate article surveys several recent approaches to defining an **expected survival curve**, all of which have been illustrated through asymptotic statistical results of Nielsen [5], as well as some further topics and pitfalls in using **Cox regression models** in this area.

HLA System

The HLA (human leukocyte antigen) **gene** complex on the short arm of chromosome 6 has been of widespread interest to scientists and physicians for more than 25 years. The most well-characterized genes are HLA-A, B, C, DR, DQ, and DP [4, 9, 14]. These code for transmembrane glycoproteins which function as receptors. They bind degraded pieces of proteins (peptides, 8–15 amino acids long) and present them to T lymphocytes to initiate immune responses.

The HLA-A, B, and C genes were identified first and are often referred to as class I genes. They are expressed on nearly all nucleated cells of the body where they allow cytotoxic T cells to recognize and eliminate tumor cells or cells infected with viruses or other intracellular pathogens [8, 10]. HLA-DR, DQ, and DP molecules (class II molecules) are expressed only on B cells, macrophages, and antigen-presenting cells. These present peptides to T helper cells to induce inflammatory immune responses [5, 8, 10].

The HLA molecules are extremely **polymorphic**. The number of alleles at each locus currently ranges from 38 to over 100 [1, 3]. Widespread amino acid substitutions occur around the molecule's peptide binding groove, and it is thought that the maintenance of polymorphism is due to selection and the evolutionary advantage of **heterozygotes** in combatting infection [7, 11, 12].

The polymorphism and immunologic function of the HLA molecules has made them of considerable interest in transplantation and disease pathogenesis. HLA molecules can induce rejection of HLA-mismatched cells and organs; matching is currently performed for kidneys and bone marrow transplants [6]. Some HLA-DR and HLA-DQ alleles show strong associations with susceptibility to autoimmune and inflammatory diseases such as rheumatoid arthritis, type I insulin-dependent diabetes mellitus, and multiple sclerosis [2, 13]. The reasons for the disease **associations** are not clear, but presumably relate to peptide-binding.

HLA allele frequencies can vary dramatically between ethnic groups [3]. Differences in allele frequencies have been used to monitor population movements and trace ancestral derivations. Some combinations of alleles at adjacent loci are inherited together on a haplotype (*see* **Haplotype Analysis**) more frequently than expected. Such **linkage disequilibrium** is often observed between HLA-B and HLA-C and between HLA-DR and HLA-DQ, and sometimes for longer distances or across the entire gene complex.

For population studies, HLA gene frequencies and two locus linkage disequilibrium coefficients can be determined by standard methods. HLA and disease associations are evident as statistically significant differences in allele frequency between patients and controls. The controls must be matched for ethnic group and adjustment made for multiple comparisons.

Although most interest has centered on HLA-A, B, C, DR, DQ, and DP, the HLA region actually covers more than 4 million base pairs of DNA and includes numerous other genes, including those for cytokines, complement components, olfactory receptors, chaperones, and many with still undefined functions [14]. Analogous gene complexes are found in other mammals [9]. The generic term *major histocompatibility complex* or MHC is frequently used to designate these gene complexes irrespective of species.

DONNA D. KOSTYU

Hogben, Lancelot Thomas

Born: December 9, 1895.
Died: August 22, 1975.

Hogben had a brilliant academic career in biology, with chairs at the London School of Economics, Aberdeen, and Birmingham, and election to Fellowship of the Royal Society in 1936. He wrote popular books on mathematics, science, and linguistics. During the 1939–1945 war he became Acting Director of Medical Statistics at the War Office, and from 1947 to 1961 he was Professor of Medical Statistics at the University of Birmingham. His main interests were in procedures for recording and tabulating medical data, and in the philosophical basis of statistics. In the latter context, he was critical of the claims made for randomized **clinical trials,** and, in a 1957 book on *Statistical Theory,* he expressed dissatisfaction with probabilistic **inference** as a basis for the interpretation of statistics. A very full biography and a complete bibliography are given in [1].

Horvitz–Thompson Estimator

The estimator known as the *Horvitz–Thompson estimator* (HTE) was developed by Horvitz & Thompson in their classic 1952 paper [4]. In that article they propose the following estimator of a population total, X, that is valid for any **sampling design with or without replacement**:

$$x'_{\text{hte}} = \sum_{i=1}^{v} \frac{x_i}{\pi_i},$$

where x_i is the value of the variable for the ith enumeration unit in the sample, π_i is the probability of the ith enumeration unit being selected into the sample and v is the number of distinct enumeration units sampled (as distinguished from n, which is the total sample size). Clearly, $n = v$ when sampling is without replacement.

In that same paper, the authors showed that the HTE is **unbiased** with **standard error** given by the following expression:

$$\text{se}(x'_{\text{hte}}) = \left[\sum_{i=1}^{N} \left(\frac{1-\pi_i}{\pi_i} \right) x_i^2 + \sum_{i=1}^{N} \sum_{j \neq i} \left(\frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j} \right) x_i x_j \right]^{1/2},$$

where N is the number of enumeration units in the population and π_{ij} is the probability that both enumeration units i and j are included in the sample.

In addition, they showed that the estimator, $\overline{v}(x'_{\text{hte}})$, given by the expression

$$\overline{v}(x'_{\text{hte}}) = \sum_{i=1}^{v} \frac{1-\pi_i}{\pi_i^2} x_i^2 + \sum_{i=1}^{v} \sum_{j \neq i} \left(\frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j} \right) \frac{x_i x_j}{\pi_{ij}},$$

is an unbiased estimator of the **variance** of x'_{hte}.

The Horvitz–Thompson estimator differs from an earlier unbiased estimator generally referred to as the *Hansen–Hurwitz estimator*:

$$x'_{\text{hh}} = \frac{1}{n} \sum_{i=1}^{n} \frac{x_i}{\pi'_i}$$

proposed by Hansen & Hurwitz [2] which is valid when sampling is with replacement, and where π'_i is the probability of selecting the ith enumeration unit at any drawing of the sample.

These estimators are illustrated in Table 1, in which $N = 3, n = 2, X_1 = 1, X_2 = 3, X_3 = 4, \pi'_1 = 1/6, \pi'_2 = 2/6, \pi'_3 = 3/6$, and the sampling is with replacement. As can be seen, the two estimators do not necessarily produce the same numerical estimate for the same sample, and both are unbiased estimators of the population total. Both estimators are used in unequal probability sampling, including widely used applications such as **sampling with probability proportionate to size** and **network sampling**. Because the Horvitz–Thompson estimator is appropriate for situations in which sampling is without replacement, however, it has been especially important in the development of design-based **estimation** theory and methodology for sample surveys.

Table 1 Comparison of estimators

Enumeration units in sample (ordered)	Probability of sample occurring	Horvitz–Thompson estimator	Hansen–Hurwitz estimator
X_1, X_1	0.0278	3.27	6.0
X_1, X_2	0.0556	8.67	7.5
X_1, X_3	0.0833	8.61	7.0
X_2, X_1	0.0556	8.67	7.5
X_2, X_2	0.1111	5.40	9.0
X_2, X_3	0.1667	10.73	8.5
X_3, X_1	0.0833	8.61	7.0
X_3, X_2	0.1667	10.73	8.5
X_3, X_3	0.2500	5.33	8.0

For more detailed discussions of the Horvitz–Thompson estimator, we refer the reader to the texts by Hedayat & Sinha [3] and Thompson [5]. Also, **Cochran** discusses this estimator in the *Encyclopedia of Statistical Sciences* [1] (this was one of Professor Cochran's last articles before his death in 1980).

PAUL S. LEVY

Hospital Market Area

A hospital market area (HMA) is the geographic area served by a hospital or a group of hospitals. Market areas are usually defined on the basis of patient origin studies, which examine the zip (postal) codes in which the patients of a hospital reside. HMAs are used in **health services research** to define the populations which provide the denominator for hospital admission rates. For example, one might use the number of back surgeries performed on people who live in a particular HMA, divided by the HMA population, as the admission rate for that area's hospital. In **small-area variation analysis**, one would examine the admission rates for different HMAs to find areas with particularly high or low admission rates, suggesting inappropriate use of services, perhaps attributable to the hospital in that HMA. Unfortunately, however, several hospitals may serve the same area, and a particular hospital may draw patients from many areas, especially in urban and suburban areas. These considerations make a hospital's admission rate both conceptually unclear and technically difficult to estimate.

Two methods have been proposed for defining HMAs and their corresponding hospital-based admission rates from population-based data. The plurality rule of Wennberg & Gittelsohn [3] assigns the population and the hospital admissions from each zip code to the hospital which is the recipient of the plurality of the admissions from the area. While simple to apply, this method is flawed by considerable **misclassification error** since many (potentially even a majority) of the persons and admissions from any given small area will be assigned to one hospital when, in truth, they "belong" to another. Furthermore, this method underemphasizes the utilization of small hospitals, since small hospitals infrequently constitute a plurality in any small area.

Griffith et al. [1] propose a "proportional allocation" method, which allocates a proportion of each small area's population to each hospital based on the proportion of that area's admissions to each hospital. Thus, if Hospital X received 24% of area A's admissions, it would be allocated 24% of Area A's population as well. By summing the populations allocated to Hospital X across all small areas, one can estimate a theoretical catchment population for Hospital X. Dividing this theoretic denominator into Hospital X's admissions yields an "admission rate" for Hospital X. The principal flaw in this method is that, because the population at risk is allocated in proportion to the numerator, it tends to diminish any true differences between hospitals in their propensity to admit.

There are other problems in defining hospital market areas. HMAs based on one patient origin study may not be appropriate for all conditions that might be studied. For example, HMAs defined by a patient origin study of all hospital admissions would not be appropriate for a study of trauma admission rates if one of the hospitals had a renowned trauma center that attracted patients from a large area. Origin studies are often based on Medicare data [2], which, since it is available primarily for people over age 65, may not be appropriate for services for younger people.

PAULA DIEHR

Hotelling, Harold

Born: September 29, 1895, in Fulda, Minnesota.
Died: December 26, 1973, in Chapel Hill, North Carolina.

Reproduced by permission of the Royal Statistical Society

Harold Hotelling was responsible for much original theoretical work in both statistics and mathematical economics and did much to advance the teaching of statistics at US universities, including Columbia and the University of North Carolina. Hotelling's undergraduate degree was a B.A. in journalism from the University of Washington in 1919, but his mathematical talent was recognized and encouraged by Eric T. Bell. Hotelling received an M.S. degree in Mathematics at the University of Washington in 1921 and a Doctorate of Philosophy at Princeton University in 1924, with a dissertation in the field of topology.

Following his doctorate, he spent seven years at Stanford University, first as Research Associate in the Food Research Institute and later as a Associate Professor of Mathematics. During his time at Stanford, he applied mathematical ideas to problems in journalism and political science, population and food supply, and theoretic economics. In 1929, he spent six months with **R.A. Fisher** at the Rothamstead Experimental Station at Harpenden in England which helped to develop his strong interest in mathematical statistics. In 1931 he published perhaps his most important contribution to statistics when he generalized to the multivariate case **Student's** t test for the **mean** of a univariate **normal distribution** [4] (*see* **Multivariate** t **Distribution**). This test has become known as **Hotelling's generalized** T^2 test and was later recognized as having wide applicability in statistics.

In 1931 Hotelling was appointed Professor of Economics at Columbia University where he stayed for 15 years. During World War II he organized the Statistical Research Group, which was engaged in statistical work relating to military problems. The group included **Abraham Wald**, W. Allen Wallis, and Jacob Wolfowitz. During this time Wald developed his theory of **sequential analysis**. In 1946 Hotelling was invited by **Gertrude Cox** to organize a Department of Mathematical Statistics at the University of North Carolina at Chapel Hill (UNC-Chapel Hill), which became an important center for statistical research and teaching. He recruited many outstanding statisticians, including R.C. Bose, S.N. Roy, W. Hoeffding, W.G. Madow, H.E. Robbins, W.L. Smith, and N.L. Johnson. Hotelling remained at UNC–Chapel Hill until his death.

Hotelling proposed a method of **principal components** [6] which is applicable to problems of **factor analysis** arising in educational testing. Using ideas of n-dimensional geometry, the principal components are linear functions of multivariate observations, the first of which has the greatest variability and each subsequent one less variability. A similar mathematical idea underlies Hotelling's theory of **canonical correlations** [7]. Among Hotelling's other contributions to statistics are his paper on differential equations subject to error [3], one of the first dealing with statistical problems related to **stochastic processes**; a paper (jointly with H. Working) on the interpretation of trends [18] which had one of the first examples of a **confidence region** and the idea of **multiple comparisons**; the derivation of the distribution of Spearman's **rank correlation** coefficient [11]; and the experimental determination of the maximum of a function [10].

In economic theory, he dealt with problems in depreciation and the importance of maximizing principles [2]; the interrelated demand and supply functions of profit maximizers [5]; and welfare economics [8], possibly his most important contribution to mathematical economics.

Hotelling had a talent for attracting excellent faculty members, both at Columbia and the University of

North Carolina, and played an important role in raising standards in statistical research and developing mathematical statistics as a respected academic discipline. He was a strong advocate of the importance of **teaching statistics** [9], which had an impact on the academic community and aided in the establishment of departments of statistics at American universities. Levene paid tribute to his excellence as a teacher and lecturer [12].

In 1955 Hotelling received an honorary LL.D. from the University of Chicago. In 1963 he received an honorary D.Sc. from the University of Rochester and was an Honorary Fellow of the **Royal Statistical Society** and a Distinguished Fellow of the American Economic Association. In 1936–37 he was the President of the Econometric Society and in 1941 of the Institute of Mathematical Statistics. In 1970 he was elected to the National Academy of Sciences and in 1972 received the North Carolina Award for Science. His final award, in 1973, was his election to membership of the Accademia Nazionale dei Lincei in Rome, which occurred shortly before his death.

Hotelling's contributions to statistics have been memorialized by Anderson [1], Madow [13, 14], **Neyman** [15], and Olkin [16], and to mathematical economics by Samuelson [17].

EDMUND A. GEHAN

Hotelling's T^2

The Hotelling T^2 statistic is a generalization of the squared univariate t (*see* **Student's t Distribution**) for testing hypotheses on the normal distribution mean, when the population variance is unknown and must be estimated from the sample observations. For a single random sample of N p-dimensional observations from the **multivariate normal distribution**, the Hotelling statistic for testing the hypothesis $\mathrm{H}_0\colon \boldsymbol{\mu} = \boldsymbol{\mu}_0$ on the mean vector $\boldsymbol{\mu}$ is

$$T^2 = N(\overline{\boldsymbol{x}} - \boldsymbol{\mu}_0)'\mathbf{S}^{-1}(\overline{\boldsymbol{x}} - \boldsymbol{\mu}_0).$$

In the squared univariate statistic the means have been replaced by mean vectors and the reciprocal of the sample variance has become the inverse of the sample **covariance matrix S**. T^2 is thus a measure of the distance of the sample mean vector from the hypothesized population vector, but in the metric of **S**. This case of Hotelling's T^2 test, its general derivation, and its application to two independent samples and repeated measures designs are covered in this article.

The Hotelling T^2 Test

Derivation

The T^2 statistic was originally proposed by Hotelling [3]. Hotelling's account of its derivation by the invariance properties of the roots of a certain determinantal equation is contained in [4]. T^2 is also the sample analog of **Mahalanobis distance** [5] of $\overline{\mathbf{x}}$ and $\boldsymbol{\mu}_0$. Construction of the hypothesis test by the generalized **likelihood ratio** principle gives a statistic that is a monotonic function of T^2 [1]. Roy [10, 11] derived the T^2 statistic by his **union–intersection principle**; the explicit single-sample case has been given by Morrison [7].

Distribution of T^2

Hotelling [3] first found the distribution of T^2 by a geometrical argument. More recently, Rao [9] has given an ingenious and simple derivation of the distribution for both the null and alternative hypotheses. We give a very general definition of T^2, state its distribution, and then apply it to cases of T^2 computed from sample observations. Let $\mathbf{Y}$ be a $p \times 1$ random vector with the multivariate normal distribution $\mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. The sums of squares and products matrix $n\mathbf{S}$ has the **Wishart distribution** [[1], Chapter 7] with parameters degrees of freedom n and covariance matrix $\boldsymbol{\Sigma}$, and is distributed independently of $\mathbf{Y}$. Then the general Hotelling statistic is

$$T^2 = \mathbf{Y}'\mathbf{S}^{-1}\mathbf{Y},$$

and its linear transformation,

$$F = \left[\frac{(n - p + 1)}{np}\right] T^2,$$

has the noncentral F **distribution** with degrees of freedom p, $n - p + 1$, and noncentrality parameter $\boldsymbol{\mu}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}$. If $\mathbf{E}(\mathrm{Y}) = \boldsymbol{\mu} = \mathbf{0}$, F has the usual central F distribution with p and $n - p + 1$ degrees of freedom. In the context of a single random sample and a test of the null hypothesis $\mathrm{H}_0\colon \boldsymbol{\mu} = \boldsymbol{\mu}_0$, $\mathbf{Y} = \overline{\mathbf{y}} - \boldsymbol{\mu}$ and $n = N - 1$. Under $\mathrm{H}_0\colon \boldsymbol{\mu} = \boldsymbol{\mu}_0$, $\overline{\mathbf{y}}$ is $\mathrm{N}[\boldsymbol{\mu}_0, (1/N)\boldsymbol{\Sigma}]$, $T^2 = \mathrm{N}(\overline{\mathbf{y}} - \boldsymbol{\mu}_0)'\mathbf{S}^{-1}(\overline{\mathbf{y}} - \boldsymbol{\mu}_0)$, and $F = [(N - p)/(N - 1)p]T^2$ has the central F distribution with p and $N - p$ degrees of freedom. For the general alternative hypothesis $\mathrm{H}_0\colon \boldsymbol{\mu} = \boldsymbol{\mu}_1$, $[(N - p)/(N - 1)/p]T^2$ has the noncentral F distribution with p and $N - p$ degrees of freedom and noncentrality parameter $\delta^2 = N(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0)'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0)$. **Power** probabilities of the T^2 test can be found from the Pearson–Hartley charts of the noncentral F distribution [7, 8], or by statistical *software* (e.g. [2] and [6]). **Sample size determination** for a given α-level test and power probability must, of course, be made iteratively, since the sample size appears both in the second degrees of freedom and in the noncentrality parameter.

Affine Invariance Property

The T^2 statistic has an important invariance property: it is unaffected by affine **transformations**

$$\mathbf{W} = \mathbf{AY} + \mathbf{h},$$

in which $\mathbf{A}$ is a $p \times p$ matrix of real constants with a nonzero determinant, and $\mathbf{h}$ is a $p \times 1$ vector of constants. The transformation must be applied to the sample mean vector $\overline{\mathbf{y}}$ as well as the population mean

vector $\boldsymbol{\mu}_0$. Use of the transformation in the single-sample Hotelling statistic gives

$$\begin{aligned} T_{\mathrm{W}}^2 &= N(\mathbf{A}\bar{\mathbf{y}} + \mathbf{h} - \mathbf{A}\boldsymbol{\mu}_0 - \mathbf{h})'(\mathbf{ASA}')^{-1} \\ &\quad \times (\mathbf{A}\bar{\mathbf{y}} + \mathbf{h} - \mathbf{A}\boldsymbol{\mu}_0 - \mathbf{h}) \\ &= N(\bar{\mathbf{y}} - \boldsymbol{\mu}_0)'\mathbf{A}'(\mathbf{ASA}')^{-1}(\bar{\mathbf{y}} - \boldsymbol{\mu}_0) \\ &= T_{\mathrm{Y}}^2, \end{aligned}$$

and, of course, the affine invariance property can be verified for other more general forms of T^2. The statistic is not only unaffected by scale and location changes, but is also unchanged by oblique linear transformations of the coordinate system as well.

Tests of Hypotheses

Single Sample

We have already introduced the single-sample T^2 test of $\mathrm{H}_0\colon \boldsymbol{\mu} = \boldsymbol{\mu}_0$ against $\mathrm{H}_1\colon \boldsymbol{\mu} \neq \boldsymbol{\mu}_0$: reject H_0 at the α level if $F = [(N-p)/(N-1)p]T^2 > F_{\alpha;p,N-p}$. The hypothesized mean vector $\boldsymbol{\mu}_0$ is given by the analyst from a substantive context: psychological test score means, dimension, or other specification means in quality assurance, or normative values of the random vector components.

Two Samples

The model for the two-sample T^2 test for equality of multivariate normal mean vectors assumes that independent random samples have been drawn from each population, and that the populations have a common covariance matrix $\boldsymbol{\Sigma}$. The observation vectors in the respective samples will be denoted by $\mathbf{x}_{11}, \ldots, \mathbf{x}_{N1}$, $\mathbf{x}_{12}, \ldots, \mathbf{x}_{M2}$. The sample mean vectors are

$$\bar{\mathbf{x}}_1 = \left(\frac{1}{N}\right)\sum_{i=1}^{N}\mathbf{x}_{i1}, \qquad \bar{\mathbf{x}}_2 = \left(\frac{1}{M}\right)\sum_{i=1}^{M}\bar{\mathbf{x}}_{i2}$$

and the pooled, or within-sample, covariance matrix estimating $\boldsymbol{\Sigma}$ is

$$\mathbf{S} = \left(\frac{1}{N+M-2}\right)\left[\sum_{i=1}^{N}(\mathbf{x}_{i1} - \bar{\mathbf{x}}_1)(\mathbf{x}_{i1} - \bar{\mathbf{x}}_1)' + \sum_{i=1}^{M}(\mathbf{x}_{i2} - \bar{\mathbf{x}}_2)(\mathbf{x}_{i2} - \bar{\mathbf{x}}_2)'\right].$$

The two-sample T^2 statistic is

$$T^2 = \left(\frac{NM}{N+M}\right)(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2).$$

When $\mathrm{H}_0\colon \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2$ is true, $F = [(N+M-p-1)/(N+M-2)p]T^2$ has the F distribution with p and $N+M-p-1$ degrees of freedom. The null hypothesis is rejected if $F > F_{\alpha;p,N+M-p-1}$. When the alternative $\mathrm{H}_1 : \boldsymbol{\mu}_1 \neq \boldsymbol{\mu}_2$ holds, F has the noncentral F distribution with degrees of freedom $p, N+M-p-1$, and noncentrality parameter $\delta^2 = [NM/(N+M)](\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)$.

Repeated Measurements

Frequently, p observations are taken successively on each of N independent sampling units for a test of the hypothesis that the p means are equal (*see* **Longitudinal Data Analysis, Overview**). For example, plasma-free fatty acid levels might be measured in blood samples taken at $p = 6$ 15-min intervals from normal subjects after they had ingested a particular food or drug. The hypothesis of a common-mean-free fatty acid level at six times might be of interest, and could be tested by Hotelling's T^2 statistic.

The repeated-measures test is equivalent to testing the hypothesis that the $p-1$ successive differences of the variables have zero means. We begin by transforming the p response variables $X_1, \ldots, X_p$ to the successive differences $Y_1, \ldots, Y_{p-1}$ by the linear transformation

$$\begin{aligned} \mathbf{Y} &= \begin{bmatrix} Y_1 \\ Y_2 \\ \cdot \\ \cdot \\ \cdot \\ Y_{p-1} \end{bmatrix} \\ &= \begin{bmatrix} -1 & 1 & 0 & \cdots & 0 & 0 \\ 0 & -1 & 1 & \cdots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & -1 & 1 \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \\ \cdot \\ \cdot \\ \cdot \\ X_p \end{bmatrix} \\ &= \mathbf{CX}. \end{aligned}$$

We test $\mathrm{H}_0\colon \mathrm{E}(Y_1) = \cdots = \mathrm{E}(Y_{p-1}) = 0$ by

$$T^2 = N\bar{\mathbf{y}}'\mathbf{S}^{-1}\bar{\mathbf{y}},$$

or equivalently in terms of the observations on the original variables,

$$T^2 = N\bar{\mathbf{x}}'\mathbf{C}'(\mathbf{CSC}')^{-1}\mathbf{C}\bar{\mathbf{x}},$$

where $\mathbf{C}$ is the $(p-1)\times p$ matrix of the successive difference transformation. As in the single-sample case, $F = [(N-p+1)/(N-1)(p-1)]T^2$ has the F distribution with $p-1$ and $N-p+1$ degrees of freedom, and we reject the null hypothesis of equal response variable means if $F > F_{\alpha;p-1,N-p+1}$.

Paired Response Variables

Some repeated-measurements experiments consist of the same p response variables observed at two different times or conditions on the same subjects or other sampling units. If we represent the $p\times 1$ response vectors at the two times by $\mathbf{X}_1$ and $\mathbf{X}_2$ we can test the hypothesis $\mathrm{H}_0 : \mathrm{E}(\mathbf{X}_1) = \mathrm{E}(\mathbf{X}_2)$ by the T^2 statistic. A random sample of N independent observation vectors partitioned according to the two times as $[\mathbf{x}_{i1}', \mathbf{x}_{i2}']$ yields the respective partitioned sample mean vector and covariance matrix

$$\begin{bmatrix}\bar{\mathbf{x}}_1'\\ \bar{\mathbf{x}}_2'\end{bmatrix}, \qquad \begin{bmatrix}\mathbf{S}_{11} & \mathbf{S}_{12}\\ \mathbf{S}_{12}' & \mathbf{S}_{22}\end{bmatrix},$$

where

$$\mathbf{S}_{ij} = \sum_{h=1}^{N}(\mathbf{x}_{hi}-\bar{\mathbf{x}}_i)(\mathbf{x}_{hj}-\bar{\mathbf{x}}_j)', \quad i,j = 1,2.$$

The Hotelling statistic is

$$T^2 = N(\bar{\mathbf{x}}_1-\bar{\mathbf{x}}_2)'(\mathbf{S}_{11}+\mathbf{S}_{22}-\mathbf{S}_{12}-\mathbf{S}_{12}')^{-1} \times (\bar{\mathbf{x}}_1-\bar{\mathbf{x}}_2),$$

and reflects the correlations between the two times through the elements of the submatrix $\mathbf{S}_{12}$. T^2 is merely the extension of the **paired *t* test** to p pairs of response variables. If the data were transformed to an $N\times p$ matrix of paired differences, then the T^2 statistic would reduce to the single-sample T^2 described previously. When H_0 is true, $F = [(N-p)/(N-1)p]T^2$ has the F distribution with p and $N-p$ degrees of freedom. H_0 would be rejected when F exceeds the right-tail α-level critical value for that distribution.

Confidence Statements Obtained from T^2

Confidence Region for a Single Mean Vector

The distribution of T^2 for a single random sample from the multinormal distribution can be used to obtain this ellipsoidal $100(1-\alpha)\%$ confidence region for the population mean vector $\boldsymbol{\mu}$:

$$N(\boldsymbol{\mu}-\bar{\mathbf{x}})'\mathbf{S}^{-1}(\boldsymbol{\mu}-\bar{\mathbf{x}}) \le [(N-1)p/(N-p)]F_{\alpha;p,N-p}$$

(*see* **Confidence Intervals and Sets**).

Simultaneous Confidence Intervals

Rejection of the null hypothesis by the T^2 test still does not indicate *which* of the p responses may have contributed to that decision. Roy's union–intersection derivation of T^2 [10] leads directly to simultaneous tests and confidence intervals for linear compounds of the population means (*see* **Simultaneous Inference**). "Simultaneous" means that one may construct an unlimited number of confidence intervals and still have an overall coverage probability of $1-\alpha$, or test infinitely many hypotheses and still enjoy an overall type I error rate no greater than α. For the single-sample case the $100(1-\alpha)\%$ Roy–Bose [12] simultaneous confidence interval for the linear compound $\mathbf{a}'\boldsymbol{\mu}$ is

$$\mathbf{a}'\bar{\mathbf{x}} - \left\{(1/N)\mathbf{a}'\mathbf{Sa} \times[(N-1)p/(N-p)]F_{\alpha;p,N-p}\right\}^{1/2} \le \mathbf{a}'\boldsymbol{\mu} \le \mathbf{a}'\bar{\mathbf{x}} + \left\{(1/N)\mathbf{a}'\mathbf{Sa} \times[(N-1)p/(N-p)]F_{\alpha;p,N-p}\right\}^{1/2},$$

where $\mathbf{a}$ is any $p\times 1$ vector of constants chosen by the investigator. For the two-sample situation the $100(1-\alpha)\%$ simultaneous confidence interval for the linear compound $\mathbf{a}'(\boldsymbol{\mu}_1-\boldsymbol{\mu}_2)$ of the differences of the mean vector elements is

$$\mathbf{a}'(\bar{\mathbf{x}}_1-\bar{\mathbf{x}}_2) - \left\{[(N+M)/NM]\mathbf{a}'\mathbf{Sa} \times[(N+M-2)p/(N+M-p-1)] \times F_{\alpha;p,N+M-p-1}\right\}^{1/2} \le \mathbf{a}'(\boldsymbol{\mu}_1-\boldsymbol{\mu}_2) \le \mathbf{a}'(\bar{\mathbf{x}}_1-\bar{\mathbf{x}}_2) + \left\{[(N+M)/NM]\mathbf{a}'\mathbf{Sa}\right.$$

$$\times [(N + M - 2)p/(N + M - p - 1)]$$
$$\times F_{\alpha;p,N+M-p-1}\}^{1/2}.$$

If the interval contains zero, then the hypothesis $H_0: \mathbf{a}'\boldsymbol{\mu}_1 = \mathbf{a}'\boldsymbol{\mu}_2$ is tenable at the α level in the simultaneous testing sense. Alternatively, in both cases families of hypotheses can also be tested with an overall type I error rate no greater than α.

DONALD F. MORRISON

Human Genetics, Overview

Mendel's laws underlie the distribution of genetic traits observed in individuals. At each genetic locus, an individual receives one **gene** which is a copy of a randomly chosen one of the two genes of the father, and one which is a copy of a randomly chosen one of the two genes of the mother. Each individual passes on to each offspring a randomly chosen one of his two genes, independently to each offspring and independently of the gene contributed by his spouse. The different allelic forms of the genes at a locus, acting in combination with alleles at other loci and with environmental effects, give rise to different phenotypes, the observable characteristics of individuals. Alleles at loci on different chromosomes are inherited independently, but alleles at loci on the same chromosome are *linked*, or correlated, in their inheritance, owing to the process of meiosis which gives rise to the gamete cells.

At the population level, new alleles arise by mutation, and frequencies of alleles are influenced by the genetic forces of selection and the demographic forces of migration and population structure. Since populations are finite, allele frequencies will change over time under random genetic drift, even in the absence of directional genetic or demographic forces (*see* **Population Genetics**). Whereas genetic analysis of other species has been directed towards an understanding of evolution and population biology, or to the increase of crop yields and animal produce, human genetics has been primarily focused on an understanding of the genetic determinants of human disease.

The year 1900 saw the rediscovery of Mendel's work, 1901 the first discovery of a human **blood group** system, and 1902 the first application of Mendelian principles in medical genetics, setting the stage for the development of human medical and population genetics. With the analysis of data from human (as opposed to experimental) populations, came the need to address questions of **ascertainment** [11, 37]. With the discovery of blood group systems, came the first array of **genetic markers** that could be used both to assess human diversity and as markers in **linkage analysis**.

In the 1930s there was a rapid expansion in the development of approaches to the statistical analysis of human genetic data, with the work of Haldane, Hogben, and Fisher. Although Mendelian principles had been applied earlier in assessing the proportion of affected offspring in families ascertained for segregation of rare recessive diseases [1, 37], this period also saw the earliest formal **segregation analyses**, comparing alternative models for the underlying basis of a genetic trait [12, 16], and consequently further development in a statistical framework and model for ascertainment [8]. Also at this time came the recognition that the methods of linkage analysis already used in experimental populations could be applied also to data collected from human families ascertained for a genetic disease [9, 13].

There is no strict separation between inferences of the genetic basis of traits from family data and from population data. One of the earliest applications of population genetic principles to human disease was Haldane's consideration of the expected frequencies of Mendelian genetic diseases in terms of mutation-selection balance [14]. One of the first statistical analyses of population data was that of Bernstein [2] leading to a resolution of the basis of the ABO blood types, while Fisher [10] regarded his analysis of the rhesus blood group system as a fine example of scientific inference. The resolution of human genetic blood groups and enzyme systems not only provided genetic markers for linkage analysis but also a source of extensive information on human diversity.

In fact, the discovery of many blood group systems in the first half of the century prompted many studies of the extent of human diversity, and a search for explanations of observed data on the basis of models of selection, and of the migration patterns of human history. Many of the population genetic ideas and models underlying such inferences were described by Cavalli-Sforza & Bodmer [5]. While **demography** may be the major factor influencing global patterns of human diversity, a gene need not itself be subject to differential selection in order for its selection to have an impact. The discovery of the many variants present in the human white blood cells **(HLA system)**, and their multiple and complex associations with disease prompted renewed effort in understanding patterns of human variation. The phenomenon of "hitchhiking" [20], where the selective effects of genes at closely linked loci affect patterns of observed variation, has been used to explain unusually high frequencies of

some human disease alleles in some human populations [35]. Thomson et al. [34] used human HLA data to examine the evolutionary interactions of selection, migration, and linkage. A more recent review of the statistical approaches to an understanding of associations of HLA and disease is given in [33]. Although current research in human genetics is often more focused towards individual data than to information at the population level, the data painstakingly compiled by Mourant et al. [23] remain a rich source of information, while the major work of Cavalli-Sforza et al. [6] shows how population allele frequencies reflect the imprint of human history.

While demography and genetic selection affect population allele frequencies, mutation is the source of new genetic variation. The estimation of mutation rates is therefore an important aspect of statistical genetics. It is hard to obtain precise estimates of human mutation rates by direct methods, since mutation rates are small. Indirect methods of estimation use current levels of genetic variation, and require assumptions about population size and structure. Over the 45 years since 1951 [25], the leader in study of human mutation rates by both direct [27] and indirect [26] methods has been J.V. Neel.

From 1935 to 1975 there were many developments in the statistical analysis of human genetic data observed on relatives, but the basic framework of segregation and linkage analysis, as developed by J.B.S. Haldane and R.A. Fisher, remained largely unchanged. For computational reasons, early analyses had been restricted to nuclear families or small pedigrees. With the widespread availability of digital computers, increasing interest in analysis of data on more extended pedigrees led to the development of new computational approaches [7]. With computational power permitting the analysis of larger data sets, and hence perhaps resolving more complex traits, came the necessity for more complex trait models such as the **mixed model in segregation analysis** [22]. In linkage analysis particularly, there were further developments, leading to a better understanding of how inferences could be drawn [15, 21] and to a better understanding of their properties of linkage likelihoods [31]. Ott [29] covers many of these developments.

Since 1980, with the development of molecular biology, there has been an explosion in the number of **polymorphisms** available for use as genetic markers in linkage analysis. Human genome maps at centimorgan density are now a reality [24], and the limitation in linkage analysis is no longer the availability of segregating markers, but the trait information. Simple Mendelian traits are rapidly being mapped, and the relevant genes identified. However, if a trait is exceedingly rare, or shows genetic heterogeneity, or if its genetic basis is uncertain or complex involving alleles at several loci, then problems in linkage analysis remain.

The computation of a linkage likelihood over a pedigree requires a specific segregation analysis model for the trait to be assumed. For traits whose basis is uncertain, particularly of incomplete **penetrance** or delayed onset, linkage detection methods using only affected individuals have been developed. These are more robust to trait model assumptions; indeed, under the null hypothesis of no linkage, the distribution of the test statistic is often independent of trait model assumptions. Such methods date back to the 1930s, when Penrose [30] introduced sib pair methods, but more recently have been extended to other types of relationship [3, 19, 36]. In many cases, the use of only affected pedigree members can greatly increase robustness with little loss of power.

Once linkage has been detected, **multipoint linkage analysis** can help to localize the position of the gene more precisely. However, multipoint methods are computationally exceedingly intensive, particularly where there are many unobserved members of the pedigree. Moreover, there are limits to the resolution of linkage mapping (*see* **Genetic Map Functions**) [4]. The scale of resolution depends on the number of segregations that can be (explicitly or implicitly) observed. Where genetic homogeneity can be assumed, disequilibrium mapping [17] or **haplotype analysis** provides an alternative. Here the exact ancestry of current carriers of a disease allele is unknown, but their shared ancestry results in **linkage disequilibrium** with marker loci at small **genetic distance**. The large number of ancestral segregations provides for a finer mapping scale. Ultimately it may be possible to map at still finer scales by considering the matching and nonmatching segments of individual genomes [28].

Genetic heterogeneity is one of the major difficulties in resolving the genetic basis of any trait. Studies within a given population or of data on a single extended pedigree reduce the chance of heterogeneity

within the data set, but such data sets are often limited in size, and results may not be relevant outside the particular population studied. Gradually, however, more complex traits are being resolved through advances both in the available genetic data and in methods of analysis and computation.

The classic text on human genetics is that of Stern [32]. The more recent text by Khoury et al. [18] provides a thorough overview of approaches in modern genetic epidemiology, while Ott [29] is the best reference text on linkage analysis in human genetics.

E. THOMPSON

Human Genome Project

The Human Genome Project (see http://www.ornl.gov/hgmis/) was formally initiated on 1 October 1990 as an international scientific effort to (a) map all of the approximately 30 000 functional human **genes** and (b) sequence the approximately 3 billion deoxyribonucleic acid (DNA) nucleotides that make up these genes [30] (*see* **DNA Sequences**; **Human Genetics, Overview**; **Sequence Analysis**). Originally envisioned as a 15-year project, the Human Genome Project has proceeded far more rapidly than anticipated, due in large part to rapidly accelerating improvements in molecular technology. A major milestone of the Project was reached in 2001 with the publication of a first draft sequence of the human genome [10]; a parallel industry effort undertaken by Celera Genomics was published contemporaneously [32].

The Project's primary goals were to enable a fuller understanding of the genetic basis of **complex diseases** and to allow new insights into human evolution through the comparison of the human genome with the genomes of other organisms. Secondary goals of the Human Genome Project included: developing informatics tools to store, disseminate and analyze the very large amounts of data produced (*see* **Bioinformatics**); technology transfer to the private sector; and developing appropriate responses to any ethical, legal or social concerns arising from the Project.

The availability of a draft outline of the human genome will greatly assist the investigation of the complex interrelationships of genetically programmed phenotypes with the constituent genes comprising each individual's unique version of the human genome. Several kinds of biologic information are being produced by the Human Genome Project to enable such investigations, including **DNA sequences**, physical maps, genetic maps (*see* **Genetic Map Functions**) and genetic **polymorphisms**. These data have increased exponentially over the last decade and are being collated in large, web-based databases.

There are many potential benefits anticipated from the Human Genome Project. These include advances in **molecular epidemiology**, allowing benefits such as improved disease diagnosis; improved risk models allowing early detection of increased disease risk; enhanced drug design; gene therapy; and drugs tailored to individual patients based on their **pharmacogenetic** profiles. Other potential benefits expected to arise from the Human Genome Project include enhancements in the fields of **statistical forensics**, bioarchaeology, evolutionary biology and **population genetics**.

Genetic Polymorphism Discovery

An important component of the Human Genome Project that is currently the focus of intense research effort internationally is the discovery and utilization of genetic **polymorphisms** for genetic **association** studies (*see* **Disease-marker Association**). The simplest and most abundant class of polymorphism derives from a single-base substitution of one nucleotide for another – a single nucleotide polymorphism (SNP; pronounced "snip") [17]. SNPs are recognized through a variety of techniques that exploit the known DNA sequence variant [17]. SNPs may be found in coding or regulatory regions of a gene and thus can directly affect gene function or expression.

The generation of SNP maps from high-throughput sequencing projects [17, 24, 31, 33] has continued to accelerate over the last decade [1, 5, 6, 18, 22, 25], with the hope that these data will facilitate the process of gene discovery in complex human disease. In addition to large government-sponsored projects in England [http://www.sanger.ac.uk/], the US [4] and Japan [23], there are now several major industrial group efforts [14, 15], a large academic–industry consortium effort [19], and a number of smaller academic programs [e.g. http://pga.bwh.harvard.edu/] devoted to large-scale SNP discovery. A current focus in human genetics is thus on SNP discovery, leading to the creation of SNP catalogues, and on improving technologies for SNP genotyping.

As part of the intense research effort to improve our ability to discover the genetic determinants of complex human disease over the last decade, technologic advances in the laboratory related to sequencing and SNP genotyping have proceeded at a very rapid rate (*see* **Genetic Markers**). Although the pace of technologic development in SNP analysis is rapid [7, 8], using microarray and other technologies [16], there are many technical problems with these systems that limit their utility at present, such as cost and the inherent lack of flexibility in hardwiring markers on a chip.

There are six primary areas of potential application for SNP technologies in improving our understanding of the etiology of complex human disease: gene mapping; candidate polymorphism association testing; pharmacogenetics; diagnostics and risk profiling; prediction of response to nonpharmacologic environmental stimuli; and homogeneity testing and epidemiologic study design [25]. While only a few of these areas are currently areas of active research in human genetics, it is likely that some or all of these areas will become relevant to investigations of the genetic susceptibility to human disease.

Implications of the Human Genome Project for Biostatistics

The Human Genome Project has had important implications for the fields of biostatistic genetics and **genetic epidemiology**. Catalyzed in part by the vast amounts of data generated by the Human Genome Project and the SNP genotyping efforts in complex human disease, it has become clear that concomitant statistical advances in the mapping of complex traits will also be required [12, 28, 35] (*see* **Linkage Analysis, Model-based**; **Linkage Disequilibrium**). The Human Genome Project and SNP genotyping efforts have caused a substantial rethinking of mapping methodologies and study designs in complex human disease [9, 21, 27, 34]. The testing of large numbers of genotypes or other genetic parameters, such as gene expression profiles for association with one or more traits, raises important statistical issues regarding the appropriate false positive rate of the tests and the level of statistical significance to be adopted given the multiple testing involved [21, 27]. Other important and unresolved issues include the appropriate use of haplotypes (*see* **Haplotype Analysis**) and the modeling of linkage disequilibrium. The required methodologic development in genetic statistics and bioinformatics is nontrivial given the complexity of many common diseases and the genetic databases being collated. Some current areas of methodologic development include haplotype analysis [11, 29, 36], distance-based mapping measures [3, 26], combined linkage and association analyses [13], techniques for modeling linkage disequilibrium and population history [36], and **Markov chain Monte Carlo**-based approaches [20] (*see* **Bioinformatics** for other areas of methodologic development).

Conclusion

The sequencing of the human genome, pursued both by government and industry, is rapidly informing us as to genetic structure and diversity [2]. The availability of a complete reference sequence for the human genome, together with new advances in high-throughput genotyping, functional genomics, chemistry, proteomics and in bioinformatics and biostatistical genetics, will likely accelerate the gene discovery process in complex human disease.

LYLE J. PALMER

Hypergeometric Distribution

Consider a clinical study of five patients A, B, C, D, and E, two of whom are randomly assigned to a new therapy (surgery plus drug) and the remaining three to surgery alone. As healthy skeptics, we wish to test the statement that the patients' fates are unaffected by the new drug. Suppose that patients A and C respond. What is the probability distribution of the number of responders in the group assigned to the new therapy?

We can easily enumerate the possible outcomes (Table 1). There are 10 equally likely assignments of patients to the treatment groups, and under our assumption of predestined fate, the probability of two, one, or no responders in the new treatment group are 10%, 60%, and 30%, respectively.

Enumeration works well when the number of possibilities is small, such as the example in Table 1 of 10 possible assignments. However, as shown later, there is a rapid increase in the number of possible assignments with a modest increase in the scope of the number of patients.

The Hypergeometric Distribution

Consider a population of N patients, among whom A are "responders" and $B = N - A$ are "failures". Suppose we select a random sample of n patients. (That is, any subset of n patients has an equal chance of being the actual sample.) What is the probability distribution of the number of responders in the sample? The answer defines the *hypergeometric distribution*.

Combinatorial Considerations

Question: How many distinct n letter words can we make from an N letter alphabet, when no letter is repeated?

Table 1 Assignments to new therapy (others to standard)

AC (two responders in new therapy):	1 way
AB, AD, AE, BC, CD, CE (one responder):	6 ways
BD, BE, DE (no responders):	3 ways

Answer:

$$\prod_{i=0}^{n-1}(N-i) = N(N-1)(N-2)\dots(N-n+1). \tag{1}$$

The first letter can be selected N ways. For each of these, the second can be chosen in $(N-1)$ ways. Hence there are $N(N-1)$ two-letter words. For each of these two-letter words there are $(N-2)$ ways to select the third letter, or $N(N-1)(N-2)$ three-letter words. The general formula follows inductively.

Question: How many ways can we select n distinct letters from an N letter alphabet, if order is unimportant?

Answer:

$$\binom{N}{n} = \frac{N!}{n!(N-n)!} = \left[\prod_{i=0}^{n-1}(N-i)\right] \Big/ n!, \tag{2}$$

where, by definition, $r! = r(r-1)(r-2)\dots 1$ and $0! = 1$. [We define $\binom{N}{n}$ as zero if $n < 0$ or $n > N$.]

By applying (1) with $N = n$, there are $n!$ ways to arrange each collection of n distinct letters into words. Hence, the number of distinct selections of n letters from an N letter alphabet is the number of n letter words per (1) divided by $n!$ This gives us the right-most result in (2). By multiplying the numerator and denominator of the right-most part of (2) by $(N-n)!$, we obtain the middle expression of (2).

Hypergeometric Probability Function

The solution of the original question posed is defined as the probability of observing x responses in a random sample of n patients from a population containing A responders and $N - A$ nonresponders:

$$h(x; n, A, N) = \binom{A}{x}\binom{N-A}{n-x} \Big/ \binom{N}{n} \tag{3}$$

$$= \binom{n}{x}\binom{N-n}{A-x} \Big/ \binom{N}{A}. \tag{4}$$

Note that (4) tells us that the roles of n and A are interchangeable.

To derive (3), note that from (2), there are $\binom{N}{n}$ possible samples. Also from (2), we can select x responders from the population of A responders in $\binom{A}{x}$ ways and for each of those, we can complete the sample by selecting the nonresponders in $\binom{N-A}{n-x}$ ways. Hence, the numerator of (3) represents the number of possible samples with exactly x responders.

To obtain (4) from (3), one can simply replace the combinatorial terms by factorials [middle part of (2)].

In the example posed in the Introduction, $N = 5$ patients, $A = 2$ responders, and $n = 2$ sampled in the experimental treatment. From (3):

$$h(2; 2, 2, 5) = \frac{1}{10},$$
$$h(1; 2, 2, 5) = \frac{6}{10},$$
$$h(0; 2, 2, 5) = \frac{3}{10}.$$

If $N = 20$ and $n = 10$, then there are 184 756 possible samples. Enumeration of the possible samples, as in the case where $N = 5$ and $n = 2$, would quickly become too time-consuming.

Properties of the Hypergeometric Distribution

Property 1. By straightforward algebra applied to (3):

$$h(x+1; n, A, N) = h(x; n, A, N)\left[\frac{(n-x)(A-x)}{(x+1)(N-A-n+x+1)}\right]. \quad (5)$$

Property 2. Since from (5), the term in square brackets decreases with increasing x, the distribution is "unimodal" and has its mode at one (or both) of the integer values of x surrounding the x value where the term in square brackets is equal to unity. That is, the mode is adjacent to or equal to (if an integer):

$$x = \frac{(A+1)(n+1)}{N+2} - 1. \quad (6)$$

A "unimodal" discrete distribution over a finite set of integers $0, 1, \ldots, K$ has probabilities that behave in one of the following ways: (i) increase to a peak and then decrease; (ii) have a peak at zero and decrease; or (iii) increase from zero to its peak at the highest possible x, K. Looking at increasing values of the random variable, it cannot show an increase in probability to the right of a decrease.

Property 3. The mean of the hypergeometric distribution, μ, is

$$\mu = \frac{nA}{N}. \quad (7)$$

Property 4. The variance of the hypergeometric distribution, σ^2, is

$$\sigma^2 = \frac{n(N-n)A(N-A)}{N^2(N-1)}. \quad (8)$$

Property 5. Although the mean and mode do not seem to be related, it can be shown that the mean is always larger than the value defined by x in (6), and the mean is always within one unit of the value of x defined in (6). Thus, the mode must occur close to the mean.

Approximations

The approximations below can be "proven" by limit theory. The astute question, however, is: How large must the various quantities be before the approximation works to our satisfaction? Hence, rather than limit theory, we use exhaustive computer searches to explore the accuracy. The demonstrations are convincing in terms of closeness over a broad range of applications.

We approximate the cumulative distribution, which has exact value:

$$\Pr[X \le x] = H(x; n, A, N) = \sum_{j=0}^{x} h(j; n, A, N), \quad (9)$$

where h is defined in (3).

Binomial Approximation

If the population, N, is "large", and the sample size, n, is a "small" fraction of the smaller of A (responders) and $(N - A)$ (failures), then the cumulative distribution satisfies the following approximation:

$$H(x; n, A, N) \cong \sum_{j=0}^{x} \binom{N}{j} p^j (1-p)^{n-j}, \quad (10)$$

where $p = A/N$.

The right-hand side of (10) is the cumulative **binomial distribution**.

Because of the "drop in the bucket" effect, successive trials are close to independent. Sampling without replacement (hypergeometric) is similar to sampling with replacement (binomial). (*see* **Sampling With and Without Replacement**).

Reality Check. We studied each of the 432.9 million binomial approximations where $100 \leq A \leq 1000$, $100 \leq N - A \leq 1000$, $n \leq 0.1A$ and $n \leq 0.1(N - A)$, and $x = 0, 1, \ldots, n$. The largest deviation between the cumulative distributions occurred where $A = 100$, $N - A = 100$, $n = 10$, and $x = 3$. Eq. (9) gave an exact value of 0.1656, while (10) gave an approximate value of 0.1719, for a difference of 0.0063.

Normal Approximation

Let us define the "smallest expected value" as

$$EC = \min\left\{\frac{An}{N}, \frac{(N-A)n}{N}, \frac{A(N-n)}{N}, \frac{(N-A)(N-n)}{N}\right\}, \tag{11}$$

the smallest of the four expectations obtained per (7), interchanging the symmetric roles of n vs. $N - n$ and A vs. $N - A$.

If EC is "large", then

$$H(x; n, A, N) \cong \Phi\left(\frac{(x-\mu)}{\sigma}\right), \tag{12}$$

where Φ is the **standard normal** cumulative distribution. The values μ and σ are defined in (7) and (8).

Since the hypergeometric distribution is discrete, Yates [8] suggested that a better approximation might result by using the following, noting that all the probabilities occur at integer values:

$$\Pr[X \leq x + 0.5] = \Pr[X \leq x] \text{ for } x = \text{integer in the hypergeometric distribution.}$$

The basic idea is to approximate the discrete probability that the hypergeometric variable is equal to an integer, by the normal probability of falling within ± 0.5 of the integer (*see* **Yates's Continuity Correction**).

The "corrected approximation" is

$$H(x; n, A, N) \cong \Phi\left(\frac{(x-\mu+0.5)}{\sigma}\right). \tag{13}$$

A rule of thumb, supposedly attributed to R.A. Fisher, claims that values of EC as low as 5 give satisfactory results.

Reality check of (13). We ran a computer check of all situations where $N \leq 250$ and $EC \geq 5$. The largest deviation between (13) and (9) occurred where $N = 250$, $A = 36$, $n = 37$, and $x = 5$. The exact probability from (9) is 0.5517, while the corrected normal approximation, (13), yielded 0.5347, for a deviation of 0.0170. The largest deviation in the "tail" (where the cumulative probability was small), occurred at $N = 245$, $A = 35$, $n = 35$, and $x = 1$. The exact probability is 0.0230, while the corrected normal approximation yields 0.0342 for a deviation of 0.0112. The computer routine compared over 19 million contingencies.

We also ran a computer check of all situations where $N \leq 250$, $EC \geq 7$, and the cumulative hypergeometric probability is below 20%. The largest deviation here was 0.0080, which occurred at $N = 250$, $A = 42$, $n = 42$, and $x = 3$. The exact value is 0.0462, while the corrected normal approximation is 0.0542.

The uncorrected normal approximation may be much more unreliable in the tails, where it is most important. For example, if $N = 50$, $A = 16$, $N = 17$, and $x = 3 (EC > 5)$, then the exact hypergeometric cumulative probability (9), is 0.1056, while the uncorrected normal approximation, (12), is only 0.0611, a deviation of 0.0445.

For more information on other approximations, see [5] and [2].

Final Commentary

The reader may wonder why we introduced approximations in an era when exact calculations are routinely available on computers. Ironically, the very hardware and software that allowed us to investigate the adequacy of the approximations, in the most extensive study yet conducted, are the very same tools

that allow us to use exact methods for every application. However, these approximations have been used in countless past research projects, and will continue to be employed by others. The investigation in this article indicates that the ***P* values** reported in these articles using binomial or corrected normal approximations are reasonably accurate, and that the inferences are qualitatively correct, provided that one is not an all-or-none type inference maker, based on a P value of 5% or 1%. Haber [2] shows that if the goodness criterion is a ratio of probabilities, then in the tails and with low expected numbers, the Yates correction was perceived to perform relatively poorly. This should not dissuade users.

In 1990, *Statistics in Medicine* devoted considerable coverage to the Yates correction (see [3] and the ensuing discussion). Shuster [6] used the binomial approximation for the analysis of **clinical trials** where the sample size is large but the events are rare. In effect, he interchanged the roles of A and n, as noted below (4).

Suissa & Shuster [7] relied heavily upon the hypergeometric distribution when they derived sample size requirements for clinical trials involving two independent samples. Their exact unconditional methods require fewer patients than a corresponding **Fisher's exact test**, when type I error and power are prespecified.

The term hypergeometric distribution [1] is based on the connection with the "hypergeometric series" defined by Euler in 1769. His series produced as special cases the geometric series which he was generalizing, and a polynomial whose coefficients are constant multipliers of the hypergeometric probabilities. For further details, see [4].

Generalization

The idea of the hypergeometric distribution can be extended to a multivariate setting as follows. Suppose a population contains N_j subjects of type j, $j = 1, 2, \ldots, J$. Suppose we wish to partition this population randomly into subgroups of size M_i, $i = 1, 2, \ldots, I$. Let X_{ij} be the number of subjects of type j in subgroup i. Then

$$\Pr\left[X_{ij} = x_{ij} : 1 \le i \le I, 1 \le j \le J\right] = \prod_{i=1}^{I} M_i! \prod_{j=1}^{J} N_j! \left\{ N! \prod_{j=1}^{J} \prod_{i=1}^{I} x_{ij}! \right\}^{-1}, \quad (14)$$

where

$$N = \sum_{i=1}^{I} M_i = \sum_{j=1}^{J} N_j.$$

If $I = J = 2$, $N_1 = A$, $N_2 = N - A$, $M_1 = n$, and $M_2 = N - n$, then (14) reduces to (3), the hypergeometric. The marginal distribution of each X_{ij} is hypergeometric with $A = N_j$ and $n = M_i$.

Finally, note that for the fixed constants N_j and M_i, the probability given in (14) is inversely proportional to

$$\prod_{j=1}^{J} \prod_{i=1}^{I} x_{ij}!.$$

This fact drives computer programs dedicated to the exact analysis of two-dimensional **contingency tables** (*see* **Exact Inference for Categorical Data**).

The same concept can be extended to multidimensional situations with probabilities inversely proportional to the product of the factorials of the individual cell counts.

Hypothesis Testing

The global responses of patients with diabetic neuropathy who had been randomly assigned to one of two different treatments (*see* **Randomized Treatment Assignment**) are displayed in Table 1. If the treatments were equally efficacious, we would expect to see the same percentage of patients deteriorating or improving in both. Since the responses of individual patients will differ, even if given the same treatment, the resulting random variation means that we would not expect to see exactly the same percentage in each group. However, note that there are 14 patients with moderate or excellent response to treatment A and only three such patients on treatment B. Could this great a difference have happened "at random"? The basic idea behind hypothesis testing is to compute the **probability** of the pattern of data that we have observed, under the assumption that any differences are "purely random". If that probability is very low, then we would be tempted to reject the hypothesis that the differences between treatments is due to "random noise" alone. If the pattern that is seen also suggests a consistent difference in response between the treatments, we would be even more inclined to reject the hypothesis of equal effect.

In Table 1, around 30% of the patients on treatment A have a moderate or excellent response versus only 6% on treatment B. If we treat these two numbers as coming from independent **binomial** random variables with the same underlying probability of response, the probability of seeing as great or greater a difference is less than 0.001. Yet, the only excellent response was under treatment B. How can we claim that treatment A is better? What would have happened if we had compared only the percentage of patients with an excellent response? Or the percentage of patients with any improvement? Or the percentage of patients who deteriorated? Of all parts of Table 1, the break between moderate improvement or better and all other responses is most favorable to treatment A. Is it acceptable to choose the most favorable part of the data before calculating the probability? What is the "right" way of applying hypothesis tests? Is there an "optimal" method of testing? Questions like this have generated a vast literature of books and articles, ranging from abstract mathematical dissertations, to philosophical discussions of the meaning of probability, to the interpretation of hypothesis tests run on medical, epidemiologic, and other biological data. There are at least two major schools of thought, and how one uses hypothesis tests or interprets them may differ, depending upon which school of thought is being invoked.

Historical Development

The basic idea behind hypothesis testing has been used in many branches of science for at least 200 years. One author [1] claims to have found the germ of the idea in a medical discussion from 1662. Other early references have included astronomical and sociological investigations (see [16]). However, the earliest clearly thought-out use of hypothesis testing probably belongs to **Karl Pearson**. Pearson was collecting biological data from all over the world and attempting to fit these data to specific probability distributions (see Galton et al. [12], for a formal statement of this program). The plan was to show the effects of natural selection and evolution on shifts in these distributions under the pressure of changes in the environment. To determine whether a given distribution fit the data, Pearson ordered the numbers and divided them into bins containing 5–20 adjacent numbers in a bin. He then computed the expected number of observations that he should have seen in each bin and compared the expected number to the observed number. If $O_i =$ the observed number in bin i, and $E_i =$ the expected number in bin i, then the sum

$$\frac{(O_1 - E_1)^2}{E_1} + \frac{(O_2 - E_2)^2}{E_2} + \cdots + \frac{(O_i - E_i)^2}{E_i} + \cdots$$

Table 1 Responses of patients with diabetic neuropathy, to two randomly assigned treatments

	Deterioration			Improvement		
	Severe	Slight	No change	Slight	Moderate	Excellent
Treatment A	1	2	20	9	14	0
Treatment B	3	2	26	15	2	1

was used to determine if the fit was good. If this sum was too large, the proposed distribution was rejected. Pearson proved that, regardless of the underlying probability distribution being tested, if the sample size was large enough, this sum had a specific distribution, which he called a **chi-square(d) distribution**. Thus, he was able to test the hypothesis that the data followed a specific random pattern with an omnibus test.

Pearson's proof was not completely rigorous, and his exact calculations were in need of some minor adjustments (derived in [6]). However, his work contains the basic components of any modern hypothesis test:

1. a well defined probability distribution that describes the hypothesis that the differences in pattern are "purely random".
2. A test statistic that can be calculated from the data, which:
   (i) has a distribution that is the same regardless of the definition of "purely random"; and
   (ii) can be used to compute a probability that measures how well the observed data fit the distribution that defines "purely random".

R.A. Fisher, a younger contemporary of Pearson, derived most of the test statistics that we now use, in a series of papers and books during the 1920s and 1930s. Fisher also published a "cook book" of methods to popularize these tests [7], which went through 10 editions. **G.W. Snedecor**, who founded the first statistics department in the US at Iowa State University, published a textbook [20] that spread Fisher's methods and test statistics into even further use. In the 1970s, a review of the *Science Citation Index* showed that Snedecor's textbook was the single most frequently cited paper or book in the scientific literature of the time.

However, there were many questions about how to use these test statistics and which test statistics to use under which circumstances. In the late 1920s, Karl Pearson's son, **Egon Pearson**, approached the young Polish mathematician **Jerzy Neyman** with a question that was bothering him. If you test whether data fit a particular probability distribution, and the test statistic is not large enough to reject that distribution, how do you know that this is the "best" that could be done? How do you know that some other test statistic might not have rejected that probability distribution? The resulting collaboration between Egon Pearson and Neyman over the next few years produced a series of papers that revolutionized the nature of hypothesis testing and introduced some of the basic ideas that now govern this field.

Following on from this work by Neyman and Pearson, Eric Lehmann published a definitive textbook [15] that elaborated on the original Neyman–Pearson formulation. This version of the Neyman–Pearson formulation is the interpretation of hypothesis testing that is usually taught in elementary statistics courses, and it dominates much of the medical and epidemiologic literature, where hypothesis testing is used.

Fisher, the creator of most of our modern methods, was critical of the Neyman–Pearson formulation (see [9]; developed more fully in [11]). He felt that the formulation may have been very nice mathematics, but that it had nothing to do with the way in which hypothesis tests are actually used in scientific investigations. In addition, the statistical literature is filled with other objections to the validity of the Neyman–Pearson formulation in terms of its use of probability and its ability to interpret experimental results (for a survey of this work, see [2]). In general, these objections come from two schools of statistical reasoning. One school follows Fisher's approach and views hypothesis tests as rough tools of **inference** that should be used only in conjunction with other tools (for a full discussion, see [5]). The other school criticizes what they consider to be irrational components of hypothesis testing and proposes that inference should be based on the **likelihood** function. These critics, in turn, fall into two general categories, the Bayesians and those who would rest all inference on likelihood alone (*see* **Bayesian Methods**; **Likelihood**). Bayesian techniques do not make use of hypothesis tests but base their inference on credibility intervals that describe a highly probable range of values for a given parameter, based on prior knowledge and the data (*see* **Prior Distribution**). The likelihood approach to inference also rejects formal hypothesis testing and bases inference on ranges of the parameters that produce relatively high likelihoods for the observed data.

Since Lehmann's definitive text, hypothesis testing has been a fruitful area for statistical research. More recent developments include locally most powerful tests, restricted tests, investigations into the **robustness** of tests, and tests of nested (or **hierarchical**) and nonnested models (*see* **Separate Families of**

Hypotheses). Some of these will be discussed briefly in what follows, but the reader should be aware that this continuing research means that the nature of hypothesis testing and the applications of these techniques will continue to change.

The Neyman–Pearson Formulation

We shall start with a simple model and build on that. Consider two hypotheses about the nature of reality. In Table 1, the two hypotheses might be

H_0: the probability of moderate or better improvement is the same for patients on treatment A as it is on treatment B.
H_1: The probability of moderate or better improvement is twice as great on treatment A as it is on treatment B.

H_0 is called the **"null hypothesis"**. H_1 is called the **"alternative hypothesis"**. We are presented with data from a study and we are asked to make one of two decisions:

D_0: H_0 is true.
D_1: H_1 is true.

This situation can be displayed as a two-by-two table, as shown in Table 2. If the decision matches the true state of nature, there is no error. Otherwise, two types of error are possible. The probability of a type I error (deciding for the alternative hypothesis when the null hypothesis is true) is labeled α. The probability of a type II error (deciding for the null hypothesis when the alternative hypothesis is true) is labeled β.

One "solution" for this simple setup is to consider all possible patterns that the data might have and order them in terms of increasing evidence in favor of the alternative hypothesis. For instance, in comparing two treatments with respect to the frequency of improvements in Table 1, we have a total of 41 $(9 + 14 + 0 + 15 + 2 + 1)$ patients improving.

Table 2 A decision table for choice between two hypotheses

	True state of nature	
Decision	H_0	H_1
D_0	No error	Type II error
D_1	Type I error	No error

A result that would be most favorable to the alternative hypothesis (that treatment A is better than treatment B) would be to assign all 41 to treatment A. The next most favorable would be to assign 40 to treatment A and one to treatment B, etc. Once the possible outcomes are ordered, the analyst can pick a specific outcome (say, a break of 30A and 11B) and calculate the probability, based on the assumption of H_0, for each outcome that was as favorable or more favorable than that specific break point. Similarly, the analyst could compute the probability, based on the assumption of H_1, for each outcome that is less favorable than that specific break point. Let the decision be as follows:

D_1: choose H_1 if the observed outcome is at that break or at one more favorable.
D_0: choose H_0 if the observed outcome is one of the events less favorable than that break.

Then, the sum of the favorable probabilities at that break and beyond, under the null hypothesis, is the probability of a type I error, α. Similarly, the sum of the unfavorable probabilities less than that break, under the alternative hypothesis, is the probability of a type II error, β.

Another approach is to decide in advance what level of α (perhaps 0.05) error the analyst is willing to have (*see* **Level of a Test**). Then, each time the analyst is faced with a decision involving a simple null and a simple alternative hypothesis, the analyst can choose a break point that corresponds to that level of α. Then, in the long run, regardless of the exact problem at hand, the proportion of times the analyst will make a type I error will be α. However, for this to hold, the complete decision process (the choice of α, of the test statistic, and of the cut-point) must be set up in advance of seeing any data and independent of the outcome of a particular trial.

This situation of a simple null and simple alternative hypothesis seldom holds in real life. For instance, in Table 1 we can propose a simple null (that the probability of response is the same for both treatments), but a simple alternative would require that we pick a specific difference in probabilities for each type of response. If we want the alternative hypothesis to be more general, such as that the probability of improvement is greater for A and that the probability of deterioration is less for A, then we have to consider an infinitude of possible differences in probabilities of response. In such a case, the alternative hypothesis

is called a composite hypothesis. However, although the comparison of a simple null and a simple alternative hypothesis seldom occurs in real-life problems, it is a useful first step in visualizing how one might proceed.

To be more realistic, let us consider a simple null hypothesis and a composite hypothesis of alternatives that are farther and farther away from the null. For instance, we might consider the null hypothesis that the probability of improvement is the same for both treatments and the composite alternative that the probability of improvement for A has the relationship

$$p_A = kp_B, \quad k > 1.$$

This includes the simple alternatives that $k = 2$ (probability of improvement for A is twice that of B), $k = 1.001$, $k = 10$, etc. As k increases, the "distance" between the simple null and the alternative increases. (There is a technical problem, here. If k gets large enough, then p_A will be greater than 1, but this can be taken care of by considering **odds** (*see* **Odds Ratio**) rather than probabilities.)

At this point, the Neyman–Pearson formulation has three parameters that govern the decision process: α, β, and δ the latter being the "distance" from the null to a specific simple alternative that is part of the composite alternative. Once they had reached this point in their development, Neyman and Pearson sought an optimum solution to the problem. Some of the critics of this formulation have attached on this attempt to find an optimum solution as one of the inherent problems. This is because one has to define what is meant by optimum, and the act of defining it often limits the nature of the solution. In this case, Neyman realized that there was no single definition of optimum when dealing with three freely ranging parameters. However, it was possible to define an optimum if the problem was constrained. Neyman's solution was the following:

1. fix α;
2. find a decision process that minimizes β for a range of δ-values.

They called $1 - \beta$, the probability of correctly deciding in favor of the alternative hypothesis, the **power** of the test procedure. Thus, in words, the optimum solution is one that fixes the probability of a type I error in advance (at, say, 0.05) and then has the greatest power for a specific range of alternative hypotheses. In this way, the analyst will make type I errors $100\alpha\%$ of the time across the entire spectrum of decisions that use this same α-level. At the same time, the analyst will be testing hypotheses is a way that is most favorable to the set of alternatives that have been chosen as important for each decision.

In such a model, the ideal decision process is one that is more powerful than any other for all possible alternatives. This is the uniformly **most powerful**, or UMP, test. If a UMP test exists, to follow the Neyman–Pearson formulation, the analyst should always use it. Unfortunately, as Neyman noted in the final paper that he wrote in this series [17], UMP tests seldom exist. In particular, they do not exist for the types of hypothesis tests most often used in medical and epidemiologic research.

There are two ways of overcoming this problem. The analyst can narrow the class of alternatives, or the analyst can seek the best decision process from a collection of decision processes that are constrained in some way. The first method (narrowing the class of alternatives) occurs with the use of restricted hypothesis tests and locally most powerful hypothesis tests (for a more complete discussion, see [18]). The second approach is done by requiring that the hypothesis tests have certain properties. Some of these properties are:

1. *unbiasedness* (the probability of a type II error is never less than α);
2. *symmetry* (the test statistic should produce the same value if the data are permuted – the nature of the permutation defining the type of symmetry);
3. *invariance* (the test statistic should produce the same value if all the data are subjected to a specific monotone transformation, such as multiplication by a constant, and an appropriate transformation is applied to the parameter value).

This has led to a plethora of terms to describe different types of optimum tests, such as UMP in the class of unbiased tests. Whether such tests are "optimum" for a given situation should depend upon whether the restriction of the alternative hypotheses or the properties defining the class of tests are

appropriate to that situation. Just because a test has a nice name (such as "exact") does not mean that it is the "best" to use.

Criticisms of the Neyman–Pearson Formulation

The major criticisms of this formulation for hypothesis testing are three-fold: (i) the validity of the α-level depends upon the definition of probability as the long-run frequency of errors that might occur; (ii) the computation of the significance level uses the probabilities of events that have not been observed; and (iii) the definition of optimum is purely arbitrary.

The Use of the Long-Run Frequency of Errors to Define α

Fisher [9] was one of the first to object on these grounds. Fisher pointed out that long-run frequency of error is a concept appropriate to quality control, where an inspector wants to be sure than no more than $100\alpha\%$ of defective products will pass. However, scientific investigation, said Fisher, is a process which involves a sequence of experiments, in which the conditions of each experiment are dependent upon the outcome of previous experiments. G.E.P. Box [3] added to this description by noting that the data from previous experiments are often reexamined in the light of later results. To Fisher, the fact that the analyst uses a cutoff significance level of 0.05 does not mean that the analyst will be wrong 5% of the time. For, according to Fisher, the analyst has no right to declare something is so until he can design a study that will invariably produce a significant result in favor of it.

There is a further problem with the Neyman–Pearson formulation whenever the observed ***P* value** is less than or equal to α. It does not allow the analyst to make any other decision. Thus, if α is set at 0.05, a P value of 0.04999 has the same interpretation as a P value of 0.00001. In Neyman–Pearson hypothesis testing, there is no such thing as "more significant", and the use of symbols such as * (for $P \leq 0.05$), ** (for $P \leq 0.01$), and *** (for $P \leq 0.001$) has no meaning. Attempts have been made to develop a theory of "evidence" that will allow for multiple decisions within this frequentist definition of probability. However, all have failed. (For a complete description of this problem, see [14].)

The Use of Events not Observed to Compute P Values

The power of an hypothesis test depends upon its ability to reject the null for events that are more favorable to the alternative. However logical the Neyman–Pearson development may seem, critics point out that it ends up with a counterintuitive procedure. Why should outcomes more extreme than the one observed play any role in the decision process? These critics point out that the only reasonable computations involve the likelihood of the observations under the null hypothesis and the likelihood under the alternative hypothesis. The ratio of these likelihoods should be used to compare the hypotheses with respect to the data. This ratio is called the Bayes factor in the development of Bayesian statistical procedures (*see* **Bayesian Methods**).

The Definition of Optimum is Arbitrary

Neyman was faced with a three-parameter problem: α (the probability of a type I error), β (the probability of a type II error), and δ (the "distance" between the null and alternative hypotheses). His definition of optimum was to fix α and minimize β over a range of δ. Other definitions are possible. One could minimize the sum $\alpha + \beta$ or the odds of α over β. The major justification for Neyman's definition of optimum is that the resulting decision process mimics closely the way in which prior workers such as Fisher had used hypothesis tests. However, there is no reason why fixing α is appropriate for medical or epidemiologic problems. In fact, some critics have asked sarcastically why the analyst's long-run probability of error should have anything to do with whether treatment A is a life-saving procedure that should be used in medicine. One alternative, called sequential Bayes, proposes that there is a finite number of patients who will be treated (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). Some of those will be treated in a controlled trial that compares treatment A to treatment B. Once the trial is over, all of the remaining patients will be given the treatment that has been declared better. The criterion

proposed is to minimize the number of patients on the poorer treatment.

Cox's Formulation of Significance Testing

Many authors have agreed with Fisher's objections and proposed alternative approaches to hypothesis tests. Like Fisher, these authors would treat P values as rough tools for inspecting data. A full development of this idea is due to D.R. Cox [5]. To distinguish between his formulation and that of Neyman and Pearson, Cox called the informal use of P values "significance testing" (as opposed to hypothesis testing). Cox would have the analyst compute the P value of a test statistic but treat it as one of many descriptors of the data. If the experiment was a difficult one to duplicate, or if the data from an epidemiologic study were difficult to accumulate, then the analyst should consider higher P values as "significant". If alternative experiments were easily and cheaply done, then the analyst should require lower P values before taking any decision in favor of an alternative hypothesis. In Cox's view, the cutoff P value is not set in advance, but is dependent upon the importance of the question, the ease of replication, and, to some extent, the data themselves. At all times, Cox warned, the evidence presented by a small P value should be part of a more general analysis of the data that pays attention to the estimated mean effects and to the plausibility of the results.

Cox claimed that there are two general ways in which significance tests and P values are used in scientific research. He called these "hypothesis dividing" and "hypothesis refining". In the hypothesis dividing mode, the scientist proposes two distinctly different hypotheses as explanations of reality. The scientist constructs an experiment or an observation that will lean one way for one hypothesis or the other way for the other hypothesis. The significance test is used to determine if there is enough information in the data to allow for a decision between the two hypotheses. The significance test is not necessarily used to decide in favor of one hypothesis or the other. That decision depends upon the design of the study and the nature of the data. The significance test is used only to discard certain studies as not providing enough information. (This echoes Fisher's view of significance tests.) In the hypothesis refining mode, the scientist has a complicated model of reality, involving many parameters, and he or she wishes to eliminate some of those parameters as having minor or negligible effects. Suppose, for instance, that we have been following a cohort of individuals for many years and wish to determine which baseline characteristics were predictive of some future event (such as a myocardial infarction). We might run a **logistic regression** using all the baseline variables that were collected and use significance tests to eliminate those that do not have a "significant" slope (*see* **Variable Selection**).

The Meaning of *P* Values

The P value of a test statistic is computed as the probability of a **critical region** of possible observations under the null hypothesis. However, it is difficult to define what that means in real life. In fact, the whole problem of linking the mathematical theory of probability to real life is a controversial one. Neyman finessed the problem by fixing the α-level and defining its meaning as the long-run proportion of times that an analyst will make a type I error. However, one cannot use this formulation to justify the statement that we are "$100(1-\alpha)\%$ sure" that the null is false. Nor does this definition make sense if a hypothesis test is going to be applied to a nonreplicated event such as a definitive placebo controled clinical study of a potentially life-saving treatment (since, once the null hypothesis has been rejected, it is unethical to do another study).

In the mathematical theory of **probability**, we propose that there exists a space of "events". Probability is a measure (similar to length or area) on that space of events. The link between mathematical probability and real life is how we define that space of events. **W.S. Gossett** (who wrote under the pseudonym "Student") applied probability theory to the outcome of experiments and said that the space of events was the set of all possible outcomes of such an experiment. But, since only one outcome is seen, this is not a well-defined idea. In sample survey theory, the population is fixed and a sample of that population is chosen at random. The space of events is, then, the set of all possible **random samples** that might have been chosen. Since the **randomization** mechanism is known, this space is well defined. The uncertainty described by probability theory for sample surveys is not about the characteristics of the population (which are fixed)

but about the estimates of those characteristics that are derived from the sample. In a **case–control study** the concept of a sample and population remains, but the calculated probabilities are the **conditional probabilities** that a person has a prior condition (e.g. a heavy coffee drinker), given that the person has the disease (for an excellent discussion of this, see [4]).

To justify the use of probability theory in controlled experiments, Fisher noted that the act of randomly assigning experimental units to treatments in a randomized controlled experiment generated a space that consisted of all possible random assignments. He was able to show that the classical distributions of test statistics that he had developed are approximations of the permutation probabilities that would result (*see* **Randomization Tests**). However, this meant that hypothesis tests were valid only in the framework of a randomized controlled study (for a discussion of some of the consequences of this view, *see* **Intention to Treat Analysis**). Fisher objected to the observational studies connecting smoking with cardiovascular disease and cancer [10], because they used hypothesis tests to "prove" the case. Following the same logic, Fisher would have objected to the use of all hypothesis tests in epidemiology, in case–control studies, or in any type of clinical study that did not involve randomized assignment to treatment.

It is tempting to use probability statements to describe how "sure" one is about the results of the investigation. This would result in phrases such as "The probability that coffee is an important factor in the development of pancreatic tumors is less than 10%". However, the only way this can be done is to describe a space of events that is either related to the state of mind of the observer (personal or **subjective probability**; for a complete discussion, see [19]), or to a general opinion that one might expect in a community of knowledgeable scholars (an idea developed in [13]). All of these fall under the heading of Bayesian statistical methods (*see* **Bayesian Methods**).

Power and the Acceptance of the Null Hypothesis

An important element of the Neyman–Pearson formulation of hypothesis testing is the concept of power. The quality of a statistical test is determined by its power. One could construct a great many test statistics from the data in Table 1. A chi-square test for the independence of the rows and columns, for instance, can be computed based on the null hypothesis that the row (treatment) has nothing to do with the columns (responses) (*see* **Chi-square Tests**). The P value for this test is greater than 0.50. On the other hand, one can use a Cochran–Armitage test (which is a restricted test) that concentrates on the class of alternatives where the probability of a patient's being in treatment A increases with the response (*see* **Trend Test for Counts and Proportions**). The P value for the Cochran–Armitage test is 0.04. The theory of restricted tests says that, if we believe that the only viable alternatives are that the better treatment is consistently better across all the possible responses, then the Cochran–Armitage test is more powerful and should be used rather than the chi-square test.

If we do not pay attention to power, then any test would be equally as "good". A *reductio ad absurdum* of this is to ignore the data from a study and pick a number from a table of **uniformly distributed** random numbers between zero and one. If the number is less than α, declare significance. Such a test is "exact". It also protects the α-level. But, the power is also exactly equal to α (since, regardless of the alternative hypothesis, it will reject the null $100\alpha\%$ of the time.)

In spite of the fact that the Neyman–Pearson formulation involves a decision to accept the null hypothesis, there is a general consensus among statisticians that hypothesis tests are not really designed for that. To quote Fisher [8],

> ... tests of significance (are) ... cogent for the rejection of hypotheses, but...by no means cogent for their acceptance...the logical fallacy of believing that a hypothesis has been proved to be true, merely because it is not contradicted by the available facts, has no more right to insinuate itself in statistical than in other kinds of scientific reasoning.

To deal with this problem, some have advocated that articles which describe the results of studies include information about the power of the study to detect a meaningful degree of effect. Alternatively, it has been urged that studies which result in a finding of no significant difference should include **confidence intervals** on the differences in effect that would be reasonable from the data. If the power of the study is inadequate to detect a meaningful effect or if the

confidence interval contains meaningful differences in effect, then the study is inadequate to accept the null hypothesis (*see* **Clinical Significance Versus Statistical Significance**).

Identifiability

Consider a vector $\mathbf{Y}$ of random variables having a distribution $F(\mathbf{y};\boldsymbol{\theta})$ that depends on an unknown parameter vector $\boldsymbol{\theta}$. $\boldsymbol{\theta}$ is *identifiable* by observation of $\mathbf{Y}$ if distinct values $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$ for $\boldsymbol{\theta}$ yield distinct distributions for $\mathbf{Y}$, that is, if $\boldsymbol{\theta}_1 \neq \boldsymbol{\theta}_2$ implies $F(\mathbf{y};\boldsymbol{\theta}_1) \neq F(\mathbf{y};\boldsymbol{\theta}_2)$ for some $\mathbf{y}$ [1]. A function $g(\boldsymbol{\theta})$ is *identifiable* by observation of $\mathbf{Y}$ if $g(\boldsymbol{\theta}_1) \neq g(\boldsymbol{\theta}_2)$ implies $F(y;\boldsymbol{\theta}_1) \neq F(y;\boldsymbol{\theta}_2)$ for some $\mathbf{y}$. Note that $\boldsymbol{\theta}$ is identifiable if and only if all functions of $\boldsymbol{\theta}$ are identifiable.

There is some variation in the definition of identifiability, the preceding being the most general. Variants typically employ the density $f(\mathbf{y};\boldsymbol{\theta})$ or the expectation $\mathrm{E}(\mathbf{Y};\boldsymbol{\theta})$ in place of the distribution; the latter variants may explicitly involve a design matrix X of regressors; for example, $\mathrm{E}(\mathbf{Y}; X, \boldsymbol{\theta})$. The basic concept, however, is that $\boldsymbol{\theta}$ [or $g(\boldsymbol{\theta})$] is a function of the $\mathbf{Y}$ distribution, and hence observations of realizations of $\mathbf{Y}$ can be used to discriminate among distinct values of $\boldsymbol{\theta}$ [or $g(\boldsymbol{\theta})$].

The term *estimable* is sometimes used as a synonym for identifiable, but is also used in more specific ways, especially in the context of linear models. For example, Scheffé [4] defines a linear function $\mathbf{c}'\boldsymbol{\theta}$ of $\boldsymbol{\theta}$ to be estimable if there exists an unbiased estimator of $\mathbf{c}'\boldsymbol{\theta}$ that is a linear function of the observed realizations of $\mathbf{Y}$. This property has also been referred to as linear estimability. In epidemiology, estimability of $g(\boldsymbol{\theta})$ is sometimes used to mean that $g(\boldsymbol{\theta})$ can be consistently estimated from observed realizations of $\mathbf{Y}$. Several other definitions have been given; see, for example, [2, 3] and [5].

Identity Coefficients

Identity (k-, or kinship) coefficients were introduced by Cotterman [3], Malécot [10, 11], and Gillois [7] to answer questions of the following sort: if an individual X, is of **genotype** Aa, what is the probability that X's relative, Y, is aa? To answer a question of this kind efficiently, it is necessary to partition the problem into two parts: (i) a measure of the relationship connecting X and Y, and (ii) genotype probabilities conditioned on the relationship. The first part depends upon the concept of "identity by descent" (ibd); the second on assumptions about the mating system in the population.

The Concept of Identity by Descent

In Figure 1, Z is the offspring of X and Y, and X is the offspring of V and W. The transmitted gametes are labeled a, b, c, and d. It is clear from a consideration of Mendelism (*see* **Mendel's Laws**) that the **gene** a is an immediate replicate of either c or d, but not both. Let R denote the relation "is an immediate replicate of" and Pr denote probability, then

$$\Pr(\mathrm{a}R\mathrm{c}) + \Pr(\mathrm{a}R\,\mathrm{d}) = 1 \quad \text{and} \quad \Pr(\mathrm{a}R\mathrm{c}, \mathrm{a}R\,\mathrm{d}) = 0.$$

The following relations are defined in terms of the fundamental relation, R, where x, y, z, and z' are arbitrary genes at a single locus:

$R^0 =$ the identity relation
(a gene is identical to itself),

$$R^2 = [(x, y) : \exists\ z\ (xRz, zRy)],$$

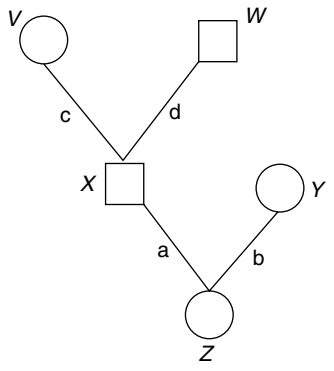

Figure 1 The concept of identity by descent

$$R^3 = [(x, y) : \exists\ z\ \exists\ z'(xRz, zRz', z'Ry)],$$

$$R^n = [(x, y) : \exists\ z\ \exists\ z'(xRz, zR^{n-2}z', z'Ry)].$$

These are the powers of the relation, R. For example, zR^2y means that x is the immediate replicate of a gene which is itself the immediate replicate of y. If we let $R^{\mathrm{U}} = R^0 \cup R \cup R^2 \cup R^3 \cup \ldots \cup R^n$, the relation of identity by descent, I, is defined as

$$I = \left[(x, y) : \exists\ z\ \left((xR^{\mathrm{U}}y) \cup (yR^{\mathrm{U}}x) \cup (xR^{\mathrm{U}}z, yR^{\mathrm{U}}z)\right)\right].$$

In practice, instead of writing xIy, it is customary to write $x \equiv y$ to mean x is identical by descent (ibd) to y. This definition is simply a restatement in set-theoretic notation of Cotterman's original definition for which he used the term "derivative". Cotterman [3] states: "...derivative genes are genes which are relatively recently descended one from the other or both from some common gene". The qualification introduced by the phrase "relatively recently" is included in the definition presented above by restricting the size of n in the definition of R^{U}.

Arbitrary Relationships

Consider two related diploid individuals, X and Y. Label the genes of X a_1 and a_2, and the genes of Y a_3 and a_4. There are 15 "identity by descent" relations among the four genes, as shown in Figure 2. A line connecting two genes denotes that those genes are ibd, the lack of a line denotes that they are not ibd. Some of the events are combined; for example, ${}_{00}k_1$ is the probability of the union of two events. The notation is mnemonic: the first prescript is 0 if X is allozygous (i.e. has nonibd genes at the locus) and 1 if X is autozygous (i.e. has ibd genes at the locus), the second prescript refers to Y in the same way, and the postscript indicates the number of genes X and Y share in common, that is, the number that are ibd. An alternative notation [9] is: ${}_{11}k_2 = \Delta_1$, ${}_{11}k_0 = \Delta_2$, $2_{10}k_1 = \Delta_3$, ${}_{10}k_0 = \Delta_4$, $2_{01}k_1 = \Delta_5$, ${}_{01}k_0 = \Delta_6$, ${}_{00}k_2 = \Delta_7$, $2_{00}k_1 = \Delta_8$, ${}_{00}k_0 = \Delta_9$.

As an example, the k-coefficients for X and Y in Figure 3 are as shown. All coefficients with a leading prescript equal to one are zero because X is assumed to be allozygous. The probability that Y is autozygous and X and Y share no gene in common is ${}_{01}k_0 = 2/32$, because this can happen only if both gametes

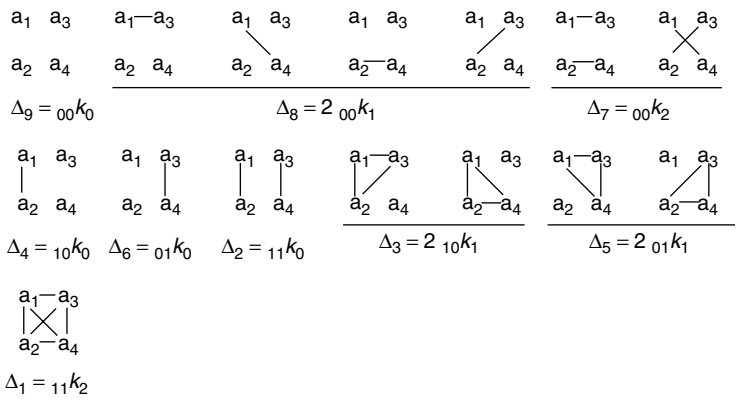

Figure 2 The 15 ibd relationships between two individuals, X and Y, and their probabilities (k-coefficients). (The genes of X are labeled a_1 and a_2, those of Y, a_3 and a_4)

that form Y are derived from the gene in X's daughter that did not come from X; the probability of this is $(1/2)^4$. The probability that both X and Y are allozygous and they share no gene in common is ${}_{00}k_0 = (1/2)^3 + (1/2)^3 + (1/2)^4 = 10/32$, and so on. In this pedigree, the k-coefficients can be calculated from a simple application of basic Mendelism. In general, the nine k-coefficients are more difficult to calculate except in very simple pedigrees [5, 12, 14].

Genotype Pair Probabilities for Pairs of Relatives

The joint genotype distribution for a two-allelic locus in terms of the k-coefficients and the gene frequencies, p and q, of A and a, respectively, is shown in Table 1. For example, the probability that X and Y are both of genotype Aa is, according to the table, $\Pr(X = \text{Aa}, Y = \text{Aa}) = 2_{00}k_2 pq + 2_{00}k_1 pq + 4_{00}k_0 p^2 q^2$.

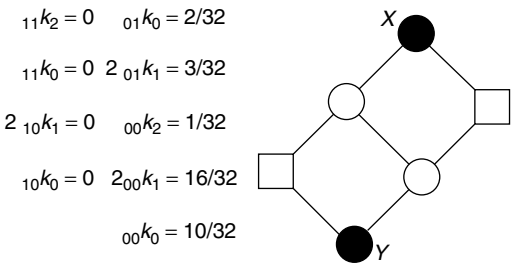

Figure 3 A sample pedigree: calculating the k-coefficients

Noninbred Relatives

Often, one does not need the full set of k-coefficients because many relationships do not involve inbreeding. When neither X nor Y is inbred (when each has an **inbreeding** coefficient, $F = 0$), then all the k-coefficients are zero except for ${}_{00}k_2$, $2_{00}k_1$, and ${}_{00}k_0$.

The k-coefficients for a number of simple noninbred relationships are shown in Table 2. Bilineal relations are those for which ${}_{00}k_2 > 0$; unilineal relationships have ${}_{00}k_2 = 0$.

To calculate the k-coefficients for any noninbred relationship is straightforward. Let a and b be the gametes that form X and c and d those that form Y. Let f_{ac} be the probability that a and c are ibd, f_{ad} be the probability that a and d are ibd, and so on. Let F_{XY} be the probability that a random gamete from X is identical to a random gamete from Y, i.e. the inbreeding coefficient of a, perhaps hypothetical, offspring of X and Y. Then

$$k_2 = f_{ac} f_{bd} + f_{ad} f_{bc}, \qquad 2k_1 = 4F_{XY} - 2k_2,$$
$$k_0 = 1 - 2k_1 - k_2$$

and the calculation is reduced to the methods used to calculate inbreeding coefficients. All of the k-coefficients in Table 2 can be calculated from these formulas.

Extensions

The k-coefficients described above apply to a single autosomal gene in a diploid organism. Several kinds

Image Analysis and Tomography

Seeing is believing: sight is fundamental to our understanding of the world. This is as true in science as in everyday life. The collection of much statistical data is dependent upon human vision. For example, the examination of samples under a microscope, observing animal behavior, and the identification and counting of plant species in a field are all forms of image analysis. We are superb at analyzing the images projected onto our retinas, using one-third of our brains for vision. However, computers are being used more and more to automate and extend the potential of image analysis. Computers are better at extracting quantitative information from images than human observers: they can be more accurate and more consistent from day to day. Furthermore, computers may spare us from much tedious image interpretation.

We see effortlessly, most of the time. Progress was expected to be rapid when research commenced in the 1960s on computer-based image analysis. The task, however, has proved to be far more difficult. At least in part, this is because we are not conscious of the processes we go through in seeing. Biological objects present an even greater challenge to computer interpretation than man-made ones, because they tend to be more irregular and variable in shape.

Application Areas

Images to be analyzed in biostatistics may come from microscopy, medical scanning systems, electrophoresis, or simply from photographing illuminated objects. Figure 1 shows several such examples.

Figure 1(a) is a back-illuminated optical *microscope image* of cashmere goat fibers whose diameters were to be measured [38]. Measurement is made more difficult because the microscope has a shallow depth of focus and some fibers are out of focus, producing either dark or light edges to the fibers, so-called "Becke lines". There is a danger of misinterpretation if the optics that produced a particular image are not correctly understood. For example, the bas-relief type of images typical of differential interference contrast microscopy may be mistaken for three-dimensional features. However, tailoring image processing **algorithms** to particular forms of microscopy poses a considerable challenge. There are many optical microscope systems, including brightfield, darkfield, phase contrast, interference contrast, fluorescence, and confocal systems (see, for example [91]). There are also many other types of microscope systems such as scanning electron microscopes and confocal microscopes. Also, the theory of microscopy is complicated and agreement with data is less than perfect.

Figure 1(b) shows an example of an image produced by a *medical imaging system*, in this case a reconstructed slice (tomogram) from positron emission tomography (PET). It shows a transverse cross-section through a woman's thorax, with a tumor circled. There are many other medical imaging systems, such as conventional radiology, angiography, X-ray transmission computed tomography (CT), ultrasound imaging, magnetic resonance imaging (MRI), and single photon emission (computed) tomography (SPET or SPECT), each with its own characteristics requiring attention in analysis (for example, [16] and [72]). Tomographic methods, including CT, SPET, and PET, seek to reconstruct slices *within* the body from observations *outside*.

Figure 1(c) shows a type of *electrophoresis gel*, a DNA sequencing gel autoradiograph, produced as one stage in the **DNA sequencing** of gene fragments. About 50 mixtures of radioactively labeled fragments are positioned as distinct spots along one side of the gel. Each mixture then migrates down the gel, and DNA fragments produce separate, approximately horizontal bands. Finally, a photographic plate is placed over the gel. This blackens in response to radioactive emissions, thus producing an autoradiograph. Electrophoresis has many variants, including two-dimensional (2D) electrophoresis, electrofocusing, isotachophoresis, and several forms of immunoelectrophoresis [45]. Various forms of chromatography and chemical assays also produce pictorial information which can be interpreted by image analysis.

Finally, Figure 1(d) is an image of *illuminated objects*, in this case of 50 wheat grains, obtained using a video camera. This was part of an experiment to see if it was possible to estimate flour yield by digital image analysis [8]. Opportunities are almost limitless for digitally analyzing images of objects illuminated in many different ways. See, for example, the review by Price & Osborne [77] of imaging applications in agriculture and plant science, and by

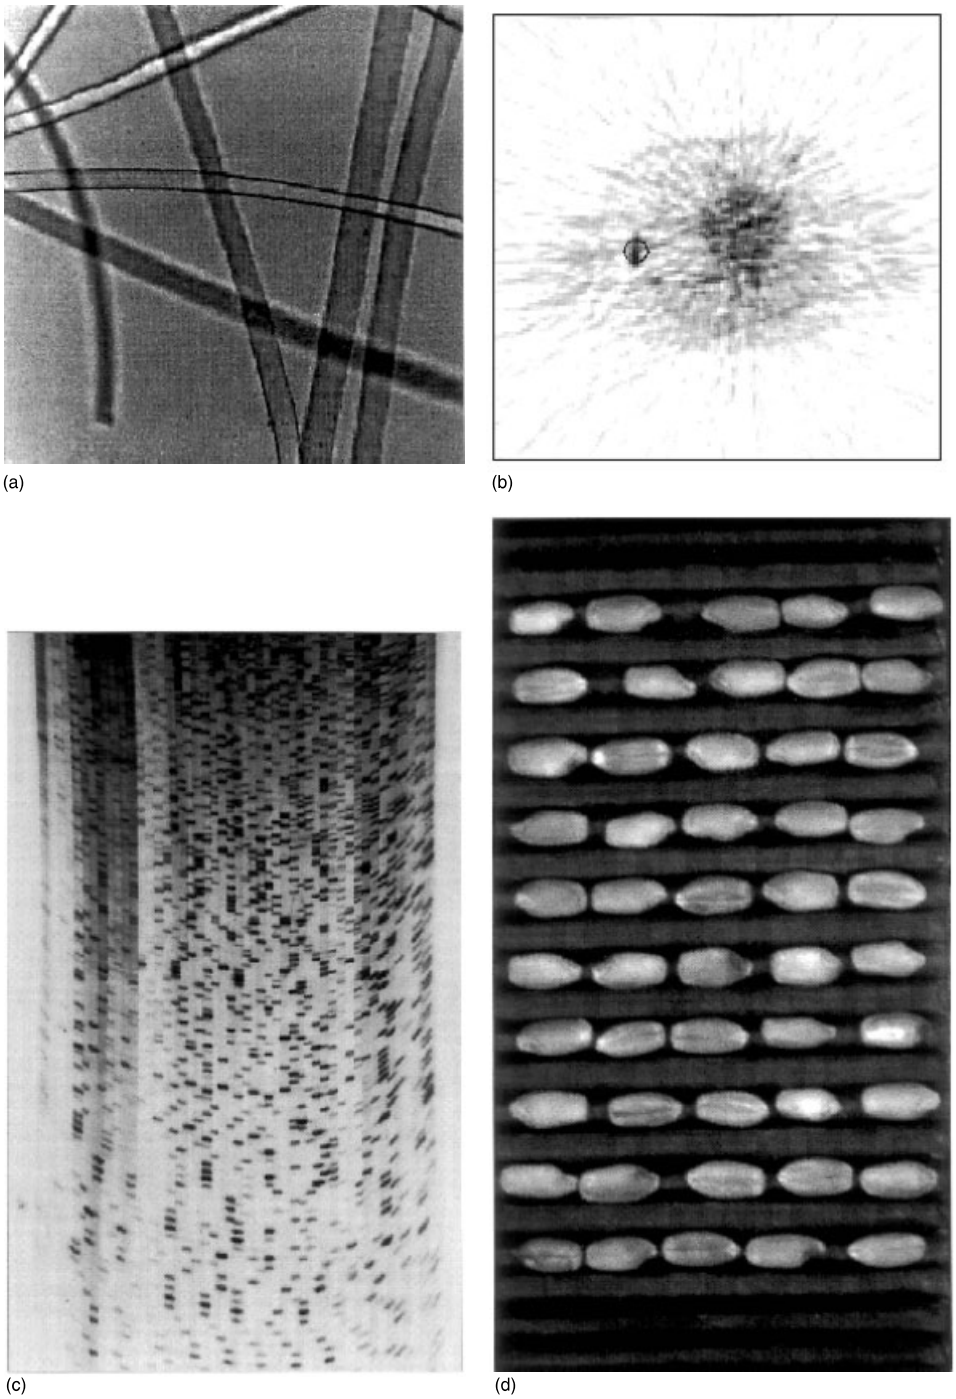

Figure 1 Examples of images: (a) microscope image of cashmere fibers; (b) positron emission tomogram (PET) of a transverse cross-section through a woman's thorax, with a tumor circled, reconstructed using the filtered-backprojection (FBP) algorithm (by courtesy of Max Lonneux and C. Michel, Positron Tomography Laboratory, UCL Belgium); (c) DNA sequencing gel autoradiograph; (d) wheat grains

Sapirstein [85] of cereal variety identification from grains.

Types of Image

Digital images are obtained via an appropriate image capture device, such as a video camera or scanner. A 2D digital image usually consists of a rectangular array of tiny squares called "picture elements", or *pixels* for short. Associated with each pixel is a number, representing the average *brightness* of that part of the original picture covered by the pixel. Usually, the brightness will be discretized to 8-bit resolution, i.e. there are $256 = 2^8$ shades of grey, with 0 representing black and 255 representing white.

The pixel brightness may represent *any* variate which has been measured on a 2D grid. Typically it is a measure of the intensity of reflected light, as in the wheat grains example [Figure 1(d)], or of transmitted light, as with the cashmere fibers [Figure 1(a)]. However, it could alternatively depend upon reflected or transmitted radiation in another part of the electromagnetic spectrum [such as gamma rays, Figures 1(b) and (c)].

The object being imaged may be essentially 2D, as with the DNA sequencing gel [Figure 1(c)], or three dimensional (3D). In the latter case, the *sampling procedure* may involve taking a cross-section, either physically or by a computer reconstruction [e.g. Figure 1(b) is a cross-section of a 3D tomography reconstruction: *tomography* techniques are, literally, those creating pictures of a slice, free of the effects of layers outside the focused plane]. Alternatively, a 3D object with either an opaque [wheat grains, Figure 1(d)] or a semi-transparent surface [cashmere fibers, Figure 1(a)], could be imaged simply by viewing it from a particular direction. Some sensors, such as confocal microscopes and magnetic resonance images, can collect *3D arrays* of data. These can be analyzed using similar methods to those for 2D images.

Although we only consider univariate, so-called *grayscale*, images in this article, it is worth pointing out the increasing use of *color* and *multispectral* image analysis. A color image actually consists of three grayscale images, representing light at red, green, and blue wavelengths, respectively. The wheat grains image [Figure 1(d)] is in fact the green component of a color image.

Methodologies

The ultimate aim of image analysis is usually to extract quantitative information, which may be in the form of binary presence/absence categories, or of measures of object location, length or area, shape statistics, etc. In some applications it may only be possible or desirable to automate some stages in an analysis, leaving the rest to human interpretation. For example, in medical diagnosis the radiologist will want to look at the SPET image. Image analysis methods constitute an eclectic collection of techniques derived from many different theoretical standpoints:

1. The first, and probably most widely used, approach arose in the 1960s from the engineering discipline of *signal processing*, as typified by the books of Rosenfeld & Kak [83] and Jain [55]. Methods include histogram transformations, linear and nonlinear filters (*see* **Spectral Analysis**) and thresholding – techniques that we illustrate later.
2. An elegant approach, termed *mathematical morphology*, emerged from the Ecole des Mines in Fontainebleau, France, in the 1970s (*see* **Stereology**). It is based on the assumption that an image consists of structures which may be handled by set theory, leading to such highly effective methods as openings, closings, skeletonization, and watershed segmentation. The seminal works are Serra [86, 87]. Soille & Rivest [93] provide a useful introduction to the subject from an applications perspective.
3. From **artificial intelligence** have arisen approaches such as *syntactic* **pattern recognition** [28] and *computer vision* [6], but these methods have not often been applied in biostatistical contexts.
4. The 1980s saw the development of **Bayesian** *image analysis* [9, 31]. **Prior** *information* on an appropriate model for an image is combined with *data*, imperfect information about the image (such as pixel values affected by noise), in order to derive the *posterior distribution* for the image.
5. Yet another aspect of image analysis, namely that of extracting *measurements* such as lengths, areas, histograms, etc. from images, is identified as a distinct approach by Serra [87, p. 10]. These descriptors are subsequently interpreted

using **stereology**, shape statistics, or classification methods.

Serra [87, p. 11] acknowledges that, although the different approaches to image analysis are somewhat contradictory, they each have their place. He suggests that an analysis might first require linear methods, then morphological ones, and finally either measurements or syntactic methods.

In the rest of this article we consider first the tomographic reconstruction of images, then the three major components of image analysis: enhancement, segmentation, and taking measurements, drawing on techniques from each of the above approaches and illustrating them using some of the images in Figure 1. We are concerned with the application of image analysis. Therefore, in this article we emphasize methods that we have found useful in practice. We are also conscious of only having space to present a subset from a very large field.

Tomography

In tomography the measured data are *projections*, from which the spatial distribution within a body is reconstructed. For example, Figure 2(a) shows PET recordings similar to those used to reconstruct the cross-section shown in Figure 1(b): these are data from only one of many planes collected in a single study. (The cross indicates the position of the cursor used as an aid to navigate through the 3D data set.) In PET, a radionuclide is introduced into the patient's bloodstream and then distributes throughout the body. Radionuclide decays are recorded on a PET scanner. The *distribution* and *intensity* of activity is recorded by the PET scanner, but the accumulated distribution of radionuclide in the body can only be inferred indirectly (by mathematical analysis) from the scanner projection data.

Projection measurements may be modeled as known linear functionals of an unknown spatial distribution (or image). The goal of reconstruction is to infer from the data the distribution within the specimen. Rosenfeld & Kak [83, Chapter 8] and Jain [55, Chapter 10] present the filtered-backprojection (FBP) algorithm [as used in Figure 1(b)] for reconstruction from data given by the Radon-transform (ray sums) of an image. See also Girard [34] and Bickel & Ritov [11], who study estimation of linear functionals and asymptotic convergence of FBP in PET.

Statistical interest has centered on PET and SPET, which exhibit significant statistical variability in camera recordings. A recent introduction to PET and SPET is given by Kay [58]. McColl et al. [68] describe statistical methods in neuroimaging, with special reference to these imaging modalities. However, many of the methods described apply more widely. We consider further: reconstruction methodologies, use of prior information in fusing reconstructions from different modalities, and parametric mapping based on **pharmacokinetic modeling**. Reconstructions are used not only for clinical studies, providing a basis for individual patient diagnosis, but they also provide data for research studies.

Statistical Reconstruction

In pioneering work, Shepp & Vardi [88] and Lange & Carson [63] applied the **EM algorithm** for **maximum likelihood** (ML) estimation of **Poisson** count data in tomography. Both transmission and emission tomography are well modeled by a description [92] based on a spatially inhomogeneous **Poisson point process**. If $f(s)$ is the (unknown) distribution, then the distribution of recorded activity [in projections such as Figure 2(a)] is expressible as

$$g(t) = \int_{s \in \mathcal{X}} a(t|s) f(s) \, \mathrm{d}s,$$

or, in suitably discretized form, $g = Af$, with $A = (a_{ts})$. Conditional probabilities $a(t|s)$ are determined by the resolution and geometry of the acquisition camera and by the physics of photon transport through the body, and may be regarded as known. There is great generality in this specification, whether in radiology, CT, SPET, or PET, for precise modeling of physical effects (attenuation, scattering) including the ability to incorporate information from other modes. See, for example, Aykroyd & Green [3], Fulton et al. [29], Hutton et al. [54], Vardi & Lee [98], and Weir & Green [100]. This model flexibility and resulting gains in restoration quality have led to a growing interest in statistical reconstruction in clinical use.

Reconstruction (i.e. estimating f from observations on g) constitutes an *inverse problem*. Many reconstruction methods apply corrections using *backprojection* (*see* **Back-calculation**), redistributing residual projection errors ($z = g - \hat{g}$) to provide the

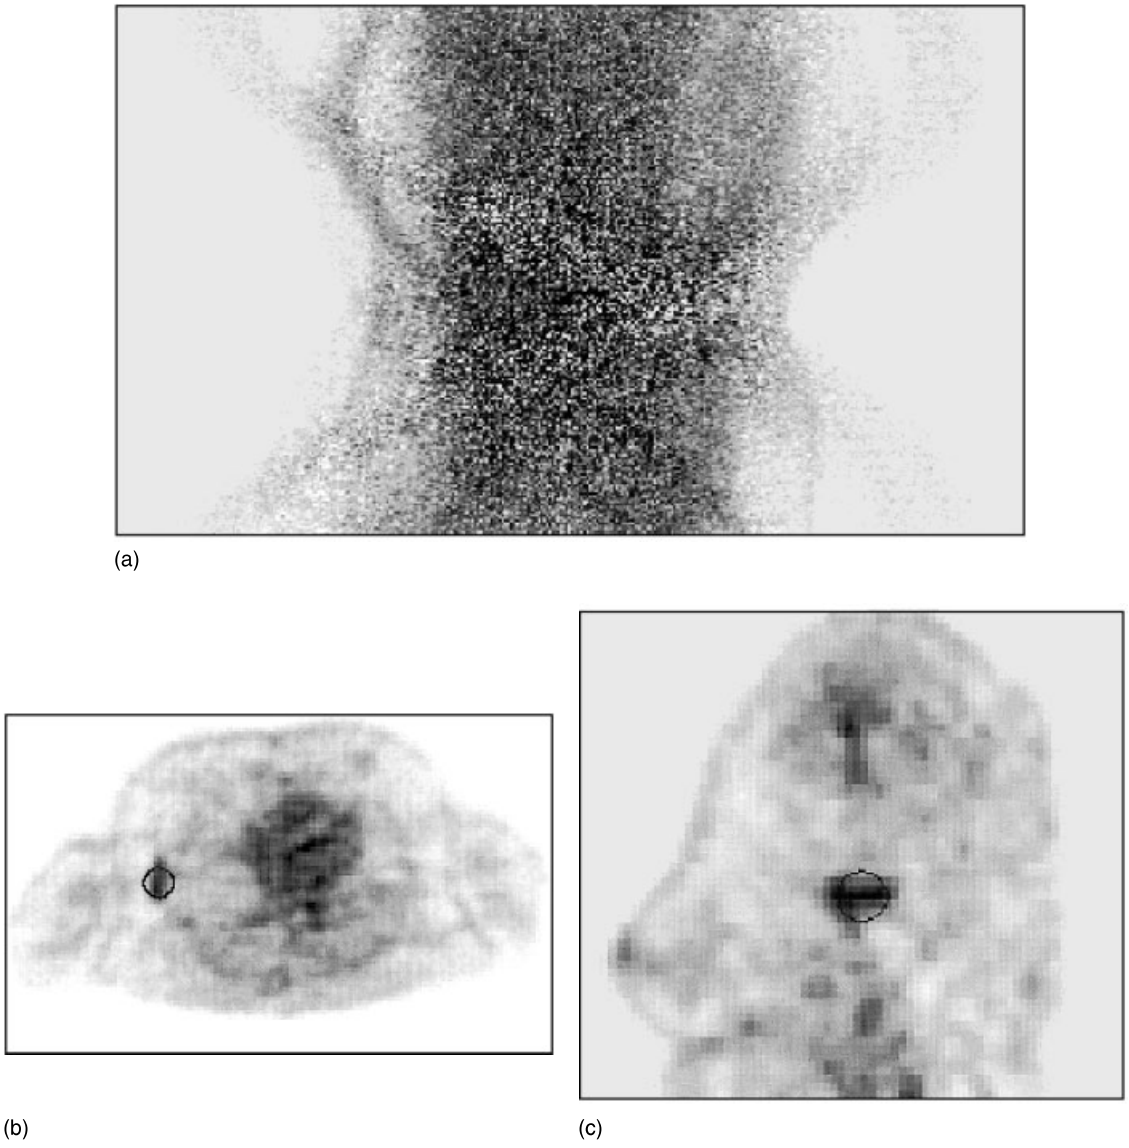

Figure 2 PET clinical study of a woman's thorax: (a) one plane of the projection data (with the cross indicating the position of the cursor used as an aid to navigate through the 3D data set); (b) a transverse cross-section, as in Figure 1(b), but reconstructed using four iterations of the OSEM algorithm; (c) a Sagittal cross-section, with a tumor circled (by courtesy of Max Lonneux and C. Michel, Positron Tomography Laboratory, UCL Belgium)

correction $\hat{f} + \hat{\delta f}$ to an initial estimate $\hat{f}$ by

$$\hat{\delta f}(s) \propto \int_{t \in y} a(t|s) z(t)\, \mathrm{d}t.$$

For example, ML–EM computations provide iterative improvements on a starting image, which is typically taken to be a **uniform distribution** within the body. ML–EM requires repetition of two steps: (i) project the current source estimate to produce fitted projection data, and (ii) backproject the ratio between observed and fitted projections to determine multiplicative corrections to be applied to the current source distribution. The usual convergence theory for EM algorithms shows that each iteration increases the

likelihood and ML–EM converges from any starting image to an ML solution. There is a heavy computational burden, with arrays typically of size 128^3, but this can be eased by exploiting the sparse structure of the matrix A.

Figure 2(b) shows a 2D slice of a reconstruction, based on the EM algorithm, of the same projection data used with the FBP algorithm in Figure 1(b). In addition, Figure 2(c) shows a Sagittal slice through the 3D reconstruction. The gain in restoration quality of the statistical reconstruction is evident, with Figure 1(b) exhibiting streaking artifacts typical of FBP. The reconstruction was produced using the ordered subsets EM (OSEM) algorithm described in Hudson & Larkin [52], which is an adaption of Shepp & Vardi's iterative ML–EM algorithm. OSEM accelerates EM in its ML and Bayesian forms. Here four OSEM iterations were employed, each requiring similar computational effort to that required for the full FBP reconstruction, but far fewer than would be required in ML–EM for the same result.

Related Issues and Approaches

While the resolution of ML–EM images continues to improve with further iterations, they also exhibit an undesirable increase in noise. The effect is similar to bias–variance tradeoffs in nonparametric **density estimation**, and is attributable to the ill-posed inverse problem formulation. A choice of a regularized solution is therefore required. Approaches here include:

1. early stopping of iterations [as in Figure 2(b)];
2. a Bayesian specification of prior information or penalized likelihood criterion (*see* **Penalized Maximum Likelihood**) (see Green & Silverman [42]);
3. post-reconstruction smoothing (see Beekman & Viergever [7]).

Silverman et al. [89] propose an approach to reduce the buildup in noise within iterative reconstruction by local smoothing. The Shepp–Vardi ML-EM algorithm is readily modified to accomplish reconstruction by adopting prior information in a Bayesian formulation (e.g. [32], [41], and [48]) as required for regularization. Multiscale reconstruction may also be advantageous, and there are obvious applications of **wavelet** methodology with body organs creating discontinuities within the imaged region. Efficient convergence is also a critical factor.

Dynamics

Parametric mapping involves modeling functional parameters (e.g. metabolism or blood flow) on the basis of the time-varying distribution of activity of a tracer introduced into the bloodstream in a controlled manner. Time sequences of images result, with the aim of reconstruction being to provide maps of parameters of the model specifying dynamics, not the activity distribution itself.

Cunningham & Jones [22] propose a semiparametric spectral decomposition useful in compartmental models of **pharmacokinetic** studies. In this approach the total activity within prespecified regions of interest (or pixels) are collected over consecutive time intervals. The methodology is nonparametric. No specific compartmental model is assumed, but the time activity curves are expressed in terms of a dense set of basis functions. Cunningham & Jones provide a number of illustrations of the interpretability of such models; the review of O'Sullivan [73] extends this methodology. The method can be applied to time activity curves of indirect observations (projection data) equally well to determine significant modes. With indirect data a staged approach separating the spatial and temporal stages of the reconstruction may be adopted, as provided in the EMPIRA algorithm of Carson & Lange [17].

Enhancement

All images are subject to some degradation from their ideal forms, whether this is the presence of noise, blurring, or a warping/distortion of the image frame. Image enhancement is a set of methods for modifying images to reduce these effects, both to aid human interpretation and as a precursor to segmentation or other digital methods of analysis. In some images the degradation is relatively minor, and image enhancement is unnecessary for the particular application. However, in many cases this will not be so. We look at methods for correcting for warping, at filters, and at deconvolution, using the DNA sequencing gel in Figure 1(c) for illustration.

Registration and Unwarping

Unwarping of images is an important stage in many applications of image analysis. It may be needed to

remove optical distortions introduced by a camera or viewing perspective [96], or to register an image with a reference grid such as a map, or to align two or more images. For example, matching is important in reconstructing a 3D shape from either a series of 2D sections or stereoscopic pairs of images. There is considerable interest in registering images produced by medical sensing systems with body atlas information [18, Section 3; 30] and in image fusion [2]. In tomography studies, MRI or CT provide accurate maps of *anatomy* while PET or SPET provide much lower resolution maps of *function*. Linking function to the anatomy is of interest. Image registration and segmentation techniques are required here.

There have been many approaches to finding an appropriate warp, but a common theme is the compromise between insisting that the distortion be *smooth* and achieving a *good match*. In some recently published cases the warp seems unnecessarily rough [19, Figure 8b; 44, Figure 7f]. Smoothness can be ensured by assuming a parametric form for the warp, such as the affine transformation, or by insisting that the warp satisfies partial differential equations such as Navier's equilibrium equations for elastic bodies [5]. Depending on the application, matching might be specified by points which must be brought into alignment [12], by local measures of **correlation** between images, or by the coincidence of edges [15].

In the DNA sequencing gel, shown in Figure 1(c), it is clear that bands are not aligned, because of a relative lengthening of the tracks near the center of the gel, known colloquially as a "smile" on the gel. Interpretation of electrophoretic gels often involves making comparisons between tracks, or between spot positions on different gels. Distortions are common. Figure 3(a) shows the result of an unwarping operation proposed by Glasbey & Wright [37]. Horgan et al. [51] show how affine and thin-plate spline transformations can be used to align two or more 2D electrophoretograms.

Filters

Filters have two roles in image analysis, either to *reduce noise* by smoothing or to *emphasize edges*, i.e. boundaries between objects or parts of objects. Filters are *linear* if the output values are linear combinations of the pixels in the original image, otherwise they are *nonlinear*.

Linear filters are well understood and fast to compute. They can be studied and implemented in either spatial or frequency domains. Linear filters can be categorized as *low-pass* or *high-pass*, according to whether they smooth by removing high-frequency components in images, or emphasize edges by removing low-frequency components. A third category, *band-pass* filters, remove both the lowest and highest frequencies from images. Use of the **Fast Fourier Transform** leads to efficient computation for filters larger than 5×5. Further details can be found in Glasbey & Horgan [36, Chapter 3]. Note that smoothing filters are a form of kernel regression (*see* **Nonparametric Regression**). See, for example, Hastie & Tibshirani [47, Chapter 2] for a review of this and alternative statistical approaches to smoothing.

In filtering to reduce noise levels, linear smoothing filters inevitably blur edges, because both edges and noise are high-frequency components of images. Nonlinear filters are able to simultaneously reduce noise and preserve edges, but they have less secure theoretical foundations and can be slow to compute. The simplest, most studied, and most widely used nonlinear filter is the moving median. However, many other *robust estimators* of location have also been used [27]. Multiresolution methods based on wavelets are a new approach to smoothing images [25], which also offer great potential in other areas of image analysis.

Morphological filters are a subclass of nonlinear filters, the simplest of which are based on "max" and "min" operations. Substantial improvements in images can often be achieved using sequences of such filters. For example, another problem with Figure 1(c) is that the brightness in the background varies. This is a common problem in image analysis, and makes comparison of similar features in different parts of the image difficult. A morphological *closing* of the image can be used to estimate the background trend. The simplest closings are obtained by first replacing each pixel by the maximum local intensity in a region (e.g. using a *structuring element* which is a disc of radius R centered on each pixel), and then performing a similar operation on the resulting image, using the local minimum. Mathematically, the pixels, z_{ij}, in the closed image will be given by

$$z_{ij} = \min_{k,l} x_{i+k,j+l} \quad \text{and} \quad x_{ij} = \max_{k,l} y_{i+k,j+l},$$

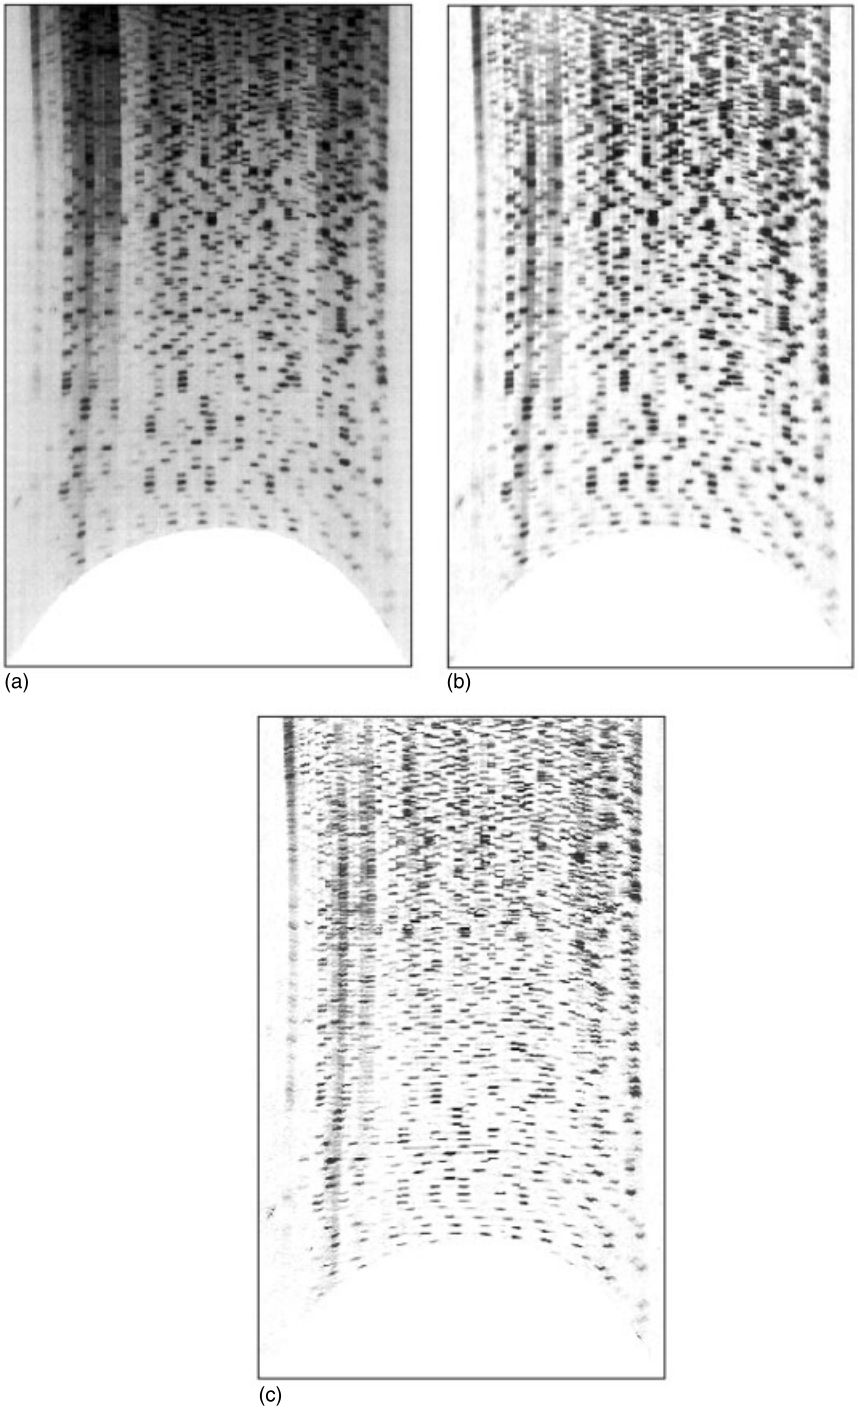

Figure 3 Enhancement of image of DNA sequencing gel autoradiograph: (a) after unwarping of Figure 1(c); (b) after application of top-hat transform to Figure 3(a) to remove background trend; (c) after constrained least squares deconvolution of Figure 3(b)

where $(k^2 + l^2)^{1/2} \leq R$ and $y_{i,j}$ denotes the original pixel value in row i, column j. If this filter is applied to Figure 3(a), then only the small groups of pixels which are darker than their surroundings will be substantially changed from y_{ij} to z_{ij}. These are the bands. By subtracting z from y, these bands will be made more distinct. Figure 3(b) shows the result using a disc of radius 10 pixels. This is known as a *top-hat filter*. Further morphological filters are discussed in [86], and [93].

Deconvolution

If an image has been contaminated by noise and blurring of forms which are either known or can be estimated, then filters can be constructed which optimally restore the original image. There are both linear and nonlinear deconvolution methods (see, for example [83, Chapter 7]). The fundamental linear method is the *Wiener filter*. Nonlinear restoration algorithms can do better than linear ones, but require substantially more computation. For example, *maximum entropy restoration* [90] is one method which exploits the constraint that the restored image is nonnegative. However, as Donoho et al. [24] point out, there are many alternate methods which are equally good. Nonparametric methods for deconvolution generally require the selection of hyperparameters that control smoothing. Rice [80] evaluates generalized **cross validation** (GCV) in this context. See also Thompson et al. [97]. O'Sullivan & Pawitan [74] describe methods for indirect estimation problems and apply them in tomography.

Examination of the pixel values in Figure 3(b) shows the blurring to be well approximated by a Gaussian distribution with variance $\sigma^2 = 2$. This suggests the following model, in which we only consider blur down columns:

$$y_{ij} = \sum_{k=-m}^{m} w_k \, x_{i+k,j} + e_{ij},$$
$$\text{for } i = 1, \ldots, M, \; j = 1, \ldots, N,$$

where

$$w_k = \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left(\frac{-k^2}{2\sigma^2}\right),$$
$$\text{for } k = -m, \ldots, m,$$

M and N are the image dimensions, m is the integer part of 3σ, x_{ij} is an ideal unblurred version of the image, which is constrained to be nonnegative, and e_{ij} is uncorrelated noise. For a more general approach to blur estimation, see, for example, [79].

We can use information about the nature of the degradations to design a filter that will smooth y and enhance the edges, so as to get as close as possible to restoring x. Deconvolution can be posed as a constrained **optimization** problem:

$$\text{minimize } S = \sum_{i=1}^{M} \sum_{j=1}^{N} \left(y_{ij} - \sum_{k=-m}^{m} w_k x_{i+k,j} \right)^2$$
$$\text{with respect to } x_{ij},$$
$$\text{for } i = 1, \ldots, M, \;\; j = 1, \ldots, N,$$
$$\text{subject to } x_{ij} \geq 0.$$

In the absence of the inequality constraint, and provided that we can consider x to be the realization of a random process, the optimal solution is the Wiener filter:

$$\hat{x}^*_{kl} = \frac{y^*_{kl}}{w^*_{kl}} \frac{|w^*_{kl}|^2}{|w^*_{kl}|^2 + S^e_{kl}/S^x_{kl}},$$

where y^* denotes the Fourier transform of y, and S^x_{kl} denotes the spectrum of x at frequency (k, l). For a derivation, see, for example, [83, Section 7.3]. The constrained problem can be solved iteratively by gradient descent. Further details are given in Horgan & Glasbey [50]. Figure 3(c) shows the result of deconvolving Figure 3(b). It can be seen that bands which are very close together have been separated in Figure 3(c), although they are indistinguishable in Figure 3(b).

Segmentation

Image segmentation is the division of an image into *regions* or *objects*. This is often a necessary step before the desired quantitative analysis can be carried out. As an example, we wish to segment the wheat grains image [Figure 1(d)], which was one of 38 such images. Each image consisted of 50 grains of the same type, and different images represented grains of different varieties or sites. The aim of the experiment was to see how well flour yield could be predicted from summary size and shape statistics obtained from each image. It is therefore natural to segment the images into individual grains before measuring and accumulating relevant summary statistics.

In some instances, of course, it is possible to estimate the parameters of interest without first resorting to segmentation. However, typically this requires strong model assumptions, upon which indirect inference can be based. Unfortunately, images are large data sets, e.g. a 512×512 image consists of more than 250 000 pixels. Therefore, there is considerable scope (as in other large data sets) for model assumptions to be violated. Often this has the consequence that the optimal solution for the theoretical model is a poor solution to the real problem! Consequently, in most problems it is necessary to segment an image first before measuring and analyzing the result. In this section we will briefly examine four classes of segmentation: thresholding, edge-based segmentation, region-based segmentation, and Bayesian approaches. The wheat grains image will illustrate some of the techniques discussed.

Thresholding

The simplest method of segmentation is thresholding, i.e. whenever a pixel's value is less than or equal to a certain number, t say, its value is replaced by 1, and otherwise given the value 2.

An obvious question is: How does one choose the threshold(s)? The simplest way is by applying some classification technique to the *histogram* of the pixel values. Glasbey [35] reviewed 11 histogram-based methods for choosing the thresholds automatically, most of which are fairly naive. Perhaps the most sophisticated is the minimum error thresholding technique of Kittler & Illingworth [61], which models the histogram as a mixture of Gaussian distributions. The parameters are estimated iteratively in such a way that the observed and estimated means and variances are equated.

Figure 4(a) shows the histogram of the wheat grains image. Clearly, there are two identifiable groups of pixels: light ones largely belonging to wheat grains, with a mean a little above 100, and dark ones, predominantly associated with the background. Note the non-Gaussian shape of the part of the histogram representing dark pixels, and especially the spike at zero due to the camera setting. Despite the fact that the histogram is not a mixture of Gaussians, we nevertheless applied the minimum error thresholding technique. It gave a value of $t = 66$. (Many other algorithms give a similar value.) Figure 4(b) shows the original wheat grains image, but with pixels whose values exceed 66 overlaid in black. This figure demonstrates a number of relevant issues. First, around each region overlaid in black is a grey halo. For the most part, these halos are 1 or 2 pixels wide. Mostly these represent "mixed" pixels, which are not definitively grain or background, but a mixture of both, caused by camera blur and shadows. In any event, where these halos are narrow, the boundaries of the overlaid regions are close enough to the true grain boundaries for most practical purposes. However, note that the darker parts of some of the grains have not been properly classified. This is perhaps not surprising, because histogram-based thresholding takes no account of spatial context. The remaining classes of segmentation discussed in this section attempt to account for spatial context in various ways. It is also possible to define an *adaptive threshold* which varies across an image (see, for example, [14]).

Edge-Based Segmentation

As the name implies, in edge-based segmentation an attempt is made to find edges in images, often by estimating a "derivative"; see [36, Chapter 3] for a description of some of the more popular edge detectors. One of the simplest edge detectors is *Prewitt's gradient filter*, which implicitly assumes a planar surface in a 3×3 window centered on each pixel, estimates the surface by least squares, and computes its maximal gradient. Figure 4(c) shows this gradient for the wheat grains image. Most of the grain boundaries are apparent, although there are some obvious gaps. Figure 4(d) is the result of thresholding Figure 4(c) at $t = 10$. Less obvious gaps are now apparent, as are some spurious features. This highlights the fundamental problem of edge-based segmentation, namely the absence of parts of boundaries and the presence of spurious edges. Edge tracking methods have been proposed by Hueckel [53], Martelli [67] and Breen & Peden [14], among others, but success is often only partial, especially in images that are more complex than the one analyzed here.

Region Growing and Merging

The basic idea behind region growing is the following. Suppose that one can find distinct points, or clusters of points, such that each distinct cluster belongs to a distinct object in the image, and the number of clusters equals the number of objects.

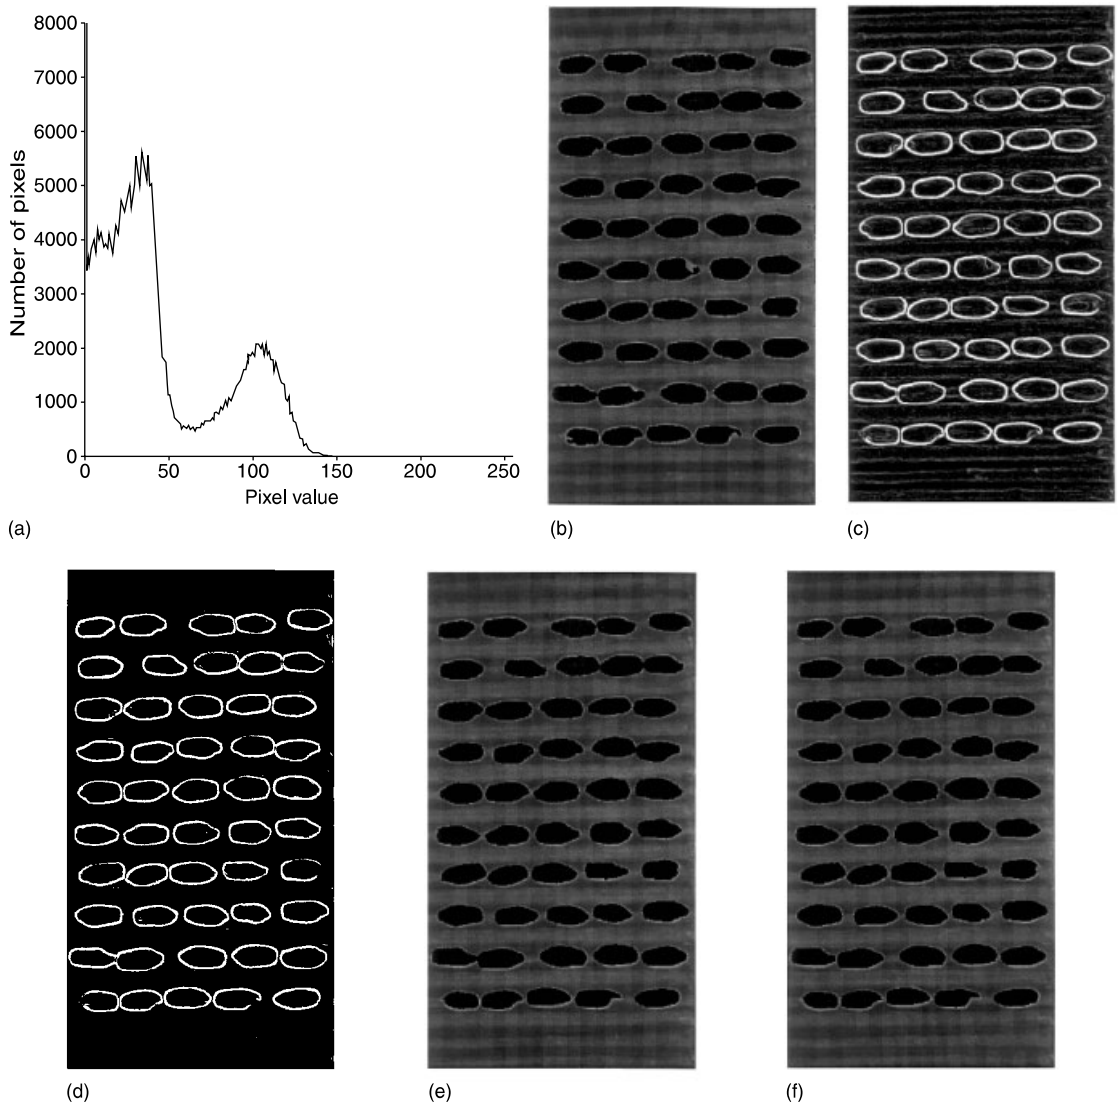

Figure 4 Approaches to segmenting the wheat grains image: (a) histogram of Figure 1(d); (b) after thresholding Figure 1(d) at $t = 66$ (pixels greater than the threshold are overlaid in black); (c) after applying Prewitt's gradient filter to Figure 1(d); (d) after thresholding Figure 4(c) at $t = 10$; (e) after applying seeded region-growing to Figure 1(d); (f) after applying a modified watershed transform to Figure 4(e)

Such points are typically called *seeds* or *markers*. Now grow out spatially from each cluster of seeds according to some mechanism, allocating pixels to objects as they grow in a way that preserves the connectedness of the objects. This process will produce objects with complete boundaries, thereby overcoming a problem with edge-based segmentation mentioned above. Fast algorithms for a number of important region-growing algorithms have been developed in recent years by using data structures that come under the collective name of *priority queues* [13]. In this subsection we apply two important region-growing algorithms to the wheat grains image.

Seeded region growing [1] first computes the mean grayscale of each cluster. Next, all neighboring pixels

of clusters are examined, and the one whose grayscale value is closest to the mean of its neighboring cluster is assigned to that cluster, and the mean value of the cluster is updated. This process continues, one pixel at a time, until all pixels are assigned to a cluster (which by the end of the process is a complete object or region). For the wheat grains image we have chosen our seeds for the grains to be all pixels with a grayscale greater than 80, and our seeds for the background to be all pixels with a grayscale less than 40 [see Figure 4(a)]. Some of the pixels greater than 80 form small (spurious) islands near the bottom of the image [see Figure 4(b)]. Any connected region of pixels less than 100 pixels in area is therefore removed as a seed for the grains. The result of applying seeded region growing using these seeds is shown in Figure 4(e). Apart from the halos mentioned above, the segmentation appears to have found the grains very well. Seeded region growing appears to be quite robust to the choice of parameters; the important thing is to obtain a reasonable number of "representative" seeds for each distinct connected region in an image.

A point to notice in Figure 4(e) is that some of the grains are touching. It is important to separate these grains for subsequent measurements relevant to size, and particularly shape. To do this we employ a variant of a widely used region-growing technique called *watershedding* [69, 99]. The result, shown in Figure 4(f), is a reliable segmentation of the wheat grains. The remaining 37 images were mostly segmented as well and required very little manual intervention.

There are many other split-and-merge algorithms in the literature, most of them more complex than the one presented above. Haralick & Shapiro [46, Chapter 10] discuss a variety of such algorithms and Gordon [40] surveyed methods for constrained classification. The *Hough transform* (see, for example, [64]) can also be used for segmentation by identifying the linear or curved features in images.

Bayesian Approaches

The Bayesian approach to image segmentation received its initial impetus from the pioneering papers of Geman & Geman [31] and Besag [9]. Since then there has been a large number of papers on the subject. However, in the authors' opinion, these techniques are still only applicable for a specialized class of images, in which the models used are good representations of the data. As pointed out earlier, there is plenty of scope for the relatively simple model assumptions used in the Bayesian literature to be violated, because images are such large data sets. However, because of its importance in the statistical literature, we give a brief survey of the area.

Many of the Bayesian approaches to image segmentation rest on variants of the following model as described in Besag [9]. Let S denote the set of all pixels in an image, and let $n = MN$ be the number of pixels in S. Assume that all pixels in the image belong to one of c classes, labeled $1, 2, \ldots, c$, respectively; we do not allow for mixed pixels. Let X_i denote the class to which pixel i belongs (double indexing of subscripts is unnecessary for the present discussion), and let $\mathbf{X} = (X_1, \ldots, X_n)$. Let y_i denote the value recorded at pixel i, and let $\mathbf{Y} = (y_1, \ldots, y_n)$.

Let $f(\mathbf{Y}|\mathbf{X}, \theta)$ denote the conditional density function of $\mathbf{Y}$ given $\mathbf{X}$, with parameter θ. Often (but not always, e.g. [59]) it is assumed that the observations are conditionally independent, i.e. $f(\mathbf{Y}|\mathbf{X}, \theta) = \prod f(y_i|X_i, \theta)$. Let $g(\mathbf{X}, \beta)$ denote the prior distribution of $\mathbf{X}$, with parameter β. In what follows we drop reference to θ and β. It is common to model g as a *locally dependent Markov Random Field* (MRF) [60]. Often, but not always, the local dependence is on the immediate eight neighbors of each pixel. MRFs usually produce a relatively simple structure for g (apart from a normalizing factor); they are also appealing because they can be modeled as limits to (possibly inhomogeneous) **Markov chains**. This means that they can be approximately simulated via **Markov chain Monte Carlo** (MCMC) techniques [10], and are therefore amenable to (computationally intensive) inference (*see* **Computer-intensive Methods**).

The maximum a posteriori (MAP) estimator chooses $\mathbf{X}$ to maximize the posterior likelihood, which is proportional to $f(\mathbf{Y}|\mathbf{X})g(\mathbf{X})$. Unfortunately, this maximization is usually difficult because of the normalization factor mentioned above. In special cases, exact maximization (e.g. [43]) or approximate maximization [26] is possible. However, to circumvent this, Geman & Geman [31] used *simulated annealing* (an inhomogeneous MCMC technique) to find the global maximum of the posterior likelihood. Apart from being computationally intensive, this method sometimes produces gross mislabeling in certain classification problems and "oversmoothing" in related surface reconstruction and image restoration problems [9, 23,

66]. This phenomenon is most probably due to the method's strong dependence on the particular model chosen.

Partly as a consequence of these apparent limitations, Besag [9] introduced the *iterated conditional modes* (ICM) algorithm. Let $h(X_i|X_{S\setminus i})$ denote the distribution of X_i conditional on the other X_js; this will usually have a simple structure for an MRF. Let $\hat{\mathbf{X}}$ denote a provisional estimate of $\mathbf{X}$. ICM *iteratively* chooses $\hat{X}_i$ to maximize

$$p(X_i|\mathbf{Y}, \hat{X}_{S\setminus i}) \propto f(\mathbf{Y}|X_i, \hat{X}_{S\setminus i})h(X_i|\hat{X}_{S\setminus i}).$$

This simplifies in an obvious way when the y_is are independent conditional on $\mathbf{X}$. Besag shows that ICM never decreases the posterior likelihood and so will usually converge to a *local* maximum.

Variants of the above model include those of Geman et al. [33], who imposed constraints on the shapes of class boundaries, and Helterbrand et al. [49], who used boundary closure constraints. A somewhat different and interesting approach is adopted by Baddeley & van Lieshout [4]. They used prior distributions on $\mathbf{X}$ more appropriate for objects of a given shape and size; for instance, in the wheat grains example, these might be ellipses with given radii. The centers of these objects were modeled as nearest-neighbor Markov **point processes**. An algorithm similar to ICM was used to find a local maximum of the posterior distribution. One of Baddeley & van Lieshout's two examples involved fitting circles to an image of (roughly) circular pellets. Their segmentation fitted reasonably well in most places, but not everywhere, in part because the circularity assumptions were not quite right. Similar discrepancies might occur if the wheat grains were modeled as ellipses. Rather than assuming a fixed size and shape, Grenander and coworkers (see Grenander & Miller [44] and references therein) used *deformable templates* to define the boundaries of objects. This requires knowledge of the mean shape of objects, and variability about the mean. They also used jump-diffusion processes to model and simulate the process of interaction between objects. The associated segmentation process appears to be extremely computationally intensive. A related method is where segment boundaries are constrained to be smooth by including roughness penalties such as bending energies in an optimization criterion [71]. This is referred to as the fitting of "snakes" [57]. For further work in this area and a range of applications, see [3], [20], [76], [78], and [81].

We applied a form of ICM [9, Eq. (7)] to the wheat grains image, but the results were only slightly better than those produced by thresholding [Figure 4(b)]. It would seem that stronger prior constraints need to be incorporated. An appropriate Bayesian model and associated estimation procedure would almost certainly segment the wheat grains image as well as the region-based methods. However, it would require a lot of research (and probably data) to find the appropriate model and the estimation procedure is likely to be computationally intensive.

Measurement

The extraction of quantitative information is the endpoint of most image analysis in biostatistics. The aim may simply be to count the number of objects in a scene, or measure their areas, or it may be more complex, such as describing the shapes of objects to discriminate between them.

It is straightforward to count the number of objects in an image provided that the segmentation has successfully associated one, and only one, component with each object. If this is not the case, then manual intervention may be necessary to complete the segmentation. However, short-cuts can sometimes be taken. For example, if the mean size of objects is known, then the number of objects in an image can be estimated, even when they are touching, through dividing the total area covered by all the objects by this average size. It is even possible to make allowance for objects overlapping each other provided that this process can be modeled, for instance by assuming that objects are positioned at random over the image and making use of the properties of Boolean models [21, pp. 753–759]. For example, Jeulin [56] has estimated the size distribution of a powder in such a way. Rudemo et al. [84] used a marked point process model to obtain estimates of plant densities in images of field crops.

Moments offer one method for summarizing segmented objects. If the object we are interested in is represented by all pixels $(i, j) \in A$, then the *(k, l)th moment* is

$$\mu_{kl} = \sum\sum_{(i,j)\in A} i^k j^l, \quad \text{for } k, l = 0, 1, 2, \ldots .$$

In particular, the zeroth-order moment, μ_{00}, specifies the area of the object. First-order moments specify the location of an object. Higher-order moments are also mainly determined by an object's location. *Central moments*, defined by

$$\mu'_{kl} = \sum_{(i,j)\in A}\sum \left(i - \frac{\mu_{10}}{\mu_{00}}\right)^k \left(j - \frac{\mu_{01}}{\mu_{00}}\right)^l,$$
$$\text{for } k + l > 1,$$

are *locationally* – but not *rotationally* – invariant. If orientation is an important feature of an object, as it will be in some applications, then it is probably desirable for the moments to be sensitive to it. However, in other cases orientation is irrelevant and moment statistics are more useful if they are invariant to rotation as well as to location. One such method is based on first specifying the direction in which the object has the maximum value for its second-order moment. This direction is

$$\phi = \frac{1}{2}\tan^{-1}\left(\frac{2\mu'_{11}}{\mu'_{02} - \mu'_{20}}\right), \quad \text{if } \mu'_{02} > \mu'_{20},$$

and is otherwise this expression plus $\pi/2$. Direction ϕ, the *major axis* of the object, has second-order moment:

$$\lambda_1 = \mu'_{20}\sin^2\phi + \mu'_{02}\cos^2\phi + 2\mu'_{11}\sin\phi\cos\phi.$$

The direction perpendicular to ϕ, i.e. the *minor axis*, has the smallest second-order moment of

$$\lambda_2 = \mu'_{20}\cos^2\phi + \mu'_{02}\sin^2\phi - 2\mu'_{11}\sin\phi\cos\phi.$$

For a derivation, see Rosenfeld and Kak [83, Volume 2, pp. 288–290].

Perimeters of objects are also useful summary statistics. Let P denote the number of pixels on the boundary of object A, specified as follows. Pixel (i, j) is on the boundary if $(i, j) \in A$, but one of its four horizontal or vertical neighbors is outside the object, i.e.

$$(i+1, j) \notin A \quad \text{or} \quad (i-1, j) \notin A \quad \text{or}$$
$$(i, j+1) \notin A \quad \text{or} \quad (i, j-1) \notin A.$$

This gives an *8-connected* boundary, with pixels linked either horizontally, vertically, or diagonally. An unbiased estimator of the perimeter is given by

$$\frac{4}{\pi}\frac{P}{\sqrt{2}}$$

provided that either all orientations in the boundary occur equally often or the sampling grid is positioned randomly on the object. This, and more complicated methods for estimating perimeters, are considered by Koplowitz & Bruckstein [62]. The use of scaling factors is part of stereology, a field which has traditionally been concerned with inference about objects using information from lower-dimensional samples, such as estimating volumes of objects from the areas of intersection with randomly positioned cutting planes (see, for example, [95, Chapter 11]). In particular, the scaling factor of $\pi/4$ arises in two of the so-called "six fundamental formulae" of classical stereology. However, the last 10 years have seen a revolution in stereology, with the discovery of the *disector* [*sic*] and other 3D sampling strategies [94]. Note, furthermore, that mathematical morphology can be used to study size distributions of objects in images. By performing openings, using structuring elements at a range of different sizes, a *granulometry* can be obtained [86, Chapter 10].

Shape information is what remains once location, orientation, and size features of an object have been dealt with. One commonly used shape statistic is a measure of *compactness*, which is defined to be the ratio of the area of an object to the area of a circle with the same perimeter. Another statistic often used to describe shape is a measure of *elongation*. This can be defined in many ways, one of which is as the ratio of the second-order moments of the object along its major and minor axes.

Summary statistics of area, perimeter, and major- and minor-axis lengths were obtained for the 50 wheat grains given by segmented regions in Figure 4(f). To illustrate these results, a **principal components analysis** was performed on the log transformed data. Table 1 gives the principal component coefficients. Figure 5 is a scatterplot of the first two

Table 1 Principal component coefficients and percentages of correlation matrix explained for log-transformed summary statistics from 50 wheat grains given by segmented regions in Figure 4(f)

Component:	1	2	3	4
Percent variability:	80.1	18.9	0.9	0.003
Area	0.55	−0.21	0.34	0.74
Perimeter	0.53	0.32	−0.78	0.06
λ_1	0.49	0.54	0.52	−0.45
λ_2	0.42	−0.75	−0.06	−0.50

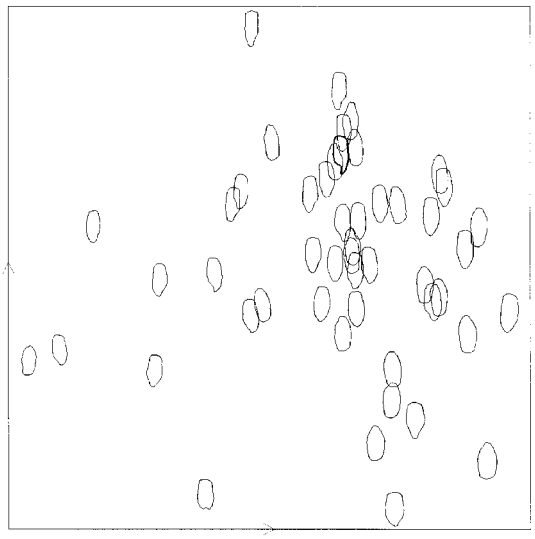

Figure 5 A scatterplot of the first two principal components of summary statistics from the segmented wheat grains [Figure 4(f)], with the first principal component along the horizontal axis. Each point is represented by that grain's outline, and the outline displayed in bold is an outlier in the third principal component

principal components, which account for 99.1% of the variation in the correlation matrix. Each point is represented by that grain's outline. Examination of Table 1 and Figure 5 reveals that the first principal component is an indicator of grain size, while the second is a composite measure of compactness and elongation. The third principal component discriminates between one unusual grain outline, that shown in bold in Figure 5, and the rest. Comparison with Figure 1(d) shows that this grain is not particularly unusual, but rather that the segmentation has failed to recognize a particularly dark part of the grain. Berman et al. [8] used these summary statistics, together with those from a further 37 images, to predict flour yield. They found that the average area of grains in each image, together with averages of λ_1, λ_2, an estimate of volume of a prolate ellipsoid proportional to $\lambda_1\lambda_2^2$, and grain weight explained 65% of the variation in flour yield.

The description of shape is an open-ended task, because there are potentially so many aspects to an object even after location, orientation, and size effects have been removed. Other approaches include the use of *landmarks* [39] and warpings such as *thin-plate splines* and other *morphometric methods* [12], which consider image plane distortions needed to move landmarks to designated locations. Rohlf & Archie [82] and Mou & Stoermer [70] compared alternate forms of *Fourier descriptors* to approximate object boundaries, and applied Zahn & Roskies' [101] method to describe the outlines of mosquito wings and diatoms, respectively. Further methods are discussed in the reviews of shape analysis by Pavlidis [75] and Mardia et al. [65].

Immunotoxicology

Immunotoxicology is a speciality of toxicology aimed at the detection, quantification, and interpretation of xenobiotic-induced direct and indirect alterations (stimulatory and/or suppressive) in the immune system and the resulting effects on morbidity (incidence of infection, duration of infection, incidence of tumors, etc.) and mortality. The immune system is a highly complicated network of lymphoid cells, nonlymphoid cells, soluble factors and regulatory molecules which protect humans from foreign substances and disease. The assays used in immunotoxicology (*see* **Bioassay**) can be divided into *in vivo* assays (in living animals) and *in vitro* assays (in cultured cells), and these can be further divided into immune function assays (measuring the responsiveness of the immune system to stimulation) and host resistance assays (measuring the ability of the immune system to protect the host from infectious agents and neoplasia) [4]. All host resistance and some immune function assays are done *in vivo*, with the remaining assays being done *in vitro* or through a combination of *in vitro* and *in vivo* methods [6]. In some cases, the same or similar immune function assays can be done in both *in vivo* and *in vitro* settings.

Host Resistance Assays

The most obvious endpoint for a host resistance assay is survival. These assays tend to be short-term and are performed in a two-step process [1, 8, 9]. In the first step, animals are exposed to a xenobiotic, generally using three dose groups and a control group. After a brief waiting period, the animals are then exposed to a carefully titrated concentration of some infectious agent (e.g. influenza virus), resulting in some known degree of mortality in the population (usually targeted for 20% in 4 days). The resulting data (the number dead out of the number exposed) are generally analyzed using pairwise comparisons (**Fisher's exact test** or its equivalent), sometimes accounting for multiple comparisons, and, when the study supports it, trend analysis (the Cochran–Armitage linear trend test). Seldom does the analysis include an analysis of the impact of titration variability in administering the infectious agent, a common problem.

More recent work utilizing infectious agents has moved away from mortality as an endpoint and has focused on body burden or tissue load of the infectious agent. Analysis of these assays is generally through the use of normality based statistical methods (e.g. **analysis of variance** (ANOVA)).

Other host resistance assays are similar to the infectious agent assays described above in that the endpoint can be viewed as a survival endpoint. An example would be administration of live tumor cells into the animal (PYB6 or B16F10 assays) with counts of the number of animals with and without tumors after a prescribed period. This type of assay is conducted in the same manner as the infectious agent survival assay described above, with administration of the xenobiotic followed by administration of the live tumor cells.

Another way in which this assay is examined is to count the number of tumors appearing in the animals. Here, the usual analysis is a comparison of the mean numbers of tumors in each dose group via a t test or a similar method. Seldom are these data analyzed by more complicated methods useful for count data such as **Poisson regression**, although there is some use of the Freeman–Tukey transformation method (*see* **Multinomial Distribution**). This is an area for further statistical development.

Immune Function Assays

Immune function assays are generally used to measure the functional competency of the immune system for dealing with antigenic response. In animals, these assays can be conducted *in vivo* by exposing animals to a xenobiotic followed by an antigen and then, following sacrifice, studying key components of the immune system (e.g. the numbers of antibodies producing B-cells in the spleen [2]). In addition, for some species it is possible to perform immune function tests in peripheral blood lymphocytes, either through exposing the host to the xenobiotic and then removing blood and performing the assay or by removing blood and doing the entire assay *in vitro*. These types of studies can also be carried out in exposed and control human populations. In most cases, the data derived from these assays are count data with very high numbers (e.g. the number of plague-forming cells in a Petri dish following stimulation of lymphocytes with sheep red blood cell antigen) and they are analyzed

under the basic assumption of normality (t tests and ANOVA) or through the use of similar **nonparametric** analyses. In some cases, the counts are converted to ratios (B-cells per million spleen cells) to control for fluctuations in physiology. Finally, some immune system markers are simple organ sizes (e.g. thymus weight, spleen weight, and cell counts) which are analyzed via assumptions of normality or **lognormality**.

In most of the analyses of immune function assays, care is taken to control for **multiple comparisons** (usually using Dunnett's' method) and, as with the analysis of host resistance assays, when data on dose–response are available, analyses for trend are common (e.g. **linear regression** and/or Jonkheere's test; *see* **Nonparametric Methods**).

Immunotoxicity and Risk Assessment

There have been considerable efforts in the past few years to develop methods to apply findings from immunotoxicity to the assessment of risks from exposure to xenobiotics (*see* **Risk Assessment**). The major challenge here is to synthesize a large array of assays into a single standard. There has been some work in this area, focusing on the relationship between immune function assays and host resistance assays [3, 5, 7], in which formal regression methods have been used. However, as general area of research, the utility of immunotoxicology for setting exposure standards is still emerging. One area of keen interest is the use of mechanistic models of immune function and response as a tool for understanding alterations due to xenobiotics.

Importance Sampling

Importance sampling is an extremely useful statistical technique with a long history. In the last ten to fifteen years, driven by the popularity of **Monte Carlo** and computationally intensive methods, it has been enriched and extended in many exciting directions. Importance sampling is based on a very simple idea. When one wants to estimate population means or expectations of random variables with respect to a distribution of interest, referred to as the target distribution, but samples are drawn from another distribution, referred to as the trial distribution, importance sampling assigns weight to the samples to make the necessary adjustments. There are three possible reasons for using samples from a trial distribution instead of the target distribution.

1. ***Variance** reduction*: the trial distribution is deliberately chosen so that the estimate obtained is actually superior to an estimate based on samples drawn from the target distribution with the same sample size.
2. *Feasibility and convenience*: drawing samples from the target distribution can be very difficult or outright impossible.
3. *Reusing and mixing samples*: sometimes means and expectations with respect to multiple distributions are of interest, and importance sampling allows us to use samples drawn from one distribution to obtain estimates of expectations under various distributions. When we have multiple sets of samples drawn from different trial distributions, an obvious approach would be to first obtain an appropriate estimate from each set of samples and then compute a weighted average of them as the overall estimate. This, however, is usually not the optimal way of using the samples. The most efficient estimates are usually obtained by treating the multiple sets of samples as a single set drawn from a mixture distribution [7]. Some of the most interesting developments in theory and applications occur in this area.

Importance sampling is used extensively in sample surveys, where the samples are concrete units such as people or households [8]. However, many of the recent developments in applications and methodology are associated with Monte Carlo estimation, where samples are computer generated. Interestingly, while many of the techniques developed end up to be applicable to a wide range of applications, human genetics, particularly pedigree analysis, has been the driving force behind many of them. Also, it was demonstrated recently that a novel recursive estimation technique developed for analyzing coalescence data in **population genetics** can also be considered as an elaborate form of importance sampling.

The basic theory behind importance sampling is as follows. Suppose x is random with outcome space Ω, $g(x)$ is some function of x, and of interest is

$$\mu = \mathrm{E}_{p_1}[g(x)] = \int_{x\in\Omega} g(x)p_1(x)\,\mathrm{d}x, \qquad (1)$$

the expectation of $g(x)$ with respect to the probability density $p_1(x)$, i.e. $p_1(x)$ is the target density. If x is discrete, then $p_1(x)$ is a probability mass function, and the integral in (1) is replaced by a summation. If it is not feasible to compute μ analytically, but Monte Carlo samples, $x_1, \ldots, x_n$, can be generated from the distribution $p_1(x)$, then

$$\frac{\sum_i g(x_i)}{n} \qquad (2)$$

is an unbiased estimate of μ. Now, suppose the samples $x_1, \ldots, x_n$ are not drawn from $p_1(x)$, but instead are generated from some trial $p_0(x)$, whose support contains the support of $p_1(x)$. Since μ can be rewritten as

$$\mathrm{E}_{p_0}\left\{\left[\frac{p_1(x)}{p_0(x)}\right]g(x)\right\} = \int_{x\in\Omega}\left[\frac{p_1(x)}{p_0(x)}\right] \times g(x)p_0(x)\,\mathrm{d}x = \int_{x\in\Omega} g(x)p_1(x)\,\mathrm{d}x, \qquad (3)$$

μ can be estimated by either

$$\tilde{\mu} = \frac{\sum_i w(x_i)g(x_i)}{n}, \qquad (4)$$

where $w_i = p_1(x_i)/p_0(x_i)$ is the importance sampling weight of x_i, or

$$\hat{\mu} = \frac{\sum_i w_i g(x_i)}{\sum_i w_i} = \sum_i w_i^* g(x_i), \qquad (5)$$

where $w_i^* = w_i/(\sum_j w_j)$ are normalized weights that sum to 1. While $\tilde{\mu}$ is the natural **unbiased** estimate, $\hat{\mu}$ is in the form of a ratio estimate that usually is biased in the technical sense. However, the **bias** is of order $1/n$, whereas the standard deviation is of order $1/\sqrt{n}$. Hence, the contribution of the bias to the mean-squared-error is often negligible for large n. There are two possible reasons for using $\hat{\mu}$ instead of $\tilde{\mu}$. If w_i is strongly positively correlated with $g(x_i)$, then $\hat{\mu}$ can have a substantially smaller variance than $\tilde{\mu}$, and hence is preferred. Often that is not the case, but we still use $\hat{\mu}$ because $\tilde{\mu}$ is not computable. Note that while evaluating $\tilde{\mu}$ requires the exact values of the w_i, $\hat{\mu}$ can be computed if the w_i are known only up to a multiplicative constant (because the constant will be canceled out in w_i^*), something that occurs in many new applications of importance sampling. For reference, Hammersley & Handscomb [5] contains many useful results with regard to Monte Carlo **simulations**, importance sampling and the choice of $p_0(x)$. On a purely theoretical level, the ideal $p_0(x)$ to use in conjunction with $\tilde{\mu}$ is $cp_1(x)/g(x)$ for some constant c. Notice that with such a $p_0(x)$, $[p_1(x)/p_0(x)]g(x) = 1/c$, which means $\tilde{\mu}$ has zero variance and c must be equal to $1/\mu$. Hence, while this choice of $p_0(x)$ may serve as a guide, implementing it exactly implies that μ is computed directly and it is no longer a Monte Carlo problem. In general, the choice of $p_0(x)$ always involves a compromise between the variance of the estimate, the ease of generating the samples and the work needed to compute the estimate given the samples. In practice, the problem is further complicated when the expectations of multiple gs, instead of a single one, are of interest. For $\hat{\mu}$ and some extensions of it, expressions of large sample variances and some useful results for comparisons of different estimates can be found in Kong et al. [12]. A rule of thumb is that the efficiency of $\hat{\mu}$ tends to be inversely proportional to one plus the variance of the importance sampling weight w_i.

An example of importance sampling being used in pedigree analysis because of reason 1 is described in Kong et al. [13]. There a trial distribution is deliberately chosen to oversample the tail of the target distribution, which is the distribution of a test statistic under the **null hypothesis** so as to obtain a much more efficient estimate of the P-value. There $\tilde{\mu}$ can be computed and is superior to $\hat{\mu}$. However, most recent developments in methodology are focused on situations falling under scenario 2, where it is difficult to draw samples from the target distribution, and often $\hat{\mu}$ is used instead of $\tilde{\mu}$. For resolving the difficulty of directly obtaining samples from the target distribution, it is important to acknowledge the existence of an alternative strategy. **Markov Chain Monte Carlo** (MCMC) techniques, which were first invented by physicists, have enjoyed unequalled attention in the last two decades in the statistics community and much progress has been made. There a **Markov chain** is constructed with the target distribution as its stationary distribution. In pedigree analysis, examples of how this is done can be found in Lange & Sobel [15], Heath [6], Jensen & Kong [10], and Thompson [20]. Under ideal conditions, this technique allows us to obtain samples that have essentially the right distribution and are assigned equal weights, but the samples are correlated instead of independent, in contrast with importance sampling, which generates independent but weighted samples. As a solution to reason 2, importance sampling and MCMC are competitors and which one performs better depends on individual applications. However, even when samples are generated by MCMC, importance sampling can often be used to expand the utility of the samples because of reason 3, and the two techniques become complementary. One good example of this is Monte Carlo expectation–maximization algorithm **EM** [21], where Monte Carlo estimates are used to perform the expectation step of the algorithm. Since EM is an iterative procedure and the expectation of the score function has to be calculated for a series of parameter values, importance sampling allows us to reuse samples generated with respect to one parameter value for subsequent steps when expectations have to be calculated for other parameter values, regardless of whether the original samples are direct samples, importance sampling samples, or MCMC samples. Irwin et al. [9] demonstrate how this can be done for estimating the recombination fractions (*see* **Linkage Analysis, Model-based**) among a set of **polymorphic markers** using pedigree data. This application also serves as an example of another way that MCMC and importance sampling can potentially be used together. Because of interference, the crossover/recombination process is not a Poisson process, and the crossover events of two neighboring but nonoverlapping regions are not independent. Even with MCMC, it is not easy to generate samples with

the desired distribution. One possible solution is to use MCMC techniques to generate samples based on a no-interference model that is as close to the desired model as possible, and then use importance sampling to do the final adjustment.

Because many of the interesting new applications occur in the area of missing data problems and **likelihood** calculations, we will go into these in more detail. Before doing that, it is worth noting that while μ is the expectation of $g(x)$ under $p_1(x)$, it is also the expectation of $g'(x) = g(x)p_1(x)/p_0(x)$ under $p_0(x)$. Because of that, while the target distribution $p_1(x)$ may have a natural meaning in a specific application, on a certain level, it does not have any special relevance independent of $g(x)$. Indeed, in many of the modern applications of importance sampling, the role of the target distribution is blurred and mathematically the problem is simply one of Monte Carlo integration.

Given any two distributions $p_0(x)$ and $p_1(x)$, let $q_0(x) = c_0 p_0(x)$ and $q_1(x) = c_1 p_1(x)$ for some constants c_0 and c_1. Obviously

$$\mathrm{E}_{p_0}\left[\frac{q_1(x)}{q_0(x)}\right] = \int \frac{c_1 p_1(x)}{c_0 p_0(x)} p_0(x)\, \mathrm{d}x = \left(\frac{c_1}{c_0}\right)\int p_1(x)\, \mathrm{d}x = \frac{c_1}{c_0}. \tag{6}$$

With samples $x_i, i = 1, \ldots, n$, from $p_0(x)$,

$$\left(\frac{1}{n}\right)\sum_i \left[\frac{q_1(x_i)}{q_0(x_i)}\right] \tag{7}$$

is an unbiased estimate of c_1/c_0. This rather simple setting actually incorporates one of the most interesting applications of Monte Carlo estimation. In a missing data problem, let y denote observed data and of interest is the likelihood function

$$L(\theta) = p(y|\theta) \tag{8}$$

as a function of θ. Suppose we cannot compute $p(y|\theta)$ directly, but if y is augmented by x, which is not actually observed, then $p(x, y|\theta)$ can be easily computed for any value of x and θ. Suppose we have samples $x_i, i = 1, \ldots, n$, drawn from some distribution $p_0(x)$ and we can compute $p_0(x_i)$. Let $p_1(x) = p(x|y, \theta)$ and $q_1(x) = p(x, y|\theta)$ so that $c_1 = q_1(x)/p_1(x) = p(y|\theta) = L(\theta)$, and let $q_0(x) = p_0(x)$ so that $c_0 = 1$. It follows from (7) that

$$\left(\frac{1}{n}\right)\sum_i \left[\frac{q_1(x_i)}{q_0(x_i)}\right] = \left(\frac{1}{n}\right) \times \sum_i \left[\frac{p(x_i, y|\theta)}{p_0(x_i)}\right] \tag{9}$$

is an unbiased estimate of $c_1 = L(\theta)$. Now consider an alternative scenario where we cannot compute $p_0(x_i)$, but we can compute $q_0(x_i) = c_0 p_0(x_i)$ for some unknown constant c_0. While the likelihoods cannot be estimated directly here, they can be estimated up to an unknown constant that allows us to estimate likelihood ratios. Specifically, if θ_1 and θ_2 are two possible values of θ, then $L(\theta_2)/L(\theta_1)$ can be estimated by

$$\frac{\sum_i [p(x_i, y|\theta_2)/q_0(x_i)]}{\sum_i [p(x_i, y|\theta_1)/q_0(x_i)]}. \tag{10}$$

This important observation originated from Ott [18] and Geyer & Thompson [3]. One typical choice of $p_0(x)$ will be $p(x|y, \theta_0)$ for some value θ_0 of θ, so that $q_0(x) = p(x, y|\theta_0)$ and $c_0 = p(y|\theta_0) = L(\theta_0)$. Note that (9) can be considered as a form of $\tilde{\mu}$ or simply a form of (2), while (10) is a ratio estimate. By rearrangement of the terms, one can show that (9) can be considered as $\hat{\mu}$ with $p_1(x) = p(x|y, \theta_1)$, $p_0(x) = p(x|y, \theta_0)$, and $g(x) = p(x, y|\theta_2)/p(x, y|\theta_1)$. In particular,

$$w_i = \frac{p(x_i|y, \theta_1)}{p(x_i|y, \theta_0)} = \frac{p(x_i, y|\theta_1)}{p(x_i, y|\theta_0)}\frac{p(y|\theta_0)}{p(y|\theta_1)}, \tag{11}$$

where $\{p(y|\theta_0)/p(y|\theta_1)\}$ is the unknown constant that cancels in

$$w_i^* = w_i \Big/ \left(\sum_j w_j\right) = \frac{p(x_i, y|\theta_1)/p(x_i, y|\theta_0)}{\sum_j \{p(x_i, y|\theta_1)/p(x_i, y|\theta_0)\}}. \tag{12}$$

From (10) and its relationship with (6), one can see that the problem of estimating **likelihood ratios** mathematically falls within the framework of estimating ratios of normalizing constants of functions [e.g. c_0^{-1} and c_1^{-1} are the normalizing constants for $q_0(x)$ and $q_1(x)$, respectively], which happens to have very

broad applications [17]. In the case here, of interest is the whole likelihood function and so, in a sense, of interest are an infinite number of likelihood ratios. Estimates of the ratios can often be greatly improved, meaning that the variance can be greatly reduced, if samples are simulated from multiple trial distributions [1], and the combined samples are treated as draws from a mixture distribution. In the case here, the multiple trial distributions will naturally be $p(x|y, \theta)$ for different values of θ. For importance sampling in general, the step of combining samples is straightforward if the $p_0(x_i)$ can be calculated easily for each of the trial distributions, but in this setting, by design, $p_0(x_i)$ is only known up to a constant and this constant is different for each of the trial distributions. In a way, the problem looks amusingly circular – we want to combine the samples to better estimate the ratios of the normalizing constants, but to properly combine the samples we need to know the ratios of the normalizing constants. Fortunately, this problem actually has a solution and the search for this solution leads to development of new methods [2, 17] and new theory [14].

It is usually the case that when samples from $p_0(x)$ are generated using MCMC, $p_0(x_i)$ can at best be computed up to a constant. By contrast, if independent samples are drawn directly from $p_0(x)$, then most likely $p_0(x_i)$ can be computed. However, the distributions one can draw from directly are much more limited than those that can be drawn from using MCMC. One way to enrich the class of distributions one can draw from directly is a technique called sequential imputations. The idea is as follows. Suppose the observed data y and the missing data x can each be partitioned as $y = [y(1), y(2), \ldots, y(T)]$ and $x = [x(1), x(2), \ldots, x(T)]$. While it is difficult to draw directly from $p(x|y)$, suppose we can draw from $p[x(1)|y(1)]$ and, for $t = 2, \ldots, T$, it is possible to draw $x(t)$ from

$$p[x(t)|y(1), \ldots, y(t), x(1), \ldots, x(t-1)] \quad (13)$$

for any fixed values of $x(1), \ldots, x(t-1)$. Instead of drawing a sample $x_i[x_i(1), x_i(2), \ldots, x_i(T)]$ in one step, sequential imputation simulates the components $x_i(t), t = 1, \ldots, T$, one at a time with each component simulated conditional on values already drawn for previous components. With $p(x|y)$ considered as the target distribution $p_1(x)$, the trial distribution is

$$p_0(x) = p[x(1)|y(1)] \times \prod_{t=2}^{T} p[x(t)|y(1), \ldots, y(t), x(1), \ldots, x(t-1)]. \quad (14)$$

As is true in many other cases, this is a technique that had been invented many times over by researchers in different areas before it was formalized and given a name. Often there is a parameter θ involved in the conditional distribution of x given y, and $p(x|y)$ can either be, in a Bayesian setup, a distribution with θ analytically integrated out [11], or it can be the distribution corresponding to some chosen value θ^* of θ. In genetics, Irwin et al. [9] used it to perform multipoint linkage analysis, while Stephens & Donnelly [19] used it to assist inference in molecular population genetics and also pointed out that an earlier recursive simulation method invented by Griffiths & Tavaré [4] could also be viewed as a form of sequential imputation. Some recent developments can be found in Liu et al. [16].

Inbreeding

Individuals with common ancestors are said to be related, and their offspring are inbred. If no further qualifications are made, then all humans are both inbred and related to everyone else simply because the population is finite. Each of us has two parents, and if we had four grandparents, eight grandparents, 16 great-grandparents, and so on, it would take only a few hundred years back in time before we would have more ancestors than there were people living on the planet at that time. Obviously our parents have some ancestors in common, but conventional definitions of inbreeding refer only to children whose parents are related through people in the past few generations.

Inbreeding in Pedigrees

The genetic consequences of inbreeding follow directly from basic Mendelian principles (*see* **Mendel's Laws**). For each **gene**, an individual receives two alleles, one from each parent, and is generally equally likely to transmit either of these two alleles to a child. The random element in such transmission means that statements about inbreeding are usually expressed as probabilities. Because related people share ancestors, there is a chance that they receive copies of the same allele from those ancestors. Half-sibs, for example, may each receive copies of the same allele from their one common parent. Because this common parent has two alleles, there is a probability of one-half that the half-sibs receive alleles that are identical by descent (ibd). There is a further one-half probability that they would each transmit these ibd alleles to an offspring. A child of half-sibs, therefore, would have an inbreeding coefficient, F, of one-eighth.

A general approach is to specify some initial or reference population, in which all members are assumed to be unrelated, and inbreeding is then measured relative to that generation. It is generally accepted, for example, that Finland was settled by a relatively small group of people about 4000 years ago. It would be convenient to quantify inbreeding, for a random member of the presently living descendants of those founders, as the probability that the person receives two alleles that trace back to a single allele among the founders. Alleles that trace to distinct founding alleles will be considered not ibd.

If the common parent in the half-sib example itself had related parents, and had an inbreeding coefficient of F, then one-half the time it would transmit copies of the same allele to two offspring and the other half of the time it would transmit alleles that had probability F of being ibd. Such arguments lead to "path-counting" equations for inbreeding coefficients. If the parents of individual I have common ancestors A, with inbreeding coefficients F_A, and if there are n_A people in the loop from one parent through A and back to the other parent, then the inbreeding coefficient of I is

$$F_I = \sum_A \left(\frac{1}{2}\right)^{n_A} (1 + F_A).$$

In the half-sib case, the common parent A is the only common ancestor and $n_A = 3$ so that $F_I = 1/8$ as before. Full sibs have two parents in common, so the inbreeding coefficient of their children would be $1/8 + 1/8 = 1/4$. First cousins have four distinct parents, two of whom are full sibs, so they have two grandparents in common ($n = 5$ for each). The inbreeding coefficient of the children of first cousins is therefore 1/16, and this is the maximum amount of inbreeding tolerated by most marriage laws.

Just as the concepts of inbreeding and relatedness are closely connected, so are the probabilities of these events. The usual measure of relatedness for individuals X and Y, the coancestry coefficient (also called the coefficient of kinship) θ_{XY}, is defined as the probability that two alleles, one taken at random from the same locus of each of X and Y, are ibd. This definition provides a value of 1/4 for full sibs, 1/8 for half sibs and 1/16 for first cousins. If individuals X and Y have a child I, then

$$F_I = \theta_{XY}.$$

Although there is not complete independence among different genes, an inbreeding coefficient of F can be interpreted as meaning that a fraction F of the genes in such an individual has two alleles that are ibd. For alleles that are both harmful and recessive, such as the ΔF508 allele responsible for most cases of cystic fibrosis, inbreeding increases the proportion of people with the harmful trait by virtue of having two copies of the deleterious allele, not masked by a normal allele. The ΔF508 allele in Caucasian populations has a (relative) frequency of about $p = 0.05$. Among individuals whose parents

are unrelated, the probability of having two copies of the allele, and therefore having cystic fibrosis, is about $p^2 = 0.0025$. Among people whose parents are cousins, however, $(1 - F) = 15/16$ of the time the probability is p^2, but $F = 1/16$ of the time it is the higher value of p. The total probability is more than doubled, to 0.0063. In general, the probability that an individual with an inbreeding coefficient of F is homozygous aa for allele a that has a frequency of p_{a} is

$$P_{\mathrm{aa}} = p_{\mathrm{a}}^2 + F p_{\mathrm{a}}(1 - p_{\mathrm{a}}). \tag{1}$$

The increased homozygosity brought about by inbreeding must be accompanied by an equivalent decrease in **heterozygosity**. If $\overline{\mathrm{a}}$ indicates an allele different from a, then for inbred individuals

$$P_{\mathrm{a}\overline{\mathrm{a}}} = 2 p_{\mathrm{a}} p_{\overline{\mathrm{a}}}(1 - F). \tag{2}$$

Homozygotes have two alleles that have the same chemical composition, and so are identical in state. Such alleles may or may not be ibd. Heterozygotes have alleles that are not identical in state, and these alleles cannot be ibd.

There is often interest in the joint probability $P_{\mathrm{a,a}}$ with which two individuals carry a specific allele a. It may be that one person, X, is alleged to be the father of a child but some other person Y is actually the father, and a is the allele known to have been received by the child from its father. The probability with which an allele chosen at random from one individual is ibd to one from the other is just the coancestry, so

$$P_{\mathrm{a,a}} = p_{\mathrm{a}}^2 + \theta p_{\mathrm{a}}(1 - p_{\mathrm{a}}) \tag{3}$$

when the two individuals have coancestry θ. There is a more complicated expression if the individuals are also inbred.

Inbreeding in Populations

Equations (1) and (2) have been derived for inbred individuals, where F is necessarily positive. Alternatively, they could be used to relate **genotypic** frequencies P_{aa} and $P_{\mathrm{a}\overline{\mathrm{a}}}$ in some population to allele frequencies p_{a} and $p_{\overline{\mathrm{a}}}$ in the same population, although it is then conventional to use the symbol f in place of F. A general treatment allows for variation among fs for different loci, and for different genotypes at a locus. Writing the frequency of allele a_i as p_i, the frequency of $\mathrm{a}_i\mathrm{a}_i$ homozygotes as P_{ii} and the frequency of $\mathrm{a}_i\mathrm{a}_j$ heterozygotes as P_{ij}:

$$P_{ii_k} = p_{i_k}^2 + \sum_{j \neq i} f_{ij} p_{i_k} p_{j_k},$$

$$P_{ij_k} = 2 p_{i_k} p_{j_k}(1 - f_{ij}), \quad i \neq j,$$

where the subscript k emphasizes that the equations hold for some particular population k.

Inferences about the f parameters are based on a model of repeated sampling from the population, and if this statistical sampling is random, the **multinomial distribution** is appropriate for large populations. Population data provide direct estimates of the genotypic frequencies, and **maximum likelihood** estimates for the p_{a}s and fs, based on sample genotype frequencies $\tilde{P}_{ijk}$ are

$$\hat{p}_{i_k} = \tilde{P}_{ii_k} + \tfrac{1}{2} \sum_{j \neq i} \tilde{P}_{ij_k},$$

$$\hat{f}_{ij_k} = 1 - \frac{\tilde{P}_{ij_k}}{2 \hat{p}_{i_k} \hat{p}_{j_k}}.$$

If a common value f, the "within-population inbreeding coefficient" is assigned to all the f_{ij}s, then iterative procedures are needed for maximum likelihood estimation. These procedures typically produce estimates of the order of 0.001 for human populations. The quantity f was written as F_{IS} by Wright [2], referring to the relation of alleles within individuals (I) relative to a subpopulation (S).

For a specific population, the within-population inbreeding coefficient f quantifies the excess homozygosity over that expected for random mating populations. **Population-genetic** analyses are likely to be concerned with the evolutionary processes that lead to extant populations, and therefore recognize that the present population itself results from genetic sampling. Because of the random processes involved in the choice of alleles transmitted between generations, as well as in other evolutionary forces such as selection and mutation, the genetic composition of a population cannot be specified with certainty over time. Instead, probabilistic models are needed.

Taking expectations $\mathcal{E}$ over populations (or over the evolutionary process) the frequency of allele a_i is

written as p_i, and of genotype $a_i a_j$ is written as P_{ij}:

$$\mathcal{E}p_{i_k} = P_i,$$
$$\mathcal{E}P_{ij_k} = P_{ij}.$$

At this total-expectation level,

$$P_{ii} = p_i^2 + Fp_i(1 - p_i),$$
$$P_{ij} = 2p_i p_j(1 - F), \quad i \neq j, \tag{4}$$

where F is the "total inbreeding coefficient." Evidently, then (1) and (2) refer in expectation to all individuals with the pedigree leading to a specific F value – even though any particular individual is either inbred or not – and invoke the expected allele frequency rather than the frequency for a specific population.

The usual interpretation of (4) is that they apply as an average over populations. One application concerns a large population considered to consist of a number of subpopulations indexed by k. Equations (1) and (2) hold for the subpopulations, but (4) holds for the total. Any variation in p_{i_k} over subpopulations causes $\mathcal{E}p_{i_k}^2$ to exceed p_i^2, so that $P_{ii} > p_i^2$ even if $P_{ii_k} = p_{i_k}^2$. This result is known as the "Wahlund principle." Wright [2] wrote F as F_{IT}, referring to the relation of alleles within individuals (I) relative to the total population (T).

The quantity $p_{i_k}^2$ can be regarded as the probability of two alleles in population k both being of type a_i:

$$P_{i,i_k} = p_{i_k}^2.$$

Taking expectations over populations:

$$P_{i,i} = p_i^2 + \theta p_i(1 - p_i),$$

illustrating why Wright wrote θ as F_{ST}, for the relationship between alleles within subpopulations (S) relative to the total population (T). The three measures of inbreeding are related by

$$f = \frac{F - \theta}{1 - \theta}.$$

It needs to be stressed that $P_{i,i}$ is the joint probability of two alleles in the same subpopulation being ibd, averaged over all subpopulations. Estimation of the inbreeding and coancestry coefficients F and θ requires data from more than one population. Otherwise there is no knowledge of the variation in allele frequencies among populations. If there is random mating within populations, then two alleles have the same relationship whether they are in the same or different individuals, $F = \theta$, and $f = 0$.

One method of estimation, under the random mating assumption, is to compare allelic variation within and among populations. The two means squares are MSW for within and MSA for among. For allele a_i and samples of size n alleles from each of r populations:

$$\text{MSW} = \frac{n}{r(n-1)} \sum_k p_{i_k}(1 - p_{i_k}),$$
$$\text{MSA} = \frac{n}{r-1} \sum_k (p_{i_k} - \overline{p}_i)^2,$$

where

$$\overline{p}_i = \frac{1}{r} \sum_k p_{i_k}.$$

The **variance components** for allele frequencies within and between populations are

$$\sigma_w^2 = p_i(1 - p_i)(1 - \theta),$$
$$\sigma_b^2 = p_i(1 - p_i)\theta,$$

and θ can be estimated [1] as

$$\hat{\theta} = \frac{\text{MSA} - \text{MSW}}{\text{MSA} + (n-1)\text{MSW}}.$$

Conditional Probabilities

It is now possible to return to the disputed **paternity** example. If the alleged father has been typed and found to carry the obligate paternal allele a, then the quantity of interest is the conditional probability $P_{a|a}$ with which some other man also carries the allele. If this unknown and untested other man belongs to the same population as the alleged father,

$$P_{a|a} = \frac{P_{a,a}}{p_a}$$
$$= p_a + \theta(1 - p_a),$$

which applies as an average over all populations. The allele frequency could be estimated from a sample from the total population, as opposed to the particular population to which the two men belong. Data from several populations would be needed if θ

is to be estimated. If the two men belong to different populations, then

$$P_{a|a} = p_a.$$

Other Measures of Inbreeding

Identity coefficients describe other measures of inbreeding. These coefficients are the probabilities that sets of more than two alleles are ibd, and they are needed to express joint and conditional probabilities of genotypes, as opposed to alleles. They find use in questions of disputed identity where one person is found to have a particular genotype and is alleged to be the donor of some biological sample. This use is described in **statistical forensics**.

Incidence Density Ratio

The incidence density ratio is the ratio of the **incidence density** in one group to that in another group. The incidence density ratio approximates the **hazard ratio** if time intervals are small and can be estimated both from **cohort studies** and from **case–control studies** in which controls are selected by **density sampling**.

MITCHELL H. GAIL

Incidence Density

An incidence density is an **incidence rate** and can be used to estimate a **hazard rate**.

MITCHELL H. GAIL

Incidence Rate

The incidence rate is the number of persons who develop a disease of interest over a defined interval of time or age divided by the corresponding **person-years at risk** among members of the source population. Subjects are only "at risk" before they develop the disease of interest if, as is common, the incidence rate describes the rate of first occurrence of a disease. Usually, relatively short time intervals are used, compared with the timescale for development of disease, such as five-year intervals for a cancer incidence study. When individual follow-up data are not available to compute person-years at risk, the person-years are often estimated as the interval width times the population size at the midpoint of the interval. Synonyms for incidence rate include **incidence density** and person-years incidence rate. Incidence rate sometimes denotes a population **hazard rate**, rather than the estimate defined above. Sometimes the term incidence rate is used instead of **cumulative incidence rate**, but the concepts are distinct.

MITCHELL H. GAIL

Incidence–Prevalence Relationships

This article attempts a statistical view on the classical epidemiologic concepts of (age-specific) incidence and **prevalence**. Each individual's dynamics in the **Lexis diagram** is modeled by a simple three-state illness–death **stochastic process** in the age direction and individuals are recruited from a **Poisson process** in the time direction. Observable quantities are regarded as *estimators* of the *parameters* (incidence, prevalence, mortality, **mean** duration, etc.) of the statistical model.

The next section discusses increasingly complex versions of the classical epidemiologic relation

$$\text{prevalence} = \text{incidence} \times \text{duration},$$

and its generalization to age- and duration-specific incidence and mortality. Then some comments are provided on statistical techniques for estimating **incidence rates** from prevalence surveys, while the following section considers, conversely, the feasibility of estimating prevalence from information on incidence and mortality. The material is also relevant in the theory of **screening**, as briefly pointed out later.

A related topic *not* touched in this article is **inference** on mortality (or further morbidity) from follow-up of a **cross-sectional** sample, the so-called *prevalent cohort study*. This topic is treated in the articles **Delayed Entry** and **Biased Sampling of Cohorts in Epidemiology**.

Prevalence, Incidence, and Duration

Most – even rather elementary – textbooks in epidemiology contain versions of the statement

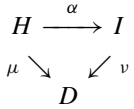
$$\text{prevalence} = \text{incidence} \times \text{duration}, \qquad (1)$$

see, for example, [19, pp. 65–66] or [10, pp. 64–66]. In broad generality, (1) is a conservation equation called Little's equation in queuing theory:

time-average number of units in the system
= arrival rule × average delay time per unit.

See Little [17] for the first general proof in the context of strictly stationary processes in steady state conditions and Ramalhoto et al. [25] for a comprehensive discussion.

In epidemiology, the archetypical situation concerns irreversible transitions between a healthy state H, a diseased state I, and the dead state D, simplest in the time- and age-homogeneous **Markov illness–death process** specified by intensities as follows:



and fed by a stationary homogeneous **Poisson process** with (birth) intensity β. Here α is disease intensity for a healthy individual (the connection to the epidemiologic concept of disease incidence to be discussed below) and μ and ν are death intensities for healthy and diseased, respectively. Sometimes ν is called the **case fatality** rate or just lethality.

In this stochastic process our approach to prevalence is to imagine a **cross-sectional** sample taken at a particular time t, say $t = 0$. We may then calculate the expected number of healthy at $t = 0$ as

$$\int_0^\infty \beta \exp[-(\alpha+\mu)a]\,\mathrm{d}a = \frac{\beta}{\alpha+\mu}$$

since a person born at time $-a$ has probability $\exp[-(\alpha+\mu)a]$ of remaining alive and healthy until time 0; similarly the expected number of diseased at $t = 0$ is

$$\int_0^\infty \int_0^a \beta \exp[-(\alpha+\mu)y]\alpha \exp[-\alpha(a-y)]\,\mathrm{d}y\,\mathrm{d}a = \frac{\alpha\beta}{(\alpha+\mu)\nu}.$$

Under the present assumptions, disease duration is **exponentially** distributed with mean ν^{-1}. Definition of disease incidence requires more care. The intensity α refers to the healthy only, while *disease incidence in the population* may be defined as the rate of occurrence of new disease in the whole population. This is

$$\beta \int_0^\infty \exp[-(\alpha+\mu)\alpha]\,\mathrm{d}a = \frac{\beta\alpha}{\alpha+\mu}$$

and we see that

$$\begin{aligned}\text{E(diseased)} &= \frac{\beta\alpha}{\alpha+\mu}\nu^{-1} \\ &= \text{disease incidence} \times \text{mean duration},\end{aligned}$$

yielding (1) in the present interpretation of units of individuals (rather than the often used prevalence proportion in relative units).

Note, furthermore, that what we shall often term prevalence odds satisfies

$$\frac{\text{E(diseased)}}{\text{E(healthy)}} = \frac{\alpha\beta/[(\alpha+\mu)\nu]}{\beta/(\alpha+\mu)} = \frac{\alpha}{\nu},$$

that is,

$$\text{prevalence odds} = \text{incidence} \times \text{mean duration},$$

where incidence is now understood as *intensity of getting diseased for a healthy individual*.

Alho [5] viewed the above relations between prevalence, incidence, and duration in the macrodemographic context of stable population theory.

The above discussion may be generalized to *time-*, *age-* and disease *duration*-dependent intensities $\beta(t), \alpha(t,a), \mu(t,a)$, and $\nu(t,a,d)$, as documented by Keiding [11]. We may then also discuss such concepts as *age-specific prevalence*, expressing the probability of having the disease for a person at age a alive at time t. The general formulas become complicated and are not reproduced here, although some applications will be indicated below.

In the particular case of *time homogeneity*, which, though not very realistic nevertheless underlies most epidemiologic folklore, similar relations between prevalence, incidence, and duration result as above. In particular, the rate of occurrence of new cases in the population becomes

$$\beta\int_0^\infty \exp\{-[\alpha(a)+\mu(a)]\}\alpha(a)\,\mathrm{d}a,$$

and the expected number of diseased at $t=0$ (prevalence on the population scale, "absolute" prevalence) becomes

$$\beta\int_0^\infty\int_0^a \exp\{-[\alpha(y)+\mu(y)]\}\alpha(y) \times \exp[-\nu(a,a-y)]\,\mathrm{d}y\,\mathrm{d}a.$$

In the simple case where the case fatality rate $\nu(a,d)$ depends only on duration d but not age a, a change of order of integration yields

$$\int_0^\infty \beta\exp\{-[\alpha(y)+\mu(y)]\}\alpha(y)\,\mathrm{d}y \times \int_0^\infty \exp[-\nu(v)]\,\mathrm{d}v,$$

where the first factor is incidence as just specified, while since $\exp[-\nu(v)]$ is the survival function of a diseased, the second factor is mean survival. This provides an interpretation of

$$\text{prevalence} = \text{incidence} \times \text{duration}$$

in the age-dependent case, and Keiding [11] specified how to obtain a similar interpretation when $\nu(a,d)$ depends also on a.

The relation *prevalence odds = disease intensity × mean duration* discussed in the time/age/duration homogeneous special case above, also generalizes to the age/duration inhomogeneous case, see again Keiding [11] and O'Neill et al. [23].

Inference on Incidence from Prevalence Data

As has been known in population statistics (**demography**) for hundreds of years, it is true under very restrictive stationarity assumptions (no dependence of birth and death rates on calendar time, no migration) that the age distribution of the living has density proportional to the survival function (= 1 − distribution function) of the mortality. Inference on mortality rates is therefore in principle available from the age distribution of the living.

The simplest generalization of this to morbidity (disease incidence) is analysis of *current status data* where age-specific incidence rates are estimated from the age distributions of diseased and healthy in a cross-sectional sample. Diamond & McDonald [8] gave a survey based on **parametric models** in discrete and continuous time while Keiding [11] and Keiding et al. [14] focused on variants of current **nonparametric survival analysis** techniques. Ades & Nokes [2] gave a useful practical discussion of the range and limitations of these ideas in modeling infectivity rates from seroprevalence studies; and Marschner [20] gave **sample size** calculations.

As emphasized by Preston [24], the crucial **stationarity** assumption may only be verified from at least two successive cross-sectional samples, which however might then be directly used for inference without the stationarity assumption. Recent work in this direction is due particularly to Marschner ([21, 22]) and Ades [1] as well as a series of papers by Brunet & Struchiner (for example [6]), in the pseudo-stochastic mathematical biology tradition.

Inference on Prevalence from Incidence and Mortality Data

It is not uncommon that disease incidence and mortality are more directly estimable (e.g. from a historically prospective incidence study with follow-up) than prevalence. In that case the relations between prevalence, incidence and duration may be used to estimate prevalence, possibly calendar time-and/or age-specifically, see Keiding [11]. Such calculations will often be variations of the nonparametric **Aalen–Johansen estimator** of a transition probability in a nonhomogeneous Markov illness–death process, and this link provides a methodology for derivation of **standard errors**. See [12, 13, 15, 16] for applications to bone marrow transplantation.

Application of such ideas has been primarily in the context of cancer [7, 9, 27], although there are also examples from neuroepidemiology [26, 28], reference [26] containing counterfactual and predictive "what if" calculations under specified past or future structures in incidence and mortality.

Screening

There are strong relations between the above material and the mathematical theory of **screening** for chronic disease [29, 30], in the simplest but also most important case by having the three states *Healthy, Preclinical* (where the patient feels healthy but screening can identify the disease), and *Clinical* (ly manifest) diseased. The same relations are valid, properly interpreted, and Zelen & Feinleib [30] actually also obtained a *prevalence* = *incidence* × *mean duration* result. O'Neill et al. [23] formalized a concept of *initiation*, equivalent to subclinical disease onset. The comprehensive exposition of the theory of screening by Albert et al. [3, 4] and Louis et al. [18] is based on probability densities rather than intensities as in this article and most of the other references.

NIELS KEIDING

Incident Case

An incident case is a subject who has just developed the disease or condition of interest for the first time. Incident cases of chronic diseases are particularly valuable for etiologic investigations because disease incidence, unlike disease **prevalence**, is determined by etiologic factors only and not by factors that influence survival following disease onset. To contrast incident with prevalent cases, (*see* **Biased Sampling of Cohorts**; **Case–Control Study, Prevalent**; **Cross-sectional Study**; **Incidence–Prevalence Relationships**; **Prevalent Case**).

MITCHELL H. GAIL

Incomplete Block Designs

Experimental designs with fixed block size k in which the number of treatments (or levels of a single factor) v to be compared exceeds the available block size are called *incomplete block designs*. Such designs first arose in agricultural experiments and were studied by, among others, **Fisher**, **Yates**, and Bose. Incomplete block designs are currently used in a wide variety of subject areas, including agricultural field and animal experiments, food-tasting experiments, industrial processes, toxicology, educational psychology, and, occasionally, in **clinical trials**. For example, in animal experiments it may be desirable to compare the test treatments within a litter, but the number of treatments may exceed the available litter sizes. In food and beverage tasting experiments, the number of items to be tasted is often greater than the number of items a judge can taste within a reasonable time period. In an experiment to compare the tread wear on different kinds of automobile tires, each car can have, at most, four distinct tires and so, if the number of treatments to be tested is greater than four, the blocks (cars) are necessarily incomplete.

Most graduate and advanced undergraduate text books on experimental design contain some material on incomplete block designs, particularly **balanced incomplete block designs** (BIBDs) and **Youden squares**. Two such books, with an applied flavor, are by Lentner & Bishop [9], and John & Quenouille [6]. Das & Giri [3] contains a full account of all the major types of incomplete block designs, their analyses, and some selected construction results. John [5] is a more theoretical discussion of the mathematical structure and analysis of incomplete block designs, and of the construction of such designs by the cyclic development of one or more initial blocks. This article describes briefly the different kinds of incomplete designs, their relationships to each other and to other well-known kinds of complete block designs (*see* **Randomized Complete Block Designs**), and general methods of analysis of such designs.

The incomplete block design problem is one of arranging the test treatments. Two technical concepts needed in a discussion of incomplete block designs are *binary* designs and *connected* designs.

An incomplete block design is said to be *binary* if no test treatment occurs more than once in any block. It can be shown that a design that is not binary may always be improved (in the sense of average or total **variance** of the treatment contrasts) by replacing all duplicates of test treatments in a given block with treatments not already in that block. Hence, we may restrict our attention to binary designs.

A design is said to be *disconnected* if the blocks of the design may be split into two groups in such a way that none of the test treatments that occurs in one group of blocks occurs in the other group of blocks. Treatments that occur in the different groups of blocks may not be compared due to **confounding** with the block effects. As a consequence, we also restrict our attention to designs that are not disconnected; that is, to designs that are *connected*.

There are many different types of incomplete block designs that are both binary and connected. *Balanced incomplete block designs* (BIBDs) have the property that all treatments occur in the same number of blocks, say r, and all pairs of treatments occur in the same number of blocks together, say λ. In BIBDs, all **paired comparisons** of treatments are estimated with equal precision. Kiefer [7, 8] has shown that BIBDs are optimal in the sense of having smallest average or total variance for the paired treatment comparisons.

A standard assumption in the analysis of block designs is that measurements on different experimental units are statistically independent. There are situations in which this is not a reasonable assumption. For example, in agricultural field experiments, fertilizer or irrigation may spill over from an experimental plot to its neighboring experimental plots. A family of experimental designs that is useful in such a situation is the *equineighbored* BIBDs in which each pair of test treatments occurs adjacent to each other in the same number of blocks.

One shortcoming of BIBDs is that for a given number of treatments and a given block size, the number of blocks required to construct a balanced incomplete block design may be too large to be of practical use. Yates [10] addressed this problem with a series of designs that he called **lattice designs**. Lattice designs exist only when $v = s^2$ and $k = s$, for some positive integer s, and are constructed using sets of mutually orthogonal **Latin squares**. Of course, the requirements that $v = s^2$ and $k = s$ are quite restrictive, so the application of lattice designs is somewhat limited.

Bose & Nair [1] discovered a more general alternative to BIBDs. In **partially balanced incomplete**

block designs, all treatments occur in the same number of blocks and pairs of treatments occur together in λ_1 or λ_2 or λ_3 or ... or λ_m blocks together. (Two treatments that occur in the same block λ_l times are said to be in the *lth associate class*). BIBDs are special cases of partially balanced incomplete block designs for which $\lambda_1 = \lambda_2 = \cdots = \lambda_m = \lambda$. Lattice designs are also special kinds of partially balanced incomplete block designs.

Partially balanced incomplete block designs exist for more combinations of parameters than do BIBDs. Das [2] and Giri [4] showed how to construct incomplete block designs for still more combinations of parameters. Their **algorithm** starts with a partially balanced incomplete block design for v treatments in b blocks of size k. Augment each block in this design with α treatments that are not among the original v treatments. The result is a design for $v + \alpha$ treatments in b blocks of size $k + \alpha$. Such designs are called *reinforced designs*.

Youden squares [11] are incomplete block designs in which two sources of variation (**blocking**) may be eliminated. First used by Youden in greenhouse studies, these designs are related to Latin square designs. Indeed, removing any row and any column from a Latin square always yields a Youden square, but Youden squares may also be constructed from certain kinds of BIBDs.

Analysis of Incomplete Block Designs

Youden squares are distinct from the other types of incomplete block designs in that they involve two blocking factors rather than one.

In the analysis of incomplete block designs with a single treatment factor and a single blocking factor, the following linear model (*see* **General Linear Model**) is usually assumed:

$$Y_{ij} = \mu + \tau_i + \beta_j + \varepsilon_{ij}, \quad \text{for } i = 1, 2, \ldots v \text{ and } j = 1, 2, \ldots, b,$$

where the τ_is denote the treatment effects and the β_js denote the block effects. No **interaction** among block and treatment effects is assumed. Indeed, because not all treatments occur in every block, not all block-treatment interactions are even estimable. The validity of the assumption of no interactions may be evaluated graphically by plotting the **residuals** from the fitted model against, for example, the predicted values. Degrees of freedom for the different factors are summarized in Table 1.

Table 1 Degrees of freedom for the different factors

Source of variation	Degrees of freedom
Blocks	$b - 1$
Treatments	$v - 1$
Error	$bk - b - v + 1$
Corrected total	$bk - 1$

Computation of appropriate sums of squares is complicated in incomplete block designs due to the lack of **orthogonality** of block and treatment effects. Simple formulae for sums of squares do exist for BIBDs but for other incomplete block designs, even for a partially balanced incomplete block design with just two associate classes, the formulae become extremely complicated. For this reason, it is recommended that analyses be carried out using a computer package. If algebraic formulae are required, the reader is referred to the books by Das & Giri [3] and Lentner & Bishop [9].

The most common analysis of incomplete block designs is often called the *intrablock* analysis, because block differences are eliminated and all treatment **contrasts** may be expressed as differences among observations in the same blocks. This is essentially a **least squares** analysis, assuming that the block effects are fixed. Usually, the block effects are not of intrinsic interest and so the block sum of squares is computed *without* adjusting for treatment effects. Then, the treatment sum of squares is computed after adjusting for block effects. In linear models jargon, this is a *type I* **analysis of variance**, and is standard in most statistical packages, including SAS (*see* **Software, Biostatistical**). If the block effects *are* of intrinsic interest, a block sum of squares adjusted for treatment effects may be computed. This is commonly called a *type II* analysis of variance.

Yates [10] proposed an alternative analysis, which he called the *interblock* analysis, in which additional information about the treatment effects might be obtained by comparing experimental units in different blocks. In modern linear models terminology, the interblock analysis is a mixed effects analysis of variance in which the treatment effects are regarded as **fixed effects**, while the block effects are viewed as independent **random variables** with **mean** zero

and variance σ_β^2. Modeling block effects by random variables is particularly appropriate when the blocks may be viewed as a sample from some population of blocks. For example, in **multicenter clinical trials** the centers at which the study takes place may be viewed as a representative sample of all possible centers (*see* **Random Effects**).

The interblock (mixed effects) analysis may be carried out using, for example, PROC GLM and PROC MIXED in the SAS computer package. Although the intrablock analysis has been the standard analysis for many years, the interblock analysis seems to be gaining in popularity as researchers are more inclined to view their block effects as random quantities.

D.R. CUTLER

Incomplete Follow-up

Longitudinal (or follow-up) study data analysis is complicated by the diversity of possible outcomes and the different lengths of observation time. Some subjects die or relapse ("failures"), some remain alive or in remission ("survivors"), and some are *lost to follow-up* (e.g. drop out or withdraw from treatment) (Colton [2, pp. 299–302]). Even if one had the time to wait until all subjects met the outcome failure criterion, the problem of accounting for those who were lost to follow-up would remain. Thus, because of their *incompleteness*, longitudinal studies often are subject to selective influences (Hill & Hill [4, p. 27]).

Substantial **bias** in longitudinal studies can result from not considering the duration of the study and from inappropriate handling of incomplete data, even when only a small proportion of the observations is missing (Andersen [1, p. 80], Colton [2, pp. 237–250], Hill & Hill [4, pp. 188–203], Murray & Findlay [6].) Average duration of survival may be a convenient way to summarize "mean observation time" for the "failures" (Colton [2, pp. 299–302]). However, it is a meaningful term *vis-à-vis* mortality or relapse only when all study subjects have had the outcome; it has no meaningful interpretation in terms of survival or prognosis (Colton [2, pp. 237–250, 299–302]). Averaging survival time only among the failures, while ignoring those who have not lived long enough to experience the outcome within the period of observation, selects for early failure and overemphasizes negative outcomes (Colton [2, pp. 299–302]; Hill & Hill [4, pp. 188–203]).

Furthermore, conclusions based solely upon individuals with complete follow-up data presume that results recorded for the failure subgroup would not be affected by including those with incomplete data, i.e. both the survivor and lost-to-follow-up subgroups. In other words, this assumption presumes that the characteristic of "being followed up" does not correlate with the characteristic being measured, for example, survival (Hill & Hill [4, pp. 23–33]). However, the characteristic of being "lost to follow-up" may correlate with being either more or less likely to be alive or dead, so that the ratio of alive/dead may differ in traced versus untraced (i.e. lost) cases (Hill & Hill [4, pp. 188–203]). For example, in a study of treatment for alcoholism, treatment drop-outs may be more likely to relapse to heavy drinking than subjects who remain in treatment.

The magnitude of the incomplete follow-up problem increases as larger numbers of individuals drop out or are withdrawn. Consequently, conclusions drawn from the analysis of outcomes from follow-up data can be considerably biased by incomplete data. Between group differences in mean survival times can be attributed to the incomplete follow-up fallacy.

In all cases, the obvious data management solution is to conduct a comprehensive follow-up or, in the case of **clinical trials**, to emphasize study retention so that concerns regarding **missing data** due to incomplete follow-up do not arise. However, this can be a lengthy, not to mention costly, undertaking. Various statistical techniques have been developed to try to deal with this problem (Gibbons et al. [3], Little & Rubin [5], Rubin [7]).

HOWARD M. KRAVITZ

Incubation Period of Infectious Diseases

The incubation period is the time interval between exposure to a disease-causing agent and the onset of symptomatic disease. For example, the incubation period of an infectious disease refers to the time interval between infection or exposure to a viral or bacterial agent and the onset of symptomatic (clinical) disease. The incubation period is also called the clinical latency period (*see* **Latent Period**). The focus of this article is on modeling and estimating the incubation period of infectious diseases. However, some of the ideas may also be applicable to the incubation period of noninfectious disease, for example the incubation period of radiation-induced cancer that refers to the time interval from **radiation** exposure to cancer diagnosis.

The length of the incubation period depends on the disease and the infectious agent. It can be very short, perhaps only several days in the case of a streptococcal sore throat, or perhaps several weeks in the case of smallpox, or perhaps a decade in the case of the acquired immune deficiency syndrome **(AIDS)**. After an individual is exposed to an infectious agent, the agent multiplies, and the host defenses are weakened. Eventually, the individual may experience the onset of clinical disease. Individuals may or may not be infectious (that is, capable of transmitting the infection to others) during the incubation period or subsequently.

The incubation period of a disease can be very variable among individuals [2, 21]. A single number, such as the **mean** or **median** incubation period, does not reveal the significant heterogeneity in incubation periods in a population for a given infectious diseases. The incubation period distribution, $F(t)$, is the probability that the incubation period is less than or equal to t time units. The probability density function of incubation periods usually is asymmetric and is **skewed** to the right. Sartwell [23, 24] suggested that the **lognormal distribution** adequately describes the incubation period distribution of a number of diseases. However, other **parametric models for survival** data may also adequately describe incubation period distributions, including the **Weibull**, **gamma**, log-logistic (*see* **Logistic Distribution**), and piecewise **exponential** models [9]. There is no requirement that all infected individuals eventually develop clinical disease. Thus, the distribution function, F, may not be proper. For example, one may postulate that a proportion, p, of infected individuals eventually develop clinical disease with incubation distribution, F_1, and the remaining proportion of infected individuals, $1 - p$, never develop disease; then we have the mixture model $F(t) = pF_1(t)$.

Studies of the incubation period distribution are important for several reasons. First, the incubation period distribution is important for forecasting the course of epidemics, and is used with either transmission models [1] or **back-calculation** approaches [9]. If the incubation period is long, then infected individuals may be silently and unknowingly spreading the infection to others. Secondly, identification of **covariates** or cofactors that may lengthen the incubation period may lead to the development of effective therapeutic interventions. Thirdly, knowledge of the incubation period is useful in counseling infected patients about their prognosis. Finally, the incubation period is a critical parameter in designing **clinical trials** of early interventions and vaccines (*see* **Communicable Diseases**; **Infectious Disease Models**; **Vaccine Studies**).

The ideal study for estimating the incubation period is to monitor a **cohort** of uninfected individuals, determine the dates of infection, and then to follow the infected patients to determine the dates of the onset of clinical disease. The data for estimating the incubation period distribution would consist of the time interval between infection and disease for those patients who became infected. If an infected individual did not develop clinical disease at the time of last follow-up, then the data would be right **censored** at that time. Classical **survival analysis** techniques could be used to estimate the incubation period distribution from right-censored *data* [12]. **Kaplan–Meier** survival curves could be used to estimate $F(t)$ nonparametrically, the cumulative distribution function of incubation periods. Parametric models could also be fit to the right-censored incubation period data (*see* **Parametric Models in Survival Analysis**). A simple example is the case of a single point source epidemic, as might occur with salmonellosis where infection is transmitted from contaminated food or water [21]. In this example a cohort may be defined as all individuals who were exposed (e.g. individuals

who are in a restaurant on the given day that contaminated food was served), in which case the date of exposure is known precisely. Another example of a point source epidemic for a noninfectious disease is the onset of leukemia associated with radiation exposure following the 1945 atomic bomb explosion in Hiroshima [11]. The incidence of leukemia appeared to peak about six years after exposure. Survival analyses could be performed on the time intervals from exposure to clinical disease, and of course some of these intervals may be right censored at the times of last follow-up (*see* **Epidemic Curve**).

Unfortunately, the ideal study of incubation periods can seldom be performed because of a number of important complications. First, it may not be possible to identify a cohort of initially uninfected individuals, and to follow them over time. Instead, we may only have available a sample of cases who already have clinical disease (see the section "Retrospective ascertainment" below). Even if a cohort is assembled and followed over time, it may not be possible to ascertain either the exact dates of infection (exposure) or the onset of clinical disease (see the section "Cohort studies" below). For example, an individual may already be infected at the time of enrollment in a cohort study, but the time that incident infection occurred is unknown. Many of these problems have surfaced in studies of the incubation period of AIDS, and have been the subject of active methodologic research among statisticians in recent years. In the next sections we discuss more fully these complexities and the methodologic approaches to address them. The issues are illustrated with studies of AIDS, although the methods are applicable more generally to other infectious diseases.

Retrospective Ascertainment

The first data on the incubation period of AIDS (time from HIV infection to AIDS diagnosis) were based on transfusion-associated AIDS cases [22]. In that study, AIDS cases were identified who had become infected by receiving a transfusion of infected blood. The date of infection was estimated retrospectively as the date of blood transfusion. There was an important selection criterion to get into the study, namely that subjects had to have AIDS. Early in an epidemic of a new disease the only data about incubation periods that may be gathered rapidly may come from symptomatic cases of disease who have already been identified. These cases of disease are then retrospectively studied to determine dates of exposure to the infectious agent. Such studies have been referred to as having "retrospective ascertainment" because only individuals with symptomatic disease are included and then they are retrospectively studied. A naive analysis of this type of data, which did not account for the selection criteria, could lead to serious underestimation of the incubation period. This is because the data are right **truncated**. Individuals with long incubation periods may not yet have symptomatic disease, and thus could not possibly be included in the data set. To analyze such data properly, the analysis must condition properly on the selection criteria [18, 19].

There are other **biases** with studies based on retrospective ascertainment. For instance in the transfusion example, patients who receive blood transfusion are often elderly and sick with chronic diseases, and thus they may die from other causes of death before developing AIDS. This leads to length-biased sampling: we are more likely to observe patients with shorter incubation periods, because patients with long incubation periods may die first from another disease and thus are never included in the data set. In a series of papers, statisticians have developed methods to correct for these and other biases (see, for example, [18], [19], and [25]). However, none of these methods can correct for the fundamental limitation of this sort of data: they are retrospective and involve only cases of disease and so without strong parametric assumptions they provide essentially no information about the prospective probability of getting a disease once one is infected.

Cohort Studies

A second type of study involves identifying a cohort of uninfected individuals, ascertaining as best one can the subsequent dates of infection, and following the infected individuals to ascertain the date of onset of clinical disease. The first issue concerns the difficulty in identifying the date of infection. The usual method is to test individuals serially with a laboratory assay such as the test for antibodies to the infectious agent. In the case of AIDS, individuals may be serially tested with ELISA or Western Blot assays to identify the dates of seroconversion to HIV antibodies [16].

A complication is that the date of seroconversion does not correspond to the date of infection. Infected individuals will be seronegative for antibodies to the virus until they develop detectable antibodies, usually within several months. Although we define the incubation period as the time from infection to the clinical diagnosis of disease, many studies cannot identify the actual dates of infection but only the time of antibody seroconversion. However, in the case of AIDS, the time from infection to antibody seroconversion is relatively short (approximate median is two months) compared with the much longer period from seroconversion to the onset of disease. Accordingly, many studies define the incubation period to be the time interval from antibody seroconversion (becoming antibody positive) to the onset of clinical disease. Nevertheless, this points out that the results of studies of incubation periods may depend on the choices of the assays that are used to ascertain infection or exposure to the infectious agent. PCR (polymerase chain reaction) testing may identify evidence of infection considerably earlier than antibody testing [17].

If individuals are periodically screened by laboratory tests for evidence of infection, then the date of infection can at best be determined up to an interval (i.e. interval censored). This interval is defined by the time of the latest screening test that was negative for infection, L, and the earliest screening test that was positive for infection, R. The term *doubly censored data* refers to time to event data for which both the time origin and failure time are censored. In cohort studies of the incubation period the data are frequently doubly censored because the date of infection is interval censored and the date of onset of clinical disease is right censored for those individuals who have not developed clinical disease by the time of the last follow-up.

A popular *ad hoc* approach for analyzing doubly censored data on incubation periods is to estimate (impute) the calendar date of infection by the midpoint of the interval. The imputed midpoint calendar date of infection is $S = (L + R)/2$. Then, standard survival analysis techniques for right-censored data are used on the incubation periods with imputed dates of infection. However, such approaches will typically be biased and give incorrect **variance** estimates. The bias of the estimated incubation resulting from midpoint imputation depends critically on the width of the intervals, $R - L$, the incubation distribution, and the density of infection times. For example, in the exponential growth phase of simple epidemics, midpoint imputation will tend to underestimate the time of infection and thus overestimates the incubation period. Law & Brookmeyer [20] studied the impact of midpoint imputation, and concluded that with a median incubation period of 10 years in the case of AIDS, the bias resulting from midpoint imputation associated with intervals even as large as two years is relatively small.

A more formal parametric approach for analyzing the doubly censored data in studies of the incubation period involves specifying parametric models and joint estimation of both the probability densities of infection times and of incubation times. The **likelihood** function is maximized to obtain the **maximum likelihood** estimators. This approach was used by Brookmeyer & Goedert [10] to estimate the incubation period of HIV infection among hemophiliacs. Bacchetti & Jewell [4] used a weakly **semiparametric** approach. A discrete time scale was used with a separate parameter to represent the discrete **hazard** for each month. To avoid irregularities that result from trying to estimate a large number of parameters (e.g. wildly varying hazards from one month to the next with large variances), a **penalized likelihood** function was used that penalized for "roughness" in the estimated hazard function. A completely **nonparametric** approach to the problem has been given by De Gruttola & Lagakos [14]. However, the completely nonparametric estimate of the incubation period distribution, $F(t)$, is often numerically unstable, and it is not defined for all values of t.

Deconvolution Methods

Occasionally, population data may be available both about the incidence of clinical disease and infection rates in the population. The expected **cumulative incidence** of clinical disease up to calendar time t, $D(t)$, is related to infection rates $g(s)$ at calendar time s (numbers of new infections per unit time) and the incubation period distribution, by the convolution equation

$$D(t) = \int_0^t g(s)F(t-s)\,\mathrm{d}s.$$

The basic idea is to use data on $D(t)$ and an estimate of $g(s)$ to glean information about F. This

method was pioneered by Bacchetti & Moss [5] and Bacchetti [3] in connection with estimating the incubation period of HIV infection. The usefulness of the method depends on the availability of accurate information on the infection rates in the population, $g(s)$, and accurate disease **surveillance** data over time. For example, detailed information about historical infection rates was available in San Francisco on the basis of several epidemiologic surveys and cohort studies [5, 26]. The statistical framework is as follows. Let y_j represent the number of cases of disease in calendar interval I_j. Suppose that N, the cumulative number of infections that have occurred, is known. Then the vector of counts of cases of disease, **y**, has a **multinomial distribution** with sample size N and cell probabilities that involve the incubation distribution and the known infection rates. Maximum likelihood estimation methods are used to estimate the parameters of the incubation period distribution. The method is closely related to the back-calculation methodology which uses data on $D(t)$ and an estimate of F to estimate historical infection rates $g(s)$. Back-calculation is a method for estimating past infection rates from disease surveillance data. The method requires reliable counts of numbers of cases of disease diagnosed over time and a reliable estimate of the incubation period distribution. The method has been used to obtain short-term projects of disease incidence and to estimate **prevalence** of infection [6, 9]. Early references on back-calculation are [7] and [8]

Synthesis of Studies of the Incubation Period

The main complications in the analysis and interpretation of studies of the incubation period include uncertainty in the dates of infection and the sampling criteria by which individuals are included in the data set. Accordingly, it is important to synthesize and compare estimates across studies because the estimates may be used on different methodologies with different underlying assumptions.

In the case of AIDS, many different methodologies outlined in this article have been used to study the incubation period distribution. The results from several different methodologies have been compared [15] and a general picture emerges [9]. The probability of developing AIDS within the first two years of HIV antibody seroconversion is very small, less than 0.03. Then the hazard of progression to AIDS begins to rise rapidly so that the cumulative probability of developing AIDS within seven years of seroconversion is approximately 0.25 and the median incubation period is nearly 10 years. When comparing incubation period estimates from different studies, an important consideration is whether treatments were available to delay progression and thus alter the incubation period distribution. Treatments such as AZT became available beginning in 1987 which may lengthen the incubation period. In the case of AIDS, the one covariate that has been shown to influence the length of the incubation period in multiple studies is the age at infection [13].

RON BROOKMEYER

Independence of a Set of Variables, Tests of

Suppose that p variables have been measured on each of n sample individuals. Denote the value of the jth variable for the ith individual by x_{ij}, and collect together the p values observed on the ith individual into the vector $\mathbf{x}_i' = (x_{i1}, \ldots, x_{ip})$. Then

$$\overline{\mathbf{x}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{x}_i = (\overline{x}_1, \ldots, \overline{x}_p)'$$

is the sample mean vector,

$$\mathbf{A} = (a_{ij}) = \sum_{i=1}^{n}(\mathbf{x}_i - \overline{\mathbf{x}})(\mathbf{x}_i - \overline{\mathbf{x}})'$$

is the corrected sum of squares and products matrix,

$$\mathbf{S} = (s_{ij}) = \frac{1}{n-1}\mathbf{A}$$

is the sample **covariance matrix**, and

$$\mathbf{R} = \mathbf{DSD}$$

is the sample **correlation** matrix, where

$$\mathbf{D} = \mathrm{diag}(s_{11}^{-1/2}, \ldots, s_{pp}^{-1/2}).$$

The two sample matrices $\mathbf{S}$ and $\mathbf{R}$ can be viewed as estimates of the corresponding population quantities $\boldsymbol{\Sigma}$ and $\boldsymbol{\Upsilon}$, respectively.

Situations often arise in which the p variables can be divided a priori into k distinct sets with p_i variables in the ith set ($i = 1, 2, \ldots, k$). For example, each child in a school class may have to sit an examination that comprises p separate tests, on each of which a mark of between 0 and 100 is awarded. However, these tests may be identifiably of four types: p_1 of them examine verbal ability, p_2 of them examine arithmetic ability, p_3 of them examine general knowledge, and p_4 of them examine logical reasoning. Clearly, *within* each set the individual tests are likely to be (highly) correlated, but a question of interest would then be whether the variables in different sets can be treated as independent. In this section, we consider testing independence of such sets of variables.

Without loss of generality, we can assume the variables to be arranged so that the first p_1 of them fall in the first set, the next p_2 in the second set, and so on. Denote by $\mathbf{S}_{ii}$ the sample covariance matrix of the variables in the ith set and by $\mathbf{S}_{ij}$ the matrix of sample covariances between those pairs of variables in which one variable comes from the ith set and the other from the jth set. Apply the same notation to the matrices $\mathbf{A}, \mathbf{R}, \boldsymbol{\Sigma}$, and $\boldsymbol{\Upsilon}$. Then the overall sample covariance matrix $\mathbf{S}$ can be expressed in partitioned form as

$$\mathbf{S} = \begin{pmatrix} \mathbf{S}_{11} & \mathbf{S}_{12} & \ldots & \mathbf{S}_{1k} \\ \mathbf{S}_{21} & \mathbf{S}_{22} & \ldots & \mathbf{S}_{2k} \\ \vdots & \vdots & & \vdots \\ \mathbf{S}_{k1} & \mathbf{S}_{k2} & \ldots & \mathbf{S}_{kk} \end{pmatrix},$$

and each of the matrices $\mathbf{A}, \mathbf{R}, \boldsymbol{\Sigma}$, and $\boldsymbol{\Upsilon}$ can be partitioned similarly. The null hypothesis that we are concerned with is

$$\mathrm{H}_0\colon\ \boldsymbol{\Sigma}_{ij} = \mathbf{0}$$

for all $i \neq j$, the only requirement on the remaining unspecified matrices $\boldsymbol{\Sigma}_{ii}$ being that they are positive definite for all i. The alternative hypothesis is the general one, i.e. that $\boldsymbol{\Sigma}_{ij} \neq \mathbf{0}$ for at least one $i \neq j$.

Assuming **multivariate normality** of the data, the **likelihood ratio test** for this situation is obtained by maximizing the likelihood of the sample under the null hypothesis and dividing the result by the unconditional maximum of the likelihood. After some algebraic simplification the test statistic can be written

$$\Lambda = \frac{|\mathbf{A}|}{|\mathbf{A}_{11}| \cdots |\mathbf{A}_{kk}|},$$

and elementary properties of determinants establish that equivalent expressions for this statistic are

$$\Lambda = \frac{|\mathbf{S}|}{|\mathbf{S}_{11}| \cdots |\mathbf{S}_{kk}|}$$

or

$$\Lambda = \frac{|\mathbf{R}|}{|\mathbf{R}_{11}| \cdots |\mathbf{R}_{kk}|}.$$

Unfortunately, the exact sampling distribution of Λ is complicated and difficult to handle, so large-sample approximations are generally employed in practice. Standard likelihood-ratio theory provides the basic result that $-n \log \Lambda$ asymptotically follows the **chi-square distribution** with $\nu = \frac{1}{2}(p^2 - \sum_i p_i^2)$ **degrees of freedom** when H_0 is true, so this distribution can be used to find an approximate significance **level** for the test. However, a more accurate large-sample approximation was obtained by Box [2], who showed that when H_0 is true, then

$$\Pr(-a \log \Lambda \le z) = \Pr(\chi_\nu^2 \le z) + ba^{-2}[\Pr(\chi_{\nu+4}^2 \le z) - \Pr(\chi_\nu^2 \le z)] + O(a^{-3}),$$

where

$$a = n - \frac{3}{2} - \frac{1}{3}\left(p^3 - \sum_i p_i^3\right)\left(p^2 - \sum_i p_i^2\right)^{-1}$$

and

$$b = \frac{1}{48}\left(p^4 - \sum_i p_i^4\right) - \frac{5}{96}\left(p^2 - \sum_i p_i^2\right) - \frac{1}{72}\left(p^3 - \sum_i p_i^3\right)^2\left(p^2 - \sum_i p_i^2\right)^{-1}$$

(see also [1, p. 385], [6, p. 534], or [8, p. 90]). Alternatively, Muirhead [6, p. 537] reproduces tables from Davis & Field [3] that contain correction factors to make the percentage points of $-a \log \Lambda$ exactly those of χ_ν^2.

Two special cases of the above test are commonly of interest. The first is when $k = p$, in which case the null hypothesis becomes the hypothesis that all the variables are mutually uncorrelated (independent if normality of data is assumed); in other words, that $\mathbf{\Sigma}$ is a diagonal matrix. In this case the likelihood ratio statistic becomes

$$\Lambda = \frac{|\mathbf{S}|}{s_{11}s_{22}\cdots s_{pp}} = \frac{|\mathbf{A}|}{a_{11}a_{22}\cdots a_{pp}} = |\mathbf{R}|,$$

where $a_{jj} = \sum_{i=1}^n (x_{ij} - \overline{x}_j)^2$ and $s_{jj} = a_{jj}/(n-1)$ for $j = 1, \ldots, p$. Exact percentage points of $-(n - [2p+11]/6)\log \Lambda$ are given by Mathai & Katiyar [5] and reproduced by Seber [8, p. 612]. Alternatively, any of the above approximations can be used with $p_i = 1$ for all i.

The second special case is when there are just two a priori groups of variables; that is, $k = 2$ with p_1 and p_2 variables in the two groups respectively. In this case the sample covariance matrix $\mathbf{S}$ has the partitioning

$$\mathbf{S} = \begin{pmatrix} \mathbf{S}_{11} & \mathbf{S}_{12} \\ \mathbf{S}_{21} & \mathbf{S}_{22} \end{pmatrix},$$

with a corresponding form for each of the matrices $\mathbf{A}, \mathbf{R}$, $\mathbf{\Sigma}$, and $\mathbf{\Upsilon}$. The null hypothesis is now simply

$$H_0\colon\ \mathbf{\Sigma}_{12} = \mathbf{0},$$

and the likelihood ratio test statistic becomes

$$\Lambda = \frac{|\mathbf{A}|}{|\mathbf{A}_{11}||\mathbf{A}_{22}|} = \frac{|\mathbf{S}|}{|\mathbf{S}_{11}||\mathbf{S}_{22}|} = \frac{|\mathbf{R}|}{|\mathbf{R}_{11}||\mathbf{R}_{22}|}.$$

When the null hypothesis is true this statistic has Wilks's lambda distribution $\Lambda_{p_2, p_1, n-p_1-1}$, which has been tabulated extensively (see, for example, Seber [8, p. 565]), so that exact significance levels are easily found.

Note also that in this case we have $|\mathbf{S}| = |\mathbf{S}_{11}||\mathbf{S}_{22} - \mathbf{S}_{21}\mathbf{S}_{11}^{-1}\mathbf{S}_{12}|$ (using results for patterned matrices given, for example, by Seber [8, p. 519]), and equivalent expressions exist for $\mathbf{A}$ and $\mathbf{R}$. The likelihood ratio statistic can thus be reduced to the form

$$\Lambda = \prod_{i=1}^{q}(1 - r_i^2),$$

where $q = \min(p_1, p_2)$ and the r_i^2s are the nonzero **eigenvalues** of $\mathbf{S}_{22}^{-1}\mathbf{S}_{21}\mathbf{S}_{11}^{-1}\mathbf{S}_{12}$ (or, equivalently, of $\mathbf{S}_{11}^{-1}\mathbf{S}_{12}\mathbf{S}_{22}^{-1}\mathbf{S}_{21}$, or of either of these expressions with $\mathbf{A}_{ij}$ or $\mathbf{R}_{ij}$ replacing $\mathbf{S}_{ij}$ for $i, j = 1, 2$). These are the squared **canonical correlations** between the two sets of variables, which are important multivariate descriptors of the inter-set associations.

In this particular special case, it is possible also to derive a **union–intersection test** of the null hypothesis (which has not been found possible to date for the general case of k sets). To derive this test, we consider the univariate hypothesis

$$\rho_{ab}^2 = \frac{(\mathbf{a}'\mathbf{\Sigma}_{12}\mathbf{b})^2}{[(\mathbf{a}'\mathbf{\Sigma}_{11}\mathbf{a})(\mathbf{b}'\mathbf{\Sigma}_{22}\mathbf{b})]} = 0,$$

where ρ_{ab} is the correlation between two arbitrary linear combinations, one from each of the two sets of variables. A suitable test statistic for this univariate hypothesis is $(\mathbf{a}'\mathbf{S}_{12}\mathbf{b})/[(\mathbf{a}'\mathbf{S}_{11}\mathbf{a})(\mathbf{b}'\mathbf{S}_{22}\mathbf{b})]^{1/2}$

and, on maximization with respect to both **a** and **b**, the union–intersection test statistic is found to be $\max_i r_i^2$. Critical values of this statistic have also been tabulated extensively; see, for example Pearson & Hartley [7, Tables 48 and 49] or Seber [8, p. 593].

Various other test statistics have been proposed for this last situation. Invariance arguments lead to statistics which are functions of the **eigenvalues** r_i^2, and the most popular variants are $\sum_{i=1}^{s} r_i^2$ or $\sum_{i=1}^{s} [r_i^2/(1 - r_i^2)]$. Muirhead [6, p. 548] discusses some power comparisons among the various statistics.

A final point concerns the behavior of all these test statistics when the data are not normal. Relatively few systematic studies have been conducted, although both Muirhead [6, p. 546] and Fang & Zhang [4, p. 170] give some results relevant to samples from elliptic distributions. Fang & Zhang derive forms of the likelihood ratio statistic appropriate for such samples, while Muirhead considers asymptotic null distributions of normal-based likelihood ratio test statistics when the data are actually from elliptic distributions. He quotes some **Monte Carlo** studies which indicate that the normal likelihood ratio test statistics should only be used with care if the data come from elliptic distributions.

Indian Statistical Institute

Research in the theory and applications of statistics as a new scientific discipline began in India in the early 1920s through the pioneering initiative and efforts of **Prasanta Chandra Mahalanobis**. Soon after his return from England, Mahalanobis began to carry out statistical studies with the help of some part-time assistants. A chance meeting with Nelson Annandale (the then Director of the Zoological and Anthropological Survey of India) and subsequent interactions with him led to the first scientific paper by Mahalanobis on the statistical analysis of stature of Anglo-Indian males of Calcutta. This was followed by further research in **anthropometry**, in meteorology and in problems of flood control in North Bengal and Orissa. Gradually, a small group of young scientists was picked up by him in the Department of Physics, Presidency College, Calcutta, where he was a professor. This group formed the nucleus of a laboratory which later came to be known as the Statistical Laboratory.

In the early 1930s, realizing the necessity for a concerted effort for the advancement of theoretical and applied statistics in India, Mahalanobis, together with P.N. Banerjee and N.R. Sen, both professors of Calcutta University, convened a meeting on December 17, 1931, to consider various steps to be undertaken for the establishment of an association for the advancement of statistics in the country. As a result of this meeting, the Indian Statistical Institute (ISI) was registered as a non-Government and nonprofit-distributing learned society on April 28, 1932, with Sir R.N. Mookerjee as President and Professor P.C. Mahalanobis as (Honorary) Secretary. The total staff strength then was only two or three. From such a modest beginning, the Institute grew, under the remarkable leadership of Mahalanobis into an all-India organization which now has a staff strength of about 1600, including about 500 scientific staff. The Institute has its headquarters in Calcutta and centers at Bangalore and Delhi and a branch at Giridih. In addition, it has a network of service units of the Statistical Quality Control and Operations Research Division at Bangalore, Baroda, Calcutta, Chennai (formerly Madras), Coimbatore, Delhi, Hyderabad, Mumbai (formerly Bombay), Pune, and Tiruvananthapuram.

From the very beginning, Mahalanobis and his associates, who included S.S. Bose, R.C. Bose, S.N. Roy, K.R. Nair, K. Kishen, and H.C. Sinha, worked with zeal and enthusiasm for the development of statistical theory and methods, and in promoting research and practical applications in different areas of the natural and social sciences. *Sankhyā*, the Indian Journal of Statistics, was started in 1933 with Mahalanobis as its Editor, and received instant international recognition, which continues till today. Pioneering research activities were carried out in many areas of statistical theory, especially in the core areas of **multivariate analysis**, sample surveys and **experimental design**. Such activities were strengthened and new directions were opened up by Professor C.R. Rao and many others who joined the Institute in the 1940s and the tradition continues. The Institute pioneered the development of statistical methods in agricultural research and in the conduct of large-scale agricultural enquiries. This led to a large number of research publications and to the introduction of training activities offering short-term courses in statistics for officers in government departments and scientific institutions. The scientists of ISI, led by Mahalanobis, helped in introducing the first post-graduate degree course in Statistics in India at the Calcutta University in 1941, and in securing a separate section for Statistics in the Indian Science Congress.

Activities of the Institute gained further momentum from 1938. Mahalanobis started sample surveys to estimate the area under the jute crop in Bengal in 1937 as an exploratory project, which later grew to a full-scale survey of the entire province in 1941. Gradually, sample surveys of agricultural crops, and other socioeconomic surveys, became some of the most important activities of the Institute, and earned the Institute and Mahalanobis international reputation. Mahalanobis was appointed Honorary Statistical Advisor to the Cabinet, Government of India, and in 1950, through his initiative, the National Sample Survey (NSS) was started for conducting socioeconomic surveys of all-India coverage on a continuing basis. This was the first ever attempt in India to have a database for various developmental programs and the five year plans.

The ISI played a pioneering role in starting the Statistical Quality Control (SQC) movement in India by organizing a visit of W.A. Shewhart, the father of SQC, to India in 1948 and later by inviting

other experts like W.E. Deming. SQC promotional work was gradually spread all over the industrial centers in India under a comprehensive program covering education and training, applied research, and consultancy services.

Research in economics was greatly stimulated when in 1954 Prime Minister Jawaharlal Nehru entrusted the preparation of the draft Second Five-Year Plan of the country to Mahalanobis and the Institute. The "draft" submitted by Mahalanobis and the plan models formulated by him in that connection have since been regarded as major contributions to economic planning in India. Since then many economists of the Institute have continued to work on various aspects of national planning and, until 1970, were directly helping the Planning Commission of the Government of India in the preparation of the long-term prospective plans for the country. Research in other disciplines of social sciences was also started in the Institute in the late 1950s. Mahalanobis's participation in 1946 in the annual scientific conferences of the Milbank Foundation led to the initiation of systematic studies in India on population growth. Earlier, the well-known Y-sample estimates for the 1941 census population were also derived by the ISI. Theoretical and empirical research in sociology using statistical techniques was started in the Institute for the first time in South-East Asia. Similarly, the development and introduction of psychometric tests for selection processes in different organizations was first made by the ISI in India besides carrying out basic research in psychometry (*see* **Psychometrics, Overview**). Studies of the phonetic structure of some major Indian languages have been made on a continuing basis in the Institute under the guidance and collaboration of the famous linguist Djordje Kostic.

The Institute, since its inception, recognized the need for development and use of accurate and fast computing equipment for the processing and analysis of data. Mahalanobis strongly believed that to be a good theoretical statistician one must also compute and must therefore have the best computing aids. The Institute has lived up to this tradition from the very beginning. In 1953 a small analog computer was designed and built in the Institute. In 1956 the Institute acquired a HEC-2M machine from the UK which was the first digital computer in India. In 1958 a digital computer URAL was received as a gift from the then USSR. From 1956 to the mid-1960s the Institute had been serving as a *de facto* national computer center for the country. In the early 1960s the Institute, in collaboration with Jadavpur University, undertook the design, development, and fabrication of a fully transistorized digital computer, called ISIJU-1, which was commissioned in 1966 by Mr M.C. Chagla, the then Minister of Education, Government of India.

Quantitative analysis in the physical and earth sciences was one of the novel ideas that Mahalanobis pursued in the true spirit of the Institute. In addition to evolving some interesting techniques and obtaining some very interesting results from the analysis of directional geological data, the Institute also made a significant contribution by discovering the bones of a 16 m (+) long sauropod dinosaur named *Barapasaurus tagoreii*, from the lower Jurassic Kota rocks near Sironcha, Gadchiroli district, Maharashtra, in the 1960s. The discovery has helped in understanding the interesting problem about the origin and evolution of sauropod dinosaurs. It represents the only intermediate form between the prosauropods and the sauropods, and is called a "missing link" in the evolution of the sauropod dinosaur.

The Institute expanded its research, teaching, training, and project activities and earned national and international recognition over time. The substantial contributions of the Institute to theoretical and applied statistical work have culminated in the recognition of the Institute by the Government of India enacting *The Indian Statistical Institute Act, 1959 (No. 57)* which declared the Institute as an "Institution of National Importance" and empowered it to award degrees and diplomas. None other than Pandit Jawaharlal Nehru, the then Prime Minister of India, piloted the bill in Parliament. With this recognition, the already existing teaching and training programs were consolidated and expanded and courses for the degrees of Bachelor of Statistics (B.Stat. (Honors)) and Master of Statistics (M.Stat.) were started in June 1960. The Institute was also empowered to award Ph.D./D.Sc. degrees from the same time. Later on, courses leading to Master of Technology degrees were started in Computer Science and in Quality, Reliability and Operations Research. Recently, the Institute has also been empowered to grant degrees and diplomas in mathematics, quantitative economics, computer science and subjects related to statistics as well as statistics itself. A master's

degree programme in quantitative economics has just been initiated.

The role and importance of ISI in conducting and promoting teaching of statistics has been appreciated by international bodies as well. In 1950 the **International Statistical Institute** initiated the International Statistical Education Centre (ISEC), Calcutta, jointly with ISI, to impart training in theoretical and applied statistics to participants selected from developing countries. The center is run by ISI under the auspices of UNESCO, the International Statistical Institute and the Government of India.

Recognition of the Institute by the Act of Parliament provided greater encouragement to research activities not only in statistics and mathematics but also in various branches of the natural and **social sciences**, without whose live contact, it was believed, the methodology of statistics could not grow. It is also due to this fact that "Unity in Diversity" has been adopted as the motto of the Institute.

The objectives of the Institute are:

1. to promote the study and dissemination of knowledge of statistics, to develop statistical theory and methods, and their use in research and practical applications generally, with special reference to problems of planning for national development and social welfare;
2. to undertake research in various fields of natural and social sciences with a view to the mutual development of statistics and these sciences; and
3. to provide for, and undertake, the collection of information, investigations, projects, and operational research for purposes of planning and the improvement of efficiency of management and production.

From the early days, the Institute has been in touch with many internationally famous scientists in different disciplines from all over the world. Some of these scientists have worked in the Institute for several months or even longer. **R.A. Fisher**, a pioneer of modern statistics, was a regular visitor to the Institute and lent it considerable support. J.B.S. Haldane, a geneticist of international repute, was a member of the faculty for several years beginning 1957. At the inspiration of these stalwarts and other renowned scientists, the Institute began to expand and/or undertake research activities in several areas of the natural and social sciences with the hope that collaboration under the same roof would foster the mutual development of statistics and other disciplines. In fact, the Institute stood up to R.A. Fisher who called statistics a "key technology" of the century, in view of its intimate relevance to all scientific endeavors which involve experimentation, measurement and **inference** from sample to aggregate.

Coming to more recent times, the Institute has continued to pursue its goal of attainment of excellence in various fields of science. Fundamental research in statistics with its roots in applications has been the bottom line ever since the inception of the Institute. The contributions from the Institute in multivariate analysis, design and analysis of experiments, sample surveys, statistical methods of data analysis and statistical inference have found their places in textbooks and monographs, and the tradition continues. In addition, **probability theory** and **stochastic processes** have also been major areas of research in the Institute. The mathematicians of the Institute, in addition to collaborating with the statisticians, are also making fundamental contributions in several fields – topology, functional analysis, harmonic analysis, algebra, combinatorics, quantum mechanics, game theory, to name a few. The current trend of research in statistics not only carries forward the traditions set up in the Institute, but is also setting new directions, both in theory and applications, in different disciplines.

The Institute has been maintaining its tradition of high-quality research and development in the field of computer science. In 1979, a microprogrammed signal processing system using the **Fast Fourier Transform (FFT)** was designed and developed. Keeping pace with the global advances in computer technology, the activities of the Institute in the field of computer science gathered a tremendous momentum in the late 1970s, resulting in diversification of research in different areas including **algorithms** and complexity, parallel and distributed processing, fault-tolerant computing, VLSI, computational geometry, fuzzy sets and systems, wave propagation, atmospheric remote sensing, speech signal processing, cybernetics, **pattern recognition**, **neural networks**, **artificial intelligence**, image processing (*see* **Image Analysis and Tomography**), computer vision, document analysis, natural language processing, particle physics, fluid dynamics, plasma physics, etc. In recognition of its contributions in the field of computer science,

the Government of India established, in collaboration with the United Nations Development Program (UNDP), one of the five national nodal centers for knowledge-based computing systems (NCKBCS) in ISI in the year 1988.

The different disciplines under the social sciences also continued to develop and flourish over time by carrying out basic research as well as inter- and multidisciplinary programs. In economics, the Institute has come to be known as a specialized center for its significant contributions in different branches of theory and also for studies on such areas as demand analysis, poverty and levels of living, measurement of inequalities, production and prices, national income and allied topics, development and planning, etc. In **demography**, sociology, psychometry and linguistics also, the Institute maintained its distinctive feature for the focus and emphasis on quantitative aspects. Mention may be made, in this context, of the pioneering theory for teaching and training for hearing-impaired children, developed by D. Kostic. Based on this theory the Electronics Unit of the Institute, in collaboration with the Linguistic Research Unit and the Government of Tripura, designed, developed and fabricated a set of instruments for hard-of-hearing children of the Institute of Speech Rehabilitation, Government of Tripura, Agartala. This has come to be regarded as having significant impact on social welfare. Recently, the Institute has established a Policy Planning Research Unit at its Delhi Center and a Survey Research and Data Analysis Center in Calcutta.

Plant and human biology have been major areas of research in biological sciences in the Institute. Both basic and applied research are conducted, with emphasis on quantification, statistical design and analysis, and modeling. In the area of plant biology, research has included quantification of natural variability and modeling animal behavior, effect of interaction of rice varieties on yield, use of protein extracted from leaves to supplement human food, mathematical modeling of ecological and embryological phenomena, etc. In the area of human biology, researches have included anthropometric, genetic and biochemical studies on population affinities, microevolution, studies on utilizing data on anthropometric variability in designing car seats, human adaptation to differing environments, human ecology and growth, (*see* **Growth and Development**), and **genetic epidemiology**.

Over the years, the SQC & OR Division has grown to the size of having ten operating units all over the country and has uniquely served for promotion, education and training and technical guidance in total quality management methodology and quality assurance systems for the benefit of the manufacturing and service industry. It has thus, as was intended, played a leading role in the dissemination of new concepts, methods and techniques in the areas of quality and productivity.

The central library of the Institute is located at Calcutta with a network extending to other locations of the Institute. Over the years, the library of the Institute has attained the distinction of being one of the richest libraries in the country, particularly in the fields of statistics and related disciplines. The library has developed a well-equipped reprography and photography unit. The library's gift collections include the personal libraries of Mahalanobis and Shewhart. The library has been recognized as the depository library for World Bank Publications. A separate collection of books and journals in mathematics, statistics, etc. known as the Eastern Regional Center of the National Board of Higher Mathematics (NBHM), has been developed out of the grants from the NBHM.

The Documentation Research and Training Centre (DRTC) established at Bangalore in 1962 by the late S.R. Ranganathan, a doyen in the field of library and information science, is engaged in research, teaching and training in documentation and information science. The Institute awards post-graduate diplomas in documentation sciences.

The continual publication of many books and monographs and a large number of scientific papers in national and international journals by the scientific staff of the Institute give a good idea of the nature and extent of the contributions of the Institute to statistics and related fields. Scientists of the Institute have also received recognition from many national and international organizations by way of awards, titles, and fellowships. With a dynamic group pursuing and guiding research work in some of the most modern topics and frontier areas of statistics, mathematics, and in various fields of the natural and social sciences, there is close interaction with scientists from all over the world.

S.B. RAO

Infant and Perinatal Mortality

An infant death is defined as the death of a live-born baby before a completed year after birth [24]. The concept of infant mortality did not emerge until the latter half of the nineteenth century, although data for much earlier periods have subsequently been used to construct infant mortality rates [3, 11]. Similarly, the idea that stillbirths and deaths in the first week of life could be grouped together and described as perinatal deaths was not put forward until 1948 [16], but perinatal mortality rates have been constructed retrospectively for earlier years.

The Emergence of the Concept of "Infantile Mortality"

In 1858, Sir John Simon, Medical Officer to the General Board of Health used the term "infantine death rate" for mortality among children under the age of five. In his introduction to *Papers Relating to the Sanitary State of the People of England* [18], he expressed the view that this rate was a proxy measure of the health of the population. Drawing attention to the wide differences between districts, he commented that these infantine death rates

> ... furnish a very sensitive test of sanitary circumstances; so that differences of infantine death-rate are, under certain circumstances, the best proof of differences of household condition in any number of compared districts. And, secondly, those places where infants are most apt to die are necessarily the places where survivors are most apt to be sickly ... [18].

He went on to suggest that, "Deaths which occur in excess within five years of birth are mainly due to two sets of causes; first to the common infectious diseases of childhood prevailing with unusual fatality; and secondly to the endemic prevalence of convulsive disorders, diarrhea and pulmonary inflammation". A factor that he did not mention was differences in the completeness of registration of births. It was likely that some babies who died shortly after birth were not registered; in particular, babies born outside marriage in big cities.

William Farr first used the current definition of infant mortality indirectly when reporting deaths in 1875, although he did not explicitly use the term "infant", nor the word "infantile", which was more commonly used in the succeeding decades. He wrote, "I show that in 1000 infants born in 1875 no less than 158 died in the first year of life ..." [5].

Infantile Mortality and Stillbirth Registration

In the same report, William Farr commented on the implications of changes in the law that had made the registration of live births compulsory in 1875. He pointed out that, "In the case of children born alive – or who breathe – both the birth and death are registered, but still-born children are not registered in England" but "Under the provisions of the new Registration Act, no still-born children, however, should be buried without a certificate stating that they were still-born" [5]. There is good evidence that these certificates were also used to bury victims of infanticide [11].

An international survey undertaken for the Select Committee on Stillbirth Registration and published in 1893 showed that Britain and Ireland lagged behind many other countries in not having stillbirth registration [10]. Nearly 20 years later, a second and fuller survey was done by the "Special Committee on Infantile Mortality" set up by the **Royal Statistical Society** [17].

These surveys covered European countries, New Zealand, states of Australia and the US and provinces of Canada. The Royal Statistical Society's survey also covered other British colonies and some Latin American countries. It found that stillbirth registration was compulsory in most countries, but that, "The large majority of the countries where registration is not required are under the British Crown, and it may be concluded that the Registration Laws in force in such countries have been based on the English model." In contrast, Sweden had introduced registration of both live and still births and deaths as early as 1749, followed by Denmark and Norway in 1801.

The surveys found wide differences between the countries in their criteria for birth registration and for distinguishing between infant deaths and stillbirths. As William Farr had already pointed out, "In France, under the provisions of the Code Napoleon, children who die (either before or after birth) before registration, are recorded as still-born. Dr **Bertillon** estimates

that twenty-two in 100 of the children registered in France as still-born breathed, and such children in England would be registered among the births and deaths" [5].

It was this problem that prompted the Royal Statistical Society's enquiry. When presenting the Committee's report to the Society, Reginald Dudfield focused his attention on the need for a definition of stillbirth, as none of the countries with stillbirth registration appeared to have one in their legislation [4]. He considered two sets of issues. The first was the question of "viability". This was linked to the **gestational age** after which the fetus should be considered a child capable of independent life. The second was how to establish whether the fetus or child was, or had been, alive at birth.

After asking the Obstetrical Section of the Royal Society of Medicine for a definition of stillbirth, he recommended the following slightly amended version:

> A "still-born child" means a child whose body at birth measures not less than 13 inches (32 centimeters) in length from the crown of the head to the sole of the heel and who, when completely born (the head, body and limbs of the child, but not necessarily the afterbirth being extruded from the body of the mother), exhibits no sign of life – that is to say whose heart has ceased to function, as demonstrated by the absence of pulsation in the cord at its attachment to the body of the child and the absence of any heart-sounds or impulses.
>
> NOTE: Crying and/or breathing – being secondary signs of life, manifested only when the heart is acting – can be relied upon as signs of life, but in the absence of either or both is not to be held to be proof of absence of life in the child [4].

When stillbirth registration was eventually introduced in England and Wales in 1927, a shorter definition based on gestational age was used:

> "Stillborn" and "stillbirth" shall apply to any child who has issued forth from its mother after the twenty-eighth week of pregnancy and which did not at any time after being completely expelled from its mother breathe or show any other signs of life [6].

Public Concern About Infantile Mortality and Developments in Analysis

The Royal Statistical Society's enquiry came at a time when there had been a growing concern about infant mortality in a number of countries. In Britain, this had been prompted by the discovery that many potential recruits for the Boer War were unfit and by the campaign by the Women's Co-operative Guild for maternity services.

The Royal Statistical Society Committee also discussed the way in which the infantile mortality rate was calculated. It had defined this as the ratio of the deaths during the first year of life to births. Its enquiries had revealed, however, that some countries had used the estimated numbers alive under the age of one year instead. Given the relative inaccuracy of population estimates, the Committee recommended using births instead.

Having pointed out that some countries compiled their birth statistics by year of registration and others by year of occurrence, it recommended using occurrences. It also recommended that stillbirths should be tabulated separately and that in countries where live-born babies who died before registration were registered as stillbirths, they should actually be counted as infant deaths [17].

As a result of public concern about infant mortality, analyses of infant mortality by age at death in the Annual Reports of the Registrar General from 1904 were more detailed than in earlier years. In addition, a series of four reports on infant mortality was published by the Local Government Board, the government department responsible for public health. In the first of these, the Board's Chief Medical Officer, Arthur Newsholme reiterated John Simon's view in stating that, "Infant mortality is the most sensitive index we possess of social welfare and of sanitary administration, especially under urban conditions" [14]. These reports compared the infant mortality rates for different parts of England and Wales and discussed the comparisons and local data in relation to factors such as sex, legitimacy, family size, the quality of help available in childbirth, the ages of mothers, poverty, overcrowding and defective sanitation.

A similar concern about infant mortality in the US at the same period has been attributed to its emergence as a world power.

> The problem of infant mortality is one of the great social and economic problems of our day ... A nation may waste its forests, its water power, its mines, and to some degree, even its lands, but if it is to hold its own in the struggle for supremacy, its children must be conserved at any cost. On

> the physical, intellectual and moral strength of the children of today the future depends [9].

One response to this was the setting up of the Children's Bureau and its enquiry in 1913 into infant mortality in eight cities. This enquiry took a cohort approach, following up children born in a given year, and was analyzed by a statistician, Robert Morse Woodbury (*see* **Birth Cohort Studies**). Having considered the same broad range of factors as Arthur Newsholme, he concluded that the level of the father's earnings was the strongest "causal" factor associated with infant mortality [21].

These conclusions underpinned calls for political action to improve the conditions for young children and their parents, but these were not the only views held at the time. Followers of the **eugenics** movement took the view that heredity was the prime factor in infant mortality and that attempts to reduce it hindered natural selection by delaying or preventing the death of children who would survive as "weaklings" [15].

The introduction of new technology in the form of punched card equipment increased the extent to which infant mortality could be analyzed by cause, age at death, and other factors [3]. Peter McKinlay's analysis of the decline in infant mortality in England and Wales in the first quarter of the twentieth century showed that, "... all ages have not shared in this amelioration to the same extent ... as a general rule, the nearer to birth the less has the mortality been affected" [12].

In his analysis, he subdivided infant mortality into two categories, "(a) the death rate from 'congenital debility, malformation and premature birth' (number 28 of causes of death given for each separate district in the Annual Reports of the Registrar General), and (b) the remainder of the infant deaths under one year". He labeled these as "neo-natal" and "post-natal", respectively, and called stillbirths "ante-natal" deaths.

He concluded from his analysis of differences between areas of England and Wales that

> only the provision of skilled assistance to mothers in childbed is of importance in connection with ante-natal mortality. ... The neo-natal death rate is related both to variations in external environment and in the obstetrical assistance available to mothers in childbed. ... The postnatal death rate seems to offer the greatest scope for administrative measures. In this case the health of the mother would appear to come first in order of appearance, environment also is of some importance, whereas the effects of variations in obstetrical services have now ceased to be reflected on the mortality of infancy [12].

The term "neonatal" was also used a few years later in an international analysis for the League of Nations [19]. This had a demographic focus and started by looking at trends in countries' infant mortality in relation to their birth rates, population changes and overall death rates. It brought together the two streams of opinion on infant mortality in stating that, "It is evident that the causes of infant mortality may be divided into two distinct categories: (a) those depending on the fitness of the infant to live at all, and (b) those arising from the unfitness of the surroundings to support infant life" [19].

In comparing the death rates for different countries, the author grouped together deaths of live-born babies under the age of one month with stillbirths, partly to get over the differences in stillbirth registration referred to earlier. The term "birth mortality" was suggested for this combined rate. This rate varied far less between countries than that for older babies. The author commented that, "Infant mortality has repeatedly been stated to be the best measure of the sanitary state of a country ... if the infant mortality rate is employed for this purpose, it should clearly be only the part relating to infants over 1 month" [19].

The Establishment of Current Definitions

In the latter half of the twentieth century, the current definitions of fetal death, stillbirth, and the components of the infant mortality rate have become established. They are shown in Figure 1. Introducing these definitions, the Registrar General's Statistical Review for England and Wales for 1951 commented that the use of the term "neonatal period" was "now traditional among obstetricians and compilers of vital statistics" and its first use by writers of Annual Reviews had been in 1936 [7]. It also pointed out the term "perinatal mortality" had first been used in 1950. The term had been coined by a demographer Sigismund Peller, who took the view that time trends in early neonatal deaths had more in common with those in stillbirths than with those in the rest of the first year of life. [16]

In most developed countries, infant mortality rates have fallen persistently and dramatically in the latter

$$\text{Stillbirth rate} = \frac{\text{still births} \times 1000}{\text{live births} + \text{stillbirths}}$$

$$\text{Perinatal mortality rate} = \frac{(\text{stillbirths} + \text{deaths at 0–6 days after live birth}) \times 1000}{\text{live births} + \text{stillbirths}}$$

$$\text{Early neonatal mortality rate} = \frac{\text{deaths at 0–6 days after live birth} \times 1000}{\text{live births}}$$

$$\text{Late neonatal mortality rate} = \frac{\text{deaths at 7–27 days after live birth} \times 1000}{\text{live births}}$$

$$\text{Neonatal mortality rate} = \frac{\text{deaths at 0–27 days after live birth} \times 1000}{\text{live births}}$$

$$\text{Postneonatal mortality rate} = \frac{\text{deaths at 1–11 months after live birth} \times 1000}{\text{live births}}$$

$$\text{Infant mortality rate} = \frac{\text{deaths under the age of 1 year after live birth} \times 1000}{\text{live births}}$$

half of the twentieth century to well below 10 infant deaths per 1000 live births. As the survival rates of preterm and immature babies have risen, the definitions used have been extended to include ever smaller babies and fetuses and countries still differ considerably in their criteria for registering live and still births. [8, 13].

The **World Health Organization**'s Expert Committee on Vital Statistics recommended in 1950 that, as a minimum, all countries register and tabulate all fetal deaths after the 28th completed week of gestation [22]. This was endorsed in the seventh revision of the **International Classification of Diseases (ICD)**. This was the first to incorporate a definition of stillbirth that separates the definition of a dead-born fetus from the criteria for registration.

A quarter of a century later, a different approach was used in the ninth revision of the ICD. This recommended that *national* perinatal statistics should include all fetuses and babies delivered "weighing at least 500 g or, where birthweight is unavailable, the corresponding gestational age (22 weeks) or body length (25 cm crown–heel), whether alive or dead" [23]. It went on to acknowledge that countries' legal requirements might have different criteria for registration purposes and that international comparisons should be restricted to fetuses and babies "weighing 1000 g or more (or, where birthweight is unavailable, the corresponding gestational age (28 weeks) or body length (35 cm crown–heel)" [23].

The tenth revision of the ICD took yet another approach and defined the perinatal period "which commences at 22 completed weeks (154 days) of gestation (the time when birthweight is normally 500 g) and ends seven completed days after live birth" [24]. Although the ICD no longer uses the term stillbirth, the term still appears in the legislation of individual countries, such as the countries of the UK.

The relevance of the upper cutoff point for the perinatal period has often been questioned in recent years. Increasingly, the use of intensive care is enabling very immature babies to survive, but there is also a tendency for those that die to do so later after birth. One response to this is to redefine perinatal deaths as the sum of all stillbirths and neonatal deaths, as is done in Australia. Another, which takes into account the view that there are increasing

differences between stillbirths and neonatal deaths, is to tabulate stillbirths, neonatal and postneonatal deaths separately and drop the use of the perinatal mortality rate.

The ninth revision of the ICD recommended using a special form of certificate for perinatal deaths, with the cause section subdivided into "main and other diseases or conditions in the fetus or infant," "main and other maternal conditions affecting the fetus or infant" and "other relevant circumstances" [23]. It did not indicate how these data should be analyzed. In response to this problem, the Office of Population Censuses and Surveys, now known as the **Office for National Statistics**, has devised a hierarchical classification to group causes of stillbirth and neonatal death from the forms of certificate it introduced in 1986 [1, 2]. This classification uses categories first proposed by Jonathan Wigglesworth for use with information derived from case notes [20] and also builds on the extensive research done over many years in Aberdeen, Scotland.

Infectious Disease Models

There are two major roles for stochastic infectious disease models. Their study provides insights into the spread of disease in a community, and they are an essential component in the analysis of data from empirical studies of infectious disease (*see* **Epidemic Models, Stochastic**).

The Epidemic Threshold Theorem

A major insight provided by epidemic models is that major epidemics can be prevented in a large community by immunizing only a fraction of the individuals. This property is sometimes referred to as herd immunity, and is quantified by the **epidemic threshold** theorem. Deterministic models for infectious diseases (*see* **Epidemic Models, Deterministic**) indicate this result, but these models assume that both the group of susceptible individuals and the group of infective individuals are large throughout the epidemic. The stochastic version of the threshold theorem also requires a large susceptible group, but the infection process may start with only one infective individual. The stochastic threshold theorem is also richer in that it quantifies the probability of a major epidemic when a small number of infective individuals enter a large community that is currently free from the disease.

In the overly simple setting of a large community of homogeneous individuals, who mix uniformly (*see* **Random Mixing**), the threshold theorem indicates that the probability of a major epidemic is zero when the proportion of individuals who are susceptible to infection is less than $1/\theta$. The parameter θ, known as the basic **reproduction number**, is the mean number of individuals infected by the direct contacts of an infective entering the community when all other individuals are susceptible.

The epidemic threshold theorem holds under quite general conditions, but the bound $1/\theta$ then depends on the community structure and the heterogeneity among individuals (see [7] and [8]).

Data on Outbreaks in Households

Infectious disease data have three features that distinguish them from other data. There is usually some knowledge about the mechanism that generates the data, the data are dependent, and the infection process is only partially observable. A consequence of these features is that the analysis of data is usually most effective when it is based on a model that describes aspects of the infection process. The level of detail that should be incorporated into the model depends on the objective of the study.

Disease transmission and the natural history of diseases evolve in continuous time, but discrete time models are often appropriate for data analysis. It may be that events are only recorded to the nearest day, say, or only the eventual outcomes of outbreaks are observed. Data on the eventual number of cases in households are often collected, because households are a manageable unit size and data on eventual infection can be verified by laboratory tests, which makes them relatively reliable.

Chain Binomial Models

In a household having initially s susceptible individuals, there will be $1, 2, \ldots,$ or s eventual cases. The probability of a specified number of eventual cases in an infected household is computed in terms of disease transmission probabilities by considering the likelihood of the various chains of infection. To illustrate, suppose that one of a total of five susceptible individuals of a household is infected and starts an outbreak in the household. Assume that the outbreak evolves without further infection from outside. Four eventual cases in the household could result via a number of different chains of infection. One such chain is $1 \to 2 \to 1 \to 0$, which means that the single initial infective infected exactly two household members, who in turn infected exactly one member, and the last remaining susceptible member escaped infection throughout.

A simple **chain binomial model** would compute the probability for this chain, given one introductory case, as

$$\binom{4}{2} p_1^2 q_1^2 \binom{2}{1} p_2 q_2 \binom{1}{0} p_1^0 q_1 = 12 p_1^2 q_1^3 p_2 q_2,$$

where q_i is the probability that a susceptible escapes infection when exposed to i infectives for the duration of their infectious periods and $p_i = 1 - q_i$. The probability that the number of eventual cases in a household is x is the sum of chain probabilities over all chains with x eventual cases.

The **EM algorithm** is a convenient tool for finding maximum likelihood estimates when fitting chain binomial models to size of household outbreak data. This is pointed out with reference to **partner studies** for HIV infection in [11] and is discussed more fully in the review paper [6] (*see* **AIDS and HIV**).

Models that capture the infection mechanism of the data generally contain parameters with clear interpretations and are well suited for testing epidemiologically important hypotheses. For example, with a chain binomial model for the size of household outbreaks, we can test the Reed–Frost hypothesis $q_2 = q_1^2$, or the Greenwood hypothesis $q_2 = q_1$. The Reed–Frost assumption is appropriate for diseases that spread primarily by direct person-to-person contact.

Many methods of analysis of household data assume that each household outbreak evolves essentially independently after the initial infection of the household. This assumption is often of concern. Longini & Koopman [10] propose an analysis based on a pragmatic chain binomial model that also allows infection from outside the household.

Epidemic Chain Models with Random Effects

It is instructive to think about disease transmission in terms of a continuous infectivity function $\lambda(t)$ that indicates how infectious an infective is t time units after being infected. The infectivity function reflects both the level of infectious agent emitted by the infective and his or her rate of making contacts with others. Often, the infectivity function is zero for a period immediately after infection, because the infectious organism is developing within the body and no infectious agent is emitted. When disease transmission is person-to-person, the probability that a given susceptible individual escapes infection when exposed to a given infective is $q_1 = \exp[-\int_0^T \lambda(t)\,\mathrm{d}t]$, where T is the duration of time from infection until the end of the infectious period.

Epidemic chain binomial models assume that infectives are homogeneous, in the sense that they all have the same infectivity function. When infectives have different infectivity functions, we still use chain binomial models if the infectives can be partitioned into homogeneous groups. Otherwise, we proceed by considering the q_1 for each infective to be a realization from a probability distribution. In these **random effects** models, see [4, Chapter 3], the probabilities of the epidemic chains are expressed in terms of the **moments** of q_1. This allows for heterogeneity in the infectivity of infected individuals. Heterogeneity in susceptibility or among households can be allowed for in a similar way. An application of random effects models to data on *Shigella sonnei* in households is given by Baker & Stevens [3].

A comprehensive analysis of infectious disease data on household outbreaks, allowing infection from outside the household, variation in the duration of the infectious period, and **covariates**, is described by Addy et al. [1].

Continuous Time Data for Households

Sometimes, when daily data are available on symptoms shown by infected individuals, the analysis is based on a continuous time model. The standard model used is a compartmental model for the irreversible compartments Susceptible $\rightarrow$ Exposed $\rightarrow$ Infective $\rightarrow$ Removed, referred to as the SEIR model. An individual in the exposed category is infected, but not yet infectious, and said to be in the **latent period**. The final category is called removed, because these individuals play no further part in the infection process. These individuals may simply have recovered and have acquired immunity from further infection for the duration of the epidemic. It is of interest to estimate characteristics, such as the mean and variance, of the latent and infectious periods. This can be done by assuming a parametric model for the distribution of the latent and infectious periods, as described in [2, Chapter 15] and [4, Chapter 4]. It is also of interest to make inferences about the functional form of the infectivity function, which is considered in the context of transmission of the human immunodeficiency virus (HIV) by Shiboski & Jewell [12] on the basis of data on partners of individuals infected with HIV.

Data on an Epidemic in a Community

Regression Analysis

When data are available on the days on which individuals show symptoms of disease, and these can be used to deduce the date of infection, with reasonable accuracy, then a comprehensive regression analysis is possible. The response variable is the

indicator of infection for each susceptible individual on each day. The **Mantel–Haenszel** test statistic has been suggested as a way of reducing the number of covariates, see [4, Chapter 5]; however, a **logistic regression** model is also convenient for determining which covariates are needed in the model. When a final set of covariates is arrived at it is useful to fit a **loglinear** regression model in these covariates to the binary data. The preference for the loglinear model stems from the more direct epidemiologic interpretation of its parameters in the infectious disease context. More specifically, if Y is the indicator of escaping infection for a given susceptible on a given day, then fitting the model $Y \simeq \text{binomial}[1, \exp(-\boldsymbol{\beta}'\mathbf{x})]$ is useful, because with this model $\boldsymbol{\beta}'\mathbf{x}$ can be interpreted as the force of infection acting on the susceptible on that day. The covariate $\mathbf{x}$ might include the number of infectives in the community and the number of infectives in the susceptible's household, for example. An illustration of such a regression analysis is given in [4, Chapter 6].

Martingale Methods

The fact that the infection process is observed only partially causes the likelihood function based on continuous time data to be very complicated. This has encouraged the development of pragmatic methods based on simplifying assumptions and approximations. In contrast, methods of analysis derived from martingales for **counting processes** have proved successful for developing simple methods of statistical inference for some crucial parameters, such as the basic reproduction number, for quite general models. Tutorial accounts of these methods are given in [5] and [4, Chapter 7].

Vaccine Efficacy

A major motivation for the study of infectious diseases is to gain insight into ways in which they can be controlled and to determine requirements for their control. The most successful method of intervention continues to be vaccination (*see* **Vaccine Studies**). The epidemic threshold theorem plays a key role here, but it can only be applied if parameter estimates are available. A crucial parameter is the vaccine efficacy. Traditionally, vaccine efficacy has been estimated by $1 - (AR_V/AR_U)$, where AR_V is the attack rate among vaccinated individuals and AR_U is the attack rate among unvaccinated individuals. The attack rate is the proportion of individuals infected in the specified risk group over a nominated period of time. As a measure of the protective effect that the vaccine provides, this concept of vaccine efficacy suffers from depending on both the community from which the data come and on the time period over which the data are collected. Recently, there has been a more careful study of the interpretation and estimation of vaccine efficacy, see [9]. Typically, as a concept of protection against infection, vaccine efficacy might be interpreted as α, where the force of infection acting on vaccinated individuals is $\alpha g(t)$ at chronological time t when the force of infection exerted on an unvaccinated susceptible is $g(t)$. Depending on the vaccine, α may be a constant in [0, 1] or a separate realization on a random variable for each vaccinated individual.

The HIV/AIDS Epidemic

The appearance of AIDS stimulated new interest in the problems of modeling and data analysis for infectious disease studies. A distinguishing feature of infection with HIV is the very long time between infection and diagnosis with AIDS. This has made it feasible, and of interest, to assess the size of the epidemic, forecast its progress, and study characteristics of disease progression during the course of the epidemic (*see* **AIDS and HIV**).

NIELS G. BECKER

Infectivity Titration

In an experiment to assay the virulence of a suspension of living, self-reproducing organisms (which we refer to here as "particles"), doses derived by successive dilution of the original suspension are administered to groups of host organisms, and the proportion of hosts infected at each dilution is recorded. The "independent action" or "one-hit" theory [13–15] assumes that infection can be initiated by one particle, which, for some reason or other, is "effective". Particles act independently, any one particle having a probability, p, of being effective on a particular occasion. The biological interpretation of p depends on the host–pathogen system. It may be the probability of a particle being retained in the host, or reaching a totally susceptible site; or, on a stochastic model, it may depend on the relative rates at which particles divide and die within a host [4] (*see* **Stochastic Processes**).

Situations for which this model has been proposed include the infection of plants by viruses [6], the titration of viruses in egg membranes [16] or portions of membrane [10], the infection of animals by bacteria [20, 21], and the initiation of tumors in animals by viruses [7].

Suppose that at the ith dilution, the mean number of particles per inoculum is λ_i, and that n_i hosts are inoculated, of which r_i are infected. If the probability of infection, p, is the same for all hosts, the probability that a host receiving this inoculum will not be infected is the first term in the **Poisson distribution**,

$$P_i = \exp(-\lambda_i p). \tag{1}$$

If this dose has a concentration equal to a fraction x_i of the original preparation, we can define $\gamma_i = \lambda_i p = \gamma x_i$, say, where γ is the mean number of effective particles per inoculum in the undiluted preparation. From a set of results at a series of different dilutions one could estimate γ as in the **dilution method for bacterial density estimation**, or the "most probable number" method (*see* **Serial Dilution Assay**).

Note, first, that the parameter to be estimated here depends both on the density of the particles in the original preparation and on the probability of infection, p. In the dilution method for counting viable bacteria it is assumed that a particle present in the inoculum will be detected without fail, so that $p = 1$ for all hosts. The absolute density of particles in a preparation can then be estimated. In the more general situation considered here, the absolute density of particles cannot be estimated without some further assumption about the probability of infection. Nevertheless, an infectivity titration can be used to compare two or more microbial populations, inoculated into randomly assigned hosts (*see* **Biological Assay, Overview**).

Note, secondly, that if p is not equal to unity universally, it may vary between hosts, and this feature leads to a number of important modifications of the model described above. However, variation in infectivity between individual particles does not invalidate the simple model, provided the hosts are identical in their susceptibility.

Host Variability

Suppose that p varies from host to host with a distribution function $F(p)$. (We avoid the use of a capital letter for the **random variable** p, as P is customarily used in the different sense of (1) above.) Then, the probability of noninfection is

$$P_i = \int_0^1 \exp(-\lambda_i p)\, \mathrm{d}F(p). \tag{2}$$

Expression (2) is a **moment generating function** for the distribution $F(p)$, and may be expanded in terms of the moments. Since p is restricted to the range (0,1), the terms involving the higher moments are, in practice, negligible for all except very large values of λ_i, and a good approximation is

$$P_i \cong \exp(-\lambda_i \mu)\frac{1 + (\lambda_i^2 \mu_2)}{2}, \tag{3}$$

where μ and μ_2 are, respectively, the mean and variance of p. Expression (3) shows that the effect of host variability is to flatten the dose–response curve relating P_i to λ_i or to the known concentration factor x_i, the proportionate effect being greater at the higher concentrations.

The general effect of host variability was noted in [21]. The precise effect has been studied for a number of specific distributional forms, including the **gamma distribution** [1, 16], truncated **exponential** [1, 5], **beta** [5] and two-point [2, 7] distributions.

For the gamma (or type III) distribution with density function

$$f(p) = \exp \frac{(-p/\mu k)(p/\mu k)^{(1/k)-1}}{(\mu k)\Gamma(1/k)}, \qquad (4)$$

with mean μ and variance $\mu_2 = k\mu^2$, (2) gives

$$P_i = (1 + \lambda_i \mu k)^{-(1/k)}, \qquad (5)$$

which is equivalent to (3) to $O(k)$ and tends to (1) as $k \to 0$. The gamma distribution, having infinite range, is strictly inappropriate as a distribution for p, but may be regarded as an adequate model for small values of μ, when truncation at $p = 1$ would have little effect.

The two-point distribution places probability masses α_i at values $p = \pi_i, i = 1, 2$, with $\pi_1 < \pi_2$. If $\pi_2 \gg \pi_1$, the effect on the dose–response curve relating the probability of infection, $Q_i = 1 - P_i$, to x_i or $\log x_i$, is to suggest a "shelf" at approximately $Q = \alpha_2$, since only the hosts with the higher level of susceptibility will be infected at the lower concentrations.

Further insight into the flattening effect [5] follows by regarding the response curve as the distribution function of a tolerance distribution (*see* **Quantal Response Models**). Let V denote the variance of the tolerance distribution of $\log x$ from (2), V_0 the corresponding value from (1) for homogeneous hosts, and $V_{\log p}$ the variance of $\log p$. Then, as noted in [5],

$$V = V_0 + V_{\log p}. \qquad (6)$$

This increase in variance caused by host variability corresponds to the flattening of the dose–response curve. Many authors [8, 10, 20] have used probit analysis to analyze dose–response curves in infectivity titrations (*see* **Quantal Response Models**). It is known [11] that the exponential model (1) leads to a tolerance distribution for the log dose closely similar to a normal distribution, and that, with logs taken to base 10, the expected slope of a probit line is about 1.8–2.0. The expression (6) shows that, in general, probit slopes against log dose for infectivity experiments will usually be less than 1.8. Systematic values below 1.8 would indicate host variability, whilst values above 2.0 would suggest departure from independent action.

Detection and Estimation of Host Variability

Probit analysis provides a rough way of checking the evidence for host variability and of estimating its magnitude through the parameter $V_{\log p}$. A better approach is based on the more correct models (1) and (2).

For a test of the null hypothesis of zero variability in a titration experiment with n hosts at each dilution, Moran [16, 17] proposed the statistic

$$T = \sum r_i(n - r_i), \qquad (7)$$

and evaluated its null distribution for series with various dilution ratios. Moran's statistic is symmetric as between infected and noninfected hosts, and thus does not use the fact, shown by (3), that departures from the null model (1) will tend to be associated with excessive numbers of noninfections at high doses.

Armitage [1] proposes a score test (*see* **Least Squares**), based on the likelihood function derived from (3). The test statistic is

$$\phi = \sum \left[\frac{n_i \hat{Q}_i - r_i}{\hat{Q}_i} \right] \frac{(\hat{\gamma}_0 x_i)^2}{2}. \qquad (8)$$

Here, $\hat{\gamma}_0$ is the maximum likelihood estimate of γ under the null model (1), and $\hat{Q}_i$ is the corresponding estimate of Q_i. Note that in (8) the discrepancies between observed and expected frequencies are more heavily weighted at the higher doses. A modified statistic ϕ' is available when γ is estimated by a consistent but inefficient estimator, such as that suggested by Fisher [9] based on $\sum r_i$.

Moran's T is identically zero for series with $n = 1$, and is therefore inappropriate in that situation. Experiments are likely to require larger values of n, but may sometimes be designed in blocks, each with $n = 1$.

Stevens [22] proposes the statistic R, equivalent to Moran's [18] $D + 1$, defined as the number of dilutions between (and including) the first at which not all hosts are infected, and the last at which at least one is infected. As an example, in the following series of increasing dilutions with single observations (+ representing infection),

$$\cdots + + 0 + 0 + + 0\,0 \ldots,$$

the value of R is 5. As with T, there is no differential weighting of the two extremes of the response curve. An alternative simple statistic [3] is J, defined as the number of infected hosts at dilutions beyond that at which the first noninfection occurs. In the example, $J = 3$. The statistic J has been shown [3] to be highly correlated with the efficient statistic ϕ and to be more powerful than R in the detection of small departures from the null model.

All tests of host variability must be one-sided, since the null hypothesis lies at one end of the parameter range. It might be argued that such tests are pointless, since some degree of host variability must exist except in the extreme case where $p = 1$ for all hosts. However, one situation leading to a mean μ less than unity might arise if a proportion, μ, of hosts were invariably susceptible, the remaining proportion, $1 - \mu$, being totally resistant. In that case, there would be no variability. Contradiction of the null hypothesis in a test for variability, then, at least rules out that possible scenario. In general, though, it will be more useful to estimate the degree of variability than to test for evidence of its existence.

Maximum likelihood estimation of k follows from the likelihood equations based on (3) [1], and less efficient estimates may be based on the simple test statistics such as T.

Dependent Action Models

Most log dose–response curves encountered in infectivity experiments are sufficiently flat to support the independent action or "one-hit" theory, for which other evidence exists [13, 15]. If infection depended on cooperation between more than one particle, the resulting "multi-hit" log dose–response curve would be steeper than that given by (1). Iwaszkiewicz & Neyman [12] discuss the estimation of the critical number of effective particles required for infection, and introduce the concept of host variability by allowing the critical number to vary between hosts, the effect again being to flatten the log dose–response curve. Independent action could conceivably also give rise to a steeper curve. In the production of tumors by viruses, for example, tumors might be too faint to be detected unless several occurred close together [19]. In the absence of host variability, the response curve would then be steeper than the exponential form (1).

PETER ARMITAGE

Inference, Foundations of

Humans learn considerable information (and misinformation) from birth and throughout their lives. This ability arises through some combination of genetic influences, direct experience in the surrounding environment, and input from others, both through interpersonal interaction (i.e. parents, friends, teachers, etc.) and stored and supplied societal information (i.e. media, books, paintings, digital information, analog information, etc.). Some learning is relatively direct and easy to assimilate (e.g. falling off a bicycle can be painful and lead to injury), but much other learning is more difficult, because of both variability in observed relationships and the complex and sophisticated underlying models and concepts that "explain" observations (e.g. the currently accepted models of particle physics or molecular biology). Multiple distinct intellectual pathways have contributed to the current methods of biostatistical inference. These pathways include randomness, **probability**, regular variability, statistical modeling, and observational vs. experimental data collection.

The ideas of randomness go back at least to biblical times where the casting of lots was used. However, the modern ideas of probability were initially developed with respect to games of chance [8]. **Jacob Bernoulli's** proof of the strong **law of large numbers** [12] set the scene for interpreting probabilities as the limit of the proportion of times that an event would occur in a long sequence of repeated identical trials. In this context it was natural that probability was thought of in a frequentist sense: "fair" games could be repeated with equal probabilities of differing outcomes in cards or dice.

A second intellectual thread was the observation that in repeatable situations with variable outcomes there was a regularity or **pattern** to the variability observed. Repeated measurements taken in the (presumed) same or similar situation clustered around some (presumed) true value. It was natural to consider ways of dealing with this variation in outcome, and natural that at some point the mathematical theory of probability theory would be used as one possible way of assessing the variability.

Probability as a concept becomes more difficult as one thinks about it. Einstein, for example, did not believe that probability was an inherent property of the universe: his view is often quoted as "God does not play dice with the universe" [3]. However, most physicists believe that probability is basic to the quantum mechanical structure of the universe. Regular variability that could "mimic" probability theory could also result from the mathematics of **chaos theory** that make it clear that very small changes in initial conditions, for even relatively simple nonlinear systems, can lead to dramatic changes in outcome over time. If for no other reason than an inability to delineate precisely the initial conditions, variability in biological systems can be expected to be the commonly observed situation. As an example of possible chaos theory, multiple card shuffling could be expected (with a number of shuffles) to approximate the usual mathematical model that all permutations are equally likely; yet there are skilled individuals who can shuffle cards with perfect knowledge of how the cards will interleave.

At the same time there are (seemingly) unique situations where only one event will be observed. For example, one presidential election, one football game, or the treatment of an individual patient may be at issue. Yet individuals evaluate such situations and at least implicitly attach **odds** or probabilities to these situations; some consistently do an excellent job, while others do not do so well. This suggests that the evaluation of probabilities or the **likelihood** of outcomes also can be related to the personal or individual beliefs of humans. This **subjective** version of probability, or **Bayesian** probability, has become another contributor to current thinking about statistical inference. Of course, thinking Bayesians also believe in an external frequentist probability (otherwise one could not talk about the data swamping the prior probability, or a state of nature). Savage [11] argues that unless one follows a Bayesian behavior system one will be in a position to lose, *no matter what the true state of nature*, if forced to bet. Note, however, that in this formulation the state of nature has an external (frequentist?) probability associated with it. Modern philosophers of science have discussed extensively the concepts of probability and **causality** when the relationships are statistical rather than deterministic. Such considerations are expected, given the current physical models of the universe. Probabilities in deterministic situations, where maximal information is not available, that have some frequency distribution of the outcome, lead to frequency-based probabilities. Because one may wish to use probabilities in a setting where an

experimental set-up with inherent indeterminism may not be repeated, there is also a need for probability that is not personal or subjective but that also is not justified by appeal to the strong law of large numbers. However, here the probability is inherent in the laws governing certain situations (e.g. quantum mechanics in physics); such probabilities are sometimes called propensity-based probabilities (e.g. [6]). In most statistical settings these latter two concepts of probability are combined and called *frequentist*.

Inference in the statistical sense has been used to describe procedures that analyze data that come from (at least conceptually) some underlying set of probability distributions. When this is the case statements can often be made that only make sense in the context of the underlying distributions. For example, one constructs an interval in such a way that 95% of the time the mean of the underlying probability distribution for repeated samples from the distribution will lie in the interval; that is, one constructs a 95% **confidence interval**. Or one compares the change in sitting diastolic blood pressure from a baseline measurement to 12 weeks in two groups: one that is **randomized** to a placebo treatment and another group randomized to a new presumed antihypertensive drug. The ***P* value** for a treatment difference is used to summarize the strength of evidence for a treatment difference. Or, in the same experiment, a Bayesian **prior distribution** about the treatment differences is updated given the data from the experiment, and the probability that the change in blood pressure is more in the new drug group is used as a summary to show the new drug is effective. In each case the inference (in the every-day use of the word) is summarized by *statements that depend upon an underlying probability model combined with the observed data*. Such inference is *statistical inference*. Statisticians often perform other activities that are not statistical inference *per se*, but when combined with further processing of the data are associated with statistical inference in many situations. Descriptive statistics, including summary statistics (e.g. sample **mean, median, standard deviation**, minimum, and maximum), **graphic** plots (e.g. scatter diagrams, histograms, line graphs of mean or median values), computer visualization of multiple variables at a time, or two-dimensional projections of higher dimensional space, etc., are not statistical inference *per se*. However, plots with confidence sets or intervals would directly involve statistical inference.

The concepts of probability theory were integrated into one formal theory of statistical inference by **Jerzy Neyman** and **Egon Pearson** (e.g. [10]). They developed their formal framework for **hypothesis testing** introducing the familiar concepts of the **null hypothesis**, the **alternative hypothesis**, type I and II errors (*see* **Level of a Test**), **power**, etc. Some philosophers of science conclude that scientific paradigms can never be essentially (i.e. up to statistical variability) proven to be true. They can only be shown to be consistent with the facts at hand; however, further data or theory combined with data may show them to be inconsistent. While this is true for complex theories, particularly in physics, for other situations (e.g. a drug lowers blood pressure on the average in some population), "theories" or "facts" could be more clearly established conceptually. Hypothesis testing, combined with Occam's razor (the simplest possible explanation is to be preferred; *see* **Parsimony**), gives a paradigm for scientific endeavor. Hypothesis testing fits nicely into this paradigm as "null hypotheses" (usually straw men shown to be false) are to be rejected. The new theory had many other benefits: by selecting conventional levels for the significance level it led to an acceptable level of scientific proof that is largely used today both by scientific journals and regulatory authorities; it allowed experiments to be designed and sample sizes to be computed using the concept of statistical power, or equivalently type I and type II errors. Hypothesis testing about the parameters of a state of nature leads naturally to the concept of confidence regions and intervals because of the duality between hypothesis testing and confidence intervals (e.g. [2]).

Hypothesis testing was not without its problems. Cornfield [4, 5] lists problems with the formal hypothesis testing paradigm. For example, if the significance level is formally set at 0.05 and one performs an experiment and fails to reject a null hypothesis, then no amount of additional evidence should ever be allowed to lead to rejection of the null hypothesis! Furthermore, in a complex situation hypothesis testing can be used to plan experiments, but if one wants formally to take into account already known, but very complex, facts and/or beliefs, then this is difficult to incorporate rationally into the formal scientific inference. Bayesian statistics would appear to be the solution to the incorporation of complex facts already known. The Bayesian prior estimate of the state of nature (or the distribution of a parameter(s)

of interest) seems ideal for such situations. However, there are also problems with using Bayesian statistical methods [7]: (i) different individuals will have (often drastically) different prior beliefs – whose prior distribution should be used; (ii) humans are at best very imperfect Bayesians and cannot process data as probability models suggest we should [9]; and (iii) like the frequentist models, in practice difficulties and new data can arrive that would not have been adequately addressed in the elicitation of prior beliefs. (For example, new animal data suggest a toxicity problem with the long-term use of a drug or biologic; another drug with the same molecular mechanism of action reports findings.) There is no known method of statistical inference that can withstand all rational criticism. Thus, the actual application of statistics to important biostatistical problems necessarily is far from **algorithmic**; scientific judgment and reasoning, as well as intuition, often enter into important decision making in addition to formal statistical inference – as embodied, say, by hypothesis testing, confidence regions, model building, or Bayesian analysis. That is to say, while statistical inference is based upon the mathematical theory of probability, the decisions and understandings that result from the statistical inference have many arbitrary aspects, both technical (e.g. the significance level to be used in a test) and judgmental (e.g. an experiment has so much **missing data** that one decides to disregard it altogether). This results in important decisions using both statistical inference and other human decision making capacities in many instances. There is good reason to believe that humans are at best very imperfect Bayesian or frequentist statisticians [9].

The rapid continuing increase in computing power has led to innovations in statistical inference methodology. For example, the ability to resample from samples of distributions (e.g. **bootstrap** techniques), to implement **Markov chain Monte Carlo** methods, and to simulate from permutation distributions (especially the randomization distribution; *see* **Randomization Tests**) allow approaches to inference that use the same underlying ideas of the last 60 years but are new techniques that were not feasible a generation ago.

Another important path to understanding modern concepts of inference – especially in biostatistics – is to understand the important difference between observationally collected data and experimental data where the observer can intervene in the system to establish stronger scientific inference. For example, the history of medicine is replete with harmful treatments given for hundreds of years [1]. The **scientific method** and appropriate experimentation has led to rapid progress in science in general, and biology and medicine in particular. Until the advent of the scientific method (or, more realistically, a growing appreciation of the scientific method) plausible, but incorrect, systems of understanding human and animal biology were seemingly accepted if they were internally self-consistent and advocated by authority. Selected subject-matter application areas of biostatistics, besides medical biostatistics, may have other difficulties. For example, epidemiologic studies, ecologic, and wild animal studies are often necessarily restricted to observational data collection and/or mathematical modeling. The inability to experiment gives less cogent scientific inference and potentially a larger probability of mistaken "knowledge" due to potential underlying **biases**. No matter how firm the basis of statistical inference, the possibility of bias from unknown sources cannot be discounted. Other areas, such as plants for food and animal breeding, are more amenable to more classic experimentation; yet even here the heterogeneity is a large issue (say compared with electrons which are all assumed to be the same in particle physics). The idea of randomization, as introduced by **R. A. Fisher**, allows much more cogent experimentation, especially in human populations, than observational data or even less controlled experimental data that may be subject to unknown important biases.

In the previous paragraph the term *the scientific method* was used. There appears to be no entirely satisfactory definition that encompasses all the situations where one might use this term. Often books on the philosophy of science introduce it by implication. One definition is: "a method of research in which a problem is identified, relevant data are gathered, a hypothesis is formulated from these data, and the hypothesis is empirically tested" [13]. Such a definition is in accord with the statistical theory of hypothesis testing.

Statistical inference in the medical biological sciences has difficulties that do not arise in the physical sciences, at least to the same degree. One of the cornerstones of modern science is the ability to replicate results. If one group reports a simple method of cold fusion, then other experimenters around the

world may try to replicate the results. In experiments with animals, and especially humans, the sanctity of life introduces ethical concerns. In certain situations there may be a strong **ethical** and practical prohibition against replicating a result. If a therapy has been "shown" to prolong life as compared with a placebo, then further placebo-controlled experimentation may be considered unethical and/or impracticable. The lack of the ability to replicate can lead to the unchecked propagation of a false "fact". Furthermore, because of the need to monitor for patient benefit and/or safety, a minimal amount of information adequate for showing benefit or harm is the rule not the exception. That is to say, if a society decides that proof consists of rejecting a null hypothesis at the 0.05 significance level, then a randomized **clinical trial** with mortality as an endpoint might be argued to be unethical if the trial does not stop when reaching this level of significance, taking into account the **multiple comparison** issues of sequential monitoring. All experimentation seems beset with difficulties, and without a doubt Murphy was an optimist (*cf.* Murphy's Law: Anything that can go wrong will). However, human experimentation may have even deeper difficulties. Subjects may deliberately unblind therapy in a randomized trial (*see* **Blinding or Masking**). Subjects may exercise the right to withdraw, go on vacation, and miss a crucial follow-up visit, etc. The combination of these and other factors leads to more dispute *that is unresolved by convincing data* than in the more "hard" sciences. Statistical inference may investigate the **sensitivity** to such experimental deviations, but the cogency of the results is usually lessened in ways difficult to quantify.

Statistical inference and associated experimental design for drugs, biologics, and devices for human use is further complicated by very important practical matters. The rewards and development costs of new therapies and diagnostic tests for human use are both extremely large in many situations. Also, the competitive nature of the market-place plays a large role in the development of new modalities of treatment or diagnosis. The first sponsor of an approved modality is in a very favorable position. This, plus possible humanitarian reasons, puts a premium on the speed of development. The large stakes place intense pressures on both industry and regulatory agencies. This can result in a very strict adherence to statistical inference guidelines for such research. However, treatments – for example a drug – are rarely all good or bad. An appropriate dose needs to be found; furthermore, the appropriate amount and/or method of delivery may differ for important human subgroups (e.g. race, older individuals and children, individuals with impaired organ function, and genetically distinct subsets). The best designs and development programs from a statistical inference point of view may not be used because of other considerations.

In summary, statistical inference in biostatistics is formally the same as in other applied areas. However, practical and ethical issues can introduce limitations not seen in many other areas of applied statistics.

LLOYD D. FISHER

Inference

Inference is usually defined as the process of drawing conclusions from facts, available evidence, and premises. *Statistical inference* is the term associated with the process of making conclusions on the basis of data that are governed by probability laws. More generally conclusions are made that are uncertain. The objective measurement of the uncertainty is one of the principal goals of statistical inference. In practical applications of statistical inference data are available and the aim of the inference is to draw conclusions about models which potentially may have generated the data. *Data analysis* is the colloquial expression which is often used to describe the statistical inferential process.

Examples of such situations are: a randomized **clinical trial** is being carried out to determine which of two therapy programs is superior for the treatment of **AIDS**; a sample survey is taken in a community having a contaminated public water supply to determine if families having higher concentrations of contaminated water also have higher rates of congenital abnormalities; data are available from individuals diagnosed as having an acute myocardial infarct – how is the infarct incidence related to age and gender?

Implicit in the inferential process is a defined population and an experimental plan which describes how data is generated from the population. The experimental plan for data collection may be very well laid out, as in a clinical trial, or may be quite informal, such as data collected from a hospital to carry out an **observational study**. The less formal the experimental plan for data collection, the greater the opportunities for blunders and systematic biases. Furthermore, any conclusions drawn from the data, strictly speaking, apply only to the population from which the data have been generated. Populations that are not well defined also create opportunities for the injection of systematic errors in the inferential process. In what follows it will always be assumed that there is both a well-defined population and a data collection plan which does not create opportunities for systematic error.

There is a general lack of agreement on the best ways to carry out statistical inferences. These differences have led to different "schools of statistical inference". These "schools" are often referred to as the frequentist, likelihood, Bayesian, and fiducial schools of inference. Major articles appear in this Encyclopedia reflecting the different schools of inference. Important criticisms have been made against some of the ideas in each of these schools of inference. Even within a school there may be sharp disagreements. In this article the major views of different schools of inference will be compared, with special emphasis on the frequency school of inference.

The problem may be formulated by considering that data represent realizations of a **random variable** X having a family of **probability** distributions $\{P_\theta(x)\}$ which is indexed by θ. The random variable X and parameter θ may be vector valued. Realizations of X are denoted by x. To concentrate on ideas, we will assume that all operations described below are defined and any required regularity conditions are satisfied. We define $f_\theta(x)$ to be a probability density function (pdf) or frequency function of X. The main goal of the inference is to draw conclusions about θ. More generally, if θ is vector valued, then the inference may be concerned with drawing inferences on a subset of values of θ. The remaining parameters are referred to as **nuisance parameters**.

The most important class of inference problems is when the vector X is composed of independent identically distributed (iid) random variables having the joint distribution $\prod_i f_\theta(x_i)$. The **likelihood** is central to nearly all schools of inference and is defined by being proportional to the joint distribution, i.e. $L(\theta|x) \propto \prod_i f(x_i|\theta)$. Usually the likelihood is defined as equal to the joint distribution except for the omission of a multiplicative constant which does not depend on θ.

In some cases the likelihood function can be written as

$$L(\theta|x) = L_1(\theta|t(x))L_2(x),$$

where $t(x)$ is a function of the observations and may be a vector. In this case $t(x)$ is called a **sufficient statistic**. Hence the probability distribution of X, conditional on $t(x)$, is not a function of θ. As a result, $t(x)$ contains all the relevant data for making inferences about θ. A minimal sufficient statistic corresponds to the smallest dimension of $t(x)$ for which the distribution of X, conditional on $t(x)$, is not a function of θ. Note that the likelihood function is a sufficient statistic. Using only the sufficient statistic to make inferences on θ leads to a data reduction method

in which the sample x is replaced by $t(x)$. This data reduction does not lose any information on θ.

Frequentist School of Inference

The frequentist school of inference is the most widely used method of inference in practice. Much of the foundations were laid by Fisher [12–18], Neyman [23], and Neyman & Pearson [24–28]. However, Fisher and Neyman & Pearson have serious disagreements about basic issues. Articles describing aspects of the frequency school of inference are scattered throughout this Encyclopedia. Major articles are: **Hypothesis Testing**, **Estimation**, and **Maximum Likelihood**. Other articles discussing aspects of estimation are: **Confidence Intervals and Sets**, **Consistent Estimator**, **Cramér–Rao Inequality**, **Efficiency and Efficient Estimators**, **Generalized Maximum Likelihood**, **Minimum Variance Unbiased (MVU) Estimator**, **Sufficient Statistic**, and **Unbiasedness**. Articles discussing the frequentist theory of hypothesis testing and related topics are: **Alternative Hypothesis**, **Critical Region**, **Likelihood Ratio Tests**, **Most Powerful Test**, **Neyman–Pearson Lemma**, **Null Hypothesis** and **Level of a Test**. Two basic texts on frequentist inference are Lehmann [21, 22].

The basic idea underlying the frequentist school of inference is to evaluate the inferential process by assuming that an "experiment" is repeated an infinite number of times. Procedures having "better properties", as judged by long-term behavior, are deemed superior. Throughout the frequentist formulation of inference there is an attempt to derive statistical methods that have "optimal" properties in the context of an infinite number of repetitions of the experiment.

In general, all probability statements generated by the frequency theory of inference are based on the frequentist interpretation of probability. Yet the conclusions are targeted at specific data sets or specific experiments. Critics dismiss the concept of using methods based on properties associated with an infinite repetition of experiments. Outcomes that did not happen should not be used to evaluate observed outcomes. They point out that the goal of a data analysis is to make an inference from the particular experiment which has generated the data, not from a hypothetical infinite repetition of experiments. Widely used methods such as tests of significance and confidence procedures are subject to these criticisms. The critics agree that frequentist ideas may be relevant prior to carrying out an experiment, but are irrelevant after the experiment is carried out. Nevertheless, these frequentist-based methods have proven to be very useful in practice. Their applicability is continuing to expand despite the presence of sharp criticisms.

For example, suppose $X_1, X_2, \ldots, X_n$ represent iid random variables following a $\mathrm{N}(\theta, \sigma^2)$ distribution with θ unknown and σ^2 known. The $100(1-2\alpha)\%$ **confidence interval** is $\overline{x} \pm z_\alpha \sigma \sqrt{n}$, where $\overline{x}$ is the sample mean and z_α is the normal deviate which cuts off probability α in the tail of the normal distribution. The formal probability statement is $\Pr\{\overline{X} - z_\alpha \sigma/\sqrt{n} < \theta < \overline{X} + z_\alpha \sigma/\sqrt{n}\} = 1 - 2\alpha$. For any fixed $\overline{x}$, the population mean is either within the interval or is outside the interval. Hence, this statement only assigns a probability 0 or 1 that the population mean θ is included within the interval. The probability $(1-2\alpha)$ refers to the process of calculating such intervals over infinite repetitions of the experiment. Operationally, confidence coefficients are usually chosen to be high (95% or 99%) and individuals "act" as if the statement is correct that the population mean is included within the interval. An additional criticism of confidence intervals is that no distinction is made as to whether the population parameter is likely to have a higher probability of being in the neighborhood of $\overline{x}$ compared with being at the ends of the interval. Intuitively, most individuals would agree that the value of the parameter is more likely to be in a neighborhood of $\overline{x}$ compared with being located in a neighborhood around the boundary of the confidence interval.

The operational use of confidence regions is essentially associating a "degree of belief" with the statement that the parameter θ is located within the calculated confidence region on the basis of specific data. The high values chosen for confidence coefficients are so close to unity, that practitioners behave as if the statement is "certain". However, this same idea of using a degree of belief to measure the uncertainty of an inference can also be used to ascribe different degrees of belief for comparing values within a confidence region. To illustrate ideas, consider the calculation of confidence intervals for a mean as described earlier. Suppose a spectrum of confidence intervals is calculated by choosing different

confidence coefficients. The point $\overline{x}$ is a degenerate confidence interval with confidence zero. Then for any potential value of the population parameter θ', there corresponds a confidence interval for which θ' is the end-point, i.e., the normal deviate corresponding to $z_{\alpha'} = \sqrt{n}(\theta' - \overline{x})/\sigma$ (if $\theta' > \overline{x}$) or $z_{\alpha'} = \sqrt{n}(\overline{x} - \theta')/\sigma$ (if $\theta' < \overline{x}$). Then the ratio of degrees of belief comparing the value θ' relative to $\overline{x}$ is α' for the population mean. Hence each end-point of a 95% two-sided confidence interval has a degree of belief of 0.025 of being the population mean compared with the sample average, whereas each end-point of a 10% two-sided confidence interval ($z_{0.45} = 0.12$) has a degree of belief of 0.45 (collectively 0.90) of being the population mean relative to $\overline{x}$.

Among the most widely used techniques in the frequentist theory of inference is the test of significance (*see* **Hypothesis Testing**). Central to a test of significance are the **null** and **alternative hypotheses**, i.e. $H_0 : \theta = \theta_0$ and $H_1: \theta \neq \theta_0$. The alternative hypothesis can also be one-sided, $H_1: \theta > \theta_0$ or $H_1: \theta < \theta_0$. The test of significance consists of calculating evidence which is "unfavorable" to the null hypothesis. The test of significance consists of using a statistic $T(x)$ so that large values of $T(x)$ indicate departures from the null hypothesis $H_0: \theta = \theta_0$. If $T_0(x)$ represents the value of the statistic from an experiment, then the test of significance calculates $P = \Pr\{T(X) \geq T_0(x) | \theta = \theta_0\}$. This so-called ***P* value** is interpreted as discrediting the null hypothesis if P is small (usually $P \leq 0.05$) and in favor of the null hypothesis if P is large. The role of the alternative hypothesis is to specify the statistic $T(x)$.

The P value is widely interpreted as summarizing the statistical evidence of an experiment. If a small value is calculated ($P \leq 0.05$), then either one has observed a rare event if H_0 is true, or if H_0 is not true, then the model for carrying out the calculation (assuming $\theta = \theta_0$), is wrong. Ordinarily the conclusion is made that the model is incorrect and H_0 is rejected.

The logic of the significance test is that if the observed $T_0(x)$ is evidence against the null hypothesis, then larger values of $T(x)$ would constitute even stronger evidence against H_0. The logic of significance tests is questioned, in that a hypothesis may be rejected on the basis of experimental outcomes which were not observed.

The test of significance does not recognize that there may be different interpretations on the P value which are dependent on both the sample size and the magnitude of the deviation from H_0. An experiment in which there is a negligible deviation from the null hypothesis, but having a very large sample size, will result in a small P value, whereas an experiment in which there is a large deviation from H_0, but with a small sample size, may not result in small P value. The uncritical use of tests of significance may result in misleading conclusions. It is often recommended that: (i) if P is small, then information should be presented on the magnitude of the deviation from the null hypothesis, and (ii) if P is large, then evidence should be presented on the power of the test.

Randomization and Permutation Tests

One of the important applications of significance tests is when the sample space is generated by the investigator. This has no analogy with any of the other methods of inference. It occurs whenever an experimental design makes use of randomization. We shall refer to these tests as **randomization tests**.

To illustrate ideas, consider an experiment where the location parameters of two treatment groups are to be compared by a significance test. The most widely used example is a randomized clinical trial in which patients are assigned to each of two treatment groups such that each patient has the same probability of being assigned to each group. If there are $2n$ patients available for the experiment and each group is assigned n patients, then there will be

$$N = \binom{2n}{n}$$

possible assignments. Hence there will be N points in the sample space. Suppose the null hypothesis is that there is no difference in outcome among the two groups. If $\overline{x}_1$ and $\overline{x}_2$ represent the sample average for each group, then $\overline{x} = (\overline{x}_1 + \overline{x}_2)/2$ will always be constant for the experiment. Hence, to show a difference in the location parameters the differences between the two sample averages $\overline{x}_1 - \overline{x}_2 = (\overline{x}_1 - \overline{x})$ will be considered. The sample space will consist of N possible values of the differences between the two sample averages, each having probability equal to $1/N$ of arising due to the randomization. Hence, if $D_0 = |\overline{x}_1 - \overline{x}_2|$ represents the absolute value of

the observed difference between the group sample averages, then the test of significance calculates $P =$ (number of absolute differences $\geq D_0)/N$. No further assumptions need to be made about the probability distributions of the outcomes. Essentially the randomization tests are distribution-free. The validity of the procedure is justified by the randomization which injected probability into the experiment. Of course, the inference only applies to patients who are in the clinical trial, i.e. the inference procedure concludes which is the best treatment for the population of patients that have been entered in the trial. To have a broader inference of making the conclusions apply to the population of patients having disease, it would be necessary to have a random sample of patients entered on the clinical trial.

A closely related set of procedures are *permutation tests*. We distinguish between randomization and permutation tests. Randomization tests are characterized by the investigator purposely introducing probability into the experimental design, whereas in permutation tests it is *assumed* that the sample space consists of equally likely outcomes. Consider the following example of a permutation test. Suppose the water supply in a community was a blend coming from several sources. Depending on the location of the residence, there would be different amounts of water from each source in the blend of water available to each residence. One of the water sources was found to be contaminated. From the time the contaminated source was put into service until the discovery of contamination there were 20 live births in the community. Two babies were born with congenital abnormalities. The amount of water going to each mother's residence during her pregnancy was known during this period of time. Is there an association between the contaminated water and birth defects? A permutation test would assume that each baby has the same risk of having a congenital abnormality. Hence there will be

$$\binom{20}{2} = 190$$

different ways in which two birth defect infants can be distributed among the 20 infants. If the residences with the two highest amounts of contaminated water also had the two birth defects, then this could happen with probability $P = 1/190 = 0.005$ if there is no relationship between birth defects and the contaminated water supply. This probability is so low that the frequentist would conclude a relationship between contaminated water and birth defects. Most people would intuitively agree there may be a relationship. A P value of 0.05 would arise if the two birth defect babies came from residences in which the amount of contaminated water delivered to the households during pregnancy ranked fourth and fifth highest. There are nine other more extreme outcomes than the observed fourth and fifth. If pairs of numbers represent the rankings then these outcomes are: (1, 2), (1, 3), (1, 4), (1, 5), (2, 3), (2, 4), (2, 5), (3, 4) and (3, 5). Since under the permutation test assumption any one of the possible 190 outcomes has the same chance of occurring, the number of outcomes equal to or more extreme than the one observed is $10/190 = 0.053$.

The randomization and permutation tests have generated the field of distribution-free or **nonparametric** methods. These methods do not require knowledge of the probability distribution of the observed outcome, as our two examples illustrate. To ease computations the observations are often replaced by **ranks** or **scores**. Very little statistical efficiency is lost by these substitutions.

Conditioning

An important modification of frequentist inference is the possibility of using information (data) to consider only a subset of the sample space. This may be done by conditioning on some aspect of the observed data which will result in a reduced sample space (*see* **Conditionality Principle**). The conditioning can only be done after the experiment has been completed and the data are available. Fisher [17] has advocated conditioning on the relevant subset of the sample space. The conditional sample space is also referred to as *recognizable subsets* or *reference sets*.

Cox [10] presented a very interesting example which leads one to make a conditional inference on a recognizable subset. His example is as follows. Suppose there are two normal populations, $\mathrm{N}(\theta, \sigma_1^2)$ and $\mathrm{N}(\theta, \sigma_2^2)$, having the same mean, but different variances. The mean is unknown, but the variances are known with $\sigma_1^2 \gg \sigma_2^2$. The experiment consists of choosing a population with probability 1/2 and drawing one observation, x. The population is known which is sampled. Consider a test of H_0: $\theta = 0$ vs. H_1: $\theta = \theta' \simeq \sigma_1$. Consider two tests – a conditional and an unconditional test to be made at an $\alpha = 0.05$ level of significance. The conditional test is

made on the population from which the sample was drawn. This leads to rejection regions $x > 1.64\sigma_1$ or $x > 1.64\sigma_2$ depending on which population has been sampled. However, this is not the most powerful test over the entire sample space. Application of the Neyman–Pearson theory results in a test which approximately has rejection regions $x > 1.28\sigma_1$ or $> 5\sigma_2$ depending on which population has been sampled. If the sample is from the second population, then almost complete discrimination is made between $\theta = 0$ against a much larger value of θ. As a result we can have a significance level of 10% if one is sampling from the first population. The power of the first test is 0.26 if population one is sampled and nearly unity if population 2 is sampled. Alternatively, the unconditional test has a power of 0.80. Thus, considering the overall sample space the first test has an average power of 0.63. Cox states

> if the object of the analysis is to make statements by a rule with certain specified long-run properties, the unconditional test just given is in order .... If, however, our object is to say "what can we learn from the data we have", the unconditional test is surely no good. The unconditional test says that we can assign a higher level of significance than we ordinarily do, because if we were to repeat the experiment, we might sample some other distributions. But this fact seems irrelevant to the interpretation of an observation which we know may come from a distribution with variance σ_1^2. That is, our calculations of power, etc. should be made conditionally within the distribution known to have been sampled.

Cox's example shows that the inference procedure should not be determined solely by considerations of power when one is considering repetitions of the experiment. In this example the indicator of the population sampled is called an **ancillary statistic** because it contains no information about θ. In general an ancillary statistic is defined as a function of the observations whose distribution is not a function of the parameter. In Cox's example, if δ is an indicator variable indicating which experiment is chosen, then the data are (δ, x) and δ is an ancillary statistic. The recognizable subset conditions on δ, i.e. $f(x|\delta)$.

Another illuminating example is provided by Berger & Wolpert [5]. Assume $X_1, X_2 \ldots, X_n$ are iid having a **uniform distribution** over the interval $\left(\theta - \frac{1}{2}, \theta + \frac{1}{2}\right)$. The sufficient statistics are $U = \min(X_i), V = \max(X_i)$. Their joint distribution is $f(\mu, v) = n(n-1)(v-u)^{n-2}, \theta - \frac{1}{2} < \mu \leq v < \theta + \frac{1}{2}$. However, $R = V - U$ is an ancillary statistic because its distribution is independent of θ. The distribution of (U, V) conditional on $R = r$ is uniform over the interval $\theta - \frac{1}{2} \leq \mu < \theta + \frac{1}{2} - r$ and should be the starting point for the statistical inference. In particular, a $100(1-\alpha)\%$ confidence interval is $(u+v)/2 \pm (1-r)(1-\alpha)/2$. In this example it is clear that the range is an ancillary statistic. However, in other situations the proper ancillary statistic may not be obvious and there may be competitive ancillary statistics.

The problem becomes more complex when $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ and the inference is to be made on $\boldsymbol{\theta}_1$ with $\boldsymbol{\theta}_2$ being regarded as a vector of nuisance parameters. If the likelihood factors into

$$L(x|\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) = L_1(\boldsymbol{\theta}_1|x, a(x))L_2(\boldsymbol{\theta}_2|a(x)),$$

then the distribution of $a(x)$ is independent of $\boldsymbol{\theta}_1$ and $a(x)$ is ancillary for $\boldsymbol{\theta}_1$. An example of this likelihood decomposition is when the data consists of pairs $(Y_i, X_i), i = 1, 2, \ldots, n$, which are iid following a bivariate normal distribution with $\mathrm{E}(Y_i) = \mu_y$, $\mathrm{var}(Y_i) = \sigma_y^2$, $\mathrm{E}(X_i) = \mu_x$, $\mathrm{var}(X_i) = \sigma_x^2$, and $\mathrm{cov}\,(X_i, Y_i) = \rho\sigma_x\sigma_y$. The object of the inference is on the parameters $\alpha = \mu_y - \beta\mu_x$ and $\beta = \rho\sigma_y/\sigma_x$ as $\mathrm{E}(Y_i|X_i) = \alpha + \beta X_i$. The likelihood can be written

$$\begin{aligned} &L(\mu_x, \mu_y, \sigma_x^2, \sigma_y^2, \rho|x, y) \\ &\quad = L_1(\mu_y, \tau^2, \alpha, \beta|x, y)L_2(\mu_x, \sigma_x^2|x), \end{aligned}$$

where $\tau^2 = \mathrm{var}(Y_i|X_i) = \sigma_y^2(1-\rho^2)$ and

$$\begin{aligned} &L_1(\mu_y, \tau^2, \alpha, \beta|x, y) \\ &\quad = \tau^{-n} \exp\left\{-\sum_{i=1}^{n} \frac{[y_i - (\alpha + \beta x_i)]^2}{2}\tau^2\right\} \\ &L_2(\mu_x, \sigma_x^2|x) \\ &\quad = \sigma_x^{-n} \exp\left\{-\sum_{i=1}^{n} \frac{(x_i - \mu_x)^2}{2\sigma_x^2}\right\}. \end{aligned}$$

Thus the regression analysis is conditional on the observed values of x_i which are treated as fixed constants.

When the likelihood factors can be written in terms of minimal sufficient statistics which factor into $L(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2|t_1, t_2) = L_1(\psi|t_1, t_2), L_2(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2|t_2)$, then it is possible to consider the distribution of t_1 conditional

on t_2 in order to make inferences on $\psi = \psi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$. This is the case for the **two by two contingency table** for comparing two **binomial distributions**. Conditioning on the total number of successes allows an inference to be made on the ratio of two **odds** in which one of the success probabilities is regarded as a nuisance parameter. Similarly, for comparing two **Poisson distributions**, with rate parameters (θ_1, θ_2), the likelihood can be written

$$L(\theta_1, \theta_2 | s_1, s_2) = \left(\frac{\theta_1}{\theta_2}\right)^{s_1} \theta_2^t \exp[-(\theta_1 + \theta_2)]$$
$$= L_1\left(\psi = \frac{\theta_1}{\theta_2} | s_1\right) \times L_2(\theta_1, \theta_2 | t = s_1 + s_2),$$

which admit of an inference on ψ by conditioning on the sum of the observed events. In both of these examples t contains "no information" about the parameter of interest, ψ. Cox [10] proposed a criterion for determining if t gives no information about ψ when nuisance parameters are present.

An important use of invoking a conditional inference arises in some censoring situations. To illustrate ideas suppose an investigator is testing a drug on patients in which the outcome is success or failure. The experiment is carried out until one observes a single failure. Hence the number of observations is a random variable following a **geometric distribution**. However, the investigator has only enough drug to treat 10 patients. The experiment could then have a maximum of 10 patients and the truncated distribution for the sample size would be

$$\Pr\{N = n | N \leq 10\} = \frac{\theta^{n-1}(1-\theta)}{(1-\theta^{10})}, \quad \text{for } n = 1, 2, \ldots, 10,$$
$$\Pr\{N = 10\} = \theta^9.$$

The experiment is carried out and the fifth patient had a failure. Should the statistician use the likelihood $\theta^4(1-\theta)$ in making the inference, or the truncated likelihood? To continue the story, the investigator tells the statistician afterwards that just before the experiment started the drug manufacturer had agreed to make available as much drug as needed. Hence there would be no need for the truncated distribution. In a final development, the drug manufacturer changed its offer to only make available the amount of drug for a maximum of 20 patients. This would change the truncated distribution. What should the statistician do? The actual experiment did not need the extra drugs, but an unconditional inference would have required taking account of the limited supply. The change of mind of the drug manufacturer would change the truncated probability distribution. Yet the manufacturer's decision had nothing to do with the actual experiment that was carried out with the available drug supply. Common sense dictates that the inference should be made conditional on what happened, not what could have happened. There was enough drug to carry out the experiment as planned. The likelihood should be conditional on the actual drug supply expended.

Estimation

The most widely used methods of **estimation** among frequentists are **minimum variance unbiased (MVU) estimation** and the method of **maximum likelihood**. Other methods in use are the **method of moments** and **generalized estimating equations**. The principle of having **unbiased** estimates sometimes leads to problems. For example, suppose $\overline{X}$ is the sample average of a sequence of n iid random variables having a $N(\theta, \sigma^2)$ distribution with σ^2 known. Then the minimum variance unbiased estimate of θ is the sample average. However, if it is desired to estimate θ^2, then we note that $E(\overline{X}^2) = \theta^2 + \sigma^2/n$. Therefore, if $T = \overline{X}^2 - \sigma^2/n$, $E(T) = \theta^2$ and T is an unbiased estimate of θ^2. However, θ^2 is always nonnegative, but there is a positive probability that $T = \overline{X}^2 - \sigma^2/n$ will be negative giving a nonsensical estimate. In general, if $g(\theta)$ is some function of θ, and T is an unbiased estimate of θ, then $g(T)$ is ordinarily not an unbiased estimate of $g(\theta)$. Despite some anomalies with the concept of unbiased estimation, the applications of the minimum variance unbiased criteria to estimation problems is very useful in applications – especially for models linear in the parameters.

Another widely used estimation procedure is the method of maximum likelihood. Estimates of θ, denoted by $\hat{\theta}$, are formed by maximizing the likelihood function, i.e. $L(\theta|x) = \max_\theta L(\theta|x)$. The properties of the maximum likelihood estimates are that they are: consistent, asymptotic minimum variance unbiased, and asymptotically normal. In addition, the

maximum likelihood estimate has the property that the estimate of $g(\theta)$ is $g(\hat{\theta})$.

Both minimum variance unbiased estimation and maximum likelihood estimation supply both point and confidence region estimates. Their justification is based on properties associated with infinite repetitions of sampling. However, Bayesian ideas have been used to justify maximum likelihood estimation.

Likelihood School of Inference

The use of the likelihood function is basic to many of the methods associated with frequentist inference. It was introduced by Fisher [12–16] as an information summary. It is essentially a minimal sufficient statistic for θ. Edwards [11] discusses the history of the likelihood function, and Berger & Wolpert [5] contains a thorough development of the statistical implications when the likelihood function is used as a basis for inference. Many of the ideas building on Fisher's early work are attributed to Barnard [1–4] and Birnbaum [6, 7].

Fisher initially introduced the likelihood function to obtain maximum likelihood estimates of parameters. The justification for maximum likelihood estimation has been made in terms of its large-sample properties relying on the frequency concepts of probability. Furthermore, ratios of likelihoods form the basis of likelihood ratio tests and the general Neyman–Pearson theory of hypothesis tests. However, all properties of these methods are judged by their behavior over the entire sample space of possible observations. This is at odds with the likelihood school of inference who regard the sample space as irrelevant after the experiment has been done. The only relevant quantities are the sample data, x, and its incorporation into the likelihood function, $L(\theta|x)$.

The basis of all **Bayesian inference** is the likelihood function. If $p(\theta)$ is the **prior distribution** on θ and $\pi(\theta|x)$ is the posterior distribution, then we have the well-known relationship $\pi(\theta|x) \propto L(\theta|x)p(\theta)$. Hence, whatever implications for inference arise from the likelihood function also apply to Bayesian inference methods.

The basis for the use of the likelihood in statistical inference is contained in the likelihood principle (*see* **Foundations of Probability**). It states that all information about θ from an experiment is contained in the likelihood function. Furthermore, two likelihood functions (from the same or different experiments) contain the same information about θ if they are proportional to one another.

The importance of the likelihood function in inference arises from its justification based on the widely accepted ideas of sufficiency and conditionality. Conversely, the likelihood function has been shown to lead to sufficiency and conditionality. These proofs were originally made by Birnbaum [6] and are correct for discrete observations. Others have modified his arguments for the continuous case. We summarize the main ideas borrowing from the development of Berger & Wolpert [5]. The ideas of conditionality and sufficiency have been discussed earlier in this article. There are two versions of each which are modified by the adjectives "weak" and "strong". We informally state the weak versions, which are all that is necessary in the proofs found in the literature.

Weak Conditionality Principle (WCP). Suppose there are two or more possible experiments, each having possibly different probability distributions, and each giving rise to different experimental outcomes. However, they all have in common the same parameter, θ. Consider the mixed experiment in which experiment i is chosen to be carried out with probability p_i. Then the WCP states that the evidence about θ from the mixed experiment is the experiment actually performed.

Weak Sufficiency Principle (WSP). Consider an experiment in which $t(X)$ is a sufficient statistic for θ. Then if x_1 and x_2 represent two different outcomes, but $t(x_1) = t(x_2)$, then the evidence about θ is the same for each outcome.

It has been proved that the WCP and the WSP imply the likelihood principle and conversely the likelihood principle implies both the WCP and WSP. The proof for the continuous case can be found in Berger & Wolpert [5].

The proponents of inference based on the likelihood principle view the rejection of the likelihood principle as also logically rejecting the WSP or WCP. However, the WSP is one of the basic ideas in frequency inference. The WCP is regarded as simply "common sense".

The likelihood principle is incompatible with many of the methods used in the frequency theory of inference. For example, **randomization**, significance tests, hypothesis testing, confidence intervals, and randomization tests are all contraindicated by the

likelihood principle. It is of interest that although randomization is rejected by the WCP, there has been no effort to negate randomized clinical trials. The idea of randomized clinical trials and the general idea of randomization appear to have been accepted by the likelihood and Bayesian schools of inference, notwithstanding the variance with the likelihood principle. One reason for accepting randomization is that it is regarded as a way to obtain "balance" among different groups being compared with respect to unknown factors affecting the outcomes.

Censoring which did not occur is considered irrelevant. For example, suppose in a clinical trial patients are only followed for a maximum period of time (say 10 years). If one had data from such a trial where the end-point was death and all patients died within the 10-year period, then the censoring at 10 years is of no consequence. Yet in calculating the behavior of a frequentist statistical procedure, it is necessary to consider infinite repetitions of the trial in which some patients may have survived 10 years and would be censored.

Stopping rules are deemed irrelevant. Hence, **sequential** methods are treated as if data arose from fixed-size experiments. For example, if X is $\mathrm{N}(\theta, \sigma^2)$ then one may sample from this population until the sample average exceeds a fixed constant, i.e. $\overline{x} > k\sigma/\sqrt{n}$. By the law of the iterated logarithm (*see* **Limit Theorems**), there is a finite probability that the event will happen. However, for (say) $\theta = 0$ and large k, the necessary number of observations may be very large. If a frequentist desires to exclude $\theta = 0$ from a 95% confidence limit, then it is only necessary to choose $k = 1.96$. Of course, this entire procedure would be misleading from a frequentist point of view. The likelihood argument is that the inference should not interpret the usual confidence interval in the frequency sense. A frequentist would also take account of the ultimate sample size in placing confidence intervals on θ. Alternatively, the Bayesian approach to this problem is to incorporate the possibility of $\theta = 0$ in a prior distribution.

Suppose one observed four successes in 10 trials from sampling a binomial distribution. This gives rise to the likelihood function $L(\theta|x) = \theta^4(1-\theta)^6$, where θ is the probability of success in a single trial. Alternatively, suppose one samples from this population until four successes are observed. If this experiment took 10 observations to observe four successes, then it will give rise to the same likelihood as observing four successes in 10 trials. The likelihood principal would treat both experiments as generating the same information even though the sampling distributions associated with each experiment are different.

One of the principal criticisms of the use of the likelihood function for inference is the need to specify the model generating the data. Furthermore, it does not encompass any nonparametric methods.

Methods for solely using the likelihood function for inference are not well developed. We cite a few examples of the use of a likelihood function for making inferences.

The ratio of likelihoods can measure the relative support of two values of θ, e.g. $L(\theta_1|x)/L(\theta_2|x)$. Since the maximum likelihood estimate $\hat{\theta}$ maximizes the likelihood, it can serve as a normalization factor and one may consider $L(\theta|x)/L(\hat{\theta}|x)$ to measure the relative support of any θ to $\hat{\theta}$. Likelihood contours may be calculated by setting $L(\theta|x)/L(\hat{\theta}|x) = k$ for a range of values of k. If we consider values of the parameter satisfying

$$\frac{L(\theta|x)}{L(\hat{\theta}|x)} \leq k,$$

then, we can obtain an expression analogous to a confidence region for θ.

Using the likelihood when nuisance parameters are present raises complications. Suppose $\theta = (\theta_1, \theta_2)$ and θ_2 is a nuisance parameter. One approach is to substitute the maximum likelihood estimate of $\hat{\theta}_2(\theta_1)$ in the ratio $L(\theta_1, \hat{\theta}_2(\theta_1)|x)L(\hat{\theta}_1, \hat{\theta}_2|x)$. For example, consider the likelihood function of a sample of n observations from a $\mathrm{N}(m, \sigma^2)$ distribution, i.e.

$$L(m, \sigma^2|x) = \sigma^{-n} \exp\left\{-\frac{1}{2}\sum_{i=1}^{n}\frac{(x_i - m)^2}{\sigma^2}\right\}.$$

The maximum likelihood estimate of σ^2, as a function of m, is $\hat{\sigma}^2(m) = \sum_{i=1}^{n}(x_i - m)^2/n$. Then one has

$$\frac{L(m, \hat{\sigma}^2(m)|x)}{L(\hat{m}, \hat{\sigma}^2|x)} = \left\{1 + \frac{(\hat{x} - m)^2}{s^2}\right\}^{-n/2} \cong \left\{1 + \frac{t^2}{n}\right\}^{-n/2},$$

where $ns^2 = \sum_{i=1}^{n}(x_i - \overline{x})^2$ and $t^2 = n(\hat{x} - m)^2/s^2$. This is the **Student *t* distribution** (except for the normalizing constant), but with n in place of $(n-1)$. If we desired bounds on m, then we could set

$L(m, \hat{\sigma}^2(m)|x)/L(\hat{m}, \hat{\sigma}^2|x) \leq k$. Then for large n we have the interval $\hat{x} \pm s(-2\log k)^{1/2}/\sqrt{n}$.

The general application of likelihood methods may be extended by noting that for large samples

$$\frac{L(\theta|x)}{L(\hat{\theta}|x)} \simeq \exp\left\{\frac{-(\theta-\hat{\theta})^2}{2\sigma^2(\hat{\theta})}\right\},$$

where

$$\sigma^2(\hat{\theta}) = -\left(\frac{\partial^2 \log\theta}{\partial\theta^2}\right)^{-1}_{\theta=\hat{\theta}}$$

Hence, the maximum likelihood estimate and the estimate of its asymptotic variance can be used to make likelihood-type inferences for large samples. The result extends to the multivariate situation.

Bayesian School of Inference

In this section we illustrate and contrast Bayesian methods of inference with frequency methods. The application of Bayesian methods to problems of medicine and biology is growing. In large measure the expansion in applications is due to the development of new computing **algorithms** which allow the calculations of posterior distributions having large numbers of parameters. This class of computer algorithms are called **Markov chain Monte Carlo** methods. Two widely used algorithms for this purpose are the Gibbs sampler and the Metropolis-Hastings algorithms: cf. Tanner & Wong [34], Smith [31], Tierney [35], Smith & Gelfand [32], and Smith & Roberts [33]. Breslow [8], in a review paper, cites many applications of Bayesian methods to biostatistics, i.e. **longitudinal data** models, **small area estimation**, **risk assessment** based on species to species **extrapolation**, **bioequivalence** and sequential clinical trials (*see* **Data and Safety Monitoring**).

The Bayes paradigm is that all inferences are based on calculating the posterior distribution of θ. The difficulty in utilizing Bayesian methods is due to both the dependence on model specification, and the meaning of Bayesian probability statements. To utilize Bayesian methods it is necessary to specify both the likelihood function and a prior distribution. Prior distributions may be chosen by subjective opinion or may reflect previous data or knowledge. Issues arise when informationless prior distributions are chosen which contain no information or parameters. The interpretation of a Bayesian probability is that it measures a degree of belief. It allows attaching a posterior probability (degree of belief) associated with hypotheses. This is in contrast to frequentist inference which attaches a value of 0 or 1 to the truth of a hypothesis. Bayesian methods are often judged in practice by their behavior over infinite repetitions. The book by Savage [30] still remains as a cogent treatise advocating the use of Bayesian methods.

Elements

The basis of all Bayesian inference is that, "Any inferential process that does not follow from some likelihood function and some set of priors has objectively verifiable deficiencies", cf. [9]. Bayesian inference places probability distributions on parameters. The elements of Bayesian inference are: that a prior distribution $p(\theta)$ summarizes information about θ prior to experimentation; the likelihood $L(\theta|x)$ incorporates information utilizing data; and the posterior distribution $\pi(\theta|x)$ depicts the probability distribution of θ after incorporating the data. More formally, the relationship between these quantities is

$$\pi(\theta|x) \propto L(\theta|x)p(\theta).$$

This expression is a direct consequence of Bayes' theorem and shows how prior beliefs are changed with the availability of data.

The interpretation of $\pi(\theta|x)$ is that it is a degree of belief, taking on values within the unit interval. In what follows it will be assumed for simplicity that θ has a prior distribution having a probability density function. This assumption is not necessary, but it eases the formalism.

Ratios of posterior distributions are often used to indicate "support" for comparing two different values of θ, i.e. $\pi(\theta_1|x)/\pi(\theta_2|x)$. If one of the θs is the mode of $\pi(\theta|x)$ (denoted by θ_{m}), then $\pi(\theta|x)/\pi(\theta_{\mathrm{m}}|x)$ compares the degree of belief of an arbitrary θ with the modal value. If θ is one dimensional, then a graph of the ratio vs. θ is particularly useful.

Although there is a great deal of debate on the choice of the prior distribution, the importance of the prior distribution diminishes when the sample size is large. This is easily seen by noting that if we write $L(\theta|x) = \prod_{i=1}^{n} L(\theta|x_i)$, then

$$\log[\pi(\theta|x)] = \log[L(\theta|x)p(\theta)]$$
$$= \sum_{i=1}^{n}\left[\log L(\theta|x_i) + \frac{1}{n}p(\theta)\right],$$

and noting that the second term in brackets goes to zero as $n \to \infty$.

The normalizing constant $P(x)$ is $P(x) = \int_\Omega L(\theta|x)p(\theta)\,\mathrm{d}\theta$ and is the expected value of the likelihood averaged over the prior distribution. The integral is over the parameter space of θ. Hence, the posterior distribution can be written

$$\pi(\theta|x) = \frac{L(\theta|x)p(\theta)}{P(x)}.$$

Note that $P(x)$ is proportional to the posterior probability of observing the data x.

An important aspect of Bayesian inference is predicting a future observation (*see* **Prediction**). If y represents a future observation and x represents data already observed, then the predictive likelihood of y is

$$L(y|x) = \int_\Omega L_1(\theta|y)\pi(\theta|x)\,\mathrm{d}\theta,$$

where $L_1(\theta|y)$ is the likelihood of a single new observation. The quantity $L(y|x)$ is the likelihood of observing a future observation given the data represented by x. If $L(y|x)$ is normalized, then

$$f(y|x) = \frac{L(y|x)}{\int_{-\infty}^{\infty} L(y|x)\,\mathrm{d}y}$$

is the predictive distribution of y. It is clear that the predictive distribution is not necessarily restricted to predicting a single observation, but can predict an arbitrary number of observations. The book by Geisser [19] is a principal reference for predictive distributions.

A fundamental problem in statistical inference is to carry out an inference when nuisance parameters are present. The methods of Bayesian inference can deal with the problem in a relatively straightforward way. Suppose $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ and inference is to be made on $\boldsymbol{\theta}_1$ with $\boldsymbol{\theta}_2$ regarded as a vector of nuisance parameters. The methods of Bayesian inference deal with this problem by considering the marginal posterior distribution of $\boldsymbol{\theta}_1$, i.e.

$$\pi(\boldsymbol{\theta}_1|x) = \int_{\Omega_2} \pi(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2|x)\,\mathrm{d}\boldsymbol{\theta}_2.$$

The comparable problem in the frequency theory of inference can be carried out only in special cases when minimal sufficient statistics exist.

Example

To illustrate ideas we shall consider the Bayesian analysis for comparing two binomial distributions. If (p_i, s_i, n_i) represent the success probabilities, number of successes, and sample sizes, respectively, for $i = 1, 2$, then the likelihood is

$$L(p_1, p_2|s_1, s_2) = p_1^{s_1}(1-p_1)^{n_1-s_1} p_2^{s_2}(1-p_2)^{n_2-s_2}.$$

Define the new parameters (α, β) by the logit transformations (*see* **Logistic Regression**), i.e.

$$\log\left[\frac{p_1}{1-p_1}\right] = \alpha, \quad \log\left[\frac{p_2}{1-p_2}\right] = \alpha + \beta.$$

Note that $\mathrm{e}^\beta = p_2(1-p_1)/p_1(1-p_2)$. The reparameterized likelihood can be written

$$L(\alpha, \beta|s, t) = \frac{\mathrm{e}^{\alpha t + \beta s}}{(1+\mathrm{e}^\alpha)^{n_1}(1+\mathrm{e}^{\alpha+\beta})^{n_2}},$$

where $t = s_1 + s_2$ and $s = s_2$. The reparameterization allows one to test H_0: $p_1 = p_2$ by considering β only. The parameter α is a nuisance parameter.

The sampling theory of inference considers the distribution of s conditional on t, which results in α being dropped. This is the basis of the analysis of 2×2 tables with all marginal totals fixed. The explicit conditional distribution is

$$f(s|t, \beta) = \frac{C(s,t)\mathrm{e}^{\beta_s}}{\sum_{z=0}^{r} C(z,t)\mathrm{e}^{\beta z}}, \quad s = 0, \ldots, r,$$

when $r = \min(t, n_2)$ and

$$C(s,t) = \binom{n_1}{t-s}\binom{n_2}{s}.$$

The Bayesian analysis finds the posterior distribution of (α, β) from which the marginal distribution of β can be calculated. Let the prior distributions of (α, β) be taken as

$$\frac{p(\alpha, \beta) \propto \mathrm{e}^{\alpha t' + \beta s'}}{(1+\mathrm{e}^\alpha)^{n_1'}(1+\mathrm{e}^{\alpha+\beta})^{n_2'}},$$

where the prime quantities are parameters of the prior distribution, but subject to the condition $0 \le s' \le t' \le$

$n_1' + n_2'$. Then the posterior distribution is

$$\frac{\pi(\alpha, \beta|s, t) \propto e^{\alpha t'' + \beta s''}}{(1 + e^{\alpha})^{n_1''}(1 + e^{\alpha+\beta})^{n_2''}},$$

where $s'' = s + s'$, $t'' = t + t'$, $n_1'' = n_1 + n_1'$, and $n_2'' = n_2 + n_2'$. Since the form of the posterior is the same as the likelihood, the prior distribution is called a *natural conjugate* or *conjugate distribution*. Finally, the marginal posterior distribution is

$$\pi(\beta|s'', t'') \propto e^{\beta s''} \int_0^1 \frac{v^{t''-1}(1-v)^{n''-t''-1}\,dv}{[1 - v + ve^{\beta}]^{n_2''}},$$

where $n'' = n_1'' + n_2''$. The integral can be found using numerical methods (*see* **Numerical Integration**).

Prior Distributions

The choice of a prior distribution is an important first step in implementing a Bayesian analysis. Prior distributions may be chosen on the basis of other similar experiments, subjective opinion, or the acknowledgment that nothing is known about the parameters, and the prior is informationless.

There is a great deal of debate when the prior distribution is informationless. Jeffreys [20] proposed that if a parameter takes on values over the real line, that the prior distribution be uniform, whereas if θ takes on values over the positive real line, that $\log\theta$ have a uniform distribution. Therefore the informationless prior for location and scale parameters, as suggested by Jeffreys, are $p(m) = 1\ (-\infty < m < \infty)$ for a location parameter and $p(\sigma) = 1/\sigma\ (0 < \sigma < \infty)$ for a scale parameter. Both are improper distributions in that their integrals over the parameter space do not exist. Another view of the improper prior distribution for the scale parameter is that it is flat over the range of the parameters of the likelihood functions. Therefore the posterior distribution is essentially the likelihood function.

Nevertheless the posterior distributions do satisfy all conditions for distribution functions. For example, suppose $X_1, \ldots, X_n$ are iid $N(m, \sigma^2)$ with m and σ^2 both unknown. The likelihood function is

$$L(m, \sigma^2|\mathbf{x}) = \sigma^{-n} \exp\left\{-\frac{1}{2}\sum_{i=1}^{n}\frac{(x_i - m)^2}{2\sigma^2}\right\},$$

resulting in the posterior distribution

$$\pi(m, \sigma^2|\mathbf{x}) \propto \frac{L(m, \sigma)}{\sigma}.$$

If the marginal distribution of m is obtained by integrating over σ, then we obtain

$$\int_0^{\infty} \pi(m, \sigma^2|\mathbf{x})\,d\sigma \propto \left[1 + \frac{t^2}{(n-1)}\right]^{-(n-1)/2},$$

with $t^2 = n(\overline{x} - m)^2/s^2$, $s^2 = \sum_{1=1}^{n}(x_i - \overline{x})^2/(n - 1)$, which is Student's t with $n - 1$ degrees of freedom. Finally, integrating our Student's t results in unity, i.e.

$$\int_{-\infty}^{\infty}\int_0^{\infty} \pi(m, \sigma^2|\mathbf{x})\,d\sigma\,dm = 1.$$

Jeffreys has also suggested an algorithm for constructing informationless priors on the basis of the Fisher information. If $X_1, X_2, \ldots, X_n$ are iid with likelihood function $L(\sigma|\mathbf{x}) = \prod_{i=1}^{n} f(x_i|\theta)$, then the Fisher **information** in the sample is

$$I_n(\theta) = E\left(\frac{\partial \log L(\theta|x)}{\partial\theta}\right)^2 = nE\left(\frac{\partial \log f(x|\theta)}{\partial\theta}\right)^2 = nI(\theta).$$

Jeffreys' algorithm for an informationless prior is $p(\theta) \propto I(\theta)^{1/2}$. Since the Fisher information is invariant under transformations, the Jeffreys algorithm is also invariant with respect to transformations. The Jeffreys algorithm for many parameters is to take $p(\theta) \propto |I(\theta)|^{1/2}$, where $|I(\theta)|$ is the determinant of the matrix of partial cross derivatives.

An important class of prior distributions is when the posterior distribution belongs to the same family of distributions as the prior distributions. These are called *conjugate* or *normal conjugate* prior distributions. For example, consider the distribution of the sample mean arising from n iid observations arising from a $N(m, \sigma^2)$ with σ^2 known. The likelihood is $L(m|x) = \exp[-n(\overline{x} - m)^2/2\sigma^2]$. The conjugate prior distribution is $p(m) \propto \exp[-n'(m - m')^2/2\sigma^2]$, where (n', m') are parameters of the prior distribution. Then the posterior distribution of m is

$$\pi(m|x) \propto L(m|x)p(m) \propto \exp\left[\frac{-n''(m - m'')}{2\sigma^2}\right],$$

where $n'' = n + n'$ and $m'' = (n\overline{x} + n'm')/n''$. Although the quantity n in the likelihood is an integer, the parameter n' is not restricted to be an integer but only to be nonnegative. Note that as $n' \to 0$,

$p(m) \propto 1$, which results in an improper prior in the limit. The form of the posterior distribution shows that the prior distribution contributed n' observations having a mean of m' to the likelihood. The informationless prior corresponding to $n' \to 0$ contributes no information to the likelihood.

There exist conjugate prior distributions for all of the distributions having minimal sufficient statistics. The book by Raiffa & Schlaifer [29] contains a compendium and an extensive discussion of conjugate prior distributions. In all of these conjugate prior distributions it is possible to interpret the parameters of the prior as adding additional information to the data.

To cite another example, in addition to the normal distribution, consider the likelihood arising from observing s successes out of n trials from a binomial distribution. The likelihood is $L(\theta|s) = \theta^s(1-\theta)^{n-s}$ and the conjugate prior is $p(\theta) \propto \theta^{s'}(1-\theta)^{n'-s'} (0 \leq s' \leq n')$ resulting in the beta posterior distribution. $\pi(\theta|s) \propto \theta^{s''}(1-\theta)^{n''-s''}$, with $s'' = s + s'$ and $n'' = n + n'$. The prior distribution has contributed s' successes from n' trials. Jeffreys [10] proposed that the informationless prior for this situation take $s' = 1/2$ and $n' = 1$, i.e. $p(\theta) \propto [\theta(1-\theta)]^{-1/2}$. The prior contributes a "half" a success from a single trial to the likelihood.

In any event, there is a determination of the information for every conjugate prior distribution. As a result, if the prior is based on past information, than it can lead to the fitting of the parameters of the conjugate prior distributions. The same remark holds for choosing priors by a subjective assessment. Any subjective assessment that is incorporated into a conjugate prior can be interpreted with regard to its information content.

Over the past several decades much of the debate concerning Bayesian inference has been concentrated on the use of prior distributions. It is unlikely that there will be closure on this topic. However, when the prior distribution can be interpreted with respect to information content, priors having information equivalent or less than one unit of information and which are smooth over the parameter space are unlikely to have a major effect on the likelihood function.

Influence Function in Survival Analysis

The influence function of an estimator was introduced by Hampel [5] in the context of robust estimation (*see* **Robustness**). Broadly speaking, the influence function evaluated at a possible data point x indicates how the estimator is changed by the addition of a data point with value x. As an example, the influence function for the sample mean is identically equal to x, showing that a single data point has an influence on the mean directly proportional to its value. This reflects the fact that the sample mean is very sensitive to **outliers**. However, the influence function for the sample **median** is a step function. The median is the simplest example of an estimator with bounded influence function. Several more **efficient** estimators with bounded influence functions have been proposed as more robust estimators [5]. An introduction to the influence function is given in [9].

The influence function of an estimator is computed by first writing the estimator as a functional of a distribution function. For an estimator that is a function of independent, identically distributed observations, this distribution function will be the empirical distribution function, $F_n(x)$ (*see* **Goodness of Fit**). For example, the sample mean $\overline{X} = n^{-1} \sum X_i$ can be expressed as $\int x \, \mathrm{d}F_n(x)$. This estimates the same functional of the true distribution function $\int x \, \mathrm{d}F(x)$: estimators with this property are called Fisher **consistent**. We can write the sample median as $F_n^{-1}\left(\frac{1}{2}\right)$, (with a suitable definition of inverse for a noncontinuous function), and this estimates $F^{-1}\left(\frac{1}{2}\right)$.

We use the general notation $T(F)$ for a functional of a distribution function. Then we define the influence function for $T(F)$ by

$$IC(x; T, F) = \lim_{t \to 0} t^{-1}\{T[(1-t)F + t\delta_x] - T(F)\}, \tag{1}$$

if this limit exists. In (1) δ_x is the distribution function that puts mass 1 at the point x. For $T(F) = \int x \, \mathrm{d}F(x)$, we have $IC(x; T, F) = x$, and for $T(F) = F^{-1}\left(\frac{1}{2}\right)$, we have

$$IC(x; T, F) = \begin{cases} -\dfrac{1}{2f[F^{-1}(1/2)]}, & \text{if } x < F^{-1}\left(\frac{1}{2}\right), \\ +\dfrac{1}{2f[F^{-1}(1/2)]}, & \text{if } x > F^{-1}\left(\frac{1}{2}\right). \end{cases}$$

The influence function defined in (1) is constructed from the so-called Gâteaux derivative of the functional T. The definition can be extended by computing the Gâteaux derivative of more complex functionals, such as functionals $T(F, u)$ that depend on an additional real parameter, or bivariate functionals $T(F, G)$, say.

In survival data analysis, the estimators of interest are typically more complex than simple functions of independent and identically distributed observations, and the definition of the influence function needs these more complex functionals. Consider the case of a single sample of independent, possibly **censored**, observations $(X_1, \delta_1), \ldots, (X_n, \delta_n)$, where X_i is the observed failure or censoring time, and δ_i is 1 if X_i is uncensored, and 0, otherwise. Assuming the random censorship model, we write $X = \min(X^0, Y)$, where X^0 has distribution $F(\cdot)$, the failure time distribution of interest, and Y has distribution G.

The influence function of the **Kaplan–Meier** estimate of the survival distribution F was introduced in [8, Eqs. (2.1), (2.2)]. This used a representation, due to Peterson [6], of the cumulative hazard function as a functional of two subsurvival functions: $S_u(\cdot)$, and $S_c(\cdot)$, where $S_u(t) = \Pr(X > t, \delta = 1)$, and $S_c(t) = \Pr(X > t, \delta = 0)$. This gives a pair of influence functions for the Kaplan–Meier estimator of $S(t) = 1 - F(t)$:

$$IC_1(s; T, S_u, S_c)(t) = S(t) \left\{ \int_0^{\min(s,t)} \frac{\mathrm{d}S_u(x)}{(S_u + S_c)^2(x)} + \frac{1(s \le t)}{(S_u + S_c)(s)} \right\},$$

$$IC_2(s; T, S_u, S_c)(t) = S(t) \left\{ \int_0^{\min(s,t)} \frac{\mathrm{d}S_u(x)}{(S_u + S_c)^2(x)} \right\}.$$

The first term in IC_1 is the effect a new observation at time s has on the estimate of $S(t)$ by increasing the size of the risk set, if $s \le t$. This is the only effect of a new censored observation, as is seen from the expression for IC_2. The second contribution to IC_1 corresponds to the additional jump point in the Kaplan–Meier estimate of $S(t)$ when a new, uncensored, observation at time s is added.

In addition to providing a descriptive summary of how sensitive an estimator can be to outliers, the influence function can be used to compute the asymptotic variance of an estimator. We assume for notational convenience that we have a simple functional of one distribution function $T(F)$. If this functional

is differentiable, then we can write

$$T(G) = T(F) + \mathrm{d}T_F(G - F) + R, \qquad (2)$$

where G is some distribution function, $\mathrm{d}T_F$ is the differential of $T(F)$ and is a linear functional, and R is a remainder term. For many statistical functionals, $\mathrm{d}T_F(G - F)$ will take the form

$$\mathrm{d}T_F(G - F) = \int IC(x; T, F)\,\mathrm{d}G(x),$$

where IC is defined in (1), but has been standardized if necessary so that $\int IC(x)\,\mathrm{d}F(x) = 0$. If we now let $G = F_n$, then we have an expression for the estimator $T(F_n)$ as the true value $T(F)$, plus a linear combination $n^{-1}\sum IC(X_i; T, F)$ and a random remainder term. Under some conditions that, in particular, ensure that the remainder goes to 0 in a suitable sense as $n \to \infty$, we may conclude that $\sqrt{n}[T(F_n) - T(F)]$ is asymptotically normally distributed with mean 0 and variance $\int IC^2(x; T, F)\,\mathrm{d}F(x)$.

The argument sketched above is an example of the *functional delta method*, described in [1, II.8], and [4]. The ordinary **delta method** uses an approximate linearization of a nonlinear function to find the limiting distribution of an estimator. The functional delta method uses the same argument with the functional derivative $\mathrm{d}T$ defined by (2). In fact, the functional derivative is not well defined by (2): we need to specify in what sense R converges to 0, as G becomes arbitrarily close to F. There are three main notions of convergence, leading to Gâteaux, compact, and Fréchet differentiability. While the definition of the influence function in (1) uses the weak notion of Gâteaux differentiability, the asymptotic argument requires that T be either compact or Fréchet differentiable. For a fuller discussion of this, see [1, II.8]. Since functional derivatives also obey a chain rule, the functional delta method can be used to find the asymptotic distribution for functions of estimators as well. The asymptotic variance of the cumulative hazard estimator was computed using this method in [8]. The functional delta method is applied to the Kaplan–Meier estimator and several functions of it in [1, IV.3] and to more complex product limit estimators in [1, IV.4].

Another important use of the influence function in survival analysis is to suggest influence **diagnostics**, or case-deletion diagnostics, for use in the **proportional hazards** regression model, analogously to the way regression diagnostics are computed routinely for linear regression models. It is shown in [3] and [10] that a sample estimate of the influence function can be used to approximate $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{-i}$, where $\hat{\boldsymbol{\beta}}$ is the usual estimate of the regression parameter in Cox's proportional hazards regression model and $\hat{\boldsymbol{\beta}}_{-i}$ is the estimate obtained when the ith observation is deleted. Storer & Crowley [11] consider various other ways to estimate $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_i$. Barlow & Prentice [2], in a discussion of various definitions of **residuals** for proportional hazards regression, relate the estimated influence function to a particular type of residual, and thereby also extend the definitions of [3] and [10] to **time-dependent covariates**. Further development, with emphasis on applications, is given in [7]. There is also a helpful summary in [1, VII.3].

Informatics in the Health Sciences

Information technology, in its widest sense, increasingly serves multiple roles in professional activities and practice. Besides being the servant that enables a number of activities, it also provides the environment to model and study those activities and domains of interest. Informatics is the use of information technology, broadly conceived, to advance a domain of work or inquiry. *Medical* informatics is the application of informatics principles and practice to clinical care; *nursing* informatics, to nursing care; *public health* informatics, to issues of public health; **bioinformatics** to biology and to the work of biologists; *statistics* informatics, to epistemology and the practice of statistics.

The word was first used in A.I. Mikhailov's (Scientific Department of the Moscow State University) book *Oznovi Informatiki* (Foundations of Informatics); it was then turned into the French word *informatique* (de medecine), or medical computing. The term was then brought into English by MF Collen in 1977 [2].

Friedman [4] has proposed a scaffold of four levels of activity within informatics: model formulation, system development, system installation, and study of effects. A complementary model is shown here, where *System* refers to a model of the target domain, *Role* speaks of the role an individual plays within that domain (in health sciences/care, the roles are clinical care, learning, teaching, research, and administration), *Functions* refers to those activities that support a particular role, and *Workflow* represents the model of the activities that support each activity. The next layer, of information resources, divides into two components: *Information Repositories* refers to the storage facilities needed to accomplish a step in the workflow and *Information Tools* refers to the software tools (*see* **Software, Biostatistical**) or **algorithms** by which an information repository is used to support that step. *Standards* refer to common formats and protocols that support the information resources to promote interoperability, and *Technology* refers to hardware and software products and protocols that support the whole enterprise (*see* **Computer Architecture and Organization**).

<table>
<tr><td colspan="2">System</td></tr>
<tr><td colspan="2">Role</td></tr>
<tr><td colspan="2">Functions</td></tr>
<tr><td colspan="2">Workflow</td></tr>
<tr><td>Information repositories</td><td>Information tools</td></tr>
<tr><td colspan="2">Standards</td></tr>
<tr><td colspan="2">Technology</td></tr>
</table>

In medical informatics, *system* refers to the clinical environment. Physicians have specific *roles* (clinician, educator, learner, manager, researcher), and tasks within those roles, in that environment, and different workflows apply to each function. For instance, in clinical care, two functions are *diagnose* and *treat*. A diagnostic decision support system helps the clinician to diagnose. In doing so, it embodies the workflow of diagnosis (the hypothetico-deductive loop of hypothesizing a number of conditions, suggesting data to collect, collecting the data, and modifying the differential diagnosis) (*see* **Computer-aided Diagnosis**). To accomplish that support, it needs an information repository of a knowledge base and an algorithm of an inference engine. (Inference engines have generally been based on logical inference, **neural networks**, or Bayesian probability networks.) For decision support systems to be interoperable, standards, such as Arden syntax, have been designed and promulgated. The decision support system can be implemented in a range of technologies, ranging from mainframe to handheld devices.

For the core clinical functions of *retrieve clinical data*, *manage*, *transact*, and *document*, the computer-based patient record and computer-based provider order entry are key repositories. *Decision support* is often sited in the latter. For the clinical function of *communicate*, the technologies of telemedicine have received attention, especially in settings with difficult access to clinicians (prisons, rural areas, shut-ins).

A range of communication, vocabulary, and technology standards are increasingly viewed as vital to integrating American healthcare into a National Health Information Infrastructure (NHII). An advisory office in the Department for Health and Human Services has been established to foster the NHII. The Consolidated Health Initiative of the eGov effort, working with the National Committee on Vital and Health Statistics, has advised government adoption of the following standards: Health Level 7® (HL7®, communication), National Council on Prescription

Drug Programs (NCDCP, standards for ordering drugs from retail pharmacies) , Institute of Electrical and Electronics Engineers 1073 (IEEE1073, "Medical Informatics Bus", for physiological systems communication), Laboratory Logical Observation Identifier name Codes® (LOINC®, laboratory values), and Digital Imaging Communications in Medicine® (DICOM®, image transmission and storage).

In all cases, efforts have been taken to understand the optimal methods of implementing and deploying these systems, as well as evaluating the systems' impact, either at the level of return on investment or at the level of impact on patient outcomes and on the processes of care. These issues have been a particular focus of nursing informatics.

In their review of the history of definitions of nursing informatics, Staggers and Thompson [6] provide the following synthesis:

> Nursing informatics is a specialty that integrates nursing science, computer science, and information science to manage and communicate data, information, and knowledge in nursing practice. Nursing informatics facilitates the integration of data, information, and knowledge to support patients, nurses, and other providers in their decision making in all roles and settings. This support is accomplished through the use of information structures, information processes, and information technology.

In supporting the role of clinical care, nursing informatics focuses on training nurse users and in specifying and designing systems to support the work of nurses. Nursing informatics tends to focus more on supporting the administrative role than does medical informatics, with attention to the functions of quality improvement, performance improvement, outcome measurement, process redesign, and disease management.

Public health informatics is a more recently articulated discipline [3, 7]. With populations as its focus, its primary roles are prevention (*see* **Preventive Medicine**), **surveillance**, **risk assessment**, and research. Recent activity has focused on recognizing the range of functions that can be supported by existing or novel information technology; enabling communication between information repositories or integration among them; the creation of novel algorithms to perform, for instance, syndromic surveillance, with these new sources of information, and enabling the dissemination of tools for using those repositories in an inexpensive manner; the modification of existing, or creation of new standards; and the creation of novel technologies, such as environmental sensors, also to support these roles.

There are disciplines of informatics to support particular subdomains of medicine, like radiology, pathology, **dermatology**, **psychiatry**, and primary care.

On the research side, **bioinformatics** tends to divide into two areas. One is the view of biology as a set of digital processes; this view leads to computational biology and the like. Second is the view of research as an activity performed by people, which leads to research informatics and the creation of **databases** and other repositories and tools to support the work of research. The importance of information technology to support clinical research has led to solutions at each level of the hierarchy: repositories of research instruments and of participant data; statistical packages for clinical research; the use of clinical standards in coding research results; and data collection tools, like those based on personal digital assistants.

Statistics also had a dual relationship with informatics. On the one hand, statistical algorithms are used in all domains, when the view of data goes across more than one **unit of analysis**, whether in the description of a population of patients, or the analysis of a set of natural-language text. On the other hand, relatively little support is available for the *work* of statistics, outside the statistical packages that ease the calculations. The statistical *workflow* involves the creation of data sources and communication among them, with an eye toward the analytic and decision goals of the data; involves the assembly of the data, with an understanding of the errors and limitations conferred by the different data sources; involves "cleaning" of the assembled data, taking the data sources and the analytic goals into account; involves the choices and sequencing of the statistical models and processes for analysis [1, 5]; and involves the reporting of the data, with the caveats and limitations of the inferences made explicit. There are few standards to support this workflow that take into account the needs of the statistician, outside the growing library of programming modules. The knowledge and experience of professionals that have been encoded in guidelines and protocols in other domains is lacking in statistics, and there are no statistical decision support tools to support this workflow.

Attention to the workflow in the spirit of informatics more generally should fill this void.

HAROLD P. LEHMANN

Information Matrix

Let $\mathbf{X}$ be an n-vector of observations relating to a vector parameter $\boldsymbol{\theta}$. In addition, let $f(\mathbf{X}|\boldsymbol{\theta})$ denote the joint density (or mass function) of $\mathbf{X}$ under $\boldsymbol{\theta}$, which, viewed as a function of $\boldsymbol{\theta}$, is the **likelihood** function. A key role in statistics is played by the matrices $\mathbf{I}^{(\mathrm{o})}$ and $\mathbf{I}$ defined as follows, where the expectation below is taken under $\boldsymbol{\theta}$:

$$\mathbf{I}^{(\mathrm{o})}_{pq}(\boldsymbol{\theta}) = -\frac{\partial^2}{\partial\theta_p \partial\theta_q} \log f(\mathbf{X}|\boldsymbol{\theta}),$$

$$\mathbf{I}_{pq}(\boldsymbol{\theta}) = \mathrm{E}\left[\mathbf{I}^{(\mathrm{o})}_{pq}(\boldsymbol{\theta})\right].$$

The matrix $\mathbf{I}(\boldsymbol{\theta})$ is called the Fisher information matrix, or sometimes, for emphasis, the expected information matrix. For a scalar parameter θ, the term used is simply Fisher information (*see* **Information**). The matrix $\mathbf{I}^{(\mathrm{o})}(\boldsymbol{\theta})$ is called the observed information matrix. Generally, the elements of the matrices $\mathbf{I}(\boldsymbol{\theta})$ and $\mathbf{I}^{(\mathrm{o})}(\boldsymbol{\theta})$ will have magnitude of order n.

The basic classic results concerning the information matrix are stated below. The most familiar setting for these results is that of independent, identically distributed (iid) observations, but they extend to more general settings. For the results to hold, certain technical conditions are required (see, for example, [4, Chapter 5]); such conditions generally hold in typical applied statistics settings. Below we denote the inverse of the information matrix $\mathbf{I}(\boldsymbol{\theta})$ by $\mathbf{V}^*$.

Cramér–Rao Inequality

Let $\tilde{\boldsymbol{\theta}}$ be any unbiased estimate of $\boldsymbol{\theta}$, and denote by $\mathbf{V}$ its **covariance matrix**. Then the matrix $\mathbf{V} - \mathbf{V}^*$ is nonnegative definite. In particular, in the case of a scalar parameter θ, this result says that the variance of any unbiased estimator of θ cannot be less than V^*. There also exists an asymptotic version of this result in which unbiasedness is replaced by asymptotic unbiasedness and covariance is replaced by asymptotic covariance.

Behavior of MLEs

The **maximum likelihood** estimate (MLE) $\hat{\boldsymbol{\theta}}$ of the true $\boldsymbol{\theta}$ is defined as the maximizer for given data $\mathbf{X}$ of the function $f(\mathbf{X}|\boldsymbol{\theta})$ over all $\boldsymbol{\theta}$. The estimator $\hat{\boldsymbol{\theta}}$ is approximately distributed according to the **multivariate normal distribution** with mean vector $\boldsymbol{\theta}$ and covariance matrix $\mathbf{V}^*$. In light of what was said above, this indicates an asymptotic optimality property of the MLEs.

Estimation of $\mathbf{V}^*$

The matrix $\mathbf{I}^{(\mathrm{o})}(\hat{\boldsymbol{\theta}})$ is a **consistent** estimator of $\mathbf{I}(\boldsymbol{\theta})$ in the sense that $\mathbf{I}(\boldsymbol{\theta})^{-1}\mathbf{I}^{(\mathrm{o})}(\hat{\boldsymbol{\theta}})$ **converges** to the identity matrix in large samples. Correspondingly, $\mathbf{I}^{(\mathrm{o})}(\boldsymbol{\theta})^{-1}$ consistently estimates $\mathbf{V}^*$.

The above results extend to more general forms of likelihood often encountered in biostatistics, including **quasi-likelihood** [3, Chapter 9] and partial likelihood [2]. Asymptotic optimality properties of MLEs in these more general settings also have been developed; see, respectively, [3, Section 9.5] and [1].

D.M. ZUCKER

Information

It is natural to try to quantify the amount of information provided by a set of data concerning an unknown quantity of interest. R.A. Fisher, in a classic 1925 work [1], proposed that the statistical information provided by a set of data on a parameter θ be defined as the inverse of the variance of an **efficient** estimator of θ. This quantity is equal to the Fisher information $I(\theta)$ defined in the article, **Information Matrix**. More broadly, one may define the information provided by a given estimator $\tilde{\theta}$, not necessarily an efficient one, to be the inverse of its variance. Intuitively, the lower the variance of an estimator, the more precisely it estimates the underlying parameter. Thus, the definition just given says simply that information equals precision.

The above concept of information arises in various contexts; here, we give two examples of interest in biostatistics.

The first example is the situation of combining several independent (asymptotically) **unbiased** estimates of the same parameter θ. This situation arises in a number of settings in biostatistics; for example, **stratified** analysis and **meta-analysis**. Typically, estimates are combined by weighted averaging. It is a classical result that the optimal method of weighting, in terms of minimizing the variance of the combined estimator, is to weight each individual estimate, $\tilde{\theta}_i$, according to the inverse of its variance, v_i. This result, which is an easy consequence of the Cauchy–Schwarz inequality, is the most basic version of the weighted **least squares** schemes that abound in applied statistics.

Intuitively, the weight assigned to a given estimate is in proportion to the amount of information contributed by that estimate. The variance of the combined estimator is easily derived, and by reciprocation the information content of the combined estimate is found to be the sum of v_i^{-1}. Thus, it is seen that the information content of an optimally weighted average of several independent estimates is equal to the sum of the information contents of the individual estimates.

The second example is the situation of sequential monitoring in clinical trials (*see* **Data and Safety Monitoring**). With certain popular monitoring schemes, particularly that of Lan & DeMets [3], it is necessary at each interim analysis to have some measure of how far the trial has progressed. A simple measure of trial progress is elapsed calendar time from the date the trial began. Some workers, however, argue that a more appropriate measure of trial progress is the proportion of statistical information accumulated by the time of the interim analysis, relative to the total amount of information that is expected to be accumulated by the planned end of the trial.

This measure of trial progress is often referred to as *information time.* The proportion of information accumulated is reflected fully by the sample size in certain special cases, but not in general. For instance, in a study monitored sequentially using the **logrank test**, the information is reflected by the number of events, while in a longitudinal study analyzed using a mixed linear model with a random slope and intercept for each subject, the information content is a function of the ratio of within-subject to between-subject variance and the observation pattern of the various individuals. See [4] for a more detailed discussion.

The foregoing conceptualizations of information are related, as will be indicated below, to S. Kullback's notion of discrimination information. Kullback's information measure, also known as relative entropy and by various other names, is in turn related to the entropy-based definition of information used in the Shannon–Weaver theory of information and coding. Consider a data vector $\mathbf{X}$ relating to the parameter θ. Let $f(\mathbf{X}|\theta)$ denote the joint density (or mass function) of $\mathbf{X}$ under θ, which, viewed as a function of θ, is the **likelihood** function. In addition, define

$$Z(\theta_1 : \theta_0) = \log \frac{f(\mathbf{X}|\theta_1)}{f(\mathbf{X}|\theta_0)},$$

which is the **likelihood ratio test** statistic for testing $\mathrm{H}_0 : \theta = \theta_0$ vs. $\mathrm{H}_1 : \theta = \theta_1$. Kullback defines the mean information for discriminating between these two hypotheses when the true θ value is θ_1 to be

$$\begin{aligned}\mathrm{Inf}(\theta_1 : \theta_0) &= \mathrm{E}_{\theta_1}[Z(\theta_1 : \theta_0)] \\ &= \int f(\mathbf{X}|\theta_1) \log \frac{f(\mathbf{X}|\theta_1)}{f(\mathbf{X}|\theta_0)} \, \mathrm{d}\mathbf{X},\end{aligned}$$

where the integral is replaced by a sum when $\mathbf{X}$ is discrete. Kullback demonstrates that this information measure possesses a number of basic properties that one would intuitively expect from an information measure. For example, the information provided by two random vectors $\mathbf{X}$ and $\mathbf{Y}$ is equal to the sum

of the information provided by **X** and the information associated with the conditional distribution of **Y** given **X**. For more detailed discussion, see [2].

Kullback shows, furthermore, by a Taylor expansion of the likelihood ratio, that if θ_0 and θ_1 are close and suitable regularity conditions hold, then

$$\text{Inf}(\theta_1 : \theta_0) \doteq \tfrac{1}{2} I(\theta_1)(\theta_1 - \theta_0)^2;$$

in the case of a vector parameter, the right-hand side becomes $\frac{1}{2}(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_0)^{\mathrm{T}} \mathbf{I}(\boldsymbol{\theta})(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_0)$, where $\mathbf{I}(\boldsymbol{\theta})$ here is the Fisher information matrix. Thus, there is a direct connection between Kullback's notion of information and Fisher's.

If the data are reduced down to some (not necessarily efficient) estimator $\tilde{\theta}$ of θ that is approximately normally distributed with mean θ, then the Fisher information of the reduced data is approximately equal to the inverse of $\text{var}_\theta(\tilde{\theta})$. This observation provides a further way of viewing inverse variance as information.

In particular, considering the **maximum likelihood** estimator (MLE) $\hat{\theta}$ of θ, assuming suitable conditions, it is known that when the sample size is large, the estimator $\hat{\theta}$ is approximately normal. Thus, if the data were reduced down to the MLE $\hat{\theta}$, then the Fisher information for the reduced data would be approximately equal to the inverse of $\text{var}_\theta(\hat{\theta})$. Now this quantity is equal precisely to the Fisher information for the unreduced data. In other words, the information contained in the MLE is approximately equal to the information in the entire data, reflecting the efficiency of the MLE.

This finding may be arrived at also by a route starting from the Kullback definition of information. Suppose that θ_0 and θ_1 are close and the sample size is large. Then, assuming suitable conditions, it is known that the likelihood ratio statistic $Z(\theta_1 : \theta_0)$ is approximately equivalent to the Wald statistic $Z_{\text{Wald}} = (\hat{\theta} - \theta_0)/\text{var}_\theta(\hat{\theta})^{1/2}$ [in practice $\text{var}_\theta(\hat{\theta})$ has to be estimated on the basis of $\hat{\theta}$] (*see* **Likelihood**). This statistic depends on the data only through $\hat{\theta}$, so that we see again that the information in $\hat{\theta}$ alone is approximately equal to the information in the entire data.

D.M. ZUCKER

Instrumental Variables in Health Services Research

The technique of instrumental variables (IV) was developed by econometricians in the 1930s and 1940s to address situations in which an **explanatory variable** or variables are correlated with the error term in an Ordinary **Least Squares regression**. In such a case, Ordinary Least Squares (OLS) methods produce inconsistent estimates of the regression coefficients. Because economists can rarely conduct controlled experiments, this situation arises frequently in analyses of economic data. As a result, IV methods have been widely used – many might say overused – in applied econometrics and are described in virtually every econometrics text (e.g. [5, Chapter 13], [6, Chapters 9, 13], [2, Chapter 7], [4, Chapters 9, 13, 16], [10, Chapter 10]). In the 1990s, IV methods began to be used in **health services research** to analyze observational data, where they have achieved a modicum of popularity [3, 7, 8].

I first give an intuitive explanation of the method and then sketch it more formally. I next describe an actual example and conclude by emphasizing the limitations of the IV estimator.

The essence of the IV method is to purge the explanatory variable(s) in a regression equation of the portion of its (their) **variance** that is not independent of the error term and then estimate the relationship between the dependent variable and the remaining variance. (In econometrics, the variation that is independent of the error term is referred to as exogenous, whereas the variation that is not independent is referred to as endogenous.) (*See* **Structural Equation Models**.) The purging is done by finding another variable or variables that are termed instrumental variables and that satisfy two assumptions. First, the IVs are independent of the error term in the regression of interest. Second, they are correlated with the explanatory variable(s) in question. Another way to say this is that the IVs have a direct effect only on the explanatory variable; they have no direct effect on the dependent variable. This is illustrated in Figure 1. The arrows indicate causal relationships; for a variable to be an IV, there must be no arrow from the IV directly to the dependent variable. There must be at least one IV for each explanatory variable that is not independent of the error term.

The effects on the dependent variable of the variation that the IV induces in an explanatory variable of interest can be estimated; that is, the covariation between the induced variation and the dependent variable can be used to estimate a regression coefficient. The results, however, should not be extrapolated outside the region of induced variation. Although such a caution is always appropriate in regression analysis, it applies with even more force here because the range of variation may be sharply reduced relative to the total variation in the observed explanatory variable (i.e. the sum of the exogenous and endogenous variations).

Although IV methods were developed for nonexperimental data, the simplest example of an IV comes from the **randomization** process in a **clinical trial**. Suppose subjects are assigned to the treatment or the control group by flipping a fair coin. As is well known, assuming no refusal and no attrition, the difference in the mean outcomes between the experimental and control groups is an **unbiased** estimate of the treatment effect.

In this case, the IV is the outcome of the coin flip. By definition, the outcome of the flip has no effect on the observed clinical outcome in any patient other than through its effect on assignment to the treatment group. Hence, the variation that the coin flip induces in assigning subjects to treatment and control groups is independent of the error term in a regression explaining outcomes. Moreover, given no refusal or attrition, it perfectly explains the assignment of subjects to treatment or control groups. Thus, it satisfies both assumptions of an IV. By contrast, in observational data, those assigned a particular medical treatment may be sicker or healthier in unobserved ways than those not given the treatment, which means the difference in outcomes between the two groups is a biased estimate of the effect of the treatment. Indeed, this is the reason randomized controlled trials are preferred to **observational studies** for estimating the effects of medical treatments.

More formally, suppose one has a sample of N observations that come from the following structure:

$$\mathbf{Y} = \mathbf{X}\beta + \varepsilon. \tag{1}$$

Let $\mathbf{Y}$ be an $N \times 1$ vector of observations on the dependent variable, $\mathbf{X}$ an $N \times k$ matrix of observations on k explanatory variables (the first column of X may be a vector of ones to allow for an intercept term), β a $k \times 1$ vector of constants to be

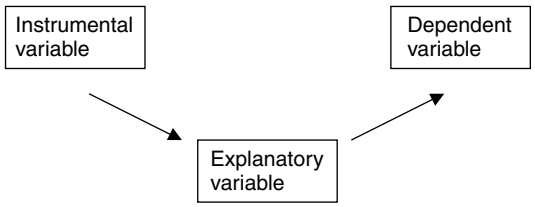

Figure 1 There is no arrow from the IV directly to the dependent variable because all of the effect of the IV on the dependent variable is through its effect on the explanatory variable. Moreover, only the variation in the explanatory variable induced by the IV is used to estimate the relationship between the dependent variable and the explanatory variable

estimated, and ε an $N \times 1$ vector of errors, which has distribution $F(0, \sigma^2)$. Let

$$b = (\mathbf{X}'\mathbf{X})^{-1}(\mathbf{X}'\mathbf{Y}) \text{ be the OLS estimator of } \beta. \quad (2)$$

Substituting (1) into (2), $\mathrm{E}(b) = \beta + \mathrm{E}(\mathbf{X}'\mathbf{X})^{-1}(\mathbf{X}'\varepsilon)$. If $\mathbf{X}$ and ε are not independent, the second term is nonzero and b is a biased estimator of β.

Let X_i represent a subset k' of the k variables of $\mathbf{X}$ that are not independent of ε ($k' \leq k$), and let $\mathbf{Z}$ be an $N \times m$ matrix of observations on m variables that are correlated with X_i but are independent of ε ($k' \leq m$). Then

$$b^{\mathrm{IV}} = (\mathbf{Z}'\mathbf{X})^{-1}\mathbf{Z}'\mathbf{Y} \text{ is the IV estimator of } \beta. \quad (3)$$

b^{IV} is a consistent estimator of β, as can be seen by substituting (1) into (3).

I turn now to an example of IV in health services research that is taken from [7]. These authors worked with a sample of Medicare patients over 65 who had suffered an Acute Myocardial Infarction (AMI or heart attack) (*see* **Medicare Data**). Motivated by the high geographic variation in procedure rates, they sought to answer the question whether cardiac catheterization followed by possible revascularization (either a coronary artery bypass graft or angioplasty, both of which open coronary arteries and provide for increased blood flow to the heart) achieved better outcomes than no cardiac catheterization. (Catheterization is always done prior to either revascularization procedure.) There were, of course, clinical trials of all these procedures, but the clinical trial results posed two difficulties in this context: (1) The trials often excluded those over 65, but around half the AMIs annually in the United States occurred among that group. Yet the benefits of the procedures had been well enough established among younger persons that it almost certainly would have been unethical to conduct a trial among the elderly; (2) The trials had been conducted in major medical centers, and it was not clear that the results applied to patients in community hospitals.

The principal IV the authors used in this example was the incremental distance from the patient's residence to a hospital with a catheterization facility relative to a hospital with no such facility. If the nearest hospital had a catheterization facility, the incremental distance was zero. This IV exploited the notion that patients who suffer an AMI tend to go to the nearest hospital and that therefore the distribution of the severity of the AMI, an unobserved determinant of both mortality and treatment, would be approximately the same at various distances. Thus, distance acted something like the flip of a coin in the clinical trial example; those living near a hospital with a catheterization facility were more likely to be treated in that fashion than patients living further away, but distance seemed independent of the severity of the heart attack, the principal factor other than treatment determining survival.

The assumption that distance is independent of mortality except through its effect on treatment must ultimately be taken on faith, although there are various tests of the plausibility of this assumption. One straightforward test is that observable variables that affect mortality should also be approximately independent of distance. Of course, the observable variables that affect mortality can be controlled for in a regression. As a result, if they are not independent of distance, that dependence will not cause the estimates to be inconsistent; nonetheless, such dependence undermines one's confidence that unobserved variables are independent of distance.

The first two columns of data in Table 1 show differences in both observable variables and outcomes for individuals who received a catheterization within 90 days of their AMI and those who did not; the last two show differences between those individuals who lived within 2.5 incremental miles of a hospital with a catheterization facility and those who did not. Both the observable covariates as well as the outcomes differ markedly between the groups that did and did not receive a catheterization (the first two columns). Mortality at four years in these

Table 1 Relationship between outcome and catheterization in groups sorted by procedure and by differential distance (%, except for age and number of observations)

	No catheterization within 90 days	Catheterization within 90 days	Incremental distance ≤ 2.5 miles	Incremental distance > 2.5 miles
Female	53.5	39.7	51.3	49.5
White	90.4	91.8	89.0	92.3
Age in years	77.4	71.6	76.1	76.1
Cancer	2.2	0.85	10.4	11.0
Pulmonary disease, uncomplicated	11.1	9.3	18.1	18.0
Diabetes	18.3	17.1	4.8	4.8
Cerebrovascular disease	5.4	2.8	45.4	5.0
Admit to cath hospital[a]	40.9	62.9	45.4	5.0
Admit to revasc hospital[a]	21.6	41.6	41.7	10.7
Admit to high-volume hosp[a]	50.0	58.0	67.1	36.5
90-day catheterization rate	0.0	100.0	26.2	19.5
One-day mortality	10.3	0.9	7.50	8.88
Seven-day mortality	22.0	3.3	16.80	18.59
30-day mortality	26.6	7.4	24.86	26.35
One-year mortality	47.1	16.6	39.79	40.54
Two-year mortality	55.3	21.3	47.20	47.89
Four-year mortality	66.7	29.9	58.06	58.52
Number of observations	158 261	46 760	102 516	102 505

[a]Catheterization hospital is one that carried out five or more catheterization procedures on patients in the sample and that is not a revascularization hospital; revascularization hospital is one that carried out ten or more revascularizations on patients in the sample; high-volume hospital is one that treated 75 or more of the AMI admissions in the sample.

two groups differs by more than a factor of two (29.9 versus 66.7%), and controlling for the observed covariates such as age does little to diminish this difference (results not shown). If those catheterized had the same distribution of unobserved factors affecting mortality as those not catheterized, one would conclude that catheterization followed by possible revascularization had a huge effect in reducing mortality.

But cardiologists and cardiac surgeons are less aggressive with those who are less healthy; for example, those who might not survive an invasive procedure are unlikely to be given one, but they are at greater risk for mortality independent of whether they receive a procedure. Hence, receipt of the procedure is correlated with the error term. The difference between the groups that did and did not receive a catheterization is strikingly illustrated by the difference in mean age; the group receiving catheterization was on average 71.6 years old, much younger than the 77.4 years average in the group that did not receive the procedure (recall that everyone in the sample was over 65 years of age). Furthermore, the group receiving the procedure had fewer **co-morbidities**, consistent with their being a generally healthier group.

The two rightmost columns divide the sample into approximately equal halves according to differential distance. Although one can exploit all the variation in an IV (in this example that means treating distance as a continuous variable), simply dividing the sample into two groups according to the value of the IV, as is done here, will show whether the observed covariates tend to be independent of the IV. In this example, the mean age in the groups sorted by incremental distance is the same to three significant digits, and the **prevalence** of co-morbidities is much more similar than in the first two columns, suggesting that distance is a reasonable choice as an IV.

From the data in these two columns, one can also derive a simple IV estimate of the effect of catheterization and possible subsequent revascularization on four-year mortality. The estimator is the difference in the mortality rates divided by the difference in the

catheterization status or:

$$\text{Estimated catheterization effect} = \frac{\Delta(\text{4-year mortality})}{\Delta(\text{catheterization})} = \frac{(58.06 - 58.52)}{(26.2 - 19.5)} = \left(\frac{-0.46}{6.7}\right) = -0.069. \quad (4)$$

In other words, an increment of one percentage point in the catheterization rate reduces the four-year mortality by about 0.07 percentage points, or about 7 in 10 000, a vastly smaller effect than would have been estimated from the first two columns, where a 100 percentage point difference in catheterization rates was associated with a 36.8 percentage point difference in mortality.

The exercise shown in the table of splitting the sample on the value of the IV is also helpful in showing the range of variation that the IV induces. In this case, just under 20% of the more distant group received a catheterization, whereas just over 26% of the group in the sample closer to the hospital received a catheterization. A finer grouping of individuals by distance somewhat expands this range from 18 to 28%.

This range illustrates an important difference between IV and a clinical trial. Ignoring refusal and attrition, the randomization in a clinical trial results in one group in which 100% of the subjects receive a treatment, the treatment or experimental group, and another group in which none of the subjects receives the treatment, the control group. The denominator in the analog to (4) thus is 100-0 or 100. The numerator is simply the difference between the outcomes in the two groups, so in this case (4) gives the usual trial result that the difference between the treatment and control group is the estimated treatment effect (dividing the percentage difference by 100 means the difference is expressed as a proportion).

By contrast, the IV result only gives the effect of increasing the catheterization rate from approximately 20% to approximately 26% (with the finer gradation of distance, this range becomes 18 to 28%). The difference between these two rates represents patients who were catheterized if they lived near a hospital with a facility but were not if they lived farther away. Another implication is that around 18 to 20% of patients were catheterized no matter where they lived (they were presumably transferred if they were initially admitted to a hospital with no catheterization facility), and around 72 to 74% of patients were not catheterized irrespective of where they lived. The data are uninformative about each of these two latter groups because there is no variation in treatment according to place of residence. It is therefore imprudent to use the estimated effect size of −0.069 to estimate what might happen to mortality if the catheterization rate fell much below 18% or rose much above 28%.

Another way to say this is that the IV estimate is informative about the person who might be called the marginal patient, namely the patient who receives a catheterization if it is convenient but not otherwise. A clinical trial, on the other hand, yields the effect of the procedure on the average patient. If the range of the IV is very large, from near zero to near 100%, the IV estimate tends toward the clinical trial estimate. As the example of the clinical trial as IV illustrates, the limiting case of the marginal effect is the average effect.

Although the IV estimator can be a highly useful tool, the two necessary assumptions required for a valid IV may be limiting. In practice, it can be difficult to find variables that are plausibly independent of the outcome of interest, except through their effect on the explanatory variable, but that induce enough variation in the explanatory variable to yield an estimate of interest. If there is little induced variation there is little power for estimating an effect, and large samples tend to be required. Less obviously, if the IV induces only a small amount of variation in the explanatory variable, the IV result will be biased toward the OLS result [1] and [9]. How much induced variation is needed to render the bias unimportant? A rough rule of thumb comes from running a regression of the explanatory variable of interest on all the covariates as well as the IV(s). In the simple case of one explanatory variable, the bias is proportional to the reciprocal of the incremental F-statistic on the IV(s) in this regression; with more than one variable correlated with the error term, the reciprocal of the F-statistic is an approximation (*see* ***F*** **Distributions**). For a derivation of this result see [9].

JOSEPH P. NEWHOUSE

Instrumental Variables

Permutt & Hebel [13] describe an analysis of the results of conducting a randomized **clinical trial** [15] using what is often called an encouragement design. Pregnant women who were cigarette smokers were randomized into two groups: those who received encouragement to reduce or stop their smoking, and those who did not (the controls). Two outcome measures were recorded: (a) the number of cigarettes smoked per day in the eighth month of pregnancy (S), and (b) the birth weight of the baby (B). Permutt & Hebel were concerned with the estimation of the **causal** effect of S on B, whilst acknowledging that the observed **association** between S and B might be subject to **confounding** (and, although they do not mention this characteristic, the measure of smoking frequency is also subject to **measurement error**). In order to solve their estimation problem, the authors made use of the randomization indicator (R), assuming that R is likely to be highly correlated with S but only has any effect on B through its effect on S (that is, conditional on S, randomization has no effect on B). In this context, the variable R is called an *instrumental variable*. Although instrumental variable methods had previously been widely used in econometrics, the Permutt & Hebel paper was one of the first examples of its use in a medical application. Another starting point for much of the work on adjustment for **selection** effects (particularly to adjust for the effects of noncompliance in randomized controlled trials (RCTs)) is the work of Bloom [1], Sommer and Zeger [16] and Robins [14] – (*see* **Noncompliance, Adjustment for**).

Consider two observed **random variables**, X and Y. X and Y could be quantitative or **categorical** (**binary**, for example) and they might be subject to measurement errors (**misclassification errors** in the case of binary variables). X and Y are assumed to be associated but their association might also be subject to hidden confounding (selection effects). The variables T_x and T_y are the true underlying values of X and Y (i.e. without measurement or misclassification errors), respectively. E_x and E_y are the corresponding measurement errors (assumed to be independent). Our aim is to estimate the strength of association between T_x and T_y after adjustment for any possible confounding. This might be via the estimation of a **regression** coefficient, for example, a **correlation** or an **odds ratio**. Is it possible to find a **consistent estimator**? Not without some unrealistic assumptions or further information. One might record the values of several potential confounders, for example, but there still might be the possibility of the existence of confounders that we have never thought of. We might also be able to obtain information on the characteristics of the measurement processes for X and Y (the variance of the respective measurement errors if they are quantitative, or of their **sensitivities** and **specificities** if they are binary), but there is no guarantee that the measures are performing in exactly the same way in the different circumstances. An alternative approach, and potentially a very useful one, is to obtain further information in the form of measurements of an *instrumental variable*. Suppose that we have access to a third variable, Z, which is strongly associated with T_x, but conditional on T_x has no effect on Y. Z is called an instrumental variable. Its potential will be illustrated through several familiar applications.

But, let us start by considering three hypothetical quantitative measures, X, Y, and Z. We describe the influence of Z on X through a simple **linear regression** model and, similarly the influence of X on Y through another simple linear model. But remember that X and Y are both subject to measurement error and we are really interested in the influence of T_x on T_y. A graphical representation to illustrate this general situation is provided by the **path** diagram in Figure 1. T_x and T_y are placed within circles to stress the fact that they are latent variables (unobserved, and possibly unobservable), whereas the observed or manifest variables, X, Y, and Z are themselves placed in square boxes. The key parameter we wish to estimate is the regression coefficient marked as β in this path diagram. The other important regression coefficient is marked as γ. Confounding is represented by the correlation (ρ) between the two random disturbance terms, D_x and D_y. A "1" next to an arrow on the path diagram implies that the corresponding regression coefficient is set to be 1 (i.e. $X = T_x + E_x$, for example). Although the full model described by the path diagram is hopelessly under **identified**, the parameter β is identified and it can be estimated in a number of equivalent ways. The approach we start with is to write down the expected

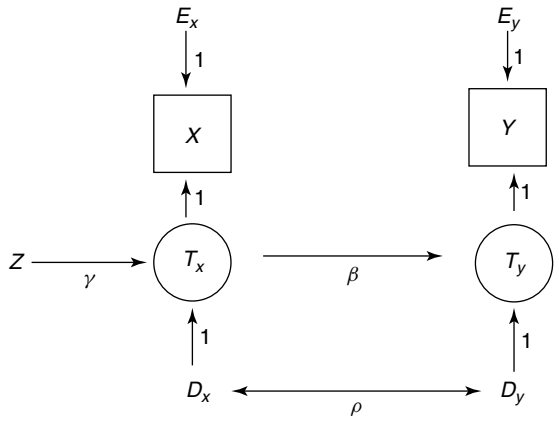

Figure 1 Illustration of a model in which we wish to estimate the effect of T_x on T_y in the presence of measurement errors (we only have observations on the error-prone variables X and Y) and selection effects (correlation between D_x and D_y). Unbiased estimation is the only problem because we also have a measure on an instrumental variable, Z

values of the covariance of Z and X, and that of Z and Y:

$$\text{Cov}(Z, X) = \gamma \text{Var}(Z) \tag{1}$$

$$\text{Cov}(Z, Y) = \gamma\beta \text{Var}(Z). \tag{2}$$

It follows immediately that:

$$\beta = \frac{\text{Cov}(Z, Y)}{\text{Cov}(Z, X)}. \tag{3}$$

One possible estimator for β is then obtained by simply estimating these two covariances from the data and substituting these estimates into (3). This is equivalent to

$$\widehat{\beta_{IV}} = \frac{\sum (Z - \overline{Z})(Y - \overline{Y})}{\sum (Z - \overline{Z})(X - \overline{X})}, \tag{4}$$

where the summation is over all subjects/observations in the dataset. It is also equivalent to

$$\widehat{\beta_{IV}} = \frac{\widehat{\beta_{yz}}}{\widehat{\beta_{xz}}}, \tag{5}$$

where $\widehat{\beta_{yz}}$ is the slope estimate obtained from the ordinary **least squares** (OLS) regression of Y on Z, and $\widehat{\beta_{yz}} = \widehat{\gamma}$ is the corresponding estimate from the OLS regression of X on Z.

Another starting point is to write down the OLS estimate for the intercept, α, and slope, β, as the solution to

$$\frac{1}{N} \sum X(Y - \widehat{\alpha_{OLS}} - \widehat{\beta_{OLS}} X) = 0, \tag{6}$$

where N is the number of observations. In our situation, of course, these estimates will be biased. It can be shown that the corresponding instrumental variable (IV) estimates are obtained from the solution to

$$\frac{1}{N} \sum Z(Y - \widehat{\alpha_{IV}} - \widehat{\beta_{IV}} X) = 0. \tag{7}$$

These are both special cases of generalized **method of moments** (GMM) estimators [7].

By far the most common IV estimation procedure, however, is the use of OLS regression in two stages – ***two-stage least squares*** (2SLS or TSLS). First one regresses X on Z to obtain the predicted value of X, that is $\widehat{X}$. The second stage involves the regression of Y on $\widehat{X}$. The estimate of the slope from the second stage is the equivalent to $\widehat{\beta_{IV}}$ above. If we were to actually do this in two stages, we would have to be aware that the second regression would give an incorrect **standard error** for $\widehat{\beta_{IV}}$. Most general-purpose **software** packages have a 2SLS routine that provides the correct standard errors and corresponding ***P* values**. The asymptotic variance of $\widehat{\beta_{IV}}$ is, in fact,

$$\text{Var}(\widehat{\beta_{IV}}) = \frac{\sigma_u^2}{N\sigma_X^2 \rho_{XZ}^2}, \tag{8}$$

where σ_X^2 is the variance of X, σ_u^2 is the variance of the deviations $u = Y - \widehat{\alpha_{IV}} - \widehat{\beta_{IV}} X$ and ρ_{XZ}^2 is the square of the correlation between X and Z (see [6] or [21] for further details). Note that, keeping everything else constant, this variance decreases with increasing values of the correlation between X and the instrumental variable Z. Note also that neither the IV estimate itself nor its asymptotic variance is dependent on any distributional assumptions. In particular, both Z and X could be binary (see section on adjustment for noncompliance in an RCT, below). If we have covariates other than the instrumental variable (or instrumental variables if we can find more than one) then the first stage of 2SLS involves the regression of X and the covariates. The second stage involves regressing Y on $\widehat{X}$ and the same covariates [21].

One final approach to IV estimation for the linear model is again a two-stage procedure. The first stage, as before, involves the regression of X on Z. But in this case we keep the **residuals** from the regression for the next stage, rather than the predicted values of X. The second stage involves the regression of Y on *both* the observed X *and* the residual from the first stage regression (see [11], for example). Again, the estimate is equivalent to $\widehat{\beta_{IV}}$ as defined above. Once again, we need care in the estimation of the correct standard errors.

IV estimation, in general, and 2SLS estimation, in particular, appear to be rarely used in medical applications (and when IV methods are used they frequently do not get an explicit description as such), with the obvious exception of the application of **econometric applications in health services** research. The methods are rarely mentioned in medical statistics texts. The general econometrics literature on IV estimation via 2SLS (and other more complex estimation methods), however, is vast. It is one of the most widely used statistical methodologies in econometrics (after OLS methods). Any textbook on econometrics will contain at least a chapter on IV/2SLS methodology. Good introductions can be found in [19, 20, 21]. Advanced topics can be found in [7]. A range of methods of IV estimation for the linear model has been provided in this section, partly to point out the equivalence of the several different approaches in the context of linear models, but mainly because they each can provide an approximate solution for nonlinear problems (**logistic regression** models in epidemiology, for example).

Estimation of Treatment or Exposure Effects in Biostatistics

Elementary reviews of the use of instrumental methods in outcomes of treatment research and in epidemiology are provided by [8, 12]. Research on the outcomes of treatment using instrumental variable methodologies has tended to concentrate on the problems of selection effects in the choice of treatments (for the special case of noncompliance in randomized studies, *see* **Noncompliance, Adjustment for**). On the whole, measurement errors in the classification of treatment received, or in the amount of treatment received, have not received much attention. In epidemiology on the other hand, it is the problem of **exposure** measurement that has lead to a surge of interest in instrumental variable methods (*see* **Measurement Error in Epidemiologic Studies**). Stefanski and Buzas [18], for example, have developed instrumental variable estimation methods in binary regression models using exposure measurements subject to measurement errors. These authors have used approximations to those in the linear model, such as the use of (3), for example, in which the two regression coefficients are obtained from the appropriate logistic regressions instead of OLS. The use of 2SLS itself does not appear to be very satisfactory for nonlinear instrumental variable regression problems (see Foster [5], for example, who advocates GMM-based methods). Nagelkerke et al. [11], however, successfully apply the second of the two-stage methodologies described above to a range of nonlinear models involving noncompliance with randomized treatment allocation. An interesting example of the development of the IV method to test some of the assumptions of a measurement error model is provided by Spiegelman et al. [17]. For a general and detailed discussion of exposure **measurement error problems in epidemiology**, readers are referred to the article in the present encyclopedia and to [2]. Greenland [8] describes how an instrumental variable can be used to adjust for hidden confounders in an epidemiological study.

Method Comparison Studies

Consider a study in which we wish to compare either two quantitative methods of measurement or two binary **diagnostic tests**. In neither case do we have access to a **gold standard** (*see* **Diagnostic Test Evaluation Without a Gold Standard**). An appropriate measurement model for two quantitative measuring instruments, X and Y might have the following form:

$$\begin{aligned} \mathrm{X} &= \alpha_{\mathrm{x}} + \beta_{\mathrm{x}}\tau + \delta, \\ \mathrm{Y} &= \alpha_{\mathrm{y}} + \beta_{\mathrm{y}}\tau + \varepsilon, \end{aligned} \tag{9}$$

where τ is "true" value of the material being measured, the α's and β's are the parameters of the two regression equations, and δ and ε are random measurement errors (assumed to be independent of each other and of the true value, τ). Our aim is to estimate the regression coefficients, together with the

variances of the measurement errors. The data from such a study can be summarized by the means and variances of X and Y, together with their covariance. Clearly, the model described by (9) is underidentified (there are far too many parameters to be estimated from the small number of summary statistics). We first need to specify a scale of measurement. One convenient way of doing this is to consider one of the methods as a standard (X, for example, by setting $\alpha_x = 0$ and $\beta_x = 1$). But the model is still underidentified. We cannot estimate the free parameters of the model without either making further assumptions or by obtaining further data. One useful approach for the latter is to obtain a third measurement, Z, that is correlated with the true value (τ) but conditional on τ is uncorrelated with both X and Y. Z is an instrumental variable. One obvious choice for Z is a third measurement of τ, taking care to ensure that the measurement errors for Z are not correlated with those of either X or Y. It is now straightforward to estimate all of the free parameters of the model (β_y, for example, is obtained from (3)). Details can be found in [3, 4, 6].

In the case of the comparison of two binary diagnostic tests (X and Y), we start by postulating the existence of a binary **latent class** (the "true" diagnosis) and related the observed tests results to the true status of the patient through a latent class or finite mixture model. With only two diagnostic tests, however, the model is underidentified [9]. We need more information. Again, we resort to an instrumental variable, Z. Z could be either categorical (but not necessarily binary) or quantitative. The only requirement is that it is strongly associated with the true status of the patient, but conditional on that true status is independent of both X and Y. Z, of course, could be a third diagnostic test. Details can be found in [4, 9, 10]. In all the applications of instrumental variable methods, the existence of measurements on a single instrumental variable enable us to get a handle on the estimation of otherwise unidentified model parameters. If we have data on more than a single instrumental variable, however, not only can we get even better estimates, but we might also be able to use the extra information to check the validity of our modeling assumptions. In the context of method comparison studies, for example, models involving three variables are just identified. That is, they fit the data perfectly and there is no way of testing whether any of the necessary assumptions might be invalid. If we have four or more measurements, however, we have the possibility of an overidentified model together with degrees of freedom to test model fit. Nagelkerke et al. [10] provide a nice example involving diagnostic tests. Dunn & Roberts [3] illustrate the point with quantitative measures.

Intention to Treat Analysis

Intention-to-treat (ITT) analysis (also referred to as "as-randomized" or "method effectiveness" analysis [25]) is defined in the context of a randomized **clinical trial** (RCT). In a RCT design for the comparison of treatments, subjects are randomly assigned to different treatments. Once this **randomized assignment to treatment** is made, the ITT principle requires that any comparison of the treatments is based upon comparison of the outcome results of all patients in the treatment groups to which they were randomly assigned. This approach is recommended to maintain the benefits of randomization.

Randomization provides two important features. First, the treatment assignment is based on chance alone. The characteristics of the group of patients receiving the different treatments should be roughly equivalent at the onset of the trial, with the only difference being their treatment assignment. If, during the implementation of the trial, the groups continue to be distinguished only by their treatment assignment, then any differences in the outcomes of the groups at the end of the study (*see* **Outcome Measures in Clinical Trials**) can be attributed solely to difference in treatment. Secondly, randomization provides the theoretical foundation for the statistical tests of significance that are used to test for observed differences (*see* **Randomization Tests**) [2, 7]. These two benefits of randomization are the foundations of the science of comparative clinical trials.

Unfortunately, once a clinical trial begins, several predictable, as well as unforeseen, conditions can (and usually do) influence the actual vs. the intended protocol under which individual subjects in each group are studied (*see* **Clinical Trials Protocols**). Thus, the groups, as treated, may no longer be comparable at the end of the trial. These circumstances may include: subjects who do not adhere to the assigned treatment regimen (*see* **Compliance Assessment in Clinical Trials**); subjects whose eligibility for trial participation has changed or was incorrect at the start of the trial (*see* **Eligibility and Exclusion Criteria**); subjects whose treatment assignment was incorrect; or subjects who terminate participation in the trial prior to the measurement of the main clinical outcome.

Partial or complete noncompliance with the regimen of the assigned treatment is fairly common in medical treatment trials. Patients may not be able to tolerate the side effects of their randomly assigned treatment and may request the termination of all medication or switch to another of the study treatments. Less common is a clerical or computer error that results in a patient being given medication other than that randomly assigned. Although such patients may take their medication faithfully, they will be noncompliant with their assigned treatment. In the extreme, widespread failure to comply with the assigned regimen can destroy a study. For example, in a trial comparing an active treatment with a control, if nearly all of the subjects randomly assigned to the active treatment do not take the drug, then a comparison of efficacy between the two groups will be meaningless. Less extreme, but very common, are instances where patients do not take the prescribed dosage of a treatment, or take the drug intermittently or for a limited duration [9, 25].

It is expected that, in general, there will be reasonable adherence to protocol in a substantial proportion of patients within each of the treatment groups. For those subjects not adhering to the protocol, the question may be raised as to whether they should be excluded from the analysis, the concern being that they do not provide information relevant to the efficacy of treatment taken as prescribed. By definition, ITT analysis does not allow treatment comparisons using only those subjects compliant with the therapies under test. Use of ITT analysis requires, with very few exceptions, that all subjects with valid outcomes be (i) included in the analysis and (ii) analyzed according to their randomly assigned treatment. Subjects who comply with their randomly assigned treatment for only a short time after its initiation, or switch to a competing treatment, are still considered, for analysis purposes, in their randomly assigned treatment group. This ensures that the randomization is protected; that is, the treatment groups can be assumed to include patients equivalent prior to the onset of therapy, and the possibility that the analysis could have been inadvertently biased by "selective" exclusion or inclusion of subjects into treatment groups is eliminated (*see* **Selection Bias**).

Contrary to the strict interpretation of the ITT principle, investigators may attempt to compare groups defined not solely by the original randomization but by factors that might be influenced by the treatments

under test. In the face of substantial noncompliance, the comparison of only those patients in the trial that actually complied with the prescribed treatment is intuitively appealing. However, in addition to the difficulty of defining compliance in an objective manner, it has been seen that subjects who comply tend to fare differently and in a sometimes unpredictable way from those who do not comply [1, 3, 14, 27]. Thus, any observed differences among treatment groups constructed in this manner may be due not to treatment, but to factors associated with compliance.

The ITT analysis approach often provides a conservative estimate of the effect of a treatment administered as prescribed. The inclusion of noncompliant patients in the assessment of efficacy, barring some peculiar **dose–response** relationship, dilutes the difference between outcomes in the treatment and control groups. For the same reasons, ITT analysis may underestimate the risk of adverse side effects.

The ITT approach may be viewed as evaluating a *treatment strategy,* as contrasted to evaluating the efficacy of a treatment taken as prescribed [14]. The effectiveness of a treatment strategy is a reasonable approximation to the effectiveness of a prescribed regimen in the community [18]. Patients prescribed a treatment outside of a clinical trial often exhibit the same or an increased level of noncompliance, without the extra encouragement to comply that is provided in most clinical trials.

In contrast to the issue of noncompliance with the study treatment regimen, the determination of a subject's eligibility for trial participation after initiation of randomized treatment is a circumstance where many clinical trialists feel that a strict interpretation of the ITT principle can produce study results that are simply not credible [9, 15]. For example, in a comparative study of treatments for sepsis in newborns, treatment must usually be started as soon as there is a presumptive diagnosis of sepsis. Sepsis is too dangerous to be left untreated, and definitive laboratory tests are not immediately available, so treatment is usually started at the first sign of infection. If subjects with a presumptive diagnosis are assigned treatment by randomization, then a portion in each of the treatment groups will be later proven not to have had sepsis. Strict application of the ITT principle requires that the subjects proved not to have had sepsis nevertheless be included in the analysis in the treatment group to which they were assigned. A more relaxed application acknowledges that sepsis was or was not present *prior to randomization* and that its presence *was not known* due to the absence of confirmatory laboratory information. Thus, the exclusion from analysis of those patients without sepsis, and thus ineligible for the trial, would be appropriate since there is no conceivable way in which the treatment assignment could have influenced which subjects previously had sepsis. The choice of analysis in this example affects not only the credibility of the study report, which might have included in the analysis patients without sepsis, but also the measure of the effect of treatment. Including the subjects without sepsis in the treated groups would provide biased estimates of efficacy, since those without the disease would be counted as cured. In contrast, for the assessment of safety, inclusion of all subjects with and without a definitive diagnosis of sepsis is reasonable. The larger sample size will allow for the detection of differences in rarer side effects.

There is a concern that if exceptions to ITT analysis, as in the sepsis example above, are routinely allowed, then analysts will inevitably be tempted to adopt exceptions or exclusions that do **bias** the results of a study. An example, not as clear as the sepsis trial, is the administration of a study drug other than that actually assigned. This can happen on rare occasions because of a clerical error at the start of treatment, or, more commonly, because a subject decides to change medication early in the course of their assigned treatment. The first example seems simple enough; an unintentional clerical mistake resulted in an incorrect drug being dispensed. It might, therefore, be reasonable to include the subject in the analysis as having taken the received treatment. The second example, however, raises severe problems, since the drug itself may have caused the switch, possibly due to a perceived lack of efficacy or unpalatable side effects [19]. Most analysts would consider the latter example to constitute crossing the ITT "line in the sand".

Patients dropping out of a clinical trial before their endpoint can be measured can bias a study severely regardless of the analysis approach utilized. If, for example, one of the tested treatments has unpleasant side effects, patients with mild disease might view the side effects as a hardship when contrasted to their mild affliction, and discontinue participation. This would create an imbalance among the treatment groups with regard to severity of disease. Information on some clinical outcomes such as mortality might be obtainable given enough time, even if a subject drops

out from a study. Other outcomes, such as laboratory evaluations at a specific time point after baseline, will not be available from alternative sources. Clinical trials should be designed and organized with the resources available and directed so that dropouts will be minimal and hopefully at random [8]. Several authors have proposed methods for imputing data for patient endpoints on the basis of previous data obtained in the study [4, 11, 13, 16], although Lachin [12] points out that of "... the majority of methods in common use ... none allow or adjust for the bias introduced by nonrandomly censored or missing observations" (*see* **Missing Data in Clinical Trials**).

The above discussion has centered around comparative trials of efficacy, with the primary example the comparison of an active treatment with a placebo, and the inherently conservative nature of an ITT analysis has been mentioned. A large number of clinical trials, known as **equivalence trials**, seek to show that a new treatment is equal to an established treatment with regard to efficacy, while being less toxic or less expensive. Suppose that the new drug, however, is less efficacious than the established drug. If subjects who fail to comply with their assignment to the new treatment, or who switch to the standard treatment, are, for analysis purposes, considered in the group to which they were originally assigned, the difference between outcomes in the two groups is brought closer together. The established treatment group will include subjects taking the less effective treatment or taking no treatment, and the new treatment group will include subjects taking the more effective treatment and/or no treatment. Thus, the ITT approach for equivalence trials may tend to mask true differences, making it easier to conclude that treatments are equivalent when they are, in fact, not [15].

Statisticians and clinical trialists generally agree that some form of the ITT principle is appropriate for most efficacy trials. The strictness of application of the principle still raises considerable discussion.

Alternative Analysis Strategies

Alternatives to ITT analysis generally attempt either to restrict analysis to those subjects who have adhered to a treatment protocol, or to incorporate measures of compliance to treatment in comparative analyses. Many titles have been given to the first of these approaches including "as-treated analysis" [6], "treatment received" [20], "explanatory approach" [24], "method effectiveness" [25], "per-protocol" [25], "efficacy analyzable patients" [9], and "biologic efficacy" [26]. The phrase "as-treated" (AT) analysis will be used in this article.

In AT analysis (i) only patients considered compliant with one of the study treatments are included in the analysis, and (ii) outcomes of subjects are attributed to the treatment groups on the basis of the treatment actually taken, regardless of their randomly assigned treatment. It is argued that the primary interest of a comparative clinical trial is in testing whether a treatment, taken as prescribed, is effective. In contrast, the ITT approach dictates that all subjects be included in the analysis, even those who have not taken the prescribed treatment; and that subjects who have complied with a study treatment other than that assigned by randomization nevertheless be counted as having taken the assigned treatment. The ITT approach is counterintuitive to many clinicians and other scientists. It is considered by AT proponents as incorrect, and it is understood by those arguing for either ITT or AT analysis that ITT analysis will, in the face of noncompliance, provide a diluted estimate of efficacy.

The primary argument against the AT approach is that it can lead to biased comparisons of treatment groups, in contrast to the ITT approach as outlined above. That is, it can lead to claims of efficacy even when a treatment is nonefficacious. There are also some difficult practical problems with AT analysis, including difficulty in defining compliance [14, 21], difficulty in determining which subjects are compliant, and loss of sample size when analysis is limited to compliant subjects.

Another alternative to ITT analysis has been developed in recent work [5, 10, 17, 22, 23, 25], which attempts to incorporate measures of compliance into the statistical analysis. This approach focuses on the information that compliance has to offer, rather than on considering compliance as a defining characteristic for the inclusion of patients in, or the exclusion of patients from, analysis. The goal of the new work is to use compliance data to provide better estimates of, or understanding of, the clinical response to treatment. These model-based approaches currently require assumptions about compliance, either its relation to treatment or to outcome, that may be difficult to accept or verify. Nonetheless,

this work may help to breach the gap between the current ITT and AT positions, and may be particularly useful for analyzing equivalence trials (*see* **Noncompliance, Adjustment for**).

Current Status

ITT analysis is a widely used strategy for the analysis of comparative clinical trials in the definitive comparison of treatments for both regulatory and nonregulatory assessments. "AT analysis" is used frequently as a secondary and confirmatory analysis to the ITT analysis, or for explanatory or exploratory assessment of efficacy in subgroups defined by characteristics or factors that could have differential response rates, such as compliance, gender or ethnic groups.

Interaction in Factorial Experiments

An important benefit obtained by using **factorial experiments** is the ability to determine whether **interactions** are present. In this context, interaction may be defined as the modification of the effect of a factor on a response, due to the influence of another factor. Put another way, the presence of an interaction means that the relationship between one factor and a response is different for different levels of another factor.

A typical factorial model which includes the interaction between factors A and B can be written as

$$\mu_{ij} = \mu_{..} + \alpha_i + \beta_j + \gamma_{ij}, \quad \text{for all } i, j,$$

where μ_{ij} represents the mean response across all observations when factor A is at level i and factor B is at level j, $\mu_{..}$ represents the overall mean, α_i represents the main effect for the ith level of factor A, β_j represents the main effect for the jth level of factor B, and γ_{ij} represents the interaction effect of the ith level of factor A and the jth level of factor B. This model clearly indicates that the effects of the factors are not simply additive, as would be the case if the interaction term were deleted (*see* **Additive Model**). Note that since the present discussion is concerned with understanding the meaning and utility of the interaction term, no constraints are imposed on the model parameters, and so models given will generally be overparameterized models.

By manipulation of the model given above, and defining the main effects as $\alpha_i = \mu_{i.} - \mu_{..}$ and $\beta_j = \mu_{.j} - \mu_{..}$, the interaction term can be expressed as a difference of differences; namely

$$\begin{aligned}\gamma_{ij} &= (\mu_{ij} - \mu_{i.}) - (\mu_{.j} - \mu_{..}) \\ &= (\mu_{ij} - \mu_{.j}) - (\mu_{i.} - \mu_{..}),\end{aligned}$$

where the "." in the subscript indicates summation over all levels of that subscript. Some authors refer to functions like $\mu_{ij} - \mu_{aj} - \mu_{ib} + \mu_{ab}$, i.e. differences of differences of cell means, as interaction effects. While such quantities are readily evaluated and interpreted from tables or graphs of treatment combination means, they are not equal to the interaction effects defined above. Such functions are actually the corresponding functions of the interaction effects, namely, $\gamma_{ij} - \gamma_{aj} - \gamma_{ib} + \gamma_{ab}$. Hence, it is true that if any of the functions $\mu_{ij} - \mu_{aj} - \mu_{ib} + \mu_{ab}$ are nonzero, then interactions are present.

Traditionally, the presence of interactions in a model has been viewed as something to be avoided, if possible. Didactic presentations of factorial models often emphasize testing for the significance of the interaction terms (*see* **Hypothesis Testing**), with the hope that the test statistics would be nonsignificant. If this no-interaction model is tenable, the relationship between the two factors and the response is easy to explain. However, in many real-life situations, interactions are appropriately included in the statistical model, since the relationship between a set of factors and the response goes beyond the simple additive (i.e. no-interaction) model.

Indeed, in certain situations the presence of interactions is viewed as desirable. For example, consider a randomized **clinical trial** where repeated measurements are taken through the course of a study comparing the effects of two different treatments on a disease of interest. The researcher anticipates that at the time of **randomization**, the average response will be the same in both treatment groups, but will eventually become different as the treatments have their desired effect. It is this divergence of response that is appropriately reflected by the treatment–time interaction effect in the analysis model.

The number of two-factor interaction terms in the model, corresponding to the **degrees of freedom** associated with that interaction effect, is the product of the numbers of levels of the two main effects in the models. By extension, the number of degrees of freedom associated with higher-order interaction terms increases multiplicatively with the number of effects included in the interaction term. This is especially noticeable when the number of levels of one or more of the factors increases beyond a simple dichotomy. In this situation, estimates of interaction effects may become unstable if the number of such terms increases but the sample size remains fixed. This instability is partly due to the loss of degrees of freedom associated with the estimated residual **variance**, since the number of observations at the combinations of the factor levels may become too small. Furthermore, computational problems can occur because the model specification may have included some interaction terms in the model which involve unobserved treatment combinations. Strong computational **algorithms** will build in methods for

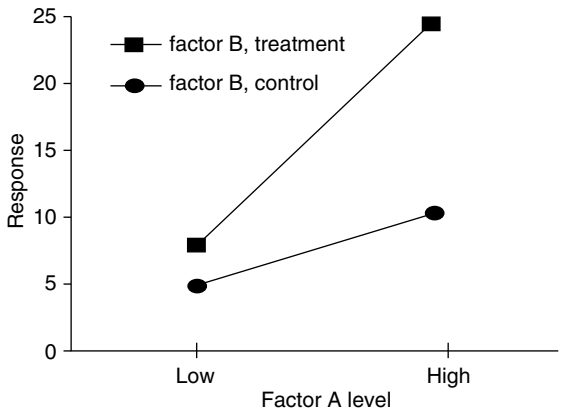

Figure 1 Graph of A–B interaction effect

recognizing and dealing appropriately with such possibilities.

As indicated in the graph (Figure 1), the interaction of two classification factors, or of a classification and a continuous factor, is straightforward to graph, and hence to interpret. However, comparable interpretation of interaction effects containing two or more continuous factors is considerably more complex. Practical experience suggests that it is next to impossible to explain and/or interpret interaction effects containing more than three terms in a straightforward verbal manner. While graphs may be useful in this regard, if the graphs involve more than one, or possibly two, continuous factors, the dimensionality of the required graph may be unreasonable.

In some situations, clarity of interpretation of interaction effects can be obtained by modeling these effects with nested effects (*see* **Multilevel Models**) rather than as true interaction effects. That is, instead of using the terms α_i, β_j, and γ_{ij} in the model that deals with factors A and B and the A $*$ B interaction, we use α_i and terms for effect B that are different for each level of A. This may be more useful as one attempts to understand the underlying relationships among the variables.

When constructing a model with the possible inclusion of interactions, the investigator should be attentive to the convention of using the hierarchy principle for determining which interactions should be included in a model. For a model to be hierarchical, the inclusion of any interaction term mandates that all lower-order effects which include the effects in the interaction must also be included in the model (*see* **Hierarchical Models**). That is, if the AB interaction effect is in the model, then the A and B main effects must also be included. By extension, if the ABC interaction effect is used in a model, then the interaction effects AB, AC, and BC, as well as the A, B, and C main effects, must be included.

Interaction is something different from what epidemiologists refer to as **confounding**. In that literature, confounding refers to the change found in the relationship between a factor (often called an effect in epidemiology) and a response when another effect (the confounding effect) is added to the model. Interaction effects need not be included in a model for confounding to be present. Rather, confounding refers to the presence of significant **correlation** among the effects.

The use of interaction effects can be especially useful, and perhaps difficult to implement, when **time-dependent covariates** are used in the model. For example, in the analysis of growth of infants in the first year of life (*see* **Growth and Development**), it would be useful to utilize information about whether the child is being breast-fed at each measurement time. Inclusion of an indicator variable about the breast-feeding condition will simply yield a linear shift of the growth curve. However, if the interaction term involving feeding condition and age is included in the model, the rate of growth can be modeled differently under the two feeding conditions.

Interaction Model

Interaction models for **categorical data** are **loglinear models** describing association among categorical variables. They are called interaction models because of the analytic equivalence of loglinear **Poisson regression** models describing the dependence of a count variable on a set of categorical explanatory variables and loglinear models for **contingency tables** based on **multinomial** or product multinomial sampling. The term is, however, somewhat misleading, because the interpretation of parameters from the two types of models are very different. *Association models* would probably be a better name.

Instead of simply referring the discussion of interaction and association models to the section on loglinear models, we will consider these models from the types of problems that one could address in connection with analysis of **association**. The first problem is a straightforward question of whether or not variables are associated. To answer this question, one must first define association and dissociation in multivariate frameworks and, secondly, define multivariate models in which these definitions are embedded. This eventually leads to a family of so-called graphical models that can be regarded as the basic type of interaction or association. The second problem concerns the properties of the identified associations. Are associations homogeneous or heterogeneous across levels of other variables? Can the strength of association be measured and in which way? To solve these problems, one must first decide upon a natural measure of association among categorical variables and, secondly, define a parametric structure for the interaction models that encapsulates this measure. Considerations along these lines eventually lead to the family of hierarchical loglinear models for nominal data and models simplifying the basic loglinear terms for **ordered categorical data**.

Graphical Interaction Models

What is meant by association between two variables? The most general response to this question is indirect. Two variables are dissociated if they are *conditionally* independent given the rest of the variables in the multivariate framework in which the two variables are embedded. Association then simply means that the two variables are not dissociated.

Association in this sense is, of course, not a very precise statement. It simply means that conditions exist under which the two variables are not independent. Analysis of association will typically have to go beyond the crude question of whether or not association is present, to find out what characterizes the conditional relationship – for instance, whether it exists only under certain conditions, whether it is homogeneous, or whether it is modified by outcomes on some or all the conditioning variables. Despite the inherent vagueness of statements in terms of unqualified association and dissociation, these statements nevertheless define elegant and useful models that may serve as the natural first step for analyses of association in multivariate frames of inference. These so-called *graphical* models are defined and described in the subsections that follow.

Definition

A graphical model is defined by a set of assumptions concerning pairwise conditional independence given the rest of the variables of the model.

Consider, for instance, a model containing six variables, A to F. The following set of assumptions concerning pairwise conditional independence defines four constraints for the joint distribution $\Pr(A, B, C, D, E, F)$. The family of probability distributions satisfying these constraints is a graphical model:

$$\begin{aligned}
A \perp C|BDEF &\Leftrightarrow \Pr(A, C|BDEF) \\
&= \Pr(A|BDEF)\ \Pr(C|BDEF), \\
A \perp D|BCEF &\Leftrightarrow \Pr(A, D|BCEF) \\
&= \Pr(A|BCEF)\ \Pr(D|BCEF), \\
B \perp E|ACDF &\Leftrightarrow \Pr(B, E|ACDF) \\
&= \Pr(B|ACDF)\ \Pr(E|ACDF), \\
C \perp E|ABDF &\Leftrightarrow \Pr(C, E|ABDF) \\
&= \Pr(C|ABDF)\ \Pr(E|ABDF).
\end{aligned}$$

Interaction models defined by conditional independence constraints are called "graphical interaction models", because the structure of these models can be characterized by so-called interaction graphs, where

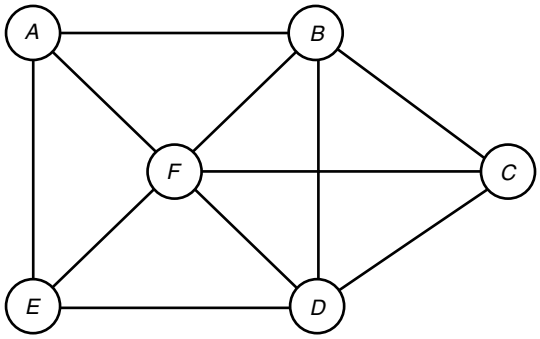

Figure 1 An interaction graph

variables are represented by nodes connected by undirected edges if and only if association is permitted between the variables. The graph shown in Figure 1 corresponds to the set of conditional independence constraints above, because there are no edges connecting A to C, A to D, B to E, and C to E.

Interaction graphs are visual representations of complex probabilistic structures. They are, however, also mathematical models of these structures, in the sense that one can describe and analyze the interaction graphs by concepts and **algorithms** from mathematical graph theory and thereby infer properties of the probabilistic model. This connection between probability theory and mathematical graph theory is special to the graphical models.

The key notion here is conditional independence, as discussed by Dawid [5]. While the above definition requires that the set of conditioning variables always includes all the other variables of the model, the results described below imply that conditional independence may sometimes be obtained if one conditions with certain subsets of variables.

Graphical models for multidimensional tables were first discussed by Darroch et al. [5]. Since then, the models have been extended both to continuous and mixed categorical and continuous data and to regression and block recursive models. Whittaker [9], Edwards [7], Cox & Wermuth [4], and Lauritzen [8] present different accounts of the theory of graphical models. The sections below summarize some of the main results from this theory.

The Separation Theorem

The first result connects the concept of graph separation to conditional independence.

First, we present a definition: a subset of nodes in an undirected graph separate two specific nodes, A and B, if all paths connecting A and B intersect the subset. In Figure 1, (B, D, F) separate A and B, as does (B, E, F). E and C are separated by both (A, D, F) and (B, D, F).

The connection between graph separation and conditional independence is given by the following result, sometimes referred to as the separation theorem.

Separation Theorem. If variables A and B are conditionally independent given the rest of the variables of a multivariate model, A and B will be conditionally independent given any subset of variables separating A and B in the interaction graph of the model.

The four assumptions on pairwise conditional independence defining the model shown in Figure 1 generate six minimal separation hypotheses:

$$A \perp C|BDF, \quad A \perp C|BEF, \quad A \perp D|BEF,$$
$$B \perp E|ADF, \quad C \perp E|ADF, \quad C \perp E|BDF.$$

Closure and Marginal Models

It follows from the separation theorem that graphical models are closed under marginalization, in the sense that some of the independence assumptions defining the model transfer to marginal models.

Collapsing, for instance, over variable C of the model shown in Figure 1 leads to a graphical model defined by conditional independence of A and D and B and E, respectively, because the marginal model contains separators for both AD and BE (Figure 2).

Loglinear Representation of Graphical Models for Categorical Data

No assumptions have been made so far requiring variables to be categorical. If all variables are categorical, however, the results may be considerably strengthened both with respect to the type of model defined by the independence assumptions of graphical models and in terms of the available information on the marginal models.

The first published results on graphical models [5] linked graphical models for categorical data to loglinear models:

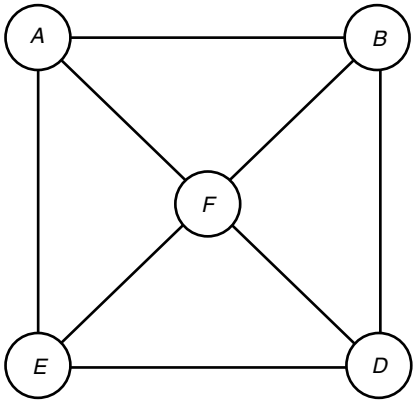

Figure 2 An interaction graph obtained by collapsing the model defined by Figure 1 over variable C

> A graphical model for a multidimensional contingency table without **structural zeros** is loglinear with generators defined by the cliques of the interaction graph.

The result is an immediate result of the fact that any model for a multidimensional contingency table has a loglinear expansion. Starting with the saturated model, one removes all loglinear terms containing two variables assumed to be conditional independent. The loglinear terms remaining after all the terms relating to one or more of the independence assumptions of the model have been deleted define a hierarchial loglinear model with parameters corresponding to each of the completely connected subsets of nodes in the graph.

The interaction graph for the model shown in Figure 1 has four cliques, $BCDF$, ABF, AEF, and DEF, corresponding to a loglinear model defined by one four-factor interaction and three three-factor interactions.

Separation and Parametric Collapsibility

While conceptually very simple, graphical models are usually complex in terms of loglinear structure. The problems arising from the complicated parametric structure are, however, to some degree to be compensated for by the properties relating to collapsibility of the models.

Parametric collapsibility refers to the situation in which model terms of a complete model are unchanged when the model is collapsed over one or more variables. Necessary conditions implying parametric collapsibility of loglinear models are described by Agresti [1, p. 151] in terms which translate into the language of graphical models:

> Suppose variables of a graphical model of a multidimensional contingency table are divided into three groups. If there are no edges connecting variables the first group with connected components of the subgraph of variables from the third group, then model terms among variables of the first group are unchanged when the model is collapsed over the third group of variables.

Parametric **collapsibility** is connected to separation in two different ways. First, parametric collapsibility gives a simple proof of the separation theorem, because a vanishing two-factor term in the complete model also vanishes in the collapsed model if the second group discussed above contains the separators for the two variables. Secondly, separation properties of the interaction graph may be used to identify marginal models permitting analysis of the relationship between two variables. If one first removes the edge between the two variables, A and B, and secondly identifies separators for A and B in the graph, then the model is seen to be parametric collapsible on to the model containing A and B and the separators with respect to all model terms relating to A and B.

The results are illustrated in Figure 3, where the model shown in Figure 3(a) is collapsed on to marginal models for $ABCD$ and $CDEF$. The separation theorem is illustrated in Figure 3(b). All terms relating to A and B vanish in the complete model. The model satisfies the condition for parametric collapsibility, implying that these parameters also vanish in the collapsed model. The second property for the association between E and F is illustrated in Figure 3(c). C and D separate E and F in the graph from which the EF edge has been removed. It follows, therefore, that E and F cannot be linked to one and the same connected component of the subgraph for the variables over which the table has been collapsed. The model is therefore parametric collapsible on to CDEF with respect to all terms pertaining to E and F.

Decomposition and Reducibility

Parametric collapsibility defines situations in which inference on certain loglinear terms may be performed in marginal tables because these parameters

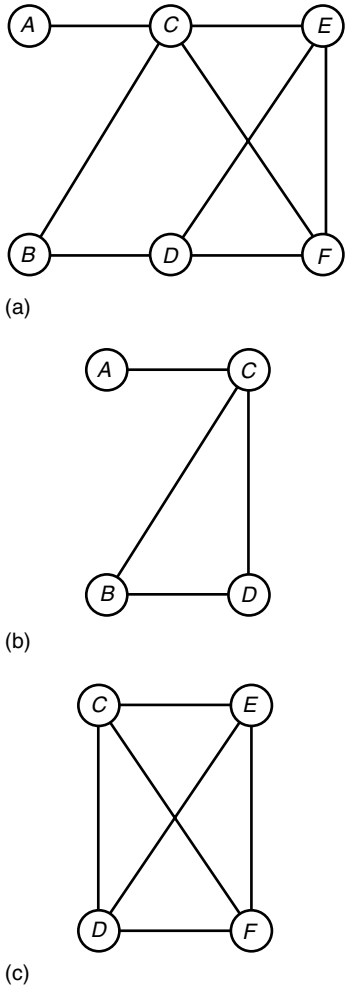

Figure 3 Collapsing the model given in (a) illustrates the separation theorem for A and B (b), and parametric collapsibility with respect to E and F (c)

are unchanged in the marginal tables. Estimates of, and test statistics for, these parameters calculated in the marginal tables will, however, in many cases differ from those obtained from the complete table. Conditions under which calculations give the same results may, however, also be stated in terms of the interaction graphs.

An undirected graph is said to be *reducible* if it partitions into three sets of nodes – X, Y, and Z – if Y separates the nodes of X from those of Z and if the nodes of Y are completely connected. If the interaction graph meets the condition of reducibility, it is said to decompose into two components, $X + Y$ and $Y + Z$. The situation is illustrated in Figure 4, which decomposes into two components, $ABCD$ and $CDEF$.

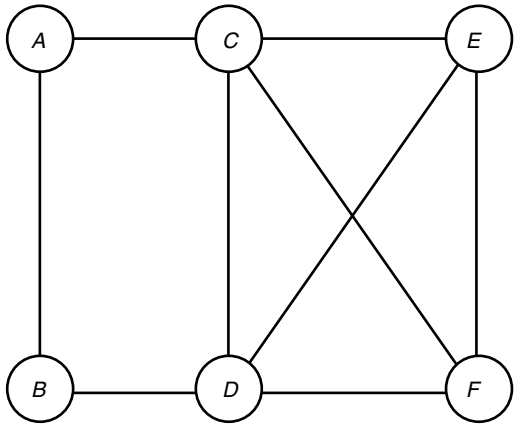

Figure 4 An interaction graph of a reducible model

It is easily seen that reducibility above implies parametric collapsibility with respect to the parameters of X and Z, respectively. It can also be shown, however, that likelihood-based estimates and test statistics obtained by analysis of the collapsed tables are exactly the same as those obtained from the complete table.

Regression Models and Recursive Models

So far, the discussion has focused on models for the joint distribution of variables. The models can, however, without any problems, be extended first to multidimensional regression models describing the conditional distribution of a vector of dependent variables given another vector of **explanatory variables** and, secondly, to block recursive systems of variables. In the first case, the model will be based on independence assumptions relating to either two dependent variables or one dependent and one independent variable. In the second case, recursive models have to be formulated as a product of separate regression models for each recursive block conditionally given variables in all prior blocks. To distinguish between symmetric and asymmetric relationships edges between variables in different recursive blocks, interaction graphs are replaced by arrows.

Parametric Structure: Homogeneous or Heterogeneous Association

The limitations of graphical models for contingency tables lie in the way in which they deal with higher-order interactions. The definition of the graphical models implies that higher-order interactions *may* exist if more than two variables are completely connected.

It is therefore obvious that an analysis of association by graphical models can never be anything but the first step of an analysis of association. The graphical model will be useful in identifying associated variables and marginal models where associations may be studied, but sooner or later one will have to address the question of whether or not these associations are homogeneous across levels defined by other variables and, if not, which variables modify the association. The answer to the question of homogeneity of associations depends on the type of measure that one uses to describe or measure associations. For categorical data, the natural measures of association are measures based on the so-called cross product ratios [2] (*see* **Odds Ratio**). The question therefore reduces to a question of whether or not cross product ratios are constant across different levels of other variables, thus identifying loglinear models as the natural framework within which these problems should be studied.

Ordinal Categorical Variables

In the not unusual case of association between ordinal categorical variables, the same types of argument apply against the hierarchical loglinear models as against the graphical models. Loglinear models are basically interaction models for nominal data; and, as such, they will give results that are too crude and too imprecise for ordinal categorical data. The question of whether or not the association between two variables is homogeneous across levels of conditioning variables can, for ordinal variables, be extended to a question of whether or not the association is homogeneous across the different levels of the associated variables. While not abandoning the basic loglinear association structure, the answer to this question depends on the further parameterization of the loglinear terms of the models. We refer to a recent discussion of these problems by Clogg & Shihadeh [3].

Discussion

The viewpoint taken here on the formulation of interaction models for categorical data first defines the family of graphical models as the basic type of models for association and interaction structure. Loglinear models are, from this viewpoint, regarded as parametric graphical models, meeting certain assumptions on the nature of associations not directly captured by the basic graphical models. Finally, different types of models for ordinal categorical data represent yet further attempts to meet assumptions relating specifically to the ordinal nature of the variables.

Interaction

Interaction is most often considered in the context of regression models, including the special case of models underlying the **analysis of variance** (ANOVA). In these models, the response variable is linked in some manner to a linear predictor of the form

$$\alpha + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k,$$

where the X_is represent **explanatory variables**, and α and the β_is represent parameters to be estimated. Here, for exposition purposes, the X_is will be regarded as representing separate factors of interest, or perhaps functions of a measurement or coding of a single factor. In this case, the linear predictor reflects an additive relationship such that a change in X_i induces the same change in the linear predictor whatever the values of the other explanatory variables.

In this framework, an interaction term is defined by the product of two or more X_is. Consider the special case of two explanatory variables. Then the linear predictor can be expanded and be represented by

$$\nu(X_1, X_2) = \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_{12} X_1 X_2.$$

The coefficient β_{12} then represents a departure from an **additive model** for the simultaneous effect of X_1 and X_2 on the response. A test of the hypothesis $\beta_{12} = 0$ is used to examine whether there is evidence for such a departure. Technically, such a test is undertaken as a standard test for a nonzero regression coefficient in the **regression** model being considered.

If X_1 is continuous, then plots of ν against X_1, with X_2 fixed, provide an illustration of interaction effects. In the absence of interaction, the curves are parallel for different values of X_2. If X_2 is also continuous, then parallel curves also arise when ν is plotted against X_2 with X_1 fixed. The nature of the variables may determine the most natural means of presentation. For example, if X_1 represents an experimental treatment level and X_2 a covariate that specifies some intrinsic characteristic of a subject, then it is natural to plot ν against X_1 with X_2 fixed. If X_1 and X_2 are *categorical*, then interaction effects are often displayed by the presentation of values of ν for different values of X_1 and X_2 in a two-way table.

The absence of interaction, when there is particular interest in the effect of both X_1 and X_2 on the response variable, indicates that the separate effects of the two variables are additive. If interest primarily focuses only on X_1, and X_2 is regarded as a covariate, then the lack of interaction indicates that the effect of X_1 is independent of X_2. Particularly in analysis of variance procedures, the interaction of a treatment variable X_1, with a covariate X_2 which varies in a haphazard or largely uncharacterizable way, may be regarded as random variation that may be used in the estimation of the error of treatment contrasts (*see* **Random Effects**).

When the term $\beta_{12} X_1 X_2$ is referred to as an interaction term, terms of the form $\beta_i X_i$ are often referred to as main-effect terms. This derives predominantly from the ANOVA literature, and is particularly relevant to the orthogonal effects that derive from the coding of explanatory variables commonly used there (*see* **Analysis of Variance**). More generally, the interpretation of main-effect terms may depend very critically on the particular representation of the explanatory variables used to define X_i, particularly in the presence of interaction terms.

A distinction is sometimes made between qualitative and quantitative interactions. A qualitative interaction is one in which the direction of the effect of X_1, say, differs depending on the value of X_2. A quantitative interaction would reflect changes in the magnitude of the X_1 effect with X_2, which do not induce a change in the direction of the effect.

Another distinction is between synergistic (*see* **Synergy of Exposure Effects**) and antagonistic interactions. Assume that a change in X_1 induces a change δ_1 in the linear predictor through the term $\beta_1 X_1$, and a change in X_2 similarly induces a change δ_2. If δ_1 and δ_2 have the same sign, say "+", then a synergistic interaction is one which causes the change in the linear predictor due to changes in both X_1 and X_2 to be greater than $\delta_1 + \delta_2$. In contrast, an antagonistic interaction will result in a change less than the sum of the individual effects.

Interactions are always defined in terms of a specific model. Another model which is defined with a transformation of the response variable or a different relationship between the response variable and the linear predictor will not necessarily manifest the same interactions. Some formal attention has been paid to defining "removable interactions", but it is

probably best to consider alternative models for this purpose on a case by case basis.

For models with more than two factors, products of all pairs of variables can be considered, and would be termed second-order or two-way interactions. In the obvious way, interactions of order m can be defined by introducing a product of m variables. When factors are defined with a set of binary **dummy variables**, interactions between factors involve products of these dummy variables, and the set of cross products corresponding to a pair of factors can be regarded as a single interaction term with **degrees of freedom** corresponding to the number of nonlinearly dependent cross products that can be defined. For factors with I and J levels, the degrees of freedom would be $(I - 1)(J - 1)$.

It has been argued that any model with an interaction term must have all main effects corresponding to terms in the interaction in the model. Such an approach produces what are called **hierarchical models**. While there are examples in which this requirement is viewed as too strong, it is in almost all situations sensible formally to test for nonzero interaction effects in the presence of the main effects.

A comprehensive review of interaction has been given by Cox [1]. In epidemiology, interaction is closely linked with the term **effect modification**.

VERN T. FAREWELL

Interim Analysis of Censored Data

In many chronic disease **clinical trials**, the major endpoint of interest is time to an event, such as time to disease progression or time to death. Often, the focus of the clinical trial is the comparison of time to event among different treatment groups. In such trials, patients enter the study during some **staggered entry** accrual period, and the final analysis is planned after a predetermined follow-up period. Usually, at the final analysis, not all events are observed, giving rise to **censored** survival data.

For ethical as well as practical reasons, these trials are monitored periodically and interim analyses are performed (*see* **Data and Safety Monitoring**). It is now common practice for all large-scale clinical trials to be monitored formally. Independent data-monitoring boards have been established for most large-scale government-sponsored clinical trials, and, increasingly, such monitoring boards are being established for pivotal clinical trials conducted by private industry such as pharmaceutical companies. The role of the data-monitoring board is to serve as an external oversight committee that reviews periodically the data from the trial as they accrue and to advise on the early termination of the trial or modification of the protocol on the basis of the emerging results (*see* **Clinical Trials Protocols**). Reasons for the termination of a trial are complex, and include serious toxicity, unexpected adverse events, design and/or logistical issues too serious to address, such as very low accrual or event rates, external information, established benefit, or no trend of interest. The board also considers carefully issues of data quality and the consistency of results across various endpoints and over time before making their recommendation.

There has been a great deal of statistical research devoted to early termination of a trial, if, during an interim analysis, a sufficiently large or small treatment difference is observed in the primary endpoint. The major question is: How large or small must the treatment difference be during the interim analysis to warrant terminating the trial? To this end, a test statistic is computed at each interim analysis and compared with a stopping boundary. If the test statistic crosses the boundary at an interim analysis, then the trial is terminated; otherwise, the trial continues until the next interim analysis. This process is continued, if necessary, until the time of a planned final analysis, and is referred to as **sequential** testing. We focus our discussion on upper boundaries only; that is, we allow the possibility of stopping the trial only if a sufficiently large treatment difference is observed during an interim analysis. In some settings, both upper and lower boundaries, allowing termination if either a sufficiently large or small treatment difference is observed, may be implemented (*see* **Data and Safety Monitoring**).

Statistical methods for sequential testing have been available for a long time, but only since the early 1980s have they been used routinely in monitoring clinical trials. One reason is that standard sequential methods require that the trial be monitored continually. Although there are many experimental conditions where this is feasible, it is generally not flexible enough to accommodate the needs of most large-scale clinical trials, where, administratively, it is too difficult for the data to be maintained for continual monitoring. Moreover, continual review is not feasible in a system where the data are monitored by an independent board that, of necessity, can meet only, at most, several times a year. The flexible method proposed by Lan & DeMets [10] has proven to be a useful way of monitoring trials that allow the number and timing of interim analyses to be left unspecified. Their method depends on specifying an alpha-spending function that may be translated into stopping boundaries. We discuss this strategy for sequential monitoring in more detail later in the article. Other strategies for monitoring clinical trials that include the use of the triangular test, the truncated sequential probability ratio test, and the restricted procedure are discussed in [25] (*see* **Sequential Analysis**).

To derive sequential tests, we must be able to characterize the joint distribution of the sequentially computed test statistics used with censored survival data. The difficulty is that there are two time axes that must be considered in evaluating the distribution of sequentially computed test statistics. Time to event for individuals is measured from the time they enter the trial, and it is the distribution of these patient times that are compared among treatments. However, sequential monitoring occurs over calendar time, which is measured as time from the start of the study. These issues are considered in more detail

below. Later, we describe how the results for the joint distribution of sequentially computed test statistics for right censored data may be used in conjunction with the flexible methods of Lan & DeMets to construct stopping rules.

Formalization of the Problem

We assume that n individuals enter the trial at calendar times $E_1, \ldots, E_n$. Each individual i has a potential survival time T_i, possibly unobserved, measured from the time of entry (*see* **Survival Analysis, Overview**). The distribution of T_i may depend on a vector of **covariates**, which includes a treatment indicator, denoted by Z_{0i}, and possible additional covariates $\mathbf{Z}_{1i}$. The relationship between survival time and the covariates is often modeled through the hazard function given by

$$\lambda(u|Z_0, \mathbf{Z}_1, \boldsymbol{\beta}) = \lim_{h \to 0} h^{-1} \times \Pr(u \le T < u + h | T \ge u, Z_0, \mathbf{Z}_1),$$

where $\boldsymbol{\beta}$ denotes a vector of parameters that may be finite dimensional (parametric model) or infinite dimensional (**semiparametric** or **nonparametric** models). The main objective is testing the null hypothesis of no treatment effect on the survival distribution (*see* **Hypothesis Testing**). For example, if we consider only treatment indicator Z_0, then the nonparametric null hypothesis may be posed as

$$\mathrm{H}_0\colon \lambda(u|Z_0 = 1) = \lambda(u|Z_0 = 0), \quad u \ge 0. \qquad (1)$$

Parametric or semiparametric models may also be used for this purpose; for example, we may assume the hazard function follows a **proportional hazards** model:

$$\lambda(u|Z_0, \mathbf{Z}_1) = \lambda_0(u) \exp(\beta_0 Z_0 + \boldsymbol{\beta}_1^{\mathrm{T}} \mathbf{Z}_1), \qquad (2)$$

where $\lambda_0(u)$ is some unknown baseline hazard function, $\mathbf{Z}_1$ is a vector of additional covariates, and the null hypothesis is $\mathrm{H}_0 : \beta_0 = 0$.

If an interim analysis is conducted at calendar time t (measured from the start of the study), then individual i will have censored survival data if $T_i > t - E_i$. Censoring may also occur from other random loss-to-follow-up causes. We define V_i to be the potential censoring time due to causes unrelated to the time of an interim analysis. Thus, assume that for individual i there exists a vector of random variables $(E_i, T_i, V_i, \mathbf{Z}_i)$, $i = 1, \ldots, n$, some of which are possibly unobserved. At analysis time t, the observable random variables are $\{X_i(t), \delta_i(t), \mathbf{Z}_i\}$, for all $i = 1, \ldots, n$, such that $E_i \le t$. Here, $X_i(t) = \min(T_i, V_i, t - E_i)$ is the observed time-on-study at analysis time t, and $\Delta_i(t) = 1$ if $T_i \le \min(t - E_i, V_i)$, 0 otherwise, denotes the failure indicator at time t. It is important to note that the data available for an individual at different interim analysis times may vary. For example, an individual with censored time-to-event data at time $t[\Delta_i(t) = 0]$ may at some later time t' be uncensored $[\Delta_i(t') = 1]$.

Typically, a test statistic is computed using all the available data at time t. This statistic, which we denote by $W(t)$, is used to test the null hypothesis H_0 of no treatment difference; that is, the null hypothesis is rejected when $W(t)$ or $|W(t)|$ is sufficiently large, depending on whether we are considering one-sided or two-sided alternatives. The most widely used methods for testing the nonparametric null hypothesis given by (1) are the class of *weighted logrank tests*. Special cases of this general class include the **logrank test** [12, 14]. Prentice's [16] generalization of the Wilcoxon test (*see* **Wilcoxon–Mann–Whitney Test**), and the G^ρ tests of Harrington & Fleming [8]. If, instead, the null hypothesis is stated using a parametric or semiparametric model such as (2), then $W(t)$ may be a standard Wald or score test statistic derived from the **likelihood** for a parametric model or from Cox's [4] **partial likelihood** for the semiparametric model (2).

In a sequential time-to-event trial, the study is monitored at interim times $t_1, \ldots, t_K$. At each analysis time, t_j, we compute the test statistic $W(t_j)$, which incorporates all of the information up to the analysis time. If this statistic exceeds the stopping boundary value b_j, i.e.

$$|W(t_j)| \ge b_j,$$

then we may terminate the study and reject the null hypothesis. The boundary values b_j must be chosen in such a way as to preserve the **level of the test**. For example, if we wish to test at level of significance α, then the b_j must satisfy

$$\Pr_{\mathrm{H}_0}\left\{\bigcup_{j=1}^{K} [|W(t_j)| \ge b_j]\right\} = \alpha, \qquad (3)$$

where $\Pr_{H_0}$ denotes probability computed under the null hypothesis. To evaluate probabilities such as those in (3), we require the joint distribution of $[W(t_1), \ldots, W(t_K)]$. The particular challenge in deriving this joint distribution arises from the fact that the data for any individual contributing to the test statistic at different interim times may vary. A **Lexis diagram** is very helpful in explaining the interrelationship of these two time-scales. For an excellent example that illustrates the use of a Lexis diagram, we refer the reader to [9]. Careful consideration of patient time vs. calendar time has allowed derivation of the joint sequential distribution for most test statistics commonly used with right censored data. Some of the main results are as follows.

A random vector has normal independent increments if its joint distribution is the same as a vector of partial sums or independent normal random variables. Tsiatis [20, 21], Slud [18], and Gu & Lai [6] show that a general class of time sequential nonparametric statistics (i.e. weighted logrank statistics) are asymptotically distributed with an independent increments normal structure. The independent increments structure is the basis for most sequential designs and analyses, enabling the immediate application of standard group sequential methods and software to compute probabilities such as those given by (3). Assuming the proportional hazards model of Cox [3] (*see* **Cox Regression Model**), Gu & Ying [7], generalizing the work of Tsiatis [21], Sellke & Siegmund [17], and Tsiatis, et al. [23], showed that the test statistic based on maximizing the partial likelihood [4] also has this independent increment structure.

Recently, Tsiatis et al. [22], under the assumption of a parametric model with a single test parameter of interest (usually corresponding to a treatment difference) and a finite number of **nuisance parameters**, proved that the joint distribution of sequentially computed maximum likelihood estimators, and the joint distribution of sequentially computed score tests, have this independent increments structure.

In summary, most test statistics for right censored data, properly normalized, have a joint asymptotic distribution corresponding to an independent increments multivariate normal random vector with variance proportional to statistical **information**. Here, information refers to the usual notion of Fisher information for parametric models. An extended definition of information for semiparametric and nonparametric models is given by Bickel et al. [2]; this is beyond the scope of this article. One important example worth mentioning is the logrank test. In a randomized trial, the information for the logrank test is proportional to the number of events.

Flexible Sequential Boundaries

We now describe how sequential boundaries $b_1, \ldots, b_K$ may be constructed satisfying (3), using the flexible method proposed by Lan & DeMets [10]. The key to this method is to note that the rejection region given in (3) may be partitioned as follows:

$$
\begin{aligned}
&|W(t_1)| \geq b_1, \text{ or}\\
&|W(t_1)| < b_1, |W(t_2)| \geq b_2, \text{ or}\\
&\cdots\\
&|W(t_1)| < b_1, \ldots, |W(t_{K-1})|\\
&\qquad < b_{K-1}, |W(t_K)| \geq b_K.
\end{aligned}
$$

Denote these mutually exclusive rejection regions as $R_1, \ldots, R_K$. If we define the rejection probabilities γ_j such that $\Pr_{H_0}(R_j) = \gamma_j$, $j = 1, \ldots, K$, then (3) will be satisfied when

$$\sum_{j=1}^{K} \gamma_j = \alpha. \tag{4}$$

If we know the joint distribution of $[W(t_1), \ldots, W(t_K)]$, then for any set of γ_j, $j = 1, \ldots, K$, satisfying (4), we may recursively derive the boundary values b_j, $j = 1, \ldots, K$, so that $\Pr_{H_0}(R_j) = \gamma_j$. This is the method proposed by Slud & Wei [19] to be used with the sequentially computed Gehan–Wilcoxon test [5], (*see* **Nonparametric Methods**).

Lan & DeMets suggest that the rejection probabilities be linked directly to the information available at the different interim analyses through the use of an "α-spending function". The use of information-based methods is discussed by Lan & Zucker [11]. Specifically, define a monotone increasing function $\alpha(\pi)$ for $0 \leq \pi \leq 1$ such that $\alpha(0) = 0$ and $\alpha(1) = \alpha$, where $\pi = \pi(t)$ denotes the proportion of statistical information at an interim analysis time t, with 100% information at the time of a final analysis. If we define MI as the maximum information and $I(t)$ as information at interim analysis time t, then

the proportion of information at t would be $\pi(t) = I(t)/MI$. The rejection probabilities, γ_j, are set equal to $\{\alpha[\pi(t_j)] - \alpha[\pi(t_{j-1})]\}$, where $t_0 = 0$ and $\pi(0) = 0$. By definition, these satisfy (4) and may be used to define stopping boundaries b_j, $j = 1, \ldots, K$. The term α-spending function refers to the fact that the probability of rejecting the null hypothesis using this strategy, by time t_j, if the null hypothesis is true, is $\alpha[\pi(t_j)]$, or, "we have spent $\alpha[\pi(t_j)]$ of the significance level by time t_j". The procedure guarantees that the level of significance will be equal to some prespecified α regardless of the number of interim analyses or the timing of these analyses.

As an example of the application of this method, consider the use of the logrank test in a randomized trial to test for the equality of the survival distribution between two treatments. In this case, the information is proportional to the number of deaths. Let $D(t)$ denote the number of deaths observed until time t and D^* denote the maximum number of deaths that determines the end of the trial. At the first analysis time, t_1, we compute the proportion of information $\pi(t_1) = D(t_1)/D^*$. The first boundary value, b_1, is the solution to

$$\Pr_{H_0}[|W(t_1)| \geq b_1] = \alpha[\pi(t_1)].$$

After this is determined, we compute the observed value of the test statistic. If it exceeds b_1, then we stop and reject H_0; otherwise, we continue to the next monitoring time.

Consider the jth ($j = 2, \ldots, K-1$) analysis time t_j, and suppose that the boundary values $b_1, \ldots, b_{j-1}$ have been computed. At t_j, the proportion of information $\pi(t_j)$ is equal to $D(t_j)/D^*$, and the boundary value b_j solves the following equation:

$$\Pr_{H_0}[|W(t_1)| \leq b_1, \ldots, |W(t_{j-1})| \leq b_{j-1}, \\ |W(t_j)| \geq b_j] = \alpha[\pi(t_j)] - \alpha[\pi(t_{j-1})].$$

The solution is easily computed using the independent increments property of the logrank statistic and the recursive numerical integration **algorithm** of Armitage, et al. [1]. The computations may be carried out using available statistical software such as EAST (Early Stopping, Cytel Corporation). Again, the observed value of the test statistic is determined and compared with the cutoff. If it exceeds b_j, then we stop and reject H_0; otherwise, we continue to the next monitoring time.

If we continue until the final analysis time, then we "use up" the remaining significance level; that is, we compute b_K, where

$$\Pr_{H_0}[|W(t_1)| \leq b_1, \ldots, |W(t_{K-1})| \leq b_{K-1}, \\ |W(t_K)| \geq b_K = \alpha - \alpha[\pi(t_{K-1})].$$

To implement these methods for sequential stopping, we must specify the maximum information and the α-spending function prior to the initiation of the trial. The choice of group sequential stopping rules has received a great deal of attention by many authors, including Pocock [15], O'Brien & Fleming [13], and Wang & Tsiatis [24]. The expected stopping times at various alternatives is the criterion that is most often used for comparing competing group sequential tests with the same significance level and **power**. Because α-spending functions and stopping boundaries have a one-to-one relationship, results on the choice of stopping boundaries may be used to determine the choice of the α-spending functions. Space limitations preclude detailed discussion of these issues; we note that two common α-spending functions have received considerable attention in the literature. These functions correspond to what are referred to as the O'Brien–Fleming boundary and the Pocock boundary, respectively [10]. The former function tends to be very conservative at the early stages of the study, while the latter is more liberal. For an O'Brien–Fleming boundary, we take $\alpha(\pi) = \alpha_1(\pi)$, where

$$\alpha_1(\pi) = 4 - 4\Phi\left(\frac{z_{\alpha/4}}{\sqrt{\pi}}\right),$$

and for a Pocock boundary, we take $\alpha(\pi) = \alpha_2(\pi)$, where

$$\alpha_2(\pi) = \alpha \log[1 + (e-1)\pi].$$

In these formulas, e is a constant whose natural logarithm is equal to one, and $\Phi(\cdot)$ and z_x are the cumulative density function and $1 - x$ **quantile** of a **standard normal** random variable, respectively.

The choice of maximum information (MI) is closely related to the power necessary to detect a clinically important alternative. When designing a clinical trial, the information necessary to detect a clinically important difference, with some predetermined power, when using a test at a specified level of significance, is computed. For example, if we test the null hypothesis (1) using the logrank test with

significance level α for a clinical trial where patients are randomized with probability 0.5 to each of two treatments, then the number of events necessary to detect a treatment difference corresponding to a log hazard ratio of β_0, with power $1 - \eta$, is given by

$$4\left(\frac{z_{\alpha/2} + z_\eta}{\beta_0}\right)^2.$$

However, when the data are monitored at several interim analysis times with the possibility of early stopping, there is a loss of power. Hence, the maximum information must be inflated by a factor that depends on the spending function, the significance level, power, and the number of interim analyses. For example, if we use the O'Brien–Fleming-type spending function with five interim analyses at the 0.05 level and 90% power, then the information must be increased by 3%. In contrast, an increase of 21% would be necessary with a Pocock-type spending function. The results of Wang & Tsiatis [24] may be used to determine the inflation factor as a function of K, α, η, and the type of spending function.

In summary, we have described a class of flexible and comprehensive methods for developing stopping rules for clinical trials with censored data, which may be used with parametric, semiparametric, and nonparametric models. These methods are used commonly by **data and safety monitoring boards**, as they guarantee the preservation of the significance level and power of the test while still allowing for early termination at interim times that do not have to be specified in advance.

International Agency for Research Against Cancer (IARC)

The International Agency for Research on Cancer (IARC) was established in May 1965, through a resolution of the XVIIth World Health Assembly as an extension of the **World Health Organization** after a French initiative. IARCs founding members were the Federal Republic of Germany, France, Italy, the UK, and the US. The Agency's headquarters' building was provided by its host, and is located in Lyon, France. Today, IARC's membership has grown to 16 countries (founding states plus Australia, Belgium, Canada, Denmark, the Russian Federation, Finland, Japan, Norway, the Netherlands, Sweden, and Switzerland). IARC activities are mainly funded by the regular budgetary contributions paid by its participating states. Each contribution is according to a formula which shares the first 70% equally amongst all participating states and apportions the remaining 30% depending upon the individual country's GNP.

A major goal of the IARC is the identification of causes of cancer, so that preventive measures may be adopted against them. The Governing Council has repeatedly stated that research dealing with treatment and other aspects of cancer patient care should not be a part of IARC's mission, nor should the Agency be directly involved in the implementation of control measures, except in cases where it is necessary in order to assess the effectiveness of the mechanisms of carcinogenicity, or when the experimental intervention is needed to permit identification of causes. Nor does IARC deal in the formulation of policies or legislation aimed at controlling carcinogens.

The main emphasis of research is on epidemiology, environmental carcinogenesis, and research training. This emphasis reflects: (i) the generally accepted notion that 80% of all cancers are, directly or indirectly, linked to environmental factors, and thus are preventable; (ii) the recent recognition of the fact that epidemiology may play an important part in cancer prevention and in the evaluation of prevention measures; and (iii) the fact that geographic variations in cancer incidence almost certainly reflect differences in the environment and are therefore particularly well suited for international research efforts.

Epidemiologic research is in two main areas: **descriptive epidemiologic** studies show the trends of cancer incidence and mortality in different populations and geographic areas, and **analytic epidemiologic** studies focus on the **associations** between incidence and mortality and specific risk factors (diet, some professional exposures, etc.).

Recent years have seen renewed interest for the study of genetic factors (*see* **Genetic Epidemiology**) and other host factors contributing to cancer. This trend came about after an increasing body of evidence showing that genetic mutations play a critical part in carcinogenesis, because of the potential importance of host factors in the modification of the carcinogenic effect of environmental agents (*see* **Environmental Epidemiology**), and because of the potential usefulness of genetic methods in the identification of people at high cancer risk who could benefit from a specific intervention.

Throughout its existence, IARC has had an active programme in biostatistics, involving several professional biostatisticians. Emphasis has been given not only to the optimal utilization of methods, but also to the development of new methodology in response to the needs of cancer research. Contribution to **case–control** and **cohort study** methodology, evaluation of **screening** programs, long-term animal experiments (*see* **Tumor Incidence Experiments**) and descriptive epidemiology are among the fields in which IARC has made notable methodologic contributions.

IARC publishes several series: the *Scientific Publications* series (154 volumes), the *IARC Monographs on the Evaluation of Carcinogenic Risks to Humans* (82 titles and eight supplements), the *Technical Reports* series, the *Directory of Agents being Tested for Carcinogenicity* and a few other nonserial publications. Of particular importance to statisticians are the volumes on statistical methods in cancer research [1–4].

IARC has around 150 staff members at the Agency's Headquarters in Lyon, and welcomes every year an average of over 600 visiting scientists and trainees from over 30 countries.

International Biometric Society (IBS)

The International Biometric Society is an

> international society for the advancement of biological science through the development of quantitative theories and the application, development, and dissemination of effective mathematical and statistical techniques. To this end the Society welcomes to membership biologists, mathematicians, and others interested in applying similar techniques.

The Society was founded on September 6, 1947, at the First International Biometric Conference at Woods Hole, Massachusetts, in the US. The first President of the Society was **R.A. Fisher** from Britain and the first Secretary was **Chester I. Bliss**, from the US. The founders of the Society were motivated by the need for an organization that would foster international cooperation in the methodology and applications of statistics to biology. Biological research was defined broadly and included medicine, agronomy, public health, epidemiology, psychometrics, crop forecasting, paleontology, plant and animal husbandry, design of experiments, etc.

Structure of the Society

The Society is comprised of geographically delimited Regions or Groups that operate both independently and in consort with the international parent organization. Each Region or Group has its own set of officers and operates scientific and educational programs within its own geographic areas as well as maintaining an active role in the activities of the parent organization. The Governing Body of the Society is its Council, with members of Council elected by the membership at large. The election procedures ensure that all geographic areas have appropriate representation on the Council. The Society had seven Regions in 1948 and in 1995 had 18 Regions and 17 Groups covering virtually the entire world. The total membership in 1995 was approximately 6300.

Publications of the Society

The Society publishes ***Biometrics*** (Founding Editor **Gertrude M. Cox**, US) a peer-reviewed journal with the general purpose "to promote and extend the use of mathematical and statistical methods in pure and applied biological sciences". Potential authors do not need to be members of the Society to submit articles for publication. *Biometrics* was first published in 1945 as the *Biometrics Bulletin* and is currently published quarterly with special issues from time to time. The *Biometric Bulletin*, first published in 1983 (Founding Editor, Robert O. Kuehl, US) also published quarterly by the Society provides information on Society activities, Regional and Group activities, scientific abstracts from Biometric Society Regional meetings, as well as expository papers on biometric applications in various areas of the world. The Society, in collaboration with the **American Statistical Association** publishes quarterly the *Journal of Agricultural, Biological and Environmental Statistics* (Founding Editor, Dallas E. Johnson, US), which focuses on the methodology and applications of statistics to the named fields. The first issue appeared in 1996.

The journal *Biometrics* is currently published by Blackwell Publishing. The journal is available online through the JSTOR initiative since 2002, with back issues also available in electronic form. The newsletter, *Biometric Bulletin*, has been converted to electronic-only publication, with the exception of the last issue of each year, which also contains the Society's Business Plan and its Strategic Plan.

Society Networks

The Society supports a series of Regional biostatistical networks. The networks provide a linkage between countries with established biostatistical centers and those with little or no expertise. Joint conferences, short courses, individual training and provision of journals and computer **software** are components of the activities that make available biometric design and analysis to the scientists in developing countries. The Society had 19 Regions and 17 Groups in 2004, as well one Network, the Sub-Saharan Network.

International Biometric Society Conferences

Since the first International Biometric Conference (IBC) in 1947 there have been 17 IBCs in countries around the world. The conferences provide

a forum for the presentation of scientific papers, discussion of these papers and interactions with biostatistical colleagues with different types of problems and perspectives. The Regions apply to host the biannual meetings and the conferences attract a large number of attendees from many different countries. The Society celebrated the fiftieth anniversary of its founding at the eighteenth IBC in Amsterdam in 1996. Over 700 people attended from more than 60 countries. Recent International Biometric Conferences were held in Cape Town, South Africa (1998), Berkeley, USA (2000), Freiburg, Germany (2002), Cairns, Australia (2004), and a meeting scheduled for Montreal, Canada in 2006.

For additional information about the International Biometric Society, contact the IBS Business Office, 808 17th Street, NW, Suite 200, Washington, DC, 20006-3910, USA. Tel: 1-202-223-9669; Fax: 1-202-223-9569. The Society now has a website `www.tibs.org`.

GEERT MOLENBERGHS

International Classification of Diseases (ICD)

The International Classification of Diseases (commonly known as the ICD) is a classification system designed to group together similar diseases, injuries, and related health problems to facilitate statistical analysis of these conditions. The classification is designed to have a finite number of categories encompassing the entire range of morbid conditions. A specific disease or condition is given its own separate category title in the classification only when separate identification is warranted because of its frequency of occurrence or importance as a medical or public health concern. However, many category titles in the classification contain groups of separate but usually related morbid conditions. There is a unique place for inclusion into one of the categories for every disease or morbid condition; therefore, a number of residual categories are reserved throughout the classification for those conditions which do not belong under one of the more specific titles. The International Classification of Diseases is a statistical classification, not a nomenclature or extensive list of approved names for morbid conditions; however, the concepts of classification and nomenclature are closely related. Some classifications are so detailed (e.g. in zoology and botany) that they in fact become nomenclatures, but these very detailed classifications often lose their value for statistical purposes.

History and Development of the International Classification of Diseases

Interest in classifying diseases and studying disease patterns is usually traced back to the work of **John Graunt** and his tabulations of causes of death based on the London Bills of Mortality in the seventeenth century. During the eighteenth and early nineteenth centuries, several classifications of diseases were prepared. The first to approach classification of diseases systematically was François Bossier de Lacroix (1706–1777), writing under the name Sauvages, in his treatise, *Nosologia Methodica*. During the same period, the naturalist and physician Carolus Linnaeus (1707–1778) prepared, in addition to his seminal classification of botany, a treatise entitled *Genera Morborum*. By the beginning of the nineteenth century, the disease classification in general use was *Synopsis Nosologiae Methodicae*, prepared by William Cullen (1710–1790) and published in 1785 [1].

When the General Register Office of England and Wales was established in 1837, **William Farr** (1807–1883) was named as its first medical statistician. Farr found the Cullen classification, still in use, to be outdated and not sufficiently useful for statistical summarization. In his annual "Letters", published in the Annual Reports of the Registrar General, Farr urged the adoption of a new, uniform, statistical classification of diseases. He noted that many diseases were denoted by more than one term, some terms were used to describe more than one disease, vague terms were used, and complications were recorded instead of primary diseases [2].

The importance of a uniform statistical classification was recognized at the first International Statistical Congress meeting in Brussels in 1853. The Congress asked Farr and Marc d'Espine of Geneva to prepare an internationally acceptable uniform classification of causes of death. At the next meeting of the Congress in 1855 in Paris, Farr and d'Espine each submitted his own classification and the Congress adopted a compromise list of 139 rubrics; the compromise list reflected Farr's arrangement into five groups: epidemic diseases, constitutional (general) diseases, local diseases arranged according to anatomical site, developmental diseases, and diseases directly resulting from violence. Over the next 30 years, this classification was revised four times but it maintained the general structure proposed by Farr.

In 1891, the **International Statistical Institute**, successor to the International Statistical Congress, charged a committee to prepare a new classification of causes of death. The committee, chaired by Jacques **Bertillon** (1851–1922), submitted its classification to the Institute in 1893, and it was adopted. This Bertillon Classification, as it was called, consisted of 161 rubrics as well as an abridged classification of 44 titles and another of 99 titles. These were based on Farr's principle of distinguishing between general diseases and those localized to a particular organ or anatomical site. The Bertillon Classification received general approval and was put into use by several countries and a number of cities. The 1899 meeting of the Institute passed a resolution acknowledging

the use of this "system of cause of death nomenclature" in all the statistical offices in North America, and some in South America and Europe. The resolution further "insists vigorously that this system of nomenclature be adopted in principle and without revision, by all the statistical institutions of Europe" and "approves. . .the system of decennial revision proposed by the American Public Health Association . . .".

The French Government, as a response to the International Statistical Institute's 1899 resolution, convened in Paris, in 1900, the first International Conference for the Revision of the Bertillon or International List of Causes of Death. This conference adopted a classification consisting of 179 groups and an abridged list of 35 groups, and it reaffirmed the desirability of decennial revisions. Accordingly, the International List of Causes of Death, and its successor classifications, has been revised approximately every 10 years thereafter.

Bertillon continued his leadership in classification matters, and the revisions of 1900, 1910, and 1920 were carried out under his guidance. During the decade following his death in 1922, there was an increasing interest in expanding the classification to accommodate morbidity and other **vital statistics** interests. At the same time, there was recognition of the need to involve other international agencies, particularly the Health Organization of the League of Nations, in future revision activity. To coordinate efforts, an international commission, known as the Mixed Commission, was created with equal representation from the International Statistical Institute and the Health Organization of the League of Nations. This Commission drafted the proposals for the fourth (1929) and fifth (1938) revisions of the International List of Causes of Death.

In 1946, the newly established **World Health Organization** was given the responsibility for the next (sixth) revision of the International List of Causes of Death and to develop an International List of Causes of Morbidity. In 1948, the International Conference for the Sixth Revision of the International Lists of Diseases and Causes of Death met in Paris. The Conference secretariat was the joint responsibility of competent French authorities and the World Health Organization. The Sixth Decennial Revision Conference introduced a new era in international vital and health statistics. In addition to recommending a comprehensive list of conditions for both morbidity and mortality, the *Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death*, the Conference agreed on rules for selecting the underlying **cause of death**, a Medical Certificate of Cause of Death form (*see* **Death Certification**), and special lists and guidelines for tabulation. These recommendations were endorsed by the first World Health Assembly in 1948, resulting in World Health Organization Nomenclature Regulations which member countries have agreed to follow.

The International Conference for the Seventh Revision of the International Classification of Diseases was held under WHO auspices in 1955; the Eighth Revision Conference took place in 1965. The seventh revision was limited to a few essential changes and amendments or corrections. The eighth revision, while more extensive than the seventh, still maintained the basic structure of the classification and the general concept of classifying diseases according to etiology rather than manifestation.

The International Conference for the Ninth Revision of the International Classification of Diseases, again convened by WHO, took place in 1975. During the period when the seventh and eighth revisions were in force, there was a growing use of the International Classification of Diseases for indexing hospital records and for other morbidity applications. These expanding uses were recognized in the ninth revision, which added considerable detail and specificity to the classification. Also introduced was an optional method of classifying selected conditions according to their manifestation in a particular organ or site as well as by the underlying general disease. In addition, based on recommendations of the Ninth Revision Conference, the World Health Assembly approved the publication by WHO of two supplementary classifications on a trial basis: one for Impairments, Disabilities, and Handicaps [4] and one for Procedures in Medicine [3] (*see* **Classifications of Medical and Surgical Procedures**). These were to be adjuncts to the International Classification of Diseases, not integral parts of the basic classification.

Planning for the preparation of the tenth revision began even before the publication of the ninth revision. Early on, it was apparent that the expanded uses of the classification and the resultant complexities and additional detail required more than the usual 10-year cycle for this revision. The longer time period would not only allow broad solicitation of input from users and producers of the data but would also permit trials

of some of the major changes being proposed. Therefore, WHO, with the concurrence of member states, postponed the Tenth Revision Conference from 1985 to 1989, with the planned implementation of the tenth revision consequently also delayed.

Characteristics of the Tenth Revision

The formal title of the tenth revision of the International Classification of Diseases (usually referred to as ICD-10) is *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* [6]. It comprises three volumes: Vol. 1 contains the main classifications; Vol. 2 contains guidance and rules for use of the ICD; and Vol. 3 is the alphabetic index.

ICD-10 is a variable-axis classification evolved from the original principles of organization proposed by Farr. It is designed as a three-character code with fourth-character subdivisions where appropriate. A letter is used in the first position and a numerical digit in the second, third, and fourth positions. The fourth character is preceded by a decimal point. Therefore, individual alphanumeric codes range from A*nn.n* to Z*nn.n*, where *n* represents any of the ten digits from 0 to 9. The letter U is not used. The alphanumeric characteristic of ICD-10 codes is an innovation designed to permit more flexibility in maintaining a hierarchical sequence of diseases while adding more detail to the classification; previous revision code numbers were completely numeric. Vol. 1 contains the list of three-character categories and the tabular list of inclusions and four-character subdivisions. The "core" classification is the list of three-character categories representing the level of reporting required for the WHO mortality database and for routine international comparisons. Many countries use the ICD only at this level of detail; further subdivision of disease categories may not be possible given the quality of the original diagnostic data. Both the core classification and the fully detailed tabular list with its fourth-character detail are arranged into 21 main chapters, and chapters into blocks of related conditions headed by an appropriate block title. In the tabular list, but not in the list of three-character categories, inclusion terms are provided under each code number as examples or guides to the intended content of the category. However, the inclusion terms so listed are not intended to be exhaustive for any given category, and the Alphabetic Index (Vol. 3) serves as a much more detailed guide to the correct placement of conditions into ICD categories.

Vol. 1 also contains a separate classification of morphology of neoplasms which may be used in addition to the main ICD codes which usually classify neoplasms only by behavior and site. These morphology codes are the same as those appearing in the adaptation of the International Classification of Diseases called the *International Classification of Diseases for Oncology* (ICD-O) [5]. In addition, Vol. 1 contains key definitions adopted by the World Health Assembly to facilitate international comparisons of data, and special tabulation lists recommended for the uniform statistical summarization and presentation of both morbidity and mortality data based on the International Classification of Diseases.

ICD-10 came into force on January 1, 1993; however, the actual implementation of this revision of the classification in countries around the world did not begin in earnest until 1995 and the next several years thereafter.

ROBERT A. ISRAEL

International Society for Clinical Biostatistics (ISCB)

The International Society for Clinical Biostatistics (ISCB) was founded in May 1979 with the aim of stimulating research into the principles and methodology used in the design and analysis of clinical research, to increase the relevance of statistical theory to clinical practice, and to further the communication between statisticians and clinicians. The Society also has the policy to work with other societies and organizations in the advancement of biostatistics and to provide a common forum for clinicians and statisticians through meetings, seminars and publications.

The ISCB is constituted by an executive committee and led by a President. The Executive Committee consists, in addition to the President, of a Vice-President, a Treasurer, a Secretary and up to eight members, the past President, the News Editor and the Webmaster. The Society's Permanent Office is located in Denmark at the following address: ISCB Permanent Office, PO Box 130, DK-3460 Birkerod, Denmark (tel.: +45 4567 2279; fax: +45 7022 1571; email: `office@iscb.info`. The Society has a website: `http://www.iscb.info`.

Scientific Meetings, Courses, and Publications

The ISCB organizes an annual scientific meeting open to anybody with an interest in statistical methodology and applications in the broad field of medical research, including statisticians, clinicians, epidemiologists, and pharmacologists.

Between its foundation in 1979 and 2003, 24 annual meetings have been held (there was no annual meeting in 1981), all but one of them in Europe – the 1997 meeting was in Boston, US. Four of these meetings have been joint meetings with other societies; in 1985 and 1999 with the German Gesellschaft für Medizinische Dokumentation, Informatik und Statistik (GMDS), and in 1991, 1997 and 2003 with the Society for Clinical Trials (SCT).

A special feature of the meeting is a mini-symposium devoted to a particular medical or statistical field. In recent years these have included environmental epidemiology, statistical challenges in pediatric research, cancer genetics, human fertility, and fecundity, emerging issues in clinical trial data monitoring.

The Society does not publish its own journal, but by an arrangement with the publishers, John Wiley & Sons Ltd, reviewed papers from the annual meetings are published in issues of ***Statistics in Medicine***. In addition, a twice/thrice yearly newsletter, *ISCB News*, is published.

The Society also performs an educational role in the sense of organizing courses on particular statistical topics relevant to the application of statistics in medicine (*see* **Teaching Medical Statistics to Statisticians**). These have generally been run in conjunction with annual meetings, either as pre- or postconference activities, with faculties of foremost researchers in their field.

The Society recognizes the political and economic difficulties of some countries and actively promotes and supports the establishment of national groups. The Society organizes courses in these countries, to enhance the development of biostatistics, and has a Conference Awards for Scientists Program for biostatisticians to attend and present papers at the annual meetings.

In order to promote participation of young researchers, the Society has a Student Conference Awards Program for postgraduate students from all over the world to attend and present papers at the annual meetings.

Special Working/Interest Groups

In recent years the Society has developed a number of working groups, called subcommittees, which deal with scientific, regulatory, or organizational issues. Among the first established subcommittees, there are the one on "Statistics in Regulatory Affairs", whose remit is to consider and influence the development of regulatory requirements, guidelines, and other documents concerning the scientific aspects of data collection, management, analysis, and reporting (*see* **Drug Approval and Regulation**); the subcommittee on **fraud,** which ended its activity after the publication of the paper " *The role of biostatistics in the prevention, detection and treatment of fraud in clinical trials"*, by Buyse M., George S.L., Evans S., Geller N., Ranstam J., Scherrer B., Lesaffre E, Murray G., Edler

L., Hutton J., Colton T., Lachenbruch P., Verma B, on behalf of ISCB, on *Statistics in Medicine*, 18(1999), p. 3435-3451. Other subcommittees currently active are those on Education, Dentistry, National Groups, Student Conference Awards, Conference Organising, and Communication. Their terms of reference and members are published on the Society's News and Web site.

Membership

The membership during the mid-1990s has been fairly stable and numbering around 800 members from some 40 countries from around the world, with the majority coming from Europe. Nonmembers attending an annual meeting automatically become members for that year. The annual membership fee in 2004 is 40 Euro.

MARIA GRAZIA VALSECCHI

International Statistical Institute (ISI)

The International Statistical Institute (ISI) was established in 1885 in London, closely following an exploratory contact of statisticians in Paris. Its predecessor organization, the International Statistical Congress (ISC), was started in 1853 in Brussels, under the leadership of the famous Belgian statistician **Adolphe Quetelet**. The ISC remained in existence until 1876 when the German–French rivalries of the time, apparently through an intervention of Chancellor Bismarck, led to the dissolution of this intergovernmental statistical cooperation. The ISI, under the circumstances, was started as a nongovernmental instrument of international statistical cooperation, with heavy reliance on its elected membership, which consists of outstanding statisticians of the world in their personal professional capacity. ISI is considered today the world academy of statisticians.

At the beginning of 2004, ISI had 1884 elected members, distinguished statisticians active in academia, government, and the private sector of about 130 countries. At the same time, 166 persons who are the heads of national and international statistical offices participate as *ex officio* members in ISI. In addition to its elected and *ex officio* members, ISI involves in its Associations (Sections) a substantial number of statisticians who are active in specialized areas of statistics.

These Associations are: the Bernoulli Society for Mathematical Statistics and Probability (1241 members); the International Association for Official Statistics (474 members); the International Association for Statistical Computing (495 members); the International Association of Survey Statisticians (1266 members); and the International Association for Statistical Education (463 members). The Sections of ISI maintain open membership for all interested statisticians; many elected or ex officio ISI members also hold membership in one or more of these specialized Associations. The total of about 5800 association members include those ISI members who hold membership both in these Sections and in the ISI. ISI is incorporated as a not-for-profit institution in the Netherlands (with its Permanent Office, established in 1913, located in Voorburg, a town adjacent to The Hague).

The goal of ISI is the development and improvement of statistical methods, and their application throughout the world, all in the widest sense of the word. The role played by ISI has changed since its inception. In the nineteenth century, for example, the promotion of standardization of statistical methodology in the official statistics of countries was a key task: the acceptance of the first **International Classification of Diseases** at the 1893 Chicago Session of the ISI was a historic step in this regard. Today, the intergovernmental organizations such as the United Nations (UN), its specialized agencies, the European Union, and the Organization for Economic Cooperation and Development (OECD) are the main forums for these types of endeavor. It is convenient to group present-day ISI activities into five areas: (i) conference services, (ii) publications, (iii) research activities, (iv) membership services, and (v) other functions.

In respect of *conferences*, the biennial ISI Sessions are the most outstanding.

The 2003 Session in Berlin was the fifty-fourth such undertaking (during World Wars I and II no Sessions were held). Recent Sessions were held in Seoul (2001), Helsinki (1999), Istanbul (1997), Beijing (1995), and Florence (1993). The number of participants in recent Sessions has reached about 2300 with nearly 285 invited, 728 contributed, and 84 poster papers presented on a wide array of statistical, theoretical, methodological, and application questions. Smaller, and more specialized conferences were held in Szczecin (2003), Cape Town (2002) amongst others, in cooperation with other national and international statistical organizations.

The *publications* of ISI include scientific journals, such as the *International Statistical Review* [3], *Bernoulli* [1], abstracting resources such as *Statistical Theory and Method Abstracts* [4], books such as *The Oxford Dictionary of Statistical Terms* [2], which has been published in several editions (between 1957 and 2003), as well as the *Newsletter of the ISI*, and so on. In addition, there are numerous journals and publications by the five ISI Sections dealing with areas of their specialization.

ISI has been a promoter of *research activities* since its inception.

The *Bulletins of the ISI* go back to the nineteenth century: these volumes have been issued after each of the ISI Sessions and printed in the host country where the Sessions were held. These “Bulletins”

are a repository of, and a testimonial to, the manifold research efforts undertaken by statisticians in numerous countries over the last 150 years. Later, in connection with the "World Fertility Survey" in the 1970s and 1980s, ISI set up an internal research facility regarding population issues, albeit budgetary restrictions by the end of the 1980s made this venture financially unsustainable. The research function of ISI, however, has been maintained. Today, it involves holding conferences on acute methodological, theoretical, or topical matters such as the statistical issues of derivatives trading, the index numbers of stock markets, or the demographic crisis of the transition countries. It also involves projects at the ISI Permanent Office such as the multilingual glossary of statistical terms and historical statistical investigations and commemorations. Moreover, the five ISI Sections are involved in a wide range of similar activities.

The *membership services* of ISI are primarily administrative in nature and result in the publication of the *Directory of ISI*, which lists all ISI and ISI Section members as well as containing a listing of national and international statistical organizations and societies.

Among the *other functions* of ISI mention should be made of the site (home page) maintained on the **internet** (`http://www.cbs.nl/isi`). Also, every second year (at the time of the world-wide Session) ISI awards the "Jan Tinbergen Prize" to the three most deserving statistical studies submitted by young statisticians from developing countries. Each winner receives 2269 Euros, transportation to, and free stay at the Session, and an opportunity to present their winning papers.

ISI also attempts to promote cooperation with statisticians active in other, primarily nonstatistical, organizations dealing with biometrics, econometrics, psychometrics, astronomy, classification science, linguistics, and so on. It is believed that in addition to the studies emanating from specialized and subspecialized areas within statistics identified as such, there are significant intellectual and practical gains to be made by fostering more integration with the rather dispersed statistical professionals active in all other fields. The Sessions of ISI, therefore, are being opened up for meetings with the "sister organizations" active in statistics.

International Studies of Infarct Survival (ISIS)

The ISIS began in 1981 as a collaborative worldwide effort to evaluate the effects of several widely available and practical treatments for acute myocardial infarction (MI). The ISIS Collaborative Group randomized more than 134 000 patients into four large simple trials assessing the independent and synergistic effects of beta-blockers, thrombolytics, aspirin, heparin, converting enzyme inhibitors, oral nitrates, and magnesium in the treatment of evolving myocardial acute infarction (Table 1). More than 20 countries participated in these trials, which were coordinated worldwide by investigators in Oxford, England.

ISIS-1: Atenolol in Acute MI [1]

Beta-blocking agents reduce the heart rate and blood pressure, as well as their product, inhibit the effects of catecholamines, and increase thresholds for ventricular fibrillation. Thus, it is not surprising that beta-blockers were among the first agents to be evaluated in randomized trials of evolving acute MI. Even by 1981, the available trials of beta-blocking agents for acute infarction were too small to demonstrate a significant benefit. However, based on an overview of the available evidence (*see* **Meta-analysis of Clinical Trials**), it was judged that the prevention of even one death per 200 patients treated with beta-blockers (*see* **Number Needed to Treat (NNT)**) would represent a worthwhile addition to usual care. Unfortunately, detecting such an effect would require the **randomization** of over 15 000 patients. It was toward this end that the First International Study of Infarct Survival (ISIS-1) trial was formed.

In a collaborative effort involving 245 coronary care units in 11 countries, the ISIS-1 trial randomized 16 027 patients with suspected acute MI to a regimen of intravenous atenolol versus no beta-blocker therapy. Patients assigned to active treatment received an immediate intravenous injection of 5–10 mg atenolol, followed by 100 mg/day orally for seven days. Similar agents were avoided in those assigned at random to no beta-blocker therapy unless it was believed to be medically indicated. As in the subsequent ISIS collaborations, all other treatment decisions were at the discretion of the responsible physician.

During the seven-day treatment period in which atenolol was given, vascular mortality was significantly lower in the treated group (3.89% vs. 4.57%, $P < 0.04$), representing a 15% mortality reduction. Almost all of the apparent benefit was observed in days 0 to 1 during which time there were 121 deaths in the atenolol group as compared with 171 deaths in the control group. The early mortality benefit attributable to atenolol was maintained at 14 days and at the end of one year follow-up (10.7% atenolol vs. 12.0% control). Treatment did not appear to decrease infarct size substantially, although the ability of a large and simple trial such as ISIS-1 to assess such a reduction was limited. Despite its large size, the 95% confidence limits of the risk reductions associated with atenolol in ISIS-1 were wide and included relative risk reductions between 1% and 25%. However, an overview that included ISIS-1 and 27 smaller completed trials of beta-blockade suggested a similar sized mortality reduction (14%). When a combined endpoint of mortality, nonfatal cardiac arrest and nonfatal reinfarction was considered from all available trials, the 10%–15% reduction persisted with far narrower confidence limits. Taken together, these data suggest that early treatment of 200 acute MI patients with beta-blocker therapy

Table 1 The International Studies of Infarct Survival (ISIS)

Trial	Year completed	Agents studied	Patients randomized
ISIS-1	1985	Atenolol vs. control	16 027
ISIS-2	1988	Streptokinase vs. placebo Aspirin vs. placebo	17 187
ISIS-3	1991	Streptokinase vs. tPA vs. APSAC Aspirin + SC heparin vs. aspirin	41 299
ISIS-4	1993	Captopril vs. placebo oral mononitrate vs. placebo Magnesium vs. control	58 050

would lead to avoidance of one reinfarction, one cardiac arrest, and one death during the initial seven-day period. Unfortunately, beta-blocker use in the setting of acute MI remains suboptimal with utilization rates ranging between 30% in the US to less than 5% in the UK. This underutilization appears related in part to poor physician education. In the GUSTO-1 trial, beta-blockers were encouraged by the study protocol and almost 50% of all patients received the drugs without any apparent increase in adverse effects.

ISIS-2: Streptokinase and Aspirin in Acute MI [2]

As with beta-blockers, data from randomized trials of thrombolytic therapy completed prior to 1985 did not yield truly reliable results. Indeed, the largest of the early studies enrolled 750 patients, a totally inadequate sample size to detect the most plausible 20%–25% reduction in mortality.

Given this situation, the Second International Study of lnfarct Survival (ISIS-2) was designed to test directly in a single randomized, double-blind, placebo-controlled trial (*see* **Blinding or Masking**) the risks and benefits of streptokinase and aspirin in acute MI. To accomplish this goal, the ISIS-2 collaborative group randomized 17 187 patients presenting within 24 hours of symptom onset using a 2×2 **factorial design** to one of four treatment groups: 1.5 million units of intravenous streptokinase over 60 minutes; 162.5 mg/day of oral aspirin for 30 days; both active treatments; or neither.

In brief, the primary endpoint (*see* **Outcome Measures in Clinical Trials**) of the trial, total vascular mortality, was reduced 25% by streptokinase alone (95% Cl, −32 to −18, $P < 0.0001$) and 23% by aspirin alone (95% CI, −30% to −15%, $P < 0.00001$). Patients allocated to both agents had a 42% reduction in vascular mortality (95% Cl, −50 to −34, $P < 0.00001$), indicating that the effects of streptokinase and aspirin are largely additive. When treatment was initiated within six hours of the onset of symptoms, the reduction in total vascular mortality was 30% for streptokinase, 23% for aspirin, and 53% for both active agents.

For aspirin, the mortality benefit was similar when the drug was started 0–4 hours (25%), 5–12 hours (21%), or 13–24 hours (21%) after the onset of clinical symptoms. Aspirin use also resulted in highly significant reductions for nonfatal reinfarction (49%) and nonfatal stroke (46%). As regards side-effects, for bleeds requiring transfusion, there was no significant difference between the aspirin and placebo groups (0.4% vs. 0.4%), although there was a small absolute increase of minor bleeds among those allocated to aspirin (0.6%, $P < 0.01$). For cerebral hemorrhage, there was no difference between the aspirin and placebo groups.

For streptokinase, those randomized within four hours of pain onset experienced the greatest mortality reduction, although statistically significant benefits were present for patients randomized throughout the 24 hour period. As expected, there was an excess of confirmed cerebral hemorrhage with streptokinase (7 events vs. 0; $2P < 0.02$), all of which occurred within one day of randomization. Reinfarction was slightly more common among those assigned streptokinase alone, but this difference was not statistically significant. Furthermore, aspirin abolished the excess reinfarction attributable to streptokinase.

In addition to demonstrating the independent as well as synergistic effects of streptokinase and aspirin, ISIS-2 also supplied important information concerning which patients to treat. Because the ISIS-2 entry criteria were broad, the trial included the elderly, patients with left bundle branch block, and those with inferior as well as anterior infarctions. In each of these subgroups, clear mortality reductions were demonstrated.

Thus, in addition to changing radically the premise that thrombolysis should be avoided in patients already on aspirin, the ISIS-2 trial was largely responsible for widening the **eligibility criteria** for patients who would benefit from thrombolytic therapy.

ISIS-3: Streptokinase vs. APSAC vs. tPA and Subcutaneous Heparin vs. No Heparin in Acute MI [3]

While ISIS-2 (streptokinase), the first Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico (GISSI-1, streptokinase), the APSAC Intervention Mortality Study (AIMS, anisoylated plasminogen streptokinase activator complex [APSAC]), Anglo–Scandinavian Study of Early Thrombolysis (ASSET, tissue plasminogen activator [tPA]) and ISIS-2 all documented clear mortality benefits for

thrombolysis, they did not provide information that allowed for directly comparing these agents. It was also unclear whether patients given aspirin would further benefit from the addition of heparin. These questions were the focus of the Third International Study of Infarct Survival (ISIS-3).

In brief, the ISIS-3 collaborative group randomized 41 299 patients to streptokinase, APSAC, and tPA. Patients presenting within 24 hours of the onset of evolving acute MI and with no clear contraindication to thrombolysis were assigned randomly to IV streptokinase (1.5 MU over one hour), IV tPA (duteplase, 0.50 million U/kg over four hours), or IV APSAC (30 U over three minutes). All patients received daily aspirin (162.5 mg), with the first dose crushed or chewed in order to achieve a rapid clinical antithrombotic effect. In addition, half were randomly assigned to receive subcutaneous heparin (12 500 IU twice daily for seven days), beginning four hours after randomization.

ISIS-3 demonstrated no differences in mortality between the three thrombolytic agents. Specifically, among the 13 780 patients randomized to streptokinase, there were 1455 deaths (10.5%) within the initial 35-day follow-up period as compared with 1448 deaths (10.6%) among the 13 773 patients randomized to APSAC and 1418 deaths (10.3%) among the 13 746 randomized to tPA.

Long-term survival was also virtually identical for the three agents at both three and six months. With regard to in-hospital clinical events, cardiac rupture, cardiogenic shock, heart failure requiring treatment, and ventricular fibrillation were similar for the three agents. For nonfatal reinfarction, there was a reduction with tPA, while streptokinase and APSAC allocated patients had higher rates of allergy and hypotension requiring treatment. Streptokinase produced fewer noncerebral bleeds than either APSAC or tPA.

While there were no major differences between thrombolytic agents in terms of lives saved or serious in-hospital clinical events, significant differences were found in ISIS-3 for rates of total stroke and cerebral hemorrhage. Specifically, there were 141 total strokes in the streptokinase group as compared with 172 and 188 in the APSAC and tPA groups, respectively. For cerebral hemorrhage there were 32 events (two per 1000) in the streptokinase group as compared with 75 (five per 1000) in the APSAC group and 89 (seven per 1000) in the tPA group. While the absolute rates for cerebral hemorrhage for all three agents was low, this apparent advantage for streptokinase was highly statistically significant ($P < 0.0001$ for streptokinase vs. APSAC, $P < 0.00001$ for streptokinase vs. tPA).

With regard to the addition of delayed subcutaneous heparin to thrombolytics there was no reduction in the prespecified endpoint of 35 day mortality. During the scheduled seven day period of heparin use, there were slightly fewer deaths in the aspirin plus heparin group compared with the aspirin group alone, a difference of borderline significance. There was, however, a small but significant excess of strokes deemed definite or probable cerebral hemorrhages among those allocated aspirin plus heparin (0.56% vs. 0.40%, $P < 0.05$). In contrast, reinfarction was more common among those randomized to aspirin alone as compared with those receiving aspirin plus subcutaneous heparin.

ISIS-4: Angiotensin Converting Enzyme Inhibition, Nitrate Therapy, and Magnesium in Acute MI [4]

In 1991 the ISIS collaboration chose to investigate several other promising but unproven approaches to the treatment of acute MI. Specifically, the Fourth International Study of Infarct Survival (ISIS-4) sought to examine treatment strategies that would benefit both high- and low-risk patients presenting with acute MI, not simply those who are eligible for thrombolysis.

To attain this goal, the ISIS collaborative group chose to study three promising agents: a twice daily dose of the angiotensin converting enzyme (ACE) inhibitor captopril for 30 days, a once daily dose of controlled release mononitrate for 30 days, and a 24-hour infusion of intravenous magnesium. As was true in each of the preceding ISIS trials, the available data were far too limited to allow reliable clinical recommendations concerning these therapies. For example, while ACE inhibiting agents had been shown to be successful in reducing mortality in patients with congestive heart failure and in patients a week or two past acute infarction, it was unclear whether these agents provided a net benefit for all patients in the setting of evolving acute MI. Similarly, while nitrates were often used in evolving MI because of their ability to reduce myocardial

afterload and potentially limit infarct size, barely 3000 patients had received intravenous nitroglycerin in randomized trials and even fewer patients had been studied on oral nitrate preparations. Finally, because of its effects on calcium regulation, arrhythmia thresholds, and tissue preservation, magnesium therapy had often been considered as an adjunctive therapy for acute infarction even though no data from a randomized trial of even modest size had been available.

Based on statistical overviews, the ISIS investigators estimated that each of these therapies had the potential to reduce mortality in acute infarction by as much as 15%–20%. However, because many patients presenting with acute infarction were treated with thrombolytic therapy and aspirin, the estimated mortality rates at one month were estimated to be as low as 7%–8%. Thus, to assess reliably whether these potentially important clinical effects were real required the randomization of a very large number of patients, perhaps as many as 60 000. To achieve this goal, a $2 \times 2 \times 2$ factorial design was employed in which patients were randomized first to captopril or captopril placebo, then to mononitrate or mononitrate placebo, and then to magnesium or magnesium control. Thus, it was possible in the trial for any given patient to receive all three active agents, no active agents, or any combination.

Captopril

Use of the ACE inhibitor captopril was associated with a significant 7% decrease in five-week mortality (2088 [7.19%] deaths among patients assigned to captopril vs. 2231 [7.69%] deaths among those assigned to placebo), which corresponds to an absolute difference of 4.9 ± 2.2 fewer deaths per 1000 patients treated for one month. The absolute benefits appeared to be larger (possibly as high as 10 fewer deaths per 1000) in some higher-risk groups, such as those presenting with heart failure or a history of MI. The survival advantage appeared to be maintained at 12 months. In terms of side-effects, captopril produced no excess of deaths on days 0–1, even among patients with low blood pressure at entry. It was associated with an increase of 52 patients per 1000 in hypotension considered severe enough to require termination of study treatment, of five per 1000 in reported cardiogenic shock, and of five per 1000 in some degree of renal dysfunction.

Mononitrate

Use of mononitrate was not associated with any significant improvements in outcomes. There was no significant reduction in overall five-week mortality, nor were there reductions in any subgroup examined (including those not receiving short-term nonstudy intravenous or oral nitrates at entry). Continued follow-up did not indicate any later survival advantage. Somewhat fewer deaths on days 0–1 were reported among individuals allocated to active treatment, which is reassuring about the safety of using nitrates early in evolving acute MI. The only significant side-effect of the mononitrate regimen was an increase in hypotension of 15 per 1000 patients.

Magnesium

As with mononitrate, use of magnesium was not associated with any significant improvements in outcomes, either in the entire group or any subgroups examined (including those treated early or late after symptom onset or in the presence or absence of fibrinolytic or antiplatelet therapies, or those at high risk of death). Further follow-up did not indicate any later survival advantage. In contrast to some previous small trials, there was a significant excess of heart failure with magnesium of 12 patients per 1000, as well as an increase of cardiogenic shock of five patients per 1000 during or just after the infusion period. Magnesium did not appear to have a net adverse effect on mortality on days 0–1. In terms of side-effects, magnesium was associated with an increase of 11 patients per 1000 in hypotension considered severe enough to require termination of the study treatment, of three patients per 1000 in bradycardia, and of three patients per 1000 in a cutaneous flushing or burning sensation.

Because of its size, ISIS-4 provided reliable evidence about the effects of adding each of these three treatments to established treatments for acute MI. Collectively, GISSI-3, several smaller studies, and ISIS-4 have demonstrated that, for a wide range of patients without clear contraindications, ACE inhibitor therapy begun early in evolving acute MI prevents about five deaths per 1000 in the first month, with somewhat greater benefits in higher-risk patients. The benefit from one month of ACE inhibitor therapy persists for at least the first year. Oral nitrate

therapy, while safe, does not appear to produce a clear reduction in one-month mortality. Finally, intravenous magnesium was ineffective at reducing one-month mortality.

Conclusion

Because of their simplicity, large size, and strict use of mortality as the primary endpoint, the ISIS trials have played a critical substantive role in establishing rational treatment plans for patients with acute MI. Methodologically, they have clearly demonstrated the utility of large simple randomized trials.

Three principles guided the design and conduct of the ISIS trials. The first was the belief that a substantial public health benefit would result from the identification of effective, widely practical treatment regimens that could be employed in almost all medical settings, as opposed to those that can be administered only at specialized tertiary care facilities. For this reason, the ISIS investigations focused on strategies to decrease mortality which, in and of themselves, did not require cardiac catheterization or other invasive procedures for either diagnostic or therapeutic purposes.

The second principle was that the benefits of truly effective therapies would be applicable to a wide spectrum of patients with diverse clinical presentations. Thus, the entry criteria for the ISIS trials were intentionally broad and designed to mimic the reality all health care providers encounter when deciding whether or not to initiate a given treatment plan. This is one reason that the ISIS trials focused on evolving acute MI in the view of the responsible physician.

The third and perhaps most important principle was that most new therapies confer small to moderate benefits, on the order of 10%–30%. While such benefits on mortality are clinically very meaningful, these effects can be detected reliably only by randomized trials involving some tens of thousands of patients. Thus, the ISIS protocols were streamlined to maximize randomization and minimize interference with the responsible physician's choice of nonprotocol therapies and interventions. Nonetheless, by selectively collecting the most important entry and follow-up variables that relate directly to the efficacy or adverse effects of the treatment in question, the ISIS trials yielded reliable data for providing a rational basis for patient care. By limiting paperwork and not mandating protocol-driven interventions, the ISIS approach proved to be remarkably **cost-effective**. Indeed, the large ISIS trials were conducted at a small fraction of the usual cost of other smaller trials which, because of their inadequate sample sizes, failed to demonstrate either statistically significant effects or informative null results.

Internet

Introduction

The internet (lower case i) is the world's biggest computer network connecting millions of machines worldwide. It offers exciting new ways for people to communicate with each other and new ways to disseminate and access information. The Internet (upper case I), which is a term used to describe what can be done over the internet, has been described as potentially the most exciting and revolutionary development in information since Caxton's printing press. It opens up whole new vistas for academics, the business community, and the general public, providing easier access to information, faster means of communication and exchange of ideas, and new ways of using leisure time.

The internet began with the military in the late 1960s. The Advanced Research Projects Agency (ARPA), a branch of the American defence department, sought a way of exchanging military research information between sites. One essential criterion was that the network had to be able to survive a nuclear war. If one computer in the network was destroyed, then the information would simply take another route. This led to a computer network known as Advanced Research Projects Agency Network (ARPANET). From its military origins, it grew considerably as more US government departments and agencies gained access to the network. In 1983, the military network moved to a separate, more secure system and in 1984, America's National Science Foundation (NSF) created the NSFNET, which linked supercomputers together to allow access by any US educational establishment, irrespective of location.

The ARPANET and NSFNET networks laid the foundations for the wide area network of computers that span the globe and which is now known as the internet. Essentially, it is a network of networks. Each country has many networks for educational, government, and commercial purposes. Each of these separate networks, such as AARNET in Australia, NSFNET in the United States and JANET in the United Kingdom, is an entity in itself. There are also networks operated by commercial Internet Service Providers, who provide access to homes and businesses throughout the world. Each of these networks is made up of smaller, local networks. This whole collection of networks interconnects across the world, allowing each site access to every other site, irrespective of the starting point. This vast interconnecting network forms what is referred to as the internet.

The interconnection of computers to form the internet is based on TCP/IP protocols that allow computers of different types, running different operating systems to communicate with each other. Each computer on the internet is identified by its IP number, which is a hierarchical number similar in nature to a telephone number with country, area, and district codes. However, there are also names for the machines, which are easier to remember, and when a name is known, it can be looked up in a Domain Name Service (DNS).

In the same way that ARPANET passed its information through any available route, depending on which machines were available, information can be routed across the internet by any available path. This makes the whole system extremely robust to failures of individual machines or subnetworks. The machines and networks that make up the internet change from day to day and year to year, but that is not important, as it was designed from its earliest beginnings to be robust to such evolution.

Types of Use

Running over the physical structure of the internet are many different types of services, in the same way that telephone companies supply many types of services over telephone lines. This array of services is generally termed the Internet (upper case I). The Internet can be used in a variety of ways, which see exciting new developments every few months. The principal types of activity are communication between individual people or within a group, gaining access to information, and operating **software**, which is held on a remote computer. These main areas are outlined below.

Communication

Electronic mail (often referred to as "e-mail") is a form of communication where text entered by an individual into one computer system is then sent in electronic form to another, where it can be read by the intended recipient. This type of communication can take place through any system that is connected

to the internet and which has software installed for sending and receiving e-mail. The messages are not transferred around the world instantaneously, but are delivered in seconds rather than days. This has made e-mail a popular form of communication.

In addition to messages between individuals, it is also possible for one person to send a single message to a group of others. Messages sent to a particular Internet address are then automatically broadcast to a list of participants of a "discussion group". Discussion groups of this kind exist for an enormous number of different interests.

Transfer of messages to the individual mailboxes of people interested in a particular subject can be avoided by conducting the discussion through UseNet News groups, where all the messages are brought together on electronic bulletin boards and accessed by interested parties at their convenience.

Again, using text exchanges, technologies such as Internet Relay Chat (IRC) and Talker services enable people to conduct discussions where the text typed by each individual is seen by all the others involved, in real time. Each day there are many people holding discussions, limited only by the speed at which they can type.

As the bandwidth of the internet increases, so the possibility of conducting real-time audio conversations, with full motion video, becomes a reality. This is currently not possible everywhere, but it is spreading rapidly. Again, this need not be confined to one-to-one exchanges. Linking many people together allows computer conferencing to take place, with the consequent reduction in the need for people to travel the world to meet face-to-face for discussion.

File Transfer

When information is transferred in message form, it is usually also possible to attach other files to the main message. However, computer files of any type, such as programs, word processor files, data, or text, can also be transferred from one system to another over the internet. This method of transfer uses the File Transfer Protocol (FTP). This facility is very convenient for a variety of purposes and it is particularly effective for large files. It also forms the backbone of many of the systems for gaining access to information.

Information Searching and Browsing

The Internet has provided a means by which a vast amount of information can be mounted in electronic form and accessed by an enormous number of people. The variety and extent of information now available is staggering. Methods of access to the information are independent of the type of computer a user has, which takes us closer to universal access to information. One of the difficulties faced by users is locating the information of particular interest to them. This has been aided by the development of "hypertext" links, where a keyword in one document is linked to another related document. This is a very flexible system of organization, which has in turn led to a crucial need for searching mechanisms to locate material of interest.

A great deal of attention has been focussed on the richer form of presentation of information within a framework called the World Wide Web. The Web, as it is often called, started at CERN (the European Laboratory for Particle Physics in Geneva) in 1989 as a system to allow researchers in high energy physics to exchange papers and information about their experiments. Its use grew exponentially and it is now a major part of the Internet. The Web is accessed by a "browser" that can be used to navigate through this information in a convenient manner, simply by clicking on words or images (called hyperlinks) which transfer the reader to another related document or resource. Resources are identified by their Uniform Resource Locator (URL), which identifies the machine containing the resource and the location of the resource in the machine's filestore. Hyperlinks may point to resources on the same machine or on another system anywhere else in the world. Navigation between systems is handled by the browser and is invisible to the user, who is free to appreciate the information available without concern for the technicalities of its retrieval. The most commonly used browsers are Internet Explorer™, Netscape™, Opera™, Mozilla™ and Firefox™. The Web allows close integration of text, graphics, sound, animation, and "virtual reality" 3D worlds. Recent developments may be found at the World Wide Web Consortium site [10]. It is good practice to construct web pages that are accessible to those with disabilities. In some countries this is a legal requirement.

There is a large number of "search engines" for locating material on the web. One of the most commonly used is Google™ [2], which has an advanced

ranking system for ordering the results of a search. One of the factors in this is the number of websites that link to the site in question. Altavista™ is another popular tool for searching the web. Most search engines feature a directory section that organizes links in a logical tree structure.

Remote Software

One feature of the Internet is that a user in one geographical location can access a computer system in another place. This allows software or processing power available on one machine to be operated from a remote location. However, recent developments have allowed the reverse to happen, so that software can be downloaded from a remote site onto a local machine and then run automatically without further expertise required on the part of the user. This makes computing much more accessible to the general public, as very little knowledge about the technology is required before using it. Currently, the most popular computer language for such developments is Java™. Code written in Java™ will run on many types of machines without modification. Information on recent developments may be found at [4].

Programs may be embedded within web pages and these are often used to create further web pages in a dynamic manner or to produce particular images. The programs may run either on the machine that is hosting the web page or on the machine that is accessing it. Examples of systems that can be used to create web pages of this type are Perl, JavaScript, and VBScript. Web browser facilities for JavaScript, Java, or ActiveX are often included with the browser software.

Intranets

Many organizations have seen the potential that the Internet has for the free distribution of information and have applied the Internet principles to their own organizations. They have set up what are called Intranets, which are freely accessible by everyone within the organization but inaccessible from outside. It is easy to see the benefits that may be gained by running such a private Internet world.

Security

Connection to the internet exposes a computer to attempts to modify or destroy files (*see* **Confidentiality and Computers**), take control, install viruses, or deny service. Viruses can be attached to e-mail and it is therefore important to install a current virus-checking program and to keep the virus definition files up-to-date. Attacks can also be made without using e-mail to both workstations and servers by exploiting loopholes in operating systems. Most institutions will have a protective "firewall" for all machines connected to the internet but an individual user at home may not. On the web, information sent by form is not encrypted as standard. To ensure the privacy of information, the HTTPS rather than the HTTP protocol should be used, as this encrypts communication in both directions.

E-science

Increasingly, scientific work needs to make use of either very large sets of data or very large amounts of computational resource. One response to these demands is to share the geographically distributed computing resources, storage capacity, and networks of many organizations and individuals, using an architecture designed for this purpose called a GRID. Once users have authenticated themselves to a particular GRID, they are free to make use of data and computational resources, within agreed limits, irrespective of location as though it were a single unified resource. This kind of activity is often referred to as e-Science.

Internet Uses in Biostatistics

In the world of biostatistics, the potential benefits of using the Internet, which are outlined above, are all available. In particular, the use of e-mail has had a large effect on the working lives of many people and the Web is having an increasing effect on the way information is made available in biostatistics (and indeed on the construction of this encyclopedia [1]). One of the great benefits of this revolution is that it allows biostatisticians who are geographically isolated from colleagues to maintain contact in a convenient way, and hence feel part of

a wider community. In addition to individual contacts, e-mail discussion lists provide a particularly helpful forum for this. There are many lists and information sources that are relevant to the interests of biostatisticians. Some Internet sites provide helpful listings of other sites that are of interest in a particular subject area. An example for statistics is at [5].

For the provision of information, many organizations have now created websites. This includes professional societies, and websites now exist for most of the major societies whose interests include biostatistics. These sites provide valuable, up-to-date information on professional activities. In particular, it is becoming increasingly common for conference information and registration facilities to be provided on the Web. Research organizations of all types are also making use of the Internet. In addition to general information on their activities, research papers are often made available. This provides a very fast means of disseminating research ideas and results. A useful list of organizations in the general statistics area which have websites is provided at [3]. In addition, information about statistical software and sometimes the software itself is readily accessible. A useful starting point for exploring this area is [8].

A significant issue in biostatistics is the availability of data and information from application areas in medicine and health sciences. From this perspective, the Internet can be thought of as providing access to a vast library of information held at a large number of sites throughout the world. Where the data itself are not made available, for copyright or other reasons, the Internet can still be extremely useful in identifying and contacting the site where information may be held. In addition to the lists of professional and research organizations mentioned above, a useful starting point for information is the **World Health Organization** (WHO) site at [9], which also provides links to a large number of organizations with medical and health interests.

The Internet has allowed the development of virtual communities of individuals with mutual interest(s). This has led to the emergence of virtual development teams, with members working on a project from worldwide locations, meeting rarely if ever. The pace and scale of development of open-source and public domain software has increased enormously over the last few years as a result of this style of development. There are a number of such projects in statistics such as the development of the statistical programming software **R** [7] and the umbrella project for statistical computing collaboration, Omegahat [6], which facilitates the sharing of ideas and interworking of statistical computing tools.

The web is also beginning to have significant effects on the practice of biostatistics in areas such as **clinical trials**. Facilities for patient entry, **randomization**, patient tracking and other aspects of the conduct of a trial are now available (*see* **Clinical Trials Audit and Quality Control**). These tools, which are particularly useful in **multicenter** studies, are rapidly evolving and are likely to be used increasingly in future studies.

The development and use of the Internet has taken place at such a phenomenal rate that it is difficult to predict what further changes will take place in the future. One area that is already developing very fast is commercial electronic publishing, with many journals available over the Internet. Another area is conferences, where a "virtual conference" over the Internet can provide a cheaper and more accessible alternative to the traditional physical event. While further developments are difficult to predict, it is certain that the Internet will continue to have an increasingly large effect on the way biostatistics is conducted.

Interpenetrating Samples

Interpenetrating sampling (IPS), also known as interpenetrating subsampling and replicated sampling, was introduced in the pioneering contribution of **P. C. Mahalanobis** [17, 18]. Mahalanobis used IPS for the jute and rice acreage surveys in Bengal and Bihar, eastern states of India, as early as 1937. Since then, many countries of different continents have started using IPS in their large-scale **sample surveys**. The United Nations Subcommission on Statistical Sampling strongly recommended the use of IPS in 1949 [26]. IPS was originally proposed in assessing the **nonsampling errors** as the so-called "interviewer errors". Interviewer effects in the measurements from IPS are compared in the **fixed-effects** setup, and the **variance component** due to interviewers is measured in the **random-effects** setup. IPS has also turned out to be an effective method of estimating the **variance** of the **estimator** of a parameter of interest in complex surveys (see Deming [3, 4], Lahiri [14], and Yates [27]). In fact, IPS is the foundation of modern **resampling** methods like **jackknife** [24] and **bootstrap** [5], and also replication methods [20, 21].

IPS consists of selecting a sample in the form of $k (k \geq 2)$ samples using the identical sampling design from the same population. Sample sizes in k samples may or may not be equal. If k interviewers are assigned to collect information from k samples, then the interviewer effects can be studied and compared. Samples may or may not be drawn independently. The sampling design can be a complex design, that is, **multistage**, **stratified**, with equal or unequal probabilities. Let θ be the parameter of interest and $t_1, \ldots, t_k$ be the k estimators of θ based on k IPS. First, assume that

$$\mathrm{E}(t_j) = \theta, \qquad \mathrm{var}(t_j) = \sigma^2,$$
$$\mathrm{cov}(t_j, t_{j'}) = \rho\sigma^2, \quad j \neq j'.$$

Consider the following estimator $\hat{\theta}$ of θ

$$\hat{\theta} = \sum_{j=1}^{k} w_j t_j,$$

where the w_js are fixed constant (known or unknown), with $\sum_{j=1}^{k} w_j = 1$. It can be seen that

$$\mathrm{var}(\hat{\theta}) = \sigma^2(1-\rho)\sum_{j=1}^{k} w_j^2 + \rho\sigma^2.$$

An estimator of $\mathrm{var}(\hat{\theta})$ is

$$\widehat{\mathrm{var}}(\hat{\theta}) = \frac{\sum_{j=1}^{k} w_j^2}{1 - \sum_{j=1}^{k} w_j^2} \sum_{j=1}^{k} w_j (t_j - \hat{\theta})^2.$$

It can be checked that

$$\mathrm{E}[\widehat{\mathrm{var}}(\hat{\theta})] = \mathrm{var}(\hat{\theta}) - \rho\sigma^2.$$

As a result, $\widehat{\mathrm{var}}(\hat{\theta})$ is an **unbiased** estimator of $\mathrm{var}(\hat{\theta})$ when $\rho = 0$, $\widehat{\mathrm{var}}(\hat{\theta})$ overestimates $\mathrm{var}(\hat{\theta})$ when $\rho < 0$, and $\widehat{\mathrm{var}}(\hat{\theta})$ underestimates $\mathrm{var}(\hat{\theta})$ when $\rho > 0$. If $w_1 = \cdots = w_k = 1/k$, then $\hat{\theta} = [(t_1 + \cdots + t_k)/k] = \bar{t}$ and

$$\widehat{\mathrm{var}}(\hat{\theta}) = \frac{1}{k(k-1)} \sum_{j=1}^{k} (t_j - \bar{t})^2.$$

In the case where k samples are drawn independently, $\widehat{\mathrm{var}}(\hat{\theta})$ is an unbiased estimator of $\mathrm{var}(\hat{\theta})$. Thus, IPS provides a quick, simple, and effective way of estimating the variance of the estimator even in a complex survey. The case $\mathrm{var}(t_j) = \sigma_j^2$, $j = 1, \ldots, k$, is considered in Murthy [22], Koop [12] and others. Suppose that $t(j)$ is the value of $\bar{t}$ when the jth estimator of θ from the jth investigator is omitted. Then

$$t(j) = \frac{t_1 + \cdots + t_{j-1} + t_{j+1} + \cdots + t_k}{k-1}, \quad j = 1, \ldots, k.$$

Let

$$t(\cdot) = \frac{t(1) + t(2) + \cdots + t(k)}{k}.$$

The jackknife version of $\bar{t}$ is given by

$$\hat{\theta}^J = k\bar{t} - (k-1)t(\cdot).$$

It can now be seen that $\hat{\theta}^J = \bar{t}$, and, consequently, the expression of $\mathrm{var}(\hat{\theta}^J)$ in Efron & Stein [6]

$$\widehat{\mathrm{var}}(\hat{\theta}^J) = \frac{k-1}{k} \sum_{j=1}^{k} [t(j) - t(\cdot)]^2,$$

is exactly the same as $\widehat{\mathrm{var}}(\hat{\theta}) = \widehat{\mathrm{var}}(\bar{t})$ given above. For comparison of several **ratio and regression estimators** based on IPS with or without jackknife, see Ghosh & Gomez [9, 10].

In IPS, k samples are drawn from the same population using the identical sampling design. If k samples are selected with replacement so that they are independent, then one can see its similarity in principle with the modern Bootstrap Sampling (BSS) (see Efron & Tibshirani [7]). In BSS, the observed data are a **random sample** of size n from an unknown probability distribution F. Bootstrap samples are random samples of size n drawn with replacement from the observed data or the empirical distribution $\hat{F}$. If we treat the observed data as a finite population of size n, then BSS are, in fact, IPS with $k = n$. Of course, there is no interviewer effect for bootstrap samples.

In IPS, three basic principles of **experimental designs**, namely, **randomization**, replication, and local control, are used. The main purpose of IPS is to identify, reduce, and control errors due to interviewers. IPS is used extensively not only in agriculture but also in **social sciences**, **demography**, epidemiology, public health, and many other fields (see Hansen et al. [11], Lahiri [15], Som [25], Fellegi [8], Bailey et al. [1], Levy & Lemeshow [16]). Fractile graphical analysis developed in [19], based on IPS, is used in comparing, analyzing, and testing the separation between two populations when a concomitant variable (*see* **Covariate**) is measured in addition to the response variable. Details on the theory of IPS are available in [2], [13], and [23].

Interval Censoring

Interval **censoring** is commonly used to denote a type of sampling scheme or to describe a type of incomplete data. By interval-censored data, we mean that a **random variable** of interest is known only to lie in an interval, instead of being observed exactly. In most applications of **survival analysis**, the random variable is the time to some event such as death or a disease. A common example of interval-censored survival data occurs in medical or health studies that entail periodic follow-up. Many **clinical trials** and **longitudinal** studies fall into this category [18]. In this situation, an individual due for the scheduled observations for a clinically observed change in disease status may miss some observations and may return with a changed status, thus contributing an interval-censored time of the occurrence of the change. Another example arises in the acquired immune deficiency syndrome (**AIDS**) studies [13] that concern the human immunodeficiency virus (HIV) infection and the AIDS **incubation period** (the time from HIV infection to AIDS diagnosis). In this case, if a subject is HIV positive at the beginning of the study, his or her HIV infection time is usually determined by a **retrospective study** of the subject's history. Thus, only an interval given by the last HIV negative test and the first HIV positive test is known for the HIV infection time.

An important special case of interval-censored data is current status data [29] and [61]. In this situation, each subject is observed only once for the status of the occurrence of the event of interest at the observation time. In other words, the observation of the time to the event is either left- or right-censored (the survival time is less or greater than the observation time). **Cross-sectional** data provide one example of current status data [31] and another example is given by nonlethal tumor data when the time to tumor onset is of interest, but not directly observable [14] (*see* **Tumor Incidence Experiments**). Note that for the first example, current status data occur because of study designs, while for the second case, they are observed because of the inability of measuring the variable directly and exactly. Current status data are also sometimes referred to as case I interval-censored data and in correspondence, the general case is referred to as case II interval-censored data [23].

Another special case of interval-censored data that may occur is left-censored data, in which the time to the event of interest is either left censored or exactly known. One reason behind the occurrence of the left-censored data is the inability of measuring the variable of interest when it is below a certain level. Such an example is given by the severity of an adverse event related to a drug, which sometimes can be determined only when it is over a certain degree.

To this point, survival time has been defined in a way that starts from time zero or a known time point. A more general framework is to define survival time as the time between two related events. This illustrates a more complicated type of interval-censored data: doubly interval-censored data [60], in which the times of the occurrences of both events defining the survival time are interval censored. An example of such data is provided by the AIDS studies discussed above when the variable of interest is AIDS incubation time [13].

For the analysis of interval-censored failure-time data, in the following, we will first discuss nonparametric estimation of the distribution function as well as the **hazard** function for survival time (*see* **Survival Distributions and Their Characteristics**). Secondly, regression analysis of interval-censored data will be investigated under various regression models. The comparison of several survival functions will be considered thirdly and followed by discussion on some other topics. These will include doubly interval-censored failure-time data, interval-censored data with truncation, multivariate interval-censored data, and interval-censored data with informative censoring. Finally, some concluding remarks will be given. Unless specified otherwise, we will assume that the censoring mechanism resulting in censoring intervals is independent of the survival time.

Nonparametric Estimation

In medical and health studies, estimation of the cumulative distribution function (cdf) of survival time or the survival function is perhaps the most important and common task. Let T denote the survival time of interest in a survival study and $F = \Pr(T \leq t)$ its cdf. Suppose that observed data can be represented by $\{I_i\}_{i=1}^n$, where $I_i = (L_i, R_i]$ is the interval known to contain the unobserved survival time associated with the ith subject. If $L_i = 0$, we have a left-censored observation and if $R_i = \infty$, we have a

right-censored observation. Let $\{s_j\}_{j=0}^{m+1}$ denote the unique ordered elements of $\{0, \{L_i\}_{i=1}^n, \{R_i\}_{i=1}^n, \infty\}$, α_{ij} be the indicator (*see* **Dummy Variables**) of the event $(s_{j-1}, s_j] \subseteq I_i$, and $p_j = F(s_j) - F(s_{j-1})$. Then the **likelihood** function of $p = (p_1, \ldots, p_{m+1})'$ is proportional to

$$L(p) = \prod_{i=1}^{n} \{F(R_i) - F(L_i)\} = \prod_{i=1}^{n} \left(\sum_{j=1}^{m+1} \alpha_{ij} p_j \right) \tag{1}$$

and the problem of finding the **nonparametric maximum likelihood estimator** (NPMLE) of F becomes that of maximizing $L(p)$ with respect to p subject to $\sum_{j=1}^{m+1} p_j = 1$ and $p_j \geq 0$ $(j = 1, \ldots, m+1)$ [20, 34, 39]. Note that a more general way to express an interval-censored observation is to use the finite union of disjoint intervals [64] and in this case, the discussion here equally applies.

To maximize $L(p)$ with respect to p, a simple and common way is to use the self-consistency **algorithm** proposed by **Turnbull** [64]. It can be seen as an application of the **EM algorithm** and iterates the equation $p_j^{\text{new}} = n^{-1} \sum_{i=1}^{n} [\alpha_{ij} p_j^{\text{old}} / (\sum_{l=1}^{m+1} \alpha_{il} p_l^{\text{gold}})]$ until convergence. This approach is easy to implement, but is known to have a slow convergence rate. An alternative is to apply the convex minorant algorithm introduced by Groeneboom and Wellner [23], which promises to converge faster than the self-consistency algorithm. Böhning et al. [10] proposed to use the vertex-exchange or other algorithms proposed for the mixture model problem because of the similarity of the two problems. All the above algorithms are iterative and in fact, there is no closed form for the NPMLE of F.

For current status data, however, a closed form of the NPMLE can be found. In this case, the NPMLE of F can be shown to be equal to the **isotonic regression** of $\{d_1/n_1, \ldots, d_m/n_m\}$ with weights $\{n_1, \ldots, n_m\}$, where $d_j = \sum_{i \varepsilon S_j} I(T_i \leq s_j)$, $n_j = |S_j|$ and S_j denotes the set of subjects who are observed at s_j, $j = 1, \ldots, m$. Thus, by using the max–min formula for an isotonic regression [3], the NPMLE of F can be written as

$$\hat{F}_n(s_j) = \max_{u \leq j} \min_{v \geq j} \left(\frac{\sum_{l=u}^{v} d_j}{\sum_{l=u}^{v} n_j} \right). \tag{2}$$

A self-consistent estimate of F may not be an NPMLE. To verify this, one approach is to use the so-called Kuhn–Tucker conditions given in [20]. Note that at the NPMLE, p_j can be nonzero only if s_{j-1} is a left endpoint L_i for some subject i and s_j is a right endpoint R_k for some possibly different subject k. Some of the p_j's that satisfy this criterion may still be zero. The Kuhn–Tucker conditions can also be applied to identify these zero p_j's, thus speeding up the self-consistency algorithm. Another approach is to use the fact that an estimate $\hat{p}$ is an NPMLE if and only if $\sup_{1 \leq j \leq m+1} \sum_{i=1}^{n} (\alpha_{ij} / \sum_{l=1}^{m+1} \alpha_{il} \hat{p}_l) = n$ [10]. Gentleman and Geyer [20] also discussed the conditions required for the uniqueness of NPMLEs.

It can be shown that the above NPMLE $\hat{F}_n$ is **consistent** [23, 66]. Furthermore, as $n \to \infty$ and at fixed time point t_0, $\hat{F}_n(t_0)$ has a limiting, nonnormal distribution at $n^{1/3}$ or $(n \log n)^{1/3}$ **convergence** rate depending on if the probability of observing $T = t_0$ is zero or away from zero [23, 65]. Note that this is different than the usual $n^{1/2}$-convergence rate. However, the integral of $\hat{F}_n$ and its linear functionals can be shown to have asymptotic normal distributions with $n^{1/2}$-convergence [21, 27]. For variance estimation of $\hat{F}_n$, Sun [59] presented two methods, a generalization of Greenwood's formula (*see* **Survival Analysis, Overview**) and a **bootstrap** approach.

Sometimes estimation of the hazard function of survival time may be of interest. In this case, one way is to use the empirical estimator, which is usually rough and difficult to interpret. Corresponding to this, several smooth estimators, which are more descriptive than the empirical estimator, of the hazard function have been proposed (*see* **Smoothing Hazard Rates**). Among others, Kooperberg and Stone [33] and Rosenberg [48] gave **spline**-based estimators (*see* **Spline Smoothing**). Bebchuk and Betensky [4] and Betensky et al. [7] considered the **multiple imputation** and local likelihood approaches, respectively.

Regression Analysis

Regression analysis of survival data is commonly performed to study the effect of various **covariate** factors such as treatment, sex, and age on survival time. Let X_i denote the covariate vector associated with the ith subject and assume that the censoring mechanism is independent of the covariates. By using the notation given above, the likelihood then has the

form:

$$L = \prod_{i=1}^{n} \{F(R_i|X_i) - F(L_i|X_i)\}$$
$$= \prod_{i=1}^{n} \left[\sum_{j=1}^{m+1} \alpha_{ij} \{F(s_j|X_i) - F(s_{j-1}|X_i)\} \right], \quad (3)$$

where $F(T|X)$ denotes the cdf of T given covariates X.

In survival analysis, the most commonly used regression model is perhaps the **proportional hazards** (PH) model, which has the form

$$\lambda(t|X) = \lambda_0(t) \exp(\beta' X) \quad (4)$$

[12], where $\lambda_0(t)$ denotes an unknown baseline hazard function and β the regression coefficients (*see* **Cox Regression Model**). For inference about β and the cumulative hazard function $\Lambda_0(t) = \int_0^t \lambda_0(s)\, ds$, a natural method is the full likelihood approach, which maximizes L over β and $\Lambda_0(t)$ simultaneously and was first discussed by Finkelstein [18]. Huang [24] also studied this approach for the case of current status data and showed that the **maximum likelihood estimator** (MLE) of the regression coefficients is consistent and **efficient** and has an asymptotic **normal distribution** with $n^{1/2}$-convergence rate.

An alternative to the above full likelihood approach is the **marginal likelihood** approach. This approach defines a marginal likelihood as the summation of the probabilities of the ranking of the T_i's over the set of all possible rankings of the T_i's that are consistent with observed interval-censored data [50]. It is a generalization of the corresponding approach for right-censored data [30] and has the advantage of not involving $\lambda_0(t)$. The disadvantage is that it does not have a simple and easily manageable form, resulting in the need for great computational effort. In addition, little is known about its properties. Another choice for inference about the PH model is to use some types of imputation approaches, which involve generating right-censored data based on observed interval-censored data [41, 51].

Although the PH model yields sound results in many cases, there are situations in which other models may provide a better fit to interval-censored data. For example, the **proportional odds regression** model given by

$$\log \left\{ \frac{[F(t|X)]}{[1 - F(t|X)]} \right\} = \alpha(t) + \beta' X \quad (5)$$

is often used for **environmental** health data, where $\alpha(t)$ is a monotone-increasing function. Among others, Rossini and Tsiatis [49] discussed the fitting of this model to current status data. Huang and Rossini [26] and Rabinowitz et al. [46] considered the sieve estimation and the approximated score function methods, respectively.

Another alternative to the PH model that has been discussed for interval-censored data is the **accelerated** regression model defined by $\log(T) = \beta' X + \varepsilon$, where the distribution of ε is unknown [9, 47]. The **additive hazards** regression model and the **logistic** model have also been investigated for regression analysis of interval-censored data. In these cases, the discussion has been confined to current status data for the former [37, 38] and to discrete survival data for the latter [54]. Some of the other models proposed recently for the regression analysis of interval-censored data can be found in references [8, 11, 25, 32].

Comparison of Survival Functions

The comparison of survival functions is often the primary goal of clinical and follow-up studies. In the case of interval-censored data, as in other situations, two commonly used approaches are to base the comparison on regression techniques and to develop distribution-free test procedures. The application of the regression techniques involves defining covariates X as group or treatment indicators and then using the Wald or score test (*see* **Likelihood**) for testing regression coefficients equal to zero [18, 47]. In this, one can apply the regression methods described above. An alternative, which was not discussed above, is to consider some **rank**-based regression models and to derive rank test procedures for the comparison [17]. For example, Self and Grossman [52] considered the linear regression model $T = \alpha + \beta' X + \varepsilon$, where α is a constant and ε denotes the error term. Under the model, they derived the **linear rank tests** defined as the score tests for $\beta = 0$ from the marginal likelihood of the ranking of the survival times T's.

Several distribution-free test procedures have been proposed for the comparison of survival functions

based on interval-censored data. Among these, Andersen and Ronn [2] and Sun and Kalbfleisch [62] proposed some **nonparametric** tests for current status data. Sun [53] presented a nonparametric procedure of **logrank** type and Pan [40] developed an approach based on multiple imputation. Most of the above mentioned procedures are rank-oriented or sensitive to ordered hazard differences. Sometimes test procedures that are sensitive to ordered survival differences may be preferred. For this purpose, Petroni and Wolfe [45] and Fang et al. [16] considered approaches based on differences between estimated survival functions. Furthermore, Lim and Sun [35] proposed three classes of nonparametric test procedures that include most of existing tests as special cases. Note that most of the existing comparison procedures require the same censoring distribution.

Other Topics

This section will discuss a few subjects not investigated above about interval censoring. One is the analysis of doubly interval-censored data, which was first studied by De Gruttola and Lagakos [13]. In this case, the analysis is more complicated since the likelihood function involves not only the distribution of the survival time, but also the distribution of the originating event that defines the survival time. Following De Gruttola and Lagakos [13], who proposed a self-consistency algorithm for estimation of the distribution function of survival time, many authors have considered the inference about doubly interval-censored data. Some recent contributions include Fang and Sun [15], who discussed the consistency of the NPMLE of the distribution function, and Sun [58], who developed a nonparametric test for treatment comparison. Also Goggins [22], Pan [42] and Sun et al. [63] studied the regression problem under the PH model. More discussion and references about doubly interval-censored data can be found in [60].

Truncation is another feature of survival data and may sometimes occur together with interval censoring. One of the early papers discussing this is given by Turnbull [64], who proposed a self-consistency algorithm for the NPMLE of a distribution for interval-censored and truncated data. More recently, among others, Pan and Chappell [43] and Sun [55] considered the one sample estimation problem when left-truncation and general truncation are involved, respectively. Lim et al. [36] also discussed the one sample estimation problem with general truncation and the existence of a **change-point** and Alioum and Commenges [1] and Pan and Chappell [44] considered the regression problem under the PH model.

The discussion so far has been focusing on univariate failure-time data and the research on multivariate failure-time data in the literature is relatively limited. This is especially the case for multivariate interval-censored data (*see* **Multivariate Survival Analysis**). One problem investigated in this case is the one sample estimation problem for bivariate interval-censored failure time data [5]. Also for bivariate failure-time data, Betensky and Finkelstein [6] generalized the Kendall's coefficient (*see* **Rank Correlation**) to the interval-censoring situation. Another subject, that often occurs in practice and has not been discussed much in the literature, is the analysis of interval-censored data when the censoring mechanism resulting in interval censoring is informative or depends on the survival of interest. For this, Sun [57] developed a nonparametric test for treatment comparison for a special case in which observed data are current status data and observation times depend on treatments. Finkelstein et al. [19] discussed both one sample and regression problems.

Concluding Remarks

For the analysis of interval-censored failure-time data, the discussion here has been focusing on more recently developed and **semiparametric** and nonparametric methods. One can find early references about interval-censored data in [28, 56]. An alternative to the semiparametric and nonparametric methods is to use **parametric methods** [56], which are usually relatively straightforward. It is worth noting that interval-censored data discussed here are different from **grouped survival** data, which are sometimes also referred to as interval-censored data in the literature. The interval-censored data reduce to grouped data if all observed intervals either completely overlap on each other or have no overlaps.

There are still a lot of open questions in the analysis of interval-censored data. One is that the properties of many proposed methods remain unknown and this is especially the case for doubly interval-censored data. Although a great deal of research for regression analysis of interval-censored data has been done,

there is no approach available as simple as the **partial likelihood** method for right-censored data. Also, there are no methods available for **model checking** for all regression models discussed above and more research is needed for multivariate and informatively interval-censored failure-time data.

Intervention Analysis in Time Series

When data are collected in the form of time series there are important questions concerning "changes" in the series. Changes may be "man-made" or they may arise "naturally". How efficient was a preventive program to decrease the monthly number of accidents? How did the frequency of traditional neurological diagnostic methods change after the introduction of computer tomography? How did the pattern of morbidity in a population change after an environmental accident? Notifications of diseases, entries in a hospital, injuries due to accidents, etc. are usually collected in fixed equally spaced intervals. Such time series observations are likely to be dependent. ARIMA models [autoregressive integrated moving average models (*see* **ARMA and ARIMA Models**) and Box–Jenkins models [1]] allow the stochastic dependence of consecutive data to be modeled. Intervention analysis proposed by Box & Tiao [2] is an extension of ARIMA modeling allowing study of the magnitude and structure of changes of ARIMA processes.

The well-known two-sample t test for a change in level after an intervention may not be appropriate in this situation due to the possible dependency of the observations. In addition, this test allows only an assessment of the magnitude of a change and not of its structure. Since the series may be nonstationary, large changes of the series could occur even when no intervention takes place (*see* **Stationarity**). Intervention analysis may allow an investigator to distinguish between what can be expected due to nonstationarity alone and what cannot.

Analogous questions of "change" may arise when studying time series data recorded in an individual patient; changes of time series, for example, may occur after the intervention "treatment". Dependence of consecutive observations may be important when data such as blood glucose are recorded within a single patient over time. Such studies on individual subjects may be interesting and relevant in basic medical research and in clinical applications. In clinical research they may allow physicians the assessment of individual treatment effects. Decisions on treatment strategy may be based on knowledge of the stochastic processes representing the observed time series, thus allowing full use to be made of the recorded data [4].

Intervention Models

Let $y_{t-1}, y_t, y_{t+1}, \ldots$ denote the observations (number of entries in a hospital, etc.) at equally spaced times, $t-1, t, t+1, \ldots$ (e.g. yesterday, today, tomorrow, etc.). The intervention model states that y_t (or a suitably transformed version of the series) may be decomposed into two parts, an "explained" part u_t and an "unexplained" or "noise" part n_t,

$$y_t = u_t + n_t. \tag{1}$$

The Noise Series n_t

The noise series (*see* **Noise and White Noise**) or unexplained part n_t is an autoregressive integrated moving average ARIMA(p, d, q) process given by

$$w_t = \nabla^d n_t, \tag{2}$$

$$w_t = \phi_1 w_{t-1} + \cdots + \phi_p w_{t-p} + a_t - \theta_1 a_{t-1} - \cdots - \theta_q a_{t-q} \text{ or}$$

$$\phi(B) w_t = \theta(B) a_t. \tag{3}$$

∇ is the differencing operator such that $\nabla n_t = n_t - n_{t-1}$ and the integer d is the number of times n_t has to be differenced to obtain a stationary series w_t. B is the backward shift operator (*see* **Backward and Forward Shift Operators**) such that $Bw_t = w_{t-1}$, $B^k w_t = w_{t-k}$, $\phi(B)$ and $\theta(B)$ are polynomials in B:

$$\phi(B) = 1 - \phi_1 B - \cdots - \phi_p B^p \text{ and}$$

$$\theta(B) = 1 - \theta_1 B - \cdots - \theta_q B^q. \tag{4}$$

$\phi(B)$ is called the autoregressive operator of order p and $\theta(B)$ the moving average operator of order q. The parameters of the noise process $\phi_1, \ldots, \phi_p$ and $\theta_1, \ldots, \theta_q$ are constrained such that the roots of $\phi(z)$ and $\theta(z)$ in the complex z-plane lie outside the unit circle. a_t is a *white noise* series consisting of independent identically distributed normal random variables with mean zero and variance σ_a^2. The ARIMA model for the noise n_t may be extended to the seasonal ARIMA model by including seasonal autoregressive and moving average operators. In the

absence of u_t, the observed series y_t is just the ARIMA process n_t.

The Explained Part u_t

The explained part u_t is the "response" of a system to a dummy input variable I_t:

$$u_t = f(I_t). \tag{5}$$

The input I_t is usually taken as the unit pulse function p_t,

$$p_t = \begin{cases} 1, & \text{for } t = T, \\ 0, & \text{otherwise,} \end{cases} \tag{6}$$

or the unit step function s_t,

$$s_t = \begin{cases} 1, & \text{for } t \geq T, \\ 0, & \text{otherwise.} \end{cases} \tag{7}$$

The pulse function p_t may represent, for example, an unusual event which acts only at time T. The step function s_t represents, for example, a preventive measure starting at time T. Since the "noise process" n_t may be nonstationary, large changes of the series could occur even when no intervention takes place.

Basic Patterns of Response

Figure 1 shows basic intervention models. In the first line the two dummy input variables s_t and p_t are depicted. The lines (a), (b), and (c) below show "responses" corresponding to the following three models:

1. Figure 1(a): *the simplest, case*

$$f(I_t) = \omega_0 I_t. \tag{8}$$

   The response is just the pulse- or step-input I_t multiplied by ω_0. The parameter ω_0 measures the "strength" of the effect. In this model, and with the step function as input, the new level is reached immediately.
2. Figure 1(b): *a refined model*:

$$\begin{aligned} f(I_t) &= \omega_0 I_t - \omega_1 I_{t-1}, \text{ or} \\ f(I_t) &= (\omega_0 - \omega_1 B) I_t, \text{ or} \\ f(I_t) &= \omega(B) I_t, \end{aligned} \tag{9}$$

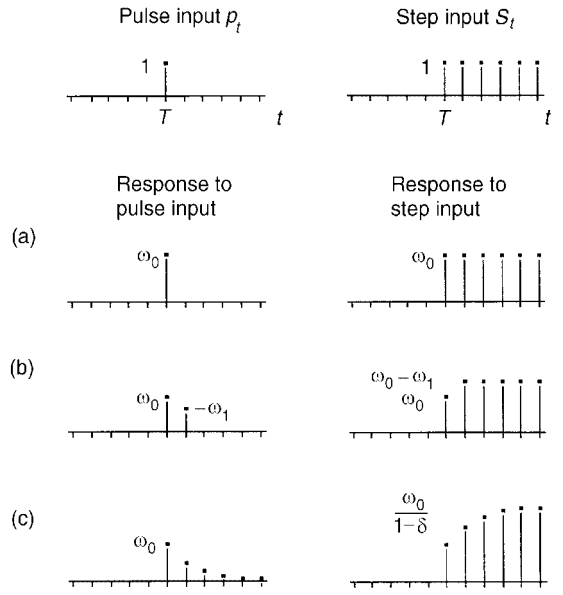

Figure 1 Responses to a unit pulse and step input: (a), (b), and (c) basic patterns of response

   where $\omega(B) = \omega_0 - \omega_1 B$ is a polynomial of first order in B.

   In this refined model, and with the step function as input, the final level is reached in two steps. If $\omega_0 = 0$ the response is as in (a) but 1 time unit delayed.
3. Figure 1(c): *gradual approach to equilibrium*:

$$\begin{aligned} f(I_t) &= \omega_0(I_t + \delta I_{t-1} + \delta^2 I_{t-2} + \cdots) \\ &= \omega_0(I_t + \delta B I_t + \delta^2 B^2 I_t + \cdots) \\ &= \omega_0(1 + \delta B + \delta^2 B^2 + \cdots) I_t \\ &= \left[\frac{\omega_0}{(1 - \delta B)}\right] I_t. \end{aligned} \tag{10}$$

   In this basic type of response the final level is reached only gradually.

The above three types of response are special cases of the *general response*

$$\begin{aligned} f(I_t) &= v(B) I_t \\ &= \left[\frac{\omega(B)}{\delta(B)}\right] I_t, \end{aligned} \tag{11}$$

where $\omega(B) = \omega_0 - \omega_1 B - \cdots - \omega_s B^s$ and $\delta(B) = 1 - \delta_1 B - \cdots - \delta_r B^r$ are polynomials in B. The

corresponding model,

$$y_t = f(I_t) + n_t, \tag{12}$$

is called an intervention model of order r. $v(B)$ is the transfer function containing infinitely many parameters in general. $\omega(B)/\delta(B)$ is a parsimonious "rational lag representation" of the transfer function $v(B)$ containing only $s + r + 1$ parameters [2].

The noise part of the model is usually obtained from the preintervention period in the same way as the ordinary ARIMA model. Standard software such as SAS or BMDP (*see* **Software, Biostatistical**) allows maximum likelihood estimation of ARIMA models and intervention models. Inspection of the data may suggest a pattern by which the known event has changed the series. Additional help may be obtained by inspection of the residuals from the corresponding model. A different way to obtain a model for the response consists in postulating one or several expected "types of change" and studying if the data provide evidence for a particular type of change.

Example

During an investigation concerned with the relationship between air pollution and respiratory diseases the environmental accident of "Schweizerhalle" occurred. In that investigation a series of medical data had been collected during about one year: the daily number of respiratory symptoms per child in a randomly selected group of preschool children (called "SYMPTOMS"). On November 1, 1986, a Sandoz storehouse containing chemical substances burned down in Schweizerhalle, located near Basle. After many people experienced symptoms and, additionally, when dead fish appeared in the Rhine, public pressure demanded investigation of possible health effects. In addition to studies specially set up for this purpose, it seemed recommendable to analyze the ongoing study with regard to the question of whether health effects could be discovered on the date of the accident.

For the preaccident period of the series SYMPTOMS an *AR(1) model* was identified. Figure 2 illustrates the process of intervention model building. Three intervention models of increasing complexity are fitted to the series SYMPTOMS in a way that each

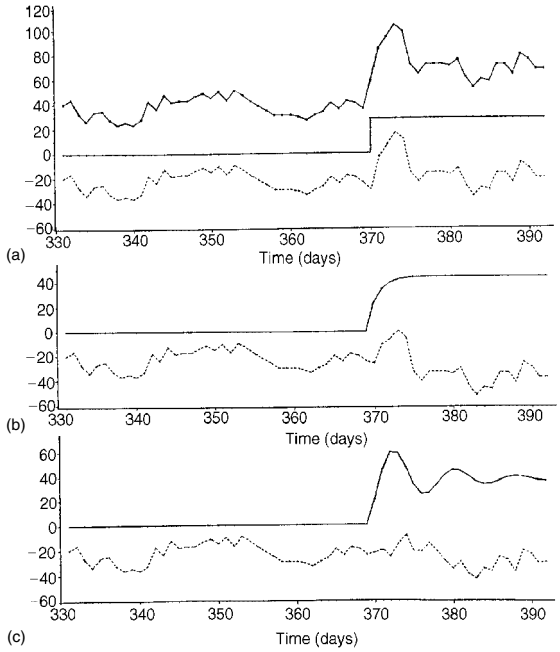

Figure 2 Three intervention models of increasing complexity. (a) Model of order zero. Upper curve: series y_t (SYMPTOMS). Second curve: "explained" part u_t. Third curve: noise series $n_t = y_t - u_t$ (shifted downwards). (b) Model of order one. Upper curve: "explained" part u_t. Lower curve: noise series $n_t = y_t - u_t$ (shifted downwards). (c) Model of order two. Same arrangement as in (b). Curves are shown multiplied by 100. Explanation in the text

additional parameter allows for a refined explanation of the data. The simplest model is as follows:

1. Intervention model of *order zero*,

$$y_t = \omega_0 s_t + n_t, \tag{13}$$

where s_t is the unit step function. The estimated parameters of this model are shown in Table 1 below the univariate model. Figure 2(a) shows, in the second row, the estimated function $\omega_0 s_t$ (the point labeled 370 corresponds to the date of the accident). This model gives a better fit to the data ($\sigma_a^2 = 0.00454$) than the univariate model ($\sigma_a^2 = 0.00476$). However, this simplified model does not fully represent all characteristic properties of the series: it predicts, for example, that the final level is reached immediately. It is

Table 1 Summary of intervention models

Model type	Estimated parameters ± se	Residual variance
Univariate	$\phi_1 = 0.91 \pm 0.02$ $\mu = 0.368 \pm 0.039$	0.00476
Intervention (order 0)	$\phi_1 = 0.87 \pm 0.03$ $\mu = 0.343 \pm 0.026$ $\omega_0 = 0.274 \pm 0.058$	0.00454
Intervention (order 1)	$\phi_1 = 0.87 \pm 0.03$ $\mu = 0.331 \pm 0.027$ $\omega_0 = 0.239 \pm 0.065$ $\delta_1 = 0.46 \pm 0.16$	0.00441
Intervention (order 2)	$\phi_1 = 0.87 \pm 0.03$ $\mu = 0.334 \pm 0.026$ $\omega_0 = 0.203 \pm 0.033$ $\delta_1 = 1.21 \pm 0.07$ $\delta_2 = 0.75 \pm 0.07$	0.00420

therefore natural to consider the following more elaborate model.

2. Intervention model of *order one*,

$$y_t = \omega_0(1 - \delta_1 B)^{-1} s_t + n_t. \qquad (14)$$

The parameters are given in Table 1 and the corresponding curves are presented in Figure 2(b). The residual variance decreases to $\sigma_a^2 = 0.00441$. This model allows for gradually reaching the final level [upper curve of Figure 2(b)]. However, the additional parameter δ_1 has a relatively large standard error. In addition, one recognizes from the lower curve of Figure 2(b) that the noise series n_t still has an unexplained "bump". This suggests introducing an additional refinement of the model.

3. Intervention model of *order two*,

$$y_t = \omega_0(1 - \delta_1 B - \delta_2 B^2)^{-1} s_t + n_t. \qquad (15)$$

The "explained" part of the model $u_t = \omega_0(1 - \delta_1 B - \delta_2 B^2)^{-1} s_t$ may be rewritten

$$(1 - \delta_1 B - \delta_2 B^2) u_t = \omega_0 s_t, \text{ or}$$

$$u_t - \delta_1 u_{t-1} - \delta_2 u_{t-2} = \omega_0 s_t \text{ or}$$

$$u_t = \delta_1 u_{t-1} + \delta_2 u_{t-2} + \omega_0 s_t. \qquad (16)$$

This second-order difference equation may represent vibrations of discrete systems (in analogy to the differential equations of order two in continuous physical systems). The lowest part of Table 1 shows the estimated parameters of this model. The parameters ω_0, δ_1 and δ_2 have small standard errors and the residual variance drops to $\sigma_a^2 = 0.00420$. The "bump" in the noise series n_t [lower curve of Figure 2(c)] has disappeared.

The upper curve of Figure 2(c), u_t, shows the characteristic behavior of a "damped vibration". The final increase of the series over the level of the preaccident period is estimated by the gain $g = \omega_0(1 - \delta_1 - \delta_2)^{-1} = 0.376$, i.e. an increase of approximately 0.38 respiratory symptoms per child per day. The introduction of additional parameters into the model did not reduce the residual variance any further. Thus, identification of a sequence of models of increasing complexity showed that the response of the series SYMPTOMS after the accident of Schweizerhalle may be parsimoniously represented by an intervention model of second order. The model corresponds to what is known in continuous physical systems as a "damped vibration". After an initial overshoot, the series settles down to a new equilibrium at a higher level.

The results obtained support the hypothesis that the number of symptoms per child increased after the accident. The identified intervention model states that after an initial overshoot following the accident the series settles down to a new level. Unfortunately, data were not available for a longer period after the accident; thus, there is a possibility that "return to normal" could have been missed. The question of

whether under the impression of the accident more symptoms were recorded (than were actually present) cannot be answered entirely satisfactorily. However, other studies conducted in this context point toward an increase in respiratory symptoms in the general population. A more detailed presentation of this study may be found in [6].

Remarks

Extensions of models as described and illustrated above are possible: intervention analysis with input consisting of multiple pulses, for example, may be used to analyze questions such as "Are there more deaths due to infarction in years with influenza A than in years without?" The sequence of pulses then represents years with influenza A.

Responses to an intervention need not to occur instantaneously; a preventive program may show an effect eventually after a delay. In addition, effects of preventive programs need not show a "permanent" effect. Decomposing the dummy input into a short-term and a long-term component may help to decide if an effect is only transient. Outliers in ARIMA time series may be detected and removed by introducing corresponding pulse inputs.

A complementary method to intervention analysis is **forecasting**: a forecast obtained from data before the intervention may be compared with actual data obtained after the intervention [3].

Literature

A nontechnical introduction to intervention analysis is given by McCleary & Hay [8]. The classical reference to ARIMA models by Box & Jenkins [1] does not include intervention analysis. The authoritative presentation of intervention analysis is that of Box & Tiao [2]. Jenkins [7] provides instructive case studies in the fields of business, industry, and economics. A review, examples, and references of studies concerned with intervention analysis in medicine may be found in [5]. Applications and references of studies concerned with intervention modeling of *single patient* time series are presented in [4].

ULRICH HELFENSTEIN

Interviewer Bias

Interviewer bias is a type of information **bias** (*see* **Bias in Observational Studies**; **Bias, Overview**) that arises when an interviewer consciously or unconsciously elicits inaccurate information from study subjects. Interviewer bias can result in **differential error**, which can seriously distort disease–exposure **associations**, if the interviewer is aware of the disease status and exposure hypothesis in a **case–control study**, or if the interviewer is aware of the exposure status and outcome hypothesis in a **cohort study**. In the former case, the interviewer may probe more deeply for evidence of exposure among cases than among **controls**. In the latter case, the interviewer may try to elicit evidence of health effects more assiduously in exposed than in unexposed cohort members. Methods used to minimize interviewer bias include providing structured questionnaires (*see* **Questionnaire Design**), training interviewers to follow a fixed pattern of questioning, and, where possible, keeping interviewers unaware of the disease status and exposure hypotheses of greatest interest in case–control studies, and unaware of exposure status and health outcome hypotheses of greatest interest in cohort studies (*see* **Blinding or Masking**).

(*See also* **Bias in Case–Control Studies**; **Bias in Cohort Studies**; **Interviewing Techniques**).

MITCHELL H. GAIL

Interviewing Techniques

Interviewers have a variety of roles and responsibilities in conducting a **survey**. Primarily, they are responsible for the collection of data by administering a data collection instrument (*see* **Questionnaire Design**). Other roles include conducting screening interviews to ensure the respondent selected meets the requirements of the survey design plan, gaining respondent cooperation, accurately coding and editing data, and representing the survey sponsor to the public. Twenty years ago, interviewer techniques were almost exclusively designed for household, face-to-face interviews. In recent years, the advent of **computer-assisted interviewing** (CAI), which includes computer-assisted telephone interviewing (CATI) and computer-assisted personal interviewing (CAPI), have had a marked effect on the techniques used by survey interviewers. The following standard techniques, as well as techniques used specifically for CAI, are based on contemporary interviewer training manuals [1, 2].

Introducing the Survey and Gaining Cooperation

An interviewer's first contact with the respondent is crucial for several reasons. First, the purpose and importance of the survey is communicated. Secondly, rapport between the interviewer and respondent is established. Thirdly, and perhaps most important, cooperation of the respondent to participate is usually received.

The interviewer must convey the purpose and importance of the study in a simple and direct manner. This is sometimes awkward if the interviewer must read verbatim a long and complex script. After reading the introduction, the interviewer must be able to paraphrase effectively what was read so that the respondent begins to feel and understand that it is important to participate. Discussing participation in a confident, friendly, empathetic tone can help to eliminate hesitancy on the respondent's part. Interviewers can allay concerns by suggesting that they start the interview and reiterating that the respondent does not have to answer any question that may be too personal. This is an effective way to coach a reluctant respondent to participate and allows the respondent to feel that he/she has some control over the interview situation.

Typically, respondents are given assurances of **confidentiality** and, if under the auspices of an official agency, authorization for the survey during the first contact. While this may seem like a technical requirement, respondents often feel more at ease and are more willing to respond once they know the purpose of the survey, and they understand that the information they are providing will be held strictly confidential. Reluctant respondents often are concerned about how they were selected. Virtually every interviewer has had a respondent ask: "How did you get my name?" If the survey is a **random sample**, then interviewers need to explain the process in a clear and concise manner. Interviewers should listen carefully to all questions and comments from the respondent and should answer only what is asked.

Handling respondents who refuse to participate (*see* **Nonresponse**) is probably the most challenging component of an interviewer's job. In any survey, there are respondents who simply do not want to be interviewed. Some respondents refuse outright and others indicate refusal indirectly by avoiding the interview or constantly rescheduling. While a relatively high number of initial interview contacts result in rescheduling, few refusals actually do occur in a well-planned survey. The interviewer is the major influence on the motivation of the respondent and on the quality of the responses received. Interviewers can subtly communicate their interest in the study, their enthusiasm about their work, and even their positive feelings about the respondent, all of which increase survey cooperation.

Interviewers are trained to convert a potential refusal into cooperation. A good interviewer will use techniques that reduce covert negative issues likely to cause refusals. Respondents may be mistrustful of the interviewer, may see participating in a survey as an invasion of their privacy, or may not understand or believe assurances of confidentiality and anonymity. Respondents may also feel threatened about the survey's topic, especially if it is sensitive. Interviewers can discuss the respondent's concerns in an open, relaxed manner and usually can convince them to start the interview.

Interviewing a Survey Respondent

Ask Each Question Exactly as Worded. This is a standard long held in survey design. If questions are not read exactly as worded, they may not yield comparable results. Research has shown that even minor changes in wording can change response distributions. It is true, however, that interviewers are allowed to depart from the standard wording, but that is only after they have first asked the standard form of the question and attempted to get an answer.

Ask Every Question. Although the answer to a given question may seem obvious, interviewers must ask the question and obtain a response. Occasionally, the respondent provides an answer which applies to a question asked later in the interview. In this case, the interviewer should verify the answer to the question.

Maintain Positive Rapport. Offering the respondents some assurance that they are doing well and that their responses are valuable can increase their willingness to participate. Comments such as "Yes, I see" show the respondents that their answers are important and interesting to the interviewer. This can stimulate a respondent to talk further and to engage more actively in the survey process.

Use Effective Probing Techniques. When the respondent's answer does not meet the question's objective, or when a respondent seems to have misunderstood the question, interviewers need to probe for clarification or correction. One of the most common probes is to ask the respondent to repeat the answer – this often prompts the respondents to expand on the answer, offer more information, or correct an answer. Another common probe technique is to reread the question. This often results in the respondent paying closer attention to the question and revising the answer.

In general, interviewers should not probe by paraphrasing a question, offering additional explanations (unless this is provided for in the interviewer's manual), or assuming responses that may seem obvious from prior answers. Rather, probing should take the form of more general questions ("What do you mean?") or should be an attempt to improve the specificity of a response ("Could you put your answer in terms of days?").

The danger of probing is that the interviewer can influence the respondent's answer and approach to other questions. Also, it can unnecessarily prolong the interview and convey a more conversational, informal tone. It is important for the interviewer to probe only when necessary and then return to asking survey questions. Probes should be neutral and not convey a right or wrong answer. For example, if the respondent says she had between five and eight visits to the doctor, a **biased** probe would be "So, would you say five is about right?" and a neutral probe would be "Would you say the number of visits was closer to five or closer to eight?" Interviewers can also probe using statements and questions that indicate their uncertainty, such as "I don't know quite what you mean," or "Which figure would you say comes closer?" It is important when using these sorts of probes to keep the tone positive, and not intimate that the respondent gave a wrong answer. In fact, some interviewers find it useful to probe with a suggestion that it is the interviewer who is misunderstanding (e.g. "I'm not sure what you mean by that; could you tell me a little more?").

One exception to the probing guidelines above is when an interviewer is conducting a cognitive interview. Cognitive interviews are typically used in pretests to identify flawed questions prior to fielding the survey. Cognitive interviewers specialize in applying cognitive psychology principles to understanding the survey response process. These interviewers depart freely from the questionnaire to probe intensively. Probes are not used to help record or code information given by the respondent; rather, they are qualitative in nature and used to determine whether the respondent is having difficulty comprehending the question, recalling the information asked, or using an inappropriate response strategy (like estimating or guessing). Examples of typical probes used in cognitive interviews include "Can you paraphrase for me what you think this question is asking?", "Tell me how you arrived at your answer?", and "How sure are you that your answer is correct?"

Interviewer's Manner and Nonverbal Communication

Whether in person or on the telephone, interviewers must uniquely combine a friendly approach with an official, businesslike manner. Respondents often begin to talk about the subject matter of a questionnaire, and if the interviewer becomes distracted or

becomes too engaged in social conversation with the respondent, it is often difficult to return to asking survey questions.

It is important that interviewers maintain an objective attitude. They should never indicate a personal opinion about a reply or a survey topic. Furthermore, they need to be acutely aware of facial expressions, mannerisms, tone of voice, and other spontaneous reactions to respondent answers. Expressions of surprise, amusement, disapproval, or even sympathy may cause respondents to give untrue answers or to withhold information. Objectivity is the most effective method for putting respondents at ease and making them feel free to answer questions honestly.

For telephone interviews, it is essential that the interviewer's tone be pleasant and friendly, that they speak clearly, and that they are familiar enough with the instrument to avoid long pauses or delays. Pauses on the telephone are awkward, and may give the impression that the interviewer is waiting for an explanation from the respondent. Hesitation and expressed uncertainty about what to ask may create a negative impression in a telephone contact that would not have necessarily occurred in a face-to-face interview.

Telephone surveys, in general, are administered more quickly than a face-to-face interview because interviewers tend to read the questions faster and respondents tend to answer quicker and are less inclined to engage in social discourse. However, rushing can also give the appearance of lacking confidence and may cause the listener to misunderstand. Telephone interviewing should be confined to shorter data-collection instruments (*see* **Telephone Sampling**).

Computer-Assisted Interviewing (CAI)

Field data collection using computers is a new approach in many surveys. Clear benefits of CAI are that it eliminates editing responsibilities of the interviewer and keying of questionnaire data, resulting in quicker availability of results. Using a computer to collect interview data offers some important advantages to actual interviewer techniques as well.

First, the computer presents the correct sequence of questions based on the information and the responses already entered. This relieves the interviewer of a burden as they do not need to follow skip instructions, check items, and so forth. The computer also checks responses to ensure that all applicable items are answered appropriately. For example, where possible answers to a question are 1 (Yes) or 2 (No), the computer will reject other answers, and prompt the interviewer either to reask the question or to check the entry they made. Clearly, the use of computers is expected to help interviewers do their job more efficiently by eliminating tedious paperwork and freeing them to concentrate on actual data collection and building rapport with respondents.

One advantage of CAI interviews is that the program can easily provide on-screen instructions or other helpful information. For example, the screen may display previously provided names of family members so that the interviewer can refer to them by name in follow-up questions. This helps the interviewer administer the questions in a more friendly, casual manner. During the interview, the disadvantage to a lot of on-screen instructions and information is that the interviewer must not devote much time to reading the screen and trying to familiarize her/himself with instructions and other screen entries. This can hurt the interviewer's credibility as a well-trained professional, and can serve to distract and/or disengage the respondent. The interviewer's training must thoroughly familiarize the interviewer with the screens and instrument flow.

Another advantage of CAI is that each displayed screen can have an accompanying HELP screen, readily providing interviewers with screen-specific information, definitions, and explanations. This preserves the interviewer's sense of confidence, and improves data quality.

In CAPI surveys, interviewers have to be sensitive to the respondents' perception of the use of a computer to enter data. Some respondents perceive the computer as a means of entering their data into some sort of an open "information highway", and need to be assured that computers actually go further to protect confidential data. The computer may also serve as a barrier to good eye contact between the interviewer and respondent. In addition, if the interviewer is not comfortable with the computer program, they may spend too much time attending to the computer to the exclusion of the respondent. One point that interviewers should remember is that the respondent usually cannot see the screen that the interviewer is looking at, in contrast to being able to see a paper and pencil questionnaire. Also, because the interviewing

program will perform internal consistency edits based on information previously and subsequently provided, the programs often identify inconsistent answers that the interviewer has to probe about. If this is not done in a sensitive manner (e.g. "I must have entered something wrong – let me ask that question again."), respondents may begin to feel defensive about their answers and disengage from the survey process.

Last, interviewers may have more difficulty showing cards, life history calendars, or other tools that they need to give to the respondent during the interview. Depending on where the computer is set up, if it is sitting on the interviewer's lap and the respondent is not close by, too much distance may be created which will make these survey aides awkward to use. Also, if interviewers are forced to stand while conducting CAPI interviews, they lose the mobility to use ancillary interviewing tools smoothly.

Conclusion

Good interviewing techniques apply to all modes of interviewing: face-to-face, telephone, CATI, and CAPI. Each interviewing mode also makes unique demands on the interviewer. The current trend towards increasing use of CAI requires interviewers to fortify themselves with all the standards of good interviewing techniques, and develop automation skills as an additional requirement. Interviewers are also being required to administer a survey for an increasingly resistant respondent pool, and to manipulate the dynamics of the interviewing situation to maintain respondent cooperation and interest. Newer and more effective training strategies need to be developed to equip interviewers with all the skills demanded by a fast-paced, changing survey environment.

SUSAN SCHECHTER &
ADRIENNE ONETO QUASNEY

Inverse Gaussian Distribution

In 1828 the English botanist Robert Brown described observations made on the motion of plant pollen immersed in water. He found a swimming, dancing motion from pollen from many different plants and he extended his research to include particles of fossilized plants and mineral specimens. Apparently, he believed that he had discovered a new type of particle. His work led to the realization that the motion was a physical phenomenon rather than biologic.

Bachelier (1900) and Einstein (1905) derived the normal distribution as the model for **Brownian motion**. Wiener (1923) gave the theory of a measure on the path space. Schrodinger (1915) considered Brownian motion with a positive drift, and obtained the distribution of the first passage time to describe the position of a particle performing Brownian motion. Tweedie [5] noticed the inverse relationship between cumulant **generating functions**, and proposed the name inverse Gaussian distribution. Wald [6] obtained the distribution as an approximation of the sample size distribution in a **sequential** probability ratio test. The distribution is sometimes known as Wald's distribution.

The probability density function of the inverse Gaussian distribution, denoted by $\mathrm{IG}(\mu, \lambda)$, is

$$f_x(x : \mu, \lambda) = \left(\frac{\lambda}{2\pi x^3}\right)^{1/2} \exp\left[\frac{-\lambda(x-\mu)^2}{2\mu^2 x}\right],$$

with $\mu > 0$, $\lambda > 0$, and $x > 0$. The mean is μ and the variance is μ^3/λ. The unimodal density function, a member of the **exponential family**, is skewed to the right (*see* **Skewness**). Its shape resembles other skewed density functions such as the **lognormal, Weibull**, and **gamma**. It can be obtained from the Wiener process $X(t)$ with positive drift ν and variance parameter σ^2 (*see* **Brownian Motion and Diffusion Processes**). Starting at zero, the time, T, for $X(t)$ to reach the barrier $a(a > 0)$ for the first time is called the *first passage time* and has an inverse Gaussian distribution with $\mu = a/\nu$ and $\lambda = a^2/\sigma^2$.

Unlike the Weibull or gamma distributions, the inverse Gaussian distribution allows exact sampling distributions. The **sufficient statistics** $\overline{X}$ and $T = \sum(1/X - 1/\overline{X})$, or a one-to-one function of $\overline{X}$ and T, are the basic quantities which are used in all of the **hypothesis tests, confidence intervals**, etc. $\overline{X}$ is also inverse Gaussian and λT is independently distributed as a **chi-square distributed** variable with $n - 1$ **degrees of freedom**.

Statistical methods based on the distribution have been developed to include the point and interval **estimation** of parameters, prediction intervals, estimation of the cumulative distribution function (cdf), analysis of **residuals** (one-way and two-way), **regression** analysis, and reliability analysis (*see* **Survival Analysis, Overview**).

The distribution has been used to describe phenomena in many of the sciences. In the biosciences, Sheppard & Savage [4] made use of the distribution to describe the length of time a particle remains in the blood. Since then it has been used in modeling maternity data, crop field size, shelf life, and many other types of data. Eaton & Whitmore [2] modeled the length of stay in a hospital as an inverse Gaussian variable.

For additional information, see [1] and [3].

J. LEROY FOLKS

Inverse Probability Weighting in Survival Analysis

Introduction

Modern epidemiologic and clinical studies aimed at analyzing a time to an event endpoint T routinely collect, in addition to (possibly **censored**) information on T, high-dimensional data often in the form of baseline (i.e. time-independent **covariates** $V(0)$) and **time-dependent covariates** $V(t), t > 0$, measured at frequent intervals. Scientific interest, however, often focuses on a low-dimensional functional $\beta = \beta(F_X)$ of the distribution F_X of the (intended) full data $X = \left(T, \overline{V}(T)\right)$ where $\overline{V}(t) \equiv \{V(u) : 0 \leq u \leq t\}$. Inverse probability weighted augmented (AIPW) estimators of β meet the analytic challenge posed by these high-dimensional data because they are **consistent** and asymptotically normal (CAN) under models that do not make assumptions about the parts of F_X that are of little scientific interest. As such, they are not subject to biases induced by **misspecification** of models for these secondary parts of F_X.

AIPW estimators were originally introduced by Robins and Rotnitzky [21] as part of a general **estimating function** methodology in coarsened, that is, incompletely observed, data models under **nonparametric** or **semiparametric** models for arbitrary full-data configurations X when the data are **coarsened at random** (CAR) [5, 6, 8] and the coarsening, that is, censoring or missingness, mechanism is either known or correctly modeled (*see* **Missing Data**). The AIPW estimators generalized and made efficient the nonaugmented inverse probability weighted estimators proposed by Koul, Susarla, and van Ryzin [12], and Keiding, Holst, and Green [10]. Robins and Rotnitzky [21] derived their methodology drawing from the modern theory of semiparametric **efficiency** due to Bickel, Klaassen, Ritov, and Wellner [3], Newey [14], van der Vaart [39, 40] among others. In this article, we restrict the discussion to coarsened data in the form of right-censored failure-time data. In this setting, the full data are $X = \left(T, \overline{V}(T)\right)$, the observed data are $Y = \left(\widetilde{T} = \min(T, C), \Delta = I(T \leq C), \overline{V}\left(\widetilde{T}\right)\right)$, where C is a censoring variable, and C and T are continuous positive random variables. Furthermore, the CAR assumption is equivalent to

$$\lambda_C(u|X) = \lambda_C\left(u|\overline{V}(u)\right) \text{ for all } u \geq 0, \qquad (1)$$

where $\lambda_C(u|\cdot) = \lim_{h \to 0^+} \Pr(u \leq C < u + h|\cdot, C \geq u, T \geq u)$ is the cause-specific hazard for censoring. Therefore, the coarsening mechanism is determined by the stochastic process $G \equiv G(\cdot)$, where $G(u) \equiv \exp\left\{-\int_0^u \lambda_C\left(t|\overline{V}(t)\right) \mathrm{d}t\right\}$.

AIPW Estimators Under CAR

Motivation: the Curse of Dimensionality

When the data are CAR, the **likelihood** $\mathcal{L}_n(F_X, G)$ based on n i.i.d. copies of Y factorizes as $\mathcal{L}_n(F_X, G) = \mathcal{L}_{1,n}(F_X)\mathcal{L}_{2,n}(G)$, where G denotes the coarsening mechanism, that is, the conditional distribution of the observed data Y given the full data X, and F_X is the cumulative distribution function of X. Thus, for models in which G and F_X are variation independent, any method that obeys the **likelihood principle** must result in the same inference about β regardless of whether G is known, completely unknown or known to follow a model. However, under non- or big semiparametric models for F_X, Robins and Ritov [20] have shown that due to the curse of dimensionality, with high- dimensional coarsened at random data, any method of inference that obeys the likelihood principle and thus ignores G must perform poorly in realistic sample sizes as the following example illustrates.

Example Suppose that no covariates $V(t)$ are measured for any $t > 0$ and, to simplify the notation, let W denote $V(0)$. Under CAR, $\mathcal{L}_n(F_X, G) = \mathcal{L}_{1,n}(F_X)\mathcal{L}_{2,n}(G)$, where $\mathcal{L}_{1,n}(F_X) = \prod_{i=1}^n f_{T|W}\left(\widetilde{T}_i|W_i\right)^{\Delta_i}\left(1 - F_{T|W}\left(\widetilde{T}_i|W_i\right)\right)^{1-\Delta_i} f_W(W_i)$. Suppose that we are interested in estimating $\beta = \Pr(T \leq t)$ for a fixed t. Because $\beta = \beta(F_X) = E_{F_W}\left\{F_{T|W}(t|W)\right\}$, its MLE $\widehat{\beta}$ is equal to $\beta\left(\widehat{F}_X\right)$, where $\widehat{F}_X$ is the **Maximum likelihood** estimator (MLE) of F_X. Since the MLE of F_W is the empirical cdf of W, then $\widehat{\beta} = n^{-1}\sum_i \widehat{F}_{T|W}(t|W_i)$. The MLE $\widehat{F}_{T|W}$ of $F_{T|W=W_i}$ is given by the Kaplan–Meier estimator based on the subsample $\{Y_i : W = W_i\}$. If W is continuous, each subsample consists of one observation, so the **nonparametric MLE** of $F_{T|W=W_i}$ assigns

probability 1 to $\widetilde{T}_i$; however, when $\Delta_i = 0$, the NPMLE of $F_{T|W=W_i}$ assigns probability 0 to the interval $\left[0, \widetilde{T}_i\right]$ and it is undefined on $\left(\widetilde{T}_i, \infty\right)$. Thus, when W is continuous the NPMLE of $F_{T|W=W_i}$ is undefined for some observed values of W_i and hence the MLE of β is also undefined. One could assume that $F_{T|W}$ was smooth in W and use multivariate smoothing techniques (*see* **Smoothing Hazard Rates**). However, when W is high dimensional, $F_{T|W}$ would not be well estimated with the moderate sample sizes found in practice, because no two units would have values of W close enough to allow the borrowing of information needed for smoothing. Thus, unrealistically large sample sizes would be required for any estimator of β to have an approximately centered normal sampling distribution with variance small enough to be of substantive use.

AIPW estimators depend on a model for G and thus violate the likelihood principle, yet they yield estimators that are well behaved with moderate sample sizes. Locally efficient AIPW estimators of β (defined in the next section) simultaneously correct for bias due to dependent censoring attributable to the covariate process $V(t)$ and recover information from the censored observations by nonparametrically exploiting the correlation between the process $V(t)$ observed up to the censoring time and the unobserved failure time T.

Even under CAR, because of the curse of dimensionality, well-behaved estimators of β in finite samples do not exist unless one imposes additional restrictions on either the coarsening mechanism G or on the non- or semiparametric model for F_X. Hence, the best that can be hoped for is an estimator that is CAN under the CAR assumption (1) when either (but not necessarily both), a lower-dimensional model for G or a lower-dimensional model for F_X is correct. Such an estimator, when it exists, is called *doubly robust* (DR). Scharfstein, Rotnitzky, and Robins [29], Robins [18], Robins, Rotnitzky, and van der Laan [25] and van der Laan, and Robins [38] provide a broad theory of double **robustness** in CAR models. Using this theory, these authors show that the locally efficient AIPW estimators (described in the next section) are doubly robust. Robins and Rotnitzky [22] provide a summary of known results on double-robust estimation, including estimation in nonignorable models, that is, when CAR is not assumed.

Locally Efficient AIPW Estimation

Suppose that $\beta = \beta(F_X)$ is a smooth $k \times 1$ parameter under a non- or semiparametric model $\mathcal{M}_{\text{Full}}$ for F_X. That is, $\beta(F_X)$ is estimable at rate $\sqrt{n}$ under all laws F_X in model $\mathcal{M}_{\text{Full}}$ when X is fully observed for all n sample units. The general **algorithm** for the construction of locally efficient AIPW estimators of a $k \times 1$ vector $\beta(F_X)$ starts with the specification of a full-data *orthogonal* estimating function $D(\beta, \rho) = d(X; \beta, \rho)$ for β. This is a $k \times 1$ vector function of the full data X, of β and, possibly, of a **nuisance parameter** ρ, such that each component of $D(\beta(F_X), \rho(F_X))$ has mean zero and covariance zero with any nuisance score under F_X, for all F_X in $\mathcal{M}_{\text{Full}}$. We need to allow the orthogonal estimating equation to possibly depend on a nuisance parameter ρ so as to make the general methodology applicable to a broad class of estimation problems. For instance, in the Cox proportional hazards model with time independent covariates, $\rho \equiv \rho(\cdot)$, where $\rho(u)$ is the mean of the covariate among subjects who fail at time u.

The full data-estimating function $D(\beta, \rho)$ gives rise to the observed data-estimating function

$$U\{D(\beta, \rho), G\} - A\left(h_{F_X}, G\right) \tag{2}$$

The term $U\{D(\beta, \rho), G\}$ is an inverse probability weighted estimating function defined as

$$U\{D(\beta, \rho); G\} = \frac{\tau D(\beta, \rho)}{G(T^*)}, \tag{3}$$

where T^* is the minimum time such that $D(\beta, \rho)$ is observed and $\tau = I(T^* < C)$ is the indicator that $D(\beta, \rho)$ is observed. The critical point of inverse probability weighting is that when $\Pr(\tau = 1|X) > 0$, the estimating function is an **unbiased** *inverse probability* estimating function because, under CAR, $\Pr(\tau = 1|X) = G(T^*)$ and, thus, $E_G[U\{D(\beta, \rho); G\}|X] = D(\beta, \rho)$.

The second term in (2) is a mean zero augmentation term which, for any function $h\left(u, \overline{V}(u)\right)$, is defined as

$$A(h, G) = \int_0^{\widetilde{T}} \left[h\left(u, \overline{V}(u)\right)/G(u)\right] \mathrm{d}M_C(u), \tag{4}$$

where $\mathrm{d}M_C(u) = I\left(\widetilde{T} = u, \Delta = 0\right) - I\left(\widetilde{T} \geq u\right) \lambda_C\left(u|\overline{V}(u)\right) \mathrm{d}u$. The function h_{F_X} in (2) depends on

F_X and G and is defined as

$$h_{F_X}\left(u, \overline{V}(u)\right) = -E\left[U D(\beta, \rho) | \overline{V}(u), T \geq u\right]. \tag{5}$$

A doubly robust, locally efficient AIPW estimator $\widehat{\beta}(D)$ that uses $D(\beta, \rho)$ is the solution to

$$\sum_{i=1}^{n}\left[U\left\{D_i(\beta, \widehat{\rho}(\beta)); \widehat{G}\right\} - A_i\left(h_{\widehat{F}_X}, \widehat{G}\right)\right] = 0, \tag{6}$$

where $\widehat{F}_X$ and $\widehat{G}$ are the maximum likelihood estimators of F_X and G under parametric or semiparametric working models $\mathcal{M}_{\text{work}} \subset \mathcal{M}_{\text{Full}}$ for F_X and $\mathcal{G}_{\text{work}}$ for G and $\widehat{\rho}(\beta)$ is an estimator of ρ such that $\widehat{\rho}(\beta)$ evaluated at the true β converges at an appropriate rate (usually $n^{1/4}$) to $\rho(F_X)$ if either, but not necessarily both, working models are true; see van der Laan and Robins, 2003, for construction of $\widehat{\rho}(\beta)$. The estimator $\widehat{\beta}(D)$ has the following properties.

(a) If $\Pr(\tau = 1|X) > \sigma > 0$, $\widehat{\beta}(D)$ is doubly robust. That is, provided $\widehat{F}_X$ and $\widehat{G}$ converge at a sufficiently fast rate to F_X and G under $\mathcal{M}_{\text{work}}$ and $\mathcal{G}_{\text{work}}$ respectively, $\widehat{\beta}(D)$ is CAN in the union model that assumes that $F_X \in \mathcal{M}_{\text{Full}}$, CAR and either $F_X \in \mathcal{M}_{\text{work}}$ or $G \in \mathcal{G}_{\text{work}}$.

(b) There exists $D_{\text{opt}}(\beta, \rho)$ such that $\widehat{\beta}\left(D_{\text{opt}}\right)$ is locally semiparametric efficient in the union model of (a) at the intersection submodel where both $\mathcal{M}_{\text{work}}$ and $\mathcal{G}_{\text{work}}$ are correct. Robins and Rotnitzky [21], and van der Laan and Robins (2002) show how to derive D_{opt}.

The previous results can be derived from the results in Robins and Rotnitzky [21], which provide a general representation for the influence functions and the efficient score of estimators of smooth parameters $\beta = \beta(F_X)$ of non- or semiparametric models $\mathcal{M}_{\text{Full}}$ for distributions F_X of arbitrary full-data configurations X under parametric, semiparametric or nonparametric CAR models for the censoring or missingness mechanism.

Example (continued) When $\beta = P(T \leq t)$ for a fixed t, then $D(\beta, \rho) = I(T \leq t) - \beta$ does not depend on a nuisance parameter and, because the full-data model is nonparametric $D(\beta, \rho)$ is, up to a multiplicative constant, the unique (orthogonal) unbiased estimating function. In this setting, we have $T^* = \min(T, t)$ and

$$\begin{aligned} h_{F_X}(u, W) &= E\{I(T \leq t) - \beta | W, T \geq u\} \\ &= F_{T|W, T \geq u}(t|W, T \geq u) - \beta. \end{aligned} \tag{7}$$

To obtain a locally efficient DR estimator of β, we specify a low dimensional, for example, parametric, model $F_{T|W}(u|W; \eta)$ for $F_{T|W}(u|W)$ and compute the maximum likelihood estimator $\widehat{\eta}$ of η under the model. We leave the marginal distribution of W unrestricted so its MLE is the empirical distribution of W. In addition, we specify a low-dimensional model for $G(u)$, for example, we may postulate a Cox proportional hazards model $\lambda_C(u|W) = \lambda_0(u)\exp\left(\gamma' m(W)\right)$ and estimate γ with the Cox partial likelihood estimator $\widehat{\gamma}$ and $\lambda_0(u)$ with the Cox baseline hazard estimator $\widehat{\lambda}_0(u)$ regarding the censoring times as the outcomes and the failure times T as the censoring times for C. We then compute $\widehat{G}(u) = \prod_{\left\{i: \widetilde{T}_i \leq u, \Delta_i = 0\right\}}\left[1 - \widehat{\lambda}_0\left(\widetilde{T}_i\right)\exp\left(\widehat{\gamma}' m(W)\right)\right]$. We compute $h_{\widehat{F}_X, \widehat{G}}(u, W)$ using $\widehat{F}_{T|W}(u|W; \eta) = F_{T|W}(u|W; \widehat{\eta})$ and $\widehat{\beta}_{\text{MLE}} = n^{-1}\sum_{i=1}^{n}\widehat{F}_{T|W}(t|W_i)$. Then we solve (6) to obtain $\widehat{\beta}(D)$. Note that $\widehat{\beta}_{\text{MLE}}$ is the MLE of β under model $F_{T|W}(u|W; \eta)$. Thus, $\widehat{\beta}(D)$ is CAN, well behaved in finite samples and generally more efficient than $\widehat{\beta}(D)$ if the working model $F_{T|W}(u|W; \eta)$ holds. However, $\widehat{\beta}_{\text{MLE}}$, in contrast to the doubly robust estimator $\widehat{\beta}(D)$, is inconsistent if the model $F_{T|W}(u|W; \eta)$ is mispecified.

A Survey of Applications of the AIPW Methodology under CAR in Survival Analysis Problems

The book of van der Laan and Robins [38] contains a comprehensive treatment of the AIPW methodology for estimation in censored and missing data models and in counterfactual models for causal inference under the CAR assumption. Here, we review the literature on AIPW estimation restricting attention to censored failure-time data in noncounterfactual models.

Robins and Rotnitzky [21], Robins [16], and Robins and Finkelstein [19] constructed locally efficient AIPW estimators of the survival distribution of

T and of regression parameters of **Cox** proportional hazards models and **accelerated failure-time models** for the conditional distribution of T given baseline covariates. Robins [17] constructed AIPW estimators of median regression models for right-censored failure-time data; and Robins, Rotnitzky, and Zhao [26], and Nan, Emond, and Wellner [13] described AIPW estimation of Cox proportional hazards regression parameters with missing covariates. Robins, Rotnitzky, and Bonetti [23] described AIPW estimation of a failure-time distribution under **double sampling** with follow-up of dropouts. Hu and Tsiatis [7] used the AIPW methodology to construct estimators of a survival function from right-censored data subject to reporting delays. Zhao and Tsiatis [41–43], and Van der Laan, and Hubbard [35] constructed AIPW estimators of the quality of life adjusted survival-time distribution from right-censored data. Bang and Tsiatis [1, 2], and Strawderman [33] derived respectively AIPW estimators of a median regression model for medical costs from right-censored data and of the mean of an increasing **stochastic process**. Van der Laan, Hubbard, and Robins [36], and Quale, van der Laan and Robins [15] constructed locally efficient AIPW estimators of a **multivariate survival** function when failure times are subject to a common censoring time and to a failure-time-specific censoring respectively. In the same setting, Keles, van der Laan, and Robins [9] derived AIPW estimators that are easier to compute and almost as efficient than the Quale et al. estimators.

Robins and Rotnitzky [21] restricted their investigation to data configurations for which the full data X has a positive probability of being completely observed. Their work was later extended to censored data structures under the CAR assumption in which X is never completely observed. These extensions include the estimation of the marginal survival function of T and of regression parameters of an accelerated failure-time model for the law of T, given baseline covariates $V(0)$ from current status and/or interval censored data when the intensity function for monitoring whether T has occurred by t depends on the observed covariate history $\overline{V}(t)$ [34, 37].

AIPW Estimation without the CAR Assumption

The CAR assumption (1) implies that the data $V(t), t \geq 0$ include all the time-dependent and time-independent **prognostic factors** for failure that also predict censoring. In most studies, however, data are typically available on some but not all joint prognostic factors for censoring and survival and hence, CAR fails. Scharfstein, Robins, Eddings, and Rotnitzky [31], and Scharfstein and Robins [30] have extended the AIPW methodology to allow estimation of the marginal survivor function at a fixed t, $\beta = \Pr(T > t)$, of a discrete and continuous failure time T respectively under non-CAR models. Their work was an extension to the analysis of failure-time data of the AIPW methodology in non-CAR models for non–failure-time endpoints derived in a series of papers by Rotnitzky and Robins [27], Rotnitzky, Shcarfstein, and Robins [28], Robins, Rotnitzky, and Scharfstein [24], and Scharfstein, Rotnitzky and Robins [29]. This methodology allows the analyst to appropriately adjust for informative censoring due to measured prognostic factors while simultaneously quantifying the sensitivity of inference to nonidentifying assumptions concerning residual dependence between the failure time and censoring due to unmeasured factors. For continuous failure-time data, their approach relies on the assumption that the censoring mechanism follows the model

$$\lambda_C\left(u|\overline{V}(u), T\right) = \lambda_{0,C}\left(u, \overline{V}(u)\right) \times \exp\left\{q\left(u, \overline{V}(u), T\right)\right\} \text{ for all } u \geq 0, \quad (8)$$

where $\lambda_{0,C}\left(u, \overline{V}(u)\right)$ is an unknown function and $q\left(u, \overline{V}(u), T\right)$ is a user-specified (i.e. known) function. The function $q\left(u, \overline{V}(u), T\right)$ quantifies, for those who remain at risk at time u, the dependence measured on the hazard ratio scale between T and censoring just after u after having adjusted for prognostic factors $\overline{V}(u)$. The choice $q\left(u, \overline{V}(u), T\right) = 0$ corresponds to an assumption slightly less stringent than the CAR assumption (1). Scharfstein and Robins, arguing like in Scharfstein, Rotnitzky, and Robins [29], showed that their model, like models proposed in the **competing risks** literature without auxiliary data $V(t)$ [4, 11, 32, 44, 45] is a nonparametric, just identified model for the law of the observed data Y; that is, the function $q\left(u, \overline{V}(u), T\right)$ is not identified, but, once specified, the survivor parameter β is identified but the law of Y is not restricted. Following the lead in the competing risks

literature, these authors recommended drawing inference about β by varying $q\left(u, \overline{V}(u), T\right)$ over a plausible range, and described a useful parameterization of this function for conducting such analysis.

Model (8) is stringent enough to allow identification for β. However, as in the CAR model, the model is not stringent enough to allow well-behaved estimation of β in finite samples when the covariate process is high dimensional because the function $\lambda_{0,C}\left(u, \overline{V}(u)\right)$ cannot be estimated well due to the curse of dimensionality. In order to reduce the dimension of the unknown function $\lambda_{0,C}\left(u, \overline{V}(u)\right)$, Scharfstein and Robins [30] assumed a lower-dimensional model for $\lambda_{0,C}\left(u, \overline{V}(u)\right)$ of the form

$$\lambda_{0,C}\left(u, \overline{V}(u)\right) = \lambda^*_{0,C}(u) \exp\left\{\gamma' w\left(u, \overline{V}(u)\right)\right\}, \tag{9}$$

where $\lambda^*_{0,C}(u)$ and γ are unknown and $w\left(u, \overline{V}(u)\right)$ is a user-specified function, and described AIPW estimators of β under this model. Unlike the CAR model, this model does not admit doubly robust estimators [22].

Ion Channel Modeling

Biological cells are enclosed by a phospholipid bilayer that is almost impermeable to water and water soluble molecules. Ion channels are proteins that span the membrane with a central pore that can open under certain conditions, allowing electrically charged ions to pass through it forming a minute flow of electrical current. Different kinds of channels allow the passage of different ions, such as Na^+ or K^+.

The opening and closing of ion channels is called *gating*. The major types of gating mechanism are *voltage gated* (channels respond to changes in membrane potential) and *ligand activated* (channels are activated by binding with molecules of certain chemicals). All electrical activity in the nervous system is regulated by ion channel gating, thereby controlling many diverse activities. Studying their behavior increases our understanding of normal physiology and the effect of drugs and toxins.

Measurements of the superposition of currents through many channels are called *macroscopic measurements.* For example, in the decay of a miniature endplate current at the neuromuscular junction, several thousand channels are involved, enough to produce a smooth curve in which the contribution of individual channels is impossible to see. Experimental macroscopic measurements are made following a jump change in conditions and the time course of the subsequent current can be fitted by the sum of several exponential curves with different time constants. If, on the other hand, we record from a moderate number of channels, the fluctuations about the average behavior become large enough to measure and they can be studied by **time series** methods.

Since the pioneering patch–clamp experiments of Neher and Sakmann [39] (see also [42]), it has become routinely possible to observe currents of a few picoamperes flowing through a single channel. Apart from noise and inertia in the recording system, we are essentially observing the opening and closing of the channel. When the channel is open there is a current of approximately constant amplitude (shown as a downward deflection in Figure 1); when the channel closes the current stops.

Single-channel Models

An ion channel consists of a single macromolecule that can exist in a number, m, say, of different chemical states, either by itself or in association with molecules of a specific ligand. Under stable conditions, we model transitions between these states by a homogeneous continuous-time **Markov chain** with transition rate matrix $\mathbf{Q}$ with elements

$$q_{ij} = \frac{\lim_{\Delta t \to 0} P(X(t + \Delta t) = j | X(t) = i)}{\Delta t}, \quad i \neq j \tag{1}$$

where $X(t)$ denotes the state occupied at time t. Define $q_{ii} = -\sum_{k \neq i} q_{ik}$ so the elements of each row sum to zero.

For example, a five-state model has been used to describe the nicotinic acetylcholine receptor. In this mechanism, there may be one agonist molecule (A) or two molecules (A_2) bound to the shut channel (R) or the open channel (R*). In Figure 2, three shut states (3, 4, 5) are shown on the bottom row and two open states (1, 2) on the top; on the right two agonist molecules are bound, one in the middle and none on the left.

The possible transitions are marked with appropriate rate constants. The rate constant for binding one molecule when the channel is free is written as $2k_{+1}$ because there are two free receptor sites; similarly, the dissociation rate for unbinding one of two occupied receptors is written as $2k_{-2}$ (for the shut channel) and $2k^*_{-2}$ (for the open channel). For a reaction involving a single molecule (e.g. a conformation change), the *transition rate* is simply the *reaction rate constant*. The same is true of dissociation (unbinding) of a single molecule of ligand that is bound to a receptor. For a reaction in which a free ligand

Figure 1 An example record of a current flowing through a single channel

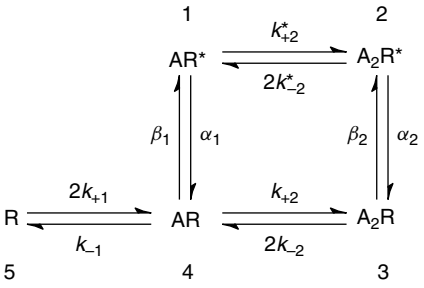

Figure 2 A simple model of an acetylcholine channel showing 5 possible states

molecule binds to a receptor, the transition rate is the product of the rate constant and the ligand concentration. The assumption that transition rates are constant over time, implies that the ligand concentration and membrane potential are constant; this is usually not true in daily life but may be in controlled experiments.

The transition rate matrix is

$$\mathbf{Q} = \begin{pmatrix} -(\alpha_1 + k^*_{+2}x) & k^*_{+2}x & 0 & \alpha_1 & 0 \\ 2k^*_{-2} & -(\alpha_2 + 2k^*_{-2}) & \alpha_2 & 0 & 0 \\ 0 & \beta_2 & -(\beta_2 + 2k_{-2}) & 2k_{-2} & 0 \\ \beta_1 & 0 & k_{+2}x & -(\beta_1 + k_{+2}x + k_{-1}) & k_{-1} \\ 0 & 0 & 0 & 2k_{+1}x & -2k_{+1}x \end{pmatrix}. \tag{2}$$

Note the multiplying factor, x, the free ligand concentration for the transition rates involving binding. In choosing numerical values for the parameters, we assume the principle of *microscopic reversibility*, so that, in the absence of an energy source, each individual reaction will proceed, on average, at the same rate in each direction. In particular, the product of transition rates around the cycle (1, 2, 3, 4) is the same in both directions. A physically plausible example, with $x = 100\,\text{nM}$, is

$$\mathbf{Q} = \left(\begin{array}{cc:ccc} -3050 & 50 & 0 & 3000 & 0 \\ 0.667 & -500.667 & 500 & 0 & 0 \\ \hdashline 0 & 15000 & -19000 & 4000 & 0 \\ 15 & 0 & 50 & -2065 & 2000 \\ 0 & 0 & 0 & 10 & -10 \end{array}\right), \tag{3}$$

where transition rates are in units of s^{-1}. The matrix has been partitioned with open states in the top left corner. The doubly occupied state opens much quicker and closes slower than the singly occupied state, which is slow to open and quick to shut.

Many models can be constructed in this way; some models can get quite large. Ball [1] studied a model for the nicotinic acetylcholine receptor based on molecular structure with 128 states of which 4 are open; by exploiting symmetry this reduces to 3 open and 69 closed states – still quite big!

Although one can eliminate some models for a particular channel on the basis of observable characteristics, some indeterminacy arises because we cannot see which state the channel is in; only if it is open or closed. Two or more distinct models may give rise to the same observable features under fixed conditions, [24, 34]. Further discrimination between models is possible by observing the same channel under different conditions of voltage or agonist concentration.

Standard Markov chain theory yields the transition probability matrix with elements $p_{ij}(t) = P(X(t) = j | X(0) = i)$ is given by $\mathbf{P}(t) = \mathrm{e}^{\mathbf{Q}t}$, $t > 0$. Spectral expansion of the matrix $-\mathbf{Q}$ with **eigenvalues** λ_i leads to the expression

$$\mathrm{e}^{\mathbf{Q}t} = \sum_{i=1}^{m} \mathrm{e}^{-\lambda_i t} \mathbf{A}_i. \tag{4}$$

Using this expansion it can be shown, [19], that macroscopic current relaxes as a mixture of $m - 1$ exponential components, omitting the zero eigenvalue, as does the **autocorrelation function** in noise measurements. Thus, for example, we expect to see four components in the five-state model. However, some components of the mixture may correspond to short-lived components (large λ) with small weight, so they may be difficult to detect in practice. The apparent number of components observed in such experiments, plus one, can thus only be taken as a lower bound for the number of states in the model.

Behavior of Single Channels Under Equilibrium Conditions

Open Times and Shut Times

If there is more than one open state, then an open time starts when the channel leaves a shut state for an open state, takes a tour round various open states and ends by entering a shut state. For example, in the five-state model an open time might start with a transition from state 4 to state 1, make several transitions back and forth between states 1 and 2, then end with a transition from state 1 to state 4 or from state 2 to state 3.

It is convenient to arrange that all the open states be labelled as states $1, 2 \ldots m_o$ where m_o is the number of open states; the shut (or closed) states having the highest numbered labels $m_o + 1$ to $m_o + m_c = m$. Then the $\mathbf{Q}$-matrix can be partitioned as

$$\mathbf{Q} = \begin{pmatrix} \mathbf{Q}_{oo} & \mathbf{Q}_{oc} \\ \mathbf{Q}_{co} & \mathbf{Q}_{cc} \end{pmatrix}, \tag{5}$$

where $\mathbf{Q}_{oo}$, a square matrix of dimension $m_o \times m_o$, contains all the transition rates between open states; $\mathbf{Q}_{cc}$ contains all the transition rates between closed states; $\mathbf{Q}_{oc}, \mathbf{Q}_{co}$ contain, respectively, the transition rates from open to closed states and from closed to open states, see (3).

The process may be seen as an alternating process of open and closed intervals. If we note the durations of these intervals and the states of the underlying system in which such intervals begin, we have a **semi-Markov process** with kernel matrix

$$\mathbf{G}(t) = \begin{pmatrix} \mathbf{0} & \mathbf{G}_{oc}(t) \\ \mathbf{G}_{co}(t) & \mathbf{0} \end{pmatrix}. \tag{6}$$

The ijth element of $\mathbf{G}(t)$ is a joint probability density for the duration of an interval and the probability that it ends with a transition into state j, conditional on starting an interval in state i. To obtain this kernel, let $\mathbf{R}_o(t)$ be a matrix function whose ijth element, where i and j are open states, is

$$\Pr\text{ob}(X(t) = j \text{ and channel open throughout time 0 to } t | X(0) = i). \tag{7}$$

Then $\mathbf{R}_o(t) = \mathrm{e}^{\mathbf{Q}_{oo}t}$, $t > 0$, and $\mathbf{G}_{oc}(t) = \mathbf{R}_o(t)\mathbf{Q}_{oc} = \mathrm{e}^{\mathbf{Q}_{oo}t}\mathbf{Q}_{oc}$. Similarly, $\mathbf{G}_{co}(t) = \mathrm{e}^{\mathbf{Q}_{cc}t}\mathbf{Q}_{co}$.

A Markov chain embedded at the points where intervals begin, records the states occupied at those times. The transition probability matrix of this chain is obtained by integrating with respect to t, yielding $\mathbf{G} = \int_0^\infty \mathbf{G}(t)\,\mathrm{d}t = \begin{pmatrix} \mathbf{0} & \mathbf{G}_{oc} \\ \mathbf{G}_{co} & \mathbf{0} \end{pmatrix}$, where $\mathbf{G}_{oc} = -\mathbf{Q}_{oo}^{-1}\mathbf{Q}_{oc}$ and $\mathbf{G}_{co} = -\mathbf{Q}_{cc}^{-1}\mathbf{Q}_{co}$. If we consider only the start of open intervals, the chain embedded at those points has transition matrix $\mathbf{G}_{oc}\mathbf{G}_{co}$. Let the equilibrium distribution of this chain be denoted by the row vector $\mathbf{\Phi}_o$. The equilibrium distribution of the entry states for closed intervals is then given by $\mathbf{\Phi}_c = \mathbf{\Phi}_o\mathbf{G}_{oc}$.

To get the pdf of open times, we have to sum over the possible closed states the channel might move to at the end and, suitably weighted, sum over the states that an open time might start in: so we get

$$\begin{aligned} f_o(t) &= \mathbf{\Phi}_o\mathbf{G}_{oc}(t)\mathbf{u}_c = \mathbf{\Phi}_o\mathrm{e}^{\mathbf{Q}_{oo}t}\mathbf{Q}_{oc}\mathbf{u}_c \\ &= -\mathbf{\Phi}_o\mathrm{e}^{\mathbf{Q}_{oo}t}\mathbf{Q}_{oo}\mathbf{u}_o, \end{aligned} \tag{8}$$

with mean open time $\mu_o = -\mathbf{\Phi}_o\mathbf{Q}_{oo}^{-1}\mathbf{u}_o$. In this equation $\mathbf{u}_o$, $\mathbf{u}_c$ are column vectors of 1's of appropriate length. Note that, because the rows of the matrix $\mathbf{Q}$ sum to zero, $\mathbf{Q}_{oo}\mathbf{u}_o + \mathbf{Q}_{oc}\mathbf{u}_c = \mathbf{0}$. If we use the spectral resolution of the matrix $-\mathbf{Q}_{oo}$, we see that the probability density function $f_o(t)$can be expressed as a mixture of exponential components with time constants given by the m_o eigenvalues of $-\mathbf{Q}_{oo}$. Unlike the matrix $-\mathbf{Q}$, it will not have a zero eigenvalue.

Similarly, interchanging o and c, we get the pdf of shut times as

$$f_c(t) = -\mathbf{\Phi}_c\mathrm{e}^{\mathbf{Q}_{cc}t}\mathbf{Q}_{cc}\mathbf{u}_c, \text{ with mean shut time}$$
$$\mu_c = -\mathbf{\Phi}_c\mathbf{Q}_{cc}^{-1}\mathbf{u}_c. \tag{9}$$

The pdf can be expressed as a mixture of exponential components with time constants given by the m_c eigenvalues of $-\mathbf{Q}_{cc}$.

So the distributions of open times and shut times tell us something about the numbers of open states and shut states, again with the caveat that we might not be able to distinguish all components from an experimental record.

Standard Markov chain theory tells us that the duration of sojourns in a single state, state i say, follow a simple exponential distribution with pdf $f(t) = -q_{ii}\mathrm{e}^{q_{ii}t}$, for $t > 0$; and mean $-1/q_{ii}$. This is a special case of the above distributions. In particular, for the five-state model, the reciprocals of (minus) the diagonal elements of $\mathbf{Q}$ give the mean lifetimes

of sojourns in individual states 1–5 as 0.328 ms, 1.997 ms, 52.6 μs, 0.484 ms, and 100 ms respectively.

Joint Distributions

The joint probability density of an open time T_o and the immediately following shut time T_c is given by

$$\mathbf{\Phi}_o \mathbf{G}_{oc}(t_o)\mathbf{G}_{co}(t_c)\mathbf{u}_o.$$

Similar results may be obtained for any pair of intervals. Joint distributions are useful in distinguishing between mechanisms; see [23, 35, 36]. We can also build up a **likelihood** for a complete sequence of open times and shut times. If there are M pairs of open and following shut times (t_j, s_j), this takes the form

$$\mathbf{\Phi}_o \prod_{j=1}^{M} (\mathrm{e}^{\mathbf{Q}_{oo}t_j}\mathbf{Q}_{oc}\mathrm{e}^{\mathbf{Q}_{cc}s_j}\mathbf{Q}_{co})\mathbf{u}_o.$$

This can be maximized to estimate the parameters of a given model and to test the fit of a model to data – see [13, 24, 32].

Correlations between open times or shut times can occur if there are at least two open states and two shut states. The correlation between the duration of an open time and the nth subsequent open time has the form

$$\rho_n = \sum w_i \lambda_i^n, \tag{10}$$

where the number of terms in the summation is $V - 1$. Here λ_i are those eigenvalues of $\mathbf{G}_{oc}\mathbf{G}_{co}$ that are neither zero nor one. V, the (vertex) connectivity of the mechanism is the smallest number of states that need to be removed (together with any links they have) in order to separate the set of open states from the set of shut states. Correlations between intervals therefore tell us something about the connectivity between open and shut states. In the five-state model, we need to remove at least two states to separate the open and shut states; so $V = 2$ and correlations die away with lag n as a single geometric term.

Results on correlations are given in [4, 10, 12, 25]. Colquhoun and Hawkes [21] also studied the distribution of openings and shuttings after a jump in agonist concentration or voltage. The behavior of various subsequent open and shut times (first, second etc.) also depends on V.

Bursting Behavior

Openings usually seem to occur in bursts of activity. A sequence of openings will be separated by brief shuttings and then there will be a long shut period before the activity starts again. This behavior can be explained by dividing the shut states into two categories: short-lived shut states and long-lived shut states.

A detailed treatment of bursting behavior is given in [20]. For the five-state model, the mean duration of a stay in state 5 is very much longer than that in any other state. Then shut times (gaps) within bursts of openings are almost certainly sojourns within the pair of shut states (3, 4); gaps between bursts will consist of sojourns within the shut states that include at least one visit to state 5. The distribution of gaps within bursts is a mixture of two exponentials with a mean of 57.6 μs, whereas gaps between bursts have a mean of 3790 ms.

Information about gaps between bursts is unreliable because there may be more than one channel in the recording environment so that, while the activity within a burst of openings almost certainly arises from one channel, different bursts may arise from different channels. This is one reason for studying the behavior of within-burst activity, as the information arising from it should be fairly reliable. Distributions derived include those for the number of openings per burst, duration of a burst, total open time per burst, individual openings within a burst (the first, second etc.).

Time Interval Omission

A big problem in observing single-channel records is that of time interval omission (TIO). Because of noise and inertia in the recording system, very short openings or shuttings, are likely to be missed. Results get distorted because, for example, what appears to be one long open time may actually be two or three open times separated by shut times too short to be distinguished. One way to cope with this is to study the total burst length or the total open time per burst, as these should be insensitive to missing short shut times.

In order to allow for missed events when dealing with the individual openings and shuttings it is usual to assume a critical constant dead-time, ξ, such that all open or shut intervals greater than this are observed accurately but shorter intervals are missed (a safe ξ value can be imposed retrospectively on recorded data). We then work with *apparent open*

times defined as periods that start with an open time of duration greater than ξ that may then be extended by a number of openings separated by shut periods each of duration less than ξ; they are terminated at the start of a shut period of duration greater than ξ. Apparent shut times are similarly defined.

Approximate solutions for the distributions of apparent open times and apparent shut times were used before Ball and Sansom, [11, 12], obtained exact results in the form of Laplace Transforms and also considered the effect of TIO on correlations between intervals. Exact expressions for the pdfs of apparent open times and shut times were found by Hawkes et al. [29]. These are fine for small to moderate values of time t, but can be numerically unstable for large t. These results were also studied in a general semi-Markov framework, [6, 7]. Asymptotic approximations can be found, [30, 33], that are extremely accurate for values of t from very large right down to fairly small; for small t the exact results are readily obtainable, so that the distributions are obtained over the whole range. If the true distribution is a mixture of k exponentials, then the approximation to the distribution of apparent times allowing for TIO is also a mixture of k exponentials; the time constants are, however, different.

These methods were used to study the effect of TIO on joint distributions of apparent open and shut times, [23], and to calculate the likelihood of a complete series of intervals, and thus estimate the model parameters; see also [18] for a study of the performance of likelihood estimation. TIO can induce some indeterminacy in the estimation of parameters. For data recorded under fixed conditions there can be two sets of parameters that seem to fit the data equally well: typically a *fast solution* and a *slow solution.* These can, however, be discriminated by observing the same channel under different conditions of voltage or ligand concentration, see [1, 3].

The TIO problem has been studied in the context of recording apparent open and shut intervals stimulated by a pulse of agonist concentration or voltage change; see [22, 38].

Multiple Levels

So far we have discussed only channels that are open or closed. Some channels, however, show several different levels of current, corresponding to different sets of states. It is possible to ignore this and just analyze the system as open or closed, but this loses information. Ball et al. [9] give a general treatment of a multilevel system, deriving burst properties including distributions of total charge transfer, total sojourn time, and number of visits to each conductance level during a burst. Merlushkin [37] studied various apparent sojourn distributions allowing for TIO in the multilevel case.

Multiple levels sometimes arise from the presence of more than one channel: if so, they are usually treated as acting independently. However, various models for systems of interacting channels are studied in [5, 8, 14].

Hidden Markov Methods of Analysis

Several authors (e.g. [15–17, 26–28, 40, 41, 43]) have applied **Bayesian** or **Hidden Markov** methods to the original noisy signals obtained from patch clamp experiments. These can be used to extract the ideal step-function signals (representing opening and shutting) from the noise; they are also used to estimate parameters in the models directly without identifying individual open and shut times. These techniques can cope with multilevel records as well as the simple open/shut case. **Markov chain Monte Carlo** methods of Bayesian analysis were applied in [2, 31].

ALAN G. HAWKES

Irwin, Joseph Oscar

Born: December 17, 1898, in London, UK.
Died: July 27, 1982, in Schaffhausen, Switzerland.

Reproduced by permission of the Royal Statisical Society

As the leading theoretician amongst British medical statisticians in the 1930s and in subsequent decades, Oscar Irwin played an important role in linking developments in statistical theory to applications in medical research.

At school, Irwin had specialized in classics before he took up mathematics. In 1917 his entry to Cambridge on a scholarship was delayed first by illness, and then by a crucial period working under **Karl Pearson** on anti-aircraft trajectories. On achieving his degree in 1921, he joined Pearson's staff at University College. Renewed illness led to a period of recuperation in Switzerland which initiated a life-long love of that country and, in later life, to his marriage to a Swiss wife.

In 1928, Irwin joined **R. A. Fisher's** department at Rothamsted, and thus became one of the few statisticians to work with both Karl Pearson and Fisher. A decade later, when Fisher and **Egon Pearson** occupied adjacent floors at University College, Irwin was said to be one of the few people to be *persona grata* in both departments. During his period with Fisher, ending in 1931, Irwin came to grips with the mathematical theory published during the 1920s by Fisher, who always retained a high opinion of Irwin's mathematical ability.

In 1931, Irwin joined the staff of the **Medical Research Council (MRC)**, housed at the London School of Hygiene and Tropical Medicine, where he was to stay for most of the next 30 years. As an MRC worker, Irwin had only a part-time university appointment. However, for about 25 years he taught a course in statistical methods, introducing many relatively recent developments in the subject. During the war years (1940–1945) he worked in Cambridge, teaching statistics to mathematicians, many of whom followed a subsequent career in statistics.

Irwin retired in 1965, after which he worked for a short time at the Galton Laboratory, University College London, before moving to Switzerland. He was a Visiting Professor at the University of North Carolina, Chapel Hill during three sabbatical periods.

Irwin's early papers reveal great mathematical fluency, which he retained throughout his life. In a paper of 1927 [1] he derived the distribution of the **mean** (*see* **Sampling Distributions**) from various distributions using the **characteristic function**. At Rothamsted he wrote on the influence of climatic factors on crop yield, but was perhaps more intrigued by theoretic work on topics such as the **analysis of variance**. In 1931, he started a series of expository papers on 'Recent advances in mathematical statistics', with bibliographies, which were particularly influential at a time at which few books on statistical theory existed.

His move to the MRC enlarged his research interests. He wrote several papers on **factor analysis**, but during the 1930s, while his colleague and close contemporary **Austin Bradford Hill** devoted himself largely to epidemiologic and (later) clinical research, Irwin's interests focused on laboratory experimentation. There were papers with H. Barkwith on the **dilution method** of estimating bacterial densities, and a developing interest in the methodology of **biological assay**, stimulated by his membership of a committee of the British Pharmacopoeia Commission. There was a major paper in the 1937 ***Journal of the Royal Statistical Society***, *Supplement* [3], and papers with E. A. Cheeseman clarifying the **maximum likelihood** solution in probit analysis (*see* **Quantal Response Models**).

His 1935 paper in *Metron* [2] described the "exact" test for **two-by-two tables**, derived and published independently from **Yates'** 1934 paper and Fisher's insertion in the 1934 edition of *Statistical*

Methods for Research Workers (*see* **Fisher's Exact Test**). He also wrote extensively on theories of **accident proneness**.

After the war he embarked on many long-term collaborative research programs, often for official committees. These included collaborative assays, especially for the standardization of vitamins, nutritional studies, work on physiologic responses to hot climates, laboratory tests for pertussis vaccines, and tests for the carcinogenicity of tars and mineral oils (*see* **Tumor Incidence Experiments**). The latter work led to papers on the analysis of animal carcinogenicity tests by **actuarial methods**. His earlier work on accident proneness stimulated a revived interest in long-tailed discrete distributions, with some pioneering studies of the Waring distributions.

Irwin played a very active role in the affairs of the **Royal Statistical Society**, as President in 1962–1964, Editor of the *Journal, Series B* from 1949 to 1959, Chairman of the Study Section in 1934–1935 and of the Research Section in 1947–1949, and recipient of the Guy Medal in Silver. He was President of the British Region of the **International Biometric Society** during 1958 and 1959.

Oscar Irwin was a man of wide cultural interests and fine sensitivity. In some ways he was ill-adapted to the more robust features of professional life, and preferred quiet and intimate conversation to public forum and debate. He exhibited great kindness to visiting scientists and students; several young medical visitors to the London School of Hygiene were given tutorials on Fisher's *Statistical Methods for Research Workers*, a book for which Irwin retained undying respect throughout his life.

PETER ARMITAGE

Isolated Populations

From the perspective of **population genetics**, a population is described as a group of individuals who can intermix freely such that there is no restriction of **gene** flow among the members within the group [11]. However, intermixing or gene flow does not always occur freely among the members of natural populations. To account for this phenomenon, population genetic theory developed the concept of "substructured populations", in which partitions within a natural population are allowed with incomplete mixing between the subpopulations [32]. In certain instances, a very small number of individuals are isolated from their parental group and become the founders of a new population. This population is often small in size and geographically so isolated that intermixing or sexual mating becomes almost exclusively restricted to the members within the group. Such groups of individuals established by a few founders having limited contact with other groups, have come to be known as "isolated populations". The degree of isolation can be varied, determined by the number of founders, time of isolation, and the extent of isolation (i.e. lack of gene flow with others).

Examples

In the context of humans, there are numerous examples of isolated populations; the relatively better known in the genetic literature are the Finns, Sardinians, Icelanders, Bedouins, Lapps, Basques, Amish, Hutterites, and some of the Polynesians islanders, among others. Each of them has a unique evolutionary and demographic history in terms of the number of founders, age of the population since founding and other population-related factors, such as the growth and expansion during the life of an isolate. Some of the isolated populations were established far back in time compared with others; some have maintained a relatively constant population size over time, e.g. the Saami of Scandinavia [14], while others like the Finns experienced a large population expansion after their founding [23, 26]. These demographic factors have profound effects on the genetic make-up of a population, which consequently reflect on the phenotype.

Genetic Characteristics of Isolated Populations

The distinctive characteristics of isolated populations, namely, a limited number of founders and lack of gene flow (or contact) with other populations, have some genetic consequences, which may be used as signatures of isolation of the population. First, being formed by a limited number of founders, irrespective of the source of the founders, an isolated population starts its evolution from a somewhat restricted amount of genetic variation. This restriction of genetic variability should be reflected in heterozygosity (i.e. proportion of heterozygous individuals averaged over loci), or gene diversity (i.e. complement of sum of squares of allele frequencies, averaged over loci), as well as in the number of segregating alleles [5, 17]. Secondly, the lack of contact with other populations (i.e. the isolation) also impacts genetic variation within isolated populations in a number of ways. New **mutations**, arising in an isolated population, do not have a chance to traverse easily to other populations, together with which, genetic drift (being particularly strong due to the small size of the isolated population) tends to reduce its genetic variation. As a consequence, an isolated population accumulates genetic divergence at a detectably fast rate from its sister populations from which it diverged after separation from their common ancestry [4, 18].

While the above genetic signatures of population isolation are generally seen at individual locus levels, there are consequences of isolation at a multilocus level of genetic variation as well. For example, the limited number of founders in an isolated population necessarily brings in a limited supply of **haplotypes** (i.e. multilocus combination of alleles on chromosomes), signifying strong **linkage disequilibrium** (LD, nonrandom association of alleles) between loci. The LD between loci in an isolated population is expected to remain strong, since the limited population size does not allow recombination to occur as frequently as in a large population, because of the smaller number of meiosis events per generation. Thus, isolated populations that are of recent origin should demonstrate stronger LD between loci in comparison with large cosmopolitan populations.

Of course, the demographic history of an isolated population, following its foundation, also plays

a role in molding its genetic variation in subsequent generations. The small founding population, combined with effects of genetic drift in subsequent generations, results in likely elimination of certain genetic attributes and enrichment of others. This makes the genome of isolates more homogeneous than that of large cosmopolitan populations. Geographic and reproductive isolation also leads to limited mate choice and consequently results in a higher coefficient of **inbreeding**. The drift effect and inbreeding level lead to increased **prevalence** of certain diseases (particularly the ones of recessive mode of inheritance). Another important characteristic feature is that the members of an isolate generally share a common environment, e.g. climate, nutrition, cultural habits, occupation and education levels, substantially reducing the **confounding** effects of environmental heterogeneity – an important factor in understanding the etiologies of common diseases, which have both genetic and environmental components.

Isolated Populations in Gene Mapping

Population isolates, thus, offer two very important advantages for gene mapping: a homogeneous genome, and a shared environment (see, for example, [7] and [27]. In fact, the confounding effects of genetic and environmental heterogeneity have been a source of discouragement for mapping genes in large cosmopolitan populations. Some isolated populations also have kept demographic records through parish or other registries enabling reconstruction of genealogies for several generations. It is, therefore, not surprising that a large number of **Mendelian** disorders have been mapped in isolated populations. The aforementioned features, typical of many isolated populations, are exemplified convincingly by the demographic history of the Finnish population [23]. A catalogue listing about 35 diseases, mostly recessive, has come to characterize the "Finnish Disease Heritage" [6, 20, 22]; and utilizing the uniqueness of the Finnish population, mutations in 19 of these diseases have thus far been identified and chromosomal regions for 13 others have been localized [31]. Other isolated populations have also been studied for mapping disease genes, such as the Amish, Ashkenazi Jews, Sardinians, French Canadians, Bedouins [2, 12, 19, 25].

This success in identifying the genetic basis of single-gene disorders had raised expectations that isolated populations would also be greatly useful in mapping **complex** traits. An important consideration of using isolated populations in this endeavor is the notion, mentioned earlier, that LD would be higher in recently founded isolated populations compared with large cosmopolitan populations. Indeed, on a global scale, the extent of LD is significantly lower in African populations compared with other world populations [24, 30]. Further isolation prevents the influx of foreign genes, leading to the retention of older haplotypes in a relatively stable fashion. In addition, reduced genetic variability in isolated populations would likely enhance the possibility of capturing alleles with minor individual effects (oligogenic) underlying complex traits because reduction in variation would lead to the enrichment of a few predisposed alleles in the population. As a result of this optimism, several major studies have been undertaken in several isolated populations for finding genes of common diseases, such as asthma, among the Hutterites [21] and Tristan da Cunha [34], type 2 diabetes among the Finns [9], Pima Indians [10], and schizophrenia in Palau [16]. The impact of this resurgence is particularly noticed in privately funded biotechnology companies; for example, the launching of the deCODE Genetics project for studying the entire Icelandic population, initiation of a similar project in Tonga by AutoGen Ltd, as well as joint collaboration between a nonprofit and a for-profit venture for launching a similar project in Estonia. Notwithstanding such excitement and several ongoing studies referred to above, however, apart from rare Mendelian forms, such as MODY [1], no genetic variant associated with a common disease has thus far been identified even though several potential genomic regions have been localized. Current literature presents a series of conflicting views, based on both empirical data and theoretical modeling, on the advantage of using isolates in mapping complex traits [8, 13, 15, 28, 29].

Based on simulation studies, Kruglyak [13] demonstrated that LD in general populations would not extend beyond a distance of 3 kb, and more importantly, isolated populations are unlikely to harbor a higher level of LD compared with general populations, minimizing the importance of population isolates in complex disease studies. Two empirical studies supported these observations: Eaves et al.

[8] in Sardinia, and Taillon Miller et al. [29] in Finland). Over-generalization of these results may, however, be erroneous. For example, Shifman & Darvasi [28] have shown that the extent of LD between SNPs at a distance of up to 200 kb does not differ between isolated (Finnish, Sardinian and Ashkenazi Jew) and outbred populations. However, when the distance between SNPs is increased beyond 200 kb, LD in the three isolated populations noted above increases by an average of 5.6 times. Consequently, the importance of isolated populations in efficiently mapping complex trait genes should not be readily dismissed.

Comments

This resurgence of interest in isolated populations points to a number of existing gaps in our knowledge of the consequences of the genetic characteristics of such populations. For example, in the context of the comparison of LD in isolated vs. outbred cosmopolitan populations, current data do not always specify what truly constitutes an isolation of a population. Since all recombination events that have occurred in the population are key determinants of the decay of LD, a critical demographic factor in designing a mapping study should be the number of generations to the most recent common ancestor (MRCA) in the population [33]. Thus, since the age of the MRCA in a recently expanded population is younger than that in a stable population, isolation alone may not be sufficient to guarantee extended LD blocks in the genome. Likewise, the founder population size at the stage of expansion is important because this initial genetic structure of the population dictates the extent of LD that would go through subsequent decay because of accumulation of subsequently occurring recombination events. Thus, comparisons of isolated vs. cosmopolitan populations with regard to the extent of contemporary LD values should be adjusted for differences of their initial population structure, which has been done rarely in the literature. Finally, since drift effects are more pronounced for loci with smaller mutation rates [3], it is important to demonstrate empirically the genome homogeneity of isolated populations at regions of the genome where mutation rates may not be so small.

Isotonic Inference

Isotonic inference concerns situations in which a set of parameters is assumed, a priori, to satisfy certain order restrictions. In the most common case, where data are arranged in ordered groups, the **mean** value of a **random variable** is assumed to change monotonically with the ordering of the groups. It is then reasonable to take account of the order restrictions in making inferences about the group means, such as point or interval estimations or significance tests. Isotonic inference extends more generally to situations where there are various shape constraints on response curves, such as convexity, concavity, or sigmoidicity.

One approach to such problems is to assume a parametric model that incorporates those order or shape constraints such as a **linear regression** equation or a particular **dose–response** function. The inference based on the parametric model can, however, be considerably **biased** and variable when the specified model is incorrect. It has been pointed out in environmental toxicology applications, for example, that no parametric dose–response model can be assumed to hold generally at very low doses of interest, and yet a monotone and convex relationship might reasonably, and more reliably, be assumed. We are therefore concerned in this article mainly with methods of inference that avoid the need to specify a rigid parametric model, but nevertheless allow for those order restrictions.

There is a large literature on **estimation** and testing (*see* **Hypothesis Testing**) in the areas of isotonic and order-restricted inferences, and comprehensive surveys of these areas include [3] and [43].

One general approach to the isotonic inference is **maximum likelihood** estimation. The problem of finding order-restricted maximum likelihood estimates is often solved by using **isotonic regression**. In its simplest case an explicit solution is obtained by the pool-adjacent-violators method, but in more general cases it is solved only by some nonlinear programming, see [46] and [10], for example, or by the aid of a formal **Bayesian** approach, as in [42]. For a restricted **likelihood ratio test** the usual asymptotic **chi-square distribution** theory does not apply. In some cases, the resulting distributions are known to be a mixture of χ^2 distributions, but in other cases some **computer-intensive methods** such as parametric **bootstrap** tests [10], or an asymptotic conservative approximation method [46] may be used. The maximum likelihood approach is outlined in another article (*see* **Isotonic Regression**). Here we are concerned mainly with other approaches to isotonic inference. As a natural method of incorporating prior knowledge in particular applications, a Bayesian approach is also briefly mentioned.

The Case for Isotonic Inference

The data in Table 1 are measurements of the half-life of an antibiotic drug in relation to the dose administered. The usual **analysis of variance** (ANOVA) is obviously inappropriate, because of the ordering of the doses, and one possible approach is to assume a parametric model. The simplest model for the monotone relationship is linear regression. However, it is generally difficult to assume that a linear relationship holds over a wide range of an **explanatory variable**. For the dose–response relationship there are of course more natural response curves, such as a sigmoid function, but it is still often difficult to assume a particular model for the given set of data. Furthermore, it also sometimes suffices to show an overall upward trend or to detect a steep **change-point** in the responses. It is then unnecessary to assume a rigid parametric model, and a nonparametric trend test or some **multiple comparisons** procedure is more appropriate (*see* **Simultaneous Inference**). We need assume only a monotone relationship in the mean half-life,

$$\mathrm{H}_1\colon \mu_1 \leq \cdots \leq \mu_a, \tag{1}$$

where at least one inequality is strong, so that the null model $\mathrm{H}_0\colon \mu_1 = \cdots = \mu_a$ is excluded.

The data in Table 2 show ordinal (i.e. **ordered) categorical data** typical of a Phase III comparative **clinical trial**. Assuming a **multinomial** model with cell probabilities p_{ij}, the **null hypothesis** that the two

Table 1 Half life of an antibiotic in rats

Dose (mg/kg)	Data (h)					Average
5	1.17	1.12	1.07	0.98	1.04	1.076
10	1.00	1.21	1.24	1.14	1.34	1.186
25	1.55	1.63	1.49	1.53		1.550
50	1.21	1.63	1.37	1.50	1.81	1.504
200	1.78	1.93	1.80	2.07	1.70	1.856

Table 2 Efficacy in a phase III trial of antibiotics

Drug	Not effective	Slightly effective	Effective	Excellent
AMPC	3	8	30	22
S6472	8	9	29	11

treatments are equal can be expressed as $p_{1j} = p_{2j}$, $j = 1, \ldots, 4$, or equivalently as

$$p_{ij} = p_{i\cdot} p_{\cdot j}, \tag{2}$$

where a dot denotes the summation with respect to the suffix replaced by the dot. Eq. (2) is the familiar independence hypothesis for a two-way **contingency table**. However, the usual **goodness-of-fit chi-square test** is inappropriate, since we are interested in a more restricted alternative

$$\begin{aligned} &p_{11}/p_{21} \le \cdots \le p_{14}/p_{24} \\ \mathrm{H}_2 : &\text{ or} \\ &p_{11}/p_{21} \ge \cdots \ge p_{14}/p_{24}, \end{aligned}$$

where at least one inequality is strong, implying that treatment 1 is superior to treatment 2 in efficacy or vice versa. **Ordered categorical data** are a special case of rank data with many ties, and any method for rank data can be applied to ordered categorical data, and vice versa.

If ordered categorical data are obtained at several doses, as in Table 3, then we are interested in testing the two-way **ordered alternative**:

$$\begin{aligned} \mathrm{H}_3 : p_{i+1,j}/p_{i,j} &\le p_{i+1,j+1}/p_{i,j+1}, \\ i &= 1, \ldots, a-1; \\ j &= 1, \ldots, b-1, \end{aligned}$$

which implies that higher doses are superior to lower doses in efficacy.

A similar hypothesis

$$\begin{aligned} \mathrm{H}_4 : \mu_{i+1,j+1} - \mu_{i+1,j} - \mu_{i,j+1} + \mu_{i,j} \ge 0, \\ i = 1, \ldots, a-1; j = 1, \ldots, b-1, \end{aligned}$$

has been considered for normal means from a two-way layout experiment, which implies that the differences, $\mu_{ij} - \mu_{i'j}$, tend upwards as the level j increases for any $i > i'$; see [14].

Various Extensions of the Monotone Relationship

A monotone dose–response relationship may be disturbed by toxicity at higher doses, and a **nonparametric** testing procedure for the downturn (or "umbrella") hypothesis,

$$\begin{aligned} \mathrm{H}_5 : \mu_1 \le \cdots \le \mu_{\tau+1} \ge \mu_{\tau+2} \ge \cdots \ge \mu_a, \\ \tau = 1, \ldots, a-1, \end{aligned}$$

has been proposed in [50]; here τ is an unknown turning point.

Some other extensions arise when responses show monotone relationships with the passage of time. Frequently encountered examples include the monotonic change of occurrence probabilities of some events, increasing treatment effects, and increasing **hazard rates** with time. For instance, the hypothesis

$$\mathrm{H}_6 : \mu_2 - \mu_1 \le \mu_3 - \mu_2 \le \cdots \le \mu_a - \mu_{a-1}$$

arises from the analysis of the age–period–cohort effects model (*see* **Age–Period–Cohort Analysis**) where only the second-order differences are estimable in each effect along with the time axis. Hypothesis H_6 is equivalent to $\mathrm{H}_6' : \mu_i - 2\mu_{i+1} + \mu_{i+2} \ge 0$, and may be called the "convexity hypothesis". Convexity, concavity, and sigmoidicity constraints are commonly employed also in the field of bioassay as reasonable shape constraints on a

Table 3 Usefulness in a dose-finding clinical trial

Drug	Undesirable	Slightly undesirable	Not useful	Slightly useful	Useful	Excellent
Placebo	3	6	37	9	15	1
AF 3 (mg/kg)	7	5	33	21	10	1
AF 6 (mg/kg)	5	6	21	16	23	6

dose–response relationship (*see* **Biological Assay, Overview**; **Quantal Response Models**).

As seen from the above examples, isotonic inference is closely related to **change-point** analysis. Actually, a one-sided change-point model may be formulated as a set of particular monotone relationships,

$$H_7 : \mu_1 = \cdots = \mu_\tau < \mu_{\tau+1} = \cdots = \mu_a, \quad \tau = 1, \ldots, a-1, \tag{3}$$

with τ an unknown change-point parameter, so that a useful statistic for change-point analysis is useful also for isotonic inference. Interestingly, (3) defines $a-1$ edges of the convex cone defined by the simple ordered alternative (1); see [24].

For other extensions, including **tree-structured**, star-shaped, unimodality, and symmetry models, the reader is referred to [3] and [43].

Testing a Simple Ordered Alternative in Normal Means

We wish to test a simple ordered alternative H_1 in the one-way layout model

$$y_{ij} = \mu_i + \varepsilon_{ij}, \quad i = 1, \ldots, a; j = 1, \ldots, n_i,$$

where the ε_{ij} are assumed to be independently distributed as **normal** $N(0, \sigma^2)$ with known **variance** σ^2. Then there are two major streams of overall trend tests and multiple contrast type tests. Most cases of unknown variance can be dealt with similarly, if an **unbiased** variance estimator distributed as a multiple of χ^2 is available.

Overall Trend Tests

One possible approach is the restricted likelihood ratio test developed extensively in [3] (*see* **Isotonic Regression**). The approach does not, however, possess any obvious optimal property for such restricted alternatives, and is rather difficult to extend to higher-way problems.

Abelson & Tukey [1] proposed a linear score statistic which maximizes the minimum **power** in the region defined by H_1 within the class of linear tests. This has been extended to the most stringent and somewhere most powerful (MSSP) test for a more general restricted alternative by Schaafsma [44, 45]. In the balanced case, Abelson & Tukey's score is determined by equalizing powers at all the $a-1$ edges of H_1 and is given by

$$c_i \propto -\left[i\left(1-\frac{i}{a}\right)\right]^{1/2} + \left[(i-1)\left(1-\frac{i-1}{a}\right)\right]^{1/2}, \quad i = 1, \ldots, a.$$

Extending Taguchi's idea [52], the cumulative χ^2 test was introduced in [15], and its power has been compared with that of the previous two approaches. The test statistic χ^{*2} is the sum of squares of the standardized accumulated statistics

$$y_i^* = \frac{1}{\sigma}\left(\frac{1}{N_i} + \frac{1}{N_i^*}\right)^{-1/2}(\overline{Y}_i^* - \overline{Y}_i), \quad i = 1, \ldots, a-1, \tag{4}$$

where $N_i = n_1 + \cdots + n_i$, $N_i^* = n_{i+1} + \cdots + n_a$, and $\overline{Y}_i = (y_{1\cdot} + \cdots + y_{i\cdot})/N_i$, $\overline{Y}_i^* = (y_{i+1\cdot} + \cdots + y_{a\cdot})/N_i^*$ with $y_{i\cdot} = (y_{i1} + \cdots + y_{in_i})$, $i = 1, \ldots, a$. The χ^{*2} statistic is characterized by the strong positive **correlations** between the serial components y_i^*, and in particular by the expansion for the balanced case in a series of independent χ^2 variables,

$$\chi^{*2} = \frac{1}{1\cdot 2}\chi_{(1)}^2 + \frac{a}{2\cdot 3}\chi_{(2)}^2 + \cdots + \frac{a}{(a-1)\cdot a}\chi_{(a-1)}^2,$$

where $\chi_{(l)}^2$ is the 1 df χ^2 statistic for detecting the departure from the null model in the direction of Chebyshev's lth order orthogonal polynomial. Hence χ^{*2} tests mainly, but not exclusively, a linear trend; see [19] and [36] for details.

Multiple Contrast Type Tests

Several multiple comparison procedures have been proposed for ordered parameters. Williams [55] proposed a closed testing procedure based on the maximum likelihood estimator for defining the maximal noneffective dose level. Marcus [30] modified the method by changing the estimator at the control level from $\overline{y}_1$. to $\hat{\mu}_1$, the maximum likelihood estimator of μ_1, so that his statistic is the maximal component of Bartholomew's $\overline{\chi}^2$. The limiting distribution of the latter statistic is obtained in [56] and more recently, an exact recursive integration procedure for calculating its distribution

function is obtained in [29]. The maximal component of χ^{*2} has been proposed also for this purpose, and is called the "max t" method, where t stands for the y_i^* of (4). The statistic is characterized as the likelihood ratio test for the change-point hypothesis H_7, and an exact and very efficient algorithm for calculating the ***P* value** has been obtained by Hawkins [12] (*see* **Change-point Problem**). The power functions of these closed multiple testing procedures have been compared in [30], [49], and [26]. More general multiple tests for ordered parameters are obtained in [32].

Confidence Interval

A **confidence interval** taking advantage of order restrictions can be obtained by inverting an appropriate test for order restricted alternatives. For example, Marcus & Peritz [31], Schoenfeld [47] and Hirotsu & Srivastava [25] obtain confidence intervals for normal means by inverting a multiple contrast type test, the restricted likelihood ratio test, and the max t test, respectively. Wynn [59] gives a general methodology for obtaining one-sided confidence intervals, and Hayter [13] obtains confidence intervals based on the one-sided **studentized range** test. Miwa & Hayter [35] obtain confidence intervals for the differences of the ordered normal means in the one-way layout setting taking the advantages of the one- and two-sided procedures. In particular, in the bioassay problem, Schmoyer [46] obtains improved upper confidence bounds for the responses at very low doses by assuming sigmoidicity in the dose–response curve.

Hwang & Peddada [28] develop a methodology under a general order restriction, which has been extended recently to a test procedure by Peddada, Prescott and Conaway [37].

There is no extensive work on the design of experiments on the ordered parameters, although an optimal allocation has been discussed in [23] (*see* **Optimal Design**).

Applications

A test of Abelson & Tukey, the cumulative χ^2 test, and some of the multiple comparison procedures, are now applied to the data in Table 1. Since the variance σ^2 is unknown, it is replaced by the usual unbiased estimate of variance, $\hat{\sigma}^2 = \sum\sum(y_{ij} - \overline{y}_{i\cdot})^2/(24 - 5) = 0.020741$.

The linear score statistic of Abelson & Tukey is calculated as

$$(-c_1\overline{y}_{1\cdot} - c_2\overline{y}_{2\cdot} + c_3\overline{y}_{3\cdot} + c_4\overline{y}_{4\cdot} + c_5\overline{y}_{5\cdot})/\hat{\sigma} = 9.1206,$$

with scores $c_1 = c_5 = (\sqrt{6} + 1)/\sqrt{5} = 1.543$, $c_2 = c_4 = (4 - \sqrt{6})/\sqrt{20} = 0.3467$, and $c_3 = 0$, giving a P value of 2.2×10^{-8} as evaluated by the t distribution with 19 df.

The null distribution of cumulative χ^2 statistic $\sum y_i^{*2}$ is well approximated by $d\chi_f^2$, a multiple of the χ^2 variable with df f, where the constants d and f are given by

$$d = 1 + \frac{2}{a-1} \times \left(\frac{\lambda_1}{\lambda_2} + \frac{\lambda_1 + \lambda_2}{\lambda_3} + \cdots + \frac{\lambda_1 + \cdots + \lambda_{a-2}}{\lambda_{a-1}}\right),$$
$$f = \frac{a-1}{d}, \tag{5}$$

with $\lambda_i = N_i/N_i^*$. An even better approximation based on the expansions by Laguerres' orthogonal polynomials, and also the approximation under the alternative hypothesis, are given in [16]. Then the P value of the statistic

$$F^* = (a-1)^{-1}\chi^{*2}|_{\sigma^2=\hat{\sigma}^2} = 54.739$$

can be evaluated as 1.1×10^{-8} by the ***F* distribution** with df $(f, \sum n_i - a)$, where $f = 2.067$ from (5).

The maximal component of the $\chi^{*2}|_{\sigma^2=\hat{\sigma}^2}$ is obtained at the partition between levels 2 and 3:

$$\max t = \left[\left(\frac{1}{10} + \frac{1}{14}\right)(0.02741)\right]^{-1/2} \times \left(\frac{23.00}{14} - \frac{11.31}{10}\right) = 8.584,$$

the one-sided P value of which is evaluated as 1.1×10^{-7} by the recurrence formula based on the Markov property of y_i^*s. According to the closed testing procedure of [32], the process proceeds to the final step where the t statistic between levels 1 and 2 shows a nonsignificant result at the one-sided significance level 0.10, thus suggesting finally the difference between the dose levels (1,2) and (3,4,5).

In applying the Williams [55] procedure and the modified Williams procedure of [30], we need the maximum likelihood estimaters of the μ_i, which are

$$\hat{\mu}_1 = 1.076, \qquad \hat{\mu}_2 = 1.186,$$
$$\hat{\mu}_3 = \hat{\mu}_4 = 1.524, \quad \hat{\mu}_5 = 1.856,$$

by the pool-adjacent-violators method. Since $\hat{\mu}_1 = \overline{y}_{1\cdot}$, both statistics coincide and equal

$$w = \max \frac{\sqrt{m}(\hat{\mu}_i - \overline{y}_{1\cdot})}{\hat{\sigma}}$$
$$= \frac{\sqrt{m}(\overline{y}_{5\cdot} - \overline{y}_{1\cdot})}{\hat{\sigma}} = 8.357,$$

where we take the repetition number m as the harmonic mean of the n_is for referring approximately to the tables for upper percentiles in the balanced case by [55] and [56], respectively. In any case, the statistic w is highly significant and the closed testing procedure stops with the nonsignificant result between levels 1 and 2, thus again suggesting a difference between the dose levels (1, 2) and (3, 4, 5).

For a more general likelihood $L(\mathbf{y}, \boldsymbol{\theta}, \boldsymbol{\nu})$ with the ordered parameter $\boldsymbol{\theta}$, and possibly with the **nuisance parameter** $\boldsymbol{\nu}$, arguments similar to those used above apply if the asymptotic normality of the likelihood estimators is assured. In particular, the cumulative χ^2 and the max t statistics can be based on the cumulative efficient scores evaluated at the null hypothesis and extended easily to two-way problems; see [7, 17, 18] for details.

Testing Ordered Alternatives in Binomial Probabilities

The data in Table 4 are from a dose–response **clinical trial**. Assuming that the y_i are independently distributed as **binomial** $B_{\text{in}}(n_i, p_i)$ we are interested in testing the simple **ordered alternative**

$$\mathrm{H}_1\colon\ p_1 \le \cdots \le p_a.$$

Table 4 Dose finding trial for a heart disease drug

Dose (mg/day)	Improved	Not improved
100	20	16
150	23	18
200	27	9
225	26	9
300	9	5

If the quantitative measures $d_1 < \cdots < d_a$ are attached to the y_i, then the locally most powerful test against a wide range of monotone relationships of p_i to d_i is obtained by Cochran [6] and Armitage [2] (*see* **Trend Test for Counts and Proportions**). For the case where there is no information on d_i, the likelihood ratio test has been developed by Chacko [5]. The tests based on the cumulative χ^2 and its maximal component have also been extended as follows:

$$\text{the cumulative } \chi^2 : \chi^{*2} = \sum y_i^{*2},$$
$$\text{the maximal component of } \chi^{*2} : \max t = \max y_i^*, \tag{6}$$

where y_i^* is given by (4) with σ replaced by $[\overline{Y}(1-\overline{Y})]^{1/2}$, $\overline{Y} = \sum y_i / \sum n_i$, and $y_{i\cdot}$ replaced by y_i in defining Y_i. Formula (5) is also valid for the χ^{*2} to give a two-sided P value of 0.113 when applied to Table 4. For max t, another exact algorithm is available based on the Markov property of the y_i^* to give a one-sided P value of 0.044 for Table 2 at the partition between levels (1, 2) and (3, 4, 5); see [26, 57, 58] for the algorithm. The Cochran–Armitage test gives a slightly larger one-sided P value of 0.049 since there is a slight downturn tendency in this example.

Analyzing the Two-Way Contingency Table with Ordered Column Categories

Two-Sample Problem

First consider the two-sample problem presented by Table 2. A popular approach to the analysis is to use a nonparametric test based on a linear score statistic such as Wilcoxon's (*see* **Wilcoxon–Mann–Whitney Test**). Now, for the two-sided alternative H_2 the two statistics,

$$\text{the cumulative } \chi^2 : \chi^{*2} = \chi_1^2 + \cdots + \chi_{b-1}^{*2}, \tag{7}$$
$$\text{the maximal component of } \chi^{*2} :$$
$$\max \chi^2 = \max \chi_j^2, \tag{8}$$

can be defined in terms of the accumulated efficient scores, where χ_j^2 is the goodness-of-fit χ^2 statistic for the **2 × 2 table** formed by accumulating the first j and the remaining $b - j$ columns. The χ_j^2 is, however, identical to the y_i^{*2} of (6) if the binomial data

are arranged in a $2 \times b$ table in an obvious way and exactly the same distribution theory applies also to this case. The two-sided P values are 0.039 for χ^{*2} and 0.154 for max χ^2, whereas it is 0.025 for the Wilcoxon test. In this case the Wilcoxon test shows the smallest P value, since approximately a linear trend is observed in p_{1j}/p_{2j}, $j = 1, \ldots, 4$. If these tests are applied to the last two rows of Table 3 for comparing AF 3 mg and AF 6 mg, then the two-sided P values are 0.0128, 0.0096, and 0.0033 for the Wilcoxon, the χ^{*2}, and max χ^2 methods, respectively. It has been verified by **simulation** that, when evaluated as two-sample nonparametric tests, the Wilcoxon method is useful for the location shift of the underlying symmetrical and light-tailed distributions such as the **logistic** or normal, the max χ^2 method is useful for skewed or heavy-tailed distributions, and the cumulative χ^2 method is characterized by its **robustness**, having relatively high **power** over a wide range of underlying distributions – normal, heavy-tailed, or skewed.

Another important approach to the problem is to assume an underlying continuous distribution for each treatment and to compare the parameters describing those distributions. The **proportional-odds** and **proportional-hazards** models are important examples; see [34] for details.

General a-*Sample Problem*

For a general a-sample problem the Wilcoxon test is extended to the Kruskal–Wallis test. The same type extensions are available for the χ^{*2} and its maximal component by defining the χ_j^2 in (7) and (8) as the goodness-of-fit χ^2 statistic for the accumulated $a \times 2$ table for the partition between columns j and $j+1$. The constants for the χ^2 approximation of χ^{*2} are obtained by

$$d = 1 + \frac{2}{b-1} \times \left(\frac{\gamma_1}{\gamma_2} + \frac{\gamma_1 + \gamma_2}{\gamma_3} + \cdots + \frac{\gamma_1 + \cdots + \gamma_{b-2}}{\gamma_{b-1}} \right),$$

$$f = \frac{(a-1)(b-1)}{d},$$

with $\gamma_j = C_j / C_j^*$, $C_j = y_{\cdot 1} + \cdots + y_{\cdot j}$, and $C_j^* = y_{\cdot j+1} + \cdots + y_{\cdot b}$. The max χ^2 can be evaluated by the calculation **algorithm** based on the Markov property of the subsequent χ_j^2s [26].

For the row-wise multiple comparisons based on the cumulative χ^2, the statistic

$$S = \max ||(\mathbf{a}' \otimes \mathbf{C}^{*'})z||^2$$

is defined where $\otimes$ is a Kronecker product, $\mathbf{z}$ a vector of $\sqrt{y_{\cdot\cdot}}\, y_{ij} / (y_{i\cdot} y_{\cdot j})^{1/2}$ arranged in dictionary order, $\mathbf{C}^{*'}$ a $b-1 \times b$ matrix defined so that the (j, j') th element of $\mathbf{C}^{*'}\mathbf{C}^*$ is $(\gamma_j / \gamma_{j'})^{1/2}$ for $j \le j'$ and the maximum is taken over all $\mathbf{a}$ that satisfy $\mathbf{a}'\mathbf{a} = 1$, and $(\sqrt{y_{1\cdot}}, \ldots, \sqrt{y_{a\cdot}})\, \mathbf{a} = 0$. When $a \ge b$ and under the null model, the statistic S is asymptotically distributed as the largest root of the Wishart matrix $W(\mathbf{C}^{*'}\mathbf{C}^*, a-1)$, which is well approximated by $\gamma_{(1)} \chi^2 (a-1)$ with $\gamma_{(1)}$ the largest root of $\mathbf{C}^{*'}\mathbf{C}^*$. The statistic S gives the Scheffé-type multiple comparison test, and has been applied to taste-testing data of five foods in five ordered categorical responses of [4] to obtain the significant classification of rows (foods) (1, 2), (3, 4) and (5). The max χ^2 is also applied to the data for multiple comparisons of the columns to obtain a highly significant classification (1, 2, 3) and (4, 5). The resulting block interaction model is expressed as

$$p_{ij} = p_{i\cdot} p_{\cdot j} q_{\mu\nu}, \quad \mu = 1, 2, 3, \nu = 1, 2,$$

if i belongs to the μth subgroup of rows and j to the νth subgroup of columns. The goodness-of-fit χ^2 has been compared with the fitting of the proportional-odds model [51] and its extension [33]; see [20] for details. The Scheffé-type multiple comparison method is applied to the normal distribution model in [21], for classifying subjects based on the upward, flat, and downward tendencies defined by repeated measurements.

Two-Way Contingency Table with Natural Orderings in Both Rows and Columns

Assuming a multinomial model $M(y_{\cdot\cdot}, p_{ij})$ for the data y_{ij} in Table 3 the cumulative χ^2 statistic and its maximal component are defined for testing H_3 using the cumulative efficient scores evaluated at the null hypothesis. These are

the doubly cumulative $\chi^2 : \chi^{**2} = \sum \sum \chi_{ij}^2$,

the maximal component of $\chi^{**2} : \max \max \chi_{ij}^2$,

with the χ_{ij}^2 being the goodness-of-fit χ^2 for the 2×2 tables obtained from partitioning and accumulating rows and columns at $i = 1, \ldots, a-1$, and $j = 1, \ldots, b-1$, respectively. The χ^{**2} is for the two-sided version of H_3, and max max χ^2 is applicable to both one- and two-sided problems. When applied to Table 3 the two-sided P values are approximately 0.0065 for the χ^{**2} and exactly 0.0142 for max max χ^2. The details of the P value calculations are given in [22]. As a semiparametric model for the ordered two-way table the constant-**odds ratio** model has been proposed by Wahrendolf [54] based on Plackett's [38] coefficient of association for **bivariate distributions** (*see* **Association, Measures of**).

As an example of the higher-way layouts, a $2 \times J \times K$ table comparing two treatments based on bivariate allele frequencies, is analyzed in [27]. An example of highly fractional factorial experiments with ordered categorical responses is given in [11]; see also the discussion following that article (*see* **Factorial Experiments**).

Bayesian Approach to Isotonic Inference

Since the purpose of an isotonic inference is to make use of the prior knowledge to enhance the efficiency of test and estimation, it is natural to consider a Bayesian approach. For example, an essentially complete class of tests for orderly constrained hypothesis is obtained as the whole set of Bayes tests with a **prior distribution** defined on those constrained supports. The cumulative χ^2 and max t methods are derived from this idea; see [7, 17, 53]. More specifically, in bioassay problems, the Dirichlet prior has been introduced for the successive differences of the responses for doses d_i, $p(d_i) - p(d_{i-1}), i = 1, \ldots, a+1$; $p(d_0) = 0$, $p(d_{a+1}) = 1$, reflecting the nondecreasing nature of the dose–response relationship, see [40, 41], for example. Shaked & Singpurwalla [48] discuss the defect of the Dirichlet prior, and introduce concavity constraints on the shape of a dose–response curve, reflecting a situation encountered in practice. Because of computational difficulties, however, they are unable to compute posteriors beyond modal estimates. The computational problem was overcome later by Gelfand & Kuo [8], who showed how a sampling-based approach could be used to develop the desired marginal posterior distributions and their features, for Dirichlet and product–beta priors; see also [9]. Ramgopal et al. [39] consider convex, concave, and ogive constraints to specify the shape of dose–response curves, and extend the sampling-based approach to calculating any posterior feature of interest in these generalized constrained problems.

C. HIROTSU

Isotonic Regression

Many regression problems involve minimizing a weighted sum of squares subject to the restriction that the solution must satisfy certain side conditions. A function $f(x)$ defined on a finite index set of numbers $\mathcal{X} = \{x_1, x_2, \ldots, x_k\}$ is isotonic or order preserving if x, y are in $\mathcal{X}$ and $x < y$ implies $f(x) \leq f(y)$. Isotonic regression minimizes a weighted sum of squares subject to the condition that the regression function is isotonic. A simple example is a one-way **analysis of variance** for ordered normal means, in which the variable $x_i = i$ indexes the groups. With each point x_i in $\mathcal{X}$ we associate a positive weight w_i, usually the number of observations on which it is based. Suppose that $g(x)$ is a given function defined on $\mathcal{X}$, then the isotonic regression of $g(x)$ with weights $w_1, w_2, \ldots, w_k$ is denoted by $g^*(x)$ and minimizes the weighted sum of squares,

$$\sum_{i=1}^{k} w_i[g(x_i) - f(x_i)]^2,$$

in the class of all isotonic functions $f(x)$ defined on $\mathcal{X}$. Note that $g^*(x)$ is the isotonic function closest to $g(x)$ as measured in weighted **least squares** distance. For a one-way analysis of variance for nondecreasing ordered normal means, $g(x_i)$ is the observed mean for group i, w_i is the number of observations on which the mean is based and $f(x_i) = \mu_i$ is the mean for group i and $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_k$. For the simple case of ordinary **linear regression** with a single independent variable, $g(x_i)$ is the mean value of the independent **explanatory** variable at x_i, w_i is the number of observations on which it is based, and $f(x) = a + bx$ is a linear regression function. Isotonic regression allows $f(x)$ to be any isotonic function rather than restricting the regression function $f(x)$ to be linear. While isotonic regression can be viewed as a smoothing procedure, one disadvantage is that the isotonic estimates are essentially step functions and, hence, are not smooth everywhere. The degree of smoothness depends on the type of assumptions made; for example, that the function is nondecreasing or convex. Another disadvantage is that the isotonic estimators are biased. Isotonic regression is important because it provides **maximum likelihood** estimators for a large class of problems involving ordered parameters, as well as solving many more constrained statistical problems than the weighted least squares problem stated above. One simple example is unimodal simple regression, which consists of an up-phase in which $\mathrm{E}(Y|X = x)$ is increasing with x and a down-phase in which $\mathrm{E}(Y|X = x)$ is decreasing with x. If the turning point is known, then it is possible to use isotonic regression for each phase separately. If the turning point is unknown, a simple modification of this idea yields the solution (see [3] for details and examples).

A number of efficient **algorithms** for isotonic regression are available, especially for the case of a single independent variable (see [2] for details). The pooled-adjacent-violators algorithm is widely used, but is only applicable for the case of a simple order. A simple order is when $x_1 < x_2 < \cdots < x_k$, and this implies $f(x_1) \leq f(x_2) \leq \cdots \leq f(x_k)$. This algorithm basically involves, possibly repeated, weighted averages of the unconstrained estimates. For recent extensions of this algorithm, including the case of concave regression and additive isotonic models, see [5] and [1], respectively. Other types of ordering such as quasi- and partial ordering exist; for example, when we have more than one independent variable, partial orderings, which deal with situations such as noncomparable elements in $\mathcal{X}$, arise (see [4] for details on types of ordering).

JOHN W. MCDONALD

Iterative Proportional Fitting

Iterative proportional fitting (IPF), also known as iterative proportional scaling, is an **algorithm** for constructing tables of numbers satisfying certain constraints. In its simplest form, the algorithm enables one to construct two-way **contingency tables** with specified marginal totals and a prescribed degree of association; from a more general perspective, it may be viewed as a cyclic ascent algorithm which maximizes a specific objective function. The algorithm can also be used to construct **maximum likelihood** estimators for table entries based upon hierarchical **log-linear models** for **Poisson**, **multinomial**, or product multinomial models. We will illustrate these aspects of the algorithm and its applications by describing some simple cases.

Suppose that we are given two pairs $\mathbf{u} = (u_1, u_2)$ and $\mathbf{v} = (v_1, v_2)$ of positive numbers satisfying $u_1 + u_2 = v_1 + v_2$, and a further positive number ψ. The IPF algorithm will enable us to construct the *unique* **two-by-two table** $\mathbf{b} = (b_{ij})$ such that, for all i and j,

$$b_{i+} = u_i, \qquad b_{+j} = v_j, \qquad \frac{b_{11}b_{22}}{b_{12}b_{21}} = \psi,$$

where the subscript $+$ denotes the result of summing over the subscript it replaces. The algorithm goes like this. Begin with the 2×2 table $\mathbf{a} = (a_{ij})$ defined by $a_{11} = \psi$, $a_{12} = a_{21} = a_{22} = 1$, noting that the cross-ratio $a_{11}a_{22}/a_{12}a_{21} = \psi$ (*see* **Odds Ratio**). Next, scale the rows of $\mathbf{a}$ to form the table $\mathbf{a}' = (a'_{ij})$:

$$a'_{ij} = a_{ij} \times \frac{u_i}{a_{i+}}, \tag{1}$$

for $i = 1, 2$ and $j = 1, 2$. It is easy to check that $\mathbf{a}'$ has the desired row sums, as well as having cross-ratio ψ. We now scale the columns of $\mathbf{a}'$ to form the table $\mathbf{a}'' = (a''_{ij})$:

$$a''_{ij} = a'_{ij} \times \frac{v_j}{a'_{+j}}. \tag{2}$$

One can check that $\mathbf{a}''$ has the desired column sums and cross-ratio, although the row sums are no longer (u_i). This completes one cycle of the IPF algorithm, beginning with the table $\mathbf{a}$.

The algorithm continues by repeatedly scaling the rows, as in (1), and then the columns, as in (2), to have the desired totals. After a number of cycles, the row totals are closer to (u_i) than they were initially, the column totals are exactly (v_j), and the cross-ratio is exactly ψ. The sequence of tables so defined converges pointwise to a 2×2 table $\mathbf{b}$ with all the desired properties; uniqueness also follows.

It is instructive to examine why these assertions are true, for in doing so we obtain further insights into the IPF algorithm. To do this, we introduce the notion of **information** (or I-) divergence between two tables $\mathbf{c} = (c_{ij})$ and $\mathbf{d} = (d_{ij})$, satisfying $c_{++} = d_{++}$, defined as follows:

$$I(\mathbf{c}|\mathbf{d}) = \sum_{ij} c_{ij} \log\left(\frac{c_{ij}}{d_{ij}}\right).$$

(A similar definition applies to singly indexed arrays.) It can be proved that $I(\mathbf{c}|\mathbf{d}) \geq 0$, and that $I(\mathbf{c}|\mathbf{d}) = 0$ if and only if $\mathbf{c} = \mathbf{d}$. Although not a symmetric function of its arguments, I behaves in many ways like a metric on tables, and it provides the basis of a proof of convergence of the IPF algorithm. We return to our construction of a table $\mathbf{b}$ having row totals $\mathbf{u}$, column totals $\mathbf{v}$, and cross-ratio ψ. First define the table $\mathbf{c} = (c_{ij})$ as follows:

$$c_{ij} = \frac{u_i v_j}{w},$$

where $w = u_+ = v_+$. The tables $\mathbf{a}$, $\mathbf{a}'$, $\mathbf{a}''$, ... become closer to $\mathbf{c}$ as the iterations continue, closeness here being in the sense of I-divergence. More precisely, we can check that

$$I(\mathbf{c}|\mathbf{a}) = I(\mathbf{c}|\mathbf{a}'') + I(\mathbf{v}|\mathbf{a}'_2) + I(\mathbf{u}|\mathbf{a}_1), \tag{3}$$

where $\mathbf{a}_1 = (a_{i+})$ and $\mathbf{a}'_2 = (a'_{+j})$. The convergence and uniqueness assertions above all follow from repeated use of this expansion and the stated properties of I. As long as there exists at least one table $\mathbf{c}$ with the desired marginal totals, we can begin the IPF algorithm with any table having the desired cross-ratio, and expect to converge to the stated limit. The repeated scaling gives tables closer and closer in the sense of I-divergence to the table $\mathbf{c}$, all the while retaining the original cross-ratio, and the row and column totals converge to their desired values.

All of the discussion so far applies with minimal changes to $r \times s$ tables; in the more general case, there are further cross-ratios to take into account.

Whereas in a 2×2 table there is only one cross-ratio whose value can be fixed, in an $r \times s$ table, there are $(r-1)(s-1)$ multiplicatively independent cross-ratios. A convenient set (cf. [12]) is the following:

$$\psi_{ij} = \frac{b_{ij} b_{rs}}{b_{is} b_{rj}}, \quad i = 1, \ldots, r-1; j = 1, \ldots, s-1.$$

Here we constructed our cross-ratios in relation to the index values r and s. Other choices give equivalent results; indeed there are quite different ways of defining the quantities which are preserved. This issue is addressed in the theory of **loglinear models**; see [2, 11] and [12]. Given an arbitrary set of $(r-1)(s-1)$ positive numbers (ψ_{ij}), and positive numbers $\mathbf{u} = (u_i)$ and $\mathbf{v} = (v_j)$ satisfying $u_+ = v_+$, the IPF algorithm may be initiated with the table $\mathbf{a} = (a_{ij})$ given by $a_{ij} = \psi_{ij}, i = 1, \ldots, r-1; j = 1, \ldots, s-1$, and $a_{rj} = 1 = a_{is}, i = 1, \ldots, r; j = 1, \ldots, s$. With this initial table, the steps are just as before, and the resulting sequence of tables converges to the unique table having row totals (u_i), column totals (v_j), and cross-ratios (ψ_{ij}).

We turn now to reasons for constructing such tables. One is simply to demonstrate the fact that the row totals, column totals, and cross-ratios of two-way tables may be specified independently, and to show how to obtain tables with arbitrarily specified (but consistent) values of these quantities. Historically, the algorithm was first used to adjust sample frequencies to expected marginal totals. In the examples in Deming [5], we have a table $\mathbf{n} = (n_{ij})$ based upon a **sample survey**, and marginal totals (N_{i+}) and (N_{-j}), but *not* the individual cell frequencies $\mathbf{N} = (N_{ij})$, from a census of the population. The result of applying the IPF algorithm with initial table $\mathbf{n}$, and desired marginal totals (N_{i+}) and (N_{+j}), can then be regarded as an estimate of what would have been obtained by cross-tabulating the entire population, instead of only a sample thereof. A modern treatment of these ideas can be found in [2], where the procedure is known as *raking* the table $\mathbf{n}$. The third application of the algorithm we note is to the construction of maximum likelihood estimates of table entries under loglinear models. We simply describe the results here; the reader may consult standard references such as [2, 11], or [1] for fuller details. Suppose that $\mathbf{n} = (n_{ij})$ is a two-way table of independent Poisson counts with parameters $\boldsymbol{\lambda} = (\lambda_{ij})$. Then the maximum likelihood estimate $\hat{\boldsymbol{\lambda}}$ of $\boldsymbol{\lambda}$ under the *multiplicative model* for the (λ_{ij}), has the same row and column totals as $\mathbf{n}$, and all cross-ratios equal to 1. In this case, the IPF algorithm begins with a table all of whose entries are 1, and scales the row and column totals to match those of the data $\mathbf{n}$. The algorithm converges after a single cycle to the unique maximum likelihood estimator $\hat{\boldsymbol{\lambda}}$.

Three- and Higher-Way Tables

There are a number of ways in which the IPF algorithm may be used with three-way tables. We illustrate two of these. Suppose that we have an $r \times s$ table $\mathbf{u} = (u_{ij})$ and an $s \times t$ table $\mathbf{v} = (v_{jk})$ of positive numbers satisfying $u_{+j} = v_{j+}$ for $j = 1, \ldots, s$. By analogy with our earlier construction, we might be interested in obtaining an $r \times s \times t$ table $\mathbf{b} = (b_{ijk})$ having

$$b_{ij+} = u_{ij}, \qquad b_{+jk} = v_{jk}.$$

This can be solved rather straightforwardly. For example, the table $\mathbf{c} = (c_{ijk})$ given by

$$c_{ijk} = \frac{u_{ij} v_{jk}}{w_j},$$

where $w_j = u_{+j} = v_{j+}, j = 1, \ldots, s$, is readily checked to have ij-margin $\mathbf{u}$ and jk-margin $\mathbf{v}$.

Of course, this is not the end of the story. We may also be interested in any further structure concerning the table $\mathbf{b}$ which may be specified, in addition to these marginal totals. It turns out that we may also ask that the table has predetermined values of certain cross-ratios. In this example, and more generally, we need rules to tell us which marginal totals and which cross-ratios can be specified independently. The issue is best discussed in the language of **hierarchical** loglinear models for multiway tables, where these are commonly described in terms of the marginal subtables which constitute the **sufficient statistics** for the models (under either independent Poisson, multinomial, or independent multinomial sampling). We refer to [1, 2], and [11] for details concerning these models. In this language, the cross-ratios that we have been specifying are the antilogarithms of elements of subspaces **orthogonal** to those that define the hierarchical loglinear model corresponding to the specified marginal totals. For example, by specifying margins corresponding to the indices

ij and jk, as we did in our example, we are also able to specify independently cross-ratios corresponding to the pair ik and the triple ijk – that is, all interactions other than those involved in the loglinear model defined by the prescribed marginal totals.

Now let us suppose that, in addition to **u** and **v** as above, we are given a $t \times r$ table $\mathbf{w} = (w_{ki})$ of positive numbers satisfying $w_{k+} = v_{+k}$ and $w_{+i} = u_{i+}$ for all k and i. Can we use IPF to construct a table $\mathbf{b} = (b_{ijk})$ satisfying

$$b_{ij+} = u_{ij}, \quad b_{+jk} = v_{jk}, \qquad b_{i+k} = w_{ki},$$

and having prescribed values for the ijk cross-ratios? One might think that this would be quite straightforward. Begin with a suitable initial table **a**. Then scale to achieve the ij, jk, and ki marginal totals **u**, **v**, and **w**, respectively. One cycle of the algorithm would be three such scalings, and after a few cycles, we might expect to have a table with the specified cross-ratios, and essentially the desired marginal totals.

How can this version of IPF go wrong? A clue is provided by our indication of the method used to prove that IPF converges. We made use of the existence of a table **c** satisfying the marginal constraints, and then everything followed. However, in the case of three-way tables, it is not hard to specify three consistent, positive two-way tables, for which *no* three-way table exists having positive entries, and the three specified tables as two-way marginal totals. A simple example is given by three 2×2 tables each having 1 in the diagonal cells and 2 in the off-diagonal cells. Although they are clearly consistent, it is easy to check that no $2 \times 2 \times 2$ table can exist with positive entries and these margins. Use of the IPF algorithm with an initial table whose entries are all 1, and these three marginal tables, results in a cycle through the same three tables. The tables constructed do not converge. Summarizing this discussion, we can say that only if there exists a three-way table with the given two-way tables as marginal totals is the IPF algorithm guaranteed to converge to a limiting table with the desired marginal totals and three-way cross-ratios. When it does, this table is uniquely specified by these properties.

We note that in the application of this result to maximum likelihood estimation with loglinear models, the assumption of the existence of *some* table with the given marginal totals is trivially satisfied as long as the observed table $\mathbf{n} = (n_{ijk})$ has positive entries, for in this case **n** itself suffices. If the observed table has some zero entries, but positive two-way marginal totals, the IPF algorithm still converges, but to a table with some zero entries. In a sense, this is an extended maximum likelihood estimator: one on the boundary of the natural parameter space.

The foregoing discussion applies without change to higher-way tables. For example, suppose that we have an initial four-way table $\mathbf{a} = (a_{ijkl})$, and we wish to scale it to have prescribed ij, jk, kl, and li marginal totals. What cross-ratios (equivalently, what loglinear structure) of this initial table will be preserved throughout the iterations, and could therefore be specified independently of the marginal totals? The answer is: all interactions other than those involved in the loglinear model defined by the prescribed marginal totals, that is, the ik, jl, ijk, ijl, ikl, jkl, and $ijkl$ interactions. Note that we still need to know that there exists a table with the specified marginal totals before the algorithm is guaranteed to converge to a limiting table with all the desired properties.

Finite Termination: Decomposable Models

Decomposable models are a class of loglinear models for complete multiway tables which possess closed-form expressions for their MLEs under the standard sampling models; see [11] and [2]. It turns out that the IPF algorithm behaves rather well for this class of models. Suppose that a set of marginal totals to be fitted via IPF defines a decomposable loglinear model. If the initial table is constant, and the margins to be fitted are taken in a suitable order, the algorithm converges after just one cycle. Furthermore, there *always* exists a table with the given set of tables as marginal subtables, when the corresponding model is decomposable. Finally, as long as the specified tables are all positive, the table whose existence has just been described has positive entries.

History

Fienberg [7] presents a discussion of the history of the IPF algorithm. Some additional references can be found in [8]. The most important early papers are [6] and [14].

Numerical Aspects

Haberman [11] proves that tables constructed by the IPF algorithm converge to their limit at a geometric (also called first-order) rate. This means that, asymptotically, the difference between the nth iterate and the limit is bounded above by ρ^n for some ρ between zero and unity. (This compares unfavorably with the behavior of Newton or modified Newton algorithms, which typically exhibit what is known as quadratic convergence.) In many cases, ρ may be quite close to unity, and so convergence may be rather slow, giving rise to a literature concerning speeding up of the algorithm. However, at that point, the algorithm ceases to be the one we are discussing.

The great advantage of the IPF algorithm is its simplicity, stability, and economy of space. When a table is large, and the number of iterations is not a limiting factor, it is the method of choice for the problems we have discussed. For other problems, such as the calculation of MLEs under loglinear models, Newton-type methods are preferred, because of their speed of convergence and the fact that variance–**covariance matrices** are an automatic byproduct. FORTRAN IV versions of the IPF algorithm can be found in [9] and [10].

Variants and Generalizations

It is implicit in the foregoing discussion that the tables being considered are all *complete*, that is, are fully rectangular, or rectangular parallelepipeds, etc., and have no so-called **structural zeros**. This was because the algorithm is mostly used, and its properties are most easily discussed, in that context. However, variant forms of the algorithm are used successfully with tables having a variety of other structures, and preserving features corresponding to models other than hierarchical loglinear models; see [11].

For generalizations of a different kind, see [3, 4, 13]. In these papers, applications of the algorithm beyond contingency tables are given, and its connections to the information measure I and entropy are more fully explored.

TERRY P. SPEED

Jackknife Method

The primary purpose of this technique is the estimation of the **standard errors** and the **bias** of estimators, $T(\mathbf{x})$. These Ts may be either too complicated to admit analytical derivation of the **sampling distributions**, or based on $\mathbf{x}$s from a probability model that is too difficult or impossible to specify. The essence of the computations for random samples of size n is the re-evaluation of the estimator on subsamples, which are typically produced by leaving out one observation at a time. For instance, the result of leaving out the ith datum may be denoted by $T_i = T[\mathbf{x}(i)]$, where $\mathbf{x}(i)$ is the particular subsample of size $n-1$ without the observation x_i.

The idea of appropriately differencing to reduce biases of order n^{-1} is credited to Quenouille. The original (1949) article [6] involves a **serial correlation** context, where the two subsets are the first and second half of the series. The second [7] has a more general context. Tukey [12] named the tool in 1958 for its parallel with the rough-and-ready boy-scout implement. He also coined the term *pseudovalues* for the individual differences, $nT - (n-1)T_i$. These are the simple ingredients for the standard error estimator. Tukey argued that in many instances these may be treated as approximately independent and their ordinary sample variance would be a reasonable estimator of var $[T(\mathbf{x})]$. This variance estimator was shown to be appropriate in large samples for the bias-corrected point estimator as well. Approximate **confidence intervals** and **hypothesis tests** are based on treating a standardized estimator as a normal or a **Student** t.

The methodology was extended to more general bias structures by Gray & Schucany [3]. Important early contributions to the theoretical foundations, by Rupert Miller, his students, and others were reviewed in 1974 [5]. There were early results on consistency of variance estimators for a broad classes of problems, including functions of **maximum likelihood** estimators (MLEs) and functions of U**-statistics**. A rigorous demonstration of the asymptotics for MLEs is given in [8]. The estimators that do not jackknife well have discontinuous *influence functions* (see [2, Section 11.6] or [9, Section 2.2.1]), of which the most notable example is the **median**. The approximate confidence intervals work better after symmetrizing **transformations**, for example, $\log s^2$ and $\tanh^{-1} r$.

The encyclopedia entry by Hinkley [4] contains the logical foundation, elementary notation, and some illustrative calculations. Efron & Tibshirani [2] give an excellent overview and the relationship of the jackknife to the **bootstrap**. These are distinct sample reuse approaches to getting information about the sampling distribution of $T(\mathbf{x})$. The bootstrap does this by simulating from the empirical distribution function, $F_n(x)$, the best estimate of $F(x)$ in a certain sense. The jackknife may be viewed as studying T in the neighborhood of F_n by quadrature (*see* **Numerical Integration**) rather than by **Monte Carlo**. Davison & Hinkley [1] present the pseudovalues as approximations of the empirical influence values for a nonparametric delta method. Distinct from this theoretical connection, they also illustrate the computation of jackknife-after-bootstrap diagnostics. For a more theoretical treatment of the jackknife and bootstrap, see [9].

Censored data are an important feature of some biostatistical problems. A recent examination of the suitability of jackknifing Kaplan–Meier integrals (*see* **Kaplan–Meier Estimator**) may be found in [11]. Stefanski & Cook [10] establish a relationship between the jackknife and SIMEX, which is a **simulation**-based method of inference for measurement error models.

WILLIAM R. SCHUCANY

James–Stein Estimator

The discovery of Stein [6] that the sample mean of a normal population is inadmissible in three or more dimensions was based on an argument using the estimator

$$\mathbf{d}^1(\mathbf{x}) = \left(1 - \frac{b}{a + |\mathbf{x}|^2}\right)\mathbf{x},$$

where we observe $\mathbf{X} = \mathbf{x}$, with $\mathbf{X} \sim \mathrm{N}(\boldsymbol{\theta}, \mathbf{I})$, a p-dimensional normal random variable (*see* **Multivariate Normal Distribution**). If $p \geq 3$, Stein showed that, for sufficiently small b and sufficiently large a,

$$\mathrm{E}_\theta|\mathbf{d}^1(\mathbf{X}) - \boldsymbol{\theta}|^2 < \mathrm{E}_\theta|\mathbf{X} - \boldsymbol{\theta}|^2, \quad \text{for all } \boldsymbol{\theta}, \qquad (1)$$

demonstrating the inadmissibility of $\mathbf{X}$ under squared error loss. This result only demonstrated the existence of a better estimator, as Stein did not give specific values of a and b that would satisfy (1). This was remedied in James & Stein [4], where it was shown that the estimator

$$\mathbf{d}^{\mathrm{JS}}(\mathbf{x}) = \left(1 - \frac{c}{|\mathbf{x}|^2}\right)\mathbf{x} \qquad (2)$$

dominates $\mathbf{X}$ as long as $0 \leq c \leq p - 2$. In fact, James & Stein [4] show that the optimal value of c is $c = p - 2$, and using this value (2) is usually referred to as the *James–Stein estimator*. Starting from (2), entire families of improved estimators of $\boldsymbol{\theta}$ have been derived. Note, in particular, that since $\mathbf{X}$ is a **minimax** estimator of $\boldsymbol{\theta}$, any estimator that dominates it is also a minimax estimator. Thus, research began into finding better families of minimax estimators of a multivariate normal mean.

One of the most important developments was due to Baranchik [1], who proved that estimators of the form

$$\mathbf{d}^{\mathrm{B}}(\mathbf{x}) = \left(1 - \frac{r(|\mathbf{x}|)}{|\mathbf{x}|^2}\right)\mathbf{x}$$

are minimax provided that (i) $0 \leq r(\cdot) \leq 2(p-2)$; and (ii) the function r is nondecreasing.

An immediate consequence of Baranchik's result was the minimaxity of (and the dominance of $\mathbf{X}$ by) the *positive-part Stein estimator*

$$\mathbf{d}^{+}(\mathbf{x}) = \left(1 - \frac{p-2}{|\mathbf{x}|^2}\right)^{+}\mathbf{x}, \qquad (3)$$

where $(\cdot)^+$ indicates that the quantity in parentheses is replaced by 0 whenever it is negative. This represents a great improvement over (2), as it does not suffer from aberrant behavior when $\mathbf{x}$ is near 0. (There, the James–Stein estimator can actually get infinitely large). In fact, the positive-part estimator (3) is so good that even though it is known to be inadmissible, it took over 25 years to exhibit an estimator that dominates it. (The inadmissibility of (3) follows from Brown [2], who showed that the admissible estimators must be generalized Bayes estimators. Because of the "point" at $|\mathbf{x}|^2 = p - 2$, (3) is not smooth enough to be generalized Bayes. The work of Efron & Morris [3, Section 5] showed that (3) was close to being a Bayes rule, and hence close to admissible, so it was suspected that it would be difficult to dominate. Finally, Shao & Strawderman [5] exhibited a dominating estimator.)

GEORGE CASELLA

Jeffreys, Harold

Born: April 22, 1891, in Fatfield, Co. Durham, UK.
Died: March 18, 1989, in Cambridge, UK.

The career of Harold Jeffreys is easily described. From his local school he went up to Cambridge, where he stayed for the rest of his life. His continuous 75 years as a fellow of St John's College is a record for any Oxbridge college. He was Plumian Professor of Astronomy and Experimental Philosophy, received numerous scientific awards, and was knighted.

During most of his life, and certainly up until his retirement from the Chair in 1958, he was best known for his important work in geophysics and related fields. The data he studied therein, and the general interest in the philosophy of science present in Cambridge in the 1920s, combined and culminated in the publication in 1939 of his book, called simply *Theory of Probability*. The substantially revised, third edition appeared in 1961 [1]. It is still in print and considered by many statisticians to be essential reading, not just for historical reasons, but because of its modern manner of thought. He was a poor oral communicator but his writing is superb. He stands with literature's greatest in the effective use of the English language.

There are two major novelties in the Theory, as he liked to call his book. The first lies in the concept of probability: the second in the development, from this concept, of operational procedures for handling data. He addressed the problem of how one's uncertainty about quantities of scientific interest, like hypotheses or values of constants, should be described. In the first chapter he demonstrated, on the basis of some simple ideas, that this could only be done through probability; so that one could speak of the probability of a hypothesis being true. Furthermore, statements of these uncertainties had to combine according to the rules of probability. One of these rules is **Bayes' theorem** and because of its ubiquity, the subject, when treated from this viewpoint, has become known as Bayesian statistics (*see* **Bayesian Methods**). The Theory was the first modern book on Bayesian statistics. This attitude towards probability was quite different from that of his near-contemporary, **R.A. Fisher**, who was, in the 1930s, revolutionizing statistics. Fisher used only the probability of data, given the hypothesis, whereas Jeffreys was advocating and justifying the concept of the probability of the hypothesis, given the data. Fisher's ideas found general acceptance and Jeffreys was initially treated as a maverick.

Although, at the time, their results seemed in good numerical agreement, it is now appreciated that they typically differ. If data x on hypothesis H has density $p(x|H)$, then Fisher used the tail-area probability $\int_x^\infty p(t|H)\,\mathrm{d}t$, or ***P*** **value**, to describe the status of H. Jeffreys used a direct probability $p(H|x) \propto p(x|H)p(H)$. In the use of the integral in the former but not in the latter, which satisfies the **likelihood** principle, the ideas contrast and the numerical values differ.

Jeffreys differed from **de Finetti** in regarding the numerical value of a probability as being shared by all rational persons, whereas de Finetti thought of it as subjective. If Jeffreys was right, then he had to have some way of producing the rational probability. The way he explored, and which later workers have followed, is first to describe a rational view of ignorance. This forms a reference point from which other states can be described, using Bayes' theorem. The invariance ideas he used have been extended into a modern development of reference priors.

Jeffreys' views have influenced the philosophy of science, and are in marked contrast to those of **Karl Popper**, who advocated the view that a hypothesis could only be disproved, whereas probability admitted values near one, effectively amounting to proof. Jeffreys was a great geophysicist who also created an original way of conducting the scientific method.

Job-exposure Matrices

Epidemiologic investigation of occupational hazards requires information on illness among workers and on their occupations or occupational exposures. Two families of epidemiologic investigations can be distinguished: industry-based studies and community-based studies. Each has unique advantages and disadvantages. Historically, community-based studies were based on analyses of job titles. With growing realization that there can be substantial variation in exposure profiles among workers who share the same job title, and that workers in different occupations can have common exposures, increasing attention has been paid to ascertaining subjects' occupational exposures (*see* **Occupational Epidemiology**; **Occupational Health and Medicine**; **Occupational Mortality**).

Since taking measurements in subjects' current workplaces is usually neither feasible nor useful for diseases of long latency, other approaches have been developed to ascertain subjects' past occupational exposures. If subjects can be interviewed, they can be asked about their exposure to various chemicals, but information thereby obtained is not sufficiently valid. Another approach is to obtain information about the jobs that subjects did and then have experts in industrial hygiene estimate the chemicals that may have been present in such workplaces. If the information collected about subjects' jobs is reasonably detailed, and the experts knowledgeable, then this can lead to quite valid exposure estimates. However, it is an expensive labor-intensive enterprise.

The job exposure matrix (JEM) approach was developed to provide a relatively inexpensive way of inferring exposures when the investigator has information on subjects' job histories. A JEM is simply a correspondence system for translating any occupation code into a list of exposures. The JEM provides the means for bringing together, for the purpose of statistical analysis, groups of subjects who share common exposures, irrespective of their occupations. A JEM consists of two primary axes, an exhaustive and mutually exclusive classification of occupations, and a list of substances. The occupation axis can be further subdivided by industries, by time periods, and conceivably by geographic areas. In the simplest form, the entry in the matrix could be a **binary** indicator of whether a worker in occupation i should be considered exposed to substance j. Applying each column in turn to a set of occupation histories allows the investigator to infer the exposure status of each study subject to each substance in the JEM. A more refined JEM could contain quantitative indicators of the probability of exposure to the substance in the job and estimates of the degree of exposure.

If the number of JEM substances is lengthy and the matrix entries are valid, this could generate useful data. While a handful of community-based JEMs have been developed in a few countries [1], they have not found wide applicability. The main limiting factor is the lack of valid and generalizable JEMs which are sufficiently broad in scope as to satisfy a wide range of research needs [3] (*see* **Validity and Generalizability in Epidemiologic Studies**). By contrast, a JEM can also be developed in the context of a **cohort study** and can be very useful if based on company records or expertise [2]. Such a JEM would not normally be applicable outside the cohort for which it was developed.

Joint Modeling of Longitudinal and Event Time Data

Many scientific investigations generate both *longitudinal measurement data*, with repeated measurements of a response variable at a number of time points (*see* **Longitudinal Data Analysis, Overview**), and **event history** *data*, in which times to transient or terminating events are recorded. Methods for the separate analyses of the two data components are well developed but procedures for their simultaneous treatment are still under study.

To fix ideas, consider **clinical trials** or observational studies in renal **transplantation**. After transplant, the performance of the graft can fluctuate over time. This can be measured through a proxy, perhaps serum creatinine, which will be high under abnormal function. The study design may call for creatinine to be measured regularly, maybe weekly during the first few months following transplantation, and this will generate a sequence $\mathbf{Y} = (Y(t_1), Y(t_2), Y(t_3), \ldots)$ of longitudinal data for each patient. Sometimes the data will be balanced, with measurement at the same time points on all patients, but often, especially in observational studies, the exact timing of measurements will be patient-specific, though nonetheless decided by the clinician or experimenter, perhaps informed by the patient's condition. In parallel to the collection of the longitudinal data, a **stochastic process** of times to or between certain events may also be observed. These may be transient events, such as intermittent reversible short-term rejection episodes (*see* **Repeated Events**), or single survival time outcomes such as death of the patient or failure of the graft (*see* **Survival Analysis, Overview**). This leads to event time data T, and joint modeling methods are appropriate when it is considered that the $\mathbf{Y}$ and T processes may not be independent. In principle, transient event data can be handled using similar techniques to single event data, but in practice, most development to date has assumed the latter. Note that T may be **censored** and may also be cause-specific: grafts can fail for a variety of reasons and the relationship between $\mathbf{Y}$ and T may well differ between causes. For instance, failures due to technical surgical reasons and failures due to rejection are likely to be associated with differing serum creatinine profiles.

Much work so far in joint longitudinal and event time modeling, henceforth just "joint modeling", has been based on specific case studies. Clearly, the statistical and scientific objectives of investigations of this kind will depend upon the application of interest. In particular, the primary focus for inference may be on:

(a) adjustment of inferences about longitudinal measurements to allow for possibly outcome-dependent dropout; (*see* **Nonignorable Dropout in Longitudinal Studies**);
(b) the distribution of time to a terminating or transient event conditional on intermediate longitudinal measurements;
(c) the possibility of using relatively quickly measured responses $\mathbf{Y}$ as a **surrogate** for survival time; or
(d) the joint evolution of the measurement and event-time processes.

The difference between (a) and (b) is reflected in the history of joint modeling, which derives principally from two originally distinct subject areas. Longitudinal researchers came to joint modeling through the 1990s as a result of the need to account for dropout from trials, which terminates observation at a random time T and is considered to be a nuisance. If the reason for dropout is related to the unobserved response, then severe bias can occur unless the analysis takes this association into account. In parallel with development in longitudinal data methodology, survival analysts arrived at effectively the same point at almost the same time through efforts to incorporate into **proportional hazards** analyses occasionally observed **covariates** subject to measurement error (*see* **Errors in the Measurement of Covariates**; **Measurement Error in Survival Analysis**). **Partial likelihood** methods for fitting **Cox regression models** can be used with **time-dependent covariates** over time, but require these to be observed at all failure times at which the patient remains at risk. In practice, this is rare for many clinical covariates, which are observed only occasionally, usually at clinic visits, and can vary between visits. In addition, many biomarkers or disease progression indicators can be measured only by proxy and/or with substantial measurement error. Denoting the covariate process by $\mathbf{Y}$, joint modeling approaches for $\mathbf{Y}$ and T were developed by survival specialists to account for the uncertainty in $\mathbf{Y}$. By the late 1990s, the two schools

merged and now use essentially the same methods. A slight difference is that longitudinal trials usually have balanced data, with a relatively small number of measurement points, and dropout is defined to be the time of first missed or last observed measurement, leading to discrete T. From the survival side, T is usually treated as continuous and the $\mathbf{Y}$ are more likely to have unbalanced measurement times.

Significant papers in the development of joint modeling methods include [1, 7, 8, 15, 17, 21, 22, 28]. To a lesser extent the methods have been motivated also by research in degradation, with $\mathbf{Y}$ a measure of wear before failure time T, and in surrogacy, with attempts to treat $\mathbf{Y}$ as a proxy for T [4, 30].

Modeling Strategies

Writing X for the fully observed covariates, interest is in the distribution $f(Y, T|X)$.

A *pattern mixture* factorization is often the simplest. Here we write

$$f(Y, T|X) = f(Y|T, X)f(T|X) \tag{1}$$

and in principle, fit a different Y-model for each cohort of patients defined by the values of T, using standard longitudinal approaches. Separately, a **marginal model** is fitted to T, using standard survival techniques. This method works well when there are only a few potential T values so that cohort sizes are fairly large. There can be problems, however, with the treatment of censored T, or when there are multiple cause events, such as dropout for a variety of reasons, not all equally associated with $\mathbf{Y}$. The approach is nonetheless easy to employ using standard software and attractive intuitively when it is believed that the population does indeed partition naturally by event times. Survival analysts, used to conditioning on the past through hazard modeling (*see* **Hazard Rate**), can be uncomfortable with the conditioning on the future implicit in $f(Y|T, X)$.

The second broad strategy reverses the conditioning through a *selection* factorization

$$f(Y, T|X) = f(T|Y, X)f(Y|X) \tag{2}$$

This approach makes censoring and multiple event causes easier to handle, but is again best employed when there are only a few possible event times T and values of $\mathbf{Y}$ are available where required in the $f(T|Y, X)$ model. An interpretive danger arises when $\mathbf{Y}$ is known to be a proxy for some unobserved true status of the patient, but $\mathbf{Y}$ is not in itself causal for event times. In that case, $f(T|Y, X)$ will describe an empirical relationship only and this needs to be recognized.

Random effects approaches usually postulate unobserved subject-specific effects U, which affect both $\mathbf{Y}$ and T. Assuming conditional independence between the observable components given the random effect, these models assume

$$f(T, Y|X) = \int f(T|X, U)f(Y|X, U)f(U)\,\mathrm{d}U \tag{3}$$

and estimation methods use standard **missing-data** approaches, almost invariably **EM** or **Markov chain Monte Carlo** (MCMC). Such models are conceptually attractive in that realistically, $\mathbf{Y}$ and T are rarely directly associated but intuitively depend jointly on some underlying true health status of the patient, captured by U. Disadvantages are that fitting is computationally intensive and the models rely on strong assumptions about the components $f(T|X, U)$, $f(Y|X, U)$, and $f(U)$, which are not directly testable from the observed data. An example of a random effects model is given later.

Variations of random effects models without conditional independence include **random-coefficient** pattern-mixture models

$$f(Y, T|X) = \int f(Y|T, X, U)f(U|X, T)f(T|X)\,\mathrm{d}U \tag{4}$$

and random-coefficient selection models

$$f(Y, T|X) = \int f(T|Y, X, U)f(Y|X, U)f(U)\,\mathrm{d}U \tag{5}$$

as described in [21]. Illustrations of the use of the above joint modeling strategies in a variety of application areas include [1–3, 8, 9, 13–16, 19, 27–29]. Other approaches to joint modeling include: parametric **multivariate analyses** with a **transformation** of T considered as a response, for example, a **multivariate normal** model for $(Y, \log T)$ [4, 6]); a **latent class** approach under which subjects are grouped into relatively homogeneous but unobserved subgroups with

differing longitudinal and event time properties [20]; and multistate modeling [12]. If interest is in estimation of treatment effects only rather than modeling per se, a variety of authors have developed methods intended to be **robust** to modeling assumptions (e.g. [10, 24]).

Ignoring Association

Given that methods for the separate analysis of **Y** and T are well developed and easily applied, the question arises as to what is gained through considerably more involved joint analysis. The answer to this is **efficiency** and, importantly, bias reduction (*see* **Unbiasedness**). Failure to account properly for the association between **Y** and T can lead to severe parameter bias in both sub-models.

A small **simulation** experiment illustrates a random effects model specification and the effect of ignoring association. Assume three **Y** measurements are scheduled, at times 0, 1, and 2 months. Responses are taken from a Gaussian linear model with a treatment indicator x (0 = placebo, 1 = active), a linear time trend, and subject-specific random intercept and slopes. Specifically,

$$\mathrm{E}[Y(t)|U_1, U_2] = \beta_x x + \beta_t t + U_1 + U_2 t$$
$$\mathrm{Var}(Y(t)|U_1, U_2) = \sigma_\varepsilon^2 \quad (6)$$

with $U_1 \sim \mathrm{N}(0, \sigma_1^2)$ and $U_2 \sim \mathrm{N}(0, \sigma_2^2)$ independently. Observation is terminated by an event at time T, taken from a hazard model

$$\lambda(t|U_1, U_2) = \lambda_0(t) \exp\{\alpha x + \gamma(U_1 + U_2 t)\} \quad (7)$$

with fixed-point censoring at three months. The data were simulated with constant baseline $\lambda_0(t)$, and although distributions are improper if $\gamma(U_1 + U_2 t)$ is negative, that is, the survival curves need not fall to zero, the censoring prevents this being a problem.

The parameter γ induces the association between the conditional distributions $f(Y|X, U)$ and $f(T|X, U)$. The following table illustrates the effect of γ on parameter estimates when the observed **Y** values are analyzed alone, with no allowance for association. The table gives mean values from 100 simulations each with sample size 250.

	$\beta_x = 1$	$\beta_t = 1$	$\sigma_1^2 = 1$	$\sigma_2^2 = 0.25$	$\sigma_\varepsilon^2 = 0.25$
$\gamma = 0$	1.00	1.00	1.00	0.26	0.25
$\gamma = 0.5$	0.99	0.93	1.02	0.25	0.25
$\gamma = 1$	0.97	0.84	1.01	0.23	0.26
$\gamma = 1.5$	0.98	0.78	0.96	0.23	0.26

Some parameters, including the mean treatment effect, are hardly affected in this scenario. Others, and in particular, the slope estimate β_t, are severely biased by ignoring the association between **Y** and T. This bias is not due to the *amount* of information lost, as for all values of γ, about 45% of patients had all three **Y** measurements. Rather, it is due to the trajectories of those missing: when $\gamma > 0$, subjects with steep slopes are more likely to have early T and hence the average and variance of observed slopes are attenuated.

Turning to event times, a Cox proportional hazards model was fitted in two ways. First, only treatment was included (OT), and second, the longitudinal **residuals** $R(t) = Y(t) - \hat{\beta}_x x - \hat{\beta}_t t$ were additionally included as time-dependent covariates, carrying forward the last value (LV) until another became available. In this second case, there is no true parameter for comparison and so results are given for the treatment effect α only.

	$\alpha = 1$	
	OT	*LV*
$\gamma = 0$	1.04	1.05
$\gamma = 0.5$	0.86	0.96
$\gamma = 1$	0.70	0.93
$\gamma = 1.5$	0.54	0.80

Ignoring the longitudinal data completely is equivalent to ignoring **frailty** effects in survival, which is well known to severely bias coefficient estimates toward zero. The simple model using longitudinal residuals as time-dependent covariates helps but does not remove the bias, which arises in part because of model **misspecification**, and in part because of the carrying forward of the last recorded value, which in general, is known to cause attenuation of regression effects and poor coverage of **confidence intervals** (e.g. [25]).

Sensitivity and Diagnostics

Fitting a correctly specified joint model overcomes bias but this gain is not made without cost. As well as

the need for more **computer-intensive** fitting methods, the joint model relies heavily on the assumptions made about the mechanism, which generates the association between $\mathbf{Y}$ and T. If the longitudinal data are divided into observed and missing components, Y_{obs} and Y_{miss}, there can sometimes be an infinite number of possible distributions for the missing data Y_{miss}, each of which is consistent with the observed data Y_{obs} and T. For example, certain illnesses involve sudden crises in condition, corresponding to rapid degradation (e.g. [18]). As a simple model, suppose that a crisis terminates observation and at the same time causes a step change in the response $\mathbf{Y}$ by an amount θ. This step change affects only Y_{miss} and therefore θ is not **identifiable** from the observed data Y_{obs} and T. Moreover, any false presumption as to the value of θ will lead to a biased estimate of the relationship between $\mathbf{Y}$ and the event-time hazard. In this example and more generally, inference about the missing data relies crucially upon the assumptions made, and these assumptions cannot be checked from the observed data alone. In applications, careful consideration of the modeling assumptions by statisticians and collaborators together is required.

If a fairly simple summary is of interest, such as the effect of treatment on the change in $\mathbf{Y}$ from start to end of the study, then **sensitivity analyses** are practicable and highly recommended. In essence, important parameters should be allowed to vary over a realistic grid of values and the effect on the summary measure investigated. In the simulation example above, a joint model could be fitted for a range of γ and changes in the treatment effects could be monitored. Stability of the estimate brings some credence to the results, although within the particular model class only. Sensitivity procedures are discussed by, for example, [5, 23, 26].

Although it is not possible to declare any particular model as correct, it *is* possible to declare models that do not fit the observed parts of the data as incorrect. This aspect is sometimes overlooked in applications but is important. Residual analysis on the longitudinal data should be carried out but with proper allowance for the event time as properties of residuals depend upon T. Conditional means, variances, and covariances of longitudinal residuals can be calculated, at least in the Gaussian case, and can be used to produce standardized residuals for assessment.

Comments

A great deal of research over the last decade has been directed toward the development of sophisticated methods for the joint analysis of longitudinal and event time data. These new methods are useful in their own right but also reveal two uncomfortable truths: ignoring the association between the two data components, or using overly simple methods to deal with it, can lead to seriously misleading conclusions; but sophisticated methods rely on assumptions that are difficult, or even impossible, to validate from the data alone. This makes it easy, if unhelpful, to conclude that the best way to deal with dropout in longitudinal studies, or measurement error in intermittently observed covariates or markers, is not to have these problems in the first place. A more constructive suggestion is that all reasonable steps should be taken during the design and data collection stages to minimize these problems.

If the primary interest is in the event times, then joint modeling procedures are helpful and conclusions are likely to be fairly robust to modeling assumptions, especially for balanced designs with a regular measurement schedule. There can be problems, however, if the decision to schedule a measurement at all is in itself informative, for instance, if measurements are taken during acute episodes of a chronic condition (e.g. [11, 18]). Methods that include the decision to take a measurement as a third process are being developed but are as yet unproven. Another issue from the survival side is that follow-up times can be long, so that simple slope-and-intercept longitudinal models are often inadequate and more sophisticated stochastic models are needed. The models need to be sufficiently flexible to describe a variety of possible trajectories of the covariate or marker, including rapid deterioration just before the event.

If the main interest is in the longitudinal data, then the question of what would happen if there was no dropout sometimes cannot be avoided. Here, sensitivity analysis is certainly required but brings new difficulty in how it should be undertaken. Sensitivity is easy to assess when there is a simple summary, such as a treatment effect on mean response, and a single parameter that links the longitudinal and event time processes. If there are multiple parameters driving the association, then sensitivity assessment is more awkward, and this problem is exacerbated further when sensitivity to model choice rather than

parameter values is to be considered. This is an area of ongoing research.

One of the cited purposes of joint modeling is to enable quick and easy prognostic information to be gleaned from longitudinal measurements, which can then be used as surrogates for an event-time outcome that may not be observed until a considerable time into the future. This suggestion needs more application-specific testing and experience before advantages of joint modeling can be conclusively argued.

Finally, almost all joint modeling techniques are computationally intensive and as yet there are no general and user-friendly routines available in statistical packages. Until these are written, there is likely to be little widespread use of the methods. This is perhaps no bad thing as it will allow specialists to gain more experience and advise influential software developers as to which models and methods can and cannot be recommended.

ROBIN HENDERSON

Journal of Biopharmaceutical Statistics

The *Journal of Biopharmaceutical Statistics* (*JBS*) is an international, applied, biopharmaceutical statistical journal, published four times per year by Marcel Dekker, Inc., a division of Taylor & Francis, UK. It was established in 1988 by Karl E. Peace, Ph.D., the Georgia Cancer Coalition's distinguished cancer scholar at Georgia Southern. The past editors include Karl E. Peace (1990–1999) and A. Lawrence Gould (2000–2002). Current editor-in-chief is Shein-Chung Chow, Ph.D., Vice President of Biostatistics and Medical Writing of Millennium Pharmaceuticals, Inc., Cambridge, MA 02139. Beginning 2004, JBS also include book review section. The first issue of the *JBS* appeared in 1991.

The *JBS* provides an information resource for applied statisticians working in biopharmaceutical areas through publication of (i) high quality applications of statistics in biopharmaceutical research and development (*see* **Pharmacoepidemiology, Overview**) and (ii) expositions of statistical methodology with clear and immediate applicability to such work. Although not exhaustive, biopharmaceutical areas include particularly those attendant to the drug, device, or biologic research development processes; drug screening; assessment of pharmacological activity; pharmaceutical formulation and scale-up; preclinical safety assessment; **bioavailability**, **bioequivalence**, pharmacokinetics, pharmacodynamics, and genomics; **phase I, Phase II** and Phase III clinical development (*see* **Clinical Trials, Overview**); pre-market approval assessment of clinical safety (*see* **Drug Approval and Regulation**); **post-marketing surveillance**; manufacturing and quality control; technical operations; and regulatory issues (*see* **Drug Approval and Regulation**). Papers submitted to the *JBS* for publication consideration should emphasize the application of statistical methods, rather than the methods *per se* – whether new or established. Substantive aspects of the application should be presented. The process of problem formulation appropriate to the statistical method should be specifically addressed. Of particular importance is attention to statistical design (*see* **Experimental Design**) and protocol development (*see* **Clinical Trials Protocols**). In reflecting applied statistics as a scientific discipline, the *JBS* aims to provide models in the biopharmaceutical areas of proper design, analysis, and interpretation of both experimental and **observational studies**.

Digital submission of all manuscripts submitted for publication consideration in JBS is required. JBS currently accepts two options for digital submission: digital storage media, including $3-\frac{1}{2}$ diskettes, zip disks, or CD-ROMs, and e-mail attachments. Manuscripts may be submitted by e-mail to `journaledit@dekker.com`. The manuscript documents, along with all files containing references, figures, tables, outline, and abstract should be attached to the e-mail. Manuscript that is embedded in the body of the e-mail cannot be accepted. Manuscripts submitted to the *JBS* for publication consideration are reviewed by an editorial board member and two referees or appropriate experts. Review below regional editors is blinded to author identity. Authors are blinded to reviewer identity. General criteria for acceptance include originality, quality, and significance of the application or methods as well as the quality of the presentation.

Publications in the *JBS* reflect the international nature of biopharmaceutical research, with contributions by authors from every continent and many countries, e.g. Australia, Canada, China, England, Finland, Germany, Japan, South Africa, Switzerland, Taiwan, and the US. As of May 2004, the second issue of the fourteenth volume is in press, and all issues of the fourteenth volume are compiled.

KARL E. PEACE & SHEIN-CHUNG CHOW

Journal of Clinical Epidemiology

The *Journal of Clinical Epidemiology* represents a continuation, under a new name, of the *Journal of Chronic Diseases* (*JCD*), which was inaugurated in 1955. During that era, before the proliferation of specialty journals in such fields as **gastroenterology**, geriatrics (*see* **Gerontology and Geriatric Medicine**), and **rheumatology**, journals concerned specifically with medical research were oriented almost exclusively to studies of pathophysiology and biologic mechanisms. Clinical studies of chronic disease were seldom encouraged or accepted, because the care of chronic disease was seldom regarded as a scientific activity in the explicatory type of laboratory research usually conducted as "clinical investigation". The investigative methods needed to study patient care and to do **clinical trials**, however, were different from those of laboratory experiments; and reports using those methods would be either unappreciated by laboratory scientists, or regarded as too pragmatic for the often theoretical orientation of biostatistical and other journals concerned with methodology. Thoughtful reviews of clinical topics and appraisals of research methods would also usually take more space than most journals were willing to allocate. The *JCD* thus offered an orientation, appreciation, editorial policy, and space that had previously been unavailable.

The first volume of the journal immediately showed its new orientation, and its lively interest in methodology. The first paper in the first issue was **Merrell** & Shulman's "Determination of prognosis in chronic disease, illustrated by systemic lupus erythematosus". The paper described the medical use of **life-table** analyses for the course of clinical ailments, and was repeatedly cited thereafter for many years as the classic publication in that field. Another classic methodologic publication in the first volume was Louis Lasagna's discussion of an investigative method that was then in its infancy: "The controlled clinical trial: theory and practice". The discussion had a substantial influence on the planning and analyzing of cancer trials at the National Institutes of Health (NIH) during the late 1950s. A third methodologic classic in Volume 1 was **Harold Dorn's** essay, "Some applications of biometry in the collection and evaluation of medical data". The latter paper contains Dorn's often quoted remark that

> Reproducibility does not establish validity, since the same mistake can be made repeatedly; but without reproducibility an observed relationship becomes merely an isolated historical event and adds nothing to accumulated scientific knowledge.

During the next few early years, the journal's continuing focus on clinical issues in chronic disease was reflected by publications concerned with topics that today might be classified as **neurology**, metabolism, rheumatology, gastroenterology, **hepatology, psychiatry**, neonatology, congenital anomalies (*see* **Teratology**), atherosclerosis (*see* **Cardiology and Cardiovascular Disease**), hematology, **oncology**, and such chronic infections as tuberculosis and syphilis. Victor McKusick's pioneering work in clinical genetics first appeared in the *JCD* in a series of instalments under the general title of "Heritable disorders of connective tissue".

In addition to these clinical topics, the early volumes of the journal continued to offer a forum for methodology. The papers referred to classification of arthritis, evaluation of **screening** tests, discussions of epidemiologic principles, uses of interview data to assess **prevalence** of disease, the measurement of pain and pain relief, uses of nonmedical interviewers to obtain data about specific symptoms, and variability of daily blood pressure measurements. The methodologic studies, then as now, revealed the frequent, but often unrecognized, problems of **bias** in research with human groups. **Donald Mainland**, after analyzing results of a questionnaire given to a class of 129 first-year medical students, concluded that "... more than one-half of them held opinions which, if allowed to influence the selection of subjects in a forward-going etiologic survey, would bias the results".

Sidney Cobb et al., reporting on "differences between respondents and nonrespondents in a morbidity survey involving clinical examination" demonstrated the type of bias that might arise from low response rates in studies for the estimation of prevalence. The authors recommended a procedure that (like many other recommendations about how to deal with bias) has often been subsequently neglected: "A study of the nonresponse problem (should) be built into each new field investigation as it is planned."

The journal also become involved in topics that were overtly controversial or that would later generate controversy. In a controlled trial reported elsewhere in 1952, anticoagulant therapy had been found unequivocally effective in reducing short-term deaths in patients with acute myocardial infarction. Many clinicians claimed, however, that the results of the trial were inconsistent with their own clinical experience, particularly for the predominance of "low risk" patients who had excellent prognoses without treatment. Only much later would it be realized that the anticoagulant trial, despite an untreated control group, was not randomized (*see* **Randomization**) or double-blind, and that the proanticoagulant results could easily be attributed to a **biased** assignment of patients. Nevertheless, anticoagulant therapy was being so vigorously advocated that physicians who failed to use it might be sued for malpractice if a patient with myocardial infarction died. In a pair of editorials in the journal in 1956, the virtues of anticoagulant therapy received a spirited denunciation by David Rytand and a vigorous defense by William Foley.

The *JCD*, in its early years, published several instalments of research, conducted by the US Public Health Service, as the Tuskegee study of "Untreated syphilis in the male Negro". The research was originally regarded as a splendid investigation of the **natural history** of a disease, but the work later became controversial and received many ethical rebukes for continuing to assess "natural history" at a time when presumably effective therapy (with penicillin) had become available. During subsequent debates about the moral and methodological issues, T.G. Benedek (in the 1978 *JCD*) pointed out that the rebukers had often overlooked the ethical context of the era in which the research was done.

The modern fervor (and dispute) about lowering cholesterol was just beginning. Several papers on how to reduce cholesterol with diet or medication had appeared in the *JCD* (and elsewhere), but an international group of experts, after a meeting in Geneva, stated in 1957 that

> There was no clear cut scientific evidence to show that any particular factor causes... coronary artery disease. Numerous public statements by scientific and other writers... give the impression that the atherosclerosis problem has been largely solved. The chief culprit is purported to be fat and diet. According to these opinions, all one has to do to mend the situation is to change one's eating habits so as to include a special kind of low-fat diet. Unfortunately, scientific proof of a causal relationship between fats in the diet (and) coronary artery disease is still lacking.

Forty years later, many experts would claim that the proof has now become convincing; but others would still argue that it is not.

In 1957, after the death of J. Earle Moore (the founding editor), the co-editors became Louis Lasagna and David Seegal. In 1966, David P. Earle became editor with Martin Branfonbrener added as co-editor a year later. In 1978, Earle again became sole editor, with Brandfonbrener and Walter O. Spitzer working as associate editors. When Earle retired, the journal resumed the geographically separated, dual-editor pattern that had originally been set by J.E. Moore in Baltimore and D. Seegal in New York. The co-editors after 1982 were Alvan R. Feinstein in New Haven and Walter O. Spitzer in Montreal.

Throughout its 33 years, the journal has published some outstanding, memorable papers. Some of them have already been mentioned, but several others can be noted as "golden oldies". They are: Seegal's 1962 editorial on the virtues of saying "I don't know"; E. Schimmel's 1963 editorial on "The physician as pathogen"; another 1963 editorial in which the author concluded that without better clinical "science at the bedside, modern medical research may yield an intricately designed, expensively produced, doubly-blind controlled, statistically significant chaos"; a 1965 reprinting of J. Evelyn's treatise, originally published in 1961, on the hazards of air pollution in London; and a randomized double-blind trial, by C.R.B. Joyce and R.M.C. Welldon, in 1965, on "The objective efficacy of prayer".

With further passage of time, the contents of the journal gradually changed as other journals became available in subspecialty medical domains, and in new specialties such as rehabilitation and geriatrics. Many of the clinical reviews and symposia that formerly might have appeared in the journal became submitted and published elsewhere. The journal's symposia increasingly began to reflect its additional methodologic orientation, with topics that included the role of computers in medicine, quantitative principles in the design and analysis

of long-term studies (*see* **Longitudinal Data Analysis, Overview**), and the development of indexes (or rating scales) to measure **health status** or to describe functional status and **quality of life**. The statistical philosophies that guided the US National Institutes of Health (NIH) in its approach to clinical-trial research were first described by several statisticians in a 1966 *JCD* "biometrics seminar" called "The role of hypothesis testing in clinical trials". The discussion included the often-quoted remark by **Jerome Cornfield** that, "I do not believe that anything that is good science can be bad statistics." The many unresolved controversies about retrospective **case–control studies** were discussed in a frequently cited 1979 symposium edited by Michel Ibrahim and W.O. Spitzer. Many other methodologic issues in epidemiology were considered in a memorial "festschrift", in 1986, for Abraham Lilienfeld.

The journal's clinical scope was still broad and the clinical topics still emphasized diagnosis, prognosis, course, and therapy, but most of the clinical publications began to include the kinds of group data and statistical analyses that today would make the work be classified as **clinical epidemiology**. The latter domain expanded the scope of "epidemiology" to include many topics in which the people under study were in clinical, rather than community, settings. The topics under study were also expanded to include behavioral, social, and familial factors – personality traits, emotional adjustment, urbanization, **social class**, social isolation, and familial structures and relationships – that could affect the development or management of human ailments such as heart disease, cancers, renal disease, schizophrenia, and disability.

Although all of these topics could today be included in the broad scope of contents for "clinical epidemiology", the journal's most striking expansion was in methodology. The *JCD* became the prime publication for creative scholarship in the analysis and development of methods for research in quantitative clinical epidemiology. The orientation required a special blend of thought: a sophisticated knowledge of clinical distinctions in human ailments; an intense awareness of epidemiologic subtleties in the way that groups of people are formed and collected; and mathematical attention to the statistical strategies with which results can be quantitatively summarized and interpreted.

Scholars who work in the multidisciplinary intersection produced by the manifold methodologic challenges of quantitative clinical epidemiology are also relatively homeless. Their interests are often too quantitative or epidemiologic to be appreciated by clinical journals, too clinical to be approved by journals of epidemiology or public health, and too clinically or epidemiologically "applied" to be welcomed by journals of mathematical or biologic statistics. By opening this multidisciplinary forum, the *JCD* became a leading outlet for methodologic advances in medical research concerned with groups of people.

The methodologic analyses and advances were sometimes presented within the text of publications on specific ailment-oriented topics, but often the methods themselves were the main focus of discussion. The methods included such clinical issues as the role of **co-morbidity** (a term and concept introduced in the *JCD* in 1970); the acquisition of cogent, high-quality data in interviews and questionnaires (*see* **Questionnaire Design**); the evaluation of diagnostic and technologic tests (*see* **Diagnostic Tests, Evaluation of**); decisions about what kind of data to assemble in describing personality, behavior, **quality of care**, or quality of life; defining the "range of normal" (*see* **Normal Clinical Values, Reference Intervals for**); and the role of necropsy research in revealing the fallacies of using "cause-specific" death certificate data for individual decisions or collective concepts about the distribution of disease.

The epidemiologic methods referred to problems that produce biased or inaccurate results in data for groups. The problems included diverse issues in life-table analysis, the first empirical demonstration of the distortion known as **Berkson's fallacy**, and attention to every aspect of the assembly, maintenance, and collection of data for the people investigated in randomized trials, **cohort studies**, case–control studies, community **cross-sections, ecologic studies**, and other architectural structures for research. The statistical concepts included problems in planning sample sizes for diverse investigative situations (*see* **Sample Size Determination**), estimating relative risks, assessing the role of repeated measures and **regression to the mean**, determining **prevalence** in longitudinal or cross-sectional studies, and understanding or evaluating the virtues and hazards of old multivariable analytic methods (such as **linear regression**) and newer **multivariate analysis** (such

as binary regression, logistic **transformations**, **discriminant functions**, and the **proportional hazards** model).

To acknowledge its focus on the intimate interchange between qualitative challenges in clinical science and quantitative issues in statistics, the *Journal of Chronic Diseases* in 1988 changed its name to the *Journal of Clinical Epidemiology*. The fertile interchange has led to many useful collaborations among clinicians, epidemiologists, psychosocial scientists, and statisticians, while producing valuable interdisciplinary cross-fertilization and communication. It has made medical people aware of the need for satisfactory "numeracy" and "reliability" in communicating with their statistical and psychometric colleagues, while making statisticians and psychometricians aware of the need for satisfactory "literacy" and "sensibility" in communicating with medical people.

The satisfactory adjustment of interdisciplinary communication is not easy. Sometimes a statistical author may submit a paper that is aimed exclusively at statisticians, and that is incomprehensible to a medical reader. By 1979, the problem was happening often enough in the *JCD* to make David Earle publish an editorial urging "potential authors to write their manuscripts so that the clinical relevance is clearly apparent, and put as much of the derivation as possible in an appendix or to publish the mathematics elsewhere". The editors of the *JCE* have often made analogous requests.

Sometimes a reviewer who is a rigorous quantitative methodologist may make demands that are impossible for an investigator to attain. A psychometric reviewer may ask, almost as a matter of routine, that **Cronbach's alpha** be calculated for a five-category ordinal scale for which the calculation (which requires an inventory of individual items) cannot be done. A biostatistical reviewer may ask for analyses of data that cannot be obtained because the research project is completed, or may want the authors to use complex multivariable procedures (beyond those already employed) that may bring more smoke and heat to the results but little light.

From the medical-content side of the spectrum, an epidemiologist may insist that the research is worthless because it was a cohort study rather than a randomized trial, or vice versa; or the reviewer may dismiss the research as useless and beyond repair because the investigators should have chosen an entirely different control group. A clinical reviewer, unwilling to learn some basic principles of numeracy, may complain about the "obscurity" of statistical writing that contains nothing more esoteric than simple regression and **correlation** coefficients. These problems have not been common, however. In general, the journal seems to have had outstanding success in attracting suitable authors, getting capable, open-minded reviewers, and producing relatively clear interdisciplinary communications. The term "clinical epidemiology" covers many methods and orientations. They include causal elucidations by a classical epidemiologist, patient care decisions by a classical clinician, analytic improvements by a classical statistician, and diverse mixtures of some or all of these activities. (At some levels of definition – such as "disease", "chronic disease", "clinical", or "epidemiology" – an encompassing vagueness may be more satisfactory than an excluding precision.)

Under the new title, the *JCE* continued its basic policies, but added some new sections. Controversial topics were regularly published as trios containing a presentation, dissent, and response. Some of the more prominent controversies discussed in this variance-and-dissent format have been classification and directionality in epidemiologic research, the use of the **kappa** statistic, and the role of Popperian causality (*see* **Causation**) in scientific reasoning. This format, which allows direct airing for controversial topics, has been popular with readers, and has subsequently been emulated at other journals. A "Second Thoughts" section was made available for "lighter" essays that would be "fun" to read. James F. Jekel was invited to prepare periodic summaries, called "Rainbow Reviews", of the reports (with multicolored covers) regularly issued by the US **National Center for Health Statistics**. With the continued application of clinical epidemiology to studies of pharmaceutical agents, a new section on **pharmacoepidemiology** was added in 1991.

In 1996, the *JCE* began publishing supplements containing the abstracts submitted to the annual meeting of the International Clinical Epidemiology Network (INCLEN). The *JCE* has also published supplements on the SUPPORT study of outcomes and risks of treatment, policy for management of asymptomatic

hypercholesterolemia, pharmacoepidemiology in developing countries, ethics in epidemiology, long-term health effects of silicone breast implants, and postvasectomy sequelae.

Since 1995, the journal has been published by Elsevier. As at 2004, the Editors are A. Knottnerus (Netherlands School of Primary Care Research) and P. Tugwell (University of Ottawa).

ALVAN R. FEINSTEIN

Journal of The American Statistical Association

The **American Statistical Association** (ASA) was founded in 1839 by men concerned about issues surrounding the nation's decennial **census** taking. Almost 50 years later, General Walker (ASA President 1883–1896), a towering figure who was impassioned in his desire and beliefs that all workers (most especially government workers and researchers throughout the land) should embrace the statistical method in their daily work, led the association beyond the then-local horizons of Boston with the adoption of a number of measures, the most fundamental one being the establishment in 1888 of a *New Series* of publications of the ASA. This title reflected the fact that previously there had been a *Collection* of the ASA (with the first and possibly only volume in 1847) plus other occasional papers, many of which had been destroyed in the Great Fire of Boston in 1872. An account of these earlier collections can be found in [4]. This *New Series* subsequently assumed the title *Quarterly Publications of the American Statistical Association* and in 1922 was renamed *Journal of the American Statistical Association (JASA)*. The header *New Series* however continued for 44 years, eventually being removed with the 1932 volume. Today, *JASA* still appears quarterly.

For its first 40 years with only two exceptions, ASA held four quarterly (or three quarterly and one annual) meetings per year; after 1894 the quarterly meetings were dropped but the annual meetings continued. Papers read at these meetings constituted a large proportion of the articles in *JASA* in its first 20 years or so. In 1928, read papers were assembled together as a Proceedings section of *JASA*, a practice continued until 1937 after which there was a return to the earlier custom whereby such read papers intermingled with general papers. This was finally discontinued with the publication of separate Proceedings of the Business and Economic Section in 1954 and of the Social Statistics Section in 1958.

Articles reflected the interests of ASA members who were primarily economists, accountants, social scientists, political scientists, historians, health professionals, and the like. That is, members were users of statistical science in their substantive field, and so articles were focused on advancing knowledge and new theories in those fields rather than in statistical methodology *per se*. Indeed, the first article of Volume 1, on water power [5] and the second one on parks and open spaces [3], illustrate amply the concerns of members with societal issues (in these cases people's basic well-being). In addition, there were numerous Reports, Miscellany, News and Notices, and Reviews entries. These articles typically included reports on **vital statistics** (of every imaginable stripe – deaths, births, divorces, diseases, suicides, etc. recorded for national, state and local municipalities, as well as international regions); they covered reviews of important papers from abroad (most often mathematical developments from British publications); and they included book reviews, among other topics. Starting in 1897, regular reports of the ASA Secretary as read at the annual meetings were included; see [1]. The Proceedings and Scientific Program of these meetings began to be published in 1910 [2]. Reports of various ASA committees would at times also be published. In short, *JASA* was the vehicle to convey information – both scientific results and operational news – to the membership.

Today, the nature and content of *JASA* have changed, at least on the surface if not in its aims. In a formal sense, the general articles now appear within the Applications and Case Studies Section or the Theory and Methods Sections. The split into separate divisions was implemented in 1968 and visible in 1970 when papers in each section were assembled together. The Applications Section was expanded to the Applications and Case Studies Section in 1989. Book reviews had been collected together from the beginning. In 1989, this section was expanded to the (General) Review Section, though book reviews still constitute the bulk of the material in this section. The extensive Reports and much of the Miscellany articles have disappeared from *JASA*; the News and Notices articles also no longer appear in *JASA*. These were essentially moved to *The American Statistician* when it began in 1947 and later to the monthly *Amstat News* begun in 1974, with the exceptions that the Reports of the Annual Meetings continued to appear in *JASA* until the 1971 meeting and the Board of Directors and related Reports until the 1969 Report, when these reports shifted to *The American Statistician*. *The American Statistician* from its inception also included articles demonstrating the uses of statistics, articles that previously occupied many pages of *JASA*. As its founding editors said, *The American*

Statistician would serve as an adjunct to the technical papers published in *JASA*.

From the content viewpoint, a reading of Information for Authors, which currently appears in each issue of *JASA*, reveals that the Applications and Case Studies Section seeks articles that contribute to a substantive field through the use of sound or innovative uses of statistical methods, present data useful to such fields, or discuss and evaluate such data and findings; methodological innovations are not requirements. This descriptor reflects very accurately and keeps intact the tenor and the goals of ASA as exemplified in the articles of the very early issues of *JASA*. Then and now the important new theoretical results were directed at the field of application with new statistical theory that may have emerged being incidental to the major thrust.

By the time of ASA's Seventy-fifth Anniversary in 1914, changes were looming on the horizon. The so-called mathematical method had appeared through **correlation**, and has remained as an integral part of statistical science. Nevertheless, mathematical statistical articles still assumed a relatively small proportion of *JASA* articles until about the 1950s. By the 1960s, mathematically based articles had become more dominant. These articles now appear in the Theory and Methods Section. As defined in the Information for Authors, this Section "publishes articles that make original contributions to the foundations, theoretical development, and methodology of statistics and probability". This mandate is "interpreted broadly. . . and may include computational and graphical methods as well as more traditional mathematical methods". However, such articles should be, and are, motivated by a practical problem arising from a substantive application.

The General Section includes the traditional Book Review Section plus Review Papers covering an area of applied statistics or a review of some specific statistical theory. Special topic papers may also appear in this general section.

In addition, at its April 1907 meeting, it was decided to ask the ASA President to address the association at its annual meeting and that this Address be published as the lead article in the following March issues of *JASA*. Accordingly, the first Presidential Address was delivered by Wright on January 17, 1908 (see [6]). Interestingly, though the ASA had but five presidents for its first 70 years, each serving till death (Fletcher 1839–45, Shattuck 1846–51, Jarvis 1852–82, Walker 1883–96, and Wright 1897–1909), subsequent presidents were limited to one year terms.

Today, in substance *JASA* is dominated by theoretical mathematically based statistical methodology, although its authors continue to be motivated by real world problems. The advances in the substantive field that totally dominated *JASA* prior to about 1950–60 are now found in other ASA journals, namely *Journal of Business and Economic Statistics* (begun in 1983), *Journal of Educational and Behavorial Statistics* (1976), *Journal of Computational and Graphical Statistics*, (1992), *Journal of Agricultural Biological and Environmental Statistics* (1996 and a joint venture with the International Biometric Society), and *Technometrics* (1959 and a joint venture with the American Society of Quality). In addition, the magazines *STATS* (1989) and *Chance* (1988) are targeted to the student and/or man-in-the-street nonstatistician audience. Earlier, ***Biometrics*** (called *Biometrics Bulletin* 1945–46) was launched under **Gertrude Cox's** editorship by the Biometrics Section of ASA to publish articles on the use of mathematical and statistical methodology in biology (including agriculture); this journal was fully assumed by the **International Biometric Society** in 1951. This applications orientation of the membership is still vibrant today and has been a strong and persistent thread throughout. The strength of this view was reflected by the unsuccessful efforts of the ASA's mathematical members to have the *Annals of Mathematical Statistics* (begun in 1930, and first edited by Harry Carver) as an ASA publication.

The first *JASA* Editor was Davis Dewey, who served from 1888 to 1907. The division in 1969 brought with it a separate editor for each section: the Applications (predecessor of the Applications and Case Studies) Section, Theory and Methods Section, and Book Review (now the General Review) Section.

With the exception of the occasional invited paper and also Invited Discussants to selected articles typically addressing a major applied topic, articles are unsolicited. Potential authors submit manuscripts to the Editor(s). Papers deemed not to fit the overall aims of the journal would be returned to the authors without going through the formal reviewing process. That said, in a typical scenerio, the Editor disseminates the submissions to a cadre of Associate Editors, who take the responsibility for selecting and monitoring the refereeing process. Double-blind refereeing

for the Applications and Case Studies and the Theory and Methods Sections was instituted in 1996.

The 2001 Editors reported that the Applications and Case Studies Section received 123 new manuscripts (125 in 2000) and that the acceptance rate (of new and resubmissions) continues to be just under 25%. The Theory and Methods Section received 374 new submissions in 2000 (370 in 2001) with an acceptance rate of 20% (19% in 2001). In the General Review Section, in 2000, 62% (57% in 2001) of new books received were sent out for reviews; three of the six review manuscripts received in 2000 were rejected and three were accepted in 2001, while four of the nine received in 2001 were rejected and three were accepted in 2001 (and one in 2002). Subsequently, there were 48 Applications and Case Studies papers, 66 Theory and Methods papers, 3 Review papers, 57 Book Reviews, and 27 Telegraphic Review articles published in 2001, plus the Presidential Address and relevant editorially related information, occupying 1543 pages. In contrast, Volume 1 published 11 Leading Articles and 49 Reviews and Miscellany articles in 492 pages. Volume 1 spanned two years; it was not until Volume 19 in 1924 that one volume per year began.

Throughout its long history, JASA has continued to be a premier journal serving the entire international statistical community. It remains the flagship publication of the ASA.

LYNNE BILLARD

Journal of The Royal Statistical Society

In May 1838, following the establishment of the Society in 1834, the Council launched the first volume of the *Journal of the Statistical Society of London*:

> The Council of the Statistical Society of London is of opinion that the time has arrived when the Fellows of the Society, and the public, will hail with satisfaction the appearance of a Journal devoted to the collection and comparison of Facts which illustrate the condition of mankind, and tend to develop the principles by which the progress of society is determined.

Since the "Science of Statistics" was in its infancy in the 1830s, the Council felt it necessary to add some explanation about the objects of the Society and its journal in their introduction to the new journal. Within the extensive scope of the subject, the importance of medical statistics was already recognized:

> Mechanics discover the means of abridging human labour; Chemistry enters largely into the economy of Arts; Medicine practises on the bodies of men; all these sciences operate upon human interests and their powers and effects are susceptible of statistical exposition.

Reviewing the content of the journal in 1865, the Council divided the subject matter into seven classes: "commercial", "industrial", "financial", "moral and social", "vital", and "miscellaneous", the last category comprising papers not presented for reading to the Society. W.A. **Guy** was an early presenter of papers, such as "Influence of the seasons and weather on sickness and mortality" and "Influence of employment and health". William **Farr**, of still greater authority, made his debut with the paper "Mortality of lunatics" and "The influence of elevation on the fatality of cholera". Other contributions included the reports of the Committee on Medical Statistics (1837) and of the Committee on Sickness among the Metropolitan Police Force (1839–1840). Although, as long ago as 1863, the Society had been urged to publish discussions at its meetings, the proposal had been defeated. It was not until the June issue in 1873 that reports of the oral discussion and the authors' replies began to appear, and the practice of having both a formal proposing and seconding of a vote of thanks, as now, did not begin until 1909.

In January 1887, the Society was granted its Royal Charter, and the journal accordingly changed its name to the ***Journal of the Royal Statistical Society***. Another important change at that time was the introduction of reviews of books on statistical and economic subjects in 1886, under the heading "Notes on some recent Additions to the Library".

Up to that point in the journal's history, the papers published had been almost entirely of a descriptive nature, with large numbers of tables presenting data, but without detailed analysis. It was only around the turn of the century that the mathematical foundations began to be developed in the pages of the journal, with papers such as "On the theory of correlation" by G. Udny **Yule** (1897) and "On the representation of statistics by mathematical formulae" by F.Y. **Edgeworth** in four parts, and concluded in the 1899 volume.

In June 1928, the Society formed its first "Study Group" for holding informal meetings. This was followed in 1933 by the formation of the first of its Sections, the Industrial and Agricultural Research Section. The papers presented at the first two meetings of the Section were published in a supplementary issue with part II of the main journal in the Society's centenary year. A second supplement was issued with part IV of the journal. The *Supplements*, two parts per volume, were initially designed to cater for the "considerable developments in the application of modern statistical methods to technical problems met with in industry and agriculture" during the previous two decades.

World War II caused the research activities of the Industrial and Agricultural Research Section to be abandoned. Only about four meetings could be held in each session during the early years. The 1940–1941 volume of the *Supplement* was slim and the next volume did not appear until 1946. However, papers continued to be accepted and published as "read" papers even though they could not be presented. One effect was therefore that written, rather than oral, contributions to the discussion appeared, and this practice persisted and grew after the war.

Some work, however, was carried out around the country under the Industrial Applications Group formed for the purpose. This prompted the Society to split the Section into two: the Industrial Applications Section and the Research Section.

The Industrial Applications Section was constituted of several Local Groups around the country whose purpose was primarily to organize meetings, whereas the *Supplement* was intended to be primarily the vehicle for publication of the proceedings of Research Section meetings and to fulfill the need "for a medium of publication for research work (not necessarily theoretical or mathematical), which is of general interest to statisticians". An editorial panel was set up for the journal under the editorship of M.G. **Kendall**, B.L. Welch, and F. **Yates**. Research Section meetings did not have the status of the Ordinary Meetings of the Society until 1958 when the meetings were called Research Methods Meetings (later changed to the current "Ordinary Meetings organized by the Research Section" in 1969).

By 1947, the *Supplement* had grown into a scientific journal of high repute. The Council therefore decided that, from 1948, the Society's two publications would both be issued under the main title of the ***Journal of the Royal Statistical Society***, the original journal being distinguished by the subtitle "Series A (General)" and the *Supplement* by the subtitle "Series B (Methodological)". Though the names had changed, the volume numbers ran on sequentially. Series A remained the organ of the Society as a whole, with publication of papers from Ordinary Meetings (other than the research type), the annual report of Council, book reviews, obituaries, and other features from time to time.

Since the war, the Council had been aware of the absence of a publication devoted to the practical statistical problems that arise in the many fields of human activity. To fill this gap, *Applied Statistics* was launched in 1952. It officially became the ***Journal of the Royal Statistical Society***, Series C, in 1964. The President, Austin Bradford **Hill**, defined its aims in the first issue as follows.

> *Applied Statistics* has been founded, therefore, to meet the needs of all workers concerned with statistics – not of professional statisticians only but also of those innumerable workers in industry, commerce, science, and other branches of daily work, who must handle and understand statistics as part of their tasks. Its aim, in short, is to present, in one way or another but always simply and clearly, the statistical approach and its value, and to illustrate in original articles modern statistical methods in their everyday applications.

The journal published three issues per volume and initially was designed more as a magazine than as a learned journal. It contained reports of the meetings of the various Groups, articles expounding statistical methods and illustrating their application, and features entitled "Questions and answers", "Notes and comments", "Letters to the Editors", and book reviews. Gradually, though, the journal became more technical in character.

In December 1966, J.A. Nelder and B.E. Cooper organized a meeting on "Statistical programming – the present situation and future prospects" at the Atlas Laboratory, Chilton, UK. The five papers presented and an account of the discussion were published in *Applied Statistics* in 1967. As a result of the meeting, the "Statistical algorithms" section of the journal was started in 1968. The main aims of the section were

> to ensure that published algorithms are clearly organized, well documented, and standardized in notation and terminology, so that they will be readily understandable to a large number of readers; ... also, that the algorithms are programmed as far as possible in languages which are widely available and clearly defined independently of individual implementations.

These aims only began to outlive their usefulness by the mid-1990s when the publication of statistical **algorithms** ceased. By this time, over 300 had been published.

In 1968, Series A made a break with tradition when it ceased to publish the Sauerbeck index of wholesale prices, which it had published annually since 1886, latterly from material supplied by the editor of the *Statist*. Other changes arising from concern over overlap with Series C refocused its editorial policy and included a change in its subtitle to "Statistics in society" and a decrease from four issues per volume to three in 1988. In contrast, Series B and Series C increased from three issues to four in 1993.

The year 1993 also saw the addition of *The Statistician* to Series A, B, and C following the merger with the Institute of Statisticians. This resulted in an integration and reorganization of the content of the four journals, with the intention that *The Statistician* would be aimed particularly at the professionally qualified members of the Society as well as at a wide international audience of practising statisticians.

Around the turn of the century, rapid advances in information technology took place, and the Society's journals evolved to take advantage of them.

Firstly, a complete run of every issue since the first in 1838 was digitized and housed in the on-line archive JSTOR. Not only is each page available to view in a facsimile form of the original but also the database has sophisticated search facilities for each item in the journals, providing powerful research tools. These tools have been extended even further for volumes since 1997 by inclusion in the CrossRef scheme, which links participating publishers' individual databases of journals to enable researchers to follow up references smoothly on line from one journal to another and from one discipline to another. Access is through Blackwell Synergy, which provides searchable hypertext on-screen versions of each paper in the Society's journals as well as downloadable versions in portable document format for subscribers.

At the prepublication end of the process, manuscripts are now almost exclusively submitted and handled in the refereeing process in electronic form.

Responding to these changes and the changing requirements of the statistical community, in 2002 the Society conducted a review of its publications. The outcome was a consolidation of its journals back into three series: a widely accessible subject-matter journal (Series A), a methodological journal (Series B) and a journal for innovative applications (Series C). In addition, in 2004 the Society launched a magazine titled *Significance*, which, as well as being of interest to all its members and other statisticians, performs an outreach role in promoting statistics to nonstatisticians.

The aims and scope of the three series and the magazine are as follows.

Series A (*Statistics in Society*) publishes papers that demonstrate how statistical thinking, design, and analyses play a vital role in all walks of life and benefit society in general. For example, important applications of statistical methods in medicine, business and commerce, industry, economics and finance, education and teaching, physical and biomedical sciences, the environment, the law, government and politics, demography, psychology, sociology, and sport all fall within the journal's remit. It is aimed at a wide statistical audience and at professional statisticians in particular. Its emphasis is on quantitative approaches to problems in the real world rather than the exposition of technical detail. Of particular interest are papers on topical or contentious statistical issues, papers that give reviews or *exposés* of current statistical concerns and papers demonstrating how statistics has contributed to our understanding of important substantive questions. Historical, professional, and biographical contributions are also welcome, as are discussions of methods of data collection and of ethical issues, provided that all such papers have substantial statistical relevance.

Series B (*Statistical Methodology*) publishes papers that contribute to the understanding of statistical methodology and/or develop and improve statistical methods. The kinds of contribution considered include descriptions of new methods of collecting or analyzing data, with the underlying theory, an indication of the scope of application and preferably a real example. Also considered are comparisons, critical evaluations, and new applications of existing methods, contributions to **probability theory**, which have a clear practical bearing (including the formulation and analysis of stochastic models), statistical computation or **simulation** where original methodology is involved and original contributions to the foundations of statistical science. Reviews of methodological techniques are also considered.

Series C (*Applied Statistics*) promotes papers that both are driven by real life problems and make a novel contribution to the subject, for example by developing methodology or by demonstrating the proper application of new or existing statistical methods to them. Applications are central, and case studies may therefore be particularly appropriate. Papers describing interdisciplinary work are especially welcome, as are those that give novel applications of existing methodology or new insights into the practical application of techniques. Methodological papers that are not motivated by a genuine application are not within the scope; nor are papers that include only brief numerical illustrations or describe simulations of properties of statistical techniques. However, papers describing developments in statistical computing are within the scope, provided that they are driven by practical examples. Other types of papers considered are those on design issues (e.g. in relation to experiments (*see* **Experimental Design**), surveys (*see* **Sample Surveys in the Health Sciences**) or **observational studies**) that arise from specific practical problems and feature an adequate description of a substantial application and a justification for any new theory.

Significance is a quarterly magazine for anyone interested in statistics and the analysis and

interpretation of data. Its aim is to communicate and demonstrate in an entertaining and thought-provoking way the practical use of statistics in all walks of life and to show how statistics benefit society. Articles are largely nontechnical and hence accessible and appealing not only to members of the profession but also to all users of statistics. Students and teachers of statistics will find articles of interest in *Significance*, as will people working in central and local government, medicine and health care, administration, economics, business and commerce, industry, social studies, survey research, science, and the environment. As well as promoting the discipline and covering topics of professional relevance internationally, *Significance* contains a mixture of statistics in the news, case studies, reviews of existing and newly developing areas of statistics, the application of techniques in practice and problem solving.

J-shaped Distribution

As a sequel to Khinchin's definition of **unimodality**, a J-shaped distribution function is defined. A characterization for a related distribution is given using a well-known result of Khinchin on unimodality and a characterization theorem for a **U-shaped** probability density function by Ghosh and Shanbhag.

We define the following:

Definition 1. A distribution function $F(x)$ is said to be negative-tailed (positive-tailed) J-shaped if there exists a value $x = a$ such that $F(x)$ is convex (concave) for $x < a$ ($x > a$) and $F(a) = 1$ (0). The point $x = a$ is called a negative (positive) pivot of $F(x)$.

Definition 2. If a J-shaped distribution $F(x)$ is differentiable except at a countable subset of the set of reals, then the derivative $F'(x)$ is called a J-shaped probability density function.

We observe that for a negative-tailed J-shaped distribution function $F(x)$ with a negative pivot at $x = a$ we have $F(x) = 1$ at $x = a$ and for $x > a$. Since a constant function is both concave and convex, we conclude that a negative-tailed J-shaped distribution is unimodal with vertex at $x = a$. Hence, by Khinchin's theorem [3, p. 92] its **characteristic function** $p(t)$ has the following representation:

$$p(t) = \left[\frac{\exp(ita)}{t}\right] \int_0^t q(u)\,\mathrm{d}u, \quad \text{for a real } t.$$

Similarly, the characteristic function $r(t)$ of a positive-tailed J-shaped distribution has the following representation:

$$r(t) = \left[\frac{\exp(itc)}{t}\right] \int_0^t s(u)\,\mathrm{d}u, \quad \text{for a real } t,$$

where c is the positive pivot.

Examples

The following are two examples of J-shaped density functions:

1. Let a random variable X measure the level of nicotine intake by human beings. Then the frequency distribution of X amongst patients with lung cancer is likely to be negative-tailed J-shaped.
2. If a cohort of children is followed from birth to age 5 years, the distribution of age at death, amongst those who die, is likely to be positive-tailed J-shaped. Conversely, among those who die in a cohort of individuals followed from, say, age 65 to 70 years, the distribution of age at death is likely to be negative-tailed J-shaped.

Related Distributions

The concepts of a U-shaped probability density function and a bimodal distribution are related to J-shaped distribution. We define the following:

Definition 3. Let X be an absolutely continuous random variable. Then the probability density function of X is said to be U-shaped if there exist real numbers a, b, and c such that $a < b < c$, $\Pr\{X < a\} = 0$, $\Pr\{X > c\} = 0$, $\Pr\{X < x\}$ is concave in (a, b) and convex in (b, c).

The following theorem [2] gives a characterization for a U-shaped density function.

Theorem. Let X be an absolutely continuous random variable with probability density function $h(x)$. Then $h(x)$ is bounded and U-shaped if and only if the characteristic function of X is given by

$$f(t) = \frac{p[\exp(itb) - \exp(ita)]}{it} - q\frac{\exp(itc)}{t}\int_0^t r(u)\,\mathrm{d}u, \quad \text{for a real } t,$$

where $r(u)$ is a characteristic function, a, b, c, and p are real numbers, and q is real and positive.

Definition 4. A distribution function $F(x)$ is said to be bimodal if there exist real numbers a, b, and c with $a < b < c$ such that (i) $F(x)$ is convex for $x < a$; (ii) $F(x)$ is concave for $a < x < b$; (iii) $F(x)$ is convex for $b < x < c$; and (iv) $F(x)$ is concave for $x > c$. The points $x = a$ and $x = c$ are called two vertices of $F(x)$. The point $x = b$ is called an antimode of $F(x)$.

If $a = c$, then $F(x)$ is unimodal in Khinchin's sense.

The following theorem [1] characterizes a bimodal distribution.

Theorem. The function $f(t)$ is the characteristic function of a bimodal distribution function $F(x)$ with

vertices a and c, with $a < c$, if and only if

$$f(t) = F(a)h(t) + \{F(c) - F(a)\}g(t) + \{1 - F(c)\}k(t),$$

where $h(t)$ is the characteristic function of a negative-tailed J-shaped distribution with a negative pivot at $x = a$, $g(t)$ is the characteristic function of a U-shaped distribution over (a, c), and $k(t)$ is the characteristic function of a positive-tailed J-shaped distribution with a positive pivot at $x = c$.

Kalman Filter

The Kalman filter is the recursive **algorithm** devised by Kalman [7, 8] often used to provide estimates of parameters in state-space models of **time series**. The original ideas and those that flowed from them have had so much impact, see [4], that Kalman filtering is sometimes taken to denote the entire state-space approach.

State-space models were proposed by several authors in times series, for example, [9, 5] and [3], but have their roots in control engineering. They relate observations to "state variables" and have wide application. Suppose that an observed series $\{x_t\}$, which may be a vector series, can be written in terms of d unobserved state variables, say a $d \times 1$ vector $\{\boldsymbol{\alpha}_t\}$. The explicit form of our model relating state and observation is

$$x_t = \mathbf{H}\boldsymbol{\alpha}_t + \varepsilon_t \tag{1}$$

where $\mathbf{H}$ is a known $1 \times d$ **matrix** and ε_t is, as usual white noise, often called measurement noise.

To make life simpler, we also assume that the state variables satisfy

$$\boldsymbol{\alpha}_t = \boldsymbol{\phi}\boldsymbol{\alpha}_{t-1} + \mathbf{K}\boldsymbol{\eta}_t \tag{2}$$

where $\boldsymbol{\phi}$ is the $d \times d$ transition matrix, and $\boldsymbol{\eta}_\mathbf{t}$ is a n dimensional noise vector, uncorrelated with ε_t, with **covariance matrix** $\boldsymbol{\Sigma}$. The matrix $\mathbf{K}$ is a $d \times n$ parameter matrix.

This rather curious set of equations can be justified in terms of **conditional** expectations in a **multivariate normal distribution**, however, the main reason for our interest is in the set of updating equations, the so called *Kalman recursions*. Many authors, notably Harvey [4] have used the state-space equations explicitly giving rise to what are known as **structural equation models**. These are a subset of the ARIMA family (*see* **ARMA and ARIMA Models**) but are valuable in modeling terms as they give an alternative approach via state variables. It is worth noting that ARIMA models can be written in state-space form but without the ε_t term in (1); see [6].

Perhaps the most important point to appreciate is that the state-space form and the Kalman algorithm give us a relatively simple model and an effective method of computing the **likelihood**.

For any estimation method based on the state-space formulation of a model, we need estimates of the state variables. Finding the best approximation to the state variables (in a conditional mean sense) is known as the filtering problem, while the corresponding problem of finding the best approximation to the observations is the smoothing problem.

Suppose that our estimate of $\boldsymbol{\alpha}_t$ at time t is a_t while the estimate made at time t-1 is $\mathbf{a}_{t|t-1}$. These estimates will have variance matrices

$$\mathbf{C}_t = \mathrm{E}[(\boldsymbol{\alpha}_t - \mathbf{a}_t)(\boldsymbol{\alpha}_t - \mathbf{a}_t)^{'}] \tag{3}$$

$$\mathbf{C}_{t|t-1} = \mathrm{E}[(\boldsymbol{\alpha}_t - \mathbf{a}_{t|t-1})(\boldsymbol{\alpha}_t - \mathbf{a}_{t|t-1})^{'}] \tag{4}$$

The beauty of the state-space representation is that we have the Kalman filter updating equations; see [7] or [6]. A comprehensive discussion can also be found in [1]

The Kalman Filter Recursions

The prediction equations

$$\mathbf{a}_{t|t-1} = \boldsymbol{\phi}\mathbf{a}_{t-1}. \tag{5}$$

$$\mathbf{C}_{t|t-1} = \boldsymbol{\phi}\mathbf{C}_{t-1}\boldsymbol{\phi}^{'} = \mathbf{K}\boldsymbol{\Sigma}\mathbf{K}^{'}. \tag{6}$$

The updating equations

$$F_t = \mathbf{H}\mathbf{C}_{t|t-1}\mathbf{H}^{'} + \sigma_\varepsilon^2 \tag{7}$$

$$\mathbf{C}_t = \mathbf{C}_{t|t-1} - \frac{1}{F_t}\mathbf{C}_{t|t-1}\mathbf{H}^{'}\mathbf{H}\mathbf{C}_{t|t-1} \tag{8}$$

$$\mathbf{a}_t = \mathbf{a}_{t|t-1} + \frac{1}{F_t}\mathbf{C}_{t|t-1}\mathbf{H}^{'}(x_t - \mathbf{H}\mathbf{a}_{t|t-1}). \tag{9}$$

For constructing the likelihood,

$$V_t = x_t - \mathbf{H}\mathbf{a}_{t|t-1}. \tag{10}$$

Given some starting values, we step through the recursions and at each stage we obtain the **prediction** errors V_t and the prediction error variances F_t for any given parameter set. This means we can compute the likelihood for any parameter set, and with a suitable maximization procedure, we can get **maximum likelihood** estimates. The Kalman approach provides compact computer code with the possibility of fast execution by comparison with alternative approaches.

The Start-up Problem

If we start our recursions at time $t = 1$, then we need the state estimate $\mathbf{a}_0$ together with a covariance estimate $\mathbf{C}_0$ at time zero. There are various possibilities, using the unconditional expected values to rather exotic ones; see [3].

A simple approach is to use the fact that the effect of the starting values is soon lost, especially with long series and we will set $\mathbf{a}_0$ to zero and the covariance $\mathbf{C}_0$ to M (a large number) times the unit matrix. This is a simple, an effective technique that is widely used. It is also common for the recursions to settle down to a steady state when we have stationary series. By this we mean that $\mathbf{C}_t$, $\mathbf{C}_{t|t-1}$, and F_t converge to fixed (time independent) values. The advantage is that when this happens, we can skip equations (6), (7), and (8). While there is no analytic result to tell us when this has happened, we can put a numerical check in the recursions.

The reader may have noticed that we could have used a vector value of x_t in most of the algebra above. Indeed, we can easily extend all our state-space models to vector series.

An Example. We take as an example a tree ring series from 1700 to 1987 [2] shown in Figure 1

Take a simple model of a drifting mean, $x_t = \mu_t + \varepsilon_t$ and

$$\mu_t = \mu_{t-1} + \beta_{t-1} + \eta_t \text{ with } \beta_t = \beta_{t-1} + \zeta_t \quad (11)$$

This simple model includes trend and mean effects but no seasonal. We start at t = 1 with

$$\boldsymbol{\phi} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad \boldsymbol{\Sigma} = \begin{pmatrix} \sigma_\eta^2 & 0 \\ 0 & \sigma_\zeta^2 \end{pmatrix},$$
$$\mathbf{C}_0 = \begin{pmatrix} 1000 & 0 \\ 0 & 1000 \end{pmatrix}, \quad \mathbf{a}_0 = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad (12)$$

The $\mathbf{K}$ matrix is just a unit matrix.

Our life can be made a little simpler by noting that we have three variances $\sigma_\varepsilon^2, \sigma_\eta^2, \sigma_\zeta^2$ What we can do is *concentrate out a parameter*. We set $\sigma_\varepsilon^2 = 1$ and regard the other two unknown variances as being scaled by σ_ε^2; see [6]. This saves us some computation. We can now use the Kalman filter equations to produce for given $\sigma_\eta^2, \sigma_\zeta^2$ a set of predictions and predictions errors, which will give us values for the likelihood. The table below shows how the $\mathbf{C}_t$ matrix converges as the value of t increases. In fact, we would normally drop the first six iteration values from the likelihood computation because they are unreliable.

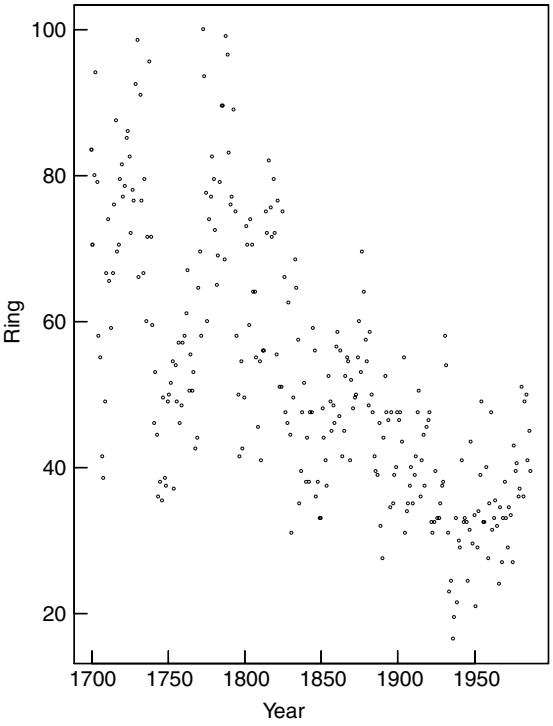

Figure 1 Model fit to tree ring widths

t	$\mathbf{a}_t$	$\mathbf{C}_t$		V_t
2	70.5	5002.25	5001.25	−54.74791
	−12.98906	5001.25	5002.25	
4	94	2.666644	1.666644	11.99685
	9.501143	1.666644	2.666644	
10	49	2.618034	1.618034	16.65551
	4.138162	1.618034	2.618034	
14	59	2.618034	1.618034	4.825807
	−4.6567	1.618034	2.618034	

As we can now construct a likelihood via the filter, we are able to seek the maximum of the likelihood. After 100 iterations, we find that the (scaled) values are

$$\sigma_\varepsilon^2 = 1, \quad \sigma_\eta^2 = 204.1846, \quad \sigma_\zeta^2 = 137.2181. \quad (13)$$

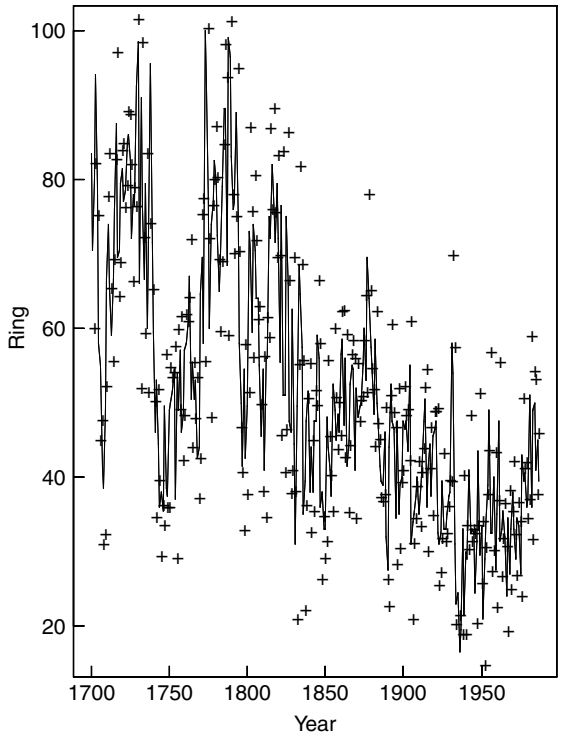

Figure 2 Tree ring widths by year

Standard errors are also available from the derivatives of the likelihood.

This is a really rather simple model and as we can see, the predicted values "+" are not very close (see Figure 2). This is, however, a fault of the model rather than the filter!

G.J. JANACEK

Kaplan–Meier Estimator

The Kaplan–Meier estimator is a **nonparametric** estimator which may be used to estimate the **survival distribution** function from **censored data**. The estimator may be obtained as the limiting case of the classical actuarial (**life table**) estimator, and it seems to have been first proposed by Böhmer [2]. It was, however, lost sight of by later researchers and not investigated further until the important paper by Kaplan & Meier [12] appeared. Today the estimator is usually named after these two authors, although sometimes it is denoted the product–limit estimator (*see* **Aalen–Johansen Estimator**). Below we describe the Kaplan–Meier estimator, illustrate its use in one particular case, and discuss estimation of the median and mean survival times. Furthermore, we show how the Kaplan–Meier estimator can be given as the product–integral of the **Nelson–Aalen estimator**, and indicate how this may be used to study its statistical properties. For almost four decades the Kaplan–Meier estimator has been one of the key statistical methods for analyzing censored survival data, and it is discussed in most textbooks on survival analysis. Rigorous derivations of the statistical properties of the estimator are provided in the books by Fleming & Harrington [7] and Andersen et al. [1]. In particular the latter presents formal proofs of almost all the results reviewed below as well as an extensive bibliography.

The Estimator and Confidence Intervals

Consider the survival data situation where we want to study the time to death (or some other event) for a homogeneous population with survival distribution function $S(t)$ representing the probability that an individual will be alive at time t. Assume that we have a sample of n individuals from this population. Our observation of the survival times for these individuals will typically be subject to right-censoring, meaning that for some individuals we only know that their true survival times exceed certain censoring times. The censoring is assumed to be independent in the sense that the additional knowledge of censorings before any time t does not alter the risk of failure at t. We denote by $t_1 < t_2 < \cdots$ the times when deaths are observed and let d_j be the number of individuals who die at t_j.

The Kaplan–Meier estimator for the survival distribution function then takes the form

$$\hat{S}(t) = \prod_{t_j \le t} \left(1 - \frac{d_j}{r_j}\right), \tag{1}$$

where r_j is the number of individuals at risk (i.e. alive and not censored: in the **risk set**) just prior to time t_j. If there are no censored observations, then (1) reduces to one minus the empirical distribution function. The variance of the Kaplan–Meier estimator is estimated by Greenwood's formula:

$$\hat{\sigma}^2(t) = \hat{S}(t)^2 \sum_{t_j \le t} \frac{d_j}{r_j(r_j - d_j)}. \tag{2}$$

In the case of no censoring, (2) reduces to $\hat{S}(t)[1 - \hat{S}(t)]/n$, the standard **binomial** variance estimator.

In large samples the Kaplan–Meier estimator, evaluated at a given time t, is approximately normally distributed so that a standard $100(1-\alpha)\%$ confidence interval for $S(t)$ takes the form

$$\hat{S}(t) \pm z_{1-\alpha/2}\hat{\sigma}(t), \tag{3}$$

with $z_{1-\alpha/2}$ the $1-\alpha/2$ fractile of the **standard normal** distribution. The approximation to the normal distribution is improved by using the log-minus-log transformation (*see* **Quantal Response Models**) giving the **confidence interval**

$$\hat{S}(t)^{\exp\{\pm z_{1-\alpha/2}\hat{\sigma}(t)/[\hat{S}(t)\ln\hat{S}(t)]\}}. \tag{4}$$

This interval is satisfactory for quite small sample sizes [3]. Confidence intervals with small-sample properties which are comparable with (4), or even slightly better, may be obtained by using the arcsine-square-root transformation [3] or by basing the confidence interval on the **likelihood ratio test** [5, Section 4.3; 16]. Note that all these confidence intervals should be given a pointwise interpretation. Simultaneous confidence bands for the survival distribution function are considered below.

Right-censoring is not the only kind of data incompleteness in survival analysis. Often, e.g. in epidemiologic applications, individuals are not followed from time zero (in the relevant time scale, typically age), but only from a later entry time (conditional on survival until this entry time). Thus, in addition to right-censoring, the survival data are subject to left truncation. For such data we may, in

principle at least still use the Kaplan–Meier estimator (1) and estimate its variance by (2). The number at risk, r_j, is now the number of individuals who have entered the study before time t_j and are still in the study just prior to t_j. However, for left-truncated data the numbers at risk, r_j, will often be low for small values of t_j. This will result in estimates $\hat{S}(t)$ which have large sampling errors and which therefore may be of little practical use. What can be usefully estimated in such situations is the conditional survival distribution function, $S(t|t_0) = S(t)/S(t_0)$, representing the probability of survival to time t given that an individual is alive at time $t_0 < t$. It may be useful to estimate such conditional distribution functions for several values of t_0 (at which there are reasonable numbers at risk), there being nothing canonical about any particular value. The estimation is performed as described earlier, the only modification being that the product in (1) and the sum in (2) are restricted to those t_j for which $t_0 < t_j \leq t$.

An Illustration

As an illustration we use data from a randomized clinical trial for patients with histologically verified liver cirrhosis. Patients were recruited from several hospitals in Copenhagen between 1962 and 1969 and were followed until death, lost to follow-up, or until the closing date of the study, October 1, 1974. The time variable of interest is time since entry into the study. Patients are right censored if alive on October 1, 1974, or if lost to follow-up before that date.

We consider only the 138 placebo-treated male patients. Their median age at entry was 57 years, while the lower and upper quartiles were 51 and 66 years, respectively. Of the 138 patients, 88 died during the study. The Kaplan–Meier estimate of the survival distribution function for these patients is shown in Figure 1 with 95% confidence intervals computed according to (4). From the figure we see, for example, that the five years survival probability is estimated as 43.0% with a 95% confidence interval from 34.0% to 51.9%, while the estimated 10 years survival probability is 18.4% with a confidence interval from 9.7% to 29.3%. We return to the liver cirrhosis example below in connection with median and mean survival times and simultaneous confidence bands. A further discussion and analysis of the data are given by Schlichting et al. [15]. The data were also used for illustrative purposes by Andersen et al. [1].

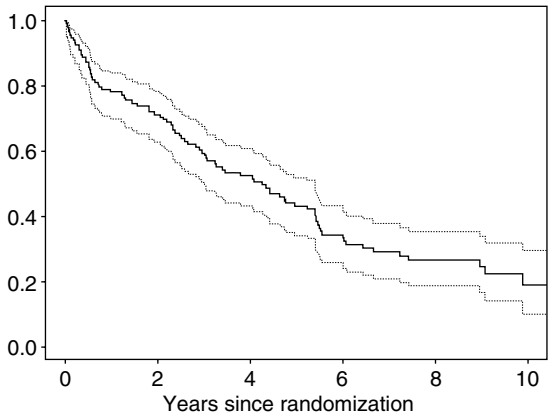

Figure 1 Kaplan–Meier estimate of the survival distribution function for 138 placebo-treated male patients with liver cirrhosis with 95% log-minus-log-transformed confidence intervals

Median Survival Time and Related Quantities

The use of the Kaplan–Meier estimator is not restricted to estimating survival probabilities for given times t. It may also be used to estimate fractiles such as the **median survival time** and related quantities like the interquartile range (*see* **Quantiles**).

Consider the pth fractile, ξ_p, of the cumulative distribution function $F(t) = 1 - S(t)$, and assume that $F(t)$ has a positive density function $f(t) = F'(t) = -S'(t)$ in a neighborhood of ξ_p. Then ξ_p is uniquely determined by the relation $F(\xi_p) = p$, or equivalently, $S(\xi_p) = 1 - p$. The Kaplan–Meier estimator is a step function and hence does not necessarily attain the value $1 - p$. Therefore a similar relation cannot be used to define the estimator $\hat{\xi}_p$ of the pth fractile. Rather, we define $\hat{\xi}_p$ to be the smallest value of t for which $\hat{S}(t) \leq 1 - p$, i.e. the time t where $\hat{S}(t)$ jumps from a value greater than $1 - p$ to a value less than or equal to $1 - p$. In large samples $\hat{\xi}_p$ is approximately normally distributed with a variance that may be estimated by

$$\widehat{\text{var}}(\hat{\xi}_p) = \frac{(1-p)^2 \hat{\sigma}^2(\hat{\xi}_p)}{[\hat{f}(\hat{\xi}_p)\hat{S}(\hat{\xi}_p)]^2}. \tag{5}$$

Here $\hat{f}(t)$ is an estimator for the density function $f(t) = -S'(t)$ (*see* **Density Estimation**). One may, for example, use

$$\hat{f}(t) = \frac{1}{2b}\left[\hat{S}(t-b) - \hat{S}(t+b)\right] \qquad (6)$$

for a suitable bandwidth b (corresponding to a kernel function estimator with uniform kernel). Furthermore, for $p < q$, $\hat{\xi}_p$ and $\hat{\xi}_q$ are approximately binormally distributed, and their correlation may be estimated by

$$\widehat{\text{corr}}(\hat{\xi}_p, \hat{\xi}_q) = \frac{\hat{\sigma}(\hat{\xi}_p)\hat{S}(\hat{\xi}_q)}{\hat{\sigma}(\hat{\xi}_q)\hat{S}(\hat{\xi}_p)}. \qquad (7)$$

Note that $\hat{S}(\hat{\xi}_p)$ in (5) and (7) is equal to or only slightly less than $1 - p$, and that (5) could have been simplified if we had used this approximate equality. We have chosen not to do so since then $\hat{S}(\hat{\xi}_p)$ in (5) and (7) cancels with the same factor in $\hat{\sigma}(\hat{\xi}_p)$; cf. (2).

The above results may be used in the usual way to determine approximate confidence intervals, e.g. for the median survival time $\xi_{0.50}$ and the interquartile range $\xi_{0.75} - \xi_{0.25}$, as illustrated below. For the purpose of determining a confidence interval for a quantile (fractile) like the median it is, however, better to apply the approach of Brookmeyer & Crowley [4]. For the pth fractile one then uses as a confidence interval all hypothesized values ξ_p^0 of ξ_p which are not rejected when testing the null hypothesis $\xi_p = \xi_p^0$ against the alternate hypothesis $\xi_p \neq \xi_p^0$ at the α level (*see* **Hypothesis Testing**). Such test-based confidence intervals can be read directly from the lower and upper confidence limits for the survival distribution function in exactly the same manner as $\hat{\xi}_p$ can be read from the Kaplan–Meier curve itself (*see* **Median Survival Time**).

For the liver cirrhosis data an estimate of the median survival time is 4.27 years (standard error 0.66 years), while the lower and upper quartiles are estimated as 1.46 years (0.35 years) and 8.97 years (1.13 years), respectively, with an estimated correlation of 0.28. In these computations the bandwidth $b = 1$ year was used in (6). An estimate of the interquartile range of the survival distribution function is $8.97 - 1.46 = 7.51$ years, with standard error $(0.35^2 + 1.13^2 - 2 \times 0.35 \times 1.13 \times 0.28)^{1/2} = 1.09$ years. From this an approximate 95% confidence interval for the median survival time is $4.27 \pm 1.96 \times 0.66$, i.e. from 2.98 to 5.56 years, while 95% confidence limits for the interquartile range are from 5.37 to 9.65 years. For the median survival time it is, as mentioned earlier, better to read the confidence limits directly from the pointwise confidence intervals for the survival distribution function given in Figure 1. This gives 95% confidence limits for the median survival time from 3.02 years to 5.41 years. Note that no estimate of the density function is needed here.

Mean Survival Time

Owing to right-censoring, in most survival studies it will not be possible to obtain reliable estimates for the mean survival time $\mu = \int_0^\infty t f(t)\,\mathrm{d}t = \int_0^\infty S(t)\,\mathrm{d}t$ (*see* **Life Expectancy**). This is one important reason why, in survival analysis, the median is a more useful measure of location than the mean. What may be usefully estimated from right-censored survival data is the expected time lived in a given interval $[0, t]$, i.e. $\mu_t = \int_0^t S(u)\,\mathrm{d}u$. This is estimated by

$$\hat{\mu}_t = \int_0^t \hat{S}(u)\,\mathrm{d}u,$$

the area below the Kaplan–Meier curve between 0 and t. Such an estimate may be of interest in its own right, or it may be compared with a similar population-based estimate to assess the expected number of years lost up to time t for a group of patients. In large samples, $\hat{\mu}_t$ is approximately normally distributed with a variance that may be estimated by

$$\widehat{\text{var}}(\hat{\mu}_t) = \sum_{t_j \le t} \frac{(\hat{\mu}_t - \hat{\mu}_{t_j})^2 d_j}{r_j(r_j - d_j)},$$

a result which may be used to give approximate confidence limits for μ_t. By letting t tend to infinity, the above results may be extended to the estimation of the mean μ itself [8]. However, the conditions (mainly on the censoring) needed for such an extension to be valid are usually not met in practice.

In the liver cirrhosis study no patient was followed for more than 13 years, making the estimation of the mean survival time impossible. We may, however, estimate the expected number of years lived up to a given time t. In particular, estimates for the expected number of years lived up to 5 years and 10 years after

the start of the study are 3.29 years (standard error 0.17 years) and 4.73 years (0.33 years), respectively.

Redistribute-to-the-right Algorithm and Self-consistency

We mentioned earlier the relationship between the Kaplan–Meier estimator and the empirical distribution function in the case of no censoring. The redistribute-to-the-right algorithm and the concept of self-consistency, both due to Efron [6], further illustrate this relation.

For notational convenience we assume that there are no ties, and we denote by $t_1^0 < t_2^0 < \cdots < t_n^0$ the ordered times of deaths and censorings combined. The redistribute-to-the-right algorithm is as follows. First, we construct the ordinary empirical (survival) distribution function which places probability mass $1/n$ at each of the observed times t_j^0. If $t_{j_1}^0$ is the smallest t_j^0 that corresponds to a censored observation, then we remove its mass and redistribute it equally among the $n - j_1$ time-points to the right of it. Then, if $t_{j_2}^0$ is the second smallest censored observation, we remove its mass, which will be $1/n + 1/[n(n - j_1)]$, and redistribute it equally among the $n - j_2$ time-points to its right, etc. This algorithm will converge in a finite number of steps to the Kaplan–Meier estimator (1) (with the modification that it is set equal to zero after t_n^0 also when this last time-point corresponds to a censored observation).

A self-consistent estimator $\tilde{S}(t)$ for the survival distribution function equals $1/n$ times an estimate for the number of individuals who survive time t. More precisely,

$$\tilde{S}(t) = \frac{1}{n}\left[\#(t_j^0 > t) + \sum_{t_j^0 \le t} a_j(t)\right], \qquad (8)$$

where $a_j(t) = \tilde{S}(t)/\tilde{S}(t_j^0)$ if the observation at t_j^0 corresponds to a censored observation, and $a_j(t) = 0$ if it corresponds to an observed death. It turns out that the Kaplan–Meier estimator (modified as just indicated) is the unique self-consistent estimator. Turnbull [17] (*see* **Turnbull Estimator**) used the idea of self-consistency to derive an iterative procedure (a version of the **EM algorithm**) for estimating the survival distribution function nonparametrically from arbitrarily grouped, censored, and truncated data, while Gill [9] showed that the self-consistency equation, (8), may be interpreted as a generalized score equation.

Product–Integral Representation and Relationship to the Nelson–Aalen Estimator

Usually one assumes that the survival distribution function $S(t)$ is absolute continuous with density function $f(t) = -S'(t)$, hazard rate function $\alpha(t) = f(t)/S(t)$, and cumulative hazard rate function $A(t) = \int_0^t \alpha(u)\,\mathrm{d}u$. However, the Kaplan–Meier estimator is discrete in nature, and the same applies to the Nelson–Aalen estimator for the cumulative hazard rate function. This makes it useful to be able to handle both discrete and continuous distributions within a unified framework. Let us therefore review how the survival distribution function $S(t)$ and the cumulative hazard rate function $A(t)$ are related for distributions which need neither to be continuous nor discrete. For such distributions

$$A(t) = -\int_0^t \frac{\mathrm{d}S(u)}{S(u-)}, \qquad (9)$$

where $S(t-)$ denotes the left-hand limit of the survival distribution function at t. For an absolute continuous distribution, (9) specializes to $A(t) = -\ln S(t) = \int_0^t \alpha(u)\,\mathrm{d}u$. For a discrete distribution it gives $A(t) = \sum_{u \le t} \alpha_u$, where the discrete hazard, α_t, is the conditional probability of death exactly at time t given that death has not occurred earlier. To express the survival distribution function by the cumulative hazard rate function it is convenient to use the product–integral $\prod\!\!\!\!\prod$, defined as the limit of approximating finite products in a similar manner as the ordinary integral $\int$ is defined as the limit of approximating finite sums (*see* **Product-integration**). With the use of the product–integral we may write

$$S(t) = \prod_{u \le t}\!\!\!\!\prod [1 - \mathrm{d}A(u)]. \qquad (10)$$

For a continuous distribution, (10) specializes to the well-known relation $S(t) = \exp[-A(t)]$, while for a discrete distribution it takes the form $S(t) = \prod_{u \le t}(1 - \alpha_u)$.

The Nelson–Aalen estimator for the cumulative hazard rate function is $\hat{A}(t) = \sum_{t_j \le t} d_j/r_j$. This corresponds to a distribution with all probability mass

concentrated at the observed failure times and with discrete hazard $\hat{\alpha}_j = d_j/r_j$ at t_j. Using (10), the corresponding survival distribution function takes the form

$$\hat{S}(t) = \prod_{u \le t} [1 - \mathrm{d}\hat{A}(u)] = \prod_{t_j \le t} (1 - \hat{\alpha}_j), \qquad (11)$$

i.e. it is the Kaplan–Meier estimator (1). Thus the Kaplan–Meier and Nelson–Aalen estimators are related in exactly the same way as are the survival distribution function and the cumulative hazard rate function themselves. This fact is lost sight of when one considers the relations $A(t) = -\ln S(t)$ and $S(t) = \exp[-A(t)]$ which are only valid for the continuous case. In fact, the latter relations have led researchers to suggest the estimators $-\ln \hat{S}(t)$ and $\exp[-\hat{A}(t)]$ for the cumulative hazard rate function and the survival distribution function, respectively. The numerical differences between these two estimators and the Nelson–Aalen and Kaplan–Meier estimators will be of little importance in most cases. But the fact that the Nelson–Aalen and Kaplan–Meier estimators are related through (9) and (10) indicates that they are the canonical nonparametric estimators for the cumulative hazard rate function and the survival distribution function. This statement is supported by the fact that they may both be given a **nonparametric maximum likelihood** interpretation [11].

Martingale Representation and Statistical Properties

The product–integral formulation (11) of the Kaplan–Meier estimator shows its close relationship to the Nelson–Aalen estimator, and it is the key to the study of its statistical properties. In fact, these are closely related to those of the Nelson–Aalen estimator. We here indicate a few main steps and refer to Andersen et al. [1, Section IV.3] for a detailed account.

Let $J(t) = 1$ if there is at least one individual at risk just before time t; $J(t) = 0$ otherwise. Furthermore, introduce $A^*(t) = \int_0^t J(u)\,\mathrm{d}A(u)$, and let

$$S^*(t) = \prod_{u \le t} [1 - \mathrm{d}A^*(u)]. \qquad (12)$$

We note that (12) is almost the same as $S(t)$ [cf. (10)] when there is only a small probability that there is no one at risk at times $u \le t$. By a general result for product–integrals (Duhamel's equation), we may write

$$\frac{\hat{S}(t)}{S^*(t)} - 1 = -\int_0^t \frac{\hat{S}(u-)}{S^*(u)}\,\mathrm{d}(\hat{A} - A^*)(u). \qquad (13)$$

Here $\hat{A} - A^*$ is a square integrable martingale (*see* **Nelson–Aalen Estimator**). It follows that the right-hand side of (13) is a stochastic integral and hence itself a mean zero square integrable martingale. As a consequence of this, $\mathrm{E}[\hat{S}(t)/S^*(t)] = 1$ for any given t, so the Kaplan–Meier estimator is almost **unbiased**. Furthermore, the predictable variation process of the martingale on the right-hand side of (13) may be used to arrive at an estimator for the variance of $\hat{S}(t)/S^*(t)$. From this, Greenwood's formula (2) follows provided one adopts a general model, not necessarily continuous. Greenwood's formula may also be derived through a standard **information** calculation starting with a binomial-type likelihood for such a general model.

A further consequence of (13) is that $\sqrt{(n)}(\hat{S} - S)/S$ is asymptotically equivalent to $-\sqrt{(n)}(\hat{A} - A)$ and therefore converges weakly to a mean zero Gaussian martingale. In particular, for a fixed t, the Kaplan–Meier estimator (1) is asymptotically normally distributed, a fact that was used in connection with the confidence intervals (3) and (4). Also, the asymptotic distributional results of the estimators for the median and mean survival times reviewed earlier are consequences of this weak convergence result.

Confidence Bands

The weak convergence of $\sqrt{(n)}(\hat{S} - S)/S$ to a mean zero Gaussian martingale also makes it possible to derive confidence bands for the survival distribution function, i.e. limits that contain $S(t)$ for all t in an interval $[\tau_1, \tau_2]$ with a prespecified probability. Two important types of such confidence bands are the equal precision bands [14] and the Hall–Wellner bands [10]. Borgan & Liestøl [3] derived transformed versions of these confidence bands and compared them with the nontransformed ones.

The standard and log-minus-log transformed equal precision bands are obtained by replacing $z_{1-\alpha/2}$ in (3) and (4) by $d_{1-\alpha}(\hat{c}_1, \hat{c}_2)$, the $1 - \alpha$ fractile in the distribution of the supremum of the absolute value

of a standardized Brownian bridge over the interval from $\hat{c}_1$ to $\hat{c}_2$ (*see* **Brownian Motion and Diffusion Processes**). Here

$$\hat{c}_i = \frac{n[\hat{\sigma}(\tau_i)/\hat{S}(\tau_i)]^2}{1 + n[\hat{\sigma}(\tau_i)/\hat{S}(\tau_i)]^2}, \quad i = 1, 2. \tag{14}$$

The fractile $d_{1-\alpha}(\hat{c}_1, \hat{c}_2)$ may be found (approximately) by solving (with respect to d) the following nonlinear equation:

$$\frac{4\phi(d)}{d} + \phi(d)\left(d - \frac{1}{d}\right)\ln\left[\frac{\hat{c}_2(1-\hat{c}_1)}{\hat{c}_1(1-\hat{c}_2)}\right] = \alpha,$$

with $\phi(d)$ the standard normal density. The equal precision bands require $0 < \hat{c}_1 < \hat{c}_2 < 1$, so they cannot be extended all the way down to $t = 0$. Typically, one will also omit the largest values of t.

The nontransformed Hall–Wellner band takes the form

$$\hat{S}(t) \pm n^{-1/2} e_{1-\alpha}(\hat{c}_1, \hat{c}_2)\left\{1 + n\left[\frac{\hat{\sigma}(t)}{\hat{S}(t)}\right]^2\right\}\hat{S}(t). \tag{15}$$

Here $e_{1-\alpha}(\hat{c}_1, \hat{c}_2)$ is the $1-\alpha$ fractile in the distribution of the supremum of the absolute value of a Brownian bridge over the interval from $\hat{c}_1$ to $\hat{c}_2$; cf. (14). For completely observed survival data the Hall–Wellner band reduces to the well-known Kolmogorov band $\hat{S}(t) \pm n^{-1/2} e_{1-\alpha}(\hat{c}_1, \hat{c}_2)$. For the band (15), one will often let $\tau_1 = 0$, in which case tables of $e_{1-\alpha}(\hat{c}_1, \hat{c}_2) = e_{1-\alpha}(0, \hat{c}_2)$ are given, for example by Koziol & Byar [13] and Hall & Wellner [10] for selected values of α and $\hat{c}_2$. We note that (15) is obtained from (3) by substituting $n^{-1/2} e_{1-\alpha}(\hat{c}_1, \hat{c}_2)\{1 + n[\hat{\sigma}(t)/\hat{S}(t)]^2\}\hat{S}(t)$ for $z_{1-\alpha/2}\hat{\sigma}(t)$. The same substitution in (4) gives the log-minus-log transformed Hall–Wellner band. This transformed band requires $\hat{c}_1 > 0$, so it cannot be extended all the way down to $t = 0$. Owing to the approximation $e_{1-\alpha}(\hat{c}_1, \hat{c}_2) \approx e_{1-\alpha}(0, \hat{c}_2)$, the above-mentioned tables may also be used for the transformed bands when $\hat{c}_1$ is close to zero.

The nontransformed equal precision band tends to achieve too high error rates when the number of observations is low, and the use of transformed bands is recommended, even for samples of a hundred or more. The achieved error rates of the nontransformed Hall–Wellner band are fairly close to the nominal ones even in small samples, and the improvement obtained by using transformed bands is of less importance.

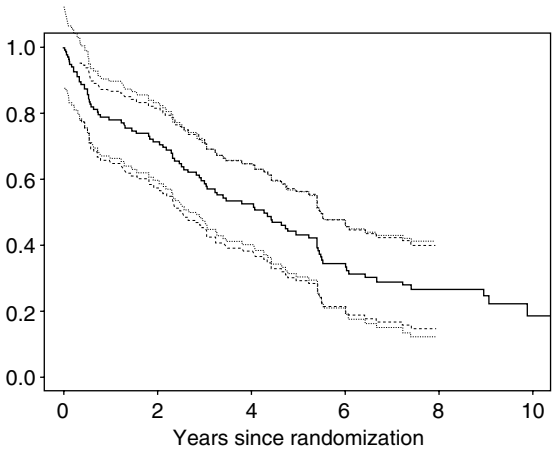

Figure 2 Kaplan–Meier estimate of the survival distribution function for 138 placebo-treated male patients with liver cirrhosis with 95% confidence bands: log-minus-log transformed equal precision band over the interval from 4 months to 8 years (- - - -); Hall–Wellner band over the interval [0, 8] years (· · ·)

Figure 2 shows the Kaplan–Meier estimate for the liver cirrhosis data with 95% confidence bands. The bands shown are the log-minus-log transformed equal precision band over the interval from 4 months to 8 years and the nontransformed Hall–Wellner band valid from time zero to 8 years. Since $\tau_1 = 1/3$ year and $\tau_2 = 8$ years correspond to $\hat{c}_1 = 0.090$ and $\hat{c}_2 = 0.789$, the fractiles $d_{0.95}(\hat{c}_1, \hat{c}_2) = 2.99$ and $e_{0.95}(0, \hat{c}_2) = 1.36$ were used. It is seen that the equal precision band is narrower than the Hall–Wellner band both for low and high values of t, while the Hall–Wellner band is slightly narrower than the equal precision band for intermediate values.

ØRNULF BORGAN

Kappa and its Dependence on Marginal Rates

The **kappa** statistic was proposed by Cohen [4] as a measure of reliability for **nominal** classification procedures and was constructed specifically to "correct" the proportion of raw agreement for agreement expected purely by random classifications given the marginal rates. Since its introduction there have been many generalizations and extensions developed and it has been applied widely in medical research. There has also been considerable debate about the utility of this index [9, 13, 14], arising in part as a result of a genuine lack of consensus on precisely how to model and measure the reliability of nominal classification procedures. The issues are most easily illustrated in the assessment of the reliability of a simple **binary** test. Let T_k denote the outcome of the kth application of a binary test for which $T_k = 1$ and $T_k = 2$ indicate the presence and absence of disease, respectively, $k = 1, 2$. Upon two applications of this test to a sample of n subjects, cross-classifying the results leads to a **2 x 2 table** (see Table 1), where x_{ij} denotes the frequency with which $T_1 = i$ and $T_2 = j$, $x_{i\cdot} = \sum_{j=1}^{2} x_{ij}$, and $x_{\cdot j} = \sum_{i=1}^{2} x_{ij}$. Conditioning on n leads to a **multinomial distribution** for $\mathbf{x} = (x_{11}, x_{12}, x_{21}, x_{22})'$, where p_{ij} is the probability of $T_1 = i$ and $T_2 = j$, $p_{i\cdot} = \sum_{j=1}^{2} p_{ij}$, and $p_{\cdot j} = \sum_{i=1}^{2} p_{ij}$. The raw agreement is $p_0 = \sum_{i=1}^{2} p_{ii}$ and, given the marginal rates $p_{i\cdot}, i = 1, 2$ and $p_{\cdot j}, j = 1, 2$, and under the assumption of independent classifications, the expected level of agreement is $p_e = \sum_{i=1}^{2} p_{i\cdot} p_{\cdot i}$ The kappa index takes the form $\kappa = (p_0 - p_e)/(1 - p_e)$. The estimate of kappa, subsequently referred to as the kappa statistic and denoted $\hat{\kappa}$, is obtained by replacing p_0 and p_e by the corresponding estimates $\hat{p}_0 = \sum_{i=1}^{2} \hat{p}_{ii}$ and $\hat{p}_e = \sum_{i=1}^{2} \hat{p}_{i\cdot}\hat{p}_{\cdot i}$ respectively, where $\hat{p}_{ii} = x_{ii}/n$, $\hat{p}_{i\cdot} = x_{i\cdot}/n$, and $\hat{p}_{\cdot i} = x_{\cdot i}/n, i = 1, 2$.

While on the surface the kappa statistic is intuitively appealing as a measure of reliability, paradoxical results can arise from computing the kappa statistic for tables of various configurations. The most often cited paradox with kappa is termed the "base rate" or "prevalence" problem and refers to the fact that for a fixed $\hat{p}_0$, values of $\hat{p}_{1\cdot} \approx \hat{p}_{\cdot 1}$ away from 0.50 in either direction lead to smaller values of $\hat{\kappa}$. Thus, a diagnostic test with fixed **sensitivity** and **specificity** when applied twice to a sample of patients with $\hat{p}_{1\cdot} \approx \hat{p}_{\cdot 1} \approx 0.50$, will generate a kappa statistic larger than would be obtained from a similar application of the test in a very low-risk population (with $\hat{p}_{1\cdot} \approx \hat{p}_{\cdot 1} \approx 0.10$), or in an extremely high-risk population (with $\hat{p}_{1\cdot} \approx \hat{p}_{\cdot 1} \approx 0.90$). Given that the diagnostic instrument is the same in both studies, this result is argued to be counter-intuitive. This paradox also raises concerns about the utility of the ranges for the kappa statistic given by Landis & Koch [10] said to correspond to poor, fair, good, and excellent agreement. Owing to this dependence on the marginal frequencies, a comparison of reliability findings, as measured by $\hat{\kappa}$, is difficult across studies involving populations with different prevalences.

Table 1

	$T_2 = 1$	$T_2 = 2$	Total
$T_1 = 1$	x_{11}	x_{12}	$x_{1\cdot}$
$T_1 = 2$	x_{21}	x_{22}	$x_{2\cdot}$
Total	$x_{\cdot 1}$	$x_{\cdot 2}$	$x_{\cdot\cdot} = n$

At the population level, some insight can be gained into the reason for this behavior. Let θ denote the **prevalence** of the disease in the population from which the subjects under study were randomly sampled. Let α and β denote the **false positive** and **false negative** error rates for the diagnostic test, respectively. Then, if successive applications of the test may be assumed to be independent, $p_{11} = \theta(1-\beta)^2 + (1-\theta)(1-\alpha)^2$, $p_{12} = \theta(1-\beta)\beta + (1-\theta)(1-\alpha)\alpha$, $p_{21} = \theta(1-\beta)\beta + (1-\theta)(1-\alpha)\alpha$, $p_{22} = \theta\beta^2 + (1-\theta)\alpha^2$, $p_0 = p_{11} + p_{22} = \theta(1-2\beta) + (1-\theta)(1-2\alpha)$, and $p_e = 1 - 2a(1-a)$, where $a = [\theta(1-\beta) + (1-\theta)(1-\alpha)]^2$. Kraemer [8] derives the relation

$$\kappa = \frac{2\theta(1-\theta)(1-\alpha-\beta)^2}{2[(\theta(1-\beta)+(1-\theta)\alpha) \times (1-\theta(1-\beta)-(1-\theta)\alpha)]}. \qquad (1)$$

For fixed (α, β), plots of κ as a function of θ are concave down taking on the value zero at $\theta = 0$ and $\theta = 1$ [13].

Several solutions to this problem have been proposed ranging from supplementing $\hat{\kappa}$ with additional statistics to facilitate disentangling the nature of the

agreement, to entirely new approaches. Feinstein & Cicchetti [7] effectively illustrate the dependence of kappa on the marginal frequencies by considering several sample tables in which the observed raw agreement $\hat{p}_0$ is fixed, but the marginal frequencies vary. In a companion paper, Cicchetti & Feinstein [3] then propose that the kappa statistic should always be reported with two accompanying statistics called the index of average positive agreement, $\hat{q}_{\text{pos}} = 2x_{11}/(x_{1\cdot} + x_{\cdot 1})$, and the index of average negative agreement $\hat{q}_{\text{neg}} = 2x_{22}/(x_{2\cdot} + x_{\cdot 2})$. The motivation is that these statistics may be used to gain insight into the marginal agreement and imbalance in the marginal frequencies and hence allow interpretation of $\hat{\kappa}$ accordingly. Byrt et al. [1] propose using what they refer to as a bias-adjusted kappa, which reduces to an index previously proposed by Scott [12]. Lantz & Nebenzahl [11] suggest that kappa statistics be accompanied with statistics $\hat{\kappa}_{\min} = \hat{p}_0^2/[(1-\hat{p}_0)^2 + 1]$ and $\hat{\kappa}_{\max} = \hat{p}_0 - 1/\hat{p}_0 + 1$ for $\hat{p}_0 < 1$, which correspond to the minimum and maximum values of κ for a given level of observed agreement, and $\hat{\kappa}_{\text{nor}} = 2\hat{p}_0 - 1$, which is also the so-called prevalence-adjusted, bias-adjusted kappa statistic of Byrt et al. [1].

Much of the work on kappa has been carried out on intuitive, but largely ad hoc, grounds. For example, there is no underlying probability function, and hence **likelihood** function, for which κ is a sole parameter of interest. Rather, it has been proposed as an "index", a function of parameters which may be estimated and, when done so, is thought to have some attractive properties. Thus, it appears that the paradox arises since the kappa statistic is not model-based, and depends in a complicated way on the observed raw agreement and the marginal frequencies. The key factor in the paradoxes is the role of $\hat{p}_e$, which serves as a "correction factor" in the numerator of $\hat{\kappa}$, as well as a rescaling factor in the denominator $1 - \hat{p}_e$. The extent to which the lack of a likelihood function relates to the above prevalence problem is worthy of consideration.

Another difficulty is that it is not generally well understood precisely what is, or should be, meant by the "reliability" of a **binary** diagnostic test. With a view to exploring this, Cook & Farewell [5] describe a likelihood-based approach for the separate examination of the marginal agreement (relative magnitude of $p_{1\cdot}$ and $p_{\cdot 1}$) and subject-specific agreement (as measured by the **odds ratio**). Likelihood factorizations, conditioning arguments, and exact distributions facilitate detailed examination of well-defined and interpretable aspects of reliability.

In all of the recommended procedures cited above it must be borne in mind that the raw data for the 2×2 table under consideration consist only of four numbers and at most three **degrees of freedom**. Hence, presentation of three or four "summary" statistics does not serve the purpose of data reduction. Nevertheless, there appears to be general agreement that for the purpose of assessing reliability of a diagnostic test with a binary outcome, a single summary statistic is not adequate. The influence of the marginal frequencies on the kappa statistic is also present in the case of multiple nominal categories, but the precise nature of this influence is more difficult to characterize and is not well understood [10]. Chamberlin & Sprott [2] and Farewell and Sprott [6] derive a discrete conditional distribution which may be used as a basis for conditional inference (*see* **Conditionality Principle**) on subject-specific agreement in this context.

RICHARD J. COOK

Kappa

In medical research it is frequently of interest to examine the extent to which results of a classification procedure concur in successive applications. For example, two psychiatrists may separately examine each member of a group of patients and categorize each one as psychotic, neurotic, suffering from a personality disorder, or healthy. Given the resulting data, questions may then be posed regarding the diagnoses of the two psychiatrists and their relationship to one another. The psychiatrists would typically be said to exhibit a high degree of agreement if a high percentage of their diagnoses concurred, and poor agreement if they often made different diagnoses. In general, this latter outcome could arise if the categories were ill-defined, the criteria for assessment were different for the two psychiatrists, or their ability to examine these criteria differed sufficiently, possibly as a result of different training or experience. Poor empirical agreement might therefore lead to a review of the category definitions and diagnostic criteria, or possibly retraining with a view to improving agreement and hence consistency of diagnoses and treatment. In another context, one might have data from successive applications of a test for dysplasia or cancer from cervical smears. If the test indicates normal, mild, moderate, or severe dysplasia, or cancer, and the test is applied at two time points in close proximity, ideally the results would be the same. Variation in the method and location of sampling as well as variation in laboratory procedures may, however, lead to different outcomes. In this context, one would say that there is empirical evidence that the test is reliable if the majority of the subjects are classified in the same way for both applications of the test. Unreliable tests would result from the sources of variation mentioned earlier. Again, empirical evidence of an unreliable test may lead to refinements of the testing procedure (*see* **Observer Reliability and Agreement**).

The Kappa Index of Reliability for a Binary Test

For convenience, consider a diagnostic testing procedure generating a binary response variable T indicating the presence ($T = 1$) or absence ($T = 2$) of a particular condition. Suppose this test is applied twice in succession to each subject in a sample of size n. Let T_k denote the outcome for the kth application with the resulting data summarized in the **two-by-two table** (Table 1). where x_{ij} denotes the frequency at which $T_1 = i$ and $T_2 = j$, $x_{i\cdot} = \sum_{j=1}^{2} x_{ij}$, and $x_{\cdot j} = \sum_{i=1}^{2} x_{ij}$, $i = 1, 2$, $j = 1, 2$. Assuming that

Table 1

	$T_2 = 1$	$T_2 = 2$	Total
$T_1 = 1$	x_{11}	x_{12}	$x_{1\cdot}$
$T_1 = 2$	x_{21}	x_{22}	$x_{2\cdot}$
Total	$x_{\cdot 1}$	$x_{\cdot 2}$	$x_{\cdot\cdot} = n$

test results on different subjects are independent, conditioning on n leads to a **multinomial distribution** for the outcome of a particular table with

$$f(\mathbf{x}; \mathbf{p}) = \binom{n}{x_{11}\ x_{12}\ x_{21}\ x_{22}} \prod_{i=1}^{2}\prod_{j=1}^{2} p_{ij}^{x_{ij}},$$

$\mathbf{x} = (x_{11}, x_{12}, x_{21}, x_{22})'$, $\mathbf{p} = (p_{11}, p_{12}, p_{21}, p_{22})'$, and $p_{22} = 1 - p_{11} - p_{12} - p_{21}$. Let $p_{i\cdot} = \sum_{j=1}^{2} p_{ij}$ and $p_{\cdot j} = \sum_{i=1}^{2} p_{ij}$. Knowledge of $\mathbf{p}$ would correspond to a complete understanding of the reliability of the test. Since knowledge of $\mathbf{p}$ is generally unattainable and estimation of $\mathbf{p}$ does not constitute a sufficient data reduction, indices of reliability/agreement typically focus on estimating one-dimensional functions of $\mathbf{p}$ (*see* **Agreement, Measurement of**).

A natural choice is $p_0 = \sum_{i=1}^{2} p_{ii}$, the probability of raw agreement, which is estimated as $\hat{p}_0 = \sum_{i=1}^{2} x_{ii}/n$. If $p_0 = 1$, then the test is completely reliable since the probability of observing discordant test results is zero. Similarly, if $\hat{p}_0$ is close to unity, then it suggests that the outcomes of the two applications concurred for the vast majority of the subjects. However, several authors have expressed reluctance to base **inferences** regarding reliability on the observed level of raw agreement (see [3] and references cited therein). The purported limitations of $\hat{p}_0$ as a measure of reliability stem from the fact that p_0 reflects both "chance" agreement and agreement over and above that which would be expected by chance. The agreement expected by chance, which we denote by p_e, is computed on the basis of the marginal distribution, defined by $p_{1\cdot}$ and $p_{\cdot 1}$, and under the assumption that the outcomes of the two

tests are independent conditional on the true status. Specifically, $p_e = \sum_{i=1}^{2} p_{i\cdot} p_{\cdot i}$ is estimated by $\hat{p}_e = \sum_{i=1}^{2} x_{1\cdot} x_{\cdot 1}/n^2$. To address concerns regarding the impact of nonnegligible chance agreement, Cohen [3] defined the index kappa which takes the form

$$\kappa = \frac{p_0 - p_e}{1 - p_e},$$

and indicated that it can be interpreted as reflecting "the proportion of agreement *after* chance agreement is removed from consideration". This can be seen by noting that $p_0 - p_e$ is the difference in the proportion of raw agreement and the agreement expected by chance, this being the agreement arising due to factors not driven by chance. If $p_0 - p_e > 0$, then there is agreement arising from nonchance factors; if $p_0 - p_e = 0$, then there is no additional agreement over that which one would expect based on chance; and if $p_0 - p_e < 0$, then there is less agreement than one would expect by chance. Furthermore, $1 - p_e$ is interpreted by Cohen [3] as the proportion "of the units for which the hypothesis of no association would predict disagreement between the judges". Alternatively, this can be thought of as the maximum possible agreement beyond that expected by chance. An estimate of κ, denoted $\hat{\kappa}$, is referred to as the kappa statistic and may be obtained by replacing p_0 and p_e with their corresponding point estimates, giving

$$\hat{\kappa} = \frac{\hat{p}_0 - \hat{p}_e}{1 - \hat{p}_e}. \tag{1}$$

The Kappa Index of Reliability for Multiple Categories

When the classification procedure of interest has multiple nominal categories, assessment of agreement becomes somewhat more involved. Consider a diagnostic test with R possible outcomes and let T_k denote the outcome of the kth application of the test, $k = 1, 2$. Then T_k takes values on $\{1, 2, 3, \ldots, R\}$ and interest lies in assessing the extent to which these outcomes agree for $k = 1$ and $k = 2$. An $R \times R$ **contingency table** may then be constructed (see Table 2), where again x_{ij} denotes the frequency with which the first application of the test led to outcome i and the second led to outcome $j, i = 1, 2, \ldots, R, j = 1, 2, \ldots, R$. A category-specific measure of agreement may be of interest to examine the extent to which the two applications tend to lead to consistent conclusions with respect to outcome r, say. In this problem there is an implicit assumption that the particular nature of any disagreements are not of interest. One can then collapse the $R \times R$ table to a 2×2 table constructed by cross-classifying subjects with **binary** indicators such that $T_k = 1$ if outcome r was selected at the kth application, $T_k = 2$ otherwise, $k = 1, 2$. A category-specific kappa statistic can then

Table 2

	$T_2 = 1$	$T_2 = 2$	$T_2 = 3$	$\cdots$	$T_2 = R$	Total
$T_1 = 1$	x_{11}	x_{12}	x_{13}	$\cdots$	x_{1R}	$x_{1\cdot}$
$T_1 = 2$	x_{21}	x_{22}	x_{23}	$\cdots$	x_{2R}	$x_{2\cdot}$
$T_1 = 3$	x_{31}	x_{32}	x_{33}	$\cdots$	x_{3R}	$x_{3\cdot}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\cdots$	$\vdots$	$\vdots$
$T_1 = R$	x_{R1}	x_{R2}	x_{R3}	$\cdots$	x_{RR}	$x_{R\cdot}$
Total	$x_{\cdot 1}$	$x_{\cdot 2}$	$x_{\cdot 3}$	$\cdots$	$x_{\cdot R}$	$x_{\cdot\cdot} = n$

be constructed in the fashion indicated earlier. This can be repeated for each of the R categories giving R such statistics.

In addition to these category-specific measures, however, an overall summary index of agreement is often of interest. The kappa statistic in (1) is immediately generalized for the $R \times R$ ($R > 2$) table as follows. Let p_{ij} denote the probability of $T_1 = i$ and $T_2 = j$, one of the R^2 multinomial probabilities, $p_{i\cdot} = \sum_{j=1}^{R} p_{ij}$, and $p_{\cdot j} = \sum_{i=1}^{R} p_{ij}, i = 1, 2, \ldots, R, j = 1, 2, \ldots, R$. Then, as before, $\hat{p}_{ij} = x_{ij}/n$, $\hat{p}_{i\cdot} = x_{i\cdot}/n$, $\hat{p}_{\cdot j} = x_{\cdot j}/n$, $\hat{p}_0 = \sum_{i=1}^{R} \hat{p}_{ii}$, $\hat{p}_e = \sum_{i=1}^{R} \hat{p}_{i\cdot}\hat{p}_{\cdot i}$, and the overall kappa statistic takes the same form as in (1). This overall kappa statistic can equivalently be written as a weighted average of category-specific kappa statistics [6].

The kappa statistic has several properties that are widely considered to be attractive for measures of agreement. First, when the level of observed agreement, reflected by $\hat{p}_0$, is equal to the level of agreement expected by chance ($\hat{p}_e$), $\hat{\kappa} = 0$. Secondly, $\hat{\kappa}$ takes on its maximum value of 1 if and only if there is perfect agreement (i.e. $\hat{p}_0 = 1$ arising from a diagonal table). Thirdly, the kappa statistic is never less than -1. The latter two features require further elaboration, however, as the actual upper and lower limits on $\hat{\kappa}$ are functions of the marginal frequencies. In particular, $\hat{\kappa}$ takes on the value 1 only when the

marginal frequencies are exactly equal and all off-diagonal cells are zero. Values less than 1 occur when the marginal frequencies are the same but there are different category assignments in the table or, more generally, when the marginal frequencies differ (when the marginal frequencies differ there are necessarily nonzero diagonal cells and hence some disagreements). It is natural then to expect the kappa statistic for such a table to be less than unity. Cohen [3] shows that the maximum possible value of $\hat{\kappa}$ takes the form

$$\hat{\kappa}_{\mathrm{M}} = \frac{x_{\cdot\cdot}\sum_{i=1}^{R}\min(x_{i\cdot}, x_{\cdot i}) - \sum_{i=1}^{R}x_{i\cdot}x_{\cdot i}}{x_{\cdot\cdot}^2 - \sum_{i=1}^{R}x_{i\cdot}x_{\cdot i}}, \qquad (2)$$

and argues that this is intuitively reasonable since differences in the marginal frequencies necessarily lead to a reduction in the level of agreement and hence $\hat{\kappa}$. Cohen then suggests that if one is interested in assessing the proportion of the agreement permitted by the margins (correcting for chance), then one computes $\hat{\kappa}/\hat{\kappa}_{\mathrm{M}}$. We return to the topic of marginal frequencies and their influence on the properties of κ later in the article.

If the marginal frequencies for the two tests are uncorrelated (as measured by the product–moment **correlation** of the margins [3]), then the lower bound for $\hat{\kappa}$ is $\hat{\kappa}_{\mathrm{L}} = -(R-1)^{-1}$. When the marginal frequencies are negatively correlated, $\hat{\kappa}_{\mathrm{L}} > -(R-1)^{-1}$. However, when the marginal frequencies are positively correlated, $\hat{\kappa}_{\mathrm{L}} < -(R-1)^{-1}$. It is only as the number of categories reduces to two, the correlation of the marginal frequencies approaches 1, and the **variances** of the marginal frequencies increase, that $\hat{\kappa}_{\mathrm{L}}$ approaches -1 [3].

Having computed a kappa statistic for a given contingency table it is natural to want to characterize the level of agreement in descriptive terms. Landis & Koch [11] provide ranges that suggest, beyond what one would expect by chance, $0.75 < \hat{\kappa}$ typically represents excellent agreement, $0.40 < \hat{\kappa} < 0.75$ fair to good agreement, and $\hat{\kappa} < 0.40$ poor agreement. While there is some appeal to this convenient framework for the interpretation of $\hat{\kappa}$, caution is warranted (*see* **Kappa and its Dependence on Marginal Rates**).

Frequently, it will be of interest to construct **confidence intervals** for the index kappa. Fleiss et al. [8] derive an approximate large sample estimate for the variance of $\hat{\kappa}$, $\widehat{\mathrm{var}}(\hat{\kappa})$, as

$$\left(\sum_{i=1}^{R}\hat{p}_{ii}[1-(\hat{p}_{i\cdot}+\hat{p}_{\cdot i})(1-\hat{\kappa})]^2 + (1-\hat{\kappa})^2\sum_{i}\sum_{j\neq i}\hat{p}_{ij}(\hat{p}_{\cdot i}+\hat{p}_{j\cdot})^2 - [\hat{\kappa}-\hat{p}_{\mathrm{e}}(1-\hat{\kappa})]^2\right) \Big/ [x_{\cdot\cdot}(1-\hat{p}_{\mathrm{e}})^2], \qquad (3)$$

and Fleiss [6] recommends carrying out tests (*see* **Hypothesis Testing**) and constructing confidence intervals by assuming approximate **normality** of $(\hat{\kappa}-\kappa)/[\widehat{\mathrm{var}}(\hat{\kappa})]^{1/2}$ and proceeding in the standard fashion. For tests regarding the **null hypothesis** $\mathrm{H}_0 : \kappa = 0$, an alternate variance estimate may be derived from (3) by substituting 0 for $\hat{\kappa}$, and $\hat{p}_{i\cdot}\hat{p}_{\cdot j}$ for $\hat{p}_{ij}$, giving

$$\widehat{\mathrm{var}}_0(\hat{\kappa}) = \left(\sum_{k=1}^{R}\hat{p}_{i\cdot}\hat{p}_{\cdot i}[1-(\hat{p}_{i\cdot}+\hat{p}_{\cdot i})]^2 + \sum_{i\neq j}\hat{p}_{i\cdot}\hat{p}_{\cdot j} \times (\hat{p}_{\cdot i}+\hat{p}_{j\cdot})^2 - p_{\mathrm{e}}^2\right) \Big/ [x_{\cdot\cdot}(1-\hat{p}_{\mathrm{e}})^2], \qquad (4)$$

with tests carried out as described above.

The Weighted Kappa Index

The discussion thus far has focused on situations in which the test serves as a **nominal** classification procedure (e.g. as in the psychiatric diagnosis example at the beginning of the article). In such settings, since there is no natural ordering to the outcomes, any disagreements are often considered to be equally serious and the methods previously described are directly applicable. In some circumstances with nominal scales, however, certain types of disagreements are more serious then others and it is desirable to take this into account. Furthermore, when the outcome is ordinal (as in the cervical cancer screening example) (*see* **Ordered Categorical Data**), it is often of interest to adopt a measure of

agreement that treats disagreements in adjacent categories as less serious than disagreements in more disparate categories. For the test based on cervical smears designed to classify the condition of the cervix as healthy, mildly, moderately, or severely dysplastic, or cancerous, if on one occasion the test suggested mild dysplasia and on another moderate, this type of disagreement would be considered less serious than if a cervix previously diagnosed as cancerous was subsequently classified as mildly dysplastic. In general, the seriousness reflects clinical implications for treatment and the consequences of wrong decisions.

Weighted versions of the kappa statistic were derived by Cohen [4] to take into account the additional structure arising from ordinal measures or from nominal scales in which certain types of disagreement are of more importance than others. In particular, the objective of adopting a weighted kappa statistic is to allow "different kinds of disagreement" to be differentially weighted in the construction of the overall index. We begin by assigning a weight to each of the R^2 cells; let w_{ij} denote the weight for cell (i, j). These weights may be determined quite arbitrarily but it is natural to restrict $0 \leq w_{ij} \leq 1$, set w_{ii} to unity to give exact agreement maximum weight, and set $0 \leq w_{ij} < 1$ for $i \neq j$, so that all disagreements are given less weight than exact agreement. The selection of the weights plays a key role in the interpretation of the weighted kappa statistic and also impacts the corresponding variance estimates, prompting Cohen [4] to suggest these be specified prior to the collection of the data.

Perhaps the two most common sets of weights are the quadratic weights, with $w_{ij} = 1 - (i - j)^2/(R - 1)^2$, and the so-called Cicchetti weights, with $w_{ij} = 1 - |i - j|/(R - 1)$ [1, 2]. The quadratic weights tend to weight disagreements just off the main diagonal more highly than Cicchetti weights, and the relative weighting of disagreements farther from the main diagonal is also higher with the quadratic weights. Clearly, these two weighting schemes share the minimal requirements cited above. The weighted kappa statistic then takes the form

$$\hat{\kappa}^{(\mathrm{w})} = \frac{\hat{p}_0^{(\mathrm{w})} - \hat{p}_{\mathrm{e}}^{(\mathrm{w})}}{1 - \hat{p}_{\mathrm{e}}^{(\mathrm{w})}}, \tag{5}$$

where $\hat{p}_0^{(\mathrm{w})} = \sum_{i=1}^{R} \sum_{j=1}^{R} w_{ij} \hat{p}_{ij}$ and $\hat{p}_{\mathrm{e}}^{(\mathrm{w})} = \sum_{i=1}^{R} \sum_{j=1}^{R} w_{ij} \hat{p}_{i\cdot} \hat{p}_{\cdot j}$. If $\overline{w}_{i\cdot} = \sum_{j=1}^{R} \hat{p}_{\cdot j} w_{ij}$ and $\overline{w}_{\cdot j} = \sum_{i=1}^{R} \hat{p}_{i\cdot} w_{ij}$, then the large-sample variance of $\hat{\kappa}^{(\mathrm{w})}$ is estimated by

$$\begin{aligned} &\widehat{\mathrm{var}}(\hat{\kappa}^{(\mathrm{w})}) \\ &= \left(\sum_{i=1}^{R} \sum_{j=1}^{R} \hat{p}_{ij} [w_{ij} - (\overline{w}_{i\cdot} + \overline{w}_{\cdot j})(1 - \hat{\kappa}^{(\mathrm{w})})]^2 \right. \\ &\quad \left. - [\hat{\kappa}^{(\mathrm{w})} - \hat{p}_{\mathrm{e}}^{(\mathrm{w})}(1 - \hat{\kappa}^{(\mathrm{w})})]^2 \right) \Big/ [x_{\cdot\cdot}^2 (1 - \hat{p}_{\mathrm{e}}^{(\mathrm{w})})^2] \end{aligned} \tag{6}$$

and, as before, tests and confidence intervals may be carried out and derived in the standard fashion assuming asymptotic normality of the quantity $(\hat{\kappa}^{(\mathrm{w})} - \kappa^{(\mathrm{w})})/[\widehat{\mathrm{var}}(\hat{\kappa}^{(\mathrm{w})})]^{1/2}$. As in the unweighted case, a variance estimate appropriate for testing $\mathrm{H}_0 : \kappa^{(\mathrm{w})} = 0$ may be derived by substituting $\hat{p}_{i\cdot} \hat{p}_{\cdot j}$ for $\hat{p}_{ij}$, and 0 for $\hat{\kappa}^{(\mathrm{w})}$ in (6).

We note in passing that the weighted kappa with quadratic weights has been shown to bear connections to the intraclass correlation coefficient. Suppose that with an ordinal outcome the categories are assigned the integers 1 through R from the "lowest" to "highest" categories, respectively, and assignment to these categories is taken to correspond to a realization of the appropriate integer value. Fleiss & Cohen [7] show that the intraclass correlation coefficient computed by treating these integer responses as coming from a Gaussian **general linear model** for a two-way **analysis of variance**, is asymptotically equivalent to the weighted kappa statistic with quadratic weights.

The Kappa Index for Multiple Observers

Thus far we have restricted consideration to the case of two applications of the classification procedure (e.g. two successive applications of a diagnostic test, two physicians carrying out successive diagnoses, etc.). In many situations, however, there are multiple (>2) applications and interest lies in measuring agreement on the basis of several applications. Fleiss [5] considered the particular problem in which a group of subjects was examined and classified by a fixed number of observers, but where it was not necessarily the same set of observers carrying out the assessments for each patient. Moreover, Fleiss [5] assumed that it was not possible to identify which observers were involved in examining the patients.

For this problem, we require some new notation. Let M denote the number of subjects, N denote the number of observers per subject, and R denote the number of categories as before. Therefore, NM classifications are to be made. Let n_{ij} denote the number of times the ith subject was assigned to the jth category. A measure of overall raw agreement for the assignments on the ith subject is given by

$$\hat{q}_i = \frac{\sum_{j=1}^{R} n_{ij}(n_{ij}-1)}{N(N-1)},$$

which can be interpreted as follows. With N observers per subjects there are $\binom{N}{2}$ possible pairs of assignments. There are $\binom{n_{ij}}{2}$ which agree on category j and hence a total number of $\sum_{j=1}^{R}\binom{n_{ij}}{2}$ pairs of assignments which concur altogether for the ith subject. Thus, (7) simply represents the proportion of all paired assignments on the ith subject for which there was agreement on the category. The overall measure of raw observed agreement over all subjects is then given by $\hat{q}_0 = M^{-1}\sum_{i=1}^{M}\hat{q}_i$, which equals

$$\hat{q}_0 = \frac{\sum_{i=1}^{M}\sum_{j=1}^{R} n_{ij}^2}{MN(N-1)} - \frac{1}{N-1}. \tag{8}$$

As before, however, some agreement would be expected among the observers simply by chance and the kappa statistic in this setting corrects for this. The expected level of agreement is computed by noting that

$$\hat{p}_j = \frac{\sum_{i=1}^{M} n_{ij}}{MN}$$

is the sample proportion of all assignments made to category j, with $\sum_{j=1}^{R}\hat{p}_j = 1$. So if pairs of observers were simply assigning subjects to categories at random and independently one can estimate that they would be expected to agree according to

$$\hat{p}_e = \sum_{j=1}^{R}\hat{p}_j^2, \tag{9}$$

then the kappa statistic is computed by correcting for chance in the usual way as

$$\hat{\kappa} = \frac{\hat{q}_0 - \hat{p}_e}{1-\hat{p}_e}. \tag{10}$$

The sample variance for (10) is derived by Fleiss et al. [9] to be

$$\widehat{\mathrm{var}}(\hat{\kappa}) = 2\left[\left(\sum_{j=1}^{R} p_j(1-p_j)\right)^2 - \sum_{j=1}^{R} p_j(1-p_j)(1-2p_j)\right] \Big/ MN(N-1)\left(\sum_{j=1}^{R} p_j(1-p_j)\right)^2 \tag{11}$$

and is typically used for tests or interval estimation in the standard fashion.

When the same set of raters assesses all subjects and individual raters scores are known, it is not possible to use the results of Fleiss [5] without ignoring the rater-specific assignments. For this context, Schouten [13] proposed the use of indices based on weighted sums of pairwise measures of observed and expected levels of agreement. In particular, for a given pair of raters and a given pair of categories, observed and expected measures of agreement may be computed as earlier. Then, for each pair of raters, a measure of overall observed agreement may be obtained by taking a weighted average of such measures over all pairwise combinations of categories. Given a corresponding measure of expected agreement, an overall kappa statistic can be computed in the usual fashion. Schouten [13] then described how to obtain kappa statistics reflecting agreement over all observers, agreement between a particular observer and the remaining observers, and agreement within and between subgroups of observers.

General Remarks

MaClure & Willett [12] provide a comprehensive review and effectively highlight a number of limitations of the kappa statistics. In particular, they stress that for ordinal data derived from categorizing underlying continuous responses, the kappa statistic depends heavily on the often arbitrary category definitions, raising questions about interpretability. They also suggest that the use of weights, while attractive in allowing for varying degrees of disagreement, introduces another component of subjectivity into the computation of kappa statistics. Perhaps the issue of

greatest debate is the so-called prevalence, or base-rate, problem of kappa statistics (*see* **Kappa and its Dependence on Marginal Rates**). Several other authors have examined critically the properties and interpretation of kappa statistics [10, 14, 15], and the debate of the merits and demerits continues unabated. Despite the apparent limitations, the kappa statistic enjoys widespread use in the medical literature and has been the focus of considerable statistical research.

RICHARD J. COOK

Kempthorne, Oscar

Born: January 31, 1919, in St. Tudy, Cornwall, England.
Died: November 15, 2000, in Annapolis, Maryland.

Oscar Kempthorne made important contributions to both statistics and statistical genetics. His books *The Design and Analysis of Experiments* [10] and *An Introduction to Genetic Statistics* [15], both published in the 1950s, brought him early recognition and have become classics, still much cited. He also had a deep interest in statistical inference, especially **randomization** theory. Kempthorne was profoundly influenced and inspired by R.A. **Fisher's** writings. He was a great admirer of Fisher, but not an uncritical one.

Born on a farm in Cornwall, the young Kempthorne soon decided that farm work was not for him. He worked hard to win needed scholarships to Cambridge, teaching himself additional mathematics in a then remote and backward county.

During his three years at Cambridge he became a Wrangler (equivalent to a first class honors) in the Mathematical Tripos examinations, which emphasized pure and applied mathematics. His interest in statistics was aroused in lectures by John Wishart and J.O. **Irwin**. Upon graduation in May 1940, Kempthorne, who had been reserved for technical work in World War II, spent a term assisting Irwin on a drug assay project. After a "useless" six months in the Ministry of Supply he joined Rothamsted Experimental Station, then directed by Frank Yates. Kempthorne worked with the influential zoologist and military advisor Solly Zuckerman on operations research associated with the war effort, and began his research career with papers on sampling (*see* **Sample Surveys in the Health Sciences**) and **experimental design** [9].

In 1946, Kempthorne was appointed to an allied mission set up by the U. S. Department of State to observe the Greek parliamentary elections and a plebiscite on whether George II was to be retained as King of the Hellenes. Kempthorne was the British member of a group of statisticians that included W. Edwards Deming and Jerzy **Neyman**. The group was led by the sampling expert Ray Jessen of the Iowa State College Statistical Laboratory. Two reports were published (e.g. [8]) and Kempthorne's life was changed when he was offered an associate professorship at Iowa State. His appointment, made possible by W.G. **Cochran's** resignation, continued the Statistical Laboratory's connection with Rothamsted Experimental Station begun some 20 years earlier when George **Snedecor** was one of the first in the United States to recognize the importance of Fisher's work.

Oscar Kempthorne arrived in Ames in January 1947 and was a key faculty member for the next 42 1/2 years. He soon became involved in consulting with agricultural research workers and continued his research on experimental design begun at Rothamsted [18]. Also, while teaching this subject, he published in 1952, the 600-page masterly Wiley text [10] which, though unchanged for many years, has been highly influential. Apart from its comprehensive coverage, the book was the first statistics text to use **matrix algebra** intensively. In the year of publication, Kempthorne was elected Fellow of the **American Statistical Association**, the Institute of Mathematical Statistics, and the American Association for the Advancement of Science (AAAS). A two-volume revision of the book is finally underway, in conjunction with Kempthorne's former student, Klaus Hinkelmann, who is preparing the second volume, the first [7] having appeared in 1994.

A special feature of [10] is the justification of the usual **analysis of variance F**-tests by their closeness to corresponding **randomization tests**. This point is elaborated in [13, 22], with due recognition of Fisher's famous illustration for the paired t-test [2] (*see* **Student's *t* Statistics**) and the pioneering work of Welch [28] and Pitman [24].

The design of experiments merged with Kempthorne's growing interest in genetic statistics in a series of papers on diallel crosses, especially when there were too many pure lines for all possible crosses to be tested [14, 17, 20]. Another way such merging occurred was via the transfer of ideas from **factorial experimentation** to genetics. Thus, if observations on a quantitative character are affected by many loci and there is random mating and independent assortment, the total effect of a **genotype** can be expressed as a sum of main effects and **interactions**. Main effects are those of individual alleles, two-way interactions between alleles are dominance deviations, if the alleles are at the same locus, and additive $\times$ additive effects if they are from different loci. The next term in the sum is an additive $\times$ dominance effect, which is a three-way interaction between an

allele at one locus and a pair of alleles at a second locus. Proceeding in this way, one is led to an expression for the total variance among genotypes as the sum of **variance components**, each of which is associated with main effects or particular interactions.

It is also the case that genetic covariances between relatives are expressible as linear combinations of the aforementioned variance components (*see* **Genetic Correlations and Covariances**). The coefficients are probabilities of identity by descent of genes or sets of genes, chosen appropriately to fit the degree of relationship between the relatives.

Fisher had, in 1918, expressed the sum of variance components, other than those associated with main effects of alleles and dominance deviations, as a single term, the epistatic variance. He had also derived expressions for covariances between relatives, involving the additive and dominance components of variance, in some special cases. Kempthorne [11, 12] generalized this work by partitioning the epistatic variance into genetically interpretable components associated with two-way and higher-order interactions, as described above. These terms also appeared in expressions for covariances between relatives. Another of his contributions in this regard was a clear and elegant notation, which easily allowed for multiple alleles at individual loci, rather than only two.

Kempthorne's research on covariances between relatives was summarized in his text [15] on genetic statistics. It was also described therein how an experimenter could estimate genetic variance components from mean squares in analysis of variance tables. Another feature of this book was the first presentation in a textbook of Sewall Wright's results on inbreeding theory [29] in terms of probabilities of **identity** by descent, rather than path coefficients (*see* **Path Analysis in Genetics**).

Kempthorne was also interested in "Fisher's Fundamental Theorem of Natural Selection". An attempt to interpret the cryptic description of this theorem in Fisher's *The Genetical Theory of Natural Selection* [3] is in his text. Further work on this subject is in three joint papers with E. Pollak [21, 25, 26], in which attempts were made to explicitly spell out mathematical consequences of definitions of fitness in populations that either have discrete generations or are age-structured. It was found, for example, in [21], that some of these definitions lead to different consequences than others in the writings of Fisher and other authors.

Another aspect of Kempthorne's thinking on genetics was his concern over misuses of quantitative genetic theory (*see* **Polygenic Inheritance**) by people who concluded that aid, such as "head start", to members of some socioeconomic or racial groups, is useless. Supporters of this view assert that the low average scores on IQ tests of people in these groups are largely due to genetic deficiencies. To support this assertion, they claim that the **heritability**, or the genetically transmissible fraction of the total variance, of the attribute IQ is high. The usual methods for estimating this fraction are indeed applicable to populations such as those of crops or livestock, which are under the control of experimenters. Kempthorne pointed out, however, that this approach is very questionable for populations of humans, who are not randomly assigned to environments [16, 23]. This is because the total variance among phenotypes contains, in this case, the covariance between genotypes and environments, as well as a variance component associated with variability among environments within genotypic groups.

These extra terms are eliminated by appropriately designed experiments with crops or livestock. Mathematical details are given by Emigh [1]. Kempthorne [16] also attacks the notion that data analysis can establish causation and "that one can establish effects of an intervention process when it does not occur".

Throughout his long career Kempthorne was struggling to understand the logic of theories of **inference**. The philosophers were ultimately a disappointment and Fisher, while much admired, remained obscure on many points. Perhaps the best summary of Kempthorne's views on Fisher's statistical writings is given in just two pages of [27]. He is deeply puzzled by the discrepancy between Fisher's strong advocacy of randomization, a procedure resting on satisfactory long-run behavior, and the complete lack of reference to long-run considerations in Fisher's theory of inference. Not that the Neyman–**Pearson** theory escapes questioning. In [19], a text for seniors and beginning graduate students, a discussion of tests of hypotheses (*see* **Hypothesis Testing**) concludes with the statement that apparently the choice of the size α of the test "has to be based on **decision theory**, with introduction of prior opinion and loss function".

A man of wide interests, Kempthorne was much sought after as a speaker. His provocative style was a further attraction. He was active in editorial work on several journals and was chief organizer and

proceedings editor of some major conferences. The offices held by Kempthorne included terms as president of the Biometric Society (*see* **International Biometric Society (IBS)**), Eastern North American Region, in 1961, as chairman, Section U (Statistics) of AAAS, in 1981, and as president of the Institute of Mathematical Statistics, 1984 to 1986.

For his researches, Kempthorne received the Sc.D. degree from Cambridge University in 1960. In 1965, he was elected to membership of the International Statistical Institute and in 1988, to Honorary Fellow of the **Royal Statistical Society**.

Kempthorne brought energy and flair to all his activities. He was a challenging teacher. Of the 42 PhD students he directed, 12 so far have become Fellows of the American Statistical Association.

For further information and insights, see the Festschrift [5], the interview [4], and the memorial article [6], the last containing a complete bibliography.

HERBERT A. DAVID & EDWARD POLLAK

Kendall, Maurice George

Born: September 6, 1907, in Kettering, UK.
Died: March 29, 1983, in Redhill, UK.

Reproduced by permission of the Royal Statistical Society

Despite showing only a belated interest in mathematics at school, Maurice Kendall obtained a scholarship to read mathematics at St John's College in Cambridge. He played cricket for his college and was a keen chess player, and gained a first class in both parts of the mathematical tripos.

After graduating, he entered the administrative class of the Civil Service. Here, at the Ministry of Agriculture and Fisheries, he was responsible for statistical work. A chance meeting with **G. Udny Yule** in 1935 led to Kendall becoming co-author of a revision of Yule's classic textbook [9]. In 1941 Kendall became statistician to the British Chamber of Shipping, and in the following years he published many papers on theoretical statistics. This work was wide-ranging, but major themes were the theory of **rank correlation** coefficients (one of which he discovered in 1938 and now bears his name), **paired comparison** experiments, k statistics, and **time series**. At the same time, Kendall was working on his *Advanced Theory of Statistics*, the first advanced textbook on the subject. This was published as two volumes in 1943 and 1946 [1].

He was appointed professor of statistics at the London School of Economics in 1949, where he founded a research techniques division which carried out large sample surveys. In addition to this work and further theoretical research, in this period Kendall published the first important dictionary of statistical terms [4] and worked on the first comprehensive bibliography of statistical literature [5].

In 1961, during his presidency of the **Royal Statistical Society**, he again changed career, becoming scientific director (and ultimately chairman) of a computer consultancy (later called SCICON). During this spell he completed the rewriting of his influential book [1] into three volumes [6].

On retiring in 1972, Kendall embarked on another, testing career as the first director of the World Fertility Survey. This was a huge multinational sample survey project, which fully tested his extraordinary organizational powers. Ill health forced his retirement from this position in 1980.

Kendall was a prolific author, producing 17 books and around 75 papers on theoretical statistics alone. Seventeen of his papers are reprinted in [7], which also contains a bibliography. His other books included [2] and [3].

His interest in language was demonstrated by his literary style – "lucid, balanced, often ironical" [8] – but also by the word play in the spoof story of Lamia Gurdleneck and Sara Nuttal by K.A.C. Manderville in Volume 2 of *The Advanced Theory of Statistics* [6], in which all the names are anagrams of either Maurice (G.) Kendall or Alan Stuart, and his Longfellow pastiche *Hiawatha Designs an Experiment* (reprinted in [1]).

Kendall was much honored. He received the Guy medal in gold from the Royal Statistical Society. In 1974 he was knighted for his services to statistics, and on retiring from the World Fertility Survey he was awarded the United Nations peace medal.

DOUGLAS G. ALTMAN

Kin–Cohort Studies

The basic idea behind a kin–cohort design is that one can estimate **penetrance** by genotyping a set of unrelated individuals and obtaining phenotype information about their relatives [16, 18]. In an important, albeit narrow set of circumstances, a kin–cohort analysis has some distinct advantages over more conventional applications of **segregation analysis** and epidemiologic designs used to estimate the penetrance of a **genotype** for its phenotype.

A kin–cohort analysis is characterized by an unusual feature [18]. The phenotypes of the individuals who are genotyped (we will call them the volunteers) are not used directly for estimating the penetrance because of the difficulty in determining the pattern of **ascertainment**; instead, the penetrance is estimated from the phenotypes of the volunteers' relatives, whose genotypes are not determined directly, but are inferred from the genotypes of the volunteers.

These characteristics give the kin–cohort approach its notable strengths and its notable weaknesses. A kin–cohort study can be implemented quickly and economically. Because the kin–cohort procedure does not (necessarily) focus on members of high-risk families, the penetrance estimate may be applicable to those who carry the **mutation**, regardless of whether they have extensive family history. The ability to study multiple phenotypes simultaneously is a further advantage; the range of questions that can be addressed from a kin–cohort study is demonstrated below. A major disadvantage is that there must be a way to determine the phenotypes of the relatives of the genotyped individuals accurately; this is easier to accomplish where there is a complete disease registry against which relatives can be checked [17] or where there is little stigma attached to a disease phenotype so that each relative is likely to know about another's diagnosis. A second major disadvantage arises from reliance on volunteers who may be more likely to participate if they themselves or members of their families have been affected by the disease being studied.

The kin–cohort method can exploit the existence of an identifiable population with a higher than average frequency of the at-risk genotype. For example, the prevalence in the US of carriers of any of the BRCA1 and BRCA2 alleles (*see* **Gene**) that confer excess risk of breast and ovary cancer is probably less than 0.5%, while the frequency of three BRCA1 and BRCA2 founder mutations in Ashkenazi Jews, an endogamous ethnic group descended from a small number of founders, is close to 2% [14]. A founder population (*see* **Founder Effect**) has the additional advantage of not needing to sequence the entire gene in each individual to search for mutations [15].

If volunteering is independent of genotype, conditional on phenotype, then the disease history of the volunteers can be incorporated into the estimate of penetrance [6]. This assumption would be violated if known carriers were more or less likely to volunteer or if survival after diagnosis depended on genotype; the survival of the relatives after diagnosis can be related to mutation status without causing bias because their disease phenotype is reported by the volunteer. In extensions of the original approach, phenotypes of volunteers can be used indirectly for estimating penetrance under some assumptions [6].

Origin

The special characteristics of the kin–cohort design are best considered in the context of the Washington Ashkenazi Study (WAS), for which it was first conceived and implemented. Earlier, Struewing et al. [15] had discovered the 185delAG mutation in BRCA1 in Ashkenazi breast/ovary cancer families; they subsequently noted that the mutation had a high enough frequency [14] in Jews to make a study of its effects worthwhile.

Jeff Struewing, Patricia Hartge, Larry Brody, Margaret Tucker, and Sholom Wacholder of the National Institutes of Health, Bethesda, MD, planned a cross-sectional study of Ashkenazi Jewish volunteers in the Washington, DC, area. The investigators noted that a study of allele **prevalence** could be used to estimate penetrance in a population without the high levels of family history seen in the Breast Cancer Linkage Consortium (BCLC) families used to derive the earlier breast cancer penetrance estimate of 85% by age 70 [4]. They recognized that if BRCA1 was 100% penetrant, over 50% of the carriers' mothers would be affected eventually, but that if the mutation were unrelated to risk, the carriers' and noncarriers' mothers should show little difference in risk, so there must be information about penetrance in the data from the study. Therefore, they determined that the main goal

of the study would be to estimate the penetrance of the 185delAG BRCA1 carriers for breast cancer in a setting without large numbers of multiply affected families. This study could address a key question: Would the penetrance estimate in carrier women from less loaded family families be as high as the 85% estimated by the BCLC? After the study began, the investigators added genotyping of two other newly identified founder mutations to the focus of the study.

The investigators developed a simple method-of-moments argument to develop an estimator of penetrance that could be applied to a study of volunteers from whom information about their relatives' years of birth and death and diagnosis of disease, if applicable, was obtained [18]. The main ideas behind the estimator are:

1. The disease experience of the volunteers themselves should not be used directly to estimate penetrance if the disease is often fatal. There would be a substantial number of individuals in the study population who had developed disease and had died and thus would not contribute to the count of disease. Even if there is no mortality from disease, affected individuals may be more likely to volunteer, leading to upward bias in the estimation of penetrance. Estimation of **relative risk** may be **unbiased**, however, unless survival after diagnosis or participation depends on genotype. The distribution of genotypes of the volunteers is used indirectly in the estimation of penetrance [16, 18]. When the **likelihood** approach of Gail et al. [6] incorporates the phenotypes of the volunteers, the ascertainment based on disease status does not lead to bias if the genotype is unrelated to volunteering, conditional on phenotype, and to time of survival after diagnosis.
2. There is information about the genotype of relatives from the genotypes of the volunteers. Simple rules of Mendelian inheritance (*see* **Mendel's Laws**) can be used to infer the relative's genotype if the mode of inheritance and the allele frequency are known. Essentially, since the allele frequency is low (and could be estimated from the study; *see* **Gene Frequency Estimation**), slightly more than half of the first-degree relatives of mutation carriers are themselves carriers, while only a small fraction (close to half of the carrier frequency) of first-degree relatives of noncarriers are themselves carriers (*see* **Genetic Counseling**). Thus, the **cumulative incidence** function for disease (time from birth until disease) among the relatives of carriers and among the relatives of noncarriers is each weighted average of the survival functions in carriers and noncarriers, but with different weights. The weights themselves are proportional to the probabilities of the relative's genotype, conditional on the volunteer's (known) genotype, and can be derived by Mendelian principles if the mode of inheritance is known (*see* **Segregation Analysis, Classical**) [18]. Because the mutation is rare, solving for two equations in two unknowns at any specified age gives an estimate of the survival functions for carriers and noncarriers from the allele frequency estimate and the survival functions of the relatives of carriers and noncarriers. A bootstrap, with resampling based on family, can be used to estimate the **variance** or point-wise **confidence intervals** (*see* **Bootstrap Method**) [16, 18].

The name "kin–cohort" derives from the use of cohorts of relatives of the volunteers to estimate penetrance.

Several assumptions need to be made to operationalize the plan; they might not be perfectly satisfied in a study that was actually feasible.

1. The volunteers must have the same level of family history and the same allele frequency as a random sample. The investigators in the WAS were not convinced that they could choose a random sample of the Jewish population in an American setting economically. Instead, they relied on volunteers; they took advantage of the community interest in breast cancer. This had the unfortunate consequence, most likely, that the penetrance estimate was too high, since those with a family history of breast cancer were more likely to volunteer than those without; the extent of the **bias** may have been mitigated to some extent by the concern in the community about breast cancer, even in those without a personal or family history.
2. Reporting of year of birth, and year of death and diagnosis of disease, if applicable, must be accurate and complete for each relative. Since the population was well-educated and breast

cancer seems not to stigmatize those affected, the authors felt that most of the reports on first-degree relatives would be complete. Reporting of ovarian cancer, particularly in parents, seemed more difficult because the exact site of a mother's reproductive-tract-organ cancer may not have been known to children.

3. The penetrance from the mutations found in the study population must be the same as the average penetrance over all mutations in the population to which one wishes to extrapolate. If the Ashkenazi founder mutations studied in the WAS are more penetrant than other mutations, or if the risk of breast cancer for any mutation among the Jewish women were higher than among non-Jewish women, the estimate from the WAS would be biased upwards *vis-à-vis* women with other mutations or non-Jewish women.
4. The distribution of any common environmental or genetic factor that is an important modifier of risk of disease and can affect penetrance estimates must be the same in the study population and in the population to which the estimates are to be applied (*see* **Gene-environment Interaction**).
5. It is the allele frequency at conception that needs to be estimated for the Mendelian arithmetic to be accurate. The estimates of penetrance may be biased if the allele frequency changes with age, perhaps due to survival differences from the disease under study or other factors.
6. Like **linkage** and segregation (and conditional and unconditional **logistic regression**), confidence intervals and test statistics from kin–cohort data depend on the assumption of conditional (on genotype) independence of the disease within families. In reports from the WAS [16, 18] the authors used a bootstrap approach where the sampling unit was the family to address this problem. Chatterjee & Wacholder [2] proposed a **marginal likelihood** approach to remove, or at least reduce, the bias in penetrance estimation due to residual **familial correlation**.
7. To estimate the survival curves for the relatives of noncarriers and carriers, one needs to assume that censoring does not depend on the unknown genotype of the relatives. The penetrance estimates, therefore, also depend on the assumption of no competing risks.

The features of the WAS carried out at the National Cancer Institute (NCI) were chosen by the investigators to be able to apply this method to estimate penetrance of three founder mutations [16]. Jewish volunteers were solicited through Jewish communal organizations, media publicity, and advertisements targeted at Jews. Each volunteer gave consent for genotyping and was asked about the year of birth and death and sites and dates of any cancer diagnoses in all first-degree relatives.

The main results of the investigation are reported in Struewing et al. [16]. Kaplan–Meier estimates of cumulative risk of breast cancer revealed a clear difference between breast cancer incidence in first-degree relatives of carriers and noncarriers. The method-of-moments estimator for cumulative incidence in carriers (penetrance) and noncarriers was substantially lower than the BCLC, particularly at older ages [4]. The authors noted that their estimate of breast cancer penetrance was probably too high because relatives of women with breast cancer were more likely to participate. But the important message from their paper was that the penetrance in a population without extreme family history is lower than in families with multiply affected individuals, even assuming correction for ascertainment. Indeed, other estimates based on women with less extensive family history [7, 17, 19] have been consistently below those from the BCLC [4]. The discrepancy may be due, in part, to the difficulty of correcting completely for ascertainment in a study with data from many collaborators; regardless of the minimal requirements to include a family, it seems reasonable that investigators tried increasingly hard to get families with increasing numbers of affected. Furthermore, and perhaps more important, modifier genes that segregate within families or environmental factors that modify risk and aggregate in families may lead to variation in penetrance even among different families with the same mutation; if so, a study that chose families on the basis of a high number of affected members would selectively pick families with higher risk, leading to a higher estimate of penetrance than a more population-based study [18].

The methods-of-equations estimator used in the early reports [16, 18] has several defects, notably the possibility, realized in the original report, that the estimate of the survival function might not be monotone. Nevertheless, this seed concept opened a floodgate of scientific and methodologic investigation.

Methodologic Extensions

Gail et al. considered a **likelihood** framework for the estimation of penetrance and studied the sample size needed for the kin–cohort design, or as they called it, a "genotyped proband design" [6]. They also considered incorporating the volunteer's disease history data into the analysis after accounting for possible differential participation by their disease status. In the likelihood approach, the information on penetrance from the use of the phenotypes of genotyped individuals is the risk ratio for the effect of the genotype. It therefore requires the same assumptions as in a cross-sectional or, at least, a **case–control** study; in particular, because the study uses prevalent cases, survival after diagnosis of disease cannot be related to genotype.

The likelihood formulation [6], which avoids the possibility of nonincreasing penetrance estimates, forms the basis for subsequent theoretical work. Moore et al. [10] considered piecewise exponential models for carriers' and noncarriers' survival curves. They found that optimization of the likelihood becomes difficult due to the complex nature of the volunteers' contribution to the likelihood, particularly for a large number of hazard intervals. They developed a **pseudo-likelihood** approach that iterates between estimating the penetrance parameters from the relatives' contributions to the likelihood and estimating the allele frequency from the volunteers' contributions to the likelihood. They did not use the phenotypes of the volunteers directly in estimating penetrance. Chatterjee & Wacholder [2] developed a marginal likelihood that treats each relative of the volunteer individually rather than jointly, as considered by Gail et al. [5]. This method had several advantages: (a) it enjoys flexibility of the likelihood approach and can correct for the monotonicity problems Wacholder et al.'s original method [16, 18] had; (b) it is computationally simpler and faster than the full likelihood approach; and (c) under the assumptions of a kin–cohort analysis listed above it produces an unbiased estimate of penetrance even if there are sources of familial aggregation of the disease other than the genes being studied (*see* **Genetic Correlations and Covariances**). A joint likelihood approach under any specific assumption of the residual correlation, although it could be slightly more efficient than the marginal likelihood approach, will produce a biased estimate of the penetrance when the assumed degree of residual correlation is wrong. However, a disadvantage of the marginal likelihood approach is that it is unclear how to account for complex ascertainment in this approach as can be done in a joint likelihood approach. Kaufman [8] took a traditional segregation analysis approach to the kin–cohort data. He used the families of 114 carrier volunteers as his pedigrees. Using the likelihood framework of Gail et al. [5] Carroll et al. developed a score test for the existence of residual familial aggregation that incorporates the volunteer's disease history data into the analysis [1]. Using a multivariate survival modeling approach, Chatterjee et al. [3] showed how one can quantify and estimate the residual familial correlation from the kin–cohort data.

Thus, a kin–cohort design can be seen as a minimalist approach to segregation analysis. In its extreme idealized form, the data available are the genotypes of a random sample of unrelated individuals and the phenotypes of their relatives. The method-of-moments analysis, with its comparison of the survival times to disease in the relatives of carriers and noncarriers, provides some additional insight beyond the segregation analysis.

Scientific Applications

Thorlacius et al. [17] was able to apply a kin–cohort design without relying on volunteers or reporting of relatives' phenotypes. Genotyping was performed from stored pathology tissue from breast cancer cases in Iceland. The family registry and cancer registry were linked to identify relatives and when and whether they developed cancer. Carriers of the 999delT founder mutation in BRCA2 were found to have a 37% penetrance by age 70; the lower penetrance estimate could be due to a lower penetrance from BRCA2 mutations than from BRCA1 generally [13], a founder mutation less penetrant than others, or to the absence of bias from volunteering and self-report.

Several other questions – clinical and etiologic – can be addressed directly from a kin–cohort design or by extensions. Lee et al. [9] investigated survival after diagnosis using the WAS data. Woodage et al. [20] explored whether there was excess risk associated with a founder mutation in the APC gene among Ashkenazi Jews using the WAS data. Moslehi et al. [11] and Risch et al. [12] have estimated penetrance for ovarian cancer using kin–cohort as well.

Design Questions

Many questions about the design of studies using the kin–cohort method remain open. Gail et al. [5] examine the degree of bias from various violations of assumptions. The tables from Gail et al. [6] can be used to compare the numbers of genotypes and numbers of individuals needed to estimate penetrance with a given precision; they also consider a variant design where some of the volunteers' relatives are also genotyped. However, in using these tables, one must consider that a special population with a high allele frequency is an ideal setting for kin–cohort but may not be practicable for a cohort or **case–control** study; also, the tables ignore residual familial aggregation, as they note [6], and use phenotypes of the genotyped individuals to estimate penetrance, which requires the attendant assumptions noted above.

A kin–cohort analysis of subjects in a case–control or cohort study may be feasible if genotyping and the collection of family histories have already been completed. The estimate of penetrance based entirely or extensively on affected cases is likely to be slightly higher than one based on controls only or on a random sample if there is any residual familial aggregation of risk, because families with more affected will be selectively included [18].

Kolmogorov is widely considered to be one of the greatest mathematicians of the twentieth century. He made important contributions to the theory of functions, topology, **probability theory**, statistics, logic, theory of dynamic systems, information theory, ergodic theory, theory of **algorithms**, mathematical education, and various applications of the above fields of mathematics. His works were mainly concerned with the intermediate areas between several "traditional" branches of mathematics and its applications, and he used fresh and striking ideas illuminating the relations between them. In the field of probability theory and statistics, Kolmogorov's main achievement is perhaps the introduction of the axioms and the clarification, through a rigorous approach, of various basic concepts. He was also famous as the leader of a school of numerous researchers, mainly his students and associates from the former USSR and Eastern block countries, whose work shaped probability theory (and to a lesser extent mathematical statistics) through the 1950s and 1960s.

During his career he held important administrative posts in the Moscow State (Lomonossov) University (MSU) and the USSR Academy of Sciences, including the headship of the Mechanics and Mathematics Department of the MSU, the Laboratory of Statistical Methods of MSU, and the chairmanship of the Mathematics Section of the Academy. Kolmogorov's personality had a great impact on everyone who came into contact with him, and in particular on hundreds of pupils at the specialist mathematical school for gifted children gathered from around the former Soviet Union, which he ran from the 1960s to the early 1980s.

In mathematical statistics, Kolmogorov is acclaimed worldwide for introducing the so-called **Kolmogorov–Smirnov statistic**. Based on this statistic (and its modifications), the Kolmogorov–Smirnov type tests of **goodness of fit** have been developed, which are among the most widely used in statistical practice. The original references are [5], [8], [12], and [22–24], a detailed account of work done before 1970 can be found in [3], and further developments are commented on in [7].

In Soviet statistics, he is also considered as a founder of the modern approach to the **least squares** method, and his papers [13, 18] are widely quoted. In the West these papers became known much later (see, for example, [20] and [21]). The third direction stemming from Kolmogorov's theoretical work is related to **unbiased** estimators and their relation to **sufficient statistics** [15]. The first application of his approach was connected with industrial quality inspection and discussed in the (almost unobtainable) brochure [14]; it was further developed in [1] (for recent references, see [2]).

Kolmogorov was deeply interested in applied statistics, specifically in regard to the analysis of genetic experiments, turbulence, weather forecasting, analysis of geologic deposits, analysis of artillery fire precision (research conducted before and during the early part of World War II), and analysis of Russian poetry. Many of his ideas were later used in practical recommendations in various fields, including the Soviet nuclear and space programs, although he was never directly involved in any of these projects (unlike most of his contemporaries of a similar stature in the USSR, a fact of which he was rather proud). He was also a keen and original popularizer of statistics, notably through his articles for the *Great Soviet*

Encyclopedia. In biostatistics, he was active in commenting on statistical confirmation of **Mendel's law** of genetics (see below) as well as in introducing and developing various mathematical models. For example, in [19] a nonlinear equation was analyzed rigorously in detail, describing the spread of an "advantageous gene". A similar equation was simultaneously proposed by **Fisher** [4], who predicted the long-term behavior of its solution, but did not provide a formal proof; this was done in [19] and subsequent papers. The equations studied in [19] and [4] are now often called Fisher or Kolmogorov–Petrovsky–Piskunov equations (another frequently used name is reaction–diffusion equations); their popularity in combustion theory far surpassed that in the analysis of biologic populations. Another notion connected with Kolmogorov's long-time interest in genetics was that of a **branching process**, introduced for the first time in [17], where the term "branching random processes" was first introduced (for related statistical considerations, see [9], [10], and [16]); again, the popularity of this concept in other applications exceeded that in the original field of theoretical biology.

Kolmogorov's participation in the discussion of the validity of Mendel's laws deserves a detailed account not only as being directly relevant to biostatistics, but also to illustrate the relation between statistics and "real life" at that time. The 1930s and the years following were a period of sharp struggle in Soviet biology. A group led by the infamous T.D. Lysenko started a ferocious campaign against Mendel's theory (and genetics in general) and its use in practice. Capitalizing on the support by Soviet officialdom, the followers of Lysenko denounced genetics as a "bourgeois pseudo-science", useless (or even harmful) for socialism and the future communist society. Their campaigning created an atmosphere of hysteria (matched by the general fear of repression of the period); as a result, many Soviet geneticists lost their jobs and some their lives. Kolmogorov had friendly ties with many of the leading USSR geneticists and was deeply interested in their experiments. In 1939 a collaborator of Lysenko published the results of a series of experiments with plants claiming that they disproved Mendel's 3:1 law. Kolmogorov [11] analyzed her data and, by performing a straightforward **chi-square test**, discovered that the experiments actually confirmed the 3:1 law. Given the circumstances of the time, this was an extraordinarily bold step. The paper [11] provoked an angry reply by Lysenko and his cronies, but luckily it did not cause serious harm to Kolmogorov. [At the same time similar experiments were conducted by another researcher, a follower of Vavilov, the leader of Soviet genetics (by that time dismissed from his positions and replaced by Lysenko; soon after, Vavilov himself was arrested and later died in prison in inhumane conditions). When the results of this series were shown to Kolmogorov, he immediately spotted that the author had "doctored" the data to make them fit exactly to the theoretical curve. I thank Prof. V.M. Tikhomirov, from Moscow State University, for providing me with this episode.] For a detailed account, see, for example, [6] and [25].

This and other episodes served to deter Kolmogorov from further experimentation in the subject. However, he kept a deep interest in biostatistics: in the 1960s he organized the department of medical statistics in the Laboratory of Statistical Methods and took an active part in its work. His ideas are widely used in medical statistical practice, mostly in Russia, but their detailed account still awaits publication.

YURII SUHOV

Kolmogorov–Smirnov and Cramer–Von Mises Tests in Survival Analysis

The classical one-sample Kolmogorov goodness-of-fit statistic and the two-sample Smirnov statistic are well-known general statistical procedures. They are collectively known as **Kolmogorov–Smirnov (K–S) tests**. Using these techniques in **survival analysis**, modifications have to be made to deal with **censored data**. There are various types of censoring. What is generally known as type I involves observations being known precisely if they are less than a fixed value and only known to exceed the value otherwise. For so-called type II censoring, the smallest r, say, observations out of a possible n are observed. These definitions of censoring are somewhat restricted in terms of survival analysis. Generally, it is assumed that censoring is random for each observation, and special modifications and assumptions are required. For further discussions of censoring see Michael & Schucany [7] for a succinct account, or Andersen et al. [1] for a full account of censoring in the context of survival data.

For type I or type II censoring, adaptations of the Kolmogorov statistic have been made by Barr & Davidson [2], where small-sample percentage points are tabulated; see also Dufour & Maag [3] for modified statistics which can be used with the asymptotic percentage points found by Koziol & Byar [6].

For survival analysis the random censoring case is more commonly met. Fleming et al. [4] proposed one sample and two sample K–S type procedures with randomly censored data. Efficient procedures exist for comparing two populations, such as the **logrank test** for **proportional hazards** and Gehan–Wilcoxon tests (*see* **Nonparametric Methods**), when survival distributions have **proportional odds**. For some alternatives, such as where the difference between two survival curves occurs primarily at a given time, the K–S two-sample statistic should have good power. Examples of this situation occur, for example, in a treatment regime where individuals might obtain short-term benefits but when compared with controls there is no benefit in the longer term. Other examples for which the logrank and Gehan–Wilcoxon tests would have little power include the class of models known as *crossing-hazards*.

Fleming et al. [4] modified the K–S procedures so as to deal with randomly right-censored data. Asymptotic results are obtained for the censoring mechanism being independent of the survival time. The K–S statistics are defined in terms of the difference of two distribution functions, $F_u(t)$ and $F_v(t)$, where $F_u(t)$ is the empirical (sample) distribution function (edf) and, for the one-sample goodness-of-fit statistic, $F_v(t)$ is a hypothesized distribution function and, for the two-sample case, $F_v(t)$ is the edf of the second sample. The classical two-sided K–S statistic is

$$D = \sup_t |F_u(t) - F_v(t)|$$

or, alternatively, with survivor functions $S_\cdot(\cdot)$ replacing distribution functions $F_\cdot(\cdot)$:

$$D = \sup_t |S_u(t) - S_v(t)|.$$

To obtain statistics which can deal with censored samples, Fleming et al. [4] modify the statistic D and they give computing formulas for the one-sample and two-sample statistics. They also give a simple formula to calculate ***P* values** based on the asymptotic distribution of the statistic, which, in **simulation** studies, were found to be conservative for the modified two-sample Smirnov statistic with heavily censored data in small samples. Later work of Guilbaud [5] gives exact small sample percentage points for the K–S type statistic.

In **Monte Carlo** simulations, Fleming et al. [4] investigate the power of the modified Smirnov two-sample statistic and compare it with Gehan–Wilcoxon and logrank statistics for various alternatives. For those alternatives purposely designed to have substantial differences between the two survivor functions at a given time and not necessarily at other times, the modified Smirnov statistic had good power. It is suggested that the modified statistics should be used in conjunction with the Gehan–Wilcoxon and logrank statistics and, of course, plots of the survivor functions.

Further results on the **power** of the modified Smirnov statistic are given by Stablein & Koutrouvelis [10] who consider crossing hazards alternatives. For such alternatives the modified Smirnov statistic has very good power, considerably in excess of the logrank statistic.

Schumacher [9] also investigates a Smirnov statistic (called by the author a K–S statistic), which has

as its asymptotic distribution the supremum of the Brownian bridge (*see* **Brownian Motion and Diffusion Processes**). In simulation studies the finite sample distributions are found to converge slowly to the asymptotic distribution, and consequently the author is not keen to recommend their use. However, with cheap computing it is a straightforward matter to simulate such statistics, and this is a harsh conclusion.

In the book by Andersen et al. [1] further references are given to more recent work and the authors take an approach which defines statistics having their asymptotic distribution given by distributions derived from the Brownian bridge.

Cramér–von Mises (C–VM) statistics can be defined for the one-sample problem for types I and II censoring as described above. In general form they are defined by

$$\omega^2 = \int [F_u(t) - F_v(t)]^2 \psi(t)\, \mathrm{d}t,$$

where the same notation is used as above for the K–S statistics and ψ is a weight function. Pettitt & Stephens [8] modify the C–VM statistic to deal with this type of censoring and give computing formulas for the one-sample statistics and tabulate asymptotic distributions when the null hypothesis completely determines the survival function.

Koziol & Green [6] introduce a Cramér–von Mises statistic to test the **goodness of fit** for randomly censored data survival times. They also assume independent censoring where the survival function of the censoring distribution is that of the survival times raised to a positive power, β. They find the asymptotic distribution of the C–VM statistic, which is quite sensitive to the value of β. They discuss how to estimate β from the sample. However, this restriction seems rather harsh for application to survival data found in practice.

Schumacher [9] considers C–VM statistics for the two-sample problem which have their asymptotic distributions given by the standard form, i.e. the integral of the square of the Brownian bridge, and in simulation studies finds that the asymptotic distribution is acceptable for small samples. In a power study, the two-sample C–VM statistic was found to have good power for a crossing survival curve alternative and an "early difference" case. Schumacher [9] also gives references to earlier works and tables of percentage points of various functionals of the Brownian bridge which arise as asymptotic distributions of K–S and C–VM type test statistics.

Values of the various goodness-of-fit and two-sample statistics should be enhanced by plots of data, or vice versa, and Michael & Schucany [7] give details of a number of plots for censored data.

In conclusion, the K–S and C–VM statistics provide useful procedures to detect differences, either in the one- or two-sample cases, which are less likely to be detected using tests based on proportional hazards or proportional odds assumptions.

ANTHONY N. PETTITT

Kolmogorov–Smirnov Test

Consider two independent groups of subjects. To be concrete, suppose an experimental group consists of sons of alcoholic fathers, and each subject consumes a precise amount of alcohol. Suppose some outcome, X, is measured, such as hangover symptoms, and let Y be the outcome for a control group. Let $F(x)$ be the probability that a randomly sampled subject from the experimental group gets a score less than or equal to x. Similarly, let $G(x)$ be the probability that a randomly sampled subject from the control group gets a score less than or equal to x. The Kolmogorov distance between these two distributions is the maximum possible value of $|F(x) - G(x)|$, the maximum being taken over all possible values of x. If the distributions are identical, meaning that $F(x) = G(x)$ for all possible values of x, then the Kolmogorov distance is zero. From a graphical point of view the Kolmogorov distance is the largest vertical distance between the two cumulative distribution functions.

Kolmogorov-type tests are methods for comparing distributions that are based on the Kolmogorov distance function. In some cases one of the distributions might be specified. For example, it might be hypothesized that $F(x)$ is a normal distribution with specified mean and variance, and the goal might be to determine whether this hypothesis is reasonable based on observations that are available. This hypothesis can be tested with what is called a Kolmogorov test. A Kolmogorov–Smirnov test is a Kolmogorov-type test where the goal is to compare two unknown distributions. That is, $F(x)$ and $G(x)$ are not known for any x, but they can be estimated based on randomly sampled subjects from each group, and the goal is to test $H_0 : F(x) = G(x)$, for any x, the hypothesis that the two distributions are identical.

Let $X_1, \ldots, X_m$ be a random sample of observations from the first group, let $Y_1, \ldots, Y_n$ be a random sample from the second, and let $Z_1, \ldots, Z_N$ be the pooled observations, where $N = n + m$. That is, $Z_i = X_i, i = 1, \ldots, m$, and $Z_{n+i} = Y_i, i = 1, \ldots, n$. For any x, let $a_i = 1$ if $X_i \leq x$, otherwise $a_i = 0$. Similarly, let $b_i = 1$ if $Y_i \leq x$, otherwise $b_i = 0$. Let $\hat{F}(x) = \sum a_i/m$ and $\hat{G}(x) = \sum b_i/n$. The Kolmogorov distance between the distributions F and G is estimated by

$$D = \max |\hat{F}(Z_i) - \hat{G}(Z_i)|,$$

where the maximum is taken over all $i = 1, \ldots, N$. If D is sufficiently large, then reject H_0. When there are no ties, the exact probability of a type I error (*see* **Level of a Test**) can be determined using an algorithm derived by Kim & Jennrich [3]. When there are tied values, results in [4] can be used. Details about these algorithms, together with appropriate software, are summarized in [7].

A common criticism of the Kolmogorov–Smirnov test is that it has low **power** under normality. Table 1 compares its power with several other methods for comparing measures of location. The methods are **Student's *t*** (T), Welch's adjusted degrees of freedom procedure (W), Yuen's [8] method for trimmed means that reduces to Welch's test when there is no trimming (Y), and a method for comparing one-step M-estimators (*see* **Robustness**) using a **bootstrap method** (OSM). (For details about these tests, see [6].) In Table 1 the first three distributions are normal with variance one, and the difference between the means is δ. The notation CN1 refers to a symmetric heavy-tailed distribution that is a mixture of two normal distributions. It has distribution

$$H(x) = 0.9\Phi(x) + 0.1\Phi\left(\frac{x}{k}\right),$$

Table 1 Estimated power, $m = n = 25, \alpha = 0.05$

Distributions	δ	T	W	Y	OSM	KS (exact)	KS (α = 0.052)
Normal	0.6	0.529	0.536	0.464	0.531	0.384	0.464
Normal	0.8	0.778	0.780	0.721	0.751	0.608	0.700
Normal	1.0	0.925	0.931	0.890	0.921	0.814	0.872
CN1	1.0	0.326	0.278	0.784	0.788	0.688	0.780
CN2	1.0	0.191	0.162	0.602	0.760	0.698	0.772
Expo	0.6	0.539	0.697	0.623	0.592	0.866	0.867
Logn	0.6	0.232	0.243	0.409	0.363	0.666	0.678

with $k = 10$, and where $\Phi(x)$ is the standard normal distribution. That is, with probability 0.9, an observation is sampled from a standard normal distribution, otherwise sampling is from a normal distribution having standard deviation $k = 10$. The difference between the standard normal and CN1 is small as measured by the Kolmogorov distance – it is less than 0.04. Despite this, the variance is equal to 10.9 vs. 1 for the standard normal. The distribution CN2 is the same as CN1, only $k = 20$. Finally, Expo indicates an **exponential distribution**, and Logn is **lognormal**. The column headed KS (exact) means that the smallest critical value is used such that the probability of a type I error does not exceed $\alpha = 0.05$. The exact probability of a type I error is 0.036. The last column reports power when the critical value is chosen so that the probability of a type I error is as close as possible to 0.05, which in this case is 0.052.

As would be expected, methods for comparing measures of location have more power when sampling from normal distributions, but, with even slight departures from normality (CN1 and CN2), the Kolmogorov–Smirnov test has substantially more power than methods based on means, and it competes well with methods based on robust measures of location.

A criticism of the Kolmogorov–Smirnov test is that when the sample sizes are small, there are situations where the exact probability of a type I error might not be acceptably close to some desired level, because the test statistic, D, has a discrete distribution. Suppose, for example, $\alpha = 0.05$, and consider $n = m = 10$. The exact probability of a type I error, based on the critical value in [1], is 0.035. For $n = m = 11$, 12, and 13 the exact type I error probabilities are 0.036, 0.031, and 0.044, but for $n = m = 14$ it is 0.019, which might be considered too small. However, the next highest significance level is 0.12 which might be considered too high. This problem might be used to argue for comparing some measure of location, but most methods for comparing measures of location can also yield unsatisfactory control over the probability of a type I error, particularly methods based on means (see, for instance [5] and [6]). An exception appears to be a percentile t bootstrap combined with a 20% **trimmed** mean (see [7]).

An advantage of the Kolmogorov–Smirnov test is that it is sensitive to several features of the data which can be revealed using the method described in [2]. This uses the Kolmogorov–Smirnov test statistic to compute a **confidence interval** for the difference between any two **quantiles** such that the simultaneous probability coverage of all such intervals is determined exactly. Note that the 0.2 quantile, for example, of the first group might be larger than the 0.2 quantile of the second, but when the 0.8 quantiles are compared the reverse can be true. That is, the confidence band can indicate a difference between subpopulations of subjects that is completely missed when attention is restricted to a measure of location. Doksum & Sievers [2] suggest plotting the estimated quantiles of the first group vs. the difference between the quantiles. Letting $\hat{x}_q$ and $\hat{y}_q$ be the quantiles of the two groups, plot $\hat{x}_q$ vs. $\delta = \hat{x}_q - \hat{y}_q$. For illustrations and software, see [7].

R. WILCOX

Kullback–Leibler Information

The Kullback–Leibler [5] information number, $I(P\|Q)$, determined for two probability measures defined on the same measurable space $(\chi, \mathcal{F})$, is a nonnegative number (possibly $+\infty$) which represents "distance" (in a certain sense) between P and Q. This "distance" is not symmetric [in general, $I(P\|Q) \neq I(Q\|P)$], but does have the property that $I(P\|Q) = 0$ if and only if $P = Q$. This quantity is also referred to by a myriad of other names, including information for discrimination, discrimination information, Renyi's information gain, entropy distance, entropy of P relative to Q, cross-entropy, directed divergence, Kullback information.

If P is absolutely continuous with respect to $Q (P \ll Q)$, the **Radon–Nikodym** derivative $P_Q(x)$ is defined almost surely (Q) and serves as a basis for the general definition:

$$I(P\|Q) = \begin{cases} \displaystyle\int_\chi \ln P_Q \, \mathrm{d}P = \int_\chi P_Q \ln P_Q \, \mathrm{d}Q, \\ \qquad\qquad P \ll Q, \\ +\infty, \qquad P \not\ll Q. \end{cases}$$

Note that, if R is a sigma-finite measure such that $P \ll Q \ll R$, we can also write

$$I(P\|Q) = \int_\chi P_R \ln \left(\frac{P_R}{Q_R} \right) \mathrm{d}R.$$

Thus, for the common situation where P and Q are discrete (and R is the counting measure), the Kullback–Leibler information number reduces to

$$I(P\|Q) = \sum_i p_i \ln \left(\frac{p_i}{q_i} \right),$$

where p_i and q_i are the standard probability mass functions. Note also that, if X is a random vector with probability distribution P, then $I(P\|Q)$ can be interpreted as the expectation of the log of a **likelihood ratio** statistic.

If Q is a uniform measure over a finite set of points and P is a probability measure on the same points, then $I(P\|Q)$ is just the negative of the well-known Shannon entropy [8]. This quantity is very important in statistical information theory, which has its mathematical roots in the concept of entropy in thermodynamics and statistical mechanics.

Given a probability measure Q on a measurable space, the convex set of probability measures defined by

$$S(Q, \rho) = [P : I(P\|Q) < \rho]$$

is often called the I-sphere with center Q and radius ρ. If $\mathcal{E}$ is a convex set of probability measures intersecting $S(Q, \infty)$, a probability measure $R \in \mathcal{E}$ satisfying

$$I(R\|Q) = \inf_{P \in \mathcal{E}} I(P\|Q) \tag{1}$$

is called the I-projection of Q onto ε. Csiszár [1] has shown that the I-projection exists if the convex set $\mathcal{E}$ is closed in variation distance and has also developed an appealing "geometric" approach which characterizes the "tangent hyperplanes" of I-spheres $S(Q, \rho)$.

Problems of the type (1) play a basic role in the information theoretic approach to statistics [4], the theory of large deviations [6], and in statistical physics [3]. Dykstra & Lemke [2] have shown that problems of the form (1) are often equivalent to **multinomial** maximum likelihood problems under various types of constraint regions.

Kullback–Leibler information numbers between distributions in a common family are often quite tractable. Thus, if P and Q are **Poisson distributions** with respective means m_1 and m_2, it is easily shown that $I(P\|Q) = m_1 \ln(m_1/m_2) + m_2 - m_1$.

If P and Q are k-variate normal distributions (*see* **Multivariate Normal Distribution**) with respective mean vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ and respective **covariance matrices** $\boldsymbol{\Sigma}_1$ and $\boldsymbol{\Sigma}_2$, then

$$\begin{aligned} I(P\|Q) = {} & \tfrac{1}{2} \ln \left(\det \boldsymbol{\Sigma}_2 \big/ \det \boldsymbol{\Sigma}_1 \right) \\ & + \tfrac{1}{2} \mathrm{tr} \boldsymbol{\Sigma}_1 \left(\boldsymbol{\Sigma}_2^{-1} - \boldsymbol{\Sigma}_1^{-1} \right) \\ & + \tfrac{1}{2} \mathrm{tr} \boldsymbol{\Sigma}_2^{-1} (\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)'. \end{aligned}$$

Thus, when $\boldsymbol{\Sigma}_1 = \boldsymbol{\Sigma}_2 = \boldsymbol{\Sigma}$, $I(P\|Q)$ reduces to the natural **Mahalanobis distance** $(1/2)(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)' \boldsymbol{\Sigma}^{-1} (\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)$ between the two mean vectors.

Though Kullback–Leibler information seems very different from the statistical concept of Fisher **information**, there is actually a rather remarkable connection. For example, if we have multinomial distributions whose probabilities $\pi_i(\theta), i = 0, 1, \ldots, k$, depend upon the parameter θ, then

$$\lim_{\Delta\theta \to 0} \frac{I[\Pi(\theta + \Delta\theta) \| \Pi(\theta)]}{(\Delta\theta)^2} = \frac{1}{2} I_{\mathrm{F}}(\theta),$$

where I_{F} denotes the Fisher information and the Kullback–Leibler information number is calculated from the appropriate multinomial distributions [7, Chapter 15].

If P_n denotes an empirical distribution from a random sample and $\mathcal{E}$ denotes a family of possible models, then a natural estimate of a model from the family is the one (in $\mathcal{E}$) closest to P_n. "Closest" here means in the sense of the Kullback–Leibler information number, i.e. the I-projection of P_n onto $\mathcal{E}$.

Moreover, $2n \inf_{P \in \mathcal{E}} I(P \| P_n)$ is often a desirable test statistic (with nice asymptotic properties) for testing whether the actual distribution is contained in $\mathcal{E}$ (*see* **Large-sample Theory**).

RICHARD DYKSTRA

Kurtosis

Kurtosis is related to the standardized fourth **moment** of a distribution. It is expressed in a number of ways, the most common being

$$\beta_2 = \mu_4/\sigma^4 \quad \text{and} \quad \gamma_2 = \beta_2 - 3,$$

where μ_4 and σ^2 are, respectively, the fourth central moment and the variance of the distribution. Often it is used as a measure to judge the deviation of a distribution from normality. For the **normal distribution**, $\beta_2 = 3$ and $\gamma_2 = 0$. Unimodal distributions with values of β_2 greater than 3 (called *leptokurtic*) usually indicate that the distribution displays a higher "peak" around the mean, and also more probability in the tails of the distribution, than does the normal (see Figure 1). These distributions are also called thick-(or long-)tailed distributions [3, Chapter 9]. Those with β_2 less than 3 (called *platykurtic*) usually are more concentrated about the mean and flatter than the normal. β_2 cannot be less than 1. Those with $\beta_2 = 3$ are called *mesokurtic*.

Sample measures of kurtosis are used in tests of normality. A common test statistic is $b_2 = m_4/m_2^2$, where m_2 and m_4 are the second and fourth moments about the mean (see [3, Chapter 9]). Extensive tables of the **sampling distribution**, as well as approximations, exist for the null distribution of b_2 [3, 4, 7]. Also, it is often used jointly with a measure of **skewness** ($b_1 = m_3/m_2^{3/2}$) to evaluate deviations from normality [2, 3]. D'Agostino & Pearson [2] and D'Agostino et al. [5] developed a **chi-square distribution** approximation that combines b_2 with b_1 for an omnibus test. It is a useful adjunct to normal probability plots [5] (*see* **Normal Scores**).

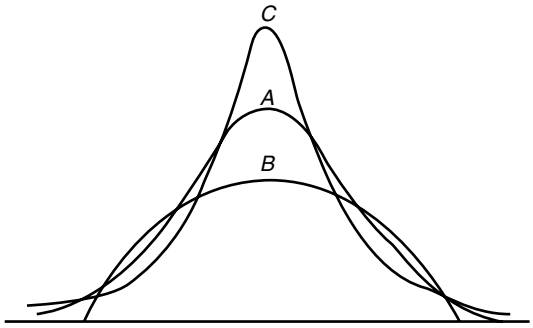

Figure 1 Unimodal distributions: $A = \beta_2 = 3$; $B = \beta_2 < 3$; $C = \beta_2 > 3$

There have been a number of attempts to generalize kurtosis to the multivariate setting. These have often been in the context of developing **tests of multivariate normality**.

In the case of nonnormality, knowledge of kurtosis is useful in evaluating the **robustness** of standard statistical procedures such as the **Student's *t* tests** [8] and in developing measures of location [1]. For this latter situation in particular, the tail thickness of a distribution is often very important and some have questioned the usefulness of b_2 for evaluating it. Alternative measures based on sample **quantiles** have been suggested [6, 9].

Lagged Dependent Variables

In **longitudinal** studies, several observations are taken from each individual at different time points. Often, an observation depends on previous observations; for example, in a **crossover** clinical trial, observations in one period may depend on the observations in the previous periods. A simple model for this scenario might include a lag-1 dependent variable as an explanatory variable [2]:

$$y_{it} = \gamma y_{i,t-1} + \mathbf{x}_{it}\boldsymbol{\beta} + u_i + e_{it}, \qquad (1)$$

where y_{it} is the observation from subject i in period t, $\mathbf{x}_{it}$ is a vector of **covariates**, u_i is a subject effect, and e_{it} is an error term. This model can be extended to include multiple lagged variables by replacing $\gamma y_{i,j-1}$ by $\sum_{l=1}^{p} \gamma_l y_{i,t-l}$ in (1). Model (1) is different from a **serially correlated** model with the same covariates. In the latter, $y_{i,t}$ depends on $\mathbf{x}_{it}$ only (not $y_{i,t-1}$), while in the former it depends on all $\mathbf{x}_{i1}, \ldots, \mathbf{x}_{it}$ [4].

Statistical inference based on model (1) includes model fitting, **model checking** and **hypothesis tests**. In biostatistics, the number of subjects is often large, but the number of observations from each subject is small. In this situation we should be careful when using the asymptotic properties of the estimated parameters. For n subjects and times $1, 2, \ldots, T$, and conditional on u_i, the log **likelihood** function of this model can be written as

$$l(\boldsymbol{\beta}, \gamma, \mathbf{u}) = \sum_{i=1}^{n}\sum_{j=1}^{T} \log[p(y_{it}|y_{i,t-1}, \boldsymbol{\beta}, \gamma, u_i)]. \quad (2)$$

When there are no subject effects ($u_i = 0$), this model can be fitted easily using the lagged dependent variables as covariates [3]. When u_i is fixed and $u_i \neq 0$ the **maximum likelihood** estimates (mle) of γ and $\boldsymbol{\beta}$ are not **consistent** for fixed T when the total sample size $n \to \infty$ [2]. To obtain consistent estimates, the **instrumental variable** procedure can be used either for fixed or random u_i. To illustrate how this procedure works we write model (1) as

$$y_{it} - y_{i,t-1} = \gamma(y_{i,t-1} - y_{i,t-2}) + \boldsymbol{\beta}(\mathbf{x}_{it} - \mathbf{x}_{i,t-1}) + e_{it} - e_{i,t-1}. \qquad (3)$$

Directly using $(y_{i,t-1} - y_{i,t-2})$ as a covariate may lead to inconsistency, since it and $e_{it} - e_{i,t-1}$ are correlated. However, $(y_{i,t-2} - y_{i,t-3})$ or $y_{i,t-2}$ is independent of $e_{it} - e_{i,t-1}$ and can be used as an instrumental variable. When assuming $u_i \sim \mathrm{N}(0, \sigma_u^2)$ the log likelihood function is more complicated than (2), but the mle can be obtained by the Newton–Raphson method (*see* **Optimization and Nonlinear Equations**). In this case the mle is consistent for fixed T and $n \to \infty$.

Model (1) can be extended to include discrete outcomes. One approach is to discretize y_{ij} by letting $y_{ij}^* = 1$ if $y_{ij} > 0$ and $y_{ij}^* = 0$ otherwise. This approach leads to the autoregressive probit model [1]. A more general approach is to use (1) as the linear predictor in a **generalized linear model**, and a wide range of data such as count data can then be modeled. Again, the model fitting without u_i is easy but the mle for random u_i is very difficult to obtain.

When there are missing data in the repeated measurements we may need to write (1) in another form. For example, when y_{i2} is missing we can write the equation for y_{i3} with y_{i1} as a covariate. This can be done by replacing y_{i2} by its regression model. However, the model becomes nonlinear, and nonlinear regression procedures should be used [4].

There are two special issues in the models with lagged dependent variables. One is the distinction between these models and other models for correlated outcomes. To distinguish these models from the models with random subject effects, we may test for given u_i if y_{ij} depends on the previous outcomes. To distinguish these models from serially correlated models, we may test if y_{ij} depends on previous covariates. Another issue concerns the initial observation y_{i0}. Assuming y_{i0} as fixed leads to a simple model, but it may not be reasonable for models with random u_i. The case when y_{i0} is random is more complicated; see [2] for details.

Lambda Criterion, Wilks'

In 1932, Wilks [35] proposed the **likelihood ratio test** criterion, known usually as Wilks' Λ criterion, for testing the equality of the mean vectors of k p-variate normal distributions with common but unknown **covariance matrix** (*see* **Multivariate Normal Distribution**). Later, Wilks [36] and Bartlett [2] extended its use for testing regression coefficients; see Anderson [1] (*see* **Multiple Linear Regression**).

The problem in its canonical form can be expressed as follows. Let $(\mathbf{X}) : p \times r$, $\mathbf{Y} : p \times m$, and $\mathbf{Z} : p \times n$ be random matrices such that the columns of $\mathbf{X}$, $\mathbf{Y}$, and $\mathbf{Z}$ are independently distributed as p-variate normal distributions with the same covariance matrix $\mathbf{\Sigma}$. The problem is to test $\mathrm{H}_0 : \mathbf{\Theta} \equiv \mathrm{E}(\mathbf{X}) = \mathbf{0}$ against $\mathrm{H}_1 : \mathbf{\Theta} \neq \mathbf{0}$, given that $\mathrm{E}(\mathbf{Z}) = \mathbf{0}$, $\mathbf{\Sigma}$ being unknown. The likelihood-ratio test, evaluated by Wilks [34], rejects H_0 if and only if

$$V_{p,r,n} \equiv \frac{\det(\mathbf{ZZ}')}{\det(\mathbf{XX}' + \mathbf{ZZ}')}$$

is too small; here "det" denotes the determinant. The Λ criterion is the $\frac{1}{2}(r+m+n)$th power of $V_{p,r,n}$. In the context of the original problem or the **multivariate analysis of variance** (MANOVA) problem, the matrices $\mathbf{XX}'$ and $\mathbf{ZZ}'$ denote the sums of products and cross products matrices due to the hypothesis H_0 and due to error, respectively. It is tacitly assumed that $n \geq p$.

Wilks [35] derived the null distribution of $V_{p,r,n}$ explicitly for $p = 1, 2, 3$ with $r = 3$, and for $p = 4$ with $r = 4$; see also Consul [5] and Mathai [17].

The null distribution of $V_{p,r,n}$ can be expressed as the distribution of $U_1, U_2, \ldots, U_p$, where the U_is are independently distributed, with the distribution of U_i being the **beta distribution** $\mathrm{B}(\frac{1}{2}(n+1-i), r/2)$; moreover, the distribution of $V_{p,r,n}$ is the same as that of $V_{r,p,n+r-p}$; see [1]. For $p = 1, 2$ and $r = 1, 2$ the distributions of $V_{p,r,n}$ take simple ***F* distribution** forms as follows [1]:

$$\frac{1 - V_{1,r,n}}{V_{1,r,n}} \frac{n}{r} \sim F_{r,n},$$

$$\frac{1 - V_{p,1,n}}{V_{p,1,n}} \frac{n+1-p}{p} \sim F_{p,n+1-p},$$

$$\frac{1 - (V_{2,r,n})^{1/2}}{(V_{2,r,n})^{1/2}} \frac{n-1}{r} \sim F_{2r,2(n-1)},$$

$$\frac{1 - (V_{p,2,n})^{1/2}}{(V_{p,2,n})^{1/2}} \frac{n+1-p}{p} \sim F_{2p,2(n+1-p)}.$$

Wald & Brookner [37] presented a method for obtaining the null distribution of $V_{p,r,n}$ for even values of p and r; see also Schatzoff [29] and Anderson [1]. For other results on the null distribution, see Pillai & Gupta [24] and the books by Seber [32] and Muirhead [20].

Tables for significance points of $V_{p,r,n}$ are obtained by Schatzoff [29], Pillai & Gupta [24], Lee [16] and Davis [9, 10]; see also Anderson [1], Muirhead [20], and Pearson & Hartley [22].

Bartlett [3] has shown that the null distribution of $-[n - \frac{1}{2}(p - r + 1)] \log V_{p,r,n}$ tends to the **chi-square distribution** with pr **degrees of freedom** as $n \to \infty$; see [1]. Mudholkar & Trivedi [19] have suggested a normal approximation to the distribution of $-\log V_{p,r,n}$ for large p or r; see [1]. This approximation is better than the chi-square approximation when n is small. Rao [27] has suggested an F approximation as follows:

$$\frac{1 - V^{1/s}}{V^{1/s}} \frac{ks - q}{pr} \sim F_{pr,ks-q},$$

where $s = [(p^2r^2 - 4)/(p^2 + r^2 - 5)]^{1/2}$, $q = (pr/2) - 1$, and $k = r - (p - r + 1)/2$. For small r, this approximation is more accurate than the chi-square approximation.

An asymptotic expansion of the null distribution of $V_{p,r,n}$ (in powers of $1/n$) in terms of chi-square distributions has been given in Rao [26], Anderson [1], and Muirhead [20].

Constantine [4] has obtained the moments of the nonnull distribution of $V_{p,r,n}$. For asymptotic expansion of the nonnull distribution in terms of noncentral chi-square distributions, see Muirhead [20], Suguira [33], Suguira & Fujikoshi [34], Fujikoshi [12], and Pillai [23].

Schwarz [31] has shown that the likelihood ratio test is **Bayes** and admissible; see also Anderson [1]. The **power** function of this test depends on the parameters only through the characteristic roots **(eigenvalues)** $\nu_1, \ldots, \nu_p$ of $\mathbf{\Theta\Theta}'\mathbf{\Sigma}^{-1}$. DasGupta et al. [8] have shown that the power of the likelihood ratio test monotonically increases as each ν_i increases; see also a review paper by DasGupta [6]. The power of this test has been studied by DasGupta & Perlman [7].

The power functions of the likelihood ratio test, the **Lawley–Hotelling trace** test, and **Pillai's trace test** for the MANOVA problem have been compared by Rothenburg [28] on the basis of asymptotic expansions. It is shown that if the coefficient of variation of the ν_is is large enough, then the power of the Lawley–Hotelling trace test is greater than that of the likelihood ratio test, which in turn is greater than that of Pillai's test; in the opposite situation, the ordering of power is reversed. For comparisons of the power function of the likelihood ratio test with the power functions of other standard tests for the MANOVA, see Itô [13], Lee [15], Mikhail [18], Olson [21], Pillai & Jayachandran [25], and Schatzoff [30]. Olson's study [21] indicates that the likelihood ratio test is quite robust under departure from covariance homogeneity. For a review of results on **robustness**, see Itô [14] (*see* **Multivariate Techniques, Robustness**).

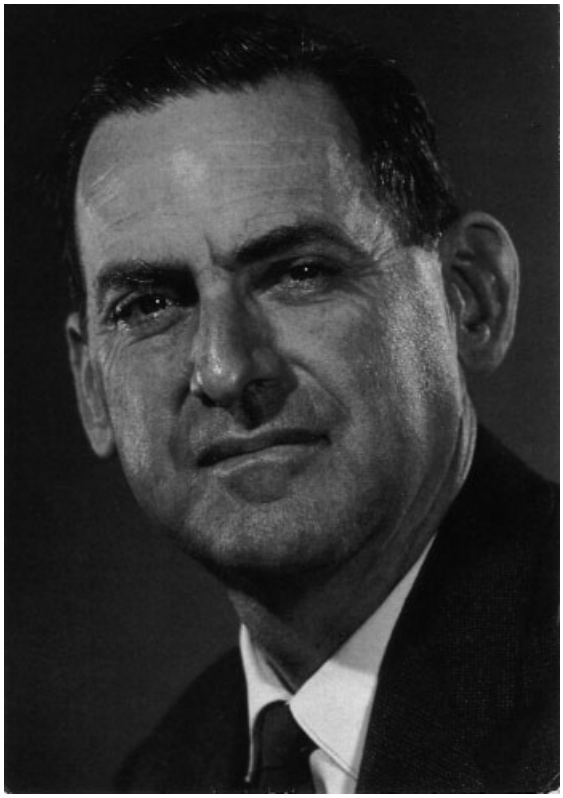
SOMESH DASGUPTA

Lancaster, Henry Oliver

Born: February 1, 1913, in Sydney, New South Wales.
Died: December 2, 2001, in Sydney.



During the twentieth century, many qualified physicians contributed in different ways to the theory or practice of statistics. Oliver Lancaster was unique in having held university chairs in both medical and mathematical statistics, in making important contributions to the history of quantitative medicine, and in his pioneering work in the bibliography of statistics.

Lancaster was the son of a doctor practicing in the country town of Kempsey on the Macleay River in northeastern New South Wales. He was born in Sydney because his mother had accompanied his father who was playing in a chess championship there, a suitable advent for a boy who was to have a precocious childhood and develop strong aptitude in all forms of games. He showed all-round ability in school with particular strength in mathematics and chemistry, and then started on an actuarial career by taking evening classes in economics at the University of Sydney, whilst working for an insurance company. He quickly switched to Arts degree classes with a broader range of science subjects and in 1931 enrolled as a medical student, qualifying in 1937. During the next three years, he served as Resident Medical Officer and then pathologist, and sought to extend his scientific range by further studies in chemistry and a reading of Yule's *Introduction to the Theory of Statistics*. In 1940, after two other hospital appointments, he joined the Royal Australian Army Medical Corps as a pathologist, a period of service in the Middle East, Australia, and New Guinea which was to last until 1946.

His work as an army pathologist introduced him to statistical problems such as the analysis of $2 \times 2 \times 2$ tables in the study of parasitic infections and **Bayesian** concepts in diagnosis. His target at this stage was a possible career in demography and he began a serious study of mathematics, enrolling as an external student in mathematics within the Arts degree. After demobilization, he had a temporary appointment as a Lecturer in Statistics at the Sydney School of Public Health and Tropical Medicine and obtained an Arts degree in 1947.

In 1948, he was awarded a Rockefeller Scholarship in Medicine, to study at the London School of Hygiene and Tropical Medicine under A. Bradford **Hill**. He arrived there with a sheaf of draft articles on a variety of topics in medical statistics, including the analysis of amoebic surveys (involving **overdispersed** binomial distributions (*see* **Beta-binomial Distribution**), the control of routine blood counting, partition of the **chi-square** statistic in **contingency tables** to identify particular contrasts with disproportionate frequencies, and the use of what is now known as the mid-P test for discrete data (*see* **Fisher's Exact Test**). He benefited from the guidance of **J.O. Irwin**, who recognized Lancaster's remarkable insight but realized that it was not matched by experience in the writing-up of his research. He also completed an analysis of the large data set published by A. Geissler in 1889 on the **sex ratio** in families of different sizes, concluding that the evidence for genetic variability in the ratio was extremely scanty.

He returned to Sydney in 1949, as a member of the Commonwealth Health Department located at the

School of Public Health, with some teaching responsibilities. He now embarked on a study of trends in Australian mortality from different causes, extending eventually to some 50 papers. He approached **vital statistics** with an investigative mind and made important epidemiologic findings. N.M. Gregg had discovered that maternal rubella in the first trimester of pregnancy can cause developmental defects, such as cataracts, in the fetus, and it was thought that this effect might be due to a recent viral mutation. Lancaster discovered that excessive incidences of deaf-mutism had occurred as long ago as 1898 and 1899, following rubella epidemics. He also found that melanoma, which was known to be associated with exposure to sunlight, was more specifically related to latitude in Australia, mortality increasing toward the equator.

In 1959, he was appointed Associate Professor of Medical Statistics in the University of Sydney, but almost immediately he applied for, and was appointed to, the new chair in Mathematical Statistics. This marked a new phase in his career. He was never to abandon his interest in medical statistics (as his later book [3] shows), but his concern now was to develop the new department and plan its courses. His research included further work on the chi-square distribution, leading to his book [2]. In this, he made use of orthogonal functions (*see* **Orthogonality**). He had published several papers on this topic, particularly in relation to their use in measuring dependence in **bivariate distributions** with given marginal distributions. His work in this area is summarized in [4]; see also [8].

Throughout his career, Lancaster had been interested in historical scientific literature, especially in relation to statistics. In his book [1], he listed bibliographies contained in a wide range of papers and continued to produce 21 addenda at approximately annual intervals until 1989. For this purpose, he created a vast card index in Sydney, the maintenance of which became one of his principal interests in later life. After his retirement in 1978, he decided to continue and consolidate his work on medical statistics, and produced a massive book [6] on trends in mortality subdivided by diseases and regions, and a history of quantitative medicine [7]. These books are important sources of information although the author's rather laconic and occasionally cryptic style makes few concessions to his less erudite readers.

Lancaster obtained doctorates from Sydney in philosophy (1953), medicine (1967), and science (1971). He was a Fellow of the Australian Academy of Science (1961) holding the Academy's Lyle Medal (1961) and the Pitman Medal of the Statistical Society of Australia (1980). In 1992, he was appointed Officer of the Order of Australia. He held many honorary fellowships and honorary life memberships of learned societies throughout the world.

Lancaster played a major role in the establishment of statistical and mathematical organizations in Australia. In 1947, the Statistical Society of New South Wales was formed and Lancaster became Secretary in 1949 and President from 1952 to 1953. He was largely responsible for the Society's *Bulletin* and was joint Editor of its successor, the *Australian Journal of Statistics*, from 1959 to 1971. After the Society became the Statistical Society of Australia, he served as President from 1965 to 1966. He helped to found the Australian Mathematical Society from 1956 to 1957 and served as its General Secretary (1959–1963) and President (1966–1967).

Lancaster had a hesitant manner of conversation, probably because of a childhood stammer, which he had gradually overcome as an adult, and this sometimes conveyed the impression of a diffident personality. He was, in fact, a man of strong opinions, often forcibly expressed. He was held in high respect and affection by those who knew him, not least his former research students, many of whom came to occupy senior positions in academia and public service.

Lancaster published his own account of his career in [5].

PETER ARMITAGE

Laplace, Pierre–Simon

Born: March 23, 1749, in Beaumont-en-Auge, France.
Died: March 5, 1827, in Paris, France.

"Laplace was among the most influential scientists in all history" [1]. The son of a well-to-do tradesman, he entered the University of Caen in 1766 to study theology, but left prematurely to study mathematics in Paris under d'Alembert. He secured an appointment at the Ecole Militaire (where he examined Napoleon), and was elected to the Académie des Sciences in 1773. His career continued to flourish after the Revolution, and for a short time he was Napoleon's Minister of the Interior. He became Chancellor of the Senate in 1803 and a Marquis in 1806.

During the first 20 years of his academic life, he worked prolifically in several areas of mathematical science, notably celestial mechanics, differential equations, and probability and statistics. These remained the central themes throughout his career. As his research findings proliferated and matured, Laplace incorporated them into two major treatises, *Mécanique céleste* (1799–1825) and *Théorie analytique des probabilités* (1812). The second edition of the latter, in 1814, was accompanied by a new introduction, *Essai philosophique sur les probabilités*.

Laplace's early work on probability adopted a **Bayesian** approach. Laplace had discovered **Bayes' theorem**, possibly unaware in 1774 of Bayes' posthumous publication of 1763. He applied this to combinatorial and demographic problems, and used the **beta** prior distribution for **binary data**. Other techniques and results introduced by Laplace included **generating functions** for discrete distributions, **characteristic functions**, the Laplace transform (at least in embryo), a form of the **central limit theorem**, and various aspects of **regression** and **least squares**. Commentators on his career usually refer to his somewhat cavalier attitude towards results obtained by other workers. According to [1], "not a single [contemporary] testimonial bespeaking congeniality survives". Nevertheless, as Grattan-Guiness [2] remarks,

> Laplace's contributions to probability and statistics were fundamental . . .He . . .changed the emphasis of probability from its preoccupation with moral sciences and jurisprudence to include also applications in scientific contexts, wither it had hitherto infrequently strayed. His most important early successors were Quetelet and Poisson; after them, both probability and statistics moved to adulthood in the family of sciences, and the heritage from Laplace began to be recognized.

The major memoir [1], written in collaboration with others, contains extensive bibliographic information. The relation between Laplace's work and that of his near-contemporaries, especially **Gauss**, is described in [3].

PETER ARMITAGE

Large-sample Theory

Large-sample theory (LST) plays a fundamental role in biostatistics in the prescription of fruitful methodology that can be well adapted in practical applications, often under conditions weaker than in standard (finite sample) parametrics. The basic clause of *large samples* is usually satisfied in real biostatistical applications, especially in investigations involving large-scale data collection. The advent of modern computers has strengthened the case for LST. The research literature on LST has gone through a phenomenal growth during the past three decades wherein delicate concepts from **probability** theory and **stochastic processes** have been blended towards a unified resolution, though at the cost of mathematical abstractions and sophistications often beyond the normal range of comprehension in biostatistics. Moreover, in biostatistics, various experimental or observational factors generally impose certain constraints on underlying statistical models, so that the classical parametric theory may not be universally adoptable, and increasingly **nonparametrics** and **semiparametrics** are being used; the LST has an even more dominant role in this setup. Yet there is a hierarchy in the methodological developments within the domain of LST with respect to their validity in moderate sample sizes, and many modern developments are geared toward a better resolution for moderate to large sample sizes. The interesting point in this context is the interplay between *validity robustness* and *efficiency robustness*; modern LST addresses this aspect quite well.

The basic concepts in probability theory underlying the evolution of LST in biostatistics are the following:

1. *stochastic, almost sure*, and other *modes of* **convergence**;
2. *probability inequalities*, and **laws of large numbers**; and
3. *weak convergence* or *convergence in distribution (law)*.

In the classical sense these concepts were mostly developed for sample *statistics* that are generally expressible as the sum or average of independent random elements. Yet, in applications one often encounters more general forms of statistics violating this postulation, and even sometimes sample functions that are *stochastic processes* in a general sense. The *empirical distribution* (*see* **Goodness of Fit**) and *survival* functions (*see* **Survival Distributions and Their Characteristics**) are classical examples of this type. In this context the emergence of *martingales, reverse martingales* and related *dependent sequences* has greatly reshaped the adaptability of LST in diverse setups, and our discussion remains somewhat incomplete without their introduction and role (*see* **Counting Process Methods in Survival Analysis**). The intricate role of LST in **transformations** on variables or statistics also deserves a closer look.

The main theme of LST relates to the *asymptotic distribution theory* for various statistics that arise in statistical analysis in biostatistics, where *point* and *confidence set* **estimation**, and **hypothesis testing** occupy a focal point. In this context, *linear*, **generalized linear**, **categorical data** models, and some semiparametric and nonparametric models deserve detailed discussion. LST in survival analysis is also a vital component of this development. For a comprehensive view, we also briefly present some *invariance principles* that play a fundamental role in these developments.

Stochastic Convergence

Let T_n be a statistic based on a sample of size N from a population with distribution function F, and let θ be a parameter which can generally be defined as a function of F. Then T_n is said to converge in probability (or stochastically) to θ if, for every positive η and ε, there exists a positive integer $n_0 = n_0(\eta, \varepsilon)$, such that

$$\Pr\{|T_n - \theta| > \eta\} < \varepsilon, \quad \text{for all } n \geq n_0. \tag{1}$$

If we view T_n as an estimator of θ, then the above definition coincides with the notion of (*weak*) **consistency** in estimation theory. Similarly, T_n converges almost surely (or strongly) to θ if

$$\Pr\{|T_n - \theta| > \eta, \text{ for some } N \geq n\} < \varepsilon, \quad \text{for all } n \geq n_0. \tag{2}$$

Again, in estimation theory this corresponds to the notion of *strong consistency*. In the same vein, T_n is said to converge in the rth mean, for some $r > 0$, if

$$\mathrm{E}\{|T_n - \theta|^r\} \to 0, \quad \text{as } n \to \infty. \tag{3}$$

Note that both almost sure convergence and convergence in the rth mean imply convergence in probability, but the converse may not be true generally. These definitions extend readily for the case of vectors T_n and θ where we need to use the Euclidean or other norms, and also to more general cases by using suitable norms. As an example consider the case of T_n being the sample distribution function defined as $F_n(\cdot)$, and consider the *sup-norm* $||F_n - F|| = \sup\{|F_n(x) - F(x)| : x \in \mathbf{R}\}$. With respect to this metric, the definitions all extend to this case of functional statistics and parameters.

Probability Inequalities

The *Chebyshev inequality*. For a nonnegative random variable U with $\mu = EU$, $\Pr\{U \geq \mu t\} \leq t^{-1}$, for all $t > 0$, provides the genesis of all probability inequalities. Letting $U = (T_n - \theta)^2$ and denoting by $\sigma_n^2 = E\{(T_n - \theta)^2\}$, we have the derived Chebyshev inequality:

$$\Pr\{|T_n - \theta| \geq \varepsilon\} \leq \varepsilon^{-2}\sigma_n^2, \quad \text{for every } \varepsilon > 0, \quad (4)$$

so that a sufficient condition for the stochastic convergence of T_n is that $\sigma_n \to 0$ as $n \to \infty$. Although this characterization does not require T_n to have independent summands, in fact it is the second (and generally rth) mean convergence property. For almost sure convergence and related results some sharper inequalities are useful. Among these, special mention may be made of (i) the *Bernstein inequality*, (ii) the *Kolmogorov–Hájek–Rényi inequality*, and (iii) the *Hoeffding inequality*, all of which were initially formulated for independent summands, but later were generalized to some dependent cases as well. Other useful inequalities in probability theory include the c_r *inequality* ($r > 0$), the *Holder inequality*, the *Cauchy–Schwarz inequality*, and the *Jensen inequality*. For details we refer the reader to Sen & Singer [21] and Ferguson [7], where other pertinent references are all cited.

Laws of Large Numbers (LLN)

For independent and identically distributed (iid) random variables, the *Khintchine Strong LLN* asserts the almost sure convergence of the sample mean to the population mean whenever the latter exists. The *Borel SLLN* refers to the particular case of Bernoulli variables (*see* **Binary Data**). However, without the iid clause, extra regularity conditions are needed for such LLNs to hold. The *Kolmogorov SLLN*, in the case of independent but not necessarily identically distributed summands, is based on the convergence of the series $\sum_{n\geq 1} n^{-2}\sigma_n^2$, where σ_n^2 stands for the variance of X_n, for $n \geq 1$. These LLNs have also been extended to some dependent sequences. The *Markov LLN* relates to stochastic convergence for the possibly nonidentically distributed case, and does not require the second moment condition, but a condition slightly more stringent than the first.

Martingales and Reversed Martingales
