Moving averages, local weighted **least-squares** methods and the so-called Whittaker–Henderson estimates have been the earliest proposals among a variety of different possible graduation methods, and are commonly adopted by actuaries (see [6, 32]). Any nonparametric regression method can be used to graduate **life tables** in order to obtain a smooth hazard rate estimate. One just applies the chosen smoother, which could be a spline or kernel method, to the scatter plot $\{(t_i, q_i),\ i = 1, \ldots, p\}$. The Whittaker–Henderson estimate resembles a spline estimate. The kernel method for graduation (see [4, 8]) is conceptually simple but needs to be applied with caution in the boundary region of the data, owing to its large bias there.

For the graduation of grouped data, we recommend the local polynomial method, which is also called the locally weighted least-squares method. This graduation method has been credited to the famous mathematician J.P. Gram, perhaps best known for his contributions to **Gram–Schmidt** orthogonalization; see [31, 51] for historical reviews. Specifically, in his doctoral dissertation, Gram [21] suggested a weighted least-squares method to fit a smooth curve locally by polynomials. The explicit form of Gram's estimate using a local linear fit is given in (4) below.

The local polynomial method is well suited for graduating initial hazard estimates based on life tables. As a least squares based procedure, it is simple to interpret, and automatically includes boundary corrections. For the kernel method, boundary corrections require the implementation of special boundary kernels. Both kernel and local polynomial methods are theoretically more tractable than the spline method, especially for lifetime data, which are often incomplete. Some asymptotic results for the local polynomial estimator are reviewed in the next section.

We note that the death rate q_i can be replaced by any initial estimate of the hazard rate. For example, the central death rate, $q_{c_i} = 2d_i/(n_i + n_{i+1})$, is a good alternative. If death rates are used in (2), it is recommended (see (13) of next section and [60]) to include a transformation of the smoothed death rates $\hat{\lambda}(t)$, and to use $-\log(1 - \hat{\lambda}(t))$ as the final hazard estimate. This transformation reduces the bias resulting from grouping the data. This bias can be substantial at extreme ages (i.e. for large t) and may result in inconsistent estimates of the hazard rate. If the central death rates are used in (2), another transformation (see (15) of next section and [42]) of the smoothed central death rates is recommended instead.

As for the choice of the smoother in (2), it is a judgment call, and typically, the choice of an adequate smoothing parameter is more important. The sampling or asymptotic properties of the resulting hazard rate estimator are much more complicated than in the standard regression setting, as the q_i or other initial hazard estimates are not independent of each other. The incompleteness of lifetime data further complicates theoretical analysis. Therefore, much is yet to be explored in hazard rate estimation based on smoothing life tables.

For an overview and details of the kernel smoothing method, see [59]; for the spline method, [25]; and for the local polynomial method, [14].

More on Local Polynomial Hazard Smoothing for Grouped Data

In addition to the grouping, we shall assume that the lifetimes $T_1, T_2, \ldots, T_n$, based on a cohort of n individuals, are subject to random censoring by $C_1, C_2, \cdots, C_n$. Let $I_1, I_2, \ldots, I_p$ denote a partition of p ordered intervals over a time interval of length L. For the jth individual, the value of $\delta_j = 1_{\{X_j = T_j\}}$ is known but not the actual value of $X_j = \min(T_j, C_j)$. It is only known that $X_j \in I_i$ for some i. Observed are (d_i, n_i), where $d_i = \sum_{j=1}^{n} 1_{\{X_j \in I_i, \delta_j = 1\}}$ is the number of observed deaths in the interval I_i, and $n_i = \sum_{j=1}^{n} 1_{\{X_j \in I_k, \text{ for some } k \geq i\}}$ is the number of individuals at risk at the beginning of the interval I_i.

For simplicity of presentation, we shall assume that the intervals I_i are of equal length Δ and that the first interval starts at zero. The nonequal length case can be handled similarly as in nonparametric regression with non-equidistant design points and will not be discussed here. The grouped data can thus be summarized in life table form, which consists of data pairs (t_i, q_i), $i = 1, \ldots, p$. Here, $t_i = \Delta(i - 1/2)$ is the midpoint of the ith interval I_i and $q_i = \tilde{q}(t_i) = d_i/(\Delta n_i)$ is the death rate (out of those alive) for interval I_i. A closer look at $\hat{q}$ reveals that it is an empirical estimate of the population death rate defined by

$$q(t) = \Delta^{-1} \Pr\left(T \in \left(t - \frac{\Delta}{2}, t + \frac{\Delta}{2}\right) \middle| T > t - \frac{\Delta}{2}\right), \tag{3}$$

and one expects $q(t)$ to be close to the true hazard function $\lambda(t)$, provided that Δ is small.

The local polynomial smoother due to Gram [21, 22], is based on smoothing the lifetable data $\{(t_i, q_i), i = 1, \ldots, p\}$ by locally fitting a polynomial of fixed degree r. Thus, given a bandwidth or window of size $b = b_n$, for estimation at age t, a polynomial $g(x - t)$ of degree r is fitted to all life table data points (t_i, q_i) for which $|t - t_i| \leq b$. The coefficients of the polynomial $g(\cdot)$ are obtained via the weighted least-squares criterion and the value of the fitted polynomial at t (i.e. the intercept) is the hazard estimate. A common choice is to fit local linear polynomials (i.e. $r = 1$).

For $r = 1$, this estimate, denoted by $\hat{q}(t)$, is equal to the minimizer for a_0 of

$$\sum_{i=1}^{p} w_i K\left(\frac{t - t_i}{b}\right) \{q_i - [a_0 + a_1(t_i - t)]\}^2. \tag{4}$$

Here w_i are case weights, typically chosen as $w_i = n_i$, and K is a nonnegative kernel function satisfying

$$V = \int K^2(x)\,\mathrm{d}x < \infty. \tag{5}$$

We recommend using either the Epanechnikov kernel

$$K(x) = .75(1 - x^2), \quad -1 \leq x \leq 1,$$
$$\text{or the Gaussian kernel } K(x) = (2\pi)^{-1/2} \mathrm{e}^{-x^2/2}. \tag{6}$$

The bandwidths should satisfy

$$b_n \to 0 \text{ and } nb_n \to \infty; \tag{7}$$

The weighted least-squares method is used for two reasons. First, in the spirit of smoothing methods, it gives remote observations less influence in a way that can be controlled by choice of bandwidth and kernel in (4). Second, it allows to address the high degree of heteroscedasticity (*see* **Scedasticity**) of the lifetable estimate q_i, through the choice of the case weights w_i in (4). Bias and variance expressions are derived in [60] and summarized below.

First, we define a constant that appears in the leading bias term:

$$B = \frac{1}{2} \int x^2 K(x)\,\mathrm{d}x \tag{8}$$

Under the kernel and bandwidth conditions (5) and (7), and if in addition

$$\Delta \to 0, \text{ and } \Delta \log n/b \to 0 \text{ as } n \to \infty, \tag{9}$$

we have for t with $F(t) < 1$ and $G(t) < 1$, and B and V as in (5), (8),

$$\begin{aligned} \mathrm{bias}(\hat{q}(t)) &= -\frac{\Delta}{2}\lambda^2(t) + \frac{\Delta^2}{24}[\lambda^{(2)}(t) + 4\lambda^3(t)] \\ &\quad + b^2\lambda^{(2)}(t)B + o(b^2) + o(\Delta^2) \end{aligned} \tag{10}$$

$$\mathrm{var}(\hat{q}(t)) = \frac{1}{nb}\left\{\frac{\lambda(t)}{[1 - F(t)]\,[1 - G(t)]}V + o(1)\right\}. \tag{11}$$

Bias Reduction Transformation

Note that the leading term of the variance in (11) is the same as for the kernel estimate for continuously observed data in (24). The terms in (10) involving b correspond to the bias due to smoothing and are also the same as for continuously observed data with $k = 2$ in (23). The terms involving Δ in (10) correspond to an additional bias due to the grouping of the data. This additional bias can be improved by the transformation $\phi(x) = -\log(1 - \Delta x)/\Delta$, which is motivated by the relation

$$\begin{aligned}\Delta q(t) &= 1 - \frac{1 - F\left(t + \frac{\Delta}{2}\right)}{1 - F\left(t - \frac{\Delta}{2}\right)} \\ &= 1 - \exp\left[-\int_{t-\frac{\Delta}{2}}^{t+\frac{\Delta}{2}} \lambda(x)\,\mathrm{d}x\right] \approx 1 - \mathrm{e}^{-\Delta\lambda(t)}.\end{aligned} \tag{12}$$

Thus, we propose the transformed estimate

$$\phi(\hat{q}(t)) = \frac{-\log(1 - \Delta\hat{q}(t))}{\Delta}, \tag{13}$$

which has the same variance expression (11) as $\hat{q}$ has, but a bias of smaller order:

$$\begin{aligned}\mathrm{bias}(\phi(\hat{q}(t))) = \frac{\Delta^2}{24}\lambda^{(2)}(t) + b^2\lambda^{(2)}(t)B \\ + o(b^2) + o(\Delta^2).\end{aligned} \tag{14}$$

Comparing (10) and (14), we see that $\hat{q}(t)$ has an additional bias, $-\frac{\Delta}{2}\lambda^2(t) + \frac{\Delta^2}{6}\lambda^3(t)$, as compared to $\phi(\hat{q}(t))$. In addition to this bias reduction there are other advantages in using $\phi(\hat{q}(t))$ rather than $\hat{q}(t)$, especially when hazards at extreme ages are of primary interest (see [60] for details). If the central death rate, q_{c_i}, is used in (4) instead of the death rate, q_i, a different transformation is proposed in [42], given by:

$$\psi(\hat{q}_c(t)) = \frac{1}{\Delta}\log\frac{2 + \Delta\hat{q}_c(t)}{2 - \Delta\hat{q}_c(t)} \tag{15}$$

We close this section by pointing out that the rate of convergence of $\hat{q}(t)$, $\phi(\hat{q}(t))$, $\hat{q}_c(t)$ or $\psi(\hat{q}_c(t))$, and the choice of the bandwidth b can be derived analogous to that of the kernel estimate $\hat{\lambda}$ in the section "More on Kernel Hazard Estimators for Continuously Observed Data", with Δ playing a role in the asymptotic bias term. The program to compute $\hat{q}(t)$ in (4) or $\hat{q}_c(t)$ and their corresponding transformed estimates, $\phi(\hat{q}(t))$ in (13) or $\psi(\hat{q}_c(t))$ in (15) is very simple, and so is the computation of the cross-validated bandwidths as employed in [42] and [60].

The hazard rate estimate, based on the least-squares cross-validated bandwidth, calculated from the lifetimes for 1000 female Mediterranean fruit flies is plotted in Figure 1. The lifetimes are grouped into days. Here the cross-validated bandwidth is fairly large ($b = 30$), owing to the large variation of the death rates after day 60. The hazard plot was truncated at day 81 when there were only 10 flies left.

Smoothing Hazard Rates for Continuously Observed Data

The grouped data situation discussed in the previous section is common for demographic data that were observed at fixed time points or grouped for convenience. The estimation of hazard rates for continuously observed data is conceptually close to **density estimation**. To see this, consider, instead of (1), the hazard rate function as the derivative of the cumulative hazard function $\Lambda(t) = \int_0^t \lambda(x)\,\mathrm{d}x$. A hazard rate estimate can thus be obtained, analogous to a density estimate, by smoothing the increments of an estimate of $\Lambda(t)$.

Watson and Leadbetter [62, 63] were the first to propose and study such a smoothed hazard estimator using the empirical cumulative hazard estimate $\Lambda_n(t)$ based on an independent and identically distributed (i.i.d.) sample of lifetimes (that is, the $\Lambda_n(t)$ in (18) with all $\delta_{[j]} = 1$). They propose the following convolution type hazard estimator.

$$\hat{\lambda}_n(t) = \int W_n(t - x)\,\mathrm{d}\Lambda_n(t), \tag{16}$$

where W_n is a sequence of smooth functions approaching the Dirac delta function for large n. This delta-sequence method is quite general and covers several types of smoothing methods, including the kernel method (with $W_n(x) = b_n^{-1}K(x/b_n)$). Another type of hazard estimator proposed in [63] is of a ratio

type,

$$\tilde{\lambda}_n(t) = \frac{\hat{f}_n(t)}{1 - \hat{F}_n(t)}, \tag{17}$$

where $\hat{f}_n$ can be any density estimate of the lifetime density f and $\hat{F}_n$ is an empirical estimate of the lifetime distribution function F. Both types of hazard estimators have the same asymptotic variance but different asymptotic biases [49]. The convolution type estimator $\hat{\lambda}_n$ has prevailed owing to its theoretical tractability (exact **mean square errors** available) and aesthetic superiority over the ratio type estimator $\tilde{\lambda}_n$.

A complete **random sample** of lifetimes as assumed above is often unavailable. In reality, lifetime data are often incomplete owing to **staggered entry**, loss to follow-up, or early termination of a study. For simplicity of presentation, we focus on the random **censoring** case for the rest of the entry. Basic references for hazard estimation for other incomplete data such as left-truncated and right-censored data can be found in [26, 58]. The related problem of estimating transition intensities for a two-state Markov Process was explored in [34].

Under the random censorship model, the actual lifetime T_i of an individual may be censored by another random variable C_i. One observes instead (X_i, δ_i), where $X_i = \min(T_i, C_i)$, the minimum of the lifetime and censoring time of the ith individual, and $\delta_i = 1_{\{X_i = T_i\}}$, which is one if the actual lifetime is observed and zero otherwise. We shall assume that the censoring times $C_1, C_2, \ldots, C_n$ have a common distribution function G and that they are independent of the lifetimes $T_1, \ldots, T_n$. Let $(X_{(i)}, \delta_{[i]})$, $i = 1, 2, \ldots, n$, be the ordered sample with respect to X_i's (that is, $X_{(1)} \le X_{(2)} \le \cdots \le X_{(n)}$, and $\delta_{[i]}$ is the corresponding censoring indicator of $X_{(i)}$).

Hazard estimators in this situation are ordinarily obtained by smoothing the increments of the **Nelson–Aalen estimator** $\Lambda_n(\cdot)$ for the cumulative hazard function $\Lambda(t)$. Let $N_n(t) = \sum_{i=1}^n 1_{\{X_i \le t, \delta_i = 1\}}$, and $Y_n(t) = \sum_{i=1}^n 1_{\{X_i \ge t\}}$. The Nelson–Aalen estimator $\Lambda_n(\cdot)$, which is instrumental in survival analysis for censored data, is defined as

$$\begin{aligned}\Lambda_n(t) &= \int_0^t \frac{1_{\{Y_n(s) > 0\}}}{Y_n(s)}\, \mathrm{d}N_n(s) \\ &= \sum_{i=1}^n \frac{\delta_{[i]} 1_{\{X_{(i)} \le t\}}}{n - i + 1}\end{aligned} \tag{18}$$

if there are no tied observations. Properties of the random step function $\Lambda_n(t)$ have been studied extensively; see, for example, [1, Section IV.1] for details.

Kernel Estimators

Substituting the Λ_n in (18) into (16) and choosing $W_n(x) = b^{-1} K((t - x)/b)$, for a particular choice of kernel K and bandwidth $b = b_n$, we arrive at the kernel hazard estimator:

$$\begin{aligned}\hat{\lambda}(t) &= \int \frac{1}{b} K\left(\frac{t - x}{b}\right) \Lambda_n(x), \\ &= \sum_{i=1}^n \frac{1}{b} K\left(\frac{t - X_{(i)}}{b}\right) \frac{\delta_{[i]}}{n - i + 1},\end{aligned} \tag{19}$$

if there are no tied observations.

Asymptotic properties on consistency are typically obtained under the following assumptions: (i) the true hazard rate is k-times differentiable for a $k \ge 0$; (ii) the bandwidths satisfy (7); and (iii) the kernel is of order k, defined as:

$$\begin{aligned}&\int K(x)\, \mathrm{d}x = 1, \quad \int K^2(x)\, \mathrm{d}x < \infty, \\ &\int x^j K(x)\, \mathrm{d}x = 0 \text{ for } 1 < j < k, \\ &\int x^k K(x)\, \mathrm{d}x \text{ is finite but nonzero.}\end{aligned} \tag{20}$$

The choice of the bandwidth is of crucial importance and regulates the trade off between the bias and variance of the estimator in (19). A small bandwidth yields a less smooth curve, with smaller bias but larger variance, as compared to a larger bandwidth (see (23) and (24)). Bandwidth choice is particularly crucial for hazard estimation near the right boundary of the data as the variance increases to infinity there. More discussions on bandwidth choice is provided in the next section.

As for the choice of the kernel, smoothness of the kernel determines the smoothness of the corresponding kernel estimate, and the order of the kernel determines the order of the bias (see (23)) and thus the rate of convergence. Often, nonnegative kernels are used in practice, and the Epanechnikov kernel in (6) has certain optimality properties (see [39]).

The kernel hazard estimate is the simplest and thus a widely adopted smooth hazard estimator. It

has been studied extensively in the literature, for example, by Ramlau–Hansen [47, 48], Yandell [65], Tanner and Wong [57], Burke and Horváth [7], Diehl and Stute [11] and Müller and Wang [40].

Spline Estimators

Another commonly adopted smoothing method is the spline method. There are several types of spline methods. The most widely investigated spline method for hazard smoothing is the penalized likelihood approach. Let $\eta(t) = \log \lambda(t)$ be the log hazard function. The log-likelihood function for censored data is

$$\ell(\eta) = \sum_{i=1}^{n} \left\{ \delta_i \eta(X_i) - \int_0^{X_i} e^{\eta} \right\}, \qquad (21)$$

which is unbounded if no shape restriction on η is imposed. A penalty $J(\eta)$, measuring the roughness of η, is therefore incorporated and the penalized likelihood estimate $\hat{\eta}$ of η is the maximizer of the penalized log likelihood

$$\frac{1}{n} \sum_{i=1}^{n} \left\{ \delta_i \eta(X_i) - \int_0^{X_i} e^{\eta} \right\} - \frac{\alpha}{2} J(\eta), \qquad (22)$$

among all η in a Hilbert space. Here α is a smoothing parameter. Smaller α yields a better fit but a more variable (rough) curve. A typical choice of $J(\eta)$ is $\int [\eta^{(2)}(x)]^2 \, dx$, which leads to a cubic spline with knots at all $X's$. More specifically, $\hat{\eta}$ is two-times continuously differentiable and is a piecewise cubic polynomial between any two consecutive $X's$. The smoothing parameter α plays a similar role to that of the bandwidth b in a kernel estimate. **Cross-validation** is a common way to determine the value of α; see [43, 44] for computational details and [26] for asymptotic results.

In (22), the roughness of $\log \lambda(t)$ is penalized so as to avoid nonnegative constraints on the hazard function. Other forms of penalty functions were proposed in [2, 3, 52]. The penalty function J determines the kind of spline resulted from (22). For example, the penalty $J(\eta) = \int [\lambda'(X)]^2 \, dx$ is employed in [2], and the resulting hazard estimate is a piecewise quadratic spline. Note that this hazard estimate may yield negative values under heavy censoring.

The above spline estimates have knots at each of the observed X values and are called smoothing splines in the literature (see [25, Chapter 2]). Another type of spline method is regression splines or B-Splines, which adopt a fixed number of knots and basis functions; see [35, 50] for details and ways to select the number and location of knots. A hazard function estimate with flexible tails, called HEFT, is proposed in [35] by estimating the log-hazard function using cubic splines.

Other Hazard Rate Estimators

The ratio type hazard estimator in (17), also due to Watson–Leadbetter, has been extended to censored data as well and was studied by Blum and Susarla [5], Földes, Rejtö and Winter [16] and Lo, Mack, and Wang [37].

Hjort [30] advocated the use of semiparametric approaches to estimate hazard rates. The approach is to start with a possibly crude parametric estimate and to improve it via some nonparametric procedures. The motivation is to reduce the bias of a parametric estimate via nonparametric correction locally, and yet to arrive at an estimate that is less variable than a fully nonparametric one.

For reviews of earlier results on hazard rate estimation, see [18, 45], and [54] for uncensored data.

More on Kernel Hazard Estimators for Continuously Observed Data

The rate of convergence of the kernel hazard estimate (19) depends on the order of the kernel, the bandwidth, and the differentiability of the hazard function. Typically, the order k of the kernel is chosen to be an even number with $k = 2$ being the standard choice. The resulting bias and variance are respectively

$$\text{bias}(\hat{\lambda}(t)) = b^k [\lambda^{(k)}(t) B_k + o(1)], \qquad (23)$$

$$\text{var}(\hat{\lambda}(t)) = \frac{1}{nb} \left\{ \frac{\lambda(t)}{[1 - F(t)][1 - G(t)]} V + o(1) \right\}, \qquad (24)$$

where $B_k = (-1)^k / k! \int x^k K(x) \, dx$ and V is as in (5).

The influence of the bandwidth b and the trade off between the bias and variance is seen from (23) and (24). The optimal rate for the mean squared error (MSE) of $\hat{\lambda}(t)$ is attained when the $(bias)^2$ and variance are of the same order. This results in an optimal MSE rate of convergence of $n^{2k/(2k+1)}$, which is $n^{4/5}$ for the standard choice of $k = 2$. This rate is

slower than the usual parametric rate of n regardless of the order of k. For the asymptotic distribution, we further assume that $d = \lim_{n\to\infty} nb^{2k+1}$ exists for some $0 \le d < \infty$. Then

$$(nb)^{1/2}(\hat{\lambda}(t) - \lambda(t)) \xrightarrow{\mathcal{D}} N \times \left(d^{1/2}\lambda^{(k)}(x)B_k, \frac{\lambda(t)}{[1 - F(t)][1 - G(t)]}V\right). \quad (25)$$

Extensions to the estimation of derivatives of hazard functions have been considered as well [40]. These essentially involve a change in the kernel. Derivatives are of interest to detect rapid changes in hazard rates or for data based bandwidth choices, as the optimal bandwidths in (26) or (27) depend on the derivatives of the hazard rates. Again, the order k of the kernel affects the convergence rate and also asymptotic constants.

Bandwidth Choice

The bandwidth for a kernel hazard estimate can be fixed at all points (global bandwidth b) or can vary for different points (local bandwidth $b(t)$). Usually, a global bandwidth is employed for a smooth density or regression estimate owing to its simplicity. However, for the hazard estimation situation discussed here, there are compelling reasons to adopt local rather than global bandwidth choices. According to (24), the variance of the kernel estimate $\hat{\lambda}(t)$ eplodes to infinity as t approaches the right boundary of the data. Thus, the variance tends to dominate the bias in the right tail and this needs to be compensated for by a larger bandwidth.

The optimal local bandwidth of $\hat{\lambda}(t)$, which minimizes the leading term of $MSE(\hat{\lambda}(t))$ is

$$b^*(t) = n^{-1/(2k+1)} \times \left\{\frac{1}{2k}\frac{\lambda(t)}{[1 - F(t)][1 - G(t)]}\frac{V}{[\lambda^{(k)}(t)B_k]^2}\right\}^{1/(2k+1)} \quad (26)$$

To find the optimal global bandwidth, we have to restrict the range of t to a compact interval $[0, \tau]$ with $F(\tau) < 1$ and $G(\tau) < 1$. The global optimal bandwidth which minimizes the leading term of $MISE(\hat{\lambda}) = E\int_0^\tau [\hat{\lambda}(x) - \lambda(x)]^2\,\mathrm{d}x$ is

$$b_{\text{opt}} = n^{-1/(2k+1)}\left\{\frac{1}{2k}\int_0^\tau \frac{\lambda(x)}{[1 - F(x)][1 - G(x)]}\,\mathrm{d}x \times \frac{V}{B_k^2\int_0^\tau [\lambda^{(k)}(y)]^2\,\mathrm{d}y}\right\}^{1/(2k+1)}. \quad (27)$$

Note that both the local and global optimal bandwidths in (26) and (27) involve unknown quantities. In practice, one has to find alternatives. There is an extensive literature on bandwidth selection and "cross-validation" and "plug-in" techniques are popular; see [40, 41, 46] for details. A bootstrap method to select the global bandwidth has been advocated in [20] as an alternative. In addition to the local bandwidth choice in (26), which adopts different bandwidths at different time point t, choosing bandwidths as the distance of t to its kth nearest neighbor among the remaining uncensored observations is a convenient way to adapt to the data by allowing for varying degrees of smoothing; see [17, 56, 57] for detailed descriptions. Other data-adaptive local or global bandwidth choices for hazard estimates can be derived analogously to the density estimation case as discussed in [53, Section 3.4] and [59, Chapter 3].

Boundary Effects

We close this section with a cautionary remark that the kernel smoothing method needs to be employed very carefully near the boundary as there is a bias problem in such regions, usually referred to in the literature as boundary effects. Boundary effects may be attributed to the fact that the support of the kernel exceeds the available range of data and are not unique to hazard estimates.

An unmodified kernel estimate is unreliable in the boundary region, which is the region within one bandwidth of the largest or smallest observations. To remedy the boundary effects, different kernels, referred to as "boundary kernels" can be used within the boundary region. As a consequence, varying kernels are employed at each location t and the bandwidths are affected accordingly. The resulting kernel estimate with varying kernels and varying local bandwidths takes the form

$$\hat{\lambda}(t) = \int \frac{1}{b(t)}K_t\left(\frac{t - x}{b(t)}\right)\mathrm{d}\Lambda_n(x), \quad (28)$$

where both the bandwidth $b = b(t)$ as well as the kernel $K = K_t$ depend on the point t. Details for the choices of the kernel K_t and bandwidths $b(t)$ can be found in [41].

Simulation Comparison of Hazard Estimators and Software

A very informative and extensive simulation study was carried out in [29] to compare the aforementioned kernel-based hazard estimators with various local and global bandwidth choices and boundary corrections, the kernel-based hazard estimators in [17] with varying bandwidth methods based on kth nearest-neighbor, and the spline-based estimators in [35]. The results indicated advantages of using HADES, the aforementioned local optimal bandwidth choice and boundary correction in [41]. There is significant improvement (over 50% on the average) in mean square error over the global bandwidth choice if a local optimal bandwidth is employed. Boundary corrections will lend additional efficiency. The locally optimal bandwidth estimators in [41] with only left boundary correction also outperformed two publicly available procedures, the spline estimator in [35] and the nearest-neighbor estimator in [17]. The latter is based on the procedures in [56, 57].

A library of Fortran and S-Plus programs for the HADES estimator in [41] and for the nearest-neighbor estimator in [17] is available under a package called "muhaz" at the website of the authors of [29] `:http://odin.mdacc.tmc.edu/anonftp/` To get the S-code follow the link: `ftp://odin.mdacc.tmc.edu/pub/S/muhaz.tar.gz` The corresponding R program for **muhaz** is also publicly available at: `cran.r-project.org/doc/packages/muhaz`

The S-plus code of the spline estimator in [35] called, **HEFT** is publicly available from the StatLib software library.

Hazard Regression

Estimating a Baseline Hazard Function

So far, we discussed hazard smoothing for a homogeneous population. Often the risk of an individual varies according to the values of some **covariates**. Thus, the hazard function of an individual with covariate $Z \in \Re^d$ is $\lambda(t, Z)$ and regression techniques are required. A semiparametric approach with a regression parameter β and a nonparametric baseline hazard function $\lambda_0(t)$ is often adopted. Examples include Cox's **proportional hazards regression model**, where $\lambda(t, Z) = \lambda_0(t) \exp(\beta^T Z)$, and the **accelerated failure-time model**, where $\lambda(t, Z) = \lambda_0(\exp(\beta^T Z)t) \cdot \exp(\beta^T Z)$.

A smooth estimate of the baseline hazard is preferable and often necessary to obtain consistent estimates of $\lambda(t, Z)$. Anderson and Senthilselvan [2] applied the penalized maximum likelihood approach, and Gray [23] and Wells [64] applied the kernel method to estimate the baseline hazard function in Cox's proportional hazard model. Andersen et al. [1, Section VII.2.5] give several examples of estimated baseline hazard functions.

The Cox proportional model has been extended in [9] to allow covariate dependent baseline hazard function. The model is $\lambda(t, Z) = \lambda_0(t, X_t) \exp[\beta^T Z_t]$, where X_t and Z_t are predictable covariate processes or covariate vectors. Another type of extension is to employ, as in [61], an unknown link function in the proportional model, where $\lambda(t, Z) = \lambda_0(t) g(\beta^T Z)$ with g completely unknown and estimated via local **partial likelihood** method. Etezadi-Amoli and Ciampi [13] also investigated another extension of Cox's proportional hazards and accelerated failure-time models of the form: $\lambda(t, Z) = \lambda_0(g_1(\alpha^T Z)t) g_2(\beta^T Z)\cdot$, where $\lambda_0(t)$ denotes the baseline hazard function, which is estimated by the regression spline method.

Generalized Additive Proportional Hazards Model

Another type of **proportional hazards** model allows an arbitrary covariate effect of the form:

$$\lambda(t, Z) = \lambda_0(t) \exp[g(Z)], \tag{29}$$

where g is an unspecified smooth function of Z. LeBlanc and Crowley [36] use the CART (Classification and Regression Trees) algorithm to estimate the relative risk g (*see* **Tree-structured Statistical Methods**), Gentleman and Crowley [19] and Fan, Gijbels, and King [15] use local full or partial likelihood methods to estimate g. Although this is the most general proportional hazards model, it is difficult to estimate $g(Z)$ when the covariate Z is of high

dimension, say $d \geq 3$. An extremely large sample size would be needed. This is called the "curse of dimensionality". Dimension reduction models and methods are thus called for. Among these, the additive regression model is a promising alternative to (29).

Under the additional assumption that g is additive in (29), that is, $g(z) = \sum_{i=1}^{d} g_i(z_i)$, Hastie and Tibshirani [28] and O'Sullivan [43, 44] use smoothing splines to estimate g (*see* **Generalized Additive Model**). Sleeper and Harrington [55] use B-splines, and Gray [24] uses penalized splines with fixed knots to estimate g and incorporate time-varying coefficients. Apart from the minor differences in the various spline methods, all the aforementioned methods adopt the partial likelihood approach with a penalty for each g_i to be estimated.

Let (X_i, Z_i, δ_i), $i = 1, \ldots, n$ denote the observed data and $Y_1 < \cdots < Y_k$ denote the k distinct failure times with d_i failures at time Y_i. The penalized log partial likelihood with smoothing parameters $\alpha_1, \ldots, \alpha_d$ is:

$$\ell(g_1, \ldots, g_d) = \sum_{i=1}^{k} \delta_i \left\{ \sum_{j \in D_i} g(Z_j) - d_i \log \left(\sum_{j \in R_i} e^{g(Z_j)} \right) \right\} - \frac{1}{2} \sum_{i=1}^{d} \alpha_i \int \left[g_i^{(2)}(t) \right]^2 dt, \quad (30)$$

where D_i is the set of indices of the failures at observed failure time X_i, and R_i is the set of indices of individuals at risk at time X_i. Minimizing $\ell(g_1, \ldots, g_d)$ then yields the smoothing spline estimates $(\hat{g}_1, \ldots, \hat{g}_d)$. Calculations of the estimates can be very time-consuming; see [27, Section 8.3] for computational issues.

Nonparametric Hazard Regression

A completely nonparametric approach to estimate $\lambda(t, Z)$ is desirable sometimes. Kooperberg, Stone, and Truong [35] used **loglinear regression** splines and their tensor products to estimate $\log \lambda(t, Z)$. Gu [26] considered the penalized likelihood approach. Doss and Li [12] used linear polynomials in Z to fit $\lambda(t, Z)$ locally in a neighborhood of Z. Martingale convergence theory for **counting processes** was used to derive the weak convergence of their hazard estimate.

For continuously observed lifetimes, one can obtain a hazard regression estimate for $\lambda(t, Z)$ by smoothing the increments of any cumulative hazard estimate $\Lambda(t, Z)$. Such a cumulative hazard estimate can be found in [10] and is further studied by McKeague and Utikal [38]. Again, any of the smoothing methods discussed so far can be extended to a nonparametric hazard regression estimate.

Note that by grouping the data along the time axis and the covariate axis, one can also apply any nonparametric regression smoother to grouped data. Gray [24] illustrates this grouping method through a local linear polynomial smoother and kernel regression.

Lexis Diagram

An interesting application of nonparametric hazard regression is the **Lexis diagram** in which individual lifelines are represented as line segments between (time at birth, 0) and (time, age) of death. Here time at birth can be used in a broad sense, that is, as the onset time of a disease. If mortality of individuals varies according to time of birth, a covariate Z based on an individual's calendar time of birth can be incorporated to model individual risks at age t represented by $\lambda(t, Z)$. Keiding [33] suggests using bivariate versions of nonparametric smoothing methods, as discussed above, to estimate $\lambda(t, Z)$, provided that the influence of Z on the hazard function is continuous in Z.

Smoothing Methods in Epidemiology

Introduction

Most observational data in the health sciences are generated by poorly understood and largely nonrandom mechanisms of exposure assignment, subject selection, and measurement error, and are analyzed to estimate causal structures that are latent under these mechanisms. In contrast, most statistical methods presume the data are generated by **identifiable** random processes (i.e. distributions known up to a parameter vector of dimension no greater than the data), and that the structures of interest are estimable under the assumed distributions. Until recently, this chasm between observational reality and statistical theory was formally addressed in no general statistics textbook. As a result, statistical methods for identifiable random processes are used routinely for inferences about unidentified structure.

The validity of these inferences depends on latent independencies (often left implicit or cast as ignorability assumptions) that identify the parameters of interest. In **observational studies** of causation, however, large departures from identifying assumptions are a distinct possibility. Most reports deal with these possibilities in a narrative fashion based on (often incorrect) intuitions about the biasing effects of departures, rather than on quantitative reasoning. Quantification of departure effects, when done at all, is usually by **sensitivity analyses** (e.g. [50], Chapter 19). By embedding assumptions in a larger parametric framework, these analyses show how departures would affect summary statistics. They do not, however, quantify the net uncertainty one should have in light of uncertainties about the departures. Furthermore, because the departures are not identified, the sensitivity results have no inferential interpretation without reference to **prior distributions** for the departures [23].

Several approaches have been developed for inference about parameters (such as causal effects) that are not identified given the uncertainties about biases in observational data. Examples include methods for inference under nonignorable data-generating mechanisms [15, 42], **Bayesian methods** for nonexperimental data analysis (e.g. [12, 18, 27, 33, 39)], and **Monte-Carlo** sensitivity analyses [29, 38, 48]. In some situations, these latent-structure analyses may be essential for coherent inferences about causation in the absence of informative experiments. But between initial data description and these structural analyses, one can mark out a preliminary smoothing or filtering step concerned with estimating expectations for the observed data, rather than with making inferences about deeper and latent structure [20].

In the health sciences, this filtering step is usually skipped or dealt with by fairly primitive means (such as adding $1/2$ to each cell of a table). The present article outlines alternatives in which saturated **hierarchical models** for random variation are used to smooth or filter out extraneous noise before structural exploration (*see* **Generalized Linear Model**). It also provides a brief overview and illustration of basic methods that can be applied using ordinary regression software. For further information on those methods, see **penalized maximum likelihood**; for other smoothing methods, see **density estimation**, **generalized additive model**, **geographical analysis**, Kalman filtering and smoothing, **nonparametric regression**, **smoothing hazard rates**, and **spline function**. At certain points, an analogy will be drawn between smoothing methods and methods for imputing missing data: Both are intended to "clean up" the data before developing inferences about the population structures of interest.

Example Data

The observed counts in Table 1 are taken from an analysis of **bias** in 14 **case–control studies** of exposure to residential magnetic fields and childhood leukemia [29]. On the basis of the earlier work [33], a cutpoint of 3 milligauss (3 mG, equal to 0.3 microtesla) was used for all the studies except the United Kingdom Childhood Cancer (UKCC) study. The latter published only categorizations at 1,2, and 4 mG, hence its estimate compares >4 mG versus ≤ 2 mG; this estimate appears consistent with the other studies, however, and reanalysis of the other studies using a 4 mG cutpoint changed the pooled estimate by only 5% [32]. A study by Green et al. based analyses on quartile categories, resulting in upper cutpoints of only 1.3 to 1.5 mG, and is excluded here because the use of such low cutpoints strongly influenced estimates from earlier studies [32]; it did however report

Table 1 Summary data from 14 case–control studies of magnetic fields and childhood leukemia, smoothed counts for numbers >3 mG (milligauss), and odds ratios. The smoother preserves all totals so totals are not repeated

[d] Final entry is MLE of common odds ratio (lower deviance $P = 0.0001$, homogeneity $P = 0.24$), which is unchanged by smoother to three digits past decimal point.

positive associations upon contrasting the top and bottom quartiles. Finally, a study by Schüz et al. [53] with only three highly exposed cases was excluded because of evidence of severe upward sparse-data bias [31] in the reported estimates (odds ratios of 5 to 11), and insufficient reporting of data to allow further evaluation.

Leukemia is a very rare disease and the usual justifications for interpreting the observed **odds ratios** as rate-ratio estimates apply [50, Chapter 7]. The odds ratios are very consistent across studies (with homogeneity $P = 0.24$). The pooled **maximum likelihood** estimate (MLE) of a common odds ratio is 1.69 with 95% confidence limits of 1.28, 2.23, nearly identical to the **Mantel–Haenszel** (MH) odds ratio of 1.68 with 95% confidence limits of 1.27, 2.22. The association is not explained or modified by any known study characteristic or feature of the available data, such as information source (e.g. measurement method), location, or current type (120v 60 Hz versus 220v 50 Hz). **Covariate** adjustment had almost no impact on the estimates. Results are unchanged using finer categories (e.g. contrasting >3 mG vs. ≤ 1 mG) or continuous field measurements, and there is no evidence of publication bias [32] (*see* **Meta-analysis of Clinical Trials**).

Nonetheless, taking the statistics in Table 1 as **unbiased** for the field effect is equivalent to assuming that each study reported an experiment in which children randomized to known residential field levels (*see* **Randomization**), were never switched from their initial assignment, and were followed until either leukemia or selection as a control or random censoring (*see* **Censored Data**) occurred. These assumptions are unacceptable, and so analyses of the impact of departures (i.e. bias analyses) were carried out [27, 29]. However, some of the methods used for these analyses require that all input counts be nonzero; hence, preliminary smoothing of the counts was done to eliminate the zeros in the observed table. The goal of this step is to smooth out obvious "holes" in the data without disturbing data summaries or patterns.

Some Basic Theory for Smoothing

Notation and Definitions

Let Y be the portion of the data to be treated as having a random component, that is, Y is a **random variable** whose range of possible values is the sample space. Let X be the portion to be treated as fixed, a set of known conditions upon which we condition our **expectation** for Y. In most of the notation that follows, X conditioning will be left implicit; in particular, $\mathrm{E} \equiv \mathrm{E}(Y|X)$ will denote the regression of Y on X, whose possible values define an expectation space Ω. This setup includes multivariate outcomes by making Y an N-row array, and further extends to random regressors by treating those regressors as part of the Y array and including only known fixed regressors in X. The present development, however, will be limited to univariate Y and fixed regressors.

Defining the residual vector as $\varepsilon \equiv Y - \mathrm{E}$, we have $Y = \mathrm{E} + \varepsilon$, where $\mathrm{E}(\varepsilon|\mathrm{X}) = 0$, even if Y has discrete components. Typically, $Y = (Y_1, \ldots, Y_N)'$ is a random vector of outcomes observed on N subjects or groups indexed by $i = 1, \ldots, N$, Ω is a subset of R^N, X is an N-by-J observed-covariate matrix with rows X_i corresponding to the Y_i, and X may include a constant. For the case-control data in Table 1, Y will be the numbers exposed above 3 mG within the $N = 2(14) = 28$ groups defined by disease status and study, X will contain design variables based on these groups, and E will be the expected exposed counts for the groups, given X and the group totals.

Parsimony, Information Loss, and Distortion

Most conventional modeling has the goal of estimating some **parsimonious** summary β for E, usually in the form of the parameter vector in a model $M_{\mathrm{E}}(\beta)$ for the regression E, coupled with a model $p(\varepsilon; \upsilon)$ for the distribution of ε, where β and υ have much lower dimension than E and may overlap. A paradigmatic example is normal **linear regression** in which $\mathrm{E} = M_{\mathrm{E}}(\beta) = X\beta$ and $p(\varepsilon; \upsilon) = \{2\pi \det(\upsilon) \exp(\varepsilon' \upsilon^{-1} \varepsilon)\}^{-1/2}$, with υ a simple **covariance matrix** for ε, for example, $\upsilon = \sigma^2 \mathrm{I}$ with σ^2 functionally independent of β. Another example is binomial **logistic regression** in which Y contains counts and hence ε is discrete (as in the example), and in which $\upsilon = \beta$ because the variance is a fixed function of the mean.

Parsimony also arises from **estimation** issues. Nothing in the above setup requires that X has independent columns or that $J < N$. Nonetheless, classical estimation procedures require independent X columns, and may exhibit many problems unless the number of X columns J is much less than the number of observations N. These procedures thus require parsimonious choice of X columns, otherwise known as **variable selection**. That selection should be heavily guided by contextual theory, such as causal ordering, but unfortunately is often left to mechanical testing procedures that distort significance levels and coverage rates of conventional tests and confidence intervals (*see* **Level of a Test**).

For the present purposes, parsimony gives rise to information loss. Indeed, conventional model-based estimates $\tilde{\mathrm{E}}$ of E (more often written $\hat{\mathrm{Y}}$) must lie within the final model manifold (i.e. the image of the β-space traced by $M_{\mathrm{E}}(\beta)$ in Ω), which has dimension no greater than J and which cannot capture any pattern not visible in this manifold. For example, if X contains only a single term for a treatment, the resulting estimates will be unable to capture (say) three-dimensional patterns in the relation of that treatment to Y. Thus, parsimony in modeling E (limiting the number of parameters) entails distortion along at least some dimensions of E, and thus seems a questionable goal in an exploratory or smoothing context.

Filtering

Consider instead the rather different goal of "filtering out" ε from Y to get and estimate $\tilde{\mathrm{E}}$ of E, without the

objective of fitting a particular structure $M_E(\beta)$ to E. We might wish to do this because we regard ε and E as representing the components of Y that are purely random and purely systematic, with the E component determined both by biases and by effects of interest. Because it is free of **random error**, E is preferable to Y for making inferences about the structure of systematic variation in Y. This does *not* mean that E is sufficient for (say) causal inference (*see* **Causation**), because causal models are unidentified (latent) structures if there is no identifiable distribution for **confounding** effects (such as a randomization distribution) [3, 19, 47, 49, 51]. Nonetheless, E would admit more straightforward modeling of latent structures than would the original Y. The idea here is akin to imputation of missing values with a goal of providing a completed data set useful to any subsequent analyst, regardless of that analyst's modeling objective [42].

To express this idea in a Bayesian formalism, suppose Y and hence ε is uninformative about any latent structure once E is known, that is, for any structure of interest $M_E(\beta)$, $p(\beta|E, Y) = p(\beta|E, \varepsilon) = p(\beta|E)$. For an estimator $\tilde{E}$ of E to be capable of conveying information in E about *any* possible structure, it cannot be constrained to lie in a subspace of Ω. Thus, the goal of filtering is the estimation of E under a saturated model, that is, a model whose range spans Ω; such a model must have at least N functionally independent parameters (*see* **Generalized Linear Model**). This sort of filtering shares few parsimony considerations with conventional modeling. For example, because the model is saturated, there need be no parsimony criterion in model selection (e.g. parsimony is not an issue in choosing columns of X, although some covariates might be deemed redundant or uninformative for E) (*see* **Model, Choice of**). In a similar fashion, concerns about mismeasurement need not arise; for example, even without validation data, a mismeasured covariate may still provide much useful information for estimating E. Again, parallel considerations arise when including covariates in missing-data analyses [42]: a mismeasured covariate may still be useful for filling in missing values of other covariates.

"Noise removal" is a more apt term than "smoothing" for this preliminary filtering stage, for in applications like image processing and threshold detection, one wishes to sharpen rather than smooth at real edges or thresholds. An ideal method would remove as much of the noise as possible while giving back all potentially informative patterns in E ("signals" in the Y vector); that is, it would clean out the noise without removing *any* potentially important information, whether "statistically significant" or not. Again we have a shift of emphasis from parsimony criteria (e.g. "include only if significant at level α") toward more generous inclusion of model terms. This shift is needed because filtering is only an intermediate step between data description and inferential modeling (which may focus on an entirely latent parameter); it is an attempt to clean out noise before making the contextual interpretations that inference represents. The patterns in the resulting estimates $\tilde{E}$ are the information input to the inferential or structural modeling stage, and thus need to be preserved; at that later stage some patterns may be clear and others may be rejected as too imprecisely estimated to be of use.

To summarize: Much as a museum will clean and restore art for public display, the goal of filtering and imputation is to clean and restore data to facilitate interpretation by a broad audience, not to impose an interpretation (structural model) $M_E(\beta)$ on the data. This idea can be especially important when structural inference is likely to be controversial, as in the magnetic-field/leukemia example.

Filtering by Shrinkage

Fitting a saturated model (*see* **Generalized Linear Model**) by conventional "unbiased" methods, such as **least squares** or maximum likelihood (ML) would only give smoothed values $\tilde{E}$ equal to the observed Y, and so achieve nothing. Choosing methods to minimize an expected loss function of $E - \tilde{E}$, without concern for **unbiasedness** or other classical constraints, leads naturally to **shrinkage estimation** of E (as opposed to β), in which $\tilde{E}$ is "stabilized" by pulling it away from Y, toward a shrinkage point. These methods include Stein, **ridge**, **penalized**, pseudo-Bayes, semi-Bayes, **empirical-Bayes**, and **random-coefficient** estimation [4, 13, 16, 55], and their modern hierarchical-Bayes variants [6, 15, 40]. Thus, smoothing can be identified with shrinkage methods for fitting saturated models. For example, **smoothing splines** are based on penalized fitting of an overparameterized "natural" cubic spline [34]. The key questions are then: what point should Y (the conventional saturated-model estimator of E) be shrunk toward, and by how much.

Intuitive answers to these questions arise naturally from noting that all shrinkage procedures can be cast in a Bayesian format, for example, ridge and penalty parameters correspond to hyperparameters in a **prior distribution** $p(\mathrm{E})$ for E [39]. The chief difference among the procedures is that some (e.g. empirical-Bayes) estimate all hyperparameters from the data, while others (e.g. semi-Bayes) fix certain hyperparameters in advance (usually the **variance components**). The resulting shrinkage point corresponds to the estimated prior mean, and the degree of shrinkage is a function of the random error and prior variances, where the latter may be estimated or fixed.

As an example, suppose $p(\varepsilon;\upsilon)$ is **multivariate normal** (MVN) with **information matrix** (inverse-covariance) $\upsilon^{-1} = \iota_\varepsilon$, and the prior $p(\mathrm{E})$ is MVN with mean μ_E and information ι_E. With $c = (\iota_\varepsilon + \iota_\mathrm{E})^{-1}$, the posterior mean $\mu_{\mathrm{E}|Y}$ of E is $c(\iota_\varepsilon Y + \iota_\mathrm{E}\mu_\mathrm{E})$, which is the result of shrinking Y toward μ_E with the degree of shrinkage determined by the relative amount of prior information for ε and E. The posterior mean for ε is $\mu_{\varepsilon|Y} = Y - \mu_{\mathrm{E}|Y} = c\iota_\mathrm{E}(Y - \mu_\mathrm{E})$, the result of shrinking the "preposterior" residual $Y - \mu_\mathrm{E}$ toward the origin by the factor $c\iota_\mathrm{E}$; the error model $p(\varepsilon;\upsilon)$ can thus be viewed as an origin-centered prior for estimating ε, with $\mu_{\mathrm{E}|Y} = Y - \mu_{\varepsilon|Y}$ the result of subtracting the ε estimate $\mu_{\varepsilon|Y}$ from Y. Symmetrically, $\mu_{\mathrm{E}|Y} - \mu_\mathrm{E} = c\iota_\varepsilon(Y - \mu_\mathrm{E})$ is the result of shrinking $Y - \mu_\mathrm{E}$ toward the origin by the factor $c\iota_\varepsilon$.

These relations extend well beyond those in which the error and prior distributions are approximately MVN. For example, if $p(Y|\mathrm{E})$ is **multinomial** with total T and cell probability vector $\pi = \mathrm{E}/T$, and the prior $p(\pi)$ is Dirichlet with mean E_π (*see* **Multivariate Distributions, Overview**) then $\mu_{\mathrm{E}|Y} = (1 - \mathrm{c})Y + c\mathrm{E}_\pi = Y - c(Y - \mathrm{E}_\pi)$ where $c = P/(T + P)$ and P is an "effective prior sample size" [4, 17], [18, Chapter 12]. The same type of relation holds under product-multinomial-Dirichlet, product-binomial-beta, and product-Poisson-gamma models for $p(Y|\mathrm{E})p(\mathrm{E})$, with c varying across the independent subvectors (blocks) within Y.

Filtering by Hierarchical Models

Semi-Bayes (SB) or partial-Bayes procedures modify elementary Bayes procedures by estimating μ_E from Y. Usually, the prior mean μ_E is given a parametric model form $\mu_\mathrm{E} = M_\mu(\beta)$, and so estimating μ_E reduces to computing an estimate $\tilde{\beta}$ of β. This resembles conventional modeling, but now only μ_E rather than E is constrained to lie in the model manifold. Overall, we obtain a hierarchical structure $Y = M_\mu(\beta) + \delta + \varepsilon$ where the partial residual $\delta = \mathrm{E} - M_\mu(\beta)$ has a mean-zero prior density $p(\delta;\tau)$. The entire model is partial-Bayes insofar as $\mathrm{E} = M_\mu(\beta) + \delta$ is partitioned into a component $M_\mu(\beta)$ with no prior on β and a component δ with a known, mean zero proper prior [1].

Because δ and ε are aliased, the partition of the estimated preposterior residual $Y - \tilde{\mu}_\mathrm{E} = Y - M_\mu(\tilde{\beta})$ into estimates $\tilde{\varepsilon} = Y - \tilde{\mu}_{\mathrm{E}|Y}$ (which will be discarded after use in **diagnostics**) and $\tilde{\delta} = \tilde{\mu}_{\mathrm{E}|Y} - \tilde{\mu}_\mathrm{E}$, is determined by the prior $p(\delta;\tau)$. $\tilde{\delta}$ may be viewed as the result of shrinking the unconstrained δ estimate $Y - \tilde{\mu}_\mathrm{E}$ toward the origin; given $p(\varepsilon;\upsilon)$, the prior $p(\delta;\tau)$ controls the amount of shrinkage. The prior parameter vector τ may be viewed as a smoothing or tuning vector (although more often τ is a scalar, and $\lambda = 1/\tau^2$ is called the tuning parameter). Empirical-Bayes (EB) procedures estimate τ as well as β, usually under a simple model for $p(\delta;\tau)$, for example, $p(\delta;\tau)$ is often assumed MVN$(0,\tau^2 C)$ with τ unknown and C a known structured matrix (identity, exchangeable, autocorrelated, etc). Bayes empirical-Bayes (BEB) procedures introduce proper hyperpriors $p(\beta)$ and $p(\tau)$ to estimate β and τ; $p(\tau)$ may be interpreted as encoding prior information about the dispersion of δ, or about how much smoothing would be best to remove the most noise without removing too much signal.

Use of lower-dimensional prior models $M_\mu(\beta)$ and $p(\delta;\tau)$ for E resurrects questions of model and covariate choice. Perhaps by analogy with conventional modeling, much of the literature on smoothing has focused on simple $M_\mu(\beta)$, for example, most table smoothers shrink toward independence models or models reduced by a **variable-selection** algorithm [4], and many scatterplot smoothers shrink toward a line [34]. As mentioned earlier, these practices can be hazardous, insofar as any patterns falling outside the prior-model manifold will be smoothed (flattened) out, and perhaps become inapparent as a result. To avoid this problem, one can keep the prior model very large, large enough to be capable of approximating any pattern that *a priori* might be of interest and of nonnegligible probability. To cite a phrase attributed to L.J. Savage, at this stage "all models should be as

big as a house"; any data-based model reduction risks conflating inferential objectives with the more limited goal of noise reduction, which as argued above should be based on a flexible model $M_\mu(\beta)$ for μ_E.

A more specific guide for elicitation of the form of the prior model (as opposed to values of β) is that $M_\mu(\beta)$ should be rich enough to make the δ components independent given β [36]. In this sense, $M_\mu(\beta)$ should exhaust all structure in any prior beliefs or information about E, leaving only a random prior residual. This use of "random" is however distinct from the description of random error ε: δ represents an allowance for uncertainty about structure, and may contain heretofore unsuspected patterns in E (signals), whereas ε represents truly uninformative noise in Y. For data in which ε is generated by a known mechanism, such as studies conducted with known random allocation or sampling designs (and other situations admitting design-based inference), $p(\varepsilon;\upsilon)$ is known, and hence can be removed from the estimable distribution of $Y - \mu_E = \delta + \varepsilon$ to estimate $p(\delta;\tau)$.

In observational data, however, $p(\delta;\tau)$ and $p(\varepsilon;\upsilon)$ are not separately identified, and τ or some transform like $\lambda = \tau^{-2}$ is used as a tuning parameter that determines how $Y - \mu_E$ will be decomposed into the signal carrier δ and pure noise ε. When τ^2 is a prior variance, as τ goes to zero ($\lambda \to \infty$), smoothing approaches conventional fitting of the model $E = \mu_E = M_\mu(\beta)$; this extreme is complete smoothing away of everything outside the model manifold, and so treats the entire departure from $M_\mu(\beta)$ as noise. Conversely, as τ grows without bound ($\lambda \to 0$) smoothing approaches conventional fitting of the saturated model; this extreme is no smoothing at all, and so treats the entire departure from $M_\mu(\beta)$ as structural. Smoothing can thus be seen as a compromise between extremes of treating $M_\mu(\beta)$ as the only structure, and on the other hand treating all variation in Y as structural (nonrandom or systematic).

Nonlinear Models

Thus far, I have used an additive decomposition of E. Nonetheless, all the procedures extend straightforwardly to forms such as $g(E) = M_\mu(\beta) + \delta$ for some known link function (*see* **Generalized Linear Model**) g, where $g(E)$ has prior mean $M_\mu(\beta)$ and δ again has a mean-zero prior density $p(\delta;\tau)$. These extensions are just special cases of generalized-linear and nonlinear hierarchical modeling [15, 36] in which the first-stage model is saturated: $g(E)$ is the vector of first-stage coefficients, with β and δ the second-stage coefficient and residual vectors. If $M_\mu(\beta) = X\beta$ with β given no prior, β is the fixed effect in a generalized-linear mixed model with random effect δ [5].

Basic Computations

Some Considerations for Current Platforms

Most current Bayesian texts presume software for posterior sampling is available, and so emphasize BEB or more general hierarchical-Bayes approaches [15], while non-Bayesian texts focus on EB or equivalent variance-components methods [10]. Many if not most epidemiologists are however committed to one or a few major packages (SAS, SPSS, or Stata) (*see* **Software, Biostatistical**), which as of this writing lack posterior sampling; also, most prefer simple programs, at least for primary analyses. This section therefore focuses on basic numeric approximations that can be carried out with popular regression software to obtain estimated prior and posterior means $\tilde{\mu}_E$ and $\tilde{\mu}_{E|Y}$.

Smoothing with a flexible $M_\mu(\beta)$ will tend to make $Y - \tilde{\mu}_E$ close to the origin, and hence $\tilde{\delta} = \tilde{\mu}_{E|Y} - \tilde{\mu}_E$ will tend to have very small components roughly proportional to τ when τ^2 is a prior variance. While this is not a problem if τ is known, it can make τ estimators from moment-based EB procedures (used for example in SAS proc Glimmix) perform very poorly in sparse binomial data [5] (*see* **Chi-square Tests**), a case in which preliminary smoothing is most important. For example, the truncated-EB moment-estimator of τ in the MVN(0,$\tau^2 C$) model for $p(\delta;\tau)$ often collapses to 0, resulting in $\tilde{\mu}_{E|Y} = \tilde{\mu}_E$, whereas the corresponding fixed-τ (semi-Bayes) $\tilde{\mu}_{E|Y}$ behaves more reasonably under the same conditions [21, 22]. These problems with "classical" EB procedures reflect the weakness of data information for separating Y into the three model components ($\mu_E, \delta, \varepsilon$), and the consequent need for strong prior information in order to produce a contextually sensible degree of filtering.

When Y is not very informative for τ under the model but $p(\tau)$ is very informative, $p(\tau|Y)$ will differ little from $p(\tau)$ and the $\mu_{E|Y}$ obtained from a full BEB procedure using $p(\tau)$ will often be well

approximated by the $\mu_{E|Y}$ obtained from the corresponding procedure that fixes τ at the mean or median of $p(\tau)$ (which is just BEB with point prior for τ). This suggests that, for smoothing purposes, Bayes or semi-Bayes procedures can be used as convenient approximations to full hierarchical procedures. Under the model $g(E) = M_\mu(\beta) + \delta$, $\mu_{E|Y}$ has first-order asymptotic approximation $\tilde{\mu}_{E|Y} = g^{-1}[M_\mu(\tilde{\beta}) + \tilde{\delta}]$, where $(\tilde{\beta}, \tilde{\delta})$ is the posterior mode of (β, δ). One can obtain $(\tilde{\beta}, \tilde{\delta})$ by maximizing the loglikelihood for the model $g(E) = M_\mu(\beta) + \delta$ with penalty $\ln\{p(\delta;\tau)\}$, that is, $(\tilde{\beta}, \tilde{\delta})$ is the maximum penalized-likelihood (MPL) estimate of (β, δ) [40]. The negative inverse of the Hessian at $(\tilde{\beta}, \tilde{\delta})$ is then an approximate posterior covariance matrix for $(\tilde{\beta}, \tilde{\delta})$, and $\tilde{\mu}_E = g^{-1}(X\tilde{\beta})$ and $\tilde{\mu}_{E|Y} = g^{-1}(X\tilde{\beta} + \tilde{\delta})$ are approximate prior and posterior means for E.

Data-augmentation Priors

For **beta**, Dirichlet, and normal priors and some generalizations with τ fixed, one can obtain $(\tilde{\beta}, \tilde{\delta})$ and hence $\tilde{\mu}_{E|Y}$ from conventional regression packages by augmenting Y and X with "prior data" [1, 7, 25, 28, 30, 37]. To illustrate, suppose $p(Y|E)$ is product-binomial with n the vector of totals and risks $\pi_i = E_i/n_i = \text{expit}(X_i\beta + \delta_i)$, where $\text{expit}(u) \equiv 1/(1 + e^{-u})$. This is a linear-logistic regression with random effects δ_i; for Table 1, π_i and n_i are the risk of high exposure and the size of group i. A mean-zero independence conjugate prior density for δ is proportional to $\Pi_i \text{expit}(\delta_i)^{ai}\text{expit}(-\delta_i)^{ai}$, a product of logistic-beta(a_i, a_i) densities, that is, densities such that $\text{expit}(\delta_i)$ is beta(a_i, a_i); in particular, $a_i = 1$ yields the standard **logistic density**. Let a be the vector of a_i, I the N-by-N identity, $\mathbf{0}$ an N-by-J matrix of zeros, and $\updownarrow$ vertical array concatenation. An ordinary ML logistic-regression program can be tricked into entering the log of this prior as a penalty function by augmenting Y, n, and X to $Y^* = Y \updownarrow a$, $n^* = n \updownarrow 2a$, and $X^* = (X, I) \updownarrow (\mathbf{0}, I)$. The exact posterior mode $(\tilde{\beta}, \tilde{\delta})$ and an approximate posterior covariance matrix for (β, δ) will then be returned as the ML estimates; if the program will provide fitted proportions $\tilde{\pi}_i$ (as most will), the first N of the $n_i\tilde{\pi}_i$ will be $\tilde{\mu}_{E|Y}$.

This data-augmentation prior (DAP) can be generalized in a number of ways [25, 28]. To give β as well as δ a proper prior, one need only add J more augmenting rows to X^* encoding the priors for the β_j. The heaviness of the prior tails (which decreases with a_i) may be controlled while preserving the scale by rescaling the density, that is, replacing δ_i with δ_i/τ_i in the density. **Skewness** may be introduced while preserving location by using a logistic-beta(a_i, b_i) density with $a_i \neq b_i$ and recentering, that is, replacing δ_i/τ_i with $(\delta_i - m_i)/\tau_i$ where m_i is the prior mode before recentering.

Because the conjugate prior approaches normality as a_i increases, one can approximate normal$(0,\tau_i^2)$ densities for the δ_i by setting $a_i = (4/h^2\tau_i^2) - 1$ and $X^* = (X, I) \updownarrow (\mathbf{0}, hI)$, where the constant h controls closeness to normality [25]. Normality is approached as h approaches 0; estimates would not change meaningfully after h drops below a certain value, but for rounding errors produced by finite machine precision; typically, h yielding all $a_i > 100$ provides adequate numerical approximations. Prior correlations among the β and δ may be introduced by using a nondiagonal matrix in place of hI in X^*, or by using an uncorrelated reparameterization for the analysis and then transforming results back to the original parameterization.

Specification of the Prior Parameters

Incorporating Contextual Information

Specification of prior parameters from contextual (subject-matter) information can be done by back-calculating those parameters from elicited prior percentiles (e.g. [9], p. 384; 2, 24, 25, 28). Continuing the above example, suppose one is 95% certain *a priori* that the odds $\pi_i/(1-\pi_i)$ is within an R-fold range around the prior median $\exp(X_i\beta)$, which implies that $\text{logit}(\pi_i) = X_i\beta + \delta_i$ falls in an interval of width $\ln(R)$ around $X_i\beta$ with 95% prior probability. Under a normal prior for δ_i, this relation further implies that the width $2(1.96)\tau_i$ of a 95% prior interval for δ_i is $\ln(R)$, so $\tau_i = \ln(R)/3.92$ (e.g. $\tau_i = 0.764$ when $R = 20$). For other prior densities, one may use tables or numerically solve for the hyperparameter values that make the difference of the prior 97.5th and 2.5th prior percentiles for δ_i equal to $\ln(R)$ (*see* **Prior Distribution**).

Because the δ_i percentiles depend entirely on context, no purely numeric guidelines can be given for their choice. It should be borne in mind, however, that δ_i are *residual* effects after factoring out effects in the smoothing model $M_\mu(\beta)$, and so should not

be very large if the model has been chosen "maximally," that is, to capture all systematic (structural) effects expected in the context. In the present example, the only expected systematic effects on the study results are from measurement type and from power-system type, both of which will be coded into $M_\mu(\beta)$. The meaning of "not very large" is rather vague; nonetheless, in lifestyle, **environmental, and occupational epidemiology**, odds ratios between 1/3 and 3 or perhaps 1/4 and 4 may be considered not very large, corresponding to an R of 9 or perhaps 16. Still larger values are defensible as a conservative choice, however: Specifying R (and hence τ) too large relative to the true residual effects δ leads to overly wide interval estimates with supranominal coverage, but specifying R too small leads to overly narrow intervals with subnominal coverage [20, 21]; hence a value of $R = 20$ is used below. Fortunately, as will be illustrated, intervals sensitive to reasonable variation in R tend to be those so wide that no useful inference can be drawn under any reasonable choice.

An alternative approach indirectly fixes τ by instead specifying the "effective degrees of freedom" (edf) desired for the smoothing, where edf is defined as a function of the projection matrix of Y to $\tilde{E}$ implicit in the final fit [34]. The rank of X is the smallest possible value for edf and corresponds to $\tau = 0$, or simply fitting $M_\mu(\beta)$ as $M_E(\beta)$ (conventional modeling); the total (data) degrees of freedom is the largest possible value. This type of specification may be natural in the context of fitting curves or surfaces in which a somewhat qualitative prior about the complexity of the curve can be visualized in relation to polynomial curves or surfaces, but does not seem as intuitive for qualitative data.

Traditional Table Smoothing Revisited

Traditional methods of handling sparse count data can be recast as primitive versions of the data-augmentation method (*see* **EM Algorithm**) with highly constrained prior parameters [4, Chapter 12]. Adding a constant c (e.g. 1/2) to each count (Y_i and $n_i - Y_i$) in the binomial case corresponds to using independent, symmetric beta(c, c) priors for the π_i rather than the residuals expit(δ_i), which implies a prior mean $c/2c = 1/2$ and variance $(c/2c)^2/(2c + 1) = 1/(8c + 4)$ for all the π_i. This prior almost never makes sense contextually. For example, if π_i is an exposure or disease risk, it rarely will have prior mean 1/2 and (with $c = 1/2$) variance 1/8 for all π_i. In fact, most disease risks are much less than 1/2 and have fairly well-known dependencies on demographic covariates, which should be accounted for by inclusion of those covariates and a constant (or equivalent) in X. Furthermore, in pooled analyses and **meta-analyses**, risks will vary across studies.

Smoothing the Example Data by a Maximal Model

Specification and Fitting

Let L be the leukemia (case) indicator, with S the vector of 14 study indicators, D the indicator that the study used direct measurements (vs. calculated), and V the indicator of 120 volt 60 Hz power system (vs. 220 volt 50 Hz); there are no $D = 0$, $V = 1$ studies, so these indicators define only three rather than four groups of studies. The prior design matrix X will be a function of L, S, D, and V. Because S contains indicators for every study and because D and V are functions of S, once S is included, no constant and no main effect for D or V is needed.

To minimize alteration of data patterns, one should want a rich prior model $X\beta$ for the logit prior mean. The richest model is the saturated model, in which X contains 28 linearly independent columns, for example, 14 corresponding to S and 14 corresponding to the product terms in LS. To avoid zeros in the fitted values, however, certain products must be excluded (those with zero **sufficient statistics**; see [4]). On the other hand, patterns in results related to measurement D and power system V were expected. Representation of such patterns requires LD and LV products; thus, X was given columns for L, S, LD, and LV (17 columns). Any larger design matrix defined from L, S, D, V alone would introduce fitted zeros; thus, X is maximal for the smoothing objective.

The prior $p(\delta; \tau)$ was $MVN(0,\tau^2 I)$. Fitting was done by data augmentation with numerical constant $h = 0.01$, and prior standard deviation $\tau = 0.764$ $(R = 20)$; this adds 28 pseudo-observations with $a_i = (2/h\tau_i)^2 - 1 \approx 68\,489$ cases and 64 489 controls each, and 28 augmenting covariate columns equal to zero everywhere except augmenting column i, which is set to h in the ith augmenting row.

Results

Let $Z = (X, I)$ and $\theta = \beta \updownarrow \delta$. Table 1 shows the resulting smoothed counts $\text{expit}(Z_i\tilde{\theta})n_i$ (the elements of $\tilde{\mu}_{E|Y}$) for the highly exposed category; the smoothing model fit by MPL preserves the totals so those are not repeated in the table. The smoothed odds ratios are identical whether computed from the smoothed counts or from the model coefficients as $\tilde{\omega} = \exp\{(Z_{L1} - Z_{L0})\tilde{\theta}\}$, where Z_{L1} and Z_{L0} comprise the rows of Z with $L = 1$ (cases) and $L = 0$ (controls). Note the modest shrinkage of Y to $\tilde{\mu}_{E|Y}$: The largest absolute change in a count is 1.49, the changes are less than 1.00 in 12 of the 14 studies, and the mean absolute change is only 0.45. Also, to the third decimal point there is no change upon applying the ML summary point and interval estimators to the smoothed counts. Thus, as desired, the smoother has not altered the main summary from these data. In contrast, adding 1/2 to each cell inflates these estimators slightly, to 1.72 (1.31, 2.26).

Turning to patterns across studies, the three *a priori* study groups encoded in $X(D = V = 0, D = 1\&V = 0, D = V = 1)$ have estimated geometric mean odds ratios of 1.63, 2.24, 1.72 ($P = 0.88$ for deviance test of equality of these means). The smoothing procedure shrinks the odds ratios toward their group geometric means, but only the most unstable odds ratios change dramatically. Odds ratios that were previously infinite (Coghill, Dockerty) or zero (Tynes) due to zero counts, are pulled back to much more reasonable values of 2.63, 3.31, and 0.68; for comparison, adding 1/2 per cell to these studies yields odds ratios of 3.05, 6.83, and 0.21. The two other outlying odds ratios are 4.53 and 3.51 (Feychting, Savitz); the smoother shrinks these estimates to 3.30 and 2.45, whereas adding 1/2 inflates them to 4.73 and 3.68.

Estimating Variances of Smoothed Quantities

Given that an end user of a smoothed data set is likely to need variance estimates for computed quantities, there is an issue as to whether naïve computations (treating the smoothed data as if it were the observed data) are adequate. To illustrate the issues, Table 1 provides approximate 95% confidence limits $\tilde{\omega}_k\exp(\pm 1.96\tilde{\sigma}_k)$ for the smoothed odds ratios ($k = 1, \ldots, 14$), where $\tilde{\sigma}_k^2$ is the kth diagonal element of the estimated covariance matrix of the log odds ratio estimates, $(Z_{L1} - Z_{L0})\tilde{\text{Cov}}(\tilde{\theta})(Z_{L1} - Z_{L0})'$, and $\tilde{\text{Cov}}(\tilde{\theta})$ is the inverse information matrix from the fitted model. Computing the limits (incorrectly) by applying the raw-data variance formulas [50], Chapters 14 and 15 to the smoothed counts makes little difference for the larger studies and almost no difference for the summaries; for example, for the Linet study, the limits from the correct formula are 0.94, 2.43, whereas the raw-data formula naïvely applied to the smoothed counts yields 0.92, 2.47. Nonetheless, the naïve intervals tend to be excessively wide because they do not use the model information to estimate variances. This excess is small when the smoothing constraints are weak (due to the large τ and large model) relative to the data information, as in large studies. For summary measures, the excess becomes negligible because those are primarily determined by the large studies.

On the other hand, the excess can be large for small studies, for example, for the Verkasalo study, the limits from the correct formula are 0.40, 7.57, whereas the raw-data formula naïvely applied to the smoothed counts yields 0.18, 17.2. Such a difference may be of little or no practical importance, however. First, both intervals are asymptotic and so are questionable when some cell counts are very small (in Verkasalo, there is only one highly exposed case); second, when the two intervals differ greatly, both are so wide that their message is the same, that is, little of interest can be said about the odds ratio from a small study without stronger assumptions about its relation to odds ratios from other studies (this consideration is why exact methods or more refined approximations may seem academic in most epidemiologic applications).

Nonetheless, to avoid variance overestimation arising from the use of smoothed counts in place of observed counts, subsequent analyses would have to be based on $\tilde{\text{Cov}}(\tilde{\theta})$ rather than naïve variances. Analogously, in missing-data problems, valid variance estimation must account for the imputation (*see* **Missing Data in Clinical Trials**), although in those problems, the naïve formulas underestimate rather than overestimate the variances [42].

Discussion

Is Sensitivity Analysis Helpful in the Face of Arbitrary Sensitivity?

A natural question is to ask whether the smoothing results are sensitive to the choice of τ (or

equivalently, R or λ) given the smoothing model. The answer is that, like latent-structure analyses, they are arbitrarily sensitive within their mathematical bounds. In the example, when $\tau > 2$ ($R > 2500$, $\lambda < 0.25$) the smoothed counts in $\tilde{\mu}_{\mathrm{E}|Y}$ are all within 0.5 of the observed counts in Y; whereas when $\tau = 0$ ($R = 1, \lambda = \infty$) the smoothed counts in $\tilde{\mu}_{\mathrm{E}|Y}$ equal the estimated prior counts in $\tilde{\mu}_{\mathrm{E}} = M_{\mu}(\tilde{\beta})$, and deviate as much as 3.5 from the observed counts. These two count vectors bracket those obtainable under intermediate choices for τ ($2 > \tau > 0$), which include any remotely reasonable choice. Consequently, statistics that are almost the same whether computed under $\tau = \infty$ (i.e. from the observed counts) or under $\tau = 0$ (i.e. under the prior model) will be insensitive to *any* choice of τ; for example, the ML and MH summary statistics hardly change. Conversely, statistics that change much between these extremes (such as odds ratios for studies with a 0 count) are those sensitive to τ; for example, the odds ratios from Coghill and Dockerty are implausibly large (5.4 and 9.2) when $\tau = 2$, but both approach the plausible value of 1.97 as τ approaches 0.

To make contextually meaningful inferences about parameters with sensitive estimates, one must confine τ to values that are reasonable, that is, values for τ that assign the bulk of probability to plausible values for δ. This brings in subjective judgment about τ as well as δ, which could (some might say should) be summarized in a prior $p(\tau)$. One could then draw choices for τ from $p(\tau)$ or $p(\tau|Y)$ and repeat the analysis. Averaging the resulting log odds ratios over $p(\tau|Y)$, however, approximates the BEB posterior mean log odds ratios, and the BEB posterior intervals have the advantage of providing a coherent integration of uncertainties about δ, including uncertainty about τ.

Does BEB then obviate the need for sensitivity analysis of τ? One might demand a Bayesian sensitivity analysis, which varies $p(\tau)$ in the BEB analysis. Such a demand only leads back to the problem of arbitrary sensitivity, however. In the above example, any $p(\tau)$ with support above two nearly reproduces the observed counts, whereas a $p(\tau)$ concentrated near 0 reproduces the counts expected under the prior structural model. Paralleling ordinary sensitivity analysis, we will only see that stable statistics are insensitive across the range of $p(\tau)$, and that unstable statistics almost completely depend on $p(\tau)$. Again, however, both facts can be seen immediately by comparing results computed from the raw data with results computed under the model $\mathrm{E} = M_{\mu}(\beta)$ (i.e. with $\tau = 0$), or by examining raw-data confidence intervals.

One rationale for presenting analyses with different τ is that it provides inferences tailored to readers with different priors on δ. Nonetheless, such multiple presentation shifts labor and space toward interpretation of sensitive statistics, which provide a poor basis for inference. On the other hand, varying τ or $p(\tau)$ will be superfluous for inferences based only on insensitive statistics, which are a better focus of inference.

Frequentists often opt to use an "empirical" point estimate of τ (e.g. from cross-validation) rather than a prior τ or $p(\tau)$. As with use of a prior, however, this option does not display sensitivity to τ. It is also objectionable because it can result in a τ estimate that is both implausible (often seeming too small) and unstable. The subjectively and objectively poor moderate-sample performance of common τ estimators (e.g. [21]) seems a crucial problem often neglected in promotions of so-called "objective" smoothing techniques based on these estimators. One way to address this problem involves the same rationale and form as basic shrinkage estimation techniques for E and β: stabilize the τ estimator by shrinking it toward a prior mean. This solution introduces a prior $p(\tau)$, and so leads back to the BEB approach.

As a technical note, given the normal-prior specification (as in the above example), the numeric constant h is not a statistical parameter in the DAP; thus there is no philosophic issue concerning sensitivity analysis for h. One simply needs to ensure that h is small enough so that the numeric results are stable, but not so small that overflow or underflow occurs. This can be done by checking to see that reducing h leaves the results essentially unchanged, without introducing numeric warnings. One could instead treat h as a hyperparameter that determines departure from normality in the DAP (with increasingly heavy tails as h increases), in which case the debate of sensitivity analysis for h versus BEB analysis with a hyperprior $p(h)$ could again be raised.

The issues just described also arise for latent-structure analyses. For a description of a hierarchical Bayes alternative to sensitivity analysis in a structural model involving latent variables, see [27].

Smoothing and Model-robust Estimation

Another way to view smoothing is as a form of model-robust regression estimation. A large class of model-robust approaches (e.g. [60]) justify the use of a restrictive form $\mathrm{E} = M_{\mathrm{E}}(\beta)$ by appeal to theorems showing that the least-squares or ML estimator of β converges to a value β_p that would be obtained by fitting the model to the population joint distribution $p(X, Y)$, where the latter is not constrained to follow the model; they also derive standard errors without assuming the model is correct (robust or "sandwich" variance estimators). These approaches assume an absence of sampling biases and measurement errors in the data generation, and are scientifically justifiable only if the population summary afforded by $M_{\mathrm{E}}(\beta_p)$ omits no contextually important information about the true regression E.

As an example in which the latter condition can fail and appears to have failed severely at times, consider the controversy over the value of **ecologic** (group-aggregate) **studies** for inference about individual risks. With E these risks, and subdividing the population into groups indexed by k, it is well known that $\mathrm{E} = X\beta$ (risk linearity) induces a group-mean regression $\overline{\mathrm{E}}_k = \overline{X}_k\beta$, reflecting the linearity of means. This relation is often used (incorrectly) to justify unrestricted inferences from the group to individual level. If, however, the individual regression contains important nonlinearities (as for many cancer risk factors, including age, cigarette use, and asbestos exposure), the group-mean regression may not resemble the individual-level regression in form or even in direction of key associations [26, 54, 59]. This should not be surprising given that the linear risk approximation can be woefully inadequate, especially for projecting risks at extreme design points (which are often the focus of health controversies).

This sort of problem is not addressed by conventional model-robust methods, which dutifully try to estimate the best approximation *of a given form*. Smoothing instead demotes the model form from a known model $M_{\mathrm{E}}(\beta)$ for E to a model $M_{\mu}(\beta)$ for the prior mean of E, thus allowing data departures from the model (whether "significant" or not) to not only alter variance estimates (as in conventional model-robust estimation) but to also alter the fitted values $\tilde{\mathrm{E}} = \tilde{\mu}_{\mathrm{E}|Y}$.

Conclusion

Smoothing can be viewed as an exploratory technique falling between raw-data description and inference about deeper (and often latent) structures of contextual interest, as well as a modeling technique that frees one from the rigidity of typical model specifications. It can also be viewed as a data-repairing technique akin to missing-value imputation. While it cannot address fundamental data inadequacies (such as **selection bias** or poor measurement), like imputation, it can ease subsequent analyses that attempt to address those inadequacies. The hierarchical-Bayes format for smoothing (which has been around at least since the 1960s) provides useful insights for both specification of smoothing models and parameters, and eases computation of smoothed data from standard software. It would thus seem practical and timely to include such smoothing methods in basic biostatistical training, and encourage their use whenever problems arise because of unstable or zero counts.

SANDER GREENLAND

Snedecor, George Waddel

Born: October 20, 1881, in Memphis, Tennessee.
Died: February 15, 1974, in Amherst, Massachusetts.

George Snedecor grew up in rural Florida and Alabama. His father, a Presbyterian minister and educator, worked training young black men for the ministry. George completed his B.S. degree in 1905 at the University of Alabama. He taught, first at the Selma Military Academy and then at Austin College, from 1905 to 1910. Then he undertook graduate work at the University of Michigan, receiving a Masters degree in physics in 1913. From 1913 to 1958 he served on the staff of Iowa State University in Ames, Iowa, beginning by teaching in the Department of Mathematics. In 1927, he became one of the two directors of the Mathematics Statistical Service in the department, a unit that provided **statistical consulting** for the campus. Iowa State organized a separate Statistical Laboratory in 1933 with Snedecor as director. He served in that position until 1947 when a policy of mandatory retirement from administrative duties required a change. The Statistical Laboratory continued, but in conjunction with a regular academic Department of Statistics founded in 1947. Snedecor continued as a staff member of the department until 1958.

The evidence indicates that George Snedecor recognized the usefulness of statistical thinking in the work of science early in his career at Iowa State. He introduced a course in statistics in 1915. He worked to bring the methods used at the Rothamsted Experimental Station to the researchers of the Iowa Agriculture and Home Economics Experiment Station. Henry A. Wallace, later Secretary of Agriculture and Vice President of the United States, shared Snedecor's views. In 1924, Snedecor assisted Wallace with a series of seminars at Iowa State on statistical methods and the use of business machines in statistical computing. This led to a publication entitled *Correlation and Machine Calculation* [1] in 1925, revised in 1931, which came to have a worldwide distribution. The Rothamsted influence came directly to Ames through summer visits by **Ronald Fisher**, first in 1931 and again in 1936. Fisher presented lectures on statistical methods to the local staff and students as well as visitors from other states and Canada.

This background, together with experience in statistical consulting in the experimental and observational sciences at Ames, led Snedecor to write a reference textbook on statistical methods [2]. The book became one of the most widely used and influential texts on the subject ever written. The first edition of *Statistical Methods Applied to Experiments in Agriculture and Biology* appeared in 1937. The eighth edition continued in print in 1996 [3]. The book has had a lifetime sales of approximately 235 000 copies. Beginning with the fifth edition, Snedecor asked **W.G. Cochran** to join in authoring the text. Cochran added a chapter on survey sampling and continued revision of the work through its sixth and seventh editions. The book had few competitors when it first appeared and became a standard reference and a graduate-level textbook on statistical methods in the agricultural research community of the US. Subsequently, it was translated into nine languages and its influence spread to other fields, serving as a model for many later textbooks on statistical methods. *Statistical Methods*, written by a man not steeped in mathematics, but endowed with a vision of the centrality of statistical thinking in science reinforced by years of consulting with active research workers, has strengthened the statistics profession and served the scientific community very well.

The world recognized the contributions Snedecor made and conferred many honors and awards including two honorary Doctor of Science degrees, one from North Carolina State University in 1956 and another from Iowa State University in 1958. Snedecor served as President of the **American Statistical Association** in 1948 and received the Samuel S. Wilks Memorial Medal in 1970. He became an Honorary Fellow of the British **Royal Statistical Society** in 1954. The building housing the statistics department on the Iowa State campus received the name Snedecor Hall in 1969.

George Snedecor directed the graduate work of **Gertrude M. Cox** and she received Iowa State's first degree in statistics. She, together with one of Snedecor's colleagues, Paul G. Homeyer, wrote a biographical and anecdotal account of the life and times of George Snedecor in 1975 [4]. The paper contains an appendix listing Snedecor's published work.

In 1959, Snedecor left Ames for work as a statistical consultant in the US Navy Electronics Laboratory in San Diego, California, which he continued

until 1963. He lived his last years in Amherst, Massachusetts with his son, James. He died in Amherst on February 15, 1974.

D.F. COX

Snowball Sampling

Snowball sampling, also known as chain referral sampling, is a nonprobability method of survey sample selection that is commonly used to locate rare or difficult to find populations. Although there are several variations, this approach involves a minimum of two stages: (a) the identification of a sample of respondents with characteristic x at the zero-stage (s_0); and (b) the solicitation of referrals to other potentially eligible respondents believed to have characteristic x at snowball stages s_1 through s_k. In many applications, this referral process continues (or snowballs) until an acceptable number of eligible respondents have been located. **Statistical inferences** can be drawn from the zero-stage of a snowball sample, assuming that probability methods of selection were used. Samples drawn at s_1 through s_k, and samples that combine the zero and snowball stages are not representative, however, and cannot be used to make statistical inferences.

Goodman [8] provided the first comprehensive overview of this technique. More recent technical assessments have been made by Erickson [4], Frank [6], and TenHouten et al. [19]. Practical considerations in implementing snowball samples have been reviewed by Biernacki and Waldorf [1]. An early application of snowball sampling was reported by Menzel and Katz [15], who used this approach to study the diffusion of a medical innovation.

Snowball sampling continues to be used widely in biomedical, social, and behavioral research today. A review of recently published literature reveals the use of snowball sampling to identify numerous special populations, including homeless adolescents [3], homosexuals [2], minority community leaders [16], cancer survivors [9], drug users [12], current and former smokers [14], and women planning to use artificial insemination techniques [5]. Snowball sampling is also a commonly used method for the identification of social networks in sociometric research [6] and in qualitative studies [1]. Snowball sampling may also be used to generate **control** groups for **program evaluations** by asking program participants to identify persons similar to themselves who are not participating in the program [18].

There are several well-known disadvantages of snowball sampling. Most critical among these is the nonrandom nature of respondent selection at stages s_1 through s_k (and in many cases also at s_0) Although some researchers have attempted to deal with this problem by sampling randomly from among respondents identified at each stage (*see* **Random Sample**), persons embedded in larger social networks will nonetheless have greater probabilities, and more isolated persons will have smaller probabilities, of being referred. Selection of respondents at stages s_1 through s_k are also based on the subjective judgments of informants and may therefore be influenced by numerous considerations not easily assessed or controlled by researchers. Nominating others, particularly in studies of deviant behavior, may also raise concerns of confidentiality and discourage informant candor. Finally, this approach makes the often difficult assumption that members of the population of interest are known to one another.

In response to these limitations, several advances in snowball sampling have been proposed in recent years. Among these are variations designed to estimate the size of hidden populations [7], a "random walk" procedure for examining social networks (*see* **Stochastic Processes**) [13], a "targeted sampling" procedure [20], a "targeted personal network sampling" procedure [17], and "respondent-driven sampling" methodology [10, 11]. The latter approach, proposed by Heckathorn, may under specified circumstances be used to develop **standard errors** for population estimates constructed using this technique.

Snowball sampling is also known for several important advantages that make it an attractive approach in many situations. Perhaps, most importantly, it is a low cost and relatively efficient method for locating hard-to-find individuals. In many settings, snowball techniques can also be deployed to collect data very quickly. As such, it is an effective method for initially exploring phenomena and populations for which there are few parameters available with which to plan more formalized sample designs (*see* **Sample Surveys in the Health Sciences**).

Social Classifications

Social classifications are needed by studies that aim to describe variations in health or health care use according to socioeconomic status (*see* **Health Services Research, Overview**). Other studies, for example on the etiology of specific diseases, need social classifications to control for **confounding** or **effect modification** by socioeconomic variables. There are three core indicators of socioeconomic status: education, income, and occupation [3–5]. Each indicator is an independent predictor of health and health care use and, therefore, each is potentially relevant to studies in medicine and public health.

Education emphasizes differences among people in knowledge, skills, and attitudes. Of all socioeconomic indicators, it is the easiest to measure. The educational level of subjects can be measured as the highest level of education that has successfully been completed. If possible, this measure also takes into account technical and vocational education, and part-time study or training after leaving school. Educational levels can be grouped according to a national, hierarchical classification. Studies among the elderly should take care to distinguish between elementary and lower secondary education. Data coding can largely be avoided by using questions with set answer categories instead of open questions. Even simpler to use are questions on the number of years of education that a person has attended school full-time, or the age at leaving school.

Income level complements educational level by its emphasis on material standards of living. It is preferably measured as the net household income, if possible corrected for household size. Questions should ensure that respondents count the incomes of all household members, and include the most relevant income components such as wages and salaries, interest, pensions, and transfer payments. Income levels are measured most accurately by an extensive battery of questions but might also be approximated by one or a few general questions. In some instances, proxy measures of long-term living standards are preferable, such as the possession of durable consumption goods, house ownership, or the quality of housing. These indicators have the advantage that they are more stable over time, and do not create the problems of **nonresponse** and inaccuracy that are typical for questions on income.

Occupation is the most comprehensive socioeconomic indicator. Unfortunately, the use of occupation as a socioeconomic indicator is laborious. Basic to its measurement is the classification of subjects according to a national three-digit classification of occupational titles. This can be, supplemented with information on employment status (self-employed or in employment) and supervisory status (number of subordinates). It is important to classify economically inactive men and women (unemployed, retired, housewives, etc) according to their last occupation. Married and cohabiting women may also be classified according to the occupation of their partner. Men or women with similar occupations can be classified according to a national social class scheme that distinguishes, among others, professionals and managers, lower nonmanual employees, skilled workers, and unskilled workers [1]. An alternative is to express the socioeconomic status of each occupation by means of their score on one-dimensional status scales [2].

ANTON E. KUNST

Social Sciences

Ideally, statistics should be a language, spoken across all the sciences, which could ease communication among disciplines, prevent duplication, and encourage research that spans disciplines. However, the types of data encountered in the social sciences are in many ways different from others. For example, it is widely acknowledged that the effects of situational variation among studies is large in the social sciences. Because of differences like this, particular concerns come to the surface in different disciplines at different times. Statistics has evolved into different dialects through the different branches of science, and statistical concerns of one group are not always discussed with others. There are four major issues of particular concern in the social sciences: **teaching statistics**, **hypothesis testing**, **categorical data analysis**, and **multilevel modeling**.

Teaching Statistics

Nobody should doubt the need for statistics and methodology training in undergraduate programmes of any science. Most agree that methodology underlies the empirical basis of any stochastic science and that statistical knowledge is a fundamental aspect of this. However, debates exist on how students should be taught. Should students be taught statistics as a set of *tools* for handling particular problems or should they be taught the underlying concepts of statistics?

While this question arises for all people concerned about students' statistical training, there is a difference between the social sciences and some other sciences with regard to the amount of prerequisite mathematics. In the social sciences we cannot assume that our students have taken, for example, calculus. In fact, we can assume that many will particularly dislike anything to do with numbers. Because of this, many textbooks present each statistical test as an unrelated **algorithm** that can passively be applied in particular situations without any conceptual understanding. Similarly, with advances in statistical computing, and the increase in "user-friendly" programs, some advocate teaching "how to run statistical tests on the computer" instead of teaching any statistical concepts. This contrasts with people who claim that the underlying concepts must be learned before they should be applied to different problems. My own view [19] is that at least some of the conceptual issues must be taught, although care must be taken not to make unrealistic demands on students' mathematical expertise.

Hypothesis Testing

Not only within psychology, but across all the social sciences, **null hypothesis** significance testing (NHST) (*see* **Hypothesis Testing**) is often used. It has been known for some time that there are conceptual and logical problems with this approach. Cohen [3] suggests that the phrase "statistical hypothesis inference testing" would yield a more appropriate acronym. The problems are particularly detrimental to the social sciences. Meehl [13] wrote that NHST is "one of the worst things that ever happened in the history of psychology". He noted [12] a difference between the physical and social sciences that he claimed was why NHST has had such detrimental effects on the social sciences. His claim was that, in the physical sciences, the null hypotheses which are put forward will often be based on a particular model that the scientists actually believe. Deviations from this substantive model allow it to be falsified in a Popperian sense (*see* **Popper, Karl R.**). In the social sciences, the null hypothesis is often a "strawman" hypothesis, like whether the relationship between social class and voting preference has changed over the years. There is no doubt that changes have taken place; it is the magnitude and direction of changes that are of substantive interest. In both physical and social sciences improved methods are increasing precision. In the physical sciences this means that more substantive models can be properly falsified. In the social sciences, as the methods become more precise, more "strawman" hypotheses are rejected. This counters the importance of falsification in theory development and validity.

Improvements have been suggested, including testing interval hypotheses rather than point hypotheses, reporting effect sizes and **confidence intervals**, considering the **power** of statistical tests, and, most importantly, testing the substantive models of interest.

Categorical Data

The work of Goodman [7, 8] and others (for example, Clogg & Shihadeh [2]) has made **loglinear modeling**

one of the most widely used techniques in the social sciences. Loglinear modeling is principally used when examining the relationships among multiple categorical – sometimes called qualitative – variables, although quantitative variables can be incorporated into the approach. In the social sciences, where assuming any sort of quantitative metric is often unjustified, the incorporation of loglinear procedures for nominal and ordinal variables into the mainstream statistics packages (*see* **Software, Biostatistical**) was welcomed.

The first extensions involved different ways of partitioning the chi-square variation (*see* **Chi-square, Partition of**) of a loglinear model. The fact that the independence model does not hold for a typical $r \times c$ **contingency table** supplies very little practical information. There are $(r-1)(c-1)$ **degrees of freedom** for the **residuals** of this model, any combination of which could account for the dependence. Researchers sought models that incorporated some of these degrees of freedom into a model that fit the data more adequately, but still were more parsimonious than the independence model. A lot of this work has been done with **square contingency tables**, where the row variable is the same as the column variable, except at a different time or different situation. An example would be comparing sons' and fathers' social class. The fact that they are related is so obvious to be uninteresting. However, how they are related, and in particular where movement off the diagonal occurs, is interesting. Goodman [8] provides a thorough discussion of the techniques for square tables.

Another strand of work in the 1990s has involved extending the loglinear model to the logmultiplicative, or the RC, model (see [2] for an introduction). This is of a class of models that attempt, in a sense, to quantify qualitative data. Assume a two-variable contingency table where the row values (R) and column values (C) are categorical. The RC model estimates new quantifications for each value so as to maximize the quantitative (linear) **correlation** between the two variables. The RC model can be extended for multiple quantifications or dimensions for each variable in a manner similar to the way in which classical **principal components analysis** operates with interval variables. Using Clogg & Shihadeh's notation, these models are called RC(M) for the M quantifications. They demonstrate the value of this approach, examining the relationship between years of schooling and occupation.

The growing realization in the value of graphing data has occurred for every type of statistics, including categorical data (*see* **Graphical Displays**). One particular approach has used RC(M) models. Often under the general title of **correspondence analysis**, these procedures (see, for example, [15] and [16] for details) produce graphical displays of **association**. There is some controversy within the social sciences as to whether these methods can replace some of the more formal model fitting and confidence interval approaches, or if they should be used to complement each other [8].

Consider the following example from Gaskell et al. [4]. They were interested in differences in age and gender for "what comes to mind when science is mentioned". They had six age categories and four categories for the field of science mentioned. When they asked a sample of about 2000 people in the UK, the model {age × gender, field} produced a residual of $\chi^2(33) = 160$. This shows that there are age and/or gender differences. Figure 1 partitions this deviation into two dimensions (see [17] for the method used here). It shows that males are more inclined to think about technology (mostly computers and engineering) and that older people are less likely to respond with "physics" (the "other" included many responses about environmental issues). Also,

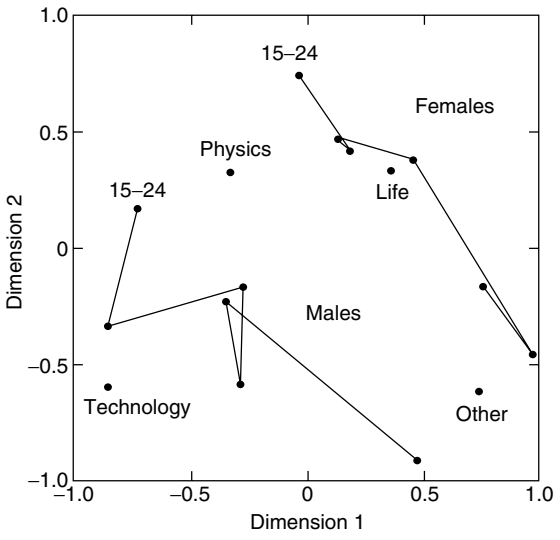

Figure 1 A two-dimensional correspondence analysis solution using a 12-category variable for gender by age. Reproduced from Wright [19], Figure 8.9, by permission of Sage Publications Ltd, 1997

there appears to be no **interaction** between age and gender on the responses {the model[age × field, age × gender, gender × field] produces a satisfactory fit [$\chi^2(15) = 20.43$, $p = 0.16$]}.

The final topic with respect to categorical analysis is its application to latent structures and **path analysis**. Different phrases are used for each of the possibilities with respect to latent (i.e. unobserved) and manifest (i.e. observed) variables being continuous or categorical. **Latent class analysis** is where latent and manifest variables are qualitative. Latent trait analysis assumes continuous latent variables but discrete manifest variables. Latent profile analysis has continuous manifest variables but discrete latent variables. Classical **factor analysis** or **LISREL** are for cases with continuous latent and manifest variables. These models have now been incorporated into path models (see [11] and [9]).

Multilevel Models

Multilevel modeling is where the data are clustered (*see* **Clustering**) or nested. For example, if you are doing research on children, you might go to many schools, visit many classrooms, and receive data from many children. An assumption in most introductory statistics textbooks is that the children are independent and identically distributed. When this is not true the **standard errors** are most often too small and therefore the estimates appear more precise than they should (e.g. [14]). Multilevel modeling accounts for this by allowing **random variables** at each level. It requires some strong assumptions about the distributions of these variables [1]. With these assumptions, some useful models about the **interactions** among groups and individuals are possible. While these models are used in biostatistics, they have become particularly popular in education and in survey research (where the geographical area or the household are often used as the higher level unit). With both of these, the structure of the hierarchy and its importance are recognized.

Goldstein [6] describes how these hierarchies occur almost everywhere you look and that ignoring the problems of independence, and more importantly not describing the model properly, will often lead to errant conclusions. These models are a particular class of **random coefficient** models. One of the reasons for the popularity of the multilevel approach is because of advantages for some estimation purposes. Kreft et al. [10] describe several specialized programs for this situation.

My own interest in multilevel models arose when analyzing the data from police eye-witness lineups in the Greater London area [21]. Many of the suspects were viewed by multiple witnesses, and hence we had witnesses nested within suspects. The response variable was categorical; witnesses could choose the suspect, a known-innocent person "picked off the street", or make no identification. When we started this work the algorithms were just being developed for multilevel modeling with categorical variables [5]. Now they are part of one of the most popular of the multilevel modeling packages, ML*n* [18].

Another aspect of multilevel modeling that is becoming of more interest is what happens when there are relatively few cases in a cluster. This happens, for example, when the hierarchy is family members nested within a household. There will be many households with only one or two people. We faced a similar situation with our witness data. Many suspects had only one or two witnesses nested within them. When we originally analyzed these data, we found extra **multinominal** variation. This is often seen as an indicator that the model and/or the hierarchical structure has been misspecified. This worried us and caused us to add various caveats to our reports on that project. More recently [20], I used **simulation** methods and found that, even when the model and structure were perfectly specified, this *sparsity* led to extra **binomial** variation (*see* **Overdispersion**). This demonstrates the importance of research on the structure of the hierarchies. While it was a big step to move from single-level analysis to multilevel analysis, the future is likely to show that not all hierarchies are the same.

DANIEL B. WRIGHT

Society for Clinical Trials

The Society for Clinical Trials, established in 1978, grew out of a need for professionals working in the field of clinical trials to exchange ideas, experiences and information. The general purpose of the Society for Clinical Trials, as stated in its by-laws, is "to promote the development and exchange of information for design and conduct of clinical trials and research using similar methods" [6]. Also, it is stated in the by-laws that "the Society shall serve as a forum for discussion of philosophical, ethical, legal, and procedural issues involved in the design, organization, operation, and analysis of clinical trials and epidemiological studies using similar methods". The Society's long-term objectives are:

1. Promotion of methodological research emphasizing design, organization, operation, and analysis.
2. Promotion of the application of sound principles of design, organization, and operation through workshops and meetings sponsored by the organization. Some of these workshops and meetings may be international in character and held in countries other than the United States.
3. Promotion of communication by development, where possible, of standard terminology.
4. Promotion of better understanding to those entering the field by serving as a resource for the design and conduct of these studies.
5. Promotion of better communication through the development of standards for the analysis and reporting of results.
6. Promotion of better understanding by the general public of the importance of clinical trials for the evaluation of health care procedures [6].

The feasibility of conducting randomized clinical trials was successfully demonstrated in Great Britain during the late 1940s under the leadership of Sir Austin Bradford Hill, who also explicated the principles and methods of randomized trials in numerous writings. Between the 1950s and 1970s there was a sustained growth in randomized clinical trials, most notably in the English-speaking world. This growth, which gradually involved an increasing number of clinical specialties and professional disciplines, was accompanied by an evolution of concepts, strategies and methodologies for the design and conduct of clinical trials (*see* **Clinical Trials, Overview**). The clinicians, biostatisticians, nurses and other health professionals who had been involved in these studies from the start were gradually joined by epidemiologists, computer scientists, clinic coordinators, and ethicists, as well as by professionals from ancillary disciplines like nutrition, behavioral psychology, and management science. The evolving concepts, strategies, and methods of clinical trials entailed a broad range of topics: ethics, design, **randomization**, data collection, assurance of data quality, patient recruitment, data analysis, **data and safety monitoring**, organization and management of multicenter studies (*see* **Data Management and Coordination**), and study closeout.

To some extent, of course, there was a sharing of ideas and information during these decades. Clinical trials topics were discussed at meetings of specialty groups and articles were appearing in statistical and clinical journals, but there was no forum for the formal and informal sharing of ideas among different specialties and disciplines. As a result, technology transfer between specialties was limited.

Many of the persons who had come to devote their careers to clinical trials were working in **multicenter trials**, and these individuals provided an important stimulus to the formation of a clinical trials society. A series of annual Symposia for Coordinating Center Personnel (Cardiovascular Trials) was organized by Curtis Meinert in 1973 and continued from 1975 to 1980. As implied by the name, the content of these well-attended symposia, held in various locations in the US, was directed mainly at those concerned with the coordination of multicenter studies: biostatisticians, computer scientists, study coordinators, and data managers. The symposia were meeting an obvious need for the sharing of ideas and information and it soon became apparent that personnel and topics beyond those concerned with the coordination of multicenter studies of cardiovascular trials should be included.

In 1976, Fred Ederer, Curtis Meinert and Dale Williams – later joined by Harold Roth – proposed the idea of forming a national or international clinical trials society to the Clinical Trials Committee of the National Institutes of Health (NIH), asking for the Committee's support in the effort. The Committee expressed interest, but, lacking evidence for widespread participatory support for a society, suggested holding a conference to test that support. Accordingly, the National Conference on Clinical

Trials Methodology, sponsored by the NIH, was held in October 1977; its proceedings were published in May 1979 [4]. Attendance of that conference by more than 700 persons, far more than expected, confirmed the need for a professional society focused on clinical trials.

An *ad hoc* Board of Directors (Harold O. Conn, Thomas C. Chalmers, Fred Ederer, Robert S. Gordon, Christian R. Klimt, Paul Meier, Curtis L. Meinert, Charles Moertel, Thaddeus Prout, Harold P. Roth, and O. Dale Williams) drew up by-laws and incorporated the organization under the name Society for Clinical Trials. Under the Presidency of Harold Roth, the Society's first annual meeting was held in Philadelphia, 6–8 May 1980 [3, 5].

Coincidental with the formation of the Society for Clinical Trials was the publication of a new journal, ***Controlled Clinical Trials***, under the editorship of Curtis Meinert [1, 2]. Its objective was to meet many of the same needs – in written rather than oral communication – as the Society. The logical next step was taken: *Controlled Clinical Trials* was designated the official journal of the Society of Clinical Trials. The program and abstracts of each annual meeting are published in *Controlled Clinical Trials*.

Two joint meetings of the Society for Clinical Trials and the International Society for Clinical Biostatistics have been held: one in July 1991 and one in July 1997. A third joint meeting is scheduled for July 2003.

Additional information about the Society for Clinical Trials is available through its website [`http://www.sctweb.org`] or the Society's journal, *Controlled Clinical Trials*.

GENELL L. KNATTERUD

Software for Clinical Trials

In attempting to summarize and contrast the available clinical trials software, one immediately encounters several difficulties. First, there is not a unique set of analytical techniques for clinical trials. There are some general characteristics of most clinical trials that do result in some restriction in the statistical tests likely to be employed in the analysis. For example, recommendations for the conduct of a clinical trial include randomization of patients, sufficient sample size to have adequate statistical power of answering the proposed clinical question, and a simple, easily interpretable clinical measure as the primary outcome [13, 14] (*see* **Outcome Measures in Clinical Trials**). These guidelines usually make it less likely that methods used primarily for identifying causal relationships (such as structural equations), computationally intensive techniques used for small sample sizes, or more complex analysis of variance (ANOVA) designs will be used. However, even with some general restrictions, the wide diversity of potential clinical outcomes in the biomedical area is greater than is found in presently existing specialized software packages and often leads to utilization of the more commonly employed general statistical packages. A treatment of general biostatistical software is described in [5].

A second problem is that the available software is constantly changing. This is an advantage to the users since there is a constant source of new tools available to address their needs. However, any comparison by the reviewer contrasting advantages and limitations of various software rapidly becomes outdated. A third problem in contrasting available software is that an individual's personal preference, general background, and the group of packages with which the individual is familiar often affect the selection. Given these problems, it is not the intent of this article to attempt to provide an exhaustive list of all available software for clinical trials or present detailed evaluations of the strengths and weaknesses of various packages. Instead, we will provide an overview and inventory of some of the available software that a researcher might consider useful in conducting and analyzing a clinical trial. We have focused mostly on software that is publicly available with a proven track record. We will also discuss some of the cautions in using this software.

In identifying clinical trials software, we considered the available options from three broad categories: (1) software used in the design phase of clinical trials, (2) software used in the tracking or conduct of the day-to-day operation of the clinical trial including data collection, and (3) the analysis and reporting of the data. The last category would not only include the statistical analysis but also the presentation of the results in tabular, numerical, and graphical forms.

There has been a gradual change over time in the availability of new packages and the expanded capabilities of existing software packages. Many vendors have focused on making their packages run more efficiently and reliably in the current operating systems. The execution time of some analyses has been drastically reduced and computations that could not be performed because of software limitations may now be tractable. Many vendors have enhanced their software in its ability to import and export data files in formats that are not native to the package, thus providing for easier data exchange between packages. More vendors are now addressing the criticisms that the output from analyses, although technically correct and complete, is often too poorly formatted to be included in reports. New options and presentation formats are appearing in software to facilitate the integration of analytical output into word processed documents, for example, SAS output can be saved as MS Word and Adobe PDF files, in addition to the standard ASCII output files.

Table 1 summarizes some of the available software packages with the corresponding vendor and contact information. The computer environment (i.e. Mac, DOS, Windows) is not given since this is often version-dependent and is constantly changing. The general-purpose packages include many procedures that are seldom used in clinical trials. Conversely, given the diversity of potential outcomes in a clinical trial, it is useful to be familiar with more than one general package, since often, packages are more highly developed in some areas than in others. Detailed comparisons of the specific statistical methods available on different packages are of limited usefulness since the major packages are constantly being updated. For example, version 10 of MINITAB had procedures neither for actuarial life tables nor for logistic regression making it an unacceptable package for several important outcome variables commonly

Table 1 Summary of software which is useful in design, conduct, and analysis of clinical trials

Title	Emphasis relevant to clinical trials	Vendor
General purpose packages		
BMDP	Parametric and nonparametric survival analysis (right, left, and interval censored data; accelerated life testing; exponential, proportional hazards, Weibull, extreme value, logistic, lognormal, log-logistic regression; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; dichotomous and polychotomous logistic regression.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
BMDP New System Professional	Functionality of BMDP with a Windows interface program. Parametric and nonparametric survival analysis (right, left, and interval censored data; accelerated life testing; exponential, proportional hazards, Weibull, extreme value, logistic, lognormal, log-logistic regression; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; dichotomous and polychotomous logistic regression; missing data analyses techniques (mean imputation, hot-deck imputation, last value carried forward, predicted mean imputation).	Statistical Solutions Stonehill Corporation Center Suite 104, 999 Broadway, Saugus, MA 01906 [781] 231-7680 [800] 262-1171 http://www.statsolusa.com
GB STAT	Parametric and nonparametric survival analysis (proportional hazards, Kaplan–Meier; log-rank procedures); repeated measures ANOVA; logistic regression.	Dynamic Microsystems, Inc. 13003 Buccaneer Road Silver Spring, MD 20904 [301] 384-2754 http://www.gbstat.com
Genstat	Parametric and nonparametric survival analysis (right, left, and interval censored data; accelerated life testing; exponential, proportional hazards, Weibull, extreme value; Kaplan–Meier; log-rank procedures); logistic regression.	NAG Ltd Wilkinson House Jordon Hill Road Oxford OX2 8DR, UK +44 1865 511245 http://www.nag.co.uk
JMP	Parametric and nonparametric survival analysis (proportional hazards model, exponential, extreme value, lognormal, Weibull; Kaplan–Meier; log-rank procedures, competing causes and recurrence analysis); ANOVA/MANOVA; logistic regression.	SAS Institute Inc. SAS Campus Drive Cary, NC 27513 [919] 677-8000 http://www.jmp.com http://www.sas.com

MINITAB	Parametric and nonparametric survival analysis (right, left, arbitrary and interval censored data; accelerated life testing; exponential, Weibull, extreme value, logistic, lognormal, log-logistic; Kaplan–Meier; log-rank procedures); probit analysis; logistic regression	Minitab, Inc. 3081 Enterprise Drive State College, PA 16801-3008 [814] 238-3280 http://www.minitab.com
NCSS	Parametric and nonparametric survival analysis (right, left, and interval censored data; accelerated life testing; exponential, proportional hazards, Weibull, extreme value, logistic, lognormal, log-logistic; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; Probit analysis; logistic regression	NCSS Statistical Software 329 North 1000 East Kaysville, UT 84037 [801] 546-0445 [800] 898-6109 http://www.ncss.com
S-PLUS	Parametric and nonparametric survival analysis (right, left, and interval censored data; accelerated life testing; exponential, proportional hazards, Weibull, lognormal, log-logistic; Kaplan–Meier; log-rank procedures; penalized survival models; smoothing splines; person-years analysis); repeated measures ANOVA; MANOVA; logistic regression	Insightful Corp. 1700 Westlake Avenue North, Suite 500 Seattle, WA 98109 [206] 283-8802 [800] 569-0123 http://www.splus.com http://www.insightful.com
SAS	Parametric and nonparametric survival analysis (right, left, and interval censored data; accelerated life testing; exponential, proportional hazards, Weibull, lognormal, log-logistic regression; Kaplan–Meier; log-rank procedures); probit analysis; repeated measures ANOVA; MANOVA; logistic regression.	SAS Institute Inc. SAS Campus Drive Cary, NC 27513 [919] 677-8000 http://www.sas.com
SPSS	Parametric and nonparametric survival analysis (proportional hazards; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; probit regression; logistic regression.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
Stata	Parametric and nonparametric survival analysis (right and left censored data; accelerated life testing; exponential, proportional hazards, Weibull, lognormal regression; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; probit analysis; dichotomous and polychotomous logistic regression. Also has facilities for analysis of correlated data resulting from cluster designs (e.g. multiple outcomes per patient, repeated outcomes per patient, cluster randomization, and nested sampling schemes).	Stata Corporation 702 University Drive East College Station, TX 77840 [800] 782-8272 http://www.stata.com

STATGRAPHICS *Plus*	Parametric and nonparametric survival analysis (Weibull model; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; logistic regression.	Manugistics, Inc. 2115 East Jefferson Street Rockville, MD 20852 [800] 592-0050 http://www.statgraphics.com
STATISTICA	Parametric and nonparametric survival analysis (exponential, Gompertz, Weibull, proportional hazards, lognormal, normal; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; probit analysis; logistic regression	StatSoft 2300 East 14th Street Tulsa, OK 74104 [918] 749-1119 http://www.statsoft.com
StatView	Parametric and nonparametric survival analysis (exponential, Weibull, proportional hazards, lognormal, log-logistic; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; dichotomous and polychotomous logistic regression	SAS Institute Inc. SAS Campus Drive Cary, NC 27513 [919] 677-8000 http://www.sas.com http://www.statview.com
SYSTAT	Parametric and nonparametric survival analysis (right, left, and interval censoring; proportional hazards; exponential, accelerated exponential, Weibull, lognormal and logistic; Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; probit analysis; logistic regression	Systat Software Inc., 501 Suite 'C', Point Richmond Tech Center, Canal Boulevard, Richmond, CA 94804-2028 [800]797-7401 http://www.systat.com
True Epistat	Parametric and nonparametric survival analysis (proportional hazards; exponential, Kaplan–Meier; log-rank procedures); repeated measures ANOVA; MANOVA; logistic regression	Tracy L. Gustafson Epistat Services 280 W. Renner Road, #2112 Richardson, TX 75080 [972] 994-0904 http://www.true-epistat.com

Graphics packages

Axum	Comprehensive graphing package including: step function plots and error bars.	Math Soft 1700 Westlake Avenue North, Suite 500 Seattle, WA 98109 [206] 283-8802 [800] 569-0123 http://www.mathsoft.com
CrossGraphs	Comprehensive graphics package including: Kaplan–Meier plots and patient summary charts and graphs.	PPD, Inc. 3151 South 17th Street Wilmington, North Carolina 28412 [910] 251 0081 http://www.ppdi.com
DeltaGraph	Comprehensive graphics package including: Kaplan–Meier plots and error bars.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
GraphExpress	Comprehensive graphing tools designed as an interface for producing graphs from SAS including: Kaplan–Meier plots and error bars.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
SigmaPlot	Comprehensive graphics package including: Kaplan–Meier, probit, and logit plots, and error bars.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com

Meta-analysis		
Advanced BASIC Meta-Analysis	Meta-analysis	Brian Mullen Syracuse University Department of Psychology [315] 443-2354 http://psychweb.syr.edu/Faculty/drmullen.htm
Comprehensive Meta-Analysis	Effect size measures (standardized differences, correlation coefficients, odds ratios, relative risks, and risk differences). Fixed and random effects models.	Biostatistical Programming Associates Biostat, Inc. 14 North Dean Street Englewood, NJ 07631 [201] 692-8155 http://www.meta-analysis.com
DSTAT	Effect size measures (correlation coefficients, standardized mean difference, t-test statistics, F-test statistics, proportional data, chi-squares, P values). Fixed effects model.	Blair T. Johnson University of Connecticut Department of Psychology, U-20 406 Babbidge Road Storrs, Connecticut 06269-1020 [860] 486-2511 http://johnson.socialpsychology.org/
Epi Meta	Effect size measures (relative risks). Fixed and random effects models.	Centers for Disease Control Statistical and Epidemiology Branch Division of Prevention Research and Analytic Methods [404] 639-3806 http://www.cdc.gov/epo/dpram/epimeta/epimeta.htm
Hunter and Schmidt programs	Effect size measures (correlation coefficients, standardized mean differences) methods consistent with [8].	John E. Hunter Michigan State University Frank L. Schmidt

		University of Iowa Available in back of [8] book and available from Frank L. Schmidt, University of Iowa.
Meta-Analysis programs	Effect size measures (standardized differences correlations and differences between proportions). Fixed and random effects models.	Ralf Schwarzer, Freie Universität Berlin, Germany, University, Toronto, Canada http://www.fu-berlin.de/gesund/gesu_engl/meta_e.htm
META (Meta-analysis easy to answer).	Effect size measures (standardized differences, correlations, and difference between proportions). Fixed effects or random effects models.	David Kenny University of Connecticut http://nw3.nai.net/dakenny/meta.htm.
Meta-analyst	Effect size measures (odds ratios, relative risks, and risk ratios). Fixed and random effects models.	Joseph Lau, MD New England Medical Center http://joseph.lau@cs.nemc.org
SAS Macros	Effect size measures (probability values, standardized mean differences, correlation coefficients, odds ratios, and vote counting methods). Fixed and random effects models.	Morgan C. Wang University of Central Florida Brad J. Bushman Iowa State University http:// www.sas.com
TRUE EPISTAT	Effect size measures (standardized differences, correlation coefficients, odds ratios, relative risks, and risk differences). Fixed and random effects models.	Tracy L. Gustafson Epistat Services 280 W. Renner Road, #2112 Richardson, TX 75080 [972] 994-0904 http://www.true-epistat.com
Design, power, and sample size		
Egret-Siz	Specialty: comprehensive evaluation for Cox proportional hazards, logistic (unmatched and conditional), and Poisson regression models. Handles adjustments for ancillary variables (e.g. confounders). Testing is under the framework of likelihood ratio testing.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com

Table 1 (*continued*)

Title	Emphasis relevant to clinical trials	Vendor
N and NSURV	General package including: exponential survival (accrual and dropouts), logrank test for user-specified accrual, hazard, and dropout rates. Equivalence tests. Logistic regression.	**idv**-Data Analysis and Study Planning Wessobrunner Straβe 6 D-82131 Gauting/Germany phone: 089/850 80 01 e-mail: idvGauting@aol.com
nQuery Advisor	General package including: exponential survival (accrual and dropouts), logrank test (simulation) for user-specified accrual, hazard, and dropout rates; equivalence and bioequivalence tests - paired design, two group and crossover designs testing difference in means and ratio of means; ANOVA; logistic regression; fold-change analysis (with optional fold-change threshold for DNA microarray studies).	Statistical Solutions Stonehill Corporation Center Suite 104, 999 Broadway, Saugus, MA 01906 [781] 231-7680 [800] 262-1171 `http://www.stat-solusa.com`
PASS	General package including: exponential survival (accrual and dropouts), logrank test for user-specified accrual, hazard, and dropout rates. Group sequential analysis; ANOVA; repeated measures ANOVA; logistic regression.	NCSS Statistical Software 329 North 1000 East Kaysville, UT 84037 [801] 546-0445 [800] 898-6109 `http://www.ncss.com`
Power and Precision	General package including: exponential survival (accrual and dropouts), logrank test for user-specified accrual, hazard, and dropout rates. Equivalence tests. ANOVA; logistic regression.	Biostatistical Programming Associates Biostat, Inc. 14 North Dean Street Englewood, NJ 07631 [201] 692-8155 `http://www.power-andprecision.com`
STATISTICA Power Analysis	General package including: exponential survival; logrank test for user-specified accrual period and dropouts rates; ANOVA	StatSoft 2300 East 14th Street Tulsa, OK 74104 [918] 749-1119 `http://www.statsoft.com`
UnifyPow	General package including: logistic, log-linear, logrank tests, and Cox survival models. An SAS module/macro, which runs in base SAS and creates SAS datasets containing the results.	Ralph O'Brien Department of Biostatistics and Epidemiology Cleveland Clinic Foundation

		http://www.bio.ri.ccf.org/power.html
Report generating		
ClinPlus	A variety of SAS macro-based modules designed to provide data entry and management, statistical analysis and reports, and patient follow-up reports consistent with the procedures of the United States Food and Drug Administration (USFDA). The modules are applicable to the needs of new drug applications and adverse drug event reporting. The modules include Data Management, Coding, Remote NDA, ADE, and Report.	DZS Software Solutions, Inc. 1661 Route 22 West Bound Brook, NJ 08805 [732] 356-6961 http://www.dzs.com
Patient Profiles	Data visualization of patient demographics, medical profile, intervention, and follow-up. Includes an assortment of reports with various display options and summarizations. Interfaces with many different statistics, database management, and spreadsheet programs. Includes ASCII format and ODBC (Open DataBase Connectivity) support. Can simultaneously combine information from multiple databases with different formats.	Statistical Solutions Stonehill Corporation Center Suite 104, 999 Broadway, Saugus, MA 01906 [781] 231-7680 [800] 262-1171 http://www.stat-solusa.com
PPD Patient Profiles	Data visualization of patient demographics, medical profile, intervention, and follow-up. Includes an assortment of reports with various display options and summarizations. Interfaces with many different statistics, database management, and spreadsheet programs. Includes ASCII format support.	PPD, Inc. 3151 South 17th Street Wilmington, North Carolina 28412 [910] 251 0081 http://www.ppdi.com
Data/information entry		
Ascent Capture	Document capture application integrating batch scanning, image processing, optical character recognition (OCR), and document indexing of data and text.	Kofax Image Products 16245 Laguna Canyon Rd. Irvine, CA, 92618-3603 [949] 727-1733 http://www.kofax.com/
BMDP Data Entry	Comprehensive data entry system including double entry (two pass verification), content verification, and comprehensive edit checking. Generates ASCII data files.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
DataFax	A fax-based data management system for data capture, forms processing and extraction, and direct data entry. Designed for management of clinical trials.	Clinical DataFax Systems Inc. 21 King Street West, Suite 305 Hamilton, Ontario, Canada L8P 4W7, [905] 522-3282 http://www.datafax.com

(*continued overleaf*)

Table 1 (*continued*)

Title	Emphasis relevant to clinical trials	Vendor
EntryPoint, FALCON	Comprehensive data entry system including double entry (two pass verification), content verification, and comprehensive edit checking.	Phoenix Software International West Century Boulevard Suite 800 Los Angeles, CA 90045 [800] 622-9292 http://www.phoenix-software.com/
FaxWare	Fax transmission and receiving software with translational capabilities to convert image documents to data files and electronic documents.	Tobit Software Limited Redwither Tower Redwither Business Park Wrexham LL13 9XT +44 1978 666900 http://www.uk.tobit.com [514] 392-9220 http://www.na.tobit.com
ImagEntry, VDE, Quantum 2000	Comprehensive data entry system including double entry (two pass verification), content verification, and comprehensive edit checking. Automated document scanning and data transfer.	Viking Software Services, Inc. 6804 South Canton Avenue, Suite 900 Tulsa, OK 74136-3419 [918] 491-6144 [800] 324-0595 http://www.viking-soft.com
Input*Accel*	Data capture, image capture, forms processing, data extraction and PDF conversion. Can handle information that arrives in the form of paper, faxes, or microfilm, and so on. User-entered digital information, such as data entered via a web site.	Captiva Software Corp. 10145 Pacific Heights Boulevard San Diego, CA 92121 [858] 320-1000 http://www.captiva-software.com
Key Entry III	Comprehensive data entry system including double entry (two pass verification), content verification, and comprehensive edit checking. Provides for monitoring and reporting operator activity and performance. Generates ASCII data files.	Scan-Optics Inc. 169 Progress Drive Manchester, CT 06040-2294 [860] 645-7878 [800] 745-6001 http://www.scanoptics.com/solutions_products.html

Rode/PC	Comprehensive data entry system including double entry (two pass verification), content verification, and comprehensive edit checking.	DPX/IDEAS, Inc. P.O. Box 7657 Menlo Park, CA 94026 [650] 233-9300 http://www.rodepc.com/
SAS/FSP	SAS module for comprehensive data entry system including ability for double entry (two pass verification), content verification, and comprehensive edit checking.	SAS Institute Inc. SAS Campus Drive Cary, NC 27513 [919] 677-8000 http://www.sas.com
SPSS Data Entry	Comprehensive data entry system including double entry (two pass verification), content verification, and comprehensive edit checking. Provides for monitoring and reporting operator activity and performance. Generates ASCII and SPSS formatted files.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
TELEform	Data capture, image capture, forms processing, and data extraction.	Cardiff Software, Inc. 3220 Executive Ridge Drive Vista, CA 92083 [760] 936-4500 http://www.cardiff.com/
Probability calculators		
NCSS Probability Calculator	Computes cumulative distribution functions (cdfs) and probability density functions (pdfs) for a variety of continuous and discrete distributions.	NCSS Statistical Software 329 North 1000 East Kaysville, UT 84037 [801] 546-0445 [800] 898-6109 http://www.ncss.com
Pcalc	Computes cdfs and pdfs for a variety of continuous and discrete distributions. User defined variables and functions can also be programmed.	Sytse Knypstra and Arjen Merckens Rijksuniversiteit Groningen Vakgroep Econometrie Postbus 800 9700 AV Groningen The Netherlands e-mail: S.Knypstra@eco.rug.nl http://www.eco.rug.nl/medewerk/knypstra/pcalc.html

Table 1 (*continued*)

Title	Emphasis relevant to clinical trials	Vendor
StaTable	Computes cdfs and pdfs for a variety of continuous and discrete distributions.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617]661-2011 http://www.cytel.com
Utilities		
DBMS/COPY	Conversion utilities to translate system files between many different statistical, graphics, database management, spreadsheet software, and data entry programs. Includes ASCII and ODBC support. Optional integration into the SAS system.	Data Flux Corp. Cary, NC [877] 846-3589 http://www.dataflux.com/Product-Services/Products/dbms.asp
Stat/Transfer	Conversion utilities to translate system files between many different statistical, database management, and spreadsheet programs. Includes ASCII and ODBC support.	Circle Systems 1001 Fourth Ave, Ste 3200 Seattle, WA 98154 [800] 366-3794 http://www.stat-transfer.com
Specialty analysis		
ACLUSTER	Analysis and sample size estimation for cluster randomization trials for three design types: completely randomized, paired-matched and stratified. Techniques include the analysis for binary, continuous, count, and time-to-event outcomes. Provides for the generation of cluster randomization schemes. Methods consistent with [3].	Alain Pinol and Gilda Piaggio UNDP/UNFPA/WHO/World Bank Special Programme of Research, Development and Training in Human Reproduction of the World Health Organization, 1211 Geneva 27, Switzerland Fax: +41-22-7913345 acluster@who.int Update Software Ltd Summertown Pavilion Middle Way, Oxford OX2 7LG United Kingdom +44 (0)1865 513902 http://www.update-software.com/acluster/

East	Design and interim monitoring of group sequential clinical trials. Includes methods for normal, binomial, and time-to-failure data. Supports various interim monitoring error spending functions and stopping boundaries.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com
Egret	Interactive program for a variety of regression models (logistic, conditional logistic, logistic with random effects, Poisson, proportional hazards, parametric regression for failure time data, Kaplan–Meier and traditional contingency tables).	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com
EquivTest	Equivalence and bioequivalence analysis and testing procedures – paired design, two group, and crossover designs testing difference in means and ratio of means. Includes both parametric and nonparametric procedures.	Statistical Solutions Stonehill Corporation Center Suite 104, 999 Broadway, Saugus, MA 01906 [781] 231-7680 [800] 262-1171 http://www.statsolusa.com
GLIM	Interactive statistics package design to fit generalized linear models.	NAG Ltd Wilkinson House Jordon Hill Road Oxford OX2 8DR, UK +44 1865 511245 http://www.nag.co.uk
LIMDEP	Comprehensive program for estimation and analysis of regression models, and quantitative and limited dependent variables. Includes multinomial and nested logit models, and probit analysis. Parametric and nonparametric procedures for survival analysis: Weibull, lognormal, Gompertz, log-logistic, exponential, gamma parametric, generalized F-models, Weibull and exponential models with gamma heterogeneity; arbitrary censoring and left truncation; time varying covariates; plots of survival, hazard, and integrated hazard functions; semiparametric hazard function estimation; split population survival models	Econometric Software 15 Gloria Place, Plainview, NY 11803 [516] 938-5254 http:://www.limdep.com
LogXact	Exact inference for logistic, Poisson, and polychotomous regression. Computes exact P values and confidence intervals for regression coefficients.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com

(*continued overleaf*)

Table 1 (*continued*)

Title	Emphasis relevant to clinical trials	Vendor
Mplus	Comprehensive modeling program for binary and polychotomous logistic regression; structural equation modeling of longitudinal data; latent variable mixture modeling.	Muthén & Muthén 3463 Stoner Ave. Los Angeles, CA 90066 [310] 391-9971 http://www.statmodel.com
PEST	Design and interim monitoring of group sequential clinical trials. Includes methods for normal, binomial, and time-to-failure data. Supports various interim monitoring error-spending functions and stopping boundaries. Available as a stand-alone package or as a SAS/AF applications for Windows.	MPS Research Unit The University of Reading PO Box 240 Earley Gate, Reading RG6 6FN, UK +44 118 931-6662 http://www.reading.ac.uk/mps
PROC LogXact	SAS procedures providing the functionality of the stand-alone version of LogXact. Seamless integration with SAS.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com
PROC StatXact	SAS procedures providing the functionality of the stand-alone version of StatXact. Seamless integration with SAS.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com
S + SeqTrial	An S-Plus software library for designing, monitoring, and analyzing clinical trials using group sequential methods. Includes methods for normal, binomial, and time-to-failure data. Supports various interim monitoring error-spending functions and stopping boundaries.	Insightful Corp. 1700 Westlake Avenue North, Suite 500 Seattle, WA 98109 [206] 283-8802 [800] 569-0123 http://www.splus.com http://www.insightful.com
SOLAS	Analysis of missing data based on techniques developed by [19]. Provides a choice of both multiple and single imputation techniques for parametric approaches using longitudinal/repeated measures, and nonparametric single observation study designs.	Statistical Solutions Stonehill Corporation Center Suite 104, 999 Broadway, Saugus, MA 01906 [781] 231-7680

		[800] 262-1171 http://www.statsolusa.com
SPSS Missing-Value Analysis	Analytic procedures for analyzing data sets with missing data. Procedures are designed around EM algorithms.	SPSS Inc. 233 S Wacker Dr 11th Floor Chicago, IL 60606 [800] 543-2185 http://www.spss.com
StatXact	Computation of exact P values and confidence intervals for a wide variety of nonparametric statistical procedures. Exact 2 and K-sample test for censored and uncensored survival data. Includes the logrank, Wilcoxon–Gehan, and Tarone–Ware tests. Computation of power and sample for a variety of nonparametric procedures.	Cytel Software Corp. 675 Massachusetts Avenue, Cambridge, MA 02139 [617] 661-2011 http://www.cytel.com
SUDAAN	Analysis of correlated data resulting from cluster designs (e.g. multiple outcomes per patient, repeated outcomes per patient, cluster randomization, and nested sampling schemes). Includes both descriptive and regression procedures (dichotomous and polychotomous logistic regression, and proportional hazards model).	Research Triangle Institute 3040 Cornwallis Road PO Box 12194 Research Triangle Park, NC 27709 [919] 541-6602 http://www.rti.org
WesVar	Analysis of data from multistage, stratified, and unequal probability samples, resulting from cluster designs (e.g. multiple outcomes per patient, repeated outcomes per patient, cluster randomization, and nested sampling schemes). Includes descriptive, ANOVA, and regression procedures (dichotomous and polychotomous logistic regression).	WESTAT 1650 Research Boulevard Rockville, MD 20850 [301]294-2006 http://www.westat.com/wevar
Testimate	Computation of exact P values and confidence intervals for a wide variety of parametric and nonparametric statistical procedures. Exact 2- and K-sample test for censored and uncensored survival data. Includes the logrank, Peto–Wilcoxon, Wilcoxon–Gehan, and Cox–Mantel tests. Procedures for equivalence tests, and ANOVA.	**idv**-Data Analysis and Study Planning Wessobrunner Straβe 6 D-82131 Gauting/Germany phone: 089/850 80 01 e-mail: idvGauting@aol.com
XPro	Computation of exact procedures for ANOVA, MANOVA, mixed models, repeated measures, growth curves, and regression. A parametric complement to StatXact and Testimate.	X-Techniques, Inc., PO Box 58, Millburn, NJ 07041 [212] 522-4539 http://www.x-techniques.com

employed in clinical trials. However, starting with version 12, these methods were incorporated making the package a more useful tool for clinical trials. S-PLUS is increasingly being used by many statisticians as an all-purpose package and several textbooks are available, which incorporate its use in the solution of biostatistical problems [20–22]. ACLUSTER, SUDAAN, Stata, and WesVar facilitate better handling of clustered or hierarchical data than many of the more widely used packages. These methods are required when randomization is by clinic or physician rather than by patient (*see* **Cluster Randomization**).

Most users will have one or two general packages with which they are familiar and these usually meet the majority of the needs occurring for the analysis of clinical trials data. However, in special instances, these may need to be supplemented with specific routines from other general packages or with the increasing number of programs designed to perform more specialized tasks. The choice of a specific package from several, which provide the same functionality may be based on how easily it integrates into the user's current array of software. For example, an individual using SAS may choose SUDAAN over ACLUSTER, Stata, or WesVar for clustered data analysis (provided the statistical needs are met by the packages), since the former can be run from SAS as an add-on module, whereas the others cannot. Horton [7] provides some additional insight on programs that handle nested study designs.

Time-to-event data is one of the most common endpoints (*see* **Outcome Measures in Clinical Trials**) analyzed in clinical trials. Generally, packages that support survival analysis procedures minimally provide nonparametric procedures, such as actuarial and Kaplan–Meier estimates, logrank statistics, and some form of plots. Differences usually arise in the assortment of parametric procedures supported, the available models, type of censoring, fit diagnostics, ability to handle time-dependent covariates, and plotting. Harrell and Goldstein [6] and Oster [12] provide comparisons for a number of packages supporting survival analysis.

Even though packages supporting Kaplan–Meier procedures provide survival plots, it is often advantageous to have software designed specifically for graphics. Packages such as Axum, SigmaPlot, CrossGraphs, DeltaGraph, and GraphExpress give greater flexibility and control in the look and style of the plots. Displays can be more easily tailored to include textual annotations, error bars, and the overlaying of multiple graphs. All of these packages contain routines to calculate Kaplan–Meier estimates and produce the respective plots.

Several recently developed packages have procedures relevant to the conduct of meta-analysis. Although meta-analytic procedures have been applied to a variety of study designs, they are most appropriate for combining results from clinical trials where randomization eliminates the likelihood of a consistent bias across the studies being combined [18] (*see* **Meta-analysis of Clinical Trials**).

After the design of the study and the formulation of the hypothesis, sample size and power estimates are typically calculated. Many of the integrated statistical packages such as SPSS, SAS, and S-PLUS provide capabilities for performing such calculations. However, these packages generally do not provide algorithms for estimation of power and sample size for designs involving survival, logistic regression, analysis of variance (ANOVA), multivariate analysis of variance (MANOVA), and equivalency testing. Programs designed specifically for power and sample size estimation such as nQuery Advisor, PASS, Power and Precision, and STATISTICA Power Analysis provide for a much richer selection of designs and outcome variables. For time-to-event data, these programs provide for the incorporation of various periods of recruitment and follow-up and various rates and patterns of recruitment, attrition, and censoring. Output from these packages often includes tabulated estimates along with graphical displays. Relatively few packages, StatXact and N being notable exceptions, provide sample size and power estimation for a variety of nonparametric procedures. PASS provides procedures for estimating sample size for group sequential designs. However, packages such as East, PEST and, S + SeqTrial handle group sequential designs in a more comprehensive manner. These packages not only provide sample size and power estimation but also include a full array of tools for the subsequent analysis of the trial.

New features appearing in recent and soon to be released versions of various sample size software include procedures for estimating the power relevant to DNA microarray studies. nQuery has added procedures for the two group t-test for fold change assuming lognormal distribution (with equal or unequal sample sizes) and the two-group t-test of equal fold change with fold-change threshold (equal

or unequal sample sizes). Other enhancements found in some software include the use of Monte Carlo methods to simulate data sets when the parameters of the statistical design cannot be explicitly described in closed form.

In general, there are no database management packages specifically designed and optimized for the conduct and management of data that is associated with clinical trials (*see* **Data Management and Coordination**). Typically, users are required to select a database management system and customize that package for their particular application. The users write their own forms, queries, reports, and applications within the package itself. One guidance offered is that the selection of such database management systems should be based on the familiarity and comfort of using the package, software capabilities that match the needs of the project, compatible computer resources and knowledgeable people within the institution with respect to the support of that package.

Moving away from strictly database management packages, three products that assist in the report generation and display of patient characteristics are ClinPlus, Patient Profiles, and PPD Patient Profiles. ClinPlus runs under the SAS system and consists of a set of predefined macro modules that are customizable for the specific needs of the study. These packages provide procedures consistent with the requirements of the US Food and Drug Administration for data collection, report summarization, and statistical analysis. Patient Profiles and PPD Patient Profiles, produced by two independent companies, provide data visualization of demographics, medical profiles, and other relevant patient data that may be stored within a database. Built into the packages is an assortment of reports with various graphical and charting display options. Both, Patient Profiles and PPD Patient Profiles, provide tools for drilling down into the data so that the details of specific individuals can be reviewed. The packages provide for a variety of data input, and interface with many database management systems and spreadsheet programs. This allows greater flexibility in areas where data management is performed.

One of the fundamental tasks of any clinical trial is the actual transfer of data from the paper forms to an electronic file that resides in the computer. Software that assists in this procedure can be divided into two broad categories: (1) data entry and (2) image capturing or the abstraction of data directly from forms. There are a number of packages that provide data entry support. BMDP Data Entry, EntryPoint, FALCON, Key Entry III, Rode/PC, SAS/FSP, and SPSS Data Entry are examples of software packages that facilitate the direct entering of information from the paper forms into the computer by an operator. Depending on the packages, a variety of options are available to the user including double entry (sometimes referred to as the two-pass verification system), content verification, and comprehensive editing tools (*see* **Clinical Trials Audit and Quality Control**). Some of these packages provide facilities to monitor the activities and the performance of the operator. Typically, these packages generate a data file in ASCII (American Standard Code for Information Interchange) format. Packages such as BMDP Data Entry, SAS/FSP or SPSS Data Entry also create a system file specific to their respective analytical software packages.

The other approach for moving data from forms to an electronic file format is image capturing or data capturing. This is provided by a number of software packages, including Ascent Capture, FaxWare, Input*Accel*, and TELEform. These packages take advantage of the scanning capabilities of computer systems through either direct use of a scanner or information abstracted from faxed material. These packages provide a mechanism for designing a form that will be used to capture the data. Programs, such as DataFax, ImagEntry, VDE, and Quantum 2000, have dual capabilities for direct data entry and data capturing. Similar to the data entry systems, various procedures are available for verifying the integrity of the data, data editing, and for data updating. Furthermore, they provide varying levels of data management.

Table 1 also summarizes a variety of specialized packages. The scope of these packages is more focused and provides the user with more comprehensive tools. LogXact, StatXact, Testimate, and XPro compute exact P values and confidence intervals for a wide variety of tests, many of which are commonly used for testing hypotheses in clinical trials. This is especially useful for rare events and small sample sizes. StatXact provides for nonparametric procedures, XPro for parametric procedures, and Testimate contains both parametric and nonparametric procedures. LogXact is used for exact inference for logistic, Poisson, and polychotomous regression. SAS and SPSS also provide modules for exact testing,

which incorporate a limited subset of the statistical engines from LogXact and StatXact. Cytel Corp., offers separate products programmed as PROC procedures (called PROC StatXact and PROC LogXact), which seamlessly interface with SAS and provide the full complement of statistical procedures that are available in respective stand-alone versions of the software. EquivTest provides methods useful for the analysis of equivalence trials. Clinical trials that are designed as equivalence studies (where we are attempting to prove the hypothesis of no-treatment effect) are increasing in number and are particularly applicable when two regimens are expected to have similar effects on treatment, but different toxicities. A number of packages are available to perform analysis for missing data. SOLAS is a package that uses single and multiple imputation, while SPSS missing value analysis uses EM algorithms. Although methods for missing data have been employed mostly in observational studies, some investigators have suggested that they be employed in clinical trials [9].

At one time, the toolbox of a good researcher included an extensive set of tables containing cumulative distribution functions (cdfs) and probability density functions (pdfs) for various distributions. These were indispensable when evaluating the significance of test statistics or computing confidence intervals. Now the output from statistical software packages includes these values. Although, the need for statistical tables has diminished over time, there are occasions when such tables are necessary. A researcher may decide to do some hand computations for a small dataset, or a power/sample size computation where P values and critical regions are needed. It is no longer necessary to consult paper or computerized versions of these tables. "Probability calculators", such as Pcalc, StaTable, and NCSS Probability Calculator provide the same information. There are some major advantages in using these packages. They have greater flexibility in that they compute value of the critical region for any specified P value, or the P value for any specified critical region. This is in contrast the older style tables, where interpolation is necessary when a particular value is not found. Depending on the program and the version, these packages cover an extensive array of common and not so common distributions. Another attractive feature of these software packages is that they can be freely downloaded and used for noncommercial purposes. More detailed discussion can be found in [1].

With the use of a variety of software, there is often the necessity to move data from one package to another. This may occur when transferring data from a data entry or data management system to analytical software, or from one statistical package to another. The universal format for data transfer is ASCII text. However, often the data is stored as a "system" file specific to the software package. System files also contain ancillary information such as variable and value labels, missing data codes, transformations and computed variables. This provides for an efficient use of the data within the software but not between software. Moving data between packages is accomplished by exporting the data as an ASCII file from the first program and then importing it into the second program as ASCII. When using this approach, variable and value names and missing data codes are usually lost in the transfer. In some instances, system files from one software package may be directly read by another and this information is not lost. However, packages usually support only a few types of system formats. Two products that specialize in facilitating data transfer are DBMS/COPY and Stat/Transfer. Each of these packages have conversion utilities to directly translate system files from one package into another. They also have the ability to filter and transform data thereby creating data subsets and new variables. DBMS/COPY can be run as a stand-alone package or integrated into SAS. In addition, it supports a broad range of system files.

Although statistical procedures are being continuously developed, there is often a time lag between when these new procedures first appear in the statistical journals and when the appropriate software is developed. Although the time between the introduction of new methodology and the development of corresponding software has decreased considerably in recent years, reliance on only the analyses available in software packages may result in less than optimum statistical procedures. Increasingly, packages have programming and macro capabilities to aid researchers in the development of their own "in-house" written software. Researchers may also program in languages of their choice such as C, Pascal, and Fortran. In addition, there are higher and object-oriented languages, such as Matlab, which handle complex mathematical and statistical manipulations making the development of new software considerably easier. To assist in this process, there are published subroutines and

numerical algorithms, such as IMSL for Fortran and C, Numerical Recipes in Fortran and C [15, 16], and Anderson Statistical Archives. A useful Web site is StatLib (`http://lib.stat.cmu.edu/`), which contains numerous mathematical and statistical codes for a variety of programming languages and packages. These are many of the same algorithms found in published articles and texts. This site also contains numerous data sets appearing in the literature along with computation results that may be used for evaluation and comparison purposes. Taking advantage of such resources should lessen considerably the amount of time spent in code writing and debugging of programs.

Randomization programs to determine treatment assignment of patients in a study have been traditionally lacking. Generally, users create their own algorithms that are specific to their particular study, or borrow and modify an existing program from a previous study. Larger clinical trials research units usually have an in-house library of software with patient randomization procedures. RANCODE and RANCODE professional, developed by **idv**, are the few commercially available programs that provide randomization schemes for a variety of study designs including parallel group and crossover. Options provide for fixed and randomly determined block sizes and stratification across study centers. The program has the capabilities for generating randomization lists, adhesive labels, envelope labels, and cards with patient/treatment assignments.

More rapid development of software for useful statistical procedures increases the possibility that some of the software may have "bugs". The user must bear the primary responsibility in determining whether newly developed software is performing the statistical computations both correctly and using the method that the user believes is being applied. A useful resource in checking the accuracy of new software is the Web, where there are example files containing both data and sample programs. Often data sets from well-known studies are readily available and can be used to validate and test software. These may be found on the vendor's Web site or at StatlLib. The results of these tests can then be compared to known or published results. Another method of testing a software package is to use data from extreme cases or boundary points where the answer is known. An excellent source for this approach is Statistics Quiz available from *SYSTAT*, written by Lee Wilkinson, which provides empirical problems that can be used in evaluating statistical packages. Although the problems in Statistics Quiz are presented for the purpose of comparing programs run on microcomputers, they can be used for verification in other computer environments.

Even if the software uses a "correct" method, the specific algorithms employed by the software package may not be clearly indicated. Often, there are multiple methods of applying the same general techniques, and different decisions on approach by various packages can lead to different answers. Situations where there are often differences among packages include methods of handling tied observations and methods of handling missing data. For some statistical tests, some packages use only asymptotic procedures, while other packages use exact procedures for small sample sizes and asymptotic methods for larger samples. The sample size that determines the crossover from an asymptotic to an exact procedure may not be the same for different packages. Similarly, different packages may vary in how they address missing data. In settings where there are multiple independent variables, a software package may perform listwise deletion, whereby analysis is performed using all available data for that particular variable; or case-wise deletion where the entire case is dropped from the analysis if any of the variables are missing for a particular case. It is both useful and essential that documentation be available for the software being used. This documentation should contain references and explicit information with regard to computations being performed within the package. Different software vendors utilize differing levels of precision in the algorithms in their software. A number of articles have been written suggesting approaches for evaluating statistical software packages and assessing their reliability [4, 10, 11]. *The American Statistician*, a journal published quarterly, has a section entitled *Statistical Computing and Graphics* and often contains articles discussing issues with respect to various statistical packages.

As statistical methods become more complex and the actual use of the analytical software becomes easier, the potential for applying an incorrect procedure to a study design increases. The user needs to understand the full implication of the analyses being employed and not merely "press a button". For example, generalized additive models (GAM) are often fit by the S-Plus software package. It has recently been

demonstrated that the default convergence criteria in S-Plus (version 3.4) do not assure convergence of its iterative estimation procedure and can provide biased estimates of regression coefficients and standard errors [2]. Thus, the user needs to be savvy enough to use a more stringent convergence to assure the convergence of the iterative procedure. However, this does not necessarily reduce the potential for the underestimation of the standard error and the presence of bias in the estimate of the regression coefficients. It has been shown that this underestimation can occur if concurvity, the nonparametric analog of multicollinearity is present in the data and might lead to significance tests with inflated type 1 error (i.e. rejection of the null hypothesis when it is in fact true) [17]. This may result in erroneously declaring a statistically significant effect when none exists. Therefore, even though the software may generate technically correct results, the appropriateness for the data set may be questionable.

Software vendors are continually updating and correcting their software. Aside from version changes, vendors often issue patches or service releases that correct errors and bugs. These patches may also impart additional functionality to the software. Typically, the researcher must be proactive in his/her search to find such fixes. More recently, some vendors have made this task a little less burdensome by providing a mechanism where the user can have the software check a predefined website for the availability of new updates. Generally, this is initiated by the user and therefore should be done on a routine basis. Fortunately, some manufacturers have carried this a step further by incorporating a "live update" mechanism whereby the software will periodically check the Web for updates and automatically notify the user when fixes are available.

Vendor Web sites also provide for compilations of user notes, macros, and add-ons that extend the capability of the basic package. Links to "frequently asked questions", "knowledge base", and "technical support" found on web sites often provide additional information that may not be readily available in the manuals that are packaged with the software. Auxiliary manuals and technical reports provide a wealth of information. These web sites may also provide files of macros and programs. Instead of transcribing programs from paper textbooks and journal articles, files can be downloaded. The most current and up-to-date versions are probably those that are on the Web or obtained by contacting authors directly.

In the business world, it is common for software vendors to change names or to be taken over by other companies. When this happens, it does not necessarily imply that the software is no longer available or no longer supported. It may mean that the product is produced under another name. When this occurs, the relevant forwarding information is not readily available, and the user needs to search the web using the vast array of Internet search engines that are available at his/her disposal. For instance, BMDP is no longer available from BMDP Statistical Software, Inc. However, it is available through Statistical Solutions as BMDP New System Professional.

The developments in microcomputer technology over the past 15 years have provided the capabilities in computational speed for computer software packages that are increasingly sophisticated and complex. There are currently many packages available that are relevant for clinical trial design and analysis. Users are not restricted to just one or two standard packages. With thought and inquiry, it is now possible for individuals to find software that is tailored exactly or nearly exactly to meet most of their needs.

Acknowledgments

The authors would like to acknowledge the contribution of Hannah Rothstein for information on the meta-analytic software packages.

Software for Genetic Epidemiology

A wide variety of software has been written to facilitate the task of managing, error-checking, and analyzing **genotype** and phenotype data for genetic studies. An exhaustive review of the software available would fill an encyclopedia of its own. A list of genetic analysis software from the Rockefeller University web site (`http://linkage.rockefeller.edu/soft/list.html`) currently includes over 150 programs. Additionally, both methodologic and software development in **genetic epidemiology** are constantly advancing and any catalog of such software will soon be rendered incomplete as new programs become available. Consequently, this review will seek to describe the types of software that are available, to discuss and characterize some of the most widely used programs, and to identify features that may differ between similar packages.

First we must define what is to be included in the category of software for genetic epidemiology. This category will be defined as including any program specifically designed for the management of genotype or pedigree data, error-checking of genotype or pedigree data, or genetic analysis using **segregation**, **linkage**, or **linkage disequilibrium** based methods. Excluded from this review are web sites such as those providing genetic **maps**, software for sequence alignment or comparison (*see* **Sequence Analysis**), software for general **variance component analysis**, and more general statistical packages, such as SAS or S-PLUS, which were not designed for genetic analysis but are often used in its service. Additionally, we will restrict our consideration to programs that are used for human genetic analysis, excluding software written for inbred lines and other study designs that are only possible in animal models. All the software discussed in this article is publicly available and, with the exception of S.A.G.E. and Cyrillic, all the programs are available free of charge for noncommercial use.

Programs for the Management and Display of Pedigree and Genotype Data

Although many researchers use standard database or spreadsheet software to store data for their genetic epidemiology studies, management software designed specifically for genetic data offers several advantages in terms of error-checking and data formatting. Errors in genotype or pedigree data may be identified through checks on Mendelian inheritance (*see* **Mendel's Laws**) and logical consistency. Data may be imported from other database systems and formatted for export to pedigree drawing or analysis programs. Commonly used software for error checking, formatting, and display of pedigree and genotype data is listed in Table 1.

Error-checking

Programs are available for detection of errors in genotype, phenotype, and pedigree data. Identification of apparent genotyping errors in family data through violations of Mendelian inheritance is performed by many data preparation and analysis programs. Checking for Mendelian consistency requires inference of the genotypes of nonsampled individuals and some error-checking programs will fill in missing **marker** genotypes when they can be unambiguously inferred. Most genetic analysis programs report errors when Mendelian inconsistencies are detected. However, only a few (e.g. ASPEX, FBAT, SimWalk2) provide explicit identifications of the likely source of the error or automatically eliminate the error by blanking suspect genotypes. PedCheck, PEDSYS, and SimWalk2 perform Mendelian consistency checks in extended pedigrees, whereas ASPEX and FBAT only accommodate nuclear families. SimWalk2 takes this one step farther and, using allele frequencies and marker maps, considers the distribution of alleles in sibships and the locations of apparent recombinations, as well as violations of Mendelian inheritance, to produce a posterior probability of error for each genotype for each individual.

The persistence of apparent genotyping errors over numerous markers may suggest pedigree errors, such as nonpaternity. Pedigree errors may also be detected by comparing empirical kinship, estimated from the observed identity-by-descent (ibd) allele sharing (*see* **Identity Coefficients**) between individuals, to the degree of relationship predicted by the assumed pedigree configuration. The program Siberror identifies probable pedigree errors in nuclear family data using genotype data at numerous markers. Similarly, RELCHECK predicts relationships between individuals (monozygotic twins, full sibs, half sibs,

Table 1 Programs for data management and pedigree drawing

Name	Mendelian error-checking	Pedigree error-checking	Data formatting	Pedigree drawing	Operating system(s)	Reference

Pedigree/Draw				X	Mac	`http://www.sfbr.org/sfbr/public/software/pedraw/peddrw.html`
PEDRAW				X	Windows, X-Windows	Curtis [8]
Cyrillic			X	X	Windows	`http://www.cyrillicsoftware.com/`

or unrelated) based on their sharing at numerous genotyped markers. RELPAIR and PREST perform the same type of analysis for slightly larger pedigrees, extending to first-cousin relationships. ACT and ASPEX, although primarily **linkage analysis** programs, also perform pedigree error-checking for sibships or nuclear families.

Pedigree and phenotype errors may be identified through checks on the logical consistency of demographic data given the constraints of family relationships. For example, mothers should be female and fathers should be male. Parents should be older than their children. Dates at which individuals are examined should be later than their dates of birth. Pedigree storage programs are also equipped to manipulate and fill in pedigree structures. Analysis programs generally require that individuals who are listed as parents have their own entry in the database and some management software will create entries for missing individuals necessary to complete the pedigree structure. Additional pedigree-based manipulations include trimming of uninformative individuals. The computational burden of some types of analyses increases exponentially by pedigree size, making it most efficient to exclude individuals who are missing crucial phenotype or genotype data. When eliminating uninformative individuals, software specifically designed for the management of pedigree data is equipped to consider whether individuals with missing data are necessary to complete the pedigree structure and thus should be retained. Some of these programs will also calculate kinship coefficients based on the provided pedigree structure. PEDSYS performs all these functions. S.A.G.E. also performs many of these functions through its specialized programs. PedHunter is designed to query genealogic databases and can calculate kinships, find individuals who are related in a specific way (e.g. find all siblings of a given individual), or identify the minimum number of common ancestors to connect a specified set of individuals (e.g. trim a pedigree to affected individuals and those necessary to connect them).

Translating Between Data Formats

Genetic analysis programs require specific data formats and there is generally little overlap in the data structure required by different programs. Management software designed specifically for genetic data is often equipped to produce data files formatted for the needs of various genetic analysis programs. PEDSYS can import data from delimited field formats (e.g. comma or space delimited) and export data formatted for Pedigree/Draw, FISHER, MENDEL, CRI-MAP, PAP, SOLAR, or LINKAGE. Mega2 formats data for use in SimWalk, MENDEL, ASPEX, APM, SLINK, SIMULATE, S.A.G.E., GeneHunter, TDTMax, and SOLAR. Cyrillic can import data from programs such as MLINK, Pedigree/Draw, and CRI-MAP and output data for these programs as well as for LIPED. PedHunter outputs data formatted for the LINKAGE or Pedigree/Draw programs. SIB-PAIR, although primarily an analysis program, formats data for APM, Arlequin, ASPEX, CRI-MAP, FISHER, GAS, GDA, LINKAGE, MENDEL, PAP and S.A.G.E.

Pedigree Drawing

Drawings of pedigrees are used by both clinicians (*see* **Genetic Counseling**) and researchers to verify family relationships and to display phenotypes, genotypes, and **haplotypes**. Two of the most widely used pedigree drawing programs are Cyrillic and Pedigree/Draw. The most immediate difference between these two programs is that Cyrillic runs under Windows whereas Pedigree/Draw is Macintosh based. Both programs can accommodate large and complex pedigrees, provide a variety of marking symbols to denote phenotype and sampling status, and display genotypes or other text. Cyrillic provides some data management and formatting capabilities and includes routines for risk assessment. However, Cyrillic is a commercial program whereas the other pedigree drawing programs listed are freely available over the web. Although less widely used than Cyrillic, PEDRAW is also Windows based, performs many of the same functions, and is available without charge over the web. CoPE is designed to allow multiple researchers to access the same pedigree database and is a Java Script program that can be used on any platform through a web browser. Cyrillic can provide haplotypes and CoPE will draw haplotypes if they are specified.

Programs for Construction of Marker Maps

Although many researchers use online databases to obtain marker maps, constructing marker maps

from one's own data set can be advantageous if sufficient pedigree information is available. Methods of **multipoint linkage analysis** that are based on correlations in ibd may suffer if an ill-fitting map is specified (*see* **Genetic Map Functions**) and loci are assumed to be more or less highly correlated (i.e. closer or farther apart) than is reflected in the current data. Map construction can also be useful for error-checking purposes. For example, apparent expansion of the marker map, as compared with published maps, may highlight problematic markers or genotyping errors that cause an apparent excess of recombinations but not Mendelian inconsistencies. In some cases, adequate map data simply may not be available from other sources. Newly identified variants in candidate genes may not be placed on the online linkage maps and may be only approximately localized in physical maps.

Any of the parametric linkage packages (*see* **Linkage Analysis, Model-based**) (listed in Table 2) could be used to estimate recombination between genotyped markers and construct a map. However, several packages automate this process. CRI-MAP [29] has a variety of map construction routines that place new markers relative to a map of old markers and evaluate the **likelihoods** of alternative map orders. In its likelihood calculations, CRI-MAP considers only meioses in which the parental transmission can be unambiguously inferred, whereas standard linkage programs would weight over the possible values of missing genotypes that cannot be unambiguously inferred. This restriction leads to some loss of information but may be viewed as conservative, particularly when good estimates of allele frequency are not available. The chrompic option of CRI-MAP can also be used to examine pictorially the grandparental origin of each genotype along a chromosome for the most likely phase. MultiMap [32] further automates this process, adding markers to the map in order of locus content, which can be specified by the user but is generally measured by the marker's heterozygosity. MultiMap uses CRI-MAP for likelihood computation and thus has the same limitations with regard to the treatment of missing data. MultiMap also has a module for the construction of **radiation hybrid maps**. Both programs are available for Unix systems and as a C source code which could be compiled under a variety of operating systems. MultiMap requires a C compiler and a Lisp interpreter to run.

Software for Genetic Analysis

Numerous programs are available for genetic analyses using segregation, linkage, and linkage-disequilibrium based methods and only the most commonly used of these programs are discussed here. To obtain a representative sample of the most widely used genetic analysis software, both the proceedings of Genetic Analysis Workshop 11 [18] and the pre-conference abstract book for Genetic Analysis Workshop 12 (held in October 2000) were surveyed. Together these two volumes contain 320 papers reporting analyses of four data sets ranging from alcoholism and quantitative measures of evoked brain potentials to asthma and related risk factors to simulated diseases and quantitative traits with genome screen and single nucleotide polymorphism (SNP) data. Any genetic analysis program that was cited by a total of 5 or more papers in these two volumes is listed in Table 2.

Segregation Analysis

The programs indicated in the "segregation" column of Table 2 are those that perform classic quantitative trait or penetrance model-based segregation analyses (*see* **Segregation Analysis, Classical**; **Segregation Analysis, Complex**). PAP and S.A.G.E. can fit a variety of environmental, polygenic, and Mendelian models. SAGE also has modules for a variety of regressive models. Loki models a quantitative trait as a function of a number of diallelic quantitative trait loci (QTLs), providing posterior probability distributions for the number of QTLs, the QTL allele frequencies, and the additive genetic **heritability** of the QTLs. These programs can also be used for combined segregation and linkage analyses in which both parameters for the penetrance model or the QTLs and the location of the trait locus are estimated simultaneously. Although not marked as segregation software in the table, programs that perform variance component analyses may also be used to examine the genetic architecture of a trait. ACT, GeneHunter, and SOLAR can be used to estimate the additive and dominance components of heritability and to compare the likelihood of models with and without genetic components of variance.

Linkage Analysis

The linkage programs in Table 2 utilize a wide variety of statistical models and methods, including

Table 2 Software for genetic analysis

Name	Segregation	Linkage	Disequilibrium	Trait[a]	Methods or models	Extras	Operating system(s)	Reference
ACT		X	X	Q	Variance component, TDT	Multivariate, pedigree error-checking	Unix	Amos et al. [3]
Allegro		X		D	Penetrance model, affected pair	Haplotypes, observed map, empirical *P* values	Unix	Gudbjartsson et al. [20]

[a]D = discrete; Q = quantitative; B = both.

model-based, affected relative pair, Haseman–Elston, and variance components (*see* **Linkage Analysis, Model-based**; **Linkage Analysis, Model-free**). Although there is a general equivalence of methods between software using the same models, there are often subtle but potentially important differences. Among programs using a Haseman–Elston test, S.A.G.E. and SIB-PAIR include both the classic [21] and modified Haseman–Elston algorithm [14], whereas GeneHunter and Mapmaker/Sibs provide only the classic Haseman–Elston [21] algorithm. Among penetrance model-based and variance component programs, differences in the handling of multipoint inference (discussed below) may lead to limitations on the size of pedigree or the number of genotyped markers that can be considered in practice.

Variance component linkage programs also differ in the types of data they use and in the ease with which various models can be parameterized. ACT and SOLAR make use of singleton individuals in addition to subjects in families to estimate trait means and standard deviations and **covariate** effects. In contrast, GeneHunter eliminates singleton individuals. Dominance components of variance can be automatically incorporated in GeneHunter but must be manually added in SOLAR through direct modification of the covariance function. However, the ability to directly modify the covariance function in SOLAR also permits advanced users to incorporate terms for **gene–environment interaction** and to construct joint tests of linkage and disequilibrium.

Affected relative pair programs differ from each other in the calculation of the test statistic and in options for correcting for the nonindependence among pairs when there are more than two affected sibs within a sibship. When some individuals are unavailable for genotyping and descent information is incomplete, the perfect data approximation of GeneHunter's nonparametric linkage (NPL) score overestimates the **variance** in its test statistic and becomes highly conservative. Allegro and GeneHunter+ use a **maximum likelihood** method that is not subject to this problem. When $n > 2$ affected sibs are available from a given family, the analytical options may include using only one pair, using the $n - 1$ independent pairs that can be constructed, or using all pairs. ASPEX also provides the option to consider only pairs where ibd sharing can be inferred unambiguously.

ASPEX, Mapmaker/Sibs, and SIB-PAIR are limited to nuclear families, whereas the other linkage programs listed can accommodate larger pedigrees. Most of the affected pair and variance component linkage programs listed estimate marker-specific and multilocus ibd allele sharing and some will output ibd matrices which may be useful for error-checking or for importation into other programs. Some of the additional features of these programs are noted in the "Extras" column of Table 2. As discussed above, some packages check for genotyping errors. A few of the programs provide haplotypes. Some permit multivariate linkage analyses of two or more traits. Some consider multilocus models that incorporate multiple loci influencing the trait with or without epistatic interaction between the loci. Several packages have some simulation capacity, permitting the estimation of empirical ***P* values**.

Linkage programs differ in their methods for multipoint inheritance inferences and these differences have implications for the type of data that can be analyzed. LINKAGE, FASTLINK, and VITESSE use the **Elston–Stewart algorithm** [13] which results in exponential increases in computing time with the number of markers analyzed. FASTLINK incorporates algorithmic improvements that make it somewhat more efficient than LINKAGE. VITESSE uses set-recoding and fuzzy inheritance methods to speed up computations, allowing it to handle more markers than LINKAGE or FASTLINK, but it is limited to pedigrees without loops descended from a single founder couple. ACT, Allegro, GeneHunter, and GeneHunter+ use the Lander–Green **Hidden Markov Model** [29] which incurs an exponential increase in computing time with the number of nonfounders in the sample, placing a practical limit on the size of the pedigrees that can be analyzed. SOLAR uses a multipoint approximation based on correlations between ibd at the individual markers [2, 16]. Computing time for this approach is linear in both the number of markers and the number of individuals, permitting analyses of larger pedigrees. However, this approximation depends on the informativeness of the genotyped markers. Thus, while it performs well for genome scanning with microsatellites, it would be suboptimal for multipoint ibd estimation given a map of SNPs. SIB-PAIR also uses this method to impute ibd between flanking markers in its Haseman–Elston linkage routine. Loki and SimWalk2 use

Markov chain Monte Carlo methods which are also approximate and linear in the number of individuals and the number of markers but do not suffer the limitations on marker informativeness imposed by the between marker correlation method. Note that SimWalk2 requires the program MENDEL [30] to compute location scores for parametric linkage analyses.

While not precisely a linkage program, HOMOG is designed to be used in conjunction with linkage software. Given the lod scores for each family in a data set, HOMOG performs heterogeneity testing to assess whether in some proportion of families the trait is unlinked to the region in question. HOMOG extension modules permit consideration of multiple locus testing, for example models in which the trait is linked to locus 1 in some families, linked to locus 2 in other families, and unlinked to either locus in another group.

Linkage Disequilibrium Based Analysis

The programs indicated in the "Disequilibrium" column of Table 2 generally fall into two broad categories: those that perform transmission disequilibrium tests (TDTs) for linkage in the presence of disequilibrium with discrete or quantitative traits, and those that model the mean of a quantitative trait as a function of genotype. A few programs perform both these functions. Some programs have additional association tests that fall into neither of these categories. GASSOC has a variety of test statistics optimized for different underlying genetic models (e.g. recessive, dominant). SIB-PAIR performs standard tests of allele frequency distribution in affected and unaffected individuals with estimation of empirical P values through gene-dropping conditional on family structure and allele frequencies.

ACT, ASPEX, FBAT, GASSOC, GeneHunter, the TDTEX module of S.A.G.E., and SIB-PAIR all perform standard TDT tests for di- or multiallelic markers using parent–child trios derived from nuclear families. ACT, ASPEX, GeneHunter, S.A.G.E., and SIB-PAIR use a variety of permutation and **Monte Carlo methods** to provide empirical P values, taking into account factors such as the use of multiple sibs within a sibship. FBAT allows **covariate** adjustments. Up to four adjacent, closely linked marker loci can be included in the TDT in GeneHunter. ACT has a macro for simultaneous consideration of multiple loci through **conditional logistic regression**. The TDT portion of ACT consists of SAS macros that require the SAS package to run.

PAP, the ASSOC module of S.A.G.E., SIB-PAIR, and SOLAR (which is based on the program FISHER) can be used for measured genotype testing in which the mean of a quantitative trait is modeled as a function of genotype. PAP, S.A.G.E., and SOLAR accommodate the inclusion of quantitative or discrete covariates in these analyses. PAP and SOLAR use maximum likelihood methods that assume a **multivariate normal distribution** for the trait values. SOLAR also has a multivariate t distribution option. S.A.G.E. uses generalized modulus **power transformations** that require less stringent assumptions about the distribution of the trait values. PAP, SOLAR, and S.A.G.E. directly account for the nonindependence among family members and model a residual familial correlation not due to the locus being tested, whereas SIB-PAIR estimates empirical P values through gene-dropping within the families.

Conclusions

There are many factors that go into deciding which of these packages to use in any given situation – the computer resources available to the project, the size and structure of family data, the type of traits to be analyzed, and the desired methods of analysis. Each of the programs discussed above has strengths and weaknesses and it is impossible to make blanket recommendations that are appropriate for all, or even most, studies. However, a number of resources exist that compare the performance and utility of some of these packages under a variety of conditions. Some of these reviews address questions of power and accuracy while others comment on ease of use and computational intensity. It should be noted that comparisons of software for genetic analysis reflect, and often cannot be separated from, comparisons of the underlying analytical methods, particularly when addressing questions of power and accuracy. Comparison of methods and software for genetic analysis is the primarily goal of the Genetic Analysis Workshop and the proceedings of this conference contain many such comparisons (e.g. [18, 19], and [41]).

Table 3 Selected publications comparing various software packages

Reference	Software compared	Context
Cervino & Hill [6]	LRAT, RCTDT, SIBASSOC, TRANSMIT	TDT with differing family structures, population stratification, nonpenetrance, nonpaternity
Davis & Weeks [9]	ASPEX, GeneHunter, Mapmaker/Sibs, S.A.G.E., and others	Linkage using affected sibpairs or sibships
Goldgar & Oniki [17]	LINKAGE, MIM	Comparison of penetrance model and ibd-based quantitative trait linkage analysis
Konigsberg et al. [25]	FISHER/MENDEL, PAP, S.A.G.E.	Quantitative trait segregation
Schaffer [38]	FASTLINK, LINKAGE	Model-based linkage with pedigree loops or ungenotyped individuals
Williams & Blangero [42]	Mapmaker/Sibs, SOLAR	Quantitative trait linkage

Other manuscripts that compare and contrast various software packages are detailed in Table 3.

There are also online sources that compare programs or are a repository of information about multiple programs. A University of Washington web site (`http://www.cs.washington.edu/homes/pmork/final_project/`) provides a fairly intensive summary of a selection of programs for quantitative trait analyses, including FBAT, GeneHunter, LOKI, and SOLAR. The Rockefeller University web site, mentioned in the introduction, is an excellent resource for finding software often with links to web sites where the programs can be downloaded. Links to downloadable versions of many programs also can be found at a European Bioinformatics Institute mirror site (`ftp://ftp.ebi.ac.uk/pub/software/linkage_and_mapping/`) or at the Weizmann Institute of Science Bioinformatics Unit (`http://bioinfo.weizmann.ac.il/repository/mapping_software.html`). Online documentation for many programs is available through `http://watson.hgen.pitt.edu/docs/` or `http://www.well.ox.ac.uk/docs/index.html`. The Computational Methods and Algorithms Group at NIH also has an extensive genetic analysis software site at `http://cmag.cit.nih.gov/Lserver.htm`.

Acknowledgment

Preparation of this manuscript was supported by US National Institutes of Health grant MH59490. I am also grateful to Ravi Duggirala and Harald Göring for their helpful comments and suggestions.

LAURA ALMASY

Software for Sample Survey Data, Misuse of Standard Packages

In the past 15 years, many researchers in the health sciences have become interested in performing primary and secondary analyses using data from complex **sample surveys**. These analyses are often descriptive or analytical, but they may also generate or test hypotheses within the context of a statistical model. Sample survey statisticians are aware that specialized software should be used to analyze complex sample survey data, particularly when analyses are descriptive or analytical and the survey design includes **clustering** [1, 4] (*see* **Software for Sample Survey Data**).

However, some researchers are not aware of the need to use specialized software or, if aware, prefer not to do so because of the need to learn new analytical techniques and software. A common error among data analysts is the inappropriate use of standard statistical software for sample survey data. Further, data analysts may be confused when they realize that there is a difference of opinion, even among sample survey statisticians, as to methods for analysis of sample survey data [2, 3, 4, 8], particularly when using statistical models.

This article uses sample survey data from BRFSS (Behavioral Risk Factor Surveillance System) surveys to illustrate that **biased** point estimates (*see* **Estimation**), inappropriate **standard errors** and **confidence intervals**, and misleading tests of significance (*see* **Hypothesis Testing**) can result from the incorrect use of standard statistical software packages (*see* **Software, Biostatistical**). This article is not a critique of standard statistical software but rather a critique of data analysts inappropriately choosing such software for survey data. Sample survey software has become more widely available in the past decade, giving survey data analysts both the opportunity and the responsibility to choose appropriate software for their analyses. The examples in this article of appropriate and inappropriate (but common) software choices illustrate the importance of using sample survey software for survey data.

Why Specialized Software is Needed

Standard statistical software generally assumes that the observational units have been obtained via **simple random sampling**. Thus, it does not take into account four common characteristics of sample survey data: (i) unequal probability selection of observations, (ii) clustering of observations, (iii) **stratification**, and (iv) **nonresponse** and other adjustments [6, 7]. Point estimates of population parameters are impacted by the value of the analysis weight for each observation. These weights depend upon the selection probabilities through survey design features such as stratification, oversampling and clustering and upon nonresponse adjustments. Incorrectly choosing to use standard statistical software without weighting will yield biased point estimates of population parameters. Estimated **variance** formulas for point estimates based on sample survey data are impacted by clustering, stratification, and the weights. By incorrectly choosing standard statistical software and ignoring these survey design aspects in the analysis, the estimated variance of a point estimate generally is underestimated, sometimes substantially so.

Most standard statistical software can perform weighted analyses, usually via a WEIGHT statement added to the program code. Use of standard statistical software with a weighting variable should yield the same point estimates for population parameters as sample survey software. However, the estimated variance of point estimates generally is not correct since the user is ignoring clustering and stratification. Further, the estimated variance can be substantially wrong, depending upon the particular standard software program being incorrectly used.

Description of BRFSS Surveys

The BRFSS [10] program, established by CDC (**Centers for Disease Control and Prevention**), provides state-level data to estimate the **prevalence** of **risk factors** for disease and poor health. States select a continuous **probability sample** of the adult noninstitutionalized population using some type of **random digit dialing** (RDD) telephone sampling. The Mitofsky–Waksberg RDD technique [11] was used for many years, but list-assisted or directory-based stratified RDD (*see* **Telephone Sampling**)

is commonly used now. Telephone numbers typically are stratified by density of residential telephone numbers, and the high-density stratum is oversampled. Once a residence is reached, almost all states select one adult, with equal probability, to undergo a telephone interview. Each state generally interviews between 1500 and 4500 adults per year.

BRFSS statewide surveys result in an unequal probability sample of adults because only one adult per sampled household is selected and there may be differential sampling fractions of telephone numbers in different strata. Weighting adjustments may be done for first-stage nonresponse (telephone not answered or household screening/enumeration not completed) and for second-stage nonresponse (the selected adult was not interviewed). Further, **post-stratification** of the observations to US Census data is generally done. Hence, each observation (interviewed adult) in the data set has a value for the variable FINALWT (final analysis weight). This value indicates the number of persons in the population represented by that observation. The value of FINALWT varies across observations within a state and between states, sometimes considerably so.

In addition to differential weighting, the Mitofsky–Waksberg RDD method clustered observations by telephone bank (usually defined as a group of 100 telephone numbers with identical area code, prefix, and first two digits of the suffix). Under list-assisted RDD the observations in BRFSS data sets are not clustered. Further, some states use geographic stratification in their sampling process. Although sampling details differ across states and across years, current statewide BRFSS surveys typically are weighted, stratified, and not clustered, whereas older surveys were weighted, clustered, and may be stratified.

This article uses calendar year 1993 BRFSS data on diabetes for the six states given in Table 1, yielding a total sample size of 20 049 observations over the six states. Mitofsky–Waksberg RDD was used in all six states. Presence/absence of diabetes is defined as a Yes/No answer to "Have you ever been told by a doctor that you have diabetes?"; the few observations with other than a Yes/No answer are excluded from all analyses.

Comparing Appropriate and Inappropriate Software Choices

Any sample survey software and any standard statistical software could have been chosen to illustrate these comparisons; numerical results equivalent to Tables 1–3 would have been obtained. A comprehensive and popular statistical software package was

used to conduct two standard and common analyses: (1) estimation of a **mean** (**prevalence**) with estimated **standard error** and (2) calculation of a **chi-square test**. Results obtained from these standard analyses demonstrate the error of an inappropriate software choice. SUDAAN Version 8 [9], a specialized package for sample survey and correlated data analysis, was used to demonstrate an appropriate software choice; Taylor Series linearization [5] is used for variance estimation (*see* **Linearization Methods of Variance Estimation**).

Each state's sampling plan was described to SUDAAN in the same way; within a state no stratification was used and observations were clustered in their appropriate primary sampling unit (PSU), a telephone bank. To perform analyses for each state and for the combined states, the six-state concatenated data set was described to SUDAAN as a **stratified** (by state) **multi-stage clustered** survey. The **finite population correction factor** was not used in estimated variance calculations. For those familiar with SUDAAN and BRFSS, the PROC statement included

DESIGN = WR (with replacement sampling at stage one), the NEST statement included the state stratification variable STSTR and the clustering (telephone bank) variable PSU, and the WEIGHT statement included the variable FINALWT.

Inappropriately chosen standard analyses were conducted using four different approaches, all of which incorrectly ignored the clustering and stratification. The four approaches differ in the way the weighting variable FINALWT is handled in the standard analyses. The first standard approach ignored FINALWT and analyzed the data set unweighted; this is equivalent to using the WEIGHT statement with the variable_ONE_ (a variable whose value is 1.0 for every observation in the data set). In Table 1 (column 2) it is shown that, with this approach, the CA sample size is 3719 and it contributes 19% to the total inference population.

The second standard approach used the WEIGHT statement with the variable FINALWT. There is great variability in FINALWT; Table 1 (column 3) indicates its range as 70 to 72 663. In Table 1 it is also shown that using FINALWT implies that the CA sample contributes 50% to the total inference population, rather than only 19% in an unweighted analysis.

The third standard approach used the WEIGHT statement with the variable NORMWT, a normed weight based on FINALWT. Some data analysts claim that using normed weights with standard statistical packages yields results comparable to those from sample survey software. For observation j within state i, let finalwt (i, j) be the value of the variable FINALWT. Then, the value of NORMWT for this observation is defined as:

$$\text{normwt}(i, j) = (20049) * \frac{\text{finalwt}(i, j)}{45\ 452\ 569} \qquad (1)$$

The figure 45 452 569 is the estimated total adult population of the six states, which is the sum of the value of FINALWT over all 20 049 observations (Table 1, column 3). The variable NORMWT has values less than 1.0 and greater than 1.0, and the sum of the values of NORMWT over the entire data set is 20 049, the total sample size. In Table 1 (column 4) it is shown that, with this approach, the CA sample contributes 50% to the total inference population.

The fourth standard approach used the WEIGHT statement with the variable STNORMWT, a second normed weight calculated from FINALWT, where the norming is done within state. Hence, the sum of the values of STNORMWT over all observations within a state equals the sample size for that state (Table 1, column 5). Clearly, the sum of STNORMWT over the entire sample equals the total sample size 20 049. In Table 1 it is shown that, with this approach, the CA sample contributes 19% to the total inference population.

First, SUDAAN DESCRIPT and the four inappropriately chosen standard approaches were compared on a descriptive analysis; that is, estimation of diabetes prevalence (with estimated standard error) for the total population (six states combined) and for each state. The diabetes variable was coded as 1 or 2 for DESCRIPT and coded as 0 (no diabetes) or 100 (have diabetes) for the standard software that estimated means.

Secondly, SUDAAN CROSSTAB and the four inappropriately chosen standard approaches were compared on a chi-square test of the **null hypothesis** that gender and diabetes are statistically independent. These analyses were performed for the total population and for each state, with diabetes coded as a categorical variable (1, 2).

Results

Descriptive Analyses

Sample survey software yields correct point estimates for diabetes prevalence and for estimated standard errors (Table 2, column 2). However, the incorrect choice of unweighted standard software (column 3) causes diabetes prevalence to be overestimated by about 10% for the total population (5.40 versus 4.86%) and for half of the states. Note also that the estimated standard errors in Table 2 are smaller by incorrectly using unweighted standard software. For the entire population, the correct estimated standard error is 35% larger than the standard error estimated by the incorrect use of unweighted standard software (0.219 versus 0.160). The combination of the biased point estimate and underestimation of the standard error could result in quite misleading confidence intervals for the prevalence of diabetes.

In Table 2 (columns 4 and 5), it is shown that standard software with FINALWT or NORMWT gives identical results, with correct point estimates for diabetes prevalence. However, the incorrect choice of standard software for analysis still results in estimated standard errors that are too low. The magnitude of

underestimation of the standard error by using standard software with FINALWT or with NORMWT is somewhat worse than with unweighted standard software. Thus, standard statistical software with a WEIGHT statement using FINALWT or NORMWT yields **unbiased** point estimates of population parameters, but it yields incorrect estimated standard errors.

In Table 2 (column 6), it is shown that standard software with STNORMWT gives identical results to standard software with FINALWT or NORMWT for state-specific analyses, but yields a biased point estimate for the total population along with an underestimated standard error.

Chi-square Analyses

The chi-square analysis tests the null hypothesis that the prevalence of diabetes is the same for males and females. In Table 3 (columns 2 and 3), it is shown that the incorrect choice of unweighted standard software, compared to sample survey software, yields a higher value for the chi-square statistic for the entire population, giving a smaller ***P* value** (0.003 versus 0.014). A comparison state by state shows no consistent pattern; the *P* value for unweighted standard software is sometimes higher and sometimes lower than for sample survey software.

In Table 3 (columns 2 and 4), it is shown that the incorrect choice of standard software with FINALWT yields an unreasonably large value of the chi-square statistic for the total population and for each state. *P* values are not included in Table 3 for these very large chi-square statistics. The standard software with FINALWT considers the sample size to be the sum of the values of FINALWT (i.e. 45 452 569) as opposed to the actual sample size of 20 049. This is the reason for the very large values of the chi-square statistic.

In Table 3 (columns 2 and 5), it is shown that the incorrect choice of standard software with NORMWT yields a chi-square value for the six-state area that is twice as large (12.64 versus 6.07). However, this relationship between sample survey and standard software with NORMWT does not hold for each of the six states in Table 3. Standard software with NORMWT yields a larger chi-square statistic value for some states but a smaller value for other states. This occurs because, within each state, the standard software considers the sample size as the sum of NORMWT. Hence, the sample size for CA is artificially inflated to 10 049 from 3719, whereas the sample size for West Virginia (WV) is artificially deflated to 598 from 2425 (see Table 1). Thus, the chi-square statistic using standard software with NORMWT, compared to survey software, is much larger for CA but much smaller for WV.

In Table 3 (columns 2 and 6), it is shown that the inappropriate choice of standard software with STNORMWT yields a chi-square statistic for the total population about twice as large (13.20 versus 6.07). For each state, the chi-square statistic based on standard software with STNORMWT is about 15–20% larger than provided by survey software. Because STNORMWT is normed within a state, the sum of the weights reflects the statewide sample size. Hence, the standard software with STNORMWT shows the common pattern that standard statistical software packages generally calculate a larger value of the chi-square statistic compared to sample survey software.

Discussion

Unweighted Analyses with Standard Statistical Software

Although the empirical evidence in this article is based only on one type of survey (BRFSS), only on six states and only on 1993 data, the findings are consistent with other similar investigations [1]. Using a standard statistical package with unweighted analyses to analyze sample survey data generally will yield (i) biased point estimates of population parameters, (ii) underestimates of the standard error for point estimates, (iii) confidence intervals on population parameters that are too narrow, and (iv) tests of significance that are too likely to reject the null hypothesis because the standard errors or variability of statistics generally are underestimated.

The extent of the bias in unweighted point estimates will depend upon the particular data set and is related to the variability of the FINALWT variable. If FINALWT has little variability in the data set, then an unweighted point estimate will be close to a weighted point estimate. In the six-state BRFSS data set, the value of FINALWT ranged from 70 to 72 663 over the six states. This extreme variability in the value of FINALWT is primarily due to varying sampling fractions across the states; that is, a small variation in state sample size (2400 to 4400) but widely different statewide populations (1.4 to 22.8 million).

Another factor that contributes to the bias of point estimates of population parameters based on unweighted analyses is the relationship between the value of FINALWT and the variable being analyzed. In the data set used here, the value of FINALWT is primarily influenced by the sampling fraction in each state; you could say that certain states are "oversampled". If states were strongly related to the analysis variable (diabetes), then point estimates of diabetes prevalence from unweighted analyses could be seriously biased. In this data set, the estimated statewide prevalences of diabetes do not differ dramatically, ranging from 4 to 6%. If blacks had been oversampled within each state to a large extent, then the bias in estimated diabetes prevalence using unweighted analyses would be substantial and positive, since blacks have a higher prevalence of diabetes than do whites.

In addition to potentially biased point estimates from unweighted standard analyses, standard errors, and other measures of variability are generally underestimated because of clustering and variability in FINALWT. The intracluster **correlation** coefficients in older BRFSS data sets using Mitofsky–Waksberg RDD are generally positive but not substantial. This might be expected because most states only had about three completed interviews per PSU (telephone bank) (*see* **Telephone Sampling**) with Mitofsky–Waksberg RDD. Variability in FINALWT, and not clustering, likely is the most important factor contributing to the higher estimated variances from sample survey software using this BRFSS data set. If other sample survey data sets had been used with a higher degree of intracluster correlation, an incorrect choice of unweighted standard analyses would have produced even smaller estimates of variability, compared to sample survey software.

Weighted Analyses with Standard Statistical Software

Using standard statistical software with weighted analyses (FINALWT or NORMWT) produces unbiased point estimates of prevalence for the entire population over all six states and for any strata (states) of interest. Although not illustrated, these weighted analyses also yield unbiased point estimates of diabetes prevalence among subpopulations based on other characteristics, such as race or gender, where the subpopulations contain observations from all or some strata. Hence, either of these two weighted standard approaches is fine if only point estimates of prevalence are desired. However, weighted standard statistical software (using FINALWT or NORMWT) tends to underestimate the standard error of estimated prevalences. The degree of underestimation depends upon the size of the intracluster correlation coefficient for the variables being analyzed; the higher the intracluster correlation, the more serious the underestimation of the variability. Weighted analyses with standard statistical software (using NORMWT or FINALWT) may be a reasonable analytical approach for point estimates of population parameters under the following condition: all intracluster correlation coefficients are near zero.

The inappropriate choice of standard software with FINALWT gives substantially incorrect results for chi-square tests because the sample size is assumed to be the population size, that is, the sum of the values of FINALWT. Whether this is true in all standard statistical packages depends upon the packages' default options for weighted analyses in chi-square tests.

The inappropriate choice of standard software with NORMWT gives a larger chi-square statistic for the entire population, about twice as large. However, this procedure yields substantially incorrect chi-square statistics for state-specific analyses. The state specific analyses are wrong because the standard software assumes an incorrect sample size for the state analyses. This will occur also whenever subpopulations are analyzed using NORMWT and the variable that defines the subpopulation is related to the value of FINALWT.

The inappropriate choice of standard software with the second normed weight, STNORMWT, gives more reasonable values for the chi-square statistic for state level analyses, although the chi-square statistics were always larger than with survey software. However, if the weight STNORMWT is used for analyses over the entire population, a biased point estimate is obtained for population parameters.

Conclusions

The empirical results above illustrate that using standard statistical software with the weights FINALWT or NORMWT are the only two of the four inappropriate approaches considered that yield unbiased point estimates for population and subpopulation parameters. All four inappropriate choices for analysis using standard statistical software yield incorrect

standard errors and tests of significance, generally in the direction of underestimating variability of statistics. In particular, using normed weights with standard statistical software, a sample survey data analytic approach advocated by some data analysts, is problematic with respect to variance estimation and in some instances can give biased point estimates of population parameters. It is recommended that sample survey software be used to analyze sample survey data, especially for estimation of population parameters, descriptive analyses, and analytical analyses. Under certain circumstances, standard statistical packages can be used to provide results approximately equal to the results obtained from sample survey software. However, recognition of these circumstances and awareness of the potential pitfalls of using standard statistical packages requires detailed information about the characteristics of the survey data set (e.g. sampling plan, weighting scheme, and intracluster correlation) as well as knowledge of the particular formulas and default options used by the standard statistical software for weighted analyses. In the end, it seems easier and less time consuming to use software developed for sample survey data analysis.

DONNA BROGAN

Software for Sample Survey Data

Introduction

A **sample survey** is a process for collecting data on a sample of observations that are selected from the population of interest using a **probability sample** design. In sample surveys, certain methods are often used to improve the precision and control the costs of survey data collection. These methods introduce a complexity to the analysis, which must be accounted for in order to produce **unbiased** estimates (*see* **Estimation**) and their associated levels of precision. This article provides a brief introduction to the impact these design complexities have on the sampling **variance**, and summarizes the characteristics and availability of software to carry out analysis on sample survey data.

Complex Sample Designs

Statistical methods for estimating population parameters and their associated variances are based on assumptions about the characteristics and underlying distribution of the observations. Statistical methods in most general-purpose statistical software tacitly assume that the data meet certain assumptions. Among these assumptions are that the observations were selected independently and that each observation had the same probability of being selected. Data collected through surveys often have sampling schemes that deviate from these assumptions. For logistical reasons, samples are often clustered geographically to reduce costs of administering the survey, and it is not unusual to sample households and then subsample families and/or persons within selected households (*see* **Multistage Sampling**). In these situations, sample members are not selected independently, nor are their responses likely to be independently distributed.

In addition, a common survey sampling practice is to oversample certain population subgroups to ensure sufficient representation in the final sample to support separate analyses. This is particularly common for certain policy-relevant subgroups, such as ethnic and racial minorities, the poor, the elderly, and the disabled. In this situation, sample members do not have equal probabilities of selection. Adjustments to sampling weights (the inverse of the probability of selection) to account for **nonresponse** as well as other weighting adjustments (such as **poststratification** to known population totals), further exacerbate the disparity in the weights among sample members.

Impact of Complex Sample Design on Sampling Variance

Because of these deviations from standard assumptions about sampling, such survey sample designs are often referred to as *complex*. While **stratification** in the sampling process can decrease the sampling variance, **cluster sampling** and unequal selection probabilities generally increase the sampling variance associated with resulting estimates. The *sampling variance* is a measure of the variation of an estimator attributable to having sampled a portion of the full population of interest. It is a measure of the variation of the *estimate* of a population parameter over repeated samples. The sampling variance becomes smaller as the sample size increases, and is zero when the full population is observed. The sampling variance differs from the *population variance*, which measures the variation among *observations* in the population, and is a constant, independent of any sampling issues.

Not accounting for the impact of the complex sample design can lead to an underestimate of the sampling variance associated with an estimate. Therefore, while standard procedures in general-purpose statistical software packages can usually produce an unbiased weighted survey estimate (*see* **Software, Biostatistical**), it is quite possible to overestimate the precision of such an estimate when using one of these standard procedures to analyze survey data.

The magnitude of this effect on the variance is commonly measured by what is known as the **design effect** [16]. The design effect is the sampling variance of an estimate, accounting for the complex sample design, divided by the sampling variance of the same estimate, assuming a sample of equal size had been selected as a simple random sample. A design effect of one indicates that the design had no impact on the variance of the estimate. A design effect of unity indicates that the design has increased the variance, and a design effect less than one indicates that the design actually decreased the variance of the estimate. The

design effect can be used to determine the *effective* sample size, simply by dividing the nominal sample size by the design effect. The effective sample size gives the number of observations that would yield an equivalent level of precision from an independent and identically distributed (i.i.d.) sample. For example, an estimate from a complex sample of size 1500 that has a design effect of 1.5 is equivalent (in terms of precision) to that same estimate from a **simple random sample** of size 1000. The benefits of the complex design in this case would be weighed against the cost of effectively losing 500 observations.

For complex designs, the exact computation of the variance of an estimate is not always possible. When estimating a total or a **mean** (when the denominator is known), the estimate is in linear form; that is, $\overline{y} = \sum_{i=1}^{n} y_i/n$ can be expressed in the form $\hat{\theta} = \sum_{i \in S} \beta_i y_i$. When an estimate is in linear form, a standard formula for the mean square error of a linear estimate can be applied to calculate the variance; however, for a weighted mean estimate, the form is no longer linear. If w_i is the weight associated with sample member i, then the weighted mean is calculated as: $\overline{y}_w = \sum_{i=1}^{n} w_i y_i / \sum_{i=1}^{n} w_i$. The mean estimate is now a **ratio estimate** with a **random variate** in both the numerator and denominator because the sample weights depend on the units selected and differ from sample to sample.

Variance Estimation Methods

Several approaches have historically been used to compute an approximation of the true variance of an estimate when the sample deviates from i.i.d assumptions. These techniques fall into two general categories: (1) the Taylor series linearization technique (*see* **Linearization Methods of Variance Estimation**) and (2) replication techniques. Both of these were first proposed in the literature for use with survey data in the 1960s. While over the years government statistical agencies, academic departments, and private survey organizations implemented their own **algorithms** and developed their own software for carrying out these techniques, several software packages have emerged for public use, first for mainframe computer applications, and now for use on personal computers and in other computing environments. The variance estimation software available to the public uses one or the other of the two general strategies for variance estimation mentioned above. What follows is a brief description of these two types of techniques. For more detailed descriptions of these techniques, the reader is advised to consult the references given. Overviews of these techniques can be found in [1, 10, 15, 19, 25, 31].

Because estimates of interest in sample surveys are nonlinear, one approach is to *linearize* such estimates using a Taylor series expansion. This approach was first suggested for use with survey estimates in 1968 by Tepping at the US Bureau of the Census [29]. In essence, the estimate is rewritten in the form of a Taylor series expansion, and an assumption is made that all higher-order terms are of negligible size, leaving only the first-order (linear) portion of the expanded estimate. A standard formula for the **mean square error** of a linear estimate can then be applied to the linearized version to approximate the variance of the estimate. This approximation works well to the extent that the assumption regarding the higher-order terms is correct; see also [32]. Note that, with this approach to variance estimation, a separate formula for the linearized estimate must be developed for each type of statistical estimator. Most survey data analysis software includes the most widely used estimates (such as means, proportions, ratios, and regression coefficients). Binder [2] introduced a general approach that can be used to derive Taylor series approximations for a wide range of estimators, including Cox **proportional hazards** and **logistic regression** coefficients.

Replication techniques are a family of approaches that take repeated subsamples, or *replicates*, from the data, recompute the weighted survey estimate for each replicate, and then compute the variance based on the deviations of these replicate estimates from the full-sample estimate. This approach was first suggested for use with survey data in 1966 by McCarthy at Cornell University as part of his work with the National Center for Health Statistics [22]. The most commonly used replication techniques are the *balanced repeated replication* (BRR) method and the **jackknife method**. Robert Fay at the US Bureau of the Census has developed his own replication technique for this purpose as well [9] (*see* **Resampling Procedures for Sample Surveys**). Other techniques less commonly used for this purpose are **bootstrapping** [24] and the random group method [13]. All replication techniques require the computation of a set of replicate weights, which are the analysis weights recalculated for each of the

replicates selected so that each replicate appropriately represents the same population as the full sample. Such computing-intensive techniques became practical only as the computing capacity on mainframes and then personal computers increased. Unlike the Taylor series method, replication methods do not require the derivation of variance formulas for each statistical estimate because the approximation is a function of the sample, not of the estimate.

With balanced repeated replication (also known as balanced half-sampling), forming a replicate involves dividing each sampling stratum into two primary sampling units (PSUs) (*see* **Sampling in Developing Countries**), and randomly selecting one of the two PSUs in each stratum to represent the entire stratum [17, 18, 23]. The jackknife repeated replication approach involves removing one stratum at a time to create each replicate [11, 30]. Fay's method is similar to the BRR approach, except that, instead of selecting one of two PSUs in each stratum, the weights of one of the two PSUs in each stratum are multiplied by a factor k between 0 and 2 and the weights of the other PSUs are multiplied by a factor of $2 - k$ [9]. See also [7, 8] for a discussion of replication methods.

Software Packages

At the time of this writing (spring 2003), a number of packages are available to the public designed specifically for use with sample survey data. A website that is maintained by Alan Zaslavsky at Harvard University (`www.fas.harvard.edu/~stats/survey-soft/survey-soft.html`) contains a list of a dozen survey analysis variance estimation packages, along with their features, contact information, and comparative reviews. Four of these packages have been developed by government agencies (Statistics Canada, US **Centers for Disease Control** and Prevention, and two from US Bureau of the Census); three have been developed in academia (University of Essex, University of Michigan, Iowa State University); and five have been developed by private organizations (including SAS Institute, Stata, Research Triangle Institute, and Westat). Many governmental statistical agencies (including those in the United States, Canada, Sweden, Holland, and France) have developed their own sample survey software to meet their needs. This software is sometimes available from the agencies for use by others, but not marketed as such.

All but one of the packages described on the website use the Taylor series approach to variance estimation, and several of these also offer replication methods. One supports only replication methods. All are available for PC (Windows or DOS) platforms, but several offer other platforms such as Macintosh, Linux, Unix, and Sun/Solaris. Two of the packages (other than SAS [26]) require SAS in order to run. All reportedly handle complex sample designs that include stratification and cluster sampling. Some are more sophisticated and handle multistage sampling, without-replacement sampling (*see* **Sampling With and Without Replacement**), and unequal probabilities at each stage of selection. The range of estimate types available on these packages range from descriptive statistics (such as totals, means, ratios, and proportions) to **multivariate analytical** techniques (such as **linear regression** logistic regression, and proportional hazards models). The focus in this article is on several of the more commonly used packages (SUDAAN, WesVar, Stata, and SAS/STAT). The reader is encouraged to visit the web page mentioned above to find out more about CENVAR, CLUSTERS, **Epi Info** GES, IVEware, PCCARP, R Survey, and VPLX.

SUDAAN (developed by Babu Shah and others at the Research Triangle Institute (RTI)) started out as software called STDERR in 1970 for use on an IBM mainframe. Starting in 1976, the software was further developed to carry out a wider array of procedures (RATIOEST, RTIFREQS, SESUDAAN, SURREGR, and RTILOGIT), some with the support of various government statistical agencies with whom the RTI was working. SUDAAN primarily uses the Taylor series approach to variance estimation, but has added replication techniques as options. Because SUDAAN was originally developed as an SAS procedure, its syntax in batch mode is similar to that of SAS. There is a bit of a learning curve in how to specify the design parameters. It is available as a stand-alone package or as a SAS-callable procedure.

Among the four packages discussed here, SUDAAN has the greatest capabilities in terms of the types of sample designs it accommodates. It can handle stratification, cluster sampling, multistage sampling, without-replacement sampling, and unequal probabilities of selection at each stage. Specifying without-replacement sampling with unequal probabilities at the first stage (the most complicated design structure) requires that the

user compute joint-inclusion probabilities for each possible pair of PSUs within each first-stage stratum. Specifying without-replacement sampling of any kind (three types are available) requires that the user supply frame counts at each stage of selection. Being able to specify without-replacement sampling becomes a factor when the sampling fraction at the first stage is relatively high, so that the **finite population correction** factor can be incorporated.

Westat first developed its variance estimation software for the work that they were doing with the US Department of Transportation's National Accident Sampling System. The first software was developed as SAS procedures for use on IBM mainframes in the 1980s by David Morganstein and was called NASSVAR. Westat's current survey analysis software, WesVar, is a stand-alone PC package that uses replication methods to estimate variances. WesVar has the option of one of several replication techniques, including BRR, two variants of the jackknife approach, and Fay's method. To use this package, the user must supply replicate weights, or supply full-sample weights and allow the software to create the replicate weights. WesVar can handle most complex sample designs (stratification, cluster sampling, multistage sampling), but does not have the capability of handling without-replacement sampling at the first stage. It should be noted, however, that in most federal surveys, with-replacement sampling of PSUs is commonly assumed in variance estimation even if the PSUs were selected without replacement (generally a conservative assumption). WesVar also has as part of its package, the capability to **poststratify** the weights to user-specified counts to account for **sample frame** shortcomings, as does SUDAAN.

Stata (Stata Corporation, College Station, Texas) added survey data analysis capabilities to an existing general-purpose statistical package in 1995. Stata uses the Taylor series approach to variance estimation, although there are some user-written additions that incorporate Jackknife and BRR methods. Stata is very popular due to its ease of use, good user support, programmability, comprehensive set of analytical procedures, and relatively lower price-tag (compared to SUDAAN and SAS/STAT). In Stata, the Taylor series capability can be added to any user-programmable estimator. Like WesVar, Stata can incorporate most complex sample designs, but cannot handle a two-stage without-replacement design with sampling at both stages; that is, it assumes with-replacement sampling of PSUs.

SAS has added a few procedures to its SAS/STAT software over the last few years for survey data. The SURVEYSELECT procedure allows the user to select probability samples of various designs – from simple random samples to complex multistage samples with stratification, clustering, and unequal probabilities of selection. It also includes two Taylor series based procedures to estimate totals, means, and ratios (SURVEYMEANS) and regression coefficients (SURVEYREG). Future plans are for them to add similar capabilities for analyzing frequency data and logistic regression.

Issues in Selecting and Using Sample Survey Software

There are several ways to evaluate the qualities of such software packages when deciding which one to use. The user must first evaluate his or her analytical needs, such as sample design complexities, statistical procedures needed, and computing environment, and then decide among those that will be the easiest to use. None of the existing packages meet all of the recommended criteria in the following paragraphs. For the packages mentioned above, or any that use either of the two variance estimation approaches described, there is no need for the user to be concerned about whether the method used to estimate the variances is statistically sound when choosing among packages. Both the Taylor series linearization approach and replication methods were derived from well-accepted approaches previously applied to other statistical problems. Each has certain circumstances in which its approximation of the variance is better than that of the other, and certain replication techniques work better than others, depending on the sample design [3, 25]. Empirical evaluations (using national survey data such as the Current Population Survey and the National Health Interview Survey) have revealed little difference in the estimates of the variance using the different approaches [1, 11, 19].

From a practical standpoint, the software must work in the computing environment in which the user works. If the user works primarily on a mainframe or on a Macintosh, he or she will find that most of the software packages are available only for use on DOS- or Windows-based personal computers. And if

one routinely works with certain types of statistical estimates, such as those resulting from multivariate logistic regression or other nonlinear models, the user may find that many of the software packages do not have the full array of statistical procedures that are currently available in the traditional statistical software packages such as SAS and SPSS [28]. In addition, the software package should be able to import the user's data sets, whether they were created using standard statistical, database, or spreadsheet packages, as well as text (ASCII) files.

The software package should be relatively easy to use; however, there is sometimes a trade-off between this ease of use and the package's capabilities in terms of handling more complex designs or analyses. Another trade-off of being easy to use is a package's propensity for being used inappropriately. Some packages are relatively straightforward to use, with a menu-driven or Windows-type approach, enabling someone unfamiliar with the underlying assumptions to unknowingly get estimates that are inappropriate for his or her design. Other packages are less "user-friendly," and require writing lines of code to be submitted as a batch job, which generally requires the user to learn more up front about the package itself. However, when a large number of similar analyses will be run, it is often easier to run analyses in batch mode than through a menu-driven or Windows-type mode. Software packages should have an option for a batch mode of execution.

In any case, user support should be readily available through thorough and well-written documentation, helpful error messages, a complete set of "help" screens, and prompt assistance from the software provider via telephone and/or electronic mail. Support from fellow users, who may communicate with one another via listservers or other means, can also be quite helpful. It should be kept in mind that most packages were initially developed to accommodate a certain type of sample design and a certain type of user (perhaps a particular government agency and a particular survey). This tends to make the packages less user-friendly to those with different data and analysis needs. Packages should have the capacity to handle nonstandard designs, or provide guidance in the documentation as to the most appropriate design to specify in these circumstances and what the consequences are (such as an overestimate of the variance). On the other hand, for even the most sophisticated packages, it should not be cumbersome to specify a relatively simple design. The statistical package should provide technical documentation, including the formulas used for point estimates and the variance estimates.

Currently, it is commonly the case that a user creates a data file using SAS, SPSS, or some other general-purpose statistical package, and then imports the file into one of these specialized packages. Unless they are part of a general statistical package (or are "callable" procedures from such a package), the specialized packages generally do not allow for much data editing, variable construction, recoding, or sorting. Depending on the specialized package and the estimates desired, it may be necessary to then take the output from the specialized package and carry out further data manipulation in the original general-purpose (or yet another) statistical package to obtain the needed estimates. Sometimes, to carry out subgroup analyses, it is necessary to create separate files for each subgroup and go through the entire process for each subgroup. Over the last several years, variance estimation capabilities for sample survey data have been added to general-purpose statistical packages such as SAS and Stata, and SPSS is planning to add survey data analysis capabilities as well.

Several of the software packages currently available or under development are being made available free to users via the Internet, but sometimes offer less in the way of support and training. Others can run over US $1000 for a single-use license, presumably providing more comprehensive technical support and training for users and notification regarding upgrades. Training itself can be in the form of formal in-person training courses (which can be expensive), Internet-based training, or documentation that is comprehensive enough to use as a training manual. In many cases, documentation is merely a reference manual, and the user must learn how to use the package from a formal training course or by working with someone familiar with the package.

The more difficult and/or expensive a software package is to obtain, learn, and use, the less likely it would be that analysts are going to use it. Many analysts do not even realize they should use weights when deriving estimates, let alone use specialized software to estimate the variances correctly. It should be made clear to users of public use data files, through the accompanying documentation, that it is necessary to account for the design when creating estimates. If it is impossible, for confidentiality reasons, to

provide variables on these files that designate the stratum, PSU, and weight for each observation, then the agency, company, or department supplying the file should be willing and able to provide **standard errors** or design effects for certain variables on request, or should provide generalized variance curves, tables of standard errors or design effects for a wide array of variables, or at the very least provide the average design effect for certain types of variables for certain subgroups [4]. If there are no such confidentiality concerns, then the public use file should come with variables for stratum, PSU, and weight, that are clearly marked as such. Ideally, such data files would come with a set of replicate weights as well. It is unreasonable to expect secondary data users to derive a rather large set of replicate weights on their own. As mentioned above, WesVar has a procedure that can be used create replicate weights under certain circumstances. (It cannot create replicate weights that adjust for unit nonresponse or other weighting adjustments other than poststratification.)

In general, to run any of these specialized packages, one needs to specify variables on the file that correspond to sampling stratum, PSU, and analysis weight. In addition, the file needs to be sorted by stratum and then the PSU within stratum. Further, there generally have to be at least two PSUs in each stratum. (If this is not the case, then the user needs to collapse across strata.) The user should have a good understanding of the design. Was stratification employed? How many sampling stages were there? At each stage of sampling, were the units selected with or without replacement? Were the units selected with equal probability or was there disproportionate sampling (such as oversampling or sampling with probability proportionate to size)? The user should also know which variables are continuous or interval, versus categorical or ordinal (*see* **Measurement Scale**). For categorical or ordinal variables, the user should know the number of categories of each. Examples of statistical analysis using Stata and WesVar can be found in Levy and Lemeshow [21].

Several papers have been published that compare the various software packages. Because many of these packages have evolved over time, many of the criticisms and comparisons found in these papers are no longer valid [5, 6, 15].

There is an ongoing debate as to whether the sample design must be considered when deriving statistical models (as opposed to estimates of means, proportions, totals, and ratios) based on sample survey data. Analysts interested in using statistical techniques such as linear regression, logistic regression, **survival analysis** or **categorical data analysis** on survey data are divided as to whether they feel it is necessary to use specialized software. The model-based analysts argue that, as long as the model is specified correctly, they can proceed without recognizing aspects of the survey design (such as stratification, clustering, and unequal selection probabilities), and can therefore use standard statistical packages. The design-based analysts argue, to the contrary, that it is important to account for the survey design when estimating models. The debate between these two factions has been ongoing for quite a while and is not likely to be resolved soon [12, 14, 20, 27]. A compromise position adopted by some is to use standard statistical software in modeling analyses, but to incorporate into the model the variables that were used to define the strata, the PSUs and the weights.

Contact information for the providers of the specialized software mentioned are found after the references under the name of the software.

BARBARA LEPIDUS CARLSON

Software Reliability

The demand for complex software systems has increased more rapidly than the ability to design, implement, test, and maintain them, and the reliability of software systems has become a major concern for our modern society. In the last decade of the twentieth century, many reported system outages or machine crashes were traced down to computer software failures. Consequently, recent literature is replete with horror stories regarding software problems.

Software failures have impaired several high-visibility programs in the health industry; they have even killed people. As described in [12], the Therac-25 radiation therapy machine was hit by software errors in its sophisticated control systems and claimed several patients' lives in 1985 and 1986. In the UK, South West Thames Regional Health Authority [28] reported an incident on October 26, 1992, when the Computer Aided Dispatch system of the London Ambulance Service broke down immediately after its installation, paralyzing the capability of the world's largest ambulance service to handle the 5000 requests to carry patients in emergency situations received each day. In the aviation industry, although several airliner crashes have remained mysteries, experts pointed out that software control could be the chief suspect in some of these incidents owing to its inappropriate response to the pilots' desperate inquires during an abnormal flight condition.

To this end, software companies recognize the need for systematic approaches to measuring and assuring *software reliability*, and they devote a major share of project development resources to this. The Institute of Electrical and Electronics Engineers (IEEE) [8] defines software reliability as

> the probability of failure-free software operations for a specified period of time in a specified environment.

Software reliability engineering is the field that quantifies the operational behavior of software systems with respect to user requirements concerning reliability. It considers:

1. The definition of various metrics measuring attributes of product design, the development process, system architecture, the operational environment, and the code itself, in as far as the metrics affect the reliability.
2. The design and implementation of operational tests and field operation of the software. When software fails, the code is analyzed to identify the responsible fault, and this is corrected. (This operation may introduce a new fault.) Note the distinction between a *fault* (erroneous code) and a *failure* (the software fails to execute correctly on a specific test). A single fault may be responsible for many failures, or none if the relevant part of the code is never executed.
3. The development of models relating the metrics in point 1 to the test results. These models can be used to estimate the current reliability of the software, and to predict future performance as the software evolves.
4. Application of these technologies in specifying and guiding system architecture, development, testing, acquisition, use, and maintenance.

Reliability is an essential ingredient in customer satisfaction. In fact, ISO 9000-3 [9] specifies measurement of field failures as the only required quality metric:

> . . . at a minimum, some metrics should be used which represent reported field failures and/or defects from the customer's viewpoint. The supplier of software products should collect and act on quantitative measures of the quality of these software products.

Many of the current software reliability engineering techniques and practices are detailed in [15]; another general reference is [21].

In this article we focus on software reliability models and measurements. A software reliability model specifies the general form of the dependence of the failure process on the principal factors that affect it: fault introduction, fault removal, and the operational environment. During the test phase, the failure rate of a software system is generally decreasing owing to the discovery and correction of software faults. With careful record-keeping procedures in place, it is possible to use statistical methods to analyze the historical record with regard to failures and faults. The purposes of these analyses is two-fold: (i) to predict the additional time needed to achieve a specified reliability objective; (ii) to predict the expected reliability and faults when the testing is finished.

Implicit in this discussion is the concept of "time". For some purposes this may be calendar time, assuming that testing proceeds roughly uniformly; another

possibility is to use computer execution time, or some other measure of testing effort. Another implicit assumption is that the software system being tested remains fixed throughout (except for the removal of faults as they are found). This assumption is frequently violated.

Software reliability measurement is based on two types of models, static and dynamic reliability estimation models, used typically in earlier and later stages of development, respectively. These will be discussed in the following two sections.

Early Stage Models

One purpose of reliability models is to perform reliability prediction in an early stage of software development. This activity determines future software reliability based upon available software metrics and measures. Particularly when failure data are not available (e.g. software is in the design or coding stage), the metrics obtained from the software development process and the characteristics of the resulting product can be used to determine reliability of the software upon testing or delivery. We discuss two prediction models: the phase-based model and the Rome Laboratory model.

Phase-Based Model

Gaffney & Davis [6] proposed the phase-based model, which makes use of fault statistics obtained during the early development phases (e.g. requirement review, design, and implementation) to predict the expected fault densities during a later phase (e.g. test or operation). In order to do this, the model makes the following assumptions:

1. Code size estimates are available during the early phases of a development effort. The faults found during the requirements analysis and software design are normalized by these estimates.
2. Faults found in different phases of life cycle follow a Rayleigh density function.

Denoting the fault density (faults per 1000 lines of noncommentary source line, or KNCSL) up to the end of phase t by V_t, the model is expressed as:

$$V_t = E[1 - \exp(-Bt^2)],$$

where E is the total lifetime fault rate expressed in faults KNCSL; t is the fault discovery index ("1" means requirements analysis, "2" means software design, "3" means implementation, "4" means unit test, "5" means software integration, "6" means system test, and "7" means acceptance test); and $B = 1/2t_p^2$, where t_p is the fault discovery phase constant, the peak of the continuous Rayleigh curve fit to the discrete failure data. This is the point at which 39% of faults have been discovered. For example, $t_p = 2.64$ means the peak happens around 2/3 of the way through the design phase and the implementation phase and is closer to the latter.

As data become available B and E can be estimated. These quantities can also be used to estimate the number of remaining faults at stage t by multiplying $E\exp(-Bt^2)$ by the number of source line statements at that point. Note that since the number of data points available to fit a Rayleigh curve is very limited (at most seven of them), the prediction for the number of faults in a future phase could be very rough.

Rome Laboratory Work

The Air Force's Rome Laboratory [22] model obtains predictions of initial fault density upon testing by:

$$d_0 = A \times D \times (SA \times ST \times SQ) \times (SL \times SS \times SM \times SU \times SX \times SR),$$

where d_0 is the initial fault density and the other factors are measures of software characteristics, which can be classified into four categories:

1. *Application type* (e.g. real-time control systems, scientific, information management), denoted by A.
2. *Development environment* (characterized by development methodology and available tools), denoted by D.
3. *Requirements and design representation metrics*, including.
   - SA for anomaly management
   - ST for traceability
   - SQ for incorporation of quality review results into the software.
4. *Software implementation metrics*, including:
   - SL for language type (assembly, high-order, etc.)
   - SS for program size

SM for modularity
SU for extent of reuse
SX for complexity
SR for incorporation of standards review results into the software.

Note that A takes a baseline fault density value while all other factors are modifiers (numerical values close to 1). Rome Laboratory obtained the estimates of these values for each level based on an empirical study over 59 projects.

Once the initial fault density has been found, a prediction of the initial failure rate is made as

$$l_0 = F \times K \times d_0 \times \text{KNCSL}.$$

The number of inherent faults is $d_0 \times$ KNCLS; F is the linear execution frequency of the program, which is the average machine instruction rate divided by the number of object instructions in the program; and K is the fault expose ratio, the expected number of failures per execution per fault. Based on historical data K is between 1.4×10^{-7} and 10.6×10^{-7}.

Testing and Operational Stage Models

Software reliability estimation determines current software reliability by applying statistical inference techniques to failure data obtained during system test or during system operation. Its main purpose is to assess the current reliability. Since reliability tends to improve during the software testing and operation periods, the models are also called *reliability growth models*. Most current software reliability models fall into this category. Details of these models can be found in [15], in which a number of the best current software reliability tools that implement these models are also included. Other surveys appear in [20] and [27].

Using Reliability Models

The success of a model is often judged by how well it fits a curve $\mu(t)$ to the observed "number of faults vs. time" function. On general grounds, this may have little to do with how useful the model is in predicting future faults in the present system (a better fit can mean worse prediction), or future experience with another system, unless we can establish statistical relationships between measurable attributes of the system and estimated parameters of the fitted models (refer to the section on Rome Laboratory work for such an effort).

Different sets of assumptions can lead to equivalent models; for example the assumption that for each fault the time-to-detection is a random variable with a **Pareto distribution**, these random variables being independent, is equivalent to assuming that each fault has an **exponential** lifetime, with these lifetimes being independent, with the rates for the different faults being distributed according to a **gamma distribution** (this is Littlewood's [13] model). A single experience cannot distinguish between a model that assumes a fixed but unknown number of faults and a model that assumes this number is random. Generally, little is known about how well the various models can be distinguished.

Assumptions

Most of the published models are based on similar assumptions. These commonly include the following:

1. The system being tested remains essentially unchanged throughout testing, except for the removal of faults as they are found. Some models allow for the possibility that faults are not corrected perfectly. Miller [16] assumes that if faults are not removed as they are found, then each fault causes failures according to a stationary **Poisson process**; these processes are independent of one another and may have different rates. By specifying the rates, many of the models mentioned below can be obtained.
2. Removing a fault does not affect the chance that a different fault will be found.
3. "Time" is measured in such a way that testing effort is constant. Musa [18] reports that execution time (processor time) is the most successful way to measure time. Others prefer time measured as effort in staff hours [5].
4. The model is Markovian, i.e. at any time the future evolution of the testing process depends only on the present state (the current time, the number of faults found and remaining, and the overall parameters of the model), and not on details of the past history of the testing process. In some models a stronger property holds, namely that the future depends only on the current state and the parameters, and not on the

current time. We call this the "strong Markov" property (*see* **Markov Processes**).
5. All faults are of equal importance (contribute equally to the failure rate).
6. At the start of testing, there is some finite total number of faults, which may be fixed (known or unknown) or random; if random, their distribution may be known or of known form with unknown parameters. Alternatively, the "number of faults" is not assumed finite, so that if testing continues indefinitely, an ever-increasing number of faults will be found.
7. Between failures, the **hazard rate** follows a known functional form; this is often taken to be simply a constant.

Fixed-Shape Models

In binomial models the total number of faults is some number N; the number found by time t has a **binomial distribution** with mean $\mu(t) = NF(t)$, where $F(t)$ is the probability of a particular fault being found by time t. The number of faults found in any interval of time (including the interval (t, ∞)) is also binomial. Letting N be **Poisson** (with some mean ν) gives the related Poisson model; now the number of faults found in any interval is Poisson, and for disjoint intervals these numbers are independent. The hazard rate at time t is $NF'(t)/(1 - F(t))$. These models are Markovian but not strongly Markovian, except when F is exponential; this case was studied in [7, 10, 17, 18, 24], and [25], and for F a **Weibull distribution** in [1] and [23]; In [29] F was made a gamma distribution; and Littlewood's model [13] is equivalent to assuming F to be Pareto. In [19] the hazard rate was assumed to be an inverse linear function of time; for this 'logarithmic Poisson' model the total number of failures is infinite.

Strongly Markov Models

These can be obtained by specifying how the hazard rate of the failure process depends on the current state. Moranda [17] assumed that the hazard rate is constant between failures, and decreases geometrically at each failure. Littlewood & Verrall [14] proposed a class of models in which, after the ith fault is found, the hazard rate becomes $G_i/\xi(i)$, where $\xi(i)$ is some simple function (typically linear or quadratic) and G_i is a random variable (independent for different i) with a gamma distribution. Models of this class were studied in [11].

Reliability Growth Modeling with Covariates

So far we have discussed a number of different kinds of reliability models of varying degrees of plausibility, including phase-based models depending upon a Rayleigh curve, growth models like the Goel–Okumoto model, etc. The growth models take as input either failure time or failure count data, and fit a **stochastic process** model to reflect reliability growth. The differences between the models lie principally in assumptions made on the underlying stochastic process generating the data.

However, most existing models assume that there are no **explanatory variables** available. When the models are used to evaluate a testing process, this assumption is assuredly simplistic for all but small systems involving short development and life cycles. For large systems (e.g. greater than 100 KNCSL) there are variables, other than time, which are very relevant. For example, it is typically assumed that the number of faults (found and unfound) in a system under test remains stable during testing. This implies that the code remains frozen during testing. However, this is rarely the case for large systems since aggressive delivery cycles force the final phases of development to overlap with the initial stages of system test. Thus, the size of code, and consequently the number of faults, in a large system can vary widely during testing. If these changes in code size are not considered as a *covariate*, one is, at best, likely to have an increase in variability and a loss in predictive performance, and, at worst, a poor fitting model with unstable parameter estimates. Dalal & McIntosh [5] describe a general approach for incorporating **covariates**. They also report a case study dealing with reliability modeling during product testing when code is changing.

When to Stop Testing Software?

Dynamic reliability growth models can be used to make decisions related to when to stop testing. Software testing is a necessary but expensive process, consuming one-third to one-half the cost of a typical

development project. Testing a large software system costs thousands of dollars per day. Overzealous testing can lead to a product that is overpriced and late to market, while fixing a fault in a released system is usually an order of magnitude more expensive than fixing the fault in the testing laboratory. The question of how much to test is therefore an important economic question. We discuss an economic formulation of the "when to stop testing" issue as proposed in [2, 3]. Other formulations have also been proposed [4, 26].

Like many other reliability models, Dalal & Mallows' stochastic model assumes that there are N (unknown) faults in the software, and the times to find faults are observable and are independent, identically distributed (iid) exponential with rate m. Their economic model defines the cost of testing at time t to be $ft - cK(t)$, where $K(t)$ is the number of faults observed to time t and f is the cost of operating the testing laboratory per unit time. The constant c is the net cost of fixing a fault after rather than before release. Under somewhat more general assumptions, Dalal & Mallows [2] found the optimal stopping rule for large N. It is very nearly: stop as soon as $f(\mathrm{e}^{mt} - 1)/(mc) \geq K(t)$. Besides the economic guarantee, this rule gives a guarantee on the number of remaining faults, namely that this number has a Poisson distribution with mean $f/(mc)$. Thus, instead of determining the ratio f/c from economic considerations, we can choose it so that there are probabilistic guarantees on the number of remaining faults. Some practitioners may find that this probabilistic guarantee on the number of remaining faults is more relevant in their application; see [4] for a more detailed discussion. Finally, by using reasoning similar to that used in deriving (4.5) of [3], it can be shown that the current estimate of the additional time required for testing, Δt, is given by: $(1/m)\log cmK(t)/[f(\mathrm{e}^{mt} - 1)]$; for applications of this, see [3].

Discussions and Conclusions

Software reliability modeling and measurement have attracted a tremendous amount of attention recently in various industries concerning the quality of software. Many reliability models have been proposed, many success stories reported, several conferences and forums formed, and much project experience shared. Here we offer some caution to users regarding the application of software reliability models.

In fitting any model to a given data set, first one must bear in mind a given model's assumptions. For example, if a model assumes a fixed number of software faults will be removed within a limited period of time, but in the observed process the number of faults is not fixed (e.g. new faults are added owing to imperfect fault removal), then one should use another model which does not make this assumption.

A second model limitation and implementation issue concerns future predictions. If the software is being operated in a manner different from the way it is tested (e.g. new capabilities are being exercised that were not tested before), the failure history of the past will not reflect these changes, and poor predictions may result. Developing operational profiles, as proposed in [20], is very important if one wants to predict accurately future reliability in the user's environment.

Another issue relates to the software development environment. Most models are primarily applicable from testing onward: the software is assumed to have matured to the point that extensive changes are not being made. These models cannot have a credible performance when the software is changing and churn of software code is observed during testing. In this case the techniques described in this article should be used to handle the dynamic testing situation.

Finally, software reliability models cannot make an impact if they are not tied to software testing and operational costs to determine the optimal time to stop testing. We have described a relevant economic model in this entry.

Software, Biostatistical

Biostatisticians, and applied researchers using statistics, started to use statistical computer packages (by which I mean pre-written and compiled instructions to the computer for performing some form of statistical analysis) for data analysis during the 1950s. Almost immediately changes occurred in what data were analyzed and in how they were analyzed. Changes in computer hardware have brought changes in the type and quantity of software available. The advent of microcomputers in the late 1970s and early 1980s increased the rate of change and the amount of new software packages. There are currently well over 1000 statistical software packages available on a range of computer hardware platforms.

A database of citations to published reviews of statistical software is available [8]. A good review should tell potential users what the package does, how well it does it, how easy the package is to learn and to use, and how flexible the package is. Also available is information on how certain extendable packages make both vendor-written and user-written extensions available to users; information about the cost, and example contributions, have been presented in the "Editor's notes" of the Statistical Computing Section of *The American Statistician* (see, for example, [8]).

Some Historical Notes

The 1950s saw the first occurrence of statistical software, usually specialized single purpose programs that would run on one type of machine only. Some of these were written by users, but hardware vendors were the first important source (for example, SSP from IBM). The appearance of FORTRAN in the late 1950s saw the first real surge of software and the first occurrence, to my knowledge, of generally useful software not written by a hardware vendor; this was "BIMED", later called BMD, then BMDP, which was started at the University of California at Los Angeles about 1960. By the mid-1960s several other packages had appeared, including PSTAT, SPSS, and SAS in the US and Genstat from England and Australia. All of these packages still exist. A number of other packages also appeared during the 1960s (e.g. OSIRIS, Datatext), but most of these, as far as I know, are no longer available.

These packages were neither well integrated nor comprehensive in coverage by the standards of today. They often used unacceptable algorithms or were prone to coding mistakes which gave wrong, or inaccurate, answers. (For example, Longley [17], using a multicollinear data set, showed problems in a number of packages.) However, prior to the availability of packages such as these, days could be spent, using a mechanical calculator or pencil and paper, to estimate, say, one regression with two covariates on a relatively small data set.

The late 1960s and early 1970s not only saw the appearance of additional software packages, some highly specialized (e.g. just for sample-size calculations) rather than general purpose, but also witnessed the setting up of committees by statistical associations to work on evaluating and designing software: GLIM originated under the auspices of a Royal Statistical Society (RSS) Committee; the American Statistical Association (ASA) set up a Committee on Statistical Program Packages in 1973 to help in evaluating software [3, 4]. The RSS committee, now called the "GLIM Working Party" still exists, as does the software, and the RSS receives a royalty on each version of GLIM sold. The ASA, however, no longer has any such committee.

A Categorization Scheme for Biostatistical Software

The range of software currently available makes any categorization scheme somewhat problematic. The categorization presented here is limited to one dimension: the type of user to whom the vendor expects to sell (and is further limited to software aimed at professionals); a broader categorization scheme can be found in [9]. It is impossible to include all existing packages. I primarily included packages well known to me; within each category the packages are listed alphabetically. Owing to space limitations, only contact information and a brief overview of the package are given. Contact information is for the headquarters of the company; many companies have sales and support offices in other countries.

General Purpose, Useful for Biostatistics

1. Integrated packages, including
   (a) BMDP, purchase via Statistical Solutions, 8 South bank, Crosse's green, Cork, Ireland;

+353 21 4319629; SPSS Inc., 444 N. Michigan Ave., Chicago, IL 60611, USA; (312) 329-4000; its original design was aimed squarely at biostatistical goals; it is available for several computer platforms (DOS, UNIX, mainframes).

(b) Data Desk, Data Description, Inc., 840 Hanshaw road, 2nd floor, Ithaca, NY 14850; it is available on both Macintosh and Windows platforms.

(c) Genstat, Numerical Algorithms Group, Ltd, Wilkinson House, Jordan Hill Road, Oxford OX2 8DR, UK; (+44) 1865-511245; runs under Windows and several workstation operating systems, including UNIX, VMS and SunOS.

(d) GLIM, Numerical Algorithms Group, Ltd, Wilkinson House, Jordan Hill Road, Oxford OX2 8DR, UK; (+44) 1865-511245; runs under DOS and several workstation operating systems (e.g. UNIX, VMS, SunOS).

(e) JMP, SAS Institute, Inc., SAS Campus Drive, Cary, NC 27513, USA; (919) 677-8000; it is available for both the Macintosh and Windows platforms.

(f) Minitab, Minitab, Inc., 3081 Enterprise Drive, State College, PA 16801, USA; (814) 238-3280; has been widely used in educational environments; it is available for several computer platforms (Macintosh, Windows, UNIX and mainframes).

(g) NCSS, 329 North 1000 East, Kaysville, UT 84037, USA; (801) 546-0445; runs under Windows.

(h) SAS, SAS Institute, Inc., SAS Campus Drive, Cary, NC 27513, USA; (919) 677-8000; runs under several platforms (Windows, UNIX, mainframes).

(i) SPSS, SPSS Inc., 444 N. Michigan Ave., Chicago, IL 60611, USA; (312) 329-4000; originally designed for use by social scientists; runs under several platforms (Macintosh, Windows, UNIX, mainframes).

(j) Stata, Stata Corp., 702 University Drive East, College Station, TX 77840, USA; (800) 782-8272; runs under several platforms (Macintosh, Windows, UNIX).

(k) Statistica, Statsoft, Inc., 2325 East 13th St., Tulsa, OK 74104, USA; (918) 749-1119; runs under Macintosh and Windows operating systems.

(l) Systat, Systat Software. Inc., 501 Suite "C", Point Richmond Tech Center, Canal Blvd., Richmond, CA 94804; SPSS Inc., 444 N. Michigan Ave., Chicago, IL 60611, USA; (312) 329-4000; runs under Macintosh, Windows and UNIX operating systems.

2. Packages based on programming languages; many of these, as well as at least some of the extensible packages mentioned elsewhere, can use subroutine libraries (*see* **Numerical Analysis**):

(a) Gauss, Aptech Systems, Inc., 23804 SE Kent-Kangley Road, Maple Valley, WA 98038, USA, (425) 432-7855; runs under Windows and UNIX; contains numerous statistical routines; there are also several "packages" (sets of Gauss routines) written in Gauss and relevant to biostatistical users.

(b) Matlab, The Mathworks, Inc., 3 Apple Hill Drive, Natick, MA 01760, USA; (508) 647-7000; runs under Windows, UNIX; although most early routines were aimed at engineers, there are now a sizable number of statistical routines.

(c) R, a public domain near-clone of S-Plus; this can be found on Statlib (www address: `http://lib.stat.cmu.edu/`).

(d) SC, Mole Software, 34 Greenville Road, Bloomfield, Belfast BT5 5EP, N. Ireland; (+44) (0) 1232 282654; runs under DOS.

(e) Insightful Corporation, StatSci Division of MathSoft, 1700 Westlake Avenue North, Suite 500, Seattle, WA 98109, USA, (800) 569-0123; based on the AT & T product "S"; S-Plus runs under Windows and UNIX; many new forms of analysis first appear as S (or S-Plus) programs (*see* **S-PLUS and S**).

(f) XLISP-STAT, available for free by anonymous ftp from umnstat.stat.umn.edu; there are versions for the Macintosh, Unix, and Microsoft Windows; there are at least four research groups that have written packages based on XLISP-STAT; an introduction to this package can be found in [22, 23]; introductions to three of the packages can be found in [21], [25], and [26].

Aimed Specifically at Biostatistical Users

1. General purpose:
   (a) EAST, CyTel Software Corp., 675 Massachusetts Avenue, Cambridge, MA 02139, USA: (617) 661-2011; for design of sequential trials; runs under DOS.
   (b) Epicure, HiroSoft International Corp., 1463 E. Republican Ave., Suite 103, Seattle, WA 98112, USA, (206) 328-5301; runs under DOS and UNIX.
   (c) EpiInfo, originated at the US Centers for Disease Control (CDC) and since then the result of collaboration between the CDC and the World Health Organization; it is available for free on the Internet (`http://www.cdc.gov/epiinfo`); can also be purchased with a printed manual of over 500 pages, from USD, Inc., 2075-A West Park Place, Stone Mountain, GA 30087, USA, (770) 469-4098; runs under DOS.
   (d) Epilog Plus, Epicenter Software, P.O. Box 90073, Pasadena, CA 91109, USA; (626) 304-9487; runs under Windows.
   (e) True Epistat, Epistat Services, 2011 Cap Rock Circle, Richardson, TX 75080, USA; (214) 680-1376; runs under DOS.
2. Special purpose:
   (a) EAST, CyTel Software Corp., 675 Massachusetts Avenue, Cambridge, MA 02139, USA; (617) 661-2011; for design of sequential trials; runs under DOS.
   (b) PEST, The MPS Research Unit, The University of Reading, Earley Gate, Reading RG6 6FN, UK; for design and analysis of sequential trials; runs under DOS.

Special Purpose Software that is Often Relevant to Biostatisticians

1. Randomization software:
   (a) RT, B.F.J. Manly, The Centre for Applications of Statistics and Mathematics, University of Otago, PO Box 56, Dunedin, New Zealand; 64-3-479-7774; randomization procedures for a number of parametric procedures, including anova, linear regression, spatial data, time series; runs on DOS.
   (b) StatXact, LogXact, CyTel Software Corp., 675 Massachusetts Avenue, Cambridge, MA 02139, USA; (617) 661-2011; StatXact includes randomization versions of a large number of nonparametric analyses; LogXact performs exact logistic regression; each runs under Windows.
   (c) Testimate, idv-Datenanalyse und Versuchsplanung, Wessobrunner Strasse 6, D-82131 Gauting/München, Germany; 089/8 50 80 01; includes randomization versions of a large number of nonparametric analyses;
2. Software for estimating sample sizes when designing studies. The following web site has information on more than two dozen such software packages: `http://www.interchg.ubc.ca/cacb/ power`. The following have specific biostatistical orientations:
   (a) EAST, CyTel Software Corp., 675 Massachusetts Avenue, Cambridge, MA 02139, USA: (617) 661-2011; for design of sequential trials; runs under DOS.
   (b) N and NSURV, idv-Datenanalyse und Versuchsplanung, Wessobrunner Strasse 6, D-82131 Gauting/München, Germany; 089/8 50 80 01; runs under DOS.
   (c) PASS, 329 North 1000 East, Kaysville, UT 84037, USA; (801) 546-0445; runs under Windows.
3. Software for correlated data, including longitudinal studies:
   (a) standard software: several of the packages included elsewhere in this list, including BMDP, LIMDEP SAS, S-Plus and Stata, include special routines for this type of analysis.
   (b) software for analyzing surveys; only one package above has adequate routines for dealing with weighted survey data: Stata; there are specialized packages, also:
      (i) SUDAAN, Research Triangle Institute, 3040 Cornwallis Road, P.O. Box 12194, Research Triangle Park, NC 27709, USA; (919) 541-6602; runs under Windows, UNIX and mainframes;
      (ii) WESVAR, Westat, Inc., 1650 Research Blvd., Rockville, MD 20850; (800) westat2, extension 2006.
   (c) software for hierarchical models:
      (i) HLM, Scientific Software International, 7383 N Lincoln Ave., Suite

100, Lincolnwood, IL 60712, (800) 247-6113; runs under Windows or DOS;

(ii) MLWin, Centre for Multilevel Modeling Project, Institute of Education, University of London, 20 Bedford Way, London WC1H 0AL, UK; +44(0)207 612 6688; runs under Windows.

4. Software from other disciplines: econometric software such as LIMDEP; Econometric Software, Inc., 15 Gloria Place, Plainview, NY 11803, USA; (516) 938-5254; runs under DOS. Many of its routines are of the same type as biostatisticians use and it has some unique features, e.g. the survival analysis routines include left-truncated data and "cure" models.
5. Software for a specific form of analysis:
   (a) Survival; see [10] and [12].
   (b) Spatial; some of the above packages, especially Epilog Plus, Genstat, RT and S-Plus have some routines; there are some very specialized packages but they tend to be oriented to geostatistics and use very different jargon.
   (c) Circular; Oriana, Kovach Computing Services, 85 Nant-y-Felin, Pentraeth, Isle of Anglesey LL75 8UY, Wales, UK; (+44) (0) 1248-450414; specifically oriented to analysis of data in degrees (e.g. angular data such as might be used in a study of spinal injuries) or time (used in health services research); runs under Windows; the only other software I know of are some user-written routines in Stata.
6. Bayesian software; while there are a number of Bayesian software packages, most have never been reviewed anywhere; overviews appear in [5], [6], and [20]. Newer packages have started to appear, including
   (a) BUGS; World Wide Web address: `http://www.mrcbsu.cam.ac.uk/bugs`; versions for Windows and UNIX; "carries out Bayesian inference on complex statistical problems for which there is no exact analytic solution".
   (b) B/D: World Wide Web address: `http://fourier.dur.ac.uk:8000/stats/bd`; runs under Windows; "an interactive programming language which allows complete a priori and diagnostic analyses of Bayesian linear statistical problems".

Some Assessment Criteria

The following issues are of particular importance in assessing any statistical software package, regardless of whether it is specifically aimed at biostatistical users: the quality of the manual, the ease of learning and the ease of use of the package, and the accuracy of its computations.

Although some vendors would have purchasers believe that their package is usable without a manual, there are reasons for users to examine the manual carefully. Information in the manual should include:

1. Information on what is available (though each user must decide whether what is available is what is wanted, and, more importantly, whether it works in the way wanted and whether all the options desired are present).
2. At least one index; if it there is at least one, how good is it?
3. Examples of using the software; are the examples complete? That is to say, do the examples only display how the new commands (menu choices, etc.) work or is everything shown that one would actually need to complete an analysis?
4. Information on other sources of help, including courses, books, web sites, etc.
5. Information on how to interface this package with the operating system and/or with other types of software packages (such as word processing software).
6. Technical information relating to the algorithm used and how the vendor tested the software; there should be citations to the professional literature as well. Note that, as yet, very few vendors actually provide this (for a discussion in the context of a comparative review, see [2]).
7. A list, and explanation, of error messages; these should be clear to someone who does not have a PhD in computer science and should also be given at the same level as the statistical text.

Manuals can also be used to discover whether the package appears to be aimed at the right type of user; for this, you should examine the manual(s) with the following in mind:

1. What type of language is used in describing and explaining the package? Jargon is rampant and differs dramatically across different disciplines.
2. What level of statistical language is used (e.g. beginner or professional)?
3. What types of graphical output are available and how integrated are the graphics and the statistical routines?
4. What types of checks and diagnostic information are available to help decide whether there are problems with the results of an estimation procedure?
5. How flexible is the software with respect to:

(a) nonstandard problems, e.g. are there choices of algorithms for standard routines such as linear regression?
(b) output; can the user affect the output of the package to ensure that it is in the most usable format for that particular use?

For a discussion of some criteria useful in assessing manuals, see [1], [18], the accompanying discussion of these articles, and the rejoinders by the authors.

A criterion often mentioned is ease of learning of the package. My experience, however, has been that this is really only important for people who will be infrequent users of the software, as these people will essentially be learning the package over again each time they use it. However, for others, the cost of learning is easily overshadowed by ease of use considerations, especially since, for even the hardest-to-learn packages, it rarely takes more than a few hours to learn at least enough to obtain some output.

Ease of use is sometimes, mistakenly, listed with ease of learning as a criterion. It is however both different and much more important. It is also, generally, harder to assess since the determination of whether something is easy to use is heavily dependent on both the level of the user and what the user is trying to do, as well as on the structure of the program. Program structure affects ease of use in many ways; a simple example relates to the difference between typing a command and clicking on a menu item. How this affects a given user depends on whether the menu defaults are what is primarily wanted and how easy it is to choose different options. Of course, at the other extreme, some users want so much of what they choose to do to be dependent on the situation, that no menu-driven program could possibly be considered "easy to use". Furthermore, there are many issues that vendors have never considered and these cannot, of course, be present in a menu. Whether they are available in a command system depends on the amount of thought the vendor put into making the package flexible (a detailed example is provided in [9]). Ease of use can also be aided by the availability of books about the packages, user groups, including e-mail lists and Usenet news groups, vendor newsletters, etc. Integration and ease of recall of various parts of the numerical and graphical output, and integration of the packages to the operating system and to other software (e.g. word processors), are also important here.

Earlier, I mentioned the issue of whether the language used in the manual was appropriate to the statistical expertise of the user. A related issue has to do with the ease with which one can assess one's analytic output. This is affected by numerous factors, including the quality of the error messages, the presence of statistics that can be used to assess assumptions underlying the technique used, and the quality and integration with the statistics of the graphics.

The final criterion to be discussed here is the quality of the numerical algorithms, which affects not only the accuracy of the result, but whether the package provides an answer, and, if it does, the efficiency with which it arrives at the answer.

1. Try the examples in the manual (the vendor should supply all example data sets on the disk with the program). If the examples cannot be reproduced, then immediately contact the vendor. While this appears to be a very simple test that no vendor should ever fail, some packages do fail this test.
2. Check reviews, especially those by reputable statisticians (e.g. reviews in *The American Statistician* or in *Applied Statistics*) (unfortunately, this latter journal is dropping its review section). A good review will supply much more information than just that related to accuracy; in particular, information should be included on the level of user targeted and on the ease of learning and using the package. Furthermore, I believe that

comparative reviews are much more useful than reviews of individual packages.

3. Look in the literature for test data sets. Many "tests" are so well known that no vendor fails them anymore (this is true, for example, of the Longley [17] data). Furthermore, some tests are not relevant to the work that any particular user does. However, there are valuable benchmarks and tests in the literature (see for example, [7], [14], [15], [19], and [24]) that will help users and vendors test (a) whether the algorithms are appropriate, (b) what happens at the boundaries of either allowed data or standard language, and (c) the quality of the algorithms being used.
4. Build your own library of test data sets that are important in your own work and for which problems have previously been found. Try this library on every new package, and every upgrade received.
5. Examine the "validation" or "certification" section of the documentation, if it exists; unfortunately, most vendors do not yet provide such a section. If such a section exists, look for information regarding the algorithms used and the range and type of issues and of data used to test the software. The documentation should also discuss carefully the issue of how the vendor decided that the test result was acceptable. Also, note whether the vendor says that all tests are re-run after making any change to the software; this "regression testing" is necessary since fixing a bug in software often introduces one or more new bugs and this possibility must be checked.
6. Finally, run the analysis in at least one other software package and carefully compare the results. For this final check, the importance of having algorithm information in the manual is highlighted because for many analyses different algorithms should produce different results. This is especially true in many nonparametric analyses where the treatment of ties greatly affects the results.

Where to Go for More Information

There are no good general sources of information on what software is available. Eventually, there will probably be a source on the Internet which can be added to frequently. The number of software packages, particularly for educational uses, is growing rapidly. Some information, of course, is already available: numerous journals print reviews and a database of citations to these reviews is available [8]; numerous data sets useful for testing exist at statlib (at Carnegie Mellon University; WWW address: `http://lib.stat.cmu.edu/`) and other places on the internet. A "Statistical Software Guide" is produced approximately every two-three years. The most recent appearance of this guide, in print, was [16], but information is currently being gathered for an update report. However, none of this information is either well organized or complete. There is one commercial source of information, SciTech International, which publishes *Software for Science*; however, even their list (almost 2000 products, but including non-analysis packages such as word-processing software) is incomplete; they are especially weak, obviously, regarding shareware and freeware, which is often specialized and is often available on the Internet. Many of the vendors mentioned above have Internet World Wide Web sites; the best source for finding these in general is via a competitor: Stata, at its site (`http://www.stata.com`) maintains links to the sites of other vendors, including several suppliers of free software.

The Future – Maybe

Statistical software has been changing rapidly in recent years. The main changes, as of 1996, relate to (a) the existence of numerous specialized software packages; (b) the movement, slowly, of these specialized routines into general purpose packages; and (c) a heavy emphasis on graphical analysis, especially new types of graphics and new ways of integrating graphics into standard analysis.

While these are valuable, necessary, and will continue, there are two other changes that would be very valuable to the profession. The first relates to a better integration of what we already know about statistical assumptions with our analysis. For example, we know that the two-sample t test is somewhat affected by different variances (the amount depending on the ratio of the groups' sample sizes); many would find it helpful if, along with requested result, the software gave some information about the validity of this, and other, assumptions, for the data used. This might also help guard against the "misuse" of statistical software

by those who are not well trained in statistics. This issue has been discussed in numerous articles dating back to at least the 1970s [11]. Though noting a number of potential problems, Goodnight clearly favored this type of "offensive validity checking". Haux [13] provides a number of citations on this issue and then gives a detailed example for the Mann–Whitney test and notes that BMDP, SAS and SPSS are each unsatisfactory. Note that the software should not stop the user from doing an analysis. Rather, a user should just want be provided with some additional information without making a number of other requests to the software (e.g. a separate request for equal variances, for symmetry, for heterogeneity, etc.).

A large part of any project relates to data management and data manipulation. Much, and in many projects all, of this is done with the same statistical software used for analysis. However, no current program keeps a reversible history of what the user does to the data and many do not even keep any history (or log or journal) of what was done. The unfortunate result is that often even the analyst cannot reproduce certain results. Thus, another desirable change is the implementation of some form of reversible history of data management and data manipulation so that any particular state of the data could be recreated. Some type of coding scheme should be attached to both this history and to each analysis so that for any given output it would be clear which state of the data was used in its production. The current reliance on *ad hoc*, individual, schemes is inefficient, ineffective, and unnecessary. Version control software, as used in software development, database management and even some word-processing software should be generalizable to statistical software.

RICHARD GOLDSTEIN

Software, Epidemiological

Historically, many specialized intellectual domains have had data analysis software specifically designed for that domain, including such areas as economics, geology, chemistry and epidemiology. Other domains, including sociology, astronomy and political science, have seen little of this specialization. Furthermore, in those areas, such as epidemiology, that have had numerous specialized packages, some of the packages have fallen by the wayside while others have grown and still others have appeared. In some areas, such as economics, the major specialized packages, for example, `Limdep`, have become more like standard general-purpose packages. However, this has generally not happened with the epidemiologic packages. Finally, at least one general-purpose package, `Stata`, has incorporated a number of epidemiologic analytic routines, jargon and all.

In this article I review some of the specialized epidemiologic software, whether related to the design of studies or to their analysis. I also discuss some of the advantages and disadvantages of having specialized software for a discipline. Both issues are clarified by the presence of a general-purpose analytic package that contains a set of epidemiologic analysis routines. Other general-purpose packages will generally be ignored (*see* **Software, Biostatistical**).

Why Epidemiologic Software?

To write about epidemiologic software, one must locate it, one must define it (or at least its boundaries), and one must have at least some idea regarding what distinguishes epidemiologic software from other data analysis software. While I have undoubtedly missed some small epidemiologic software packages, I hope that I have included all major packages and at least a representative selection of the smaller packages. The following, in alphabetic order, is a list of the packages I will be emphasizing in this article:

- `Cluster`, version 3.1 (free from the Centers for Disease Control (CDC)): this DOS-based package has 12 different techniques to help in disease clustering. It is fairly straightforward to use, but is certainly not elegant.
- `Egret` for Windows, version 1 (commercial; other packages from the same company include `StatXact` and `LogXact`): this package is primarily for fairly specialized modeling of epidemiologic and biomedical data. It includes **additive** and **multiplicative** versions of several models (e.g. logistic and Poisson) as well as random-effects logistic regression. It is very easy to use, much easier than when it was a DOS package. This is its first appearance as a Windows package. The same vendor sells `Egret SIZ`, a DOS package for determining sample size or power for nonlinear regressions, `StatXact`, a package for the exact analysis of tabular data, and including a power module for data to be analyzed via tables, and `LogXact`, a package for exact **logistic** or **Poisson regression**. `LogXact` also contains a Monte Carlo option for data sets for which maximum-likelihood estimates do not converge, but that are too large for exact analysis. `Egret SIZ` is the only package of these that is not easy to use. Furthermore, it requires the user to collapse continuous predictor variables into categorical variables, which can be difficult to do without biasing one's result (*see* **Bias**). The material in `Egret SIZ` is based on Self & Mauritsen [11].
- `Epicalc`, version 1.02 (free): this simple Windows package is just for analyzing epidemiologic tables. It is very easy to use when you already have summary data.
- `Epicure`, version 2.10 (commercial): this package is primarily for specialized modeling of epidemiologic and biomedical data. A wide range of models are included. This package is DOS-based and is fairly easy to use, but not as easy as, say, `Egret`.
- `EpiInfo`, version 6.04, and `EpiMap`, version 2 (free from the CDC): `EpiInfo` has extensive capabilities regarding questionnaires, data entry and data checking, but modest analytic capacity. Taking full advantage requires some programming skill. `EpiMap` has extensive mapping abilities and uses `EpiInfo` data directly. If one only wants a little from these packages, they are easy to use. However, using their full power requires some work by the user.
- `Epilog` Windows, version 1 (commercial): this package is easier to use as a Windows package than it was as a DOS package. It is very modular, which I am not a fan of, but it is also the most complete of the specialized packages.

- `EpiMeta`, version 1 (free from the CDC): relatively easy to use for its quite limited purpose of simple meta-analyses.
- `PEPI`, version 3.01 (free): this DOS package is slowly being made into a Windows package. It is comprised of a large number of separate modules, which can make it a pain to use. This pain is somewhat ameliorated in DOS by an integrated menu that accesses all modules and by a Windows help file that tells the user which module to use. The preliminary parts of the new Windows version go some way to solving the problems caused by separate modules. `PEPI` is primarily for use on summary data and has no data management facilities of its own.
- `Stata`, version 6 (commercial; general purpose): this large, general-purpose, Windows/Macintosh/UNIX package is the most complete of all considered here. It is included because it has specialized routines for epidemiologists. It is very easy to use, even at a fairly advanced level. If the user requires, the program is extensible and there is a wide-ranging user community that is actively extending this program. The Windows version was used in writing this article.
- `True Epistat`, version 5.3 (commercial): this is a DOS package and is very modular. I find the data management facilities awkward to use, though this version is an improvement over earlier versions.
- `Win Episcope`, version 2.0 and `WinEpi Ratios`, version 1.0 (free): these simple packages are easy to use for tables when you already have summary data.

Note that several major, general-purpose packages are not included here as they have no specialized epidemiologic routines, including the Biomedical Data Processing Program (BMDP), `SAS`, `SPSS`, `S-Plus` and `Systat`. The last four, at least, are under active development and are used by many epidemiologists. Each of these has many of the elements discussed below and/or listed in one of the two tables. However, because they do not use epidemiologic jargon, I have not included them in this article (*see* **Software, Biostatistical**).

As part of my preparation, I invited the producers of each of the above packages (except for `Cluster` and `EpiMeta`) to tell me why they thought there should, or should not, be specialized epidemiological software. I received responses from all except the `WinEpi` series (note: the `WinEpi` series is aimed at veterinary epidemiology). As one would expect, the providers of specialized epidemiologic software provided reasons for having such specialized software, while the people from `Stata`, a general-purpose package with some specialized epidemiologic routines included, provided reasons why one would not want specialized software. I received a total of seven responses from different software providers; since there was a lot of overlap in their responses, I just summarize the major issues raised:

1. *The output produced is the type of output used by epidemiologists*. Three vendors said this, with one adding that it was desirable to exclude the "statistical clutter" that general-purpose packages added even when they also produced the type of output desired by epidemiologists. This issue seems best exemplified by tables where many epidemiologists expect specific output (e.g. **odds ratio** (OR) and a confidence interval for this ratio). An example of the added clutter produced by some packages might be, I suppose, statistics such as lambda or Cramer's V. Note, however, some problems with this.
   (a) There are cases where one should want the additional statistics; that is, what one person might call "statistical clutter" might be desirable to other people or even to that person if the person learned about that statistic. (Lambda is an example of a proportional reduction in the error statistic; if one uses it in models, as epidemiologists do, might not one also want to use it for tables?)
   (b) One trend that has clearly increased over the last 20 years is for analysts in one area to read, and contribute to, the literature in other areas. If every discipline used its own specialized software, this would be a harder task. Certain choices by software providers already make this harder; for example, `Stata`, in its epidemiologic tables routine (`epitab`), includes McNemar's test for matched case–control data. Their output tables even use standard epidemiologic language (e.g. the rows and columns are labeled exposed and unexposed). One problem arises here because other disciplines, including various social sciences,

call **case–control studies** by other names and do not use the words "exposed" and "unexposed". A related issue, which ties this to the first point above, is that Quinn McNemar was not an epidemiologist – he was a social psychologist, and when he designed this test he was not using data that were related to health in any way. Rather, he was interested in those who changed preferences regarding presidential candidates according to consecutive public opinion polls (McNemar [6]). When general-purpose packages bend a statistic like this, they endanger their general use (note: `Stata` has another, not specifically epidemiologic, procedure that also produces McNemar's test, this time without the epidemiologic jargon). When specialized users refuse to acknowledge other uses, and other users, they risk becoming dead ends.

(c) While I agree that cluttered output is undesirable, I see no problem with software producers giving users the option to choose which output is to be shown. At the extreme, asking for a table would show only the table with no inference procedures shown unless specifically requested, and each type of inferential procedure desired would have to be specifically requested. Software that includes macros could include example macros showing, for example, the output that an epidemiologist might want, while a second macro might show the output that a psychologist would want.

2. *Ease of use, particularly via epidemiologic jargon.* At least four software providers mentioned this. Several providers specifically mentioned the desirability of this for users who were not full-time epidemiologists. I certainly agree that extreme ease of use, accompanied by standard epidemiologic jargon (to the extent it exists) makes misuse of the software less likely by these people and is therefore a good thing. Inclusion of this jargon in general-purpose statistical software is, by the same token, dangerous (unless one feels that the only possible misusers are the epidemiologists, something I strongly doubt). Related to this was the idea that single-purpose packages (i.e. software that only does one type of analysis, or that is useful with respect to a certain design issue) are generally easier to use than are general-purpose packages. Similarly, certain support issues are clearly part of this, including manuals that give fully worked out epidemiologic examples, textbooks that use a particular software package, and the presence of Usenet news groups and/or e-mail list-servers related to the package. Only the manual examples seem to argue against general-purpose packages (since all the others can, and do, easily coexist with general-purpose packages) and even this can be handled, though some ways of attempting this may work better than others.
3. *Hard-to-find statistical procedures and tests*. This was mentioned by at least five providers. An example is disease **clustering**. There is no question that in epidemiology, as in other disciplines, specialized software packages that include useful analytic routines not available in most general-purpose packages are highly desirable. Some of these might be added to an extensible general-purpose package by a user, or by the provider, but some are so unusual, and difficult to program, that a specialized package might be the only realistic alternative.
4. *Epidemiology has unique demands for data entry and for data manipulation*. One provider argued this. The examples provided (double entry and verification, changing the ordering of categories in a table) are not convincing since users from many disciplines need all of these and more.

My conclusion is that there is a place, and a need, for specialized epidemiologic software, primarily for routines that are not included, or only rarely included, in general-purpose statistical software packages. However, many of the other reasons for specialized software packages are unconvincing at best. Worse, specialized packages that offer only "simple" routines are dangerous. For example, use of tables without the ability to generalize to a model allows too much chance of misleading the researcher. Many epidemiologic tables provide exactly the same result that one would receive from a simple **logistic regression** or **Poisson regression**. The general-purpose package that provides both tables and models allows one to test assumptions and to use covariates – the specialized tool that only has the tables, no matter how perfectly epidemiologic they are, is dangerous.

Software for Designing and Implementing Studies

Historically, the primary emphasis in software has been on analyzing data. Specialized packages, outside of epidemiology, exist for sample size determination and for the assignment of subjects to groups. Some of the epidemiologic software discussed here has the capability of helping a researcher to design or implement a study and those capabilities are discussed in this section. The capabilities of nonepidemiologic specialized software and of other general-purpose software are not discussed here. Software for determination of power, or sample size, have been reviewed elsewhere (e.g. Goldstein [3], Thomas & Krebs [12]) (*see* **Software, Biostatistical**). Software for subject assignment, including matching, has unfortunately not been generally reviewed, to my knowledge.

Several of the packages included here have routines for sample size determination. For the most part, only fairly simple situations are covered. Many statisticians will use simulation for complicated studies, but most of the specialized epidemiologic software has no simulation ability. Table 1 shows what is available for those packages that have any capability for either sample size determination or for simulation. In addition, some of the developers of `Epicure` have produced a separate, and free, power program that is unique in that it can easily be used for tests of interactions. This program, "`Power`", is currently included as a module in the package "`Epitome`" and is being turned into a stand-alone Windows-based program. Note that there is little in any of the packages with respect to calculating power and/or determining sample size for any type of regression model.

None of the specialized packages includes any routines, or simulation capability, to allow for the determination of sample size for research studies involving complex samples. Furthermore, only `Egret SIZ`, a separate product requiring that it be separately purchased, has extensive regression capabilities and the requirement for categorizing any continuous predictor reduces the usefulness of this package. On the other hand, several of the specialized packages include the ability to calculate the needed sample size for simple **case–control** or for simple **cohort studies**, both of which are important in epidemiology. On the face of it, the above table is depressing – specialized packages should be, at least through simulation, capable of much more than they are. The simple studies that are currently covered are, in my opinion, mostly useful for beginners and students.

What other aspects of study design, particularly of the design of epidemiologic studies, are available? There are at least three other areas in which software can help: the design of data collection instruments (e.g. questionnaires); the assignment or allocation of study subjects (e.g. **matching** or blocked randomization); and data editing (i.e. data checking and correction). Unfortunately, in these aspects also, the various packages are fairly weak. This is not,

Table 1 Type of sample size determination

Software	Means	Proportions	Other models[a]	Simulation
`Egret SIZ/StatXact`		`StatXact`	nonlinear reg.	`Egret SIZ`
`Epicalc`[b]	Yes	Yes	cc	
`EpiInfo`		Yes	cc, cohort	
`Epilog (Power)`[c]	Yes	Yes		
`PEPI`	Yes	Yes	OLS	
`Win Episcope`	Yes	Yes	cc, cohort	
`Stata`	Yes	Yes	rm	Yes
`True Epistat`	Yes	Yes	survival	

[a]Nonlinear reg. refers to `Egret SIZ`, which will calculate sample sizes for several types of nonlinear regression: logistic, conditional logistic, Poisson, Cox proportional hazards. cc = case–control study, cohort = cohort study, rm = repeated measures study, survival = comparison of two survival curves.

[b]Mark Myatt, the provider of `Epicalc`, also provides some specialized packages for calculating sample size for simple surveys and for "LQAS triage-style surveys".

[c]Epicenter Software, the vendor of `Epilog`, also sells a program called "`Power`" specifically for sample size determination. This was reviewed in Goldstein [3] and in Thomas & Krebs [12], but was not re-reviewed for this article.

however, to say that there is nothing available or that what is available is weak – it is just that too little is available, even though what is available is generally pretty good. With respect to data collection, the EPED module in `EpiInfo` can be very helpful, particularly regarding questionnaires. When combined with the CHECK module for data checking and verification, `EpiInfo` can be very helpful to researchers. Some other packages have provided less useful routines for data checking including `Epilog` (`Proc Check`) and `Stata` (`assert`, `inspect`, etc.). Any reasonable analytic package will provide some ability to check one's data for problems through standard descriptive statistics. `Epilog`'s `Proc Check` allows one to go a little further by allowing user input to flag, in different ways, any problem records as they are found. With some programming on the part of the user, `Stata`'s relevant commands can also provide additional help.

Although many authors have pointed out problems with matching, it can still be useful in epidemiologic studies. The biggest problem, for many, is how to find the matches. Of the packages examined, only `Epilog` (`Proc Control`) provides help here: for example, caliper matching (i.e. matching within limits, such as ± 5 years of age) is fairly easy to set up and the user can select the number of matches to select per case. A related issue is the ability to set up blocked randomization; `PEPI`, `Stata` and `True Epistat` have routines for this.

One can easily imagine other tasks that would be useful. For example, in longitudinal studies, software that helped with the tracing process, either through helping to find people via hooks to internet databases, or that helped determine which of several people found was the correct one, would be very useful. `Stata`'s extensibility could be used here, though it has not been. Another possibility relates to the presence of multiple control groups – none of the packages has anything, either on the data management end or in analysis (except for relatively simple tables and hypothesis tests) related to this potentially very useful procedure.

Data Management Issues

Some data management issues (e.g. data entry and verification) were discussed above. A few others are mentioned here. However, because of the wide variety of possible issues, I cannot hope to cover everything. I believe that there is a certain minimum that each package (except the simplest special-purpose analysis packages) should contain, including:

- merging files (adding new variables to the same cases), including many-to-one merges
- appending files (adding new cases to the data set)
- recoding variables
- transformations of variables, including a wide variety of built-in mathematical, statistical and string functions; some, at least, should be usable "on the fly" when estimating models (e.g. $\log(y) = f(x_1, x_2$, etc.)
- splitting files
- generating random numbers/samples
- changing files from wide format (repeated measures as part of the same case) to long format (each measure as a separate case) and back again; this is often necessary for different kinds of longitudinal analysis
- an extensive ability to deal with character data, especially names, addresses and, at least to some extent, free text
- the ability to override any automatic decisions made by the software (e.g. one should be able to change easily the way data, or results, are displayed)
- date functions, both so that, e.g. calculation of age at any given time point is easy, and so that graphs and other output can easily be labeled in an appropriate way
- time-series, including seasonal effects
- automatic generation of appropriate indicator variables from a categorical variable, including user choice of reference group when estimating models
- easy ways to find any duplicate cases in the data
- multiple indicators for missing values (to indicate different reasons for being missing), and correct handling of missing values during transformations and the generation of new variables (e.g. when forming a new indicator variable that is coded as 1 when either $x > 5$ or $y > 3$, the new variable should be equal to 1 if x is equal to 6 even if y is missing)
- dealing with runs, or spells, or series of events (particularly those that do not fit into standard time-series formats).

None of the packages here is ideal in this respect and most of them are pretty weak with relatively short

lists of built-in abilities. Stata is the strongest in this regard, even if one excludes user-added capabilities. With the addition of user-written routines, Stata is much stronger than any of the other packages with respect to data management. Stata even has the ability to add notes to the data, or to individual variables in the data, that will be permanently saved with the data and can be edited.

Data Analysis

The heart of any of these packages is its analytic capabilities. Unfortunately, this is also the heart of one of the major disputes between some statisticians and some epidemiologists: whether to emphasize OR or **relative risk** (RR). It appears that many epidemiologists prefer measures of RR while many statisticians prefer the OR. In fact, a major strand of epidemiologic literature deals with the question of when an event is rare enough so that the OR is a good approximation of the RR! For many statisticians, the dependence of RR on the rate in the control group makes it a poor choice for any use. A cross-cutting, and more meaningful, dispute is whether to emphasize absolute or relative measures of effect. In a sense, the answer to both issues is the inclusion of multiple measures of effect, or at least the ability to obtain any effect measure the user desires. For tables, the software could offer options that the user could pick from; for models, different effects result naturally from different models. Thus, offering numerous models, especially when they are closely related, seems the obvious answer. For example, generalized linear models (GLMs) offer, through different choices of link functions, the ability to obtain different measures of effect. A simple example involves models based on the binomial distribution: using a logit link results in **logistic regression** with an OR effect; using a log link gives an RR effect, while using an identity link gives an effect measured in rate differences.

Another difference appears to be the dependence of many users on tables. However, ignoring potential **confounders**, or other relevant covariates, can be dangerous, since their inclusion could mean very different results. Again, a package that includes both tables and models should solve this problem. If the documentation of the package discusses which models appropriately build on which tables, as does Stata's, the user is in the best possible situation.

Table 2 presents a simple checklist of various relevant forms of analysis for the major packages. Those packages that only include tables (Epicalc and Win Episcope/WinEpi Ratios) are not included in the table. Also, the column for EpiInfo includes the other CDC packages (EpiMeta and Cluster). The danger of such a table, of course, is that it can be misleading for certain specialized issues and packages. There is little doubt that Epicure, for example, looks weaker than it actually is in such a table because it has a number of unique models that are not included but should be considered. In particular, it is the only included package that has models that are neither additive nor multiplicative (*see* **Additive Model**; **Multiplicative Model**). Egret also suffers in this way, though to a lesser extent. Even Stata suffers as it is the only package with a full GLM (though Epicure has aspects of GLM), which I have not included in the table.

The items in Table 2 were largely selected on the basis of three sources: Clayton & Hills [2], Oster [8], and Rothman & Greenland [9]. The table is not complete (an impossible task), but does cover most of the regularly used analytic procedures. Note that I have excluded descriptive statistics and epidemiologic tables, since all packages include these (PEPI does, however, have one interesting unique aspect to its tables: when the user wants kappa, a measure of agreement, PEPI also provides bias-adjusted and prevalence-adjusted bias-adjusted versions; see Byrt et al. [1] and Lantz & Nebenzahl [5]) (*see* **Kappa**). There is little difference in the way that epidemiologic tables are handled by these packages, too little difference to matter to most users. The same is true with respect to tabular analysis of matched case–control data: all packages offer something, most include some form of exact analysis and some form of **stratification**. I have also left out nonparametric statistics since this would require either a simple, misleading row on whether there are any, or an additional table. Instead, note that Egret, EpiInfo and PEPI have some nonparametric techniques, while Epilog, Stata and True Epistat have quite a lot of nonparametric statistical routines. All of the named packages have some exact procedures, but here I mean the more traditional nonparametric (e.g. Mann–Whitney rank sum, sign test) techniques.

The following are brief descriptions of those routines that might not be obvious from their row title.

Table 2 Data analysis routines

Analysis	Egret	Epicure	EpiInfo	Epilog	PEPI	Stata	True Epistat
Standardization	Y		Y	Y	Y	Y	Y
SMR		Y		Y	Y	Y	Y
Multidimensional tables				Y			
Complex surveys			Y			Y	
Disease clustering			Cluster	Y			
Meta-analysis			EpiMeta	Y	Y	Y	Y
Linear models	Y	Y		Y	Simple	Y	Y
Censored linear models				Y		Y	
Logistic regression	Y	Y		Y	Y	Y	Y
Additive logistic regression	Y	Y				Y	
Exact logistic	LogXact			Y			
Ordinal logistic				Y		Y	
Polytomous logistic				Y		Y	
Conditional logistic	Y	Y		Y	Y	Y	Y
Poisson regression	Y	Y		Y	Y	Y	
Cox models	Y	Y		Y		Y	Y
Parametric survival models	Y	Y		Y		Y	
Kaplan–Meier analysis	Y	Y		Y	Y	Y	Y
Extensive nonlinear models		Y		Y		Y	
Recursive partitioning (trees)				Y			
Simulations	Y	Y				Y	
Bootstrap						Y	
Multilevel models	Y			Y		Y	
Seasonality				Y	Y		
Maps			EpiMap	Y			

Note: Entries in the table, other than "Y", refer to other packages from the same provider (counting the CDC as one provider).

- *Multidimensional tables, often called loglinear analysis*: this refers to tables with three or more variables. Note that most such tables are relatively easy to estimate in packages with **Poisson regression**. Some people might expect stub-and-banner tables here, but I have not included them since only Stata has anything like such tables and its version is quite limited. "Stub-and-banner" tables can have multiple variables as the rows and/or as the columns. They are often used when summarizing the study population in one table (e.g. showing the distribution by group and by gender, showing the mean ages of each group, and the mean time since exposure).
- *Complex surveys*: this refers to analysis of data gathered via a nonsimple random sample (e.g. a clustered random sample). Note that EpiInfo can only analyze means and rates, while Stata can also estimate a number of regression models on these samples.
- *PEPI*: this provides simple, but not multiple, linear and nonparametric regression.
- *Censored linear models*: the Buckley–James model in Epilog appears to be superior to the Tobit model in Stata (Moon [7]).
- *Parametric survival models*: these include, for example, exponential or Weibull models for survival analysis. More on various forms of survival analysis and software can be found in Goldstein et al. [4] (*see* **Survival Analysis, Overview**).
- *Extensive nonlinear models*: with the recent interest in neural networks, there has been a corresponding increase in statistical models with extensive nonlinearities among the predictor variables in a model. Epilog has a neural network routine. Stata, instead, has more statistical procedures, including generalized additive models (GAMs), cubic splines and fractional polynomials. Stata also has a more traditional nonlinear least squares routine.
- *Simulations and bootstrap*: as we learn more about the weaknesses of traditional models, and as computers become more powerful, many

researchers are turning to computer-intensive methods. The row for "exact logistic regression" is one type of computer-intensive routine, a specific use of randomization of the data. Simulation and bootstrap are two other computer-intensive methods. Their implementation in Stata calls on the user to write some code for their specific use, but supplies all the front-end and back-end and housekeeping work so that actually doing a simulation to see the effect of errors in the predictor variables, for example, is very little work. The work required in Epicure is, however, considerable. Egret has especially easy-to-use Monte Carlo routines. However, the user can only use Monte Carlo where offered in the package and thus there is no flexibility. If it is offered and what it simulates is what you want (e.g. a p-value or confidence interval) then it is very easy to use; if it is not offered, then it cannot be used. Note that for small samples, either exact or simulated results will usually provide more accurate results than will use of the bootstrap.

- *Multilevel models, sometime called random coefficient or hierarchic models*: these are relatively limited in epidemiologic software as yet, but some packages have at least some capabilities (e.g. random effects logistic regression).
- *Seasonality*: the reference here is to epidemiologic uses for, for example, the detection of seasonal or secular trends in disease incidence (as compared, for example, with the use of traditional time-series techniques, which usually need more data).

Note that those packages that have extensive regression routines (Egret, Epicure, Epilog, Stata and True Epistat) also have extensive diagnostics for these regressions, including goodness-of-fit statistics and procedures. While there are minor differences in the offered routines, I believe that any of them would be sufficient for most users.

There are two other important analytic techniques that I think should be included: errors-in-variables (or misclassification) and multiple imputation. It is surprising, and disturbing, that of all the epidemiologic literature dealing with **misclassification**, only PEPI and Stata have anything of relevance, and neither is very good, though Stata's simulation abilities can be of great help. Multiple imputation (Rubin [10], Vach & Blettner [13]) is of importance when there are **missing data**, as, in my experience, there always are. Stata has an impute command, but it is for single imputation and will often give a result that is misleadingly precise – no other package has anything. I believe that these are major failures of all the included software.

None of the packages has excellent graphics, either analytic or publication. All could benefit from more effort in this area. On the other hand, the analytic graphics in most of the packages are sufficient for everyday use by a data analyst. Many of the graphic procedures would have been considered excellent as recently as 10 years ago – but now they are all behind the times. In addition, as noted above, many of these packages are still DOS-based; many of the Windows graphics adapters do not work well in DOS, further impairing the value of the graphics offered by these packages.

I have not specifically commented on importing or exporting data as a general matter (although a few comments are scattered above). In general, the presence of two specialized file-format transfer packages (DBMS/COPY and StatTransfer) makes this issue relatively unimportant. Either of these packages can be used for file import or export. DBMS/COPY can also be used to summarize data either for input into one of the summary-data-only packages (e.g. EpiCalc or PEPI) or for making stub-and-banner tables for inclusion in a report or publication. Both of these programs can import from, and export to, many other packages, including DBMS programs (e.g. ACCESS), spreadsheets (e.g. QuattroPro), statistical packages such as Stata, SAS or SPSS, and even some specialized graphics packages.

Finally, no matter how much thought a software provider puts into the output from their data management and analysis routines, not everyone will be happy. This presents another advantage of an extensible package – users, or the provider, can provide alternative ways to analyze the data or to present results. While several software providers mentioned output and reporting as one of the reasons for having specialized epidemiologic software, the examples they cited are unimpressive – in almost all cases users will want to change the presentation of results for publication purposes; in almost all cases, this will be very difficult, requiring users to type in the results anew. The only exception is Stata, where

user-written routines have added important output flexibility.

The importance of having an extensible package is, I hope, clear, even for those who do not expect ever to extend a package themselves. After all, if there are easy ways to share extensions, all can benefit from the extensions of a few. For example, `Stata`, the only extensible package here, has several ways to share additions to the package: there is a bimonthly publication, the *Stata Technical Bulletin* (STB) that is filled with new routines from both users and the vendor (and the software is available over the Internet); there is an active user community that both supplements the company's technical support and is a source of additions, primarily from users, to the package – this e-mail `listserv` can be joined via the company's web site (see below).

Documentation

Over the years, I have examined dozens, if not hundreds, of statistical software packages. The packages discussed here have particularly strong manuals – a very pleasant surprise. All the commercial packages, as well as those from the CDC, have extensive documentation, with extensive professional citations and fully worked examples of the use of the software. Furthermore, in general, the free packages, such as `PEPI`, at least have extensive help files, which are unusually good, in my opinion (note that `PEPI` also has a complete manual, as does `EpiInfo`). Several of the packages even include references to their manual in their online help, something I like and find helpful. The major weakness of most of the packages is in their indexes: only `Egret`'s is as extensive and well-organized as I like (`Epicure`'s is almost as good; its major weakness is that one has to remember to go to the index in the Release 2.0 manual to obtain coverage for all three manuals).

Conclusion

My answer to whether there should be specialized epidemiologic software is a qualified yes: there is always a place (1) for relatively limited specialized software that is primarily useful for quick calculations on tables and provides output that is almost exactly what an epidemiologist is expecting, and (2) for analytic techniques that are primarily useful for particular disciplines, and that have not, yet, made it into general-purpose packages. However, it is a mistake to think that specialized software is all that is needed: no discipline is entirely self-sufficient – there are techniques from other disciplines that are useful and important for epidemiologists. It would be prohibitively expensive for a provider of epidemiologic software to try to match `Stata`, `SAS` or `S-Plus`; it would also be a terrible waste of resources. There is also an important place, in my opinion, for both free and shareware analytic software and I am glad to find that there are several healthy free epidemiologic software packages.

In addition, there is great value to having free packages available (particularly for students and for those who are really part-time epidemiologists), especially if they are very easy to use and include unique features. Several of the free packages discussed here are very easy to use and both `EpiInfo` and `PEPI` have unique features. I hope that the commercial vendors pay attention to these, and other, free packages. However, there is a danger with these packages. Too little attention has been paid to the biasing effects of using simple statistical models, such as $2 \times K$ tables. When combined with the tendency to ignore misclassification and the effects of **missing data**, we can see, I think, one major need in the field: easy to use packages that allow users to build from tables to regression models of various kinds and that allow, and adjust, for misclassification and other types of errors in variables.

RICHARD GOLDSTEIN

Soper, Herbert Edward

Born: September 6, 1865, in London; UK.
Died: September 10, 1930.

Soper studied mathematics at Cambridge under Bertrand Russell. He then worked in electrical engineering, but studied statistics under **Karl Pearson** in 1907. During the next decade, Soper published, in ***Biometrika***, mathematical and computational studies of the distribution of the **correlation** coefficient, forerunners of Fisher's exact solution of 1915, and various other computational papers. In 1922 he published a book on *Frequency Arrays*, an individual approach to the use of probability **generating functions**. In 1923, he joined **John Brownlee** at the National Institute for Medical Research, later working there with **Major Greenwood**. In 1929, he contributed importantly to the theory of measles epidemics, formalizing mathematically the mechanism previously described by W.H. Hamer in 1906.

PETER ARMITAGE

Spatial Models for Categorical Data

Spatially referenced counts, proportions, and **rates** present particular data analytic challenges. Such statistics typically arise from a set of prespecified regions partitioning a study area. Cressie [20] refers to such an arrangement as "lattice data", where the lattice may consist of regions formed and arranged regularly (e.g. a square or hexagonal grid system), or irregularly (e.g. a set of administrative districts such as United States **census** tracts, or United Kingdom post code areas).

To begin, we may think of such data as analogous to a **contingency table**, with regions corresponding to the usual notion of "cells". Each cell contains an observed count or proportion, and we often wish to compare these values to those expected under some sort of model, perhaps based on regionally specified **covariates**. However, unlike traditional contingency tables, a spatial lattice has no margins, or underlying row by column independence hypothesis, of scientific interest. For irregular regions, there are no margins other than the observed total count, and for regular regions the margins rarely have substantive meaning (unless the orientation of the lattice happens to correspond to a particular trend).

The spatial structure of the data complicates direct application of traditional statistical methods in at least two more general ways. First, one may be reluctant to employ traditional assumptions of independence between observations (here, regional counts or proportions), instead wishing to allow for positive **correlation** between nearby observations, as would occur in the presence of an influential but unmeasured covariate with a spatial pattern or trend. Second, traditional notions of asymptotic approximation often fail in the spatial setting, where one cannot add additional regions without either expanding the study area (increasing domain asymptotics) or subdividing the current set of regions (infill asymptotics) (cf. [20, pp. 100–101]). Neither of these asymptotic approaches provides an entirely satisfactory scenario for many analyses of spatially referenced categorical data.

The lost or at least diminished applicability of these two standard tools for classical statistics impacts upon the manner in which **likelihood**-based methods of **estimation** and **inference** may be employed. Below, we briefly survey three general classes of statistical methods for modeling spatially referenced counts and proportions. The first class builds upon the family of "auto-models" defined in detail by Besag [6–8]. The second class uses **quasi-likelihood** estimation within a **generalized linear model** (GLM) framework. The third class uses mixed models wherein **random effects** induce spatial correlation. All approaches build inference from a GLM foundation based on underlying **binomial** or **Poisson** distributions for counts, resulting in **logistic** or **Poisson regression** models, respectively. Models for proportions typically consider the denominators to be fixed and known (e.g. population sizes from a census), and reduce to count-based GLMs where the denominator of the proportion becomes an offset in the model [42, p. 206].

Auto-models

Besag [7] presents a thorough development of the structure and analysis of so-called "auto-models". These are based on Markov random fields wherein, for $i = 1, \ldots, I$, the distribution of the outcome in region i, conditional on all other observations, depends only on those observations occurring in a set of neighboring regions (*see* **Markov Chain Monte Carlo**). The Hammersley–Clifford Theorem [7] specifies exactly when a set of conditional distributions for each region defines a valid joint distribution, with induced spatial correlations (*see* **Conditional Probability**).

Auto-Gaussian Models

The most flexible and frequently applied family of auto-models employs conditional Gaussian distributions yielding (under proper conditions) a valid joint multivariate Gaussian distribution for the outcome data (*see* **Multivariate Normal Distribution**). While a multivariate Gaussian joint distribution directly implies Gaussian conditional distributions, the converse is not so straightforward [3, 10]. However, as will become clear below, the conditions required for other conditional distributions to define a valid joint distribution are often more restrictive than those for Gaussian distributions. Direct applicability of

"auto-Gaussian" models to categorical data is limited, particularly for counts of rare events, where transformations and approximations are often inadequate to satisfactorily compensate for the underlying discrete, non-Gaussian variability.

Auto-logistic Models

For **binary data** associated with regions (e.g. species presence or absence), we turn instead to the "auto-logistic" model originally detailed in [6, 7]. Recent applications extend the model to allow covariates [30, 33, 34], and we present this more general formulation here. Let Y_i denote a **random variable** associated with region i and y_i its observed value, for $i = 1, \ldots, I$. For binary data, $y_i = 0$ or 1 for each region. Assume we observe a vector of covariates $\boldsymbol{x}_i$ and let N_i be a set of region i's "neighbors" (e.g. $N_i =$ the set of regions bordering region i). Then, the auto-logistic model is

$$\begin{aligned} &\text{logit}[\Pr(Y_i = 1 | \boldsymbol{x}_i, \{y_j, j \in N_i\})] \\ &\qquad = \boldsymbol{x}_i' \boldsymbol{\beta} + \sum_{j \in N_i} \gamma_{ij} y_j, \end{aligned} \tag{1}$$

where $\boldsymbol{\beta}$ represents the vector of covariate effects and the γ_{ij} $(j \in N_i)$ denote parameters governing the impact of the neighboring observations on Y_i. The last term in equation (1) follows an autoregressive format, wherein we regress (within the link function) each observation on its neighboring observed values (*see* **ARMA and ARIMA Models**).

The autoregressive term in (1) generates an unwieldy normalizing constant, thereby hampering traditional likelihood approaches for all but very small numbers of regions. Besag [8] addresses this issue through the introduction of "**pseudo-likelihood**" estimation, in which one chooses parameter values that minimize the product of the conditional binomial probabilities in (1). While this product is not the true likelihood, it often provides a reasonable approximation. However, the addition of covariates further complicates matters. Markov chain Monte Carlo (MCMC) **algorithms** provide an alternative strategy [34] for fitting auto-logistic models. Indeed, the conditional structure of auto-models is custom-made for recursively updating algorithms such as the Gibbs sampler. Geyer [23] defines the use of MCMC to obtain **maximum likelihood** estimates (MLEs) in a variety of statistical models. Gumpertz et al. [30] illustrate pseudo-likelihood estimation and contrast it with the MCMC **maximum likelihood** approach, preferring pseudo-likelihood in their application for its computational convenience. Indeed, they note that one can obtain pseudo-likelihood estimates using maximum likelihood algorithms available from any standard logistic regression routine [49, 51, 52]. In contrast, Huffer and Wu [34] prefer an MCMC approach to obtain MLEs of model parameters, based on their **simulation** study [61] showing that MCMC estimates provide substantial improvement over pseudo-likelihood results when the amount of spatial interaction (determined by the parameters γ_{ij} above) is large. In practice, the choice of estimation technique is largely a matter of preference between computational simplicity (pseudo-likelihood) and statistical efficiency (MCMC MLE), somewhat guided by the suspected strength of any spatial correlation (*see* **Efficiency and Efficient Estimators**).

Auto-Poisson Models

Besag [7] presents an "auto-Poisson" model for counts, assigning each regional count a conditional Poisson distribution with mean dependent upon its neighboring counts. The auto-Poisson model serves as an extreme example of the care one must take in defining auto-models. Owing to the infinite support of the Poisson distribution, by the Hammersley–Clifford theorem, a valid joint distribution only exists for auto-Poisson conditional models with exclusively negative autoregressive parameters. Auto-Poisson models thus require neighboring values (counts) to be *negatively* correlated, as in resource competition models. This is quite opposite the intent of most spatial modeling, to reflect shared latent sources of variation (see also [20, pp. 427–428]).

Ferrándiz et al. [22] propose the use of an auto-model based on *truncated* Poisson counts, where the regional count of a rare disease is not allowed to exceed the number of persons at risk within the region. The truncation avoids the infinite support problem. They compare maximum pseudo-likelihood estimates to MCMC MLEs (using a Monte Carlo scoring approach) in the following model:

$$\begin{aligned} Y_i | \{y_j, j \neq i\} &\sim \text{Poisson}(\mu_i) \\ \log(\mu_i) &= \boldsymbol{x}_i' \boldsymbol{\beta} + \sum_{j \in N_i} \gamma_{ij} y_j, \end{aligned} \tag{2}$$

where $\boldsymbol{x}_i$, $\boldsymbol{\beta}$, the γ_{ij}, and N_i are as defined previously. We can extend the model to rates or proportions (i.e. models of Y_i/n_i where n_i denotes the (fixed) number of people or person-years at risk in the ith region), by including an additive term $\log(n_i)$ as an offset on the right-hand side of equation (2).

Kaiser and Cressie [35] formalize the truncation proposed in [22]. By "Winsorizing" Poisson variables through the **transformation**

$$Y_i^* = Y_i \cdot \mathcal{I}\{Y_i \leq L\} + L \cdot \mathcal{I}\{Y_i > L\}, \qquad (3)$$

for some predetermined upper limit L (where $\mathcal{I}\{\cdot\}$ denotes the indicator function), one can define automodels allowing positive spatial correlation for values $Y_i^*, i = 1, \ldots, I$ (*see* **Trimming and Winsorization**). Kaiser and Cressie [35] illustrate maximum likelihood estimation (based on standard iterative techniques such as Newton–Raphson) for such models (*see* **Optimization and Nonlinear Equations**). They note the dependence of results upon the choice of the upper limit L, and suggest use of values of L considerably larger than the largest observed value of Y_i.

Generalized Linear Models

Quasi-likelihood

The formal development of generalized linear models [48, 42] includes the class of "quasi-likelihood" estimation techniques, based on the specification of the first two **moments** of the likelihood function rather than the entire function itself. While directing most attention to independent observations, McCullagh and Nelder [42, Section 9.3] extend the ideas to dependent data.

In particular, let $\boldsymbol{X}$ be the **matrix** with rows $\boldsymbol{x}_i'$, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_I)'$ denote the vector of mean values for the regional counts $Y_1, \ldots, Y_I$, and $g(\boldsymbol{\mu})$ denote the link function such that $g(\boldsymbol{\mu}) = \boldsymbol{X}\boldsymbol{\beta}$. Then the quasi-likelihood function $Q(\mu_i; y_i)$ is defined by the relationship

$$\frac{\partial Q(\boldsymbol{\mu}; \boldsymbol{y})}{\partial \boldsymbol{\mu}} = \boldsymbol{V}^{-1}(\boldsymbol{y} - \boldsymbol{\mu}), \qquad (4)$$

where $\boldsymbol{V}$ represents a general symmetric positive definite matrix whose elements are functions of $\boldsymbol{\mu}$. Differentiating $Q(\boldsymbol{\mu}; \boldsymbol{y})$ with respect to $\boldsymbol{\beta}$, yields the quasi-likelihood score equations

$$\boldsymbol{U} = \boldsymbol{\Delta}'\boldsymbol{V}^{-1}(\boldsymbol{y} - \boldsymbol{\mu}), \qquad (5)$$

where $\boldsymbol{\Delta}$ is the matrix with elements $[\partial\mu_i/\partial\beta_j]$ and $j = 0, \ldots, p$ indexes the parameters in the GLM's linear predictor. Setting the score equations to zero and solving for $\boldsymbol{\beta}$ yields the quasi-likelihood estimates of the model parameters.

McCullagh and Nelder [42, pp. 333–335] note that the precision matrix $\boldsymbol{V}^{-1}$ must satisfy several conditions, some not easily verified in practice, to guarantee that a solution to the score equations exists. As a result, Wolfinger and O'Connell [60] and Gotway and Stroup [26], following Liang and Zeger [40, 63], limit attention to variance–**covariance matrices** written as

$$\boldsymbol{V} = \mathbf{v}_{\boldsymbol{\mu}}^{1/2}\boldsymbol{R}(\boldsymbol{\alpha})\mathbf{v}_{\boldsymbol{\mu}}^{1/2}. \qquad (6)$$

Here $\boldsymbol{R}$ denotes a matrix of correlations among the $Y_1, \ldots, Y_I$, as functions of the parameter vector $\boldsymbol{\alpha}$, and $\mathbf{v}_{\boldsymbol{\mu}}^{1/2}$ is a diagonal matrix of scale parameters, perhaps incorporating **overdispersion**. Liang and Zeger [40, 63] show that, under mild regularity conditions, even misspecified correlation matrices will generate **consistent estimators** of $\boldsymbol{\beta}$. In the spatial setting, Gotway and Stroup [26] suggest estimation of the elements of $\boldsymbol{R}$ via standard geostatistical techniques (e.g. based on the **variogram** or correlogram), then substituting the estimated matrix $\widehat{\boldsymbol{R}}$ into the score equations above, and solving for $\boldsymbol{\beta}$.

The quasi-likelihood approach outlined above provides *marginal* inference regarding covariate effects (i.e. estimates of effects averaged across the entire study population). For related analytic approaches for spatial data, see [27, 39, 44].

Generalized Linear Mixed Models (GLMMs)

Including random effects within a GLM allows covariate effects to vary between regions, and can offer different insights into data patterns than the marginal analyses above. For our purposes, the primary difference between the two approaches is how the models structure spatial correlation. **Marginal models** incorporate spatial correlation directly into the likelihood, while mixed models take an hierarchical approach, combining spatially correlated random effects with

conditionally independent observations given the random effects (*see* **Hierarchical Models**). The random effects typically follow a multivariate Gaussian joint distribution. The result is a somewhat simpler first stage (conditional independence), and a more convenient structure for modeling spatial correlations than with marginal modeling (i.e. a correlated Gaussian model rather than a correlated Bernoulli, binomial, or Poisson model).

The somewhat simpler conceptual structure still involves complicated inference, especially from the computational perspective, and various methods and approximations appear in the literature. Agresti et al. [2] provide a detailed introduction to **generalized linear mixed models**, including an excellent overview of approaches for model fitting. We outline two general classes of such approaches, the first based on modifications to a likelihood approach and the second based on MCMC implementations of Bayesian hierarchical models (*see* **Bayesian Methods**; **Bayesian Methods for Contingency Tables**).

Approximations to the Likelihood

As noted above (and detailed in [2]), specifying a GLMM involves two steps. First, conditional on the random effects, we assume the outcomes follow a distribution within the **exponential family** (e.g. Bernoulli, binomial, or Poisson distributions). Second, we specify the distribution of the random effects. In the spatial setting, we typically embed spatial correlations in the distribution of the random effects. The full likelihood function for the GLMM combines the conditionally independent first stage with the distribution of the random effects, often resulting in an intractable (or at least inconvenient) multidimensional integral. Likelihood-based approaches to fitting GLMMs involve some sort of approximation to this integral.

The type and extent of approximation varies between approaches. Some methods employ **numerical integration** and others use simulation-based **Monte Carlo** approximations (see, e.g. [14] and [59], respectively). Such approaches converge to "exact" likelihood inference as one takes finer and finer resolution, or larger and larger Monte Carlo sample sizes, respectively. The resolution of numerical methods and the Monte Carlo sample size are computational components under the control of the analyst and are not based on particular probabilistic or statistical approximations. Hence, one can make the "exact" methods as precise as computational resources allow.

Other approaches trade some amount of "exactness" for computational simplicity and stability, using additional simplifying approximations, primarily through the use of first-order Taylor series expansions of the integrand around estimates of the random effects [2, Section 4.2]. Two popular methods using this strategy are **penalized quasi-likelihood** (PQL) (Breslow and Clayton [15], Green [29]) and "pseudo-likelihood" (PL) [60]. The "penalty" in PQL adjusts the quasi-likelihood for the presence of the random effects. The term "pseudo-likelihood" derives from the use of "pseudo-data" (defined below) and differs from the "pseudo-likelihood" for auto-models introduced above, as well as from other uses of the same term (e.g. [25]), creating some potential for confusion.

The PQL and PL approaches are very similar (see [41, Section 11.4.3], and [2]), and both build from assumed normality (or near-normality) of the model residual process $\boldsymbol{y} - \boldsymbol{\mu}$, using a "working dependent variable" (Wolfinger and O'Connell's "pseudo data") defined by

$$\boldsymbol{y}_w = g(\widehat{\boldsymbol{\mu}}) + \Delta_{\widehat{\boldsymbol{\mu}}}(\boldsymbol{y} - \widehat{\boldsymbol{\mu}}), \tag{7}$$

where $\Delta_{\widehat{\boldsymbol{\mu}}}$ denotes the matrix with elements $[\partial g(\mu_i)/\partial \mu_i]$ evaluated at $\widehat{\boldsymbol{\mu}}$ (*see* **Residuals**). The working data lead to a system of score equations involving the fixed effects and the parameters defining the variance–covariance matrix of the random effects. The PQL and PL approaches update the current fixed effect given the current estimate of the covariance parameters using normal mixed model theory ([2, Section 4.2]; [50, Section 7.6]), maximizing the product of the conditional density of the data given the random effects and the density of the random effects given the current estimate of the associated covariance parameters. The update of the covariance parameters follows an assumed normal linear mixed model for the working (pseudo) data, given the current estimates of the fixed and random effects. Note that both steps involve assumptions of normality of the working (pseudo) data and linearity (at least locally) for the application of the normal linear mixed model theory (e.g. [31]) (*see* **Linear Mixed Effects Models for Longitudinal Data**).

Similar to the quasi-likelihood method outlined for generalized linear models above, Wolfinger and

O'Connell [60] focus on variance–covariance matrices of the form

$$\boldsymbol{V} = \mathbf{v}_{\boldsymbol{\mu}}^{1/2} \boldsymbol{R}(\boldsymbol{\alpha}) \mathbf{v}_{\boldsymbol{\mu}}^{1/2}. \quad (8)$$

For marginal models, $\boldsymbol{R}$ represents a spatial correlation matrix and we set the (spatial) random effects to zero. For conditional models, we set $\boldsymbol{R}$ to an identity matrix or a diagonal matrix to incorporate overdispersion, and incorporate spatial correlation through the distribution of the random effects.

PQL and PL provide two popular approaches to fitting GLMMs in general, and spatial GLMMs in particular, due to their relative simplicity, ease of implementation, and applicability to large data sets in comparison with the "exact" maximum likelihood approaches outlined earlier. (Recall that the latter are "exact" in the sense that their precision depends only on computational limitations, rather than on distributional or linearity assumptions, or on asymptotic or other approximations, that can introduce additional biases if unjustified.) McCulloch [43] provides a thorough discussion of the impact of the working pseudo data assumptions and additional numerical approximations in PQL and PL, and compares these methods to other classes of maximum likelihood algorithms for GLMMs.

Bayesian Hierarchical Models

The two-stage nature of GLMMs naturally lends itself to a hierarchical Bayes interpretation [16]. Such models are common in the "disease mapping" literature, where analysts seek accurate small area estimates of rates and proportions through "borrowing strength" from neighboring regions (*see* **Mapping Disease Patterns**). Tsutakawa [55] provides an early example. He assigns a Gaussian **prior** distribution to region-specific logits of disease risk, producing local estimates that represent a compromise between individual regional estimates and the overall disease rate. Clayton and Kaldor [18] expand this basic idea, and associated empirical Bayesian inference for region-specific **standardized** mortality/morbidity ratios (SMRs), to allow spatial correlation between neighboring regions (*see* **Empirical Bayes**). To accomplish this, they consider auto-Gaussian prior distributions inducing pairwise spatial dependence between region-specific expected counts. Besag et al. [11] extend these approaches to a fully Bayesian setting using MCMC algorithms. Clayton and Bernardinelli [17], Mollié [45], Wakefield et al. [57], and Congdon [19, Chapter 7] provide thorough introductions to the fully Bayesian approach. The models in [11] and [18] are widely applied in a variety of settings, so we detail these below.

Typical disease mapping data contain observed (Y_i) and expected (often age-standardized) disease counts (E_i) for each region $i, i = 1, \ldots, I$. The maximum likelihood estimate of the SMR for region i is Y_i/E_i. The first stage of the model presumes conditionally independent Poisson distributions for each regional count, parameterized by log-**Relative Risks** (θ_i) associated with each region i, that is

$$Y_i|\theta_i \overset{\text{ind}}{\sim} \text{Poisson}(E_i \exp(\theta_i)), i = 1, \ldots, I. \quad (9)$$

While the disease mapping models involve SMRs, the setting may be thought of more generally as a GLM with an offset (here, E_i) for each Y_i, where θ_i represents a linear function $\boldsymbol{x}_i'\boldsymbol{\beta}$ of region-specific covariates.

To induce spatial correlation at the second stage of the model, Clayton and Kaldor [18] propose the addition of region-specific random intercept terms defined by an auto-Gaussian prior distribution, resulting in regional SMR estimates compromising between the local MLE (Y_i/E_i) and the SMRs observed in neighboring regions. Besag et al. [11] expand this approach to include, separately, influence of both the overall disease rate in the entire study area, and the special influences of neighboring disease rates. In this case, one replaces θ_i by a linear combination of covariate effects and random effects, that is,

$$\theta_i = \boldsymbol{x}_i'\boldsymbol{\beta} + u_i + v_i, \quad (10)$$

where u_i and v_i denote random effects (intercepts) measuring spatial similarity and excess heterogeneity (i.e. overdispersion, extra-Poisson variation), respectively. The basic structure resembles that of the auto-models above, but incorporates spatial pattern into random rather than fixed effects.

One typically assumes independence between $\mathbf{u}$ and $\mathbf{v}$, and models excess heterogeneity through a set of **exchangeable** priors for the v_i, for example, by $v_i \overset{\text{ind}}{\sim} N(0, 1/\tau)$, $i = 1, \ldots, I$. To model spatial similarity in residuals, [18] and [11] assign an auto-Gaussian model defining a *conditional autoregressive* structure for the set of u_i. Specifically, we define

the prior distribution of each u_i conditional on the u_j, $j \neq i$, as

$$u_i | u_{j \neq i} \sim N\left(\frac{\sum_{j \neq i} w_{ij} u_j}{\sum_{j \neq i} w_{ij}}, \frac{1}{\lambda \left(\sum_{j \neq i} w_{ij} \right)} \right), \quad i = 1, \ldots, I. \tag{11}$$

The w_{ij} denote weights defining the extents to which regions i and j are neighbors (by convention all $w_{ii} = 0$), and λ denotes a hyperparameter controlling how similar u_i is to its neighboring u_j, $j \neq i$. Typical applications consider adjacency-based binary weights where $w_{ij} = 1$ if regions i and j are adjacent and $w_{ij} = 0$ otherwise, although other options appear in the literature (e.g. [12]).

As noted above, Besag [7] shows that the collection of conditional distributions uniquely defines a corresponding multivariate normal joint distribution. However, the choice of binary adjacency weights leads to a joint distribution with singular precision matrix, so that the spatial similarity implied by the conditional distributions (in this case, an *intrinsic autoregression*) does not translate directly into a model of spatial correlation [10, 38]. Also, such multivariate priors are improper by virtue of the singularity, since they only define contrasts between pairs of the u_i. However, the inclusion of any informative data (through the likelihood function) results in a proper posterior (see [9, 11]). Finally, the constraint $\sum_{i=1}^{I} u_i = 0$ is often imposed in order to allow **identifiability** of an intercept in $\boldsymbol{x}_i' \boldsymbol{\beta}$. Detailed discussions of conditional autoregressive structures are provided by [7, 10, 11] and [20, pp. 407–408, 410–423].

Specification of the hierarchical model is completed by defining (vague) priors for the covariate effects $\boldsymbol{\beta}$, and proper hyperprior distributions for the hyperparameters τ and λ. In practice, conjugate inverse **gamma distributions** are popular for the latter. Ghosh et al. [24] and Sun et al. [54] discuss restrictions on parameters for these hyperpriors to ensure posterior propriety.

Incorporation of two random intercepts u_i and v_i for each region overparameterizes the model, so the likelihood only identifies the regional sums $(u_i + v_i)$. The prior distributions allow posterior identifiability ([16], p. 308), however. A related research question involves determination of a "fair" allocation of prior variability between τ and λ to balance prior emphasis on the roles of global and local rates. This issue is complicated by the marginal nature of τ and the conditional nature of λ [4, 12, 21].

Inference proceeds via MCMC algorithms, which provide the analyst with sample-based posterior distributions for each model parameter. These in turn allow posterior inferences for SMRs, counts, proportions, and rates.

Extensions

Several authors provide spatiotemporal extensions to the approaches outlined above. Typically, either space or time plays a primary role, leading analysts to investigate temporally evolving spatial structures or spatially correlated time series [5, 32, 36, 37, 53, 58, 62]. The distinction primarily involves the structure of the data, with the former arising in space-rich, time-poor data sets and the latter in space-poor, time-rich data.

Another area of current development involves the analysis of data from incompatible spatial scales, for example, observed counts from census tracts and covariate values from counties. Such "misaligned" data complicate matters, particularly for auto-models and the hierarchical models outlined above, since such models are defined for a particular set of regions and do not readily scale up or down to different regions [1, 13, 46, 47]. Gotway and Young [28] provide a thorough review of methods from a wide variety of disciplines that attempt to address this issue.

In conclusion, the models above provide inference for spatially correlated counts, proportions, and rates. Each approach contains its own set(s) of assumptions, and most involve iterative computational techniques. Hence, analysts must be aware of the assumptions and computational requirements involved when applying such methods.

Finally, while spatial modeling provides inference for data violating some key assumptions of traditional statistical inference, spatial techniques are no panacea for the problems produced by inaccurate or **missing** observations, or the inherent major limitations of ecological inferences. Wakefield [56] provides details putting spatial modeling in a broader perspective, and illustrating several key inferential challenges in

ecologic analyses of observational data that spatial modeling does not address (*see* **Ecologic Fallacy**; **Ecologic Study**).

LANCE A. WALLER

Spearman Rank Correlation

In a study of the relationship between two variables, the use of measures of **correlation** assumes that neither is functionally dependent upon the other. So, for example, we might ask whether body weight is related to height in 35-year-old men; or whether examination scores in music theory are related to examination scores in mathematics for first-year college students; or whether the blood levels of two steroid hormones are related in 20-year-old women. A quantitative measure of the strength of the correlation is a correlation coefficient, which expresses how closely a change in the magnitude of one of the variables is accompanied by a change in the magnitude of the other variable. This is also referred to as a measure of association or of correspondence (*see* **Association, Measures of**).

If the distributions underlying the two variables are far from **bivariate normal**, or if the data are ordinal (e.g. we know relative magnitudes–such as man A is taller than man C but shorter than man D–but we do not know their actual heights) (*see* **Ordered Categorical Data**), then **nonparametric** correlation techniques should be employed to test hypotheses about the relationship between variables or to set **confidence limits** around the correlation coefficients. Nonparametric correlation also is less sensitive to **outliers** than is its parametric analog. The underlying assumptions for nonparametric correlation are that the n pairs of ratio, interval, or ordinal data (*see* **Measurement Scale**) constitute a **random sample** and that the two members of each of the n pairs of data are measurements taken on the same subject.

Among the correlation coefficients proposed by Charles Spearman [19, 20] is a commonly used nonparametric correlation measure that Maurice Kendall formally associated with Spearman's name a quarter of a century later [14], and that is one of the oldest statistics based on ranks. The Spearman rank coefficient computed for a sample of data is typically designated as r_S.

If each of the n measurements of one of the variables is denoted as X_i (i.e. $X_1, X_2, \ldots, X_n$), then $\mathcal{R}(X_i)$ may represent the **rank** of X_i, where each rank is an integer, from 1 through n, indicating relative magnitude. The measurements may be ranked from high to low (e.g. rank 1 indicates the tallest person, rank 2 the next tallest, and so on, with rank n the shortest) or from low to high (rank 1 denotes the shortest and rank n the tallest). Similarly, each of the n measurements of the second variable may be denoted as Y_i (i.e. $Y_1, Y_2, \ldots, Y_n$), and $\mathcal{R}(Y_i)$ would denote the rank of Y_i, where the sequence of ranking (either high to low or low to high) is the same as for $\mathcal{R}(X_i)$. This is shown in Table 1.

Table 1

Person, i	1	2	3	4	5
Height (m), Y_i	1.59	1.66	1.82	1.73	1.91
Weight (kg), X_i	75.8	77.2	89.3	72.2	81.5
Rank of height, $\mathcal{R}(X_i)$	1	2	4	3	5
Rank of weight, $\mathcal{R}(Y_i)$	2	3	5	1	4
$d_i = \mathcal{R}(X_i) - \mathcal{R}(Y_i)$	−1	−1	−1	2	1
d_i^2	1	1	1	4	1

An $r_S = 0$ ("no correlation") indicates that the magnitudes of the ranks of one variable are independent of the magnitudes of the ranks of the second variable. A positive value of r_S ("positive correlation") indicates that the $\mathcal{R}(X_i)$s tend to increase as the $\mathcal{R}(Y_i)$s increase; a negative r_S ("negative correlation") indicates that the $\mathcal{R}(X_i)$s tend to decrease as the $\mathcal{R}(Y_i)$s increase.

If the sequence of ranks were identical for the two variables, we would say that there was a perfect positive correlation, and $r_S = 1.0$. This would occur, for example, if five pairs of data had these ranks:

$$\begin{array}{ccccc} 1 & 2 & 3 & 4 & 5 \\ 1 & 2 & 3 & 4 & 5 \end{array} \quad \text{or these:} \quad \begin{array}{ccccc} 1 & 2 & 4 & 3 & 5 \\ 1 & 2 & 4 & 3 & 5 \end{array}$$

A perfect negative correlation (where $r_S = -1.0$) would be one in which the magnitudes of the ranks for one variable vary inversely with the sizes of the ranks of the second; for example,

$$\begin{array}{ccccc} 1 & 2 & 3 & 4 & 5 \\ 5 & 4 & 3 & 2 & 1 \end{array}$$

Computing the Coefficient

The widely used parametric correlation coefficient, known as the Pearson product–moment correlation

coefficient (*see* **Correlation**), is defined as

$$r = \frac{\sum (X_i - \overline{X})(Y_i - \overline{Y})}{\left[\sum (X_i - \overline{X})^2 \sum (Y_i - \overline{Y})^2\right]^{1/2}}, \quad (1)$$

and commonly computed as

$$r = \left(\sum XY - \frac{\sum X \sum Y}{n}\right) \Bigg/ \left\{\left[\sum X^2 - \frac{\left(\sum X\right)^2}{n}\right]\left[\sum Y^2 - \frac{\left(\sum Y\right)^2}{n}\right]\right\}^{1/2}, \quad (2)$$

where $\overline{X}$ and $\overline{Y}$ are the means of the X_is and the Y_is, respectively, and where the summations ($\sum$) are each over all n data.

The Spearman **rank correlation** coefficient, r_S, may be obtained by subjecting the ranks, instead of the raw measurements, to the above calculations. For the example above, and substituting $\mathcal{R}(X_i)$ for X_i and $\mathcal{R}(Y_i)$ for Y_i:

$$\sum X_i = 1 + 2 + 4 + 3 + 5 = 15,$$

$$\sum (X_i)^2 = 1^2 + 2^2 + 4^2 + 3^2 + 5^2 = 55,$$

$$\sum Y_i = 2 + 3 + 5 + 1 + 4 = 15,$$

$$\sum (Y_i)^2 = 2^2 + 3^2 + 5^2 + 1^2 + 4^2 = 55,$$

and

$$\sum (X_i Y_i) = (1)(2) + (2)(3) + (4)(5) + (3)(1) + (5)(4) = 51.$$

Then,

$$\overline{X} = 15/5 = 3 \quad \text{and} \quad \overline{Y} = 15/5 = 3,$$

and

$$\sum (X_i - \overline{X})^2 = (1-3)^2 + (2-3)^2 + (4-3)^2 + (3-3)^2 + (5-3)^2 = 10,$$

$$\sum (Y_i - \overline{Y})^2 = (2-3)^2 + (1-3)^2 + (5-3)^2 + (3-3)^2 + (4-3)^2 = 10,$$

$$\sum (X_i - \overline{X})(Y_i - \overline{Y}) = (1-3)(2-3) + (2-3) \times (3-3) + (4-3)(5-3) + (3-3)(1-3) + (5-3) \times (4-3) = 6.$$

Eq. (1) yields

$$r_S = \frac{6}{[(10)(10)]^{1/2}} = \frac{6}{10} = 0.60,$$

while (2) yields

$$r_S = \frac{51 - (15 \times 15)/5}{\left[\left(55 - (15)^2/5\right)\left(55 - (15)^2/5\right)\right]^{1/2}} = \frac{6}{[(10)(10)]^{1/2}} = 0.60.$$

As the sum of integers 1 through n (i.e. the sum of all n ranks) is $n(n+1)/2$, (2) employed for Spearman rank correlation may be written as

$$r_S = \frac{\sum \mathcal{R}(X_i)\mathcal{R}(Y_i) - n(n+1)^2/4}{\left\{\left\{\left[\sum \mathcal{R}(X_i)^2 - n(n+1)^2/4\right] \times \left[\sum \mathcal{R}(Y_i)^2 - n(n+1)^2/4\right]\right\}^{1/2}\right\}}. \quad (3)$$

Also, as the sum of the squares of all n ranks is $n(n+1)(2n+1)/6$, (2) using ranks can be reduced to

$$r_S = \frac{12\left[\sum \mathcal{R}(X_i)\mathcal{R}(Y_i) - n(n+1)^2/4\right]}{n^3 - n} \quad (4)$$

or

$$r_S = \frac{12\sum \mathcal{R}(X_i)\mathcal{R}(Y_i)}{n^3 - n} - \frac{3(n+1)}{n-1}. \quad (5)$$

Alternatively, the difference, d_i, for each pair of ranks may be obtained, and the following equation used:

$$r_S = 1 - \frac{6\sum d_i^2}{n^3 - n}, \quad (6)$$

which, for the above example, is

$$r_S = 1 - \frac{6(1+1+1+4+1)}{5^3 - 5} = 1 - \frac{48}{120} = 1 - 0.40 = 0.60.$$

Eq. (6) is most commonly encountered in textbooks, but (1) is very convenient on a computer.

Instead of the differences between pairs of ranks, one may use the sums of the ranks for each pair [15, p. 227; [20]]:

$$r_S = \frac{6\sum S_i^2}{n^3 - n} - \frac{7n + 5}{n - 1}, \tag{7}$$

where

$$S_i = \mathcal{R}(Y_i) + \mathcal{R}(X_i). \tag{8}$$

It can be shown [13] that in bivariate normal populations the Pearson correlation coefficient, ρ, is

$$\rho = 2 \sin\left(\frac{\pi}{6}\rho_S\right). \tag{9}$$

Tied Ranks

If two or more data have the same value, then they are said to be "tied", and each of their ranks may be set equal to the mean of the ranks of the positions they occupy in the ordered data set. For example, in the data set 70, 74, 74, 78, and 79 kg, data 2 and 3 are tied; the mean of 2 and 3 is 2.5, so the ranks of the five data are 1, 2.5, 2.5, 4, and 5. In the data set 1.6, 1.7, 1.9, 1.9, and 1.9 m, data 3, 4, and 5 are tied; the mean of 3, 4, and 5 is 4, so the ranks of the five data are 1, 2, 4, 4, 4.

Then these ranks would be subjected to (1), or, equivalently, the following calculation [9, p. 366] would be used as an alternative to (4):

$$r_S = \left(12\left[\sum \mathcal{R}(X_i)\mathcal{R}(Y_i) - n(n+1)^2/4\right]\right) \Big/ \left\{\left[(n^3 - n) - 12\sum t_x\right] \times \left[(n^3 - n) - 12\sum t_Y\right]\right\}^{1/2} \tag{10}$$

and the following [12, p. 38; [20]] is an alternative to (6):

$$r_S = \left((n^3 - n)/6 - \sum d_i^2 - \sum t_X - \sum t_Y\right) \Big/ \left\{\left[(n^3 - n)/6 - 2\sum t_X\right] \times \left[(n^3 - n)/6 - 2\sum t_Y\right]\right\}^{1/2}, \tag{11}$$

where

$$\sum t_X = \frac{\sum (t_i^3 - t_i)}{12}, \tag{12}$$

where t_i is the number of tied values of X in a group of ties (two in the paragraph above) and the summation is over all groups of tied Xs, and

$$\sum t_Y = \frac{\sum (t_i^3 - t_i)}{12}, \tag{13}$$

where t_i is the number of tied values of Y in a group of ties (three in the paragraph above) and the summation is over all groups of tied Ys. Similarly, the following [21] is an alternative to (7):

$$r_S = \frac{\left\{\begin{array}{c}\sum S_i^2 - [(n^3 - n)/6][(7n + 5)/(n - 1)] \\ -\sum t_X - \sum t_Y\end{array}\right\}}{\left\{\begin{array}{c}\left\{\left[(n^3 - n)/6 - 2\sum t_X\right]\right. \\ \left.\times\left[(n^3 - n)/6 - 2\sum t_Y\right]\right\}^{1/2}\end{array}\right\}}, \tag{14}$$

If $\sum t_X$ and $\sum t_Y$ are both zero, then (10) is equivalent to (4), (11) equals (6), and (14) is equivalent to (7). The results from these equations for tied and nontied data are noticeably different only if there are many ties.

Testing Hypotheses

The r_S calculated from a sample of data is an estimate of ρ_S, the Spearman rank correlation coefficient that would be obtained from the entire population of data from which that sample came; ρ_S is sometimes called "Spearman's rho".

A common desire in rank correlation analysis is to test the **null hypothesis** that there is no correlation in the population between the paired ranks, i.e. we wish to test the two-tailed hypotheses $H_0 : \rho_S = 0$ vs. $H_a : \rho_S \neq 0$ (*see* **Hypothesis Testing**). There are many tables of critical values of r_S, and if r_S is greater than the relevant critical value, then H_0 is rejected. The use of $\sum d_i^2$, instead of r_S, as the test statistic for rank-correlation testing is sometimes called the "Hotelling–Pabst test" [10]. $\sum d_i^2$ is small when r_S is large, and H_0 is rejected if $\sum d_i^2$ is *less than* the critical value. Published tables offer critical values for various sample sizes, n, and levels of significance,

α. The most extensive of such tables for r_S are those of Zar [22, Appendix, pp. 115–116] and, with slight improvements, of Ramsey [17]. If there are tied data, critical values are only approximate. It should be noted that computer software packages may use approximations that are not as accurate as published tables.

One-tailed hypotheses may also be considered. For $H_0 : \rho_S \leq 0$ vs. $H_a : \rho_S > 0, H_0$ is rejected if r_S is positive and greater than the critical value for $\alpha/2$. For $H_0 : \rho_S \geq 0$ vs. $H_a : \rho_S < 0, H_0$ is rejected if r_S is negative and its absolute value is greater than the critical value for $\alpha/2$. If n is larger than that in these large tables, then one may compute

$$t = \frac{r_S}{s}, \tag{15}$$

where s, the standard error of r_S, is

$$s = \left(\frac{1 - r^2}{n - 2}\right)^{1/2}, \tag{16}$$

for which two- and one-tailed critical values of t (**Student's *t* distribution**), for $df = n - 2$, are readily found. Equivalently, one may employ

$$F = \frac{1 + |r_S|}{1 - |r_S|} \tag{17}$$

[2], referring to two- or one-tailed critical values of the ***F* distribution** for numerator and denominator $df = n - 2$. Using t or F is valid even with tied data, and is preferable in any case to employing the normal approximation,

$$Z = r_S(n - 1)^{1/2}. \tag{18}$$

The Fisher Transformation

If n is at least moderately large, the Spearman correlation coefficient may be subjected to the Fisher z transformation by

$$z = 0.5 \ln \frac{1 + r_S}{1 - r_S}, \tag{19}$$

and there are tables, e.g. [22, Appendix pp. 110–111], available to obviate the need to perform this computation. With this transformed value, one may test null hypotheses that ρ_S equals some value other than zero; i.e. $H_0 : \rho = \rho_0$ vs. $H_a : \rho = \rho_0$, where $\rho_0 \neq 0$. This is done via

$$Z = \frac{z - \zeta_0}{\sigma_z}, \tag{20}$$

where z is the transform of r_S; ζ_0 is the transform of the hypothesized coefficient, ρ_0; the standard error of z is approximated by

$$\sigma_z = \left(\frac{1.060}{n - 3}\right)^{1/2} \tag{21}$$

[7, 8], and Z is a normal deviate. In this fashion both two-tailed and one-tailed hypotheses may be tested.

Confidence Limits

The z transformation also allows the setting of approximate $1 - \alpha$ confidence limits for ρ_S. The confidence limits for the z transformation are

$$z \pm Z_\alpha \sigma_z, \tag{22}$$

where $Z_\alpha = t_\alpha(\infty)$. Then, the lower confidence limit of the transformation, $L_1 = z - Z_\alpha \sigma_\alpha$, is converted to the lower confidence limit of ρ_S by

$$\frac{\exp(2L_1) - 1}{\exp(2L_1) + 1}, \tag{23}$$

and the upper confidence limit of the transformation, $L_2 = z + Z_\alpha \sigma_\alpha$, is converted to the upper confidence limit of ρ_S by substituting L_2 for L_1 in (23) above. Published tables, e.g. [22, Appendix, pp. 112–114], execute these conversions.

Power of Testing

For data that meet the normality assumptions of parametric correlation analysis, use of the Spearman method has a relative **efficiency** of $9/\pi^2 = 0.912$ compared with the parametric procedure for testing hypotheses about the population correlation coefficient [10]. For other data distributions, the Spearman procedure may perform even better. The power of hypothesis tests for ρ_S, and the determination of the minimum sample size needed to achieve a desired power, may be approximated by an adaptation of the procedures of Cohen [4, p. 546], as shown by Zar [22, pp. 379–380, 392].

Other Rank Correlation Measures

The Kendall rank correlation coefficient [11, 12] is the other commonly encountered rank correlation measure (*see* **Rank Correlation**). It is often referred to as Kendall's tau, with the population parameter designated as τ and the sample estimate of τ denoted as $\hat{\tau}, t, T$, or (unfortunately) τ. Whereas $\hat{\tau}$ is an unbiased estimate of τ, r_S is a biased estimate of ρ_S, with $E(r_S) = [3\tau + (n-2)\rho_S]/(n+1)$ [6], but this **bias** disappears rapidly as n increases.

The two rank-correlation procedures have different underlying premises and influences (e.g. r_S is more affected by larger d_is), so they do not necessarily yield identical coefficients, $\hat{\tau}$ and r_S; indeed, data sets may have the same $\hat{\tau}$s yet different r_Ss. However, there is a very strong correlation between the two coefficients, and they each may range between -1.0 and 1.0. Daniels [5] found the relationship

$$-(n-2) \le 3n\hat{\tau} - 2(n+1)r_S \le (n-2),$$

which, for large n, is

$$-1 \le 3\hat{\tau} - 2r_S \le 1.$$

A better relationship was proved by Durbin & Stuart [6] to be

$$\frac{3n\hat{\tau} - (n-2)}{2(n+1)} \le r_S \le 1 - \frac{(1-\hat{\tau})}{2(n+1)} \times [(n-1)(1-\hat{\tau}) + 4].$$

Whether r_S or $\hat{\tau}$ is preferable depends upon the criteria employed to make the judgment; Chow et al. [3] judged r_S to be the preferable estimator.

Spearman's [19, 20] introduction of correlation between ranks was accompanied by a correlation measure of which he was fond, the "Spearman footrule", based upon $\sum |\mathcal{R}(X_i) - \mathcal{R}(Y_i)|$ instead of $\sum[\mathcal{R}(X_i) - \mathcal{R}(Y_i)]^2$. This measure is less useful than r_S in statistical analysis and is no longer encountered.

If one's interest is predominantly in the correlation among the largest (or smallest) members in the two populations, then the weighted rank correlation concept [18, 16; see also [22], pp. 392–395] might usefully be employed.

The Spearman rank correlation coefficient, r_S, is related to the Kendall coefficient of concordance, W, when there are two sets of ranks, as

$$W = \frac{(r_S + 1)}{2}. \tag{24}$$

Basler [1] discusses a relationship between $\sum d_i^2$ and the **chi-square test** statistic in a fourfold **contingency table** with ordinal marginal categories (*see* **Two-by-Two Table**).

Specificity

For diagnostic or **screening** tests, the specificity is the probability that an individual without the disease will receive a correct, negative test result. A synonym is the true negative rate, this being the proportion of negative results assigned among the denominator of true noncases of disease. In the table for the entry on **sensitivity**, the specificity is $d/(b+d)$. The **false positive** rate $b/(b+d)$ is the complement of specificity; in other words, it is the probability that an individual without disease will get a positive test result.

A test with high specificity is useful clinically for ruling in potential disease; a positive result from such a test implies a relatively high chance of having the disease. Typically, if a test is designed to have high specificity, its **false negative** rate $c/(a+c)$ will also be high and the test sensitivity $a/(a+c)$ will be correspondingly low.

Achievement of high specificity is important when the implied costs of giving false positive test results to noncases are high relative to the costs of incorrectly assigning negative test results to individuals with the disease (the so-called false-negative results). For instance, in population screening programs for rare diseases such as cancer, high specificity is desirable to avoid large numbers of false positive test results that would require clinical follow-up to determine their true, nondisease status.

A second meaning of specificity refers to the capability of a measuring device (e.g. in the clinical chemistry laboratory) to detect a particular target substance in a sample of material, as opposed to giving a false positive reading with other substances.

In **multivariate analysis**, particularly in **factor analysis**, specificity refers to the proportion of total variation that is associated with a factor.

Spectral Analysis

Often when examining a **time series** $\{X(t)\}$ we are interested in cyclic effects (*see* **Circadian Variation**); that is, effects, $g(t)$, which repeat themselves at regular intervals. Sometimes such cyclic or periodic effects are fairly clear to the eye (see Figure 1), but this may not always be so. The study of this kind of cyclic behavior gives rise to harmonic analysis and spectral analysis. The spectral analysis of time series, with its concern with cyclic effects, can give quite different insights to time domain methods (*see* **ARMA and ARIMA Models**).

We start with the basic ideas of periodic functions. Formally, we say that a function $g(t)$ is periodic if it repeats itself at a fixed interval, so

$$g(t) = g(t \pm s) = g(t \pm 2s) = \cdots = g(t \pm ks) = \cdots.$$

The smallest (nonzero) s value is called the *period* of the function. The frequency f of oscillations is the number of repeats, i.e. periods or cycles per unit time. The frequency $f = 1/s$ is measured in cycles per unit time. Cycles per second, the most common measure in engineering, are called hertz.

Because the study of cycles will involve time, we will naturally have to take into account the interval Δt between observations, often known as the *sampling interval*, since we will assume a series observed at discrete time points. In theory we can have continuous records, often known as *analog signals*, but we shall assume a digital signal. The traces given in Figures 1 and 2 are examples of two quite different series; Figure 2 is sampled at 100 times per second, while the other, in Figure 1, is sampled annually.

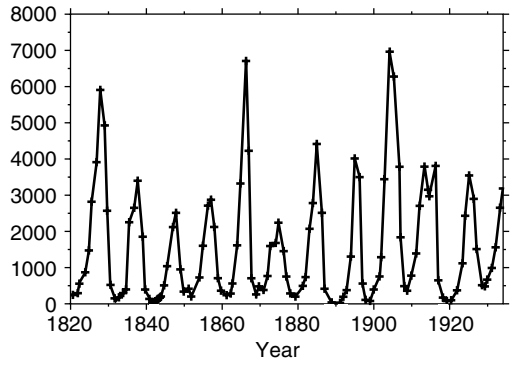

Figure 1 Annual number of lynx trapped, 1821–1934, MacKenzie River

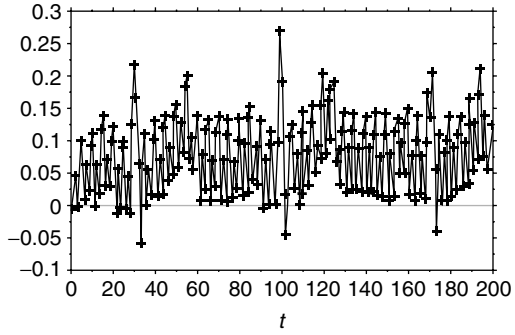

Figure 2 ECG trace, 2 s at 100 Hz

Harmonic Analysis

An obvious idea is to model a time series $X_1, X_2, X_3, \ldots, X_N$, the result of observations at times $\Delta t, 2\Delta t, 3\Delta t, \ldots, N\Delta t$ using regression techniques. If our interest is in cyclic effects, then we can think of trigonometric terms like $\cos(2\pi kt/N\Delta t)$ and $\sin(2\pi kt/N\Delta t)$ as providing the explanatory variables in a multiple regression. Since we may not know the periodic frequencies we could postulate a model of the form

$$X_t = \sum_{k=0}^{[N/2]} \left\{ a_k \cos\left(\frac{2\pi kt}{N\Delta t}\right) + b_k \sin\left(\frac{2\pi kt}{N\Delta t}\right) \right\}, \tag{1}$$

where the constant term becomes the coefficient at zero frequency. Notice that the highest frequency we may observe, the **Nyquist frequency**, is $1/2\Delta t$.

We can imagine performing some kind of stepwise regression procedure to find the nonzero coefficients and, consequently, the real frequencies. An early example of this is [6]. If we do the calculations, then we find that the component of the regression sum of squares explained by $\cos(2\pi kt/N\Delta t)$ is just $\hat{a}_k^2$, the square of the estimated coefficient of the cosine term. In the same way, $\hat{b}_k^2$ is the contribution from the $\sin(2\pi kt/N\Delta t)$ term; see [8] for details. Since these sums of squares give the importance of the corresponding frequency all we have to do is to plot

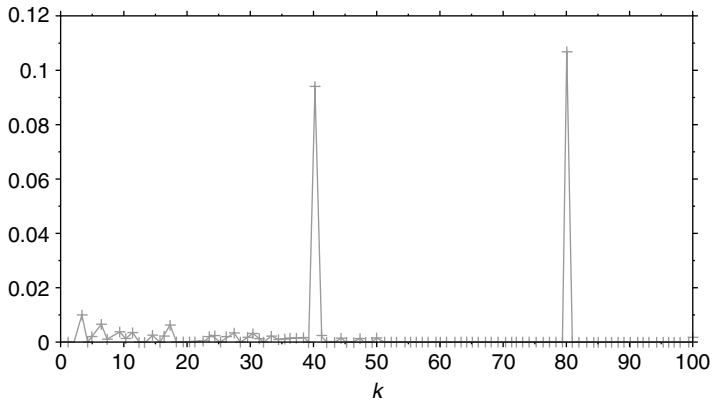

Figure 3 Periodogram of ECG series

the *periodogram*, $P(2\pi k/N\Delta t) = \hat{a}_k^2 + \hat{b}_k^2$, against $2\pi k/N\Delta t$ or, more simply, k. If the plot has a peak at k, then this implies that the corresponding frequency may well correspond to a periodic effect. Thus a spike at frequency $2\pi k/N\Delta t$ implies an interesting cyclic effect with frequency $k/N\Delta t$ (or period $N\Delta t/k$).

In Figure 3 the periodogram of an ECG trace, we see peaks in the periodogram at $k = 40$ and $k = 80$ indicating possible cyclic effects, one with period $200/40 = 5$ hundredths of a second or 0.05 s and another of 0.025 s.

Using the periodogram becomes even more attractive when we find, after some algebra, that the coefficients a_k and b_k have particularly simple forms. If we write our model in the usual complex form

$$X_t = \sum_{k=0}^{N/2} \left[a_k \cos\left(\frac{2\pi kt}{N\Delta t}\right) + b_k \sin\left(\frac{2\pi kt}{N\Delta t}\right) \right] = \sum_{k=0}^{N/2} \left\{ c_k \exp\left[i\left(\frac{2\pi kt}{N\Delta t}\right)\right]\right\}, \quad (2)$$

where $c_k = a_k + ib_k$ so that the periodogram is $|c_k|^2 = a_k^2 + b_k^2$ and in addition

$$c_k = \left(\frac{2}{N}\right)^{1/2} \sum_{t=1}^{N} X_t \exp\left(-\frac{2\pi kt}{N\Delta t}\right), \quad k = 0, 1, \ldots, \left[\frac{N}{2}\right]. \quad (3)$$

These complex trigonometric sums are widely used in engineering and signal processing where they are known as discrete Fourier transforms, or DFTs. These are popular because the coefficients c_k or, equivalently, the a_k and b_k give a unique description of the series; that is, if we know the $c_0, c_1, \ldots, c_N$ then we can reconstruct the original series since one can show that

$$c_k = \left(\frac{2}{N}\right)^{1/2} \sum_{t=1}^{N} X_t \exp\left(-\frac{2\pi kt}{N\Delta t}\right). \quad (4)$$

Many spectral calculations are based on the DFT of a series and because of the importance of DFTs, a fast and efficient method of computing them, known as the **Fast Fourier transform (FFT)**, has been developed.

We have seen that the coefficients c_k express the contribution of periodic components at differing frequencies to the observed series. This can be useful in modifying a series. If we consider (4), we could modify a series by setting the coefficient c_k to zero for frequencies of some chosen value f_0 thus eliminating higher frequency oscillations. After using (4) to recover the (modified) X_t using the modified c_ks, the resulting series with just the lower frequency contributions will be smoother. To demonstrate the effect of the just lower frequencies we set all the c_ks for the ECG data to zero after the 41st. The resulting plot in Figure 4 shows the effect of this operation. For a comprehensive account of DFTs see [9] or [16].

Angular Frequencies and Notation

We have used conventional frequencies f and have ended up with some quite complex formulas. To

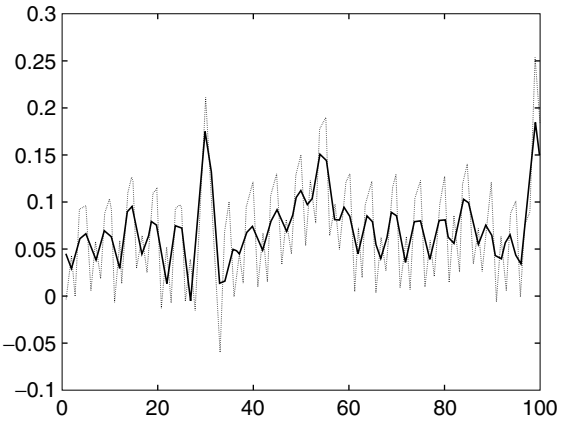

Figure 4 First 100 values of smoothed ECG trace

make matters more confusing, mathematical texts use angular frequencies, ω, measured in radians per unit time. This approach has the advantage of simplifying the formulas and is widely used in the (nonengineering) literature, so giving a more uniform notation. We shall use angular frequencies from now on and we will also simplify matters by assuming that sampling interval Δt is one. This means that we use the sampling times as the basic time measurement. To convert from f measured in cycles per unit time to angular frequencies ω is simple, we use $\omega = 2\pi f$, while in the other direction $f = \omega/2\pi$.

The Concept of the Power Spectrum

The clear and rather useful connections between the observed series and sums of trigonometric terms in the harmonic analysis above hint at a more intimate connection. Suppose we modify the expression in (2),

$$X_t = \sum_{k=0}^{p} \{a_k \cos \omega_k + b_k \sin \omega_k\}, \qquad (5)$$

and think of the $\{a_k\}$ and $\{b_k\}$ as zero mean sequences of independent random variables having variances σ_j^2. We can regard a model of this form as an attempt to explain the signal X_t in terms of contributions at the "angular frequencies" $\omega_0, \omega_1, \omega_2, \omega_3, \ldots, \omega_p$. A close analogy is that of a musical instrument; a note played on an instrument is the sum of harmonic vibrations at different frequencies.

We can rewrite (5) as

$$X_t = \sum_{k=0}^{p} \{a_k \cos \omega_k + b_k \sin \omega_k\} = \sum_{k=-p}^{p} z_k \exp(i\omega_k) \qquad (6)$$

for some p, and in angular terms. Here the z's are complex for $0 < |j| < p$, while at the end point $z_p = a_p$. The frequencies ω_{-k} are to be taken as $-\omega_k$, and if we take the obvious step of writing z_{-k} as the complex conjugate of z_k, then we have a nice equation and the novel idea of a "negative frequency".

If we use this complex formulation, then we can show that $\text{var}(X_t) = \sum_{j=0}^{p} \sigma_j^2$, so the variance of the process is made up of contributions from the individual frequencies. Suppose now we imagine that the number of frequency points in our model becomes very large and becomes a continuous range. Then the contributions from individual frequencies will tend to zero and we have a smooth function which describes the distribution of the variability over frequency. This is an exact analogy to the cumulative distribution function of a continuous random variable. We think of the contribution to the total variance made in a *frequency band* rather than at a specific frequency, thus the band $[\omega, \omega + \delta\omega]$ contributes $h(\omega)\delta\omega$ to the total variation. Notice we have assumed that there is no dominant frequency contributing a finite amount of power and the contribution *from any point frequency* is zero. This function h is called the power *spectrum*, and describes the amount of power contributed to the variance of the series in a narrow band.

The reader should keep in mind that the *h need not be a smooth and continuous function*. If a frequency ω contributes a finite amount of power, then the spectrum will have a singularity or peak at that frequency ω; indeed, a major use of the spectrum is to locate the peak and hence find to the frequencies which give finite power.

Properties of the Spectrum

For any second-order *stationary time series* we can define a power spectrum $h(\omega)$ defined on $-\pi \leq \omega \leq \pi$ and

1. The power spectrum $h(\omega)$ defines the amount of "power" or the contribution to the total variance made by frequencies in the band $[\omega, \omega + \delta\omega]$.

2. Harmonic components with finite power produce spikes or delta functions in $h(\omega)$.
3. The spectrum is symmetric (for real series), i.e. $h(\omega) = h(-\omega)$.
4. In the case where the power spectral $h(\omega)$ has no spikes we can show that the spectrum $h(\omega)$ and the autocovariance at lag k, $\gamma(k)$, are related by

$$h(\omega) = \frac{1}{2\pi} \sum_{k=-\infty}^{\infty} \gamma(k) \cos k\omega, \quad -\pi \leq \omega \leq \pi, \tag{7}$$

$$\gamma(k) = \int_{-\pi}^{\pi} h(\omega) \exp(-ik\omega)\, \mathrm{d}\omega, \quad k = 0, 1, 2, \ldots. \tag{8}$$

For real processes we can simplify a little, because $\gamma(k) = \gamma(-k)$, to give

$$h(\omega) = \frac{1}{2\pi} \sum_{k=-\infty}^{\infty} \gamma(k) \cos k\omega, \quad -\pi \leq \omega \leq \pi. \tag{9}$$

So if we have the autocovariances we can (with difficulty) calculate the spectrum, and vice versa. The implication is that all the information in the autocovariances is also contained in the spectrum, and vice versa. Some examples of spectra are:

1. A white noise process (*see* **Noise and White Noise**). Now $h(\omega) = \sum_{k=-\infty}^{\infty} \gamma(k) \cos k\omega$ for $-\pi \leq \omega \leq \pi$ and the autocovariances are zero apart from the first which is σ^2 so $h(\omega) = \sigma^2/2\pi$, a flat spectrum.
2. A first-order autoregressive (AR) model $X_t = \alpha X_{t-1} + \varepsilon_t$, where $\{\varepsilon_t\}$ is white noise (*see* **ARMA and ARIMA Models**). Using the autocovariances and some algebra we get

$$h(\omega) = \frac{\sigma^2}{2\pi(1 + \alpha^2 - 2\alpha \cos \omega)}.$$

3. A moving average (MA) process, say $X_t = \varepsilon_t - \beta\varepsilon_{t-1}$

$$h(\omega) = \frac{\sigma^2(1 + \beta^2 - 2\beta \cos \omega)}{2\pi}.$$

The flat white noise spectrum shows that the contributions to the variance are equally distributed across the entire frequency range, while for the AR model, here with parameter 0.5, the contributions are greater from the low frequency and hence long period end. This would imply that there are rather weak short period effects and in consequence a smoother series than white noise. The MA spectrum, again with a parameter of 0.5, shows the opposite effect; the power is concentrated towards the high frequency end of the frequency range and in consequence we expect a strong high frequency, i.e. short period effects giving an irregular appearance to a realization generated by such a model. (See Figure 5.)

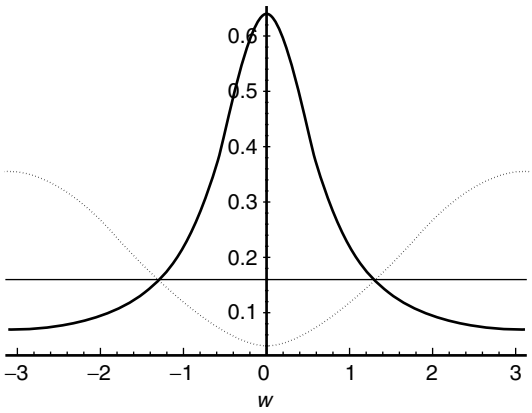

Figure 5 Three power spectra

The Spectral Representation

Looking back at (6) we have written the series as a sum of complex random variables of the form $X_t = \sum_{k=-p}^{p} z_k \exp(\omega_k t)$. One might ask: What happens to this as the number of individual frequencies becomes infinite? We can handle this by defining a stochastic process $Z(\omega)$ which is in some sense the accumulation of the z_js up to frequency ω. We take the limiting form as $X_t = \int_{-\pi}^{\pi} \exp(i\omega t)\, \mathrm{d}Z(\omega)$, where the process $Z(\omega)$ satisfies $\mathrm{E}[\mathrm{d}Z(\omega)\, \mathrm{d}Z(\phi)] = 0$ when $\omega \neq \phi$ and $\mathrm{E}[|\mathrm{d}Z(\omega)|^2] = h(\omega)\, \mathrm{d}\omega$.

This representation, known as the *spectral representation*, is mainly of technical interest for those who study the theory of spectra.

Linear Filters

Suppose we have a series $\{X_t\}$ which passes into a "black box", which produces $\{Y_t\}$ as output, rather as in the schematic in Figure 6. We could regard the

Figure 6 Black box

effect of the box as an operation on the input giving output, say $Y_t = \mathcal{L}X_t$. This would model many common situations; for example, the impact of a bump on the road is modified by the suspension system to give an output to the car occupants. The model is so general that it is difficult to handle, so we make two restrictions: (i) that the relationship is *linear*, and (ii) that the relationship is *invariant* over time. While it is not obvious, these restrictions mean, in effect, that for any t, Y_t is a weighted linear combination of past and future values of the input, namely

$$Y_t = \sum_{j=-\infty}^{\infty} a_j X_{t-j}, \quad \text{with} \quad \sum_{j=-\infty}^{\infty} a_j^2 < \infty. \qquad (10)$$

For technical details, see, for example, [11].

We call the relationship in (10) a *linear filter* and much of time series analysis is concerned with the study of such filters. Their virtue is that the relationship between the input and output *spectra* is simple. If the input series $\{X_t\}$ has a power spectrum $h_x(\omega)$ and the output $\{Y_t\}$ a corresponding spectrum $h_y(\omega)$, then they are related by

$$h_y(\omega) = \left| \sum_{j=-\infty}^{\infty} a_j \exp(-i\omega j) \right|^2 h_x(\omega). \qquad (11)$$

If we write $h_y(\omega) = |\Gamma(\omega)|^2 h_x(\omega)$, where $\Gamma(\omega) = \sum_{j=-\infty}^{\infty} a_j \exp(-ij\omega)$, then the function $\Gamma(\omega)$ is called the *transfer function* or the *frequency response function*, while $|\Gamma(\omega)|$ is often called the *amplitude gain*. The squared value, $|\Gamma(\omega)|^2$, is known as the *gain* or the *power transfer function* of the filter. The argument $\arg\{\Gamma(\omega)\}$ is the *phase gain* or just the *phase*. There is rather a rich variety of nomenclature since filters are widely used in many fields, especially in engineering.

We can see the value of this result in a simple case. Suppose we apply a **moving average** to a series, say a five-point moving average:

$$Y_t = \frac{X_{t-2} + X_{t-1} + X_t + X_{t+1} + X_{t+2}}{5}$$

$$= \frac{1}{5} \sum_{j=-2}^{2} X_{t-j}.$$

We know that this will remove a cycle in the data of period 5. Now we can investigate its properties using the transfer function. We can work out the transfer function as follows:

$$\begin{aligned} 5\Gamma(\omega) &= \exp(-2i\omega) + \exp(-i\omega) + 1 \\ &\quad + \exp(i\omega) + \exp(2i\omega) \\ &= 1 + 2\cos\omega + 2\cos 2\omega, \end{aligned}$$

and the squared gain is plotted in Figure 7. If this filter is applied to a series with a cycle of period 5, i.e. frequency $\omega = 2\pi/5$, then the resulting output spectrum, given by $h_y(\omega) = |\Gamma(\omega)|^2 h_x(\omega)$, will have a zero at this frequency and in consequence the output series will not contain this cyclic effect. Thus, as we expect, the moving average is a filter that removes cycles of period 5. In addition we see from Figure 7 that low-frequency (long-period) effects are not diminished, while high-frequency terms are reduced by the filter, so the filter will also smooth the series and will have only a small effect on long-term, low-frequency, components.

The filter above describes an action in the time domain in frequency terms, but in some circumstances it is natural to work in the other direction. Thus we might decide that the ECG trace could be distorted by the effects of the mains frequency (60 Hz) in our recording instrument. To eliminate this effect we would try to find a filter with a gain which is zero in a band around the 60 Hz mark. To find a

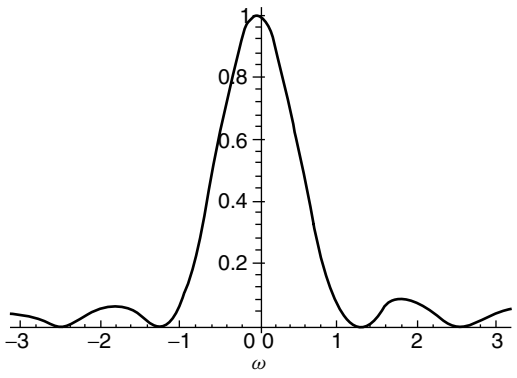

Figure 7 Squared gain for a five-point moving average

filter with a gain specified in this way requires some work (see [4]).

We can also make the black box serve our own purposes. Suppose our black box is a measuring instrument with the output signal being our experimental result. Suppose, further, that the instrumentation has an effect which distorts the observed signal. We can eliminate this effect by finding the gain due to the instrument. To do this we input a signal with a known spectrum, say a flat white noise spectrum, $f_{\mathrm{w}}(\omega)$, and find the output spectrum, $f_{\mathrm{o}}(\omega)$. The gain due to the system is then just the ratio of these two spectra, giving us the response of the instrument. This is rather like seismic surveying where an explosion provides an input signal which passes though rock while the reflected noise gives an output. The aim is to deduce the properties of the black box, the rock though which the signal has passed.

The design of filters is of considerable importance and much attention has been paid to the problems involved. See [4, 5], and [13].

Estimation of the Power Spectrum

We have discussed the spectrum and its uses but have avoided any statistics. We now consider estimation of the power spectrum. The obvious approach is to replace the autocorrelations in definition (9) by their estimates, $r(s)$, giving

$$\hat{h}(\omega) = \frac{1}{2\pi} \sum_{s=-m}^{m} r(s) \cos(s\omega), \tag{12}$$

where m is some suitable number of autocorrelations. Depending on our choice of covariance estimates we find that this is, approximately, a multiple of the periodogram.

Unfortunately, the periodogram is a poor estimate of the power spectrum. It is not a consistent estimator and because its values at adjacent frequencies are independent it is an erratic fluctuating function. Since the periodogram fluctuates wildly, one possibility is to smooth the function to make it more tractable. This nonparametric or windowed approach (*see* **Window Estimate**) uses as an estimate

$$\hat{h}(\omega) = \frac{1}{2\pi} \int_{-\pi}^{\pi} W(\omega - \theta) I_N(\theta)\, \mathrm{d}\theta. \tag{13}$$

The window $W(\theta)$ is a suitably chosen function, with $\int_{-\pi}^{\pi} W(\theta)\ \mathrm{d}\theta = 1$ and

$$I_N(\omega) = \frac{1}{2\pi N} \left| \sum_{t=1}^{N} X_t \exp(-it\omega) \right|^2$$

is the (modified) periodogram. We choose the functions $W(\theta)$ which are concentrated around zero and which decay to zero as $|\omega|$ becomes large. In fact, since the periodogram is calculated at discrete frequency points we should really have a sum $(1/N) \sum_{j=i}^{N} W(\omega - \omega_j) I_N(\omega_j)$, the idea being to average the periodogram ordinates near the frequency of interest, ω. It is rather convenient, however, to use the integral form as a notation, and this appears in much of the literature.

The problem is to select the window function $W(\theta)$ to ensure a reasonable estimate. For a sharply peaked function we can approximate crudely as follows:

$$\mathrm{E}[\hat{h}(\omega)] \approx h(\omega) \int_{-\pi}^{\pi} W(\theta)\ \mathrm{d}\theta, \tag{14}$$

$$\mathrm{var}[\hat{h}(\omega)] \approx 2\frac{h^2(\omega)\pi}{N} \int_{-\pi}^{\pi} W^2(\theta)\ \mathrm{d}\theta, \tag{15}$$

$$\mathrm{cov}[\hat{h}(\omega)\hat{h}(\phi)] \approx \frac{2\pi}{N} \int_{-\pi}^{\pi} (\omega - \theta) \times W(\phi - \theta) h(\theta)^2\ \mathrm{d}\theta. \tag{16}$$

A fairly sharply peaked window is generally a good idea, but if the window has subsidiary peaks, so-called "side lobes", then the estimate at a particular frequency ω may be contaminated by effects at other frequencies. The resulting distortion is called "leakage". To get some feel for the parameters we require we must define the peakedness or bandwidth of the window function. A simple definition of the bandwidth B_{w} is the width of a rectangular window having the same maximum height as $W(\omega)$ and the same area in the frequency of interest. Thus,

$$B_{\mathrm{w}} = \frac{1}{W(0)} \int_{-\pi}^{\pi} W(\theta)\ \mathrm{d}\theta = \frac{1}{W(0)}.$$

Three common windows are given in Table 1. These have differing bandwidths, etc. as can be seen from Table 2. The shape of the window is

Table 1 $W(\theta)$ functions

Unit	Bartlett	Parzen
$\frac{1}{2\pi}\left\{\frac{\sin\left(M+\frac{1}{2}\right)\theta}{\sin(\theta/2)}\right\}$	$\frac{1}{2\pi M}\left\{\frac{\sin(M\theta/2)}{\sin(\theta/2)}\right\}^2$	$\frac{3}{8\pi M^3}\left\{\frac{\sin(M\omega/4)}{\frac{1}{2}\sin(\omega/4)}\right\}^4$

Table 2

Window	Bandwidth	$\frac{\text{Variance}}{h^2(\omega)}$	Equivalent degrees of freedom (EDF)
Unit	$2(\pi/M)$	$2.00(M/N)$	N/M
Bartlett	$2(\pi/M)$	$2M/3N$	$3(N/M)$
Parzen	$8\pi/3M$	$0.54(M/N)$	$3.7(N/M)$

important if we are to have a *well-resolved* estimate, i.e. one that does not change very much over the bandwidth of the window. There have been many arguments over the choice of window; happily in almost all cases there is very little difference.

The choice of M is problematic. Obviously, we would like to make M as large as possible so as to decrease the bandwidth. If we do so, then the variance of the estimate at any frequency must increase. Thus, we need to find some compromise value for M. The usual pragmatic approach is to try values of M between $N/3$ and $N/5$. As M increases, the estimate becomes smoother and we choose a value that seems "smooth enough".

If there is a peak in the spectrum which is of interest and has a bandwidth, say B_f, which we can specify, we can choose the bandwidth $W(\theta)$, B_w, to fit this criterion. We require $B_w < B_f$ and take as a reasonable choice $B_w = \frac{1}{2}B_f$. Without a minimum bandwidth, B_f, any choice of the parameter M is somewhat arbitrary. For a fixed length of series the requirements of bandwidth and variance are contradictory. If one decreases the other increases and we need to come to some sensible compromise.

Lag Windows

We can look at these estimates in a rather different light if we assume that

$$W(\theta) = \frac{1}{2\pi}\sum_{-\infty}^{\infty}\lambda_j \exp(-i\theta j).$$

In this case our spectral estimate can be written

$$h(\omega) = \frac{1}{2\pi}\sum_{j=-M}^{M}\lambda_j r(j)\exp(-i\theta j) \qquad (17)$$

for some $M < N$. As we see, this is a weighted sum of estimated autocorrelations, $r(j)$, the weight sequence $\{\lambda_j\}$ being known as the *lag window*. We can in consequence think of the smoothed periodogram as a weighted sum of covariances, the trick being to choose a suitable sequence $\{\lambda_j\}$ or window $W(\theta)$.

An illustration of the effects of smoothing by changing the parameter in the spectral window is given in Figure 8. Here we look at a fox series of 93 annual observations [9], taken from Hudson Bay records. We use a Parzen window, and M values of $0.1N$, $0.2N$, and $0.3N$ are 9, 18, and 28.

As the truncation point decreases we have, as expected, a smoother estimate. The $0.1N$ seems rather too smooth so we concentrate on the $0.2N$ value. We are being rather arbitrary but having no background information it is not possible to set up any bandwidth arguments to select the appropriate smoothness. We have an apparent peak at frequency 0.26 cycles per year (1.62 radians per year) corresponding to a period of around four years and a subsidiary one at frequency 0.39.

Sampling Properties of the Smoothed Spectral Estimate

Given that the estimates we have considered are weighted sums of periodograms and the periodograms are independent χ^2 variables, we would expect to be able to approximate the distribution of our spectral estimates by a χ^2 distribution. In fact:

1. The spectral estimate $\hat{h}(\omega)$ has a distribution which is approximately χ^2 with ν degrees of

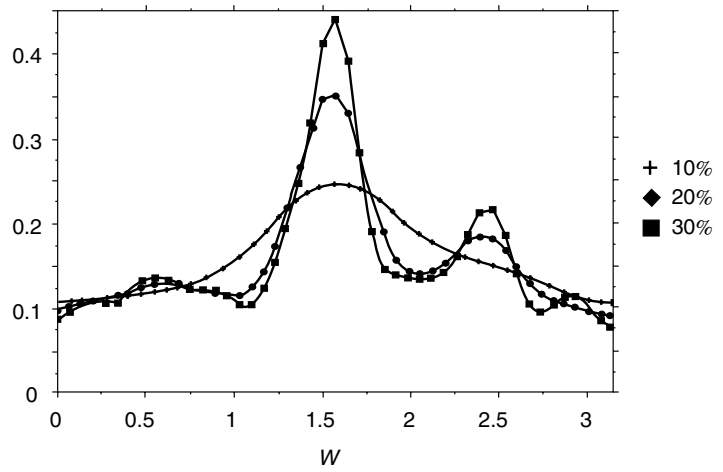

Figure 8 Estimates of spectrum of the fox series with three different truncation points

freedom. The *equivalent degrees of freedom* (EDF), ν, is defined as

$$\nu = 2\frac{\{\mathrm{E}[\hat{h}(\omega)]\}^2}{\mathrm{var}(\hat{h}(\omega))}.$$

These are given in Table 2 for three windows.

2. Spectral estimates at least one bandwidth apart will be assumed to be independent.

Given this approximate distribution it is easy to produce a confidence interval for the $\hat{h}(\omega)$. If we are given α, if a and b are the $\alpha/2$ quantiles of the χ^2 distribution with ν degrees of freedom say, $\Pr(\chi^2 \leq a) = \Pr(\chi^2 \geq b) = \alpha/2$, then the $(1-\alpha)100\%$ confidence interval is $[\nu\hat{h}(\omega)/b, \nu\hat{h}(\omega)/a]$. This gives a *pointwise* estimate rather than a confidence interval over a frequency band. For most cases this will suffice. One can find a band over all frequencies and in this case the reader is referred to [4, Chapter 6].

It is rather more satisfactory to consider $\log h(\omega)$ since the corresponding confidence intervals $[\log\hat{h}(\omega) + \log(\nu/b), \log\hat{h}(\omega) + \log(\nu/a)]$ have uniform width and are much easier to handle.

Tapering and Prewhitening

Two common techniques used for cutting down the bias in periodogram-based estimates are prewhitening and tapering. Prewhitening is a simple concept, the aim being to flatten the spectrum by filtering *before* estimating the spectrum. This is sensible because the most difficult spectra to estimate are those with sharp peaks and large ranges. In practice it is rather more complex since to design a filter to perform this "whitening" we need to know the form of the function we wish to estimate. Nevertheless it can be a valuable option and it is common for an approximate autoregressive model to be fitted to the data and for this to be used as a prewhitening filter.

Tapering is another bias reduction technique and involves adjustment of the data by multiplying by a sequence of constants $\{a_t\}$. The resulting values, $Y_t = a_t X_t$, are then used for the spectral analysis. If we regard the time series as extending into the infinite future, then our finite sample $X_1, \ldots, X_N$ is a tapered version of the infinite series with $h_t = 0$ for t exceeding N and $a_t = 1$ for $t \leq N$. The periodogram is then

$$\frac{1}{2\pi N}\left|\sum_{t=1}^{N} Y_t \exp(-i\omega t)\right|^2$$

$$= \frac{1}{2\pi N}\left|\sum_{t=1}^{N} a_t X_t \exp(-i\omega t)\right|^2$$

and we can show that the smoothed spectral estimate based on the tapered data has an effective smoothing window of the form $\int_{-\pi}^{\pi} D(\theta)W(\omega-\theta)\,\mathrm{d}\theta$, where $D(\omega) = |A(\omega)|^2 / \int_{-\pi}^{\pi} |A(\omega)|^2\,\mathrm{d}\omega$ and $A(\omega)$ is the Fourier transform of the taper sequence. The "finite

taper" above has a rectangular shape whose sharp corner gives a pronounced "ringing". The taper should smooth this corner and reduce the bias in the spectral estimate.

An important and interesting extension of this idea, called *multi-tapering*, was proposed by Thompson [17]. The data are smoothed with a sequence of "orthogonal tapers", i.e. a taper which give rise to uncorrelated periodogram estimates. The resulting periodogram estimates can then be averaged. The method appears to be very successful in reducing bias, especially at low frequencies. For a good account see Percival & Walden [13] and Waldren [18].

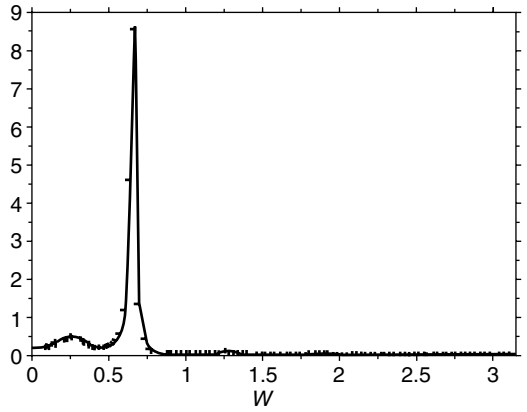

Figure 9 AR spectrum log lynx series

Parametric Spectral Estimates

The most popular parametric estimate for the spectrum are the so-called "autoregressive estimates". These are obtained by fitting an autoregressive model $\Psi(B)X_t = a_t$ and using as a spectral estimate $h(\omega) = \sigma^2/2\pi|\Psi[\exp(-i\omega)]|^2$ with the model estimates of σ and the autoregressive coefficients. A criterion is of course required to select the order (see [10]) of the autoregression and **Akaike's** information criterion (AIC) is often used. Parzen [12] suggested an alternative CAT criterion, while Akaike [1] suggested selecting the order that minimizes the final prediction error (FPE). There is little useful theory to help one choose a criterion (see [10]) while experience shows that the procedures tend to select AR orders in the range $N/3$ to $N/2$ for reasonable results.

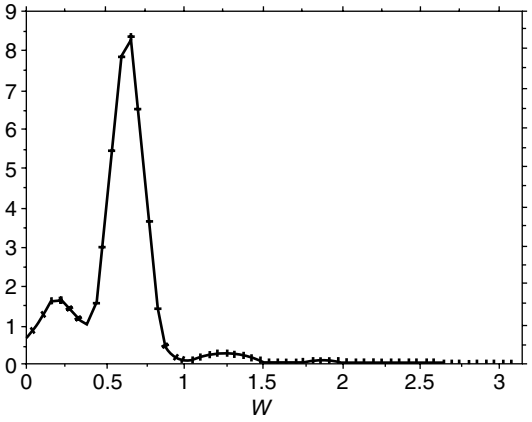

Figure 10 Nonparametric estimate of log lynx spectrum

A relatively simple approach is to use the **Yule–Walker equations** and solve to obtain estimates for the model

$$X_t + \varphi_1 X_{t-1} + \varphi_2 X_{t-2} + \varphi_3 X_{t-3} + \cdots + \varphi_p X_{t-p} = \varepsilon_t$$

and then to estimate σ^2 using the following equation:

$$\gamma(0) + \varphi_1\gamma(1) + \varphi_2\gamma(2) + \varphi_3\gamma(3) + \cdots + \varphi_p\gamma(p) = \sigma^2.$$

The log of the lynx series was chosen as an example (see Figure 9) and the spectrum is given in Figure 10. The least squares estimates gave a model of the form

$$\begin{aligned} X_t &- 1.139X_{t-1} + 0.508X_{t-2} - 0.213X_{t-3} \\ &+ 0.270X_{t-4} - 0.113X_{t-5} + 0.124X_{t-6} \\ &- 0.068X_{t-7} + 0.040X_{t-8} - 0.134X_{t-9} \\ &- 0.185X_{t-10} + 0.311X_{t-11} = \varepsilon_t, \end{aligned}$$

with residual variance 0.226. The resulting spectrum is then

$$\begin{aligned} h(\omega) = \frac{0.226}{2\pi}|&1 - 1.139\exp(-i\omega) \\ &+ 0.508\exp(-i2\omega) - 0.213\exp(-i3\omega) \\ &+ \cdots + 0.311\exp(-i11\omega)|^{-2}. \end{aligned}$$

The contrast with the nonparametric estimate is characteristic of the method, see Figures 9 and 10.

While least squares is commonly used to estimate the parameters, a variant known as "maximum entropy" spectral estimation due to Burg [7] is popular: see also [2] and [3] for further details.

Multiple Series

We can extend our spectral techniques to more than one series and, as in the time domain, we get a rich and interesting theory. The drawback is that the complexity increases.

For simplicity we concentrate on the bivariate case, that is with a pair of stationary series X_t, Y_t. This is often written as a vector of the form $\mathbf{X}_t = (X_t, Y_t)$. We assume a zero mean and covariance matrix:

$$\mathbf{C}(k) = \begin{bmatrix} \mathrm{E}[X_t X_{t+k}] & \mathrm{E}[X_t Y_{t+k}] \\ \mathrm{E}[Y_t X_{t+k}] & \mathrm{E}[Y_t Y_{t+k}] \end{bmatrix} = \begin{bmatrix} \gamma_{xx}(k) & \gamma_{xy}(k) \\ \gamma_{yx}(k) & \gamma_{yy}(k) \end{bmatrix}.$$

We also define the *spectral density matrix* $\mathbf{H}(\omega)$ as

$$\frac{1}{2\pi} \sum_{k=-\infty}^{\infty} \mathbf{C}(k) \exp(-ik\omega) = \begin{bmatrix} h_{xx}(\omega) & h_{xy}(\omega) \\ h_{yx}(\omega) & h_{xy}(\omega) \end{bmatrix}.$$

Here $\gamma_{xx}(k)$ and $\gamma_{yy}(k)$ are the autocovariances of each series while $\gamma_{xy}(k)$ and $\gamma_{yx}(k)$ are called the *cross-covariances*. In the same way, $h_{xx}(\omega)$ and $h_{yy}(\omega)$ are the *univariate* or *autospectra*, while $h_{xy}(\omega)$ is the *cross-spectrum*.

From the definition

$$h_{xy}(\omega) = \frac{1}{2\pi} \sum_{k=-\infty}^{\infty} \gamma_{xy}(\omega) \exp(-ik\omega)$$

$$= \frac{1}{2\pi} \sum_{k=-\infty}^{\infty} \gamma_{yx}(-\omega) \exp(-ik\omega) = \overline{h_{yx}(\omega)}$$

since $\gamma_{xy}(k) = \mathrm{E}[X_t,\ Y_{t+k}] = \mathrm{E}[Y_{r-k}, X_r] = \gamma_{yx}(-k)$, so $h_{xy}(\omega)$ and $h_{yx}(\omega)$ are complex conjugates. Because we are dealing with a complex valued quantity, $h_{xy}(\omega)$, it is best to work in one of the traditional representations of complex numbers, either

1. $h_{xy}(\omega) = c_{xy}(\omega) - iq_{xy}(\omega)$, where c_{xy} is known as the *co-spectrum* and q_{xy} as the *quadrature spectrum*, or
2. The alternative polar form $h_{xy}(\omega) = \alpha_{xy}(\omega) \exp[i\phi_{xy}(\omega)]$, where $\alpha_{xy}(\omega)$ is the *amplitude spectrum* and $\phi_{xy}(\omega)$ the *phase spectrum*.

Most people find it useful to work with *coherency spectrum*, or *coherency*,

$$c(\omega) = \frac{|h_{xy}(\omega)|}{[h_{xx}(\omega) h_{yy}(\omega)]^{1/2}}$$

and the *gain*

$$G_{xy}(\omega) = \left| \frac{h_{xy}(\omega)}{h_{xx}(\omega)} \right|.$$

We use the cross-spectrum in its various guises, usually the coherency or its modulus and gain, to understand the relationship between series.

The modulus of the coherence measures the strength of the relationships between corresponding frequency components of the two series in almost exactly the same way as a correlation coefficient. The gain is the analog of the regression of the frequency ω component of the first series on the second. The lead or lag of this relationship is measured by the slope of the phase.

We can show that the coherence is unchanged under linear transformations. If $\mathbf{Z}_t$ is a filtered version of $\mathbf{X}_t$, say

$$\mathbf{Z}_t = \begin{pmatrix} a_{11}(B) & a_{12}(B) \\ a_{21}(B) & a_{22}(B) \end{pmatrix} \mathbf{X}_t,$$

then the coherency does not involve any of the filter functions $a_{ij}(z)$.

For a rather simpler case, suppose $X_t = \beta Y_{t-d} + \varepsilon_t$. Then $\phi_{xy}(\omega) = -\omega d$. This illustrates an important point: when there is a time delay the phase spectrum is a linear function of frequency with the slope representing the size of the delay. If we go further and assume that the ε_t process is uncorrelated with the Y_t series, then

$$\gamma_{yx}(k) = \mathrm{E}[Y_t X_{t+k}] = \mathrm{E}[Y_t\{\beta Y_{t+k} + \varepsilon_{t+k}\}]$$

$$= \beta \gamma_{yy}(k) \quad \text{for } k \neq 0,$$

so $h_{xy}(\omega) = \beta h_{yy}(\omega)$, while $h_{xx}(\omega) = \beta^2 h_{yy}(\omega) + \sigma^2/2\pi$, and hence the coherency is $1/\{1 + \sigma^2/(2\pi\beta)\}^{1/2}$. As we might expect, this decreases as the variance of the added noise increases.

One important application to linear relationships with extra noise is a slight extension of the above.

Suppose we have $Y_t = \sum_{S-\infty}^{\infty} g_s X_{t-s} + \eta_t$. Then we have $h_{yx} = G_{yx}(\omega)h_{xx}(\omega)$, where G_{yx} is the gain defined above. In addition, if X_t and the noise series are uncorrelated, then

$$h_{yy}(\omega) = |G_{yx}(\omega)|^2 h_{xx}(\omega) + h_{\eta\eta}(\omega).$$

Now $\phi_{yx}(\omega) = \tan^{-1}\{h_{yx}(\omega)\}$, while the gain $|h_{yx}(\omega)|$ is $|G_{yx}(\omega)|h_{xx}(\omega)$. Thus the transfer function, *complete with the gain and the phase information*, can be computed from the spectral matrix.

As one might expect, there are rather more problems involved in estimating the spectral matrix than in estimating the individual spectra. Another problem, the alignment of the series, arises because the cross-covariance is not necessarily an even function and hence its maximum need not occur at the zero lag. For details of a suitable procedure, see [14].

Evolutionary Spectra

We have only considered stationary series when dealing with spectra. The extension of the idea to types of nonstationary processes is possible, but raises some interesting problems. Suppose we have a nonstationary process and we consider a representation of the form

$$X_t = \int_{-\pi}^{\pi} \exp(i\omega t) A_t(\omega)\, \mathrm{d}Z(\omega),$$

where for each value of ω the sequence of functions $\{A_t(\omega)\}$ has a (generalized) Fourier transform. The evolutionary spectral density function $h_t(\omega)$ is defined as

$$h_t(\omega)\, \mathrm{d}\omega = |A_t(\omega)|^2 \mathrm{E}[|\, \mathrm{d}Z(\omega)|^2], \quad -\pi < \omega < \pi.$$

The evolutionary spectrum gives the decomposition of total power in the neighborhood of time point t.

To reduce the possibilities for the representations of the series, Priestley suggests that $A_t(\omega)$ should be a slowly changing function of time with a Fourier transform which is concentrated about zero. This leads to the concept of a semistationary series, which is one for which such a representation exists.

The estimation of evolutionary spectra is a two-stage process. First the series is filtered using a filter

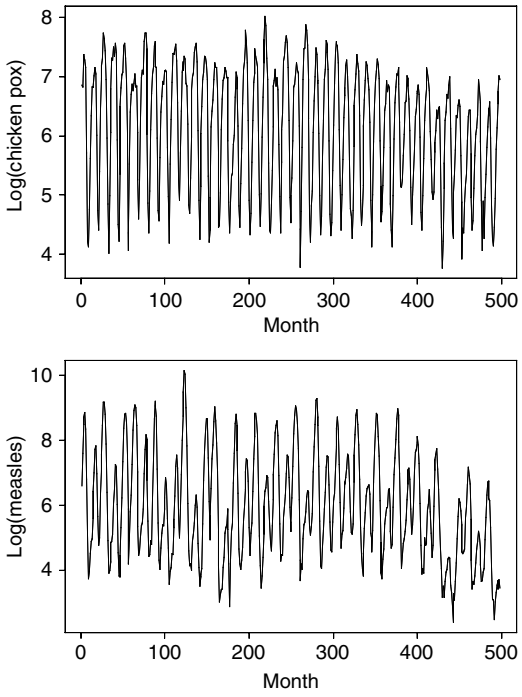

Figure 11 Log series

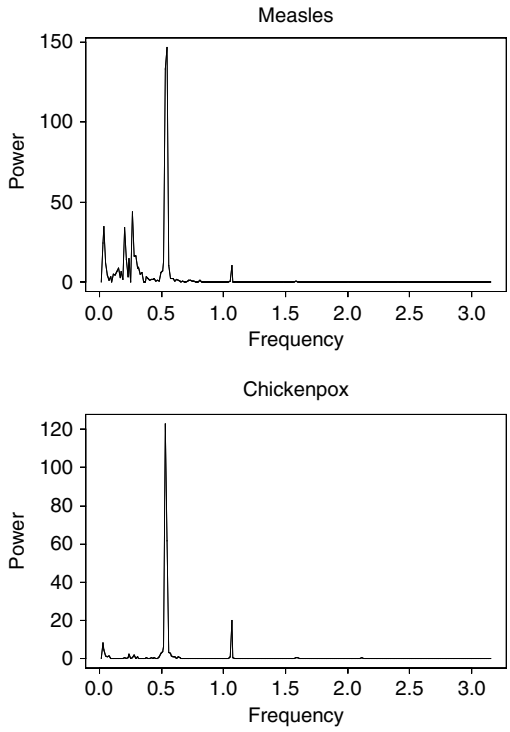

Figure 12 Periodograms

centered on a frequency ω_0, then the output of the filter is averaged in the neighborhood of time t to give the appropriate estimate. A good exposition is given by Priestley [15] who has been responsible for much of the development.

We use the techniques we considered above on two series, the reported monthly cases of measles and the reported monthly cases of chickenpox (1931–1972) in New York City. In fact, both of the observations are fairly skewed and we shall work with the log of both series.

There is a fairly obvious annual cycle in both series as can be seen from series plots and the periodograms; see Figures 11 and 12.

If we filter out a 12-month cycle in each series both spectra have spikes indicating power at period 240 months.

This seems quite curious, we almost include cross-correlations with the sunspot series! What we have done is to look at the cross spectrum between the two series; see Figure 13. As we expect at high frequencies (short periods) the high coherence indicates that the two series are very similar, they are both like noise.

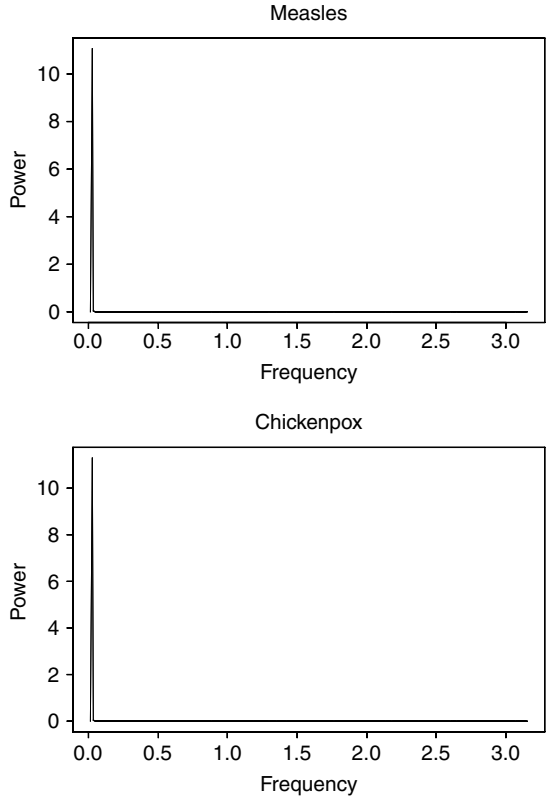

Figure 13 Spectra of smoothed series

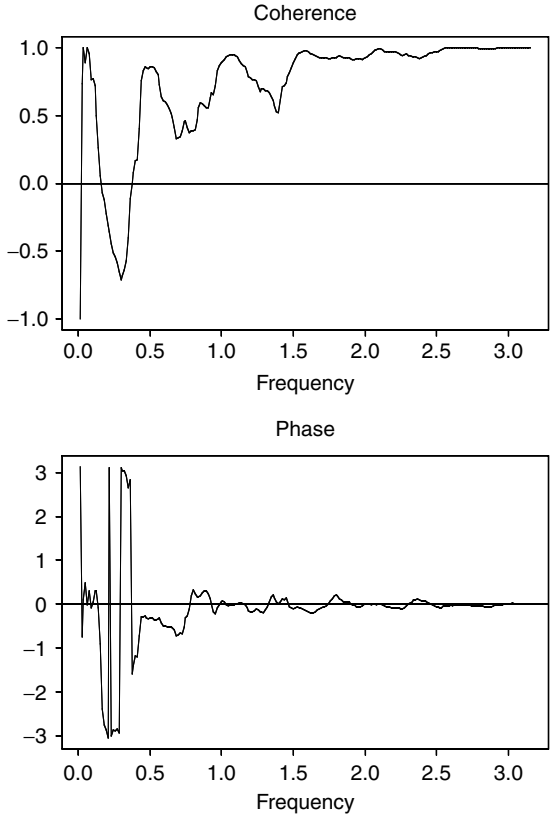

Figure 14 Coherency and phase

However, there is an interesting long period effect in the coherence with a corresponding phase change; see Figure 14. This probably reflects the fact that the series are very similar in the long term, this is the common 10-year effect while in the short term they both look random.

G.J. JANACEK

Sphericity Test

The equal-density contours of a p-variate normal distribution (*see* **Multivariate Normal Distribution**) with **covariance matrix** $\mathbf{\Sigma}$ reduce to hyperspheres in the p-dimensional real space $\mathbb{R}^p$ with the mean vector $\boldsymbol{\mu}$ as the center, when $\mathbf{\Sigma} = \sigma^2\mathbf{I}_p$. The most common test of the sphericity hypothesis $\mathrm{H}_0 : \mathbf{\Sigma} = \sigma^2\mathbf{I}_p$ against $\mathrm{H}_1 : \mathbf{\Sigma} \neq \sigma^2\mathbf{I}_p$, where $\boldsymbol{\mu}$ and σ^2 are unknown, is the **likelihood ratio test**, based on a random sample of size N from the p-variate normal distribution $N_p(\boldsymbol{\mu}, \mathbf{\Sigma})$ with mean $\boldsymbol{\mu}$ and covariance matrix $\mathbf{\Sigma}$, which rejects H_0 when

$$\lambda \equiv \frac{|\mathbf{S}|^{N/2}}{(\mathrm{tr}(\mathbf{S})/p)^{Np/2}}$$

is too small, where $\mathbf{S}$ is the sample covariance matrix. Here $\mathrm{tr}(\mathbf{S})$ means the trace of the matrix $\mathbf{S}$. This test was proposed by Mauchly in 1940 [11].

For $p = 2$, the distribution of $W \equiv \lambda^{2/N}$ is **beta** $((n-1)/2, 1)$, where $n = N - 1$; see Mauchly [11] and Anderson [1]. Steffens [16] has suggested a **Student's *t* test** for this case. The exact null distributions of W for $p = 3$, 4, and 6 are obtained by Consul [3]; see also Mathai & Rathie [10], and John [6]. The exact null distribution of W in a series form has been derived by Nagarsenker & Pillai [13] for general p. The asymptotic expansion of the distribution of $n\rho \log W$ under H_0, where $\rho = 1 - (2p^2 + p + 2)/6pn$, is given in Anderson [1]; the first term of this expansion is the **chi-square distribution** with $p(p+1)/2 - 1$ **degrees of freedom** (df).

The nonnull distribution of W is obtained by Girshick [4] in the two-root case, and by Pillai & Nagarsenker [14] and Khatri & Srivastava [7] in the general case. The asymptotic distribution of W under H_1 is given by Sugiura [17] and Gleser [5].

Kiefer & Schwarz [8] have shown that the above test is Bayes and admissible (*see* **Decision Theory**). Sugiura & Nagao [19] have proved its **unbiasedness**. A special monotonicity property of its **power** function is obtained by Carter & Srivastava [2].

The locally best invariant test of H_0 against H_1 rejects H_0 if $T = \mathrm{tr}(\mathbf{S}^2)/(\mathrm{tr}\ \mathbf{S})^2$ is too large; see Sugiura [18] and John [6]. The asymptotic expansion of the null distribution of T is given by Nagao [12]. Sugiura [18] has obtained the asymptotic distribution of T under H_1.

The **union–intersection principle** of Roy leads to a test that rejects H_0 if $(l_1 + l_p)^2/4l_1l_p$ is too large, where l_1 and l_p are the extreme roots of $\mathbf{S}$; see Srivastava & Khatri [15]. Percentage points for the null distribution of l_1/l_p are given by Krishnaiah & Schuurmann [9] for some values of the parameters.

The sphericity test discussed above can be used to test that the covariance matrix $\mathbf{\Sigma} = (\sigma_{ij})$ has the following form:

$$\sigma_{ij} = \begin{cases} \sigma^2, & \text{for } i = j, \\ \rho\sigma^2, & \text{for } i \neq j. \end{cases}$$

Such a problem arises in a repeated measure analysis (*see* **Longitudinal Data Analysis, Overview**). To use the sphericity test, note that the above structure of $\mathbf{\Sigma}$ is equivalent to the following: $\mathbf{C}'\mathbf{\Sigma}\mathbf{C} = (1-\rho)\sigma^2\mathbf{I}_{p-1}$, where $\mathbf{C}$ is a $p \times (p-1)$ matrix, the columns of which form an orthonormal basis of the linear space orthogonal to the linear space spanned by the unit vector $\mathbf{1}$ (*see* **Orthogonality**).

SOMESH DAS GUPTA

Spiegelman, Mortimer

Born: December 10, 1901, in Brooklyn, New York.
Died: March 25, 1969, in New York.

Mortimer Spiegelman was an important contributor to biostatistics, particularly in the areas of **demography** and public health. His major contribution to the field of public health and epidemiology came toward the end of his career when he conceived of, coordinated, edited, and carried to a successful conclusion the publication of a series of monographs sponsored by the **American Public Health Association** (APHA) and published by the Harvard University Press. Each monograph pertained to a specific set of diseases in which the 1960 **Census** was used in a standard way as the denominator for **rates** of disease. In his role as editor of this series he used his considerable powers of persuasion with the authors of the monographs to ensure comparability among them and to make certain that the work on each was completed. Sixteen monographs resulted from this effort, covering a wide range of topics as evidenced by the following titles: *Accidents and Homicides; Infectious Diseases; Trends and Variations in Fertility in the U.S.; Infant, Perinatal, Maternal, and Childhood Mortality; The Epidemiology of Oral Health; Tuberculosis; Syphilis and Other Venereal Diseases; Cardiovascular Diseases in the U.S.; The Frequency of Rheumatic Diseases; Digestive Diseases; Mental Disorders and Suicide; Cancer in the U.S.; The Epidemiology of Neurological and Sense Organ Diseases; Mortality and Morbidity in the U.S.; Differential Mortality in the U.S.*

In 1970, the Mortimer Spiegelman Gold Medal Award was established by his family and has been presented annually by the Statistics Section of the APHA to a young statistician (under 40 years of age) who has made important contributions to the field of health statistics. This has been, from the beginning, a coveted award and the list of awardees is most impressive. Many of the awardees are now heads of departments of biostatistics, deans or associate deans of schools of public health, and heads of large statistical agencies. A list of awardees from 1970 to 2001 follows:

1970 Edward Perrin
1971 P.A. Lachenbruch
1972 Manning Feinleib
1973 Joseph Fleiss
1974 Gary Koch
1975 Jane Menken
1976 A.A. Afifi
1977 David Hoel
1978 Ross Prentice
1979 Mitchell Gail
1980 Norman Breslow
1981 Robert F. Woolson
1982 Joel Kleinman
1983 J. Richard Landis
1984 Stephen Lagakos
1985 John Crowley
1986 Anastasios Tsiatis
1987 L.J. Wei
1988 Thomas Fleming
1989 Colin Begg
1990 Kung-Yee Liang
1991 Scott Zeger
1992 Ronald Brookmeyer
1993 Martin Tanner
1994 Louise Ryan
1995 Christopher Portier
1996 Jeremy Taylor
1997 Margaret Pepe
1998 Peter Bacchetti
1999 Danyu Lin
2000 Bradley Carllin
2001 Daniel Weeks

Mr Spiegelman was a native of Brooklyn, New York, and received a masters of engineering degree from the Polytechnic Institute of Brooklyn in 1923 and a masters of business administration degree from Harvard University in 1925. He spent 40 years on the staff of the Metropolitan Life Insurance Company where he published many articles and volumes that attained national and international recognition. He coauthored with Dublin and Lotka *The Money Value of Man* and *Length of Life*, both of which have been standard reference volumes. Although his employment was in an organization that was concerned primarily with **actuarial** science, his interests were much broader. He published two editions of *Introduction to Demography*, which has been a standard text in demography. The second edition, in particular, is oriented toward the general demographer and student of public health statistics rather than toward the actuary. He did extensive work on

life tables including what he referred to as "segmented generation" mortality. This approach allows one to follow the mortality experience of a given age group over successive 10-year periods as an alternative to analyzing trends in the current mortality. His development of the APHA monograph series further illustrates the breadth of his interests. Mr Spiegelman was a Fellow of the Society of Actuaries, Fellow of the **American Statistical Association**, and Fellow of the American Public Health Association. Each year, upon the presentation of the Mortimer Spiegelman Award, he is remembered again for his extraordinary contributions to public health statistics.

EARL POLLACK

Spline Function

Suppose we have n observations (t_j, y_j), $j = 1, 2, \ldots, n$, where y_j and t_j are related by the model

$$y_j = \mu(t_j) + e_j, \tag{1}$$

where $\{e_j\}$ are zero mean uncorrelated random variables with common variance σ^2. Here $\mu(t)$ is usually known as the **regression** function. If $\mu(t) = \sum_{j=1}^{p} \beta_j x_j(t)$, where $x_1(t), x_2(t), \ldots, x_p(t)$ are known functions, then the estimation of $(\beta_1, \beta_2, \ldots, \beta_p)$ given $(y_1, y_2, \ldots, y_n)$ is a classic **multiple regression** problem. This is known as a parametric regression problem. In the **nonparametric regression** context one assumes that $\mu(t)$ belongs to some infinite dimensional collection of functions. For example, μ may be differentiable with square integrable second derivatives. One can estimate $\mu(t)$ by considering the estimators of the form

$$\mu_\lambda(t) = \sum_{j=1}^{n} K(t, t_j, \lambda) y_j, \tag{2}$$

where $K(t, t_j; \lambda)$, $j = 1, 2, \ldots, n$, is a collection of weight functions. The weights are derived from a single function $K(\cdot)$ that is independent of the design. These are called *kernel estimators*. A detailed discussion of these estimators can be found in the book by Eubank [1, chapter 4]. An alternative approach is the spline approach.

Smoothing splines are related to **polynomial regression**. Consider model (1), and assume $a \le t_1 \le \cdots \le t_n \le b$, and $\mu(t)$ belongs to $W_2^{(m)}[a, b]$. Hence $W_2^{(m)}[a, b]$ is the set of all functions on $[a, b]$, where the jth derivative, $\mu^j(t)$, $j = 0, 1, 2, \ldots, m-1$, is absolutely continuous, and $\mu^m(t) \in L_2[a, b]$. One can expand $\mu(t)$ in the form

$$\mu(t) = \sum_{j=0}^{m-1} \theta_j t^j + \mathrm{Rem}(t), \tag{3}$$

where

$$\mathrm{Rem}(t) = [(m-1)!]^{-1} \int_a^b \mu^{(m)}(x)(t-x)_+^{m-1}\, \mathrm{d}x, \tag{4}$$

$(x)_+ = \max\{0, x\}$. If $\mathrm{Rem}(t)$ can be neglected, then estimating $\mu(t)$ reduces to the estimation of the coefficients $\{\theta_j\}$ of the polynomial $\sum_{j=0}^{m-1} \theta_j t^j$. One can show

$$\sup_{t \in [a,b]} |\mathrm{Rem}(t)| \le c[J_m(\mu)]^{1/2},$$

where c depends on m but not on μ. Here $J_m(\mu) = \int_a^b [\mu^{(m)}(t)]^2\, \mathrm{d}t$. We can now find an estimate μ by minimizing $(1/n)\sum_{j=1}^{n} [y_j - f(t_j)]^2$ subject to the condition that $J_m(\mu) \le \rho$ for some $\rho \ge 0$. Here $f \in W_2^{(m)}\{a, b\}$. This is essentially equivalent to estimating μ by minimizing

$$\frac{1}{n}\sum_{j=1}^{n} [y_j - f(t_j)]^2 + \lambda \int_a^b [f^{(m)}(t)]^2\, \mathrm{d}t \tag{5}$$

over $f \in W_2^{(m)}[a, b]$. This is also called the *roughness penalty approach* (see [2]) and $\lambda > 0$, is called the *smoothness parameter*. The function f that minimizes (5) is unique and is a natural spline, and it is clear that splines are related to polynomials. Splines are defined as piecewise polynomials subject to a maximum number of continuity constraints.

A spline of order r with knots of $\zeta_1, \zeta_2, \ldots, \zeta_k$ is defined to be any function

$$g(t) = \sum_{i=0}^{r-1} \theta_i t^i + \sum_{i=1}^{k} \delta_i (t - \zeta_i)_+^{r-1}. \tag{6}$$

This definition of a spline is equivalent to the following specifications:

1. $g(t)$ is a piecewise polynomial of order r on any subinterval $[\zeta_i, \zeta_{i+1}]$;
2. $g(t)$ has $r-2$ continuous derivatives; and
3. $g(t)$ has an $(r-1)$th derivative that is a step function with jumps at $\zeta_1, \zeta_2, \ldots, \zeta_k$.

If we impose further restrictions on $g(t)$ we would arrive at natural splines. A natural spline of order $r = 2m$ with $k = n$ knots at $(\zeta_1, \zeta_2, \ldots, \zeta_n)$ is defined as a polynomial $g(t)$ which satisfies conditions 1–3 and further satisfies the extra condition, namely:

4. $g(t)$ is a polynomial of order m outside $[t_1, t_n]$.

We can define $S^r(t_1, t_2, \ldots, t_k)$ as the set of all functions of the form (6) with knots $(\zeta_1, \zeta_2, \ldots, \zeta_k)$. We note that $(1, t, t^2, \ldots, t^{n-1}, (t-\zeta_1)_+^{n-1}, \ldots (t-\zeta_k)_+^{r-1})$ form the basis of this space. We can denote the collection of all natural splines with knots at

$(t_1, t_2, \ldots, t_n)$ by $S^{2m}(t_1, t_2, \ldots, t_n)$ and this is a subspace of $S^{2m}(t_1, t_2, \ldots, t_n)$.

Let $(x_1(t), x_2(t), \ldots, x_n(t))$ be the basis of $S_1^{2m}(t_1, t_2, \ldots, t_n)$. Then one can write

$$x_j(t) = \sum_{i=0}^{m-1} \theta_{ij} t^i + \sum_{i=1}^{n} \delta_{ij} (t - t_i)_+^{2m-1}, \qquad (7)$$

and the minimizer f that minimizes (5) is of the form [1, p. 205]

$$f_\lambda(t) = \sum_{j=1}^{n} \beta_{\lambda j} x_j(t), \qquad (8)$$

where $\beta_\lambda' = (\beta_{\lambda 1}, \beta_{\lambda 2}, \ldots, \beta_{\lambda n})$ and is the solution of

$$(\mathbf{x}'\mathbf{x} + n\lambda \boldsymbol{\Omega})\boldsymbol{\beta}_\lambda = \mathbf{x}'\mathbf{y}, \qquad (9)$$

$\Omega = (\int_a^b x_i^{(m)}(t)\, x_j^{(m)}(t)\, \mathrm{d}t;\ i, j = 1, 2, \ldots, n)$ and $\mathbf{y}' = (y_1, y_2, \ldots, y_n)$. We note that the above solution depends on the smoothness parameter λ, and one can estimate λ by the method of cross validation. We refer to the books of Green & Silverman [2] and Eubank [1] for actual numerical evaluations, and also to several papers by Wahba referred to in the those books.

One interesting application of the above approach is in the context of **time series** [3, 4]. Suppose we have a zero mean second order discrete parameter Gaussian time series $(x_1, x_2, \ldots, x_n)$. Let $R(s) = \mathrm{cov}(x_t, x_{t+s})$ and let

$$f(w) = \frac{1}{2\pi} \sum_{-\infty}^{\infty} R(s) \exp(isw),$$

and let $g(w) = \ln f(w)$. Consider the problem of estimation of $g(w)$. It is well known that the periodogram $I(w)$, where

$$I(w) = \frac{1}{2\pi n} \left| \sum_{t=1}^{n} x_t \exp(itw) \right|^2$$

provides an **unbiased** estimator of $f(w)$, but it is not a **consistent** estimator (*see* **Spectral Analysis**). Hence one can estimate $f(w)$ by smoothing $I(w)$ using a set of suitably weighted functions. Alternatively, as done earlier, one can use a spline approach [3, 4].

Let us estimate $g(w)$ at the frequencies $w_j = 2\pi j/2n$, $j = -(n-1), \ldots, 0, 1, 2, \ldots, n$. To a good approximation, we can write $I(j) = I(w_j) = f(w_j)U_j$, where U_j, $j = 1, 2, \ldots, n-1$, are independent, identically distributed as chi-square random variables. Let $y_j = \ln I_j + C_j$, $C_j = C$ be the Euler constant for $j = 1, 2, \ldots, n-1$, and $C_0 = C_n = (\ln 2 + C)/\pi$. Then

$$y_j = g(w_j) + \varepsilon_j, \qquad (10)$$

where $\varepsilon_j = \ln U_j + c_j$. The model (10) is similar to (1), and estimating the logarithm of the spectral density is similar to the estimation of $\mu(t_j)$ in (1). We refer to [3] and [4] for further details.

Spline Smoothing

Introduction

Assume we have observations (x_i, y_i), $i = 1, \ldots, n$, on a (one-dimensional) regressor variable x and a response variable y, that follow the model $y_i = r(x_i) + \varepsilon_i$, where the ε_i's are i.i.d. errors and $r(\cdot)$ is an unknown **regression** function. This problem is called a **nonparametric regression** problem if we allow the regression function $r(\cdot)$ to belong to some infinite dimensional collection of functions. For example, we may assume that $r(\cdot)$ is differentiable or differentiable with a square integrable derivative, and so on.

Over the past few decades, several methods for estimating $r(\cdot)$ have been proposed and studied intensively. Among these methods are kernel smoothers, **orthogonal** series estimators, **wavelet** smoothers, and spline smoothers. This entry provides a brief description of the latter by discussing regression splines, smoothing splines, and penalized splines.

Most (if not all) regression smoothing methods mentioned in the previous paragraph can be viewed as trying to estimate the response variable via

$$\hat{y}_i = \hat{a}_1 f_1(x) + \hat{a}_2 f_2(x) + \cdots + \hat{a}_k f_k(x), \quad i = 1, \ldots, n, \tag{1}$$

where the $\hat{y}_i$'s are the fitted values, the $f_i(\cdot)$'s are some basis functions (that depend on the smoothing method used) and the $\hat{a}_i$'s are estimated coefficients. The way the $\hat{a}_i$'s are estimated also differs from method to method. Spline smoothing methods typically use either ordinary **least squares** or **ridge regression** to estimate the coefficients; as basis functions $f_i(\cdot)$, they use (piecewise) polynomials. Note that if the coefficients $\hat{a}_i$'s were calculated by ordinary least squares, then k has the interpretation as being the **degrees of freedom** of the fit; otherwise, it would be necessary to resort to approximate degrees of freedom for the fit.

An example of a spline smoother is given in Figure 1 using the follicle data set from [1]. This data set contains information on the number of ovarian follicles counted from sectioned ovaries of women of various ages. Here, age was used as the regressor variable, and the number of ovarian follicles, on a log scale, as the response variable. The figure shows the data with a smoothing spline superimposed; details on how this was done using the **R** software [32] is given at the end of this entry. From this figure, it is clear that there is a nonlinear relationship between these two variables.

Preliminaries

To fix notation, a **spline function** $s(\cdot)$ of order $p + 1$ with knots at $\tau_1 < \tau_2 < \cdots < \tau_m$ is defined to be any function such that (see also [36])

1. is piecewise polynomial of order $p + 1$ on any subinterval $[\tau_i, \tau_{i+1}]$;
2. has $p - 1$ continuous derivatives; and
3. whose pth derivative is a step function with (possible) jumps at $\tau_1, \ldots, \tau_m$.

An important subset of spline functions, called *natural spline functions*, is defined by one further restriction. If $p + 1 = 2q$ is even, then $s(\cdot)$ is a natural spline if, in addition to conditions 1 to 3, it also fulfills the following condition:

4. $s(\cdot)$ is a polynomial of order q outside of $[\tau_1, \tau_m]$.

For illustrative and theoretical purposes, it is often convenient to parameterize spline functions using the

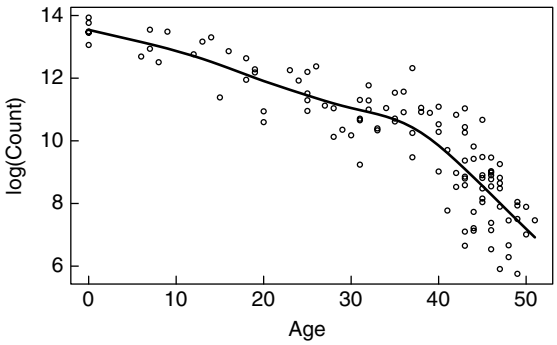

Figure 1 The picture shows a spline smooth fitted to the data on the number of ovarian follicle for women of various ages. The age of the women is depicted on the horizontal axis and the logarithm of the number of ovarian follicles is shown on the vertical axis

truncated power basis:

$$s(x) = \beta_0 + \beta_1 x + \cdots + \beta_p x^p + \sum_{i=1}^{m} \gamma_i (x - \tau_i)_+^p, \tag{2}$$

where $(x - \tau_i)_+ = \max(0, x - \tau_i)$, and $(x - \tau_i)_+^p = \{\max(0, x - \tau_i)\}^p$.

Any spline function of order $p + 1$ with knots $\tau_1, \ldots, \tau_m$ can be expressed in the form (2). This shows that the space of spline functions of order $p + 1$ with knots at $\tau_1 < \tau_2 < \cdots < \tau_m$ is a $m + p + 1$-dimensional space. Hence, since condition 4 imposes $p + 1 = 2q$ constraints, the space of natural spline functions of order $p + 1$ with m given knots is an m-dimensional space.

For practical purposes, it is usually preferable to use other basis functions that have better numerical properties, for example, B-splines (see, among others, [4] and [7]) or the Demmler–Reinsch basis functions (see, among others, [10]). Basis function such as B-splines also provide an easier parameterization of natural splines. To represent natural splines using (2), one would have to impose some awkward constraints on the parameters $\beta_0, \ldots, \beta_p, \gamma_1, \ldots, \gamma_m$.

The next sections discuss some of the main approaches to spline smoothing; more details can be found in the books of Eubank [10], Gu [15], Wahba [48] and some chapters of Schimek [42]. Discussion on spline smoothing techniques can also be found, among others, in [13, 17, 18, 35] and [41], although these books concentrate more on statistical applications of spline smoothing.

Regression Splines

Regression spline smoothing is most conveniently discussed using representation (2). After choosing p (typically $p = 3$) and the locations for the knots, the problem of estimating $r(\cdot)$ reduces to a **multiple linear regression** problem with design matrix,

$$X = \begin{pmatrix} 1 & x_1 & \ldots & x_1^p & (x_1 - \tau_1)_+^p & \ldots & (x_1 - \tau_m)_+^p \\ 1 & x_2 & \ldots & x_2^p & (x_2 - \tau_1)_+^p & \ldots & (x_2 - \tau_m)_+^p \\ \vdots & \vdots & & \vdots & \vdots & & \vdots \\ 1 & x_n & \ldots & x_n^p & (x_n - \tau_1)_+^p & \ldots & (x_n - \tau_m)_+^p \end{pmatrix}. \tag{3}$$

Together with the vector $Y = (y_1, \ldots, y_n)'$ of responses, we can calculate estimates $(\hat{\beta}', \hat{\gamma}') = (\hat{\beta}_0, \ldots, \hat{\beta}_p, \hat{\gamma}_1, \ldots, \hat{\gamma}_m)$ using least squares regression:

$$\underset{\beta,\gamma}{\text{minimize}} \left(Y - X \begin{pmatrix} \beta \\ \gamma \end{pmatrix} \right)' \left(Y - X \begin{pmatrix} \beta \\ \gamma \end{pmatrix} \right).$$

To estimate $r(\cdot)$ at an arbitrary point x_0, we just evaluate

$$\hat{r}(x_0) = \hat{\beta}_0 + \hat{\beta}_1 x_0 + \cdots + \hat{\beta}_p x_0^p + \sum_{i=1}^{m} \hat{\gamma}_i (x_0 - \tau_i)_+^p. \tag{4}$$

The advantage of this approach to spline smoothing is that the parameter estimates are least squares estimates and, hence, to study the regression estimate $\hat{r}(\cdot)$, one has the power of multiple linear regression theory available.

Not surprisingly, the biggest difficulty with this approach is the choice of the number of knots and their placement. Choose too many knots and the regression estimate $\hat{r}(\cdot)$ may show spurious features and is too wiggly, that is, the estimate shows too much variability. With too few knots the regression estimate is too restricted and may not be able to detect some important features of the underlying regression function $r(\cdot)$, that is, the estimate has too much bias. For some data sets, empirical evidence indicates that regression spline estimates that differ with respect to the placement of knots but not their number may vary markedly and give different impressions about the underlying regression function.

Thus, much research has focused on how to select the number of knots and where to place these knots. Essentially, two approaches to this problem exist. The first approach tries to choose the knots $\tau_1, \ldots, \tau_m$ from among the observed regressor variables $x_1, \ldots, x_n$. This can be done by traditional **variable selection** tools as proposed by Smith [44] (see also [46]), by **Bayesian** variable selection approaches [6, 43], or by other recently proposed variable selection methods such as the LASSO [28]. The second approach allows the knots $\tau_1, \ldots, \tau_m$ to freely vary within the range of the observed regressor variables; see [24, 25, 31] and the references therein.

Simulation studies that compare regression splines with other smoothing methods and compare some of the different knot selection schemes are reported, among others, in [2] and [49].

Smoothing Splines

Smoothing splines try to estimate $r(\cdot)$ by minimizing the residual sum of squares over a certain space of functions, typically, for technical reasons, a Sobolev space, that is, a space of functions with derivatives up to order q and the integral of the squared qth derivative being finite. Unrestricted minimization, however, would lead to a nonunique estimate, as any function in that space that interpolates the y_i's would be a solution. To avoid this nonuniqueness, a penalty is imposed on the roughness of the regression estimate $\hat{r}(\cdot)$ with the natural roughness measure being $\int\{r^{(q)}(u)\}^2\,\mathrm{d}u$, where $r^{(q)}$ is the qth derivative (*see* **Penalized Maximum Likelihood**).

Thus, smoothing splines are the solution to the following optimization problem:

$$\underset{r(\cdot)}{\text{minimize}} \sum_{i=1}^{n}(y_i - r(x_i))^2 + \lambda \int \{r^{(q)}(u)\}^2\,\mathrm{d}u, \quad (5)$$

where $\lambda > 0$ is given. Here, λ controls the influence of the penalty term and hence the smoothness of the solution of (5).

It can be shown that the solution to (5) is a natural spline of order $p + 1 = 2q$ with n knots and the set of knots equals the set of observed regressor variables. (Here, we assume for simplicity that the x_i's are distinct.) Hence, problem (5) reduces to a finite dimensional minimization problem. Specifically, if $b_1(\cdot), \ldots, b_n(\cdot)$ denotes a basis for the natural splines of order $2q$ with knots at $x_1, \ldots, x_n$ (e.g. the B-splines basis), then we can estimate $r(\cdot)$ at an arbitrary point x_0 as

$$\hat{r}(x_0) = \sum_{i=1}^{n} \hat{\beta}_i b_i(x_0), \quad (6)$$

where in this case, the parameter estimates $\hat{\beta}_1, \ldots, \hat{\beta}_n$ are obtained from

$$\underset{\beta}{\text{minimize}}\,(Y - X\beta)'(Y - X\beta) + \lambda\beta' K\beta$$

with

$$\boldsymbol{X} = \begin{pmatrix} b_1(x_1) & \ldots & b_n(x_1) \\ b_1(x_2) & \ldots & b_n(x_2) \\ \vdots & \vdots & \vdots \\ b_1(x_n) & \ldots & b_n(x_n) \end{pmatrix}$$

and

$$K = \left(\int b_i^{(q)}(u) b_j^{(q)}(u)\,\mathrm{d}u \right)_{i,j=1}^{n}. \quad (7)$$

Thus, we see that smoothing splines are essentially ridge regression estimators. The theoretical and statistical properties of smoothing splines are discussed in depth in [10, 11, 48], and the references given therein.

In (5), the smoothing parameter λ controls the balance between the residual sum of squares and the roughness penalty. If λ is small, the residual sum of squares term dominates (5) and the regression estimate will be rough and wiggly, that is, very variable, and will nearly interpolate the y_i's. However, for a large λ, the penalty term will dominate (5) and the regression estimate tends, in the limit $\lambda \to \infty$, toward a polynomial of order q.

Hence, to calculate a smoothing spline for some given data, one has to choose q and λ. A popular choice is $q = 2$ leading to cubic smoothing splines. Once q and λ are chosen, fast and numerically stable algorithms exist to calculate the solution of (5); see [21, 22, 37, 38]. The case $q = 2$ is also discussed in [13].

From a practical point of view, the choice of λ is much more crucial since this parameter controls the smoothness of the estimate. A popular way to choose λ using the data is via generalized **cross-validation**, originally proposed in [3]. A recent discussion on smoothing-parameter selection for smoothing splines is given in [47], and a simulation study comparing different methods for selecting the smoothing parameter can be found in [23].

Penalized Splines

While regression splines use only a few knots (whose placement is important), smoothing splines use a large number of knots (typically n) and achieve smoothness of the regression estimate by imposing a roughness penalty. A middle way, now popularized under the name "penalized splines", between these two extremes was suggested in [29, 30]; but see also [9] and [40].

These approaches use a moderate number of knots, more than a regression spline would use but less than smoothing splines. With such a number of knots, a regression spline estimate would be too rough and, hence, these approaches also incorporate a roughness

penalty. Typically, this roughness penalty is discrete and not continuous as in the case of smoothing splines. For example, [9] uses a B-spline basis with equidistant knots and penalizes the sum of squared higher-order finite differences of the coefficients of adjacent B-splines.

Here, we describe in more detail the approach given in [40], which is best explained using the truncated power basis (2). The knots are selected from the observed x_i's and details about this are given below. The design matrix X is the same as in the section "Regression Splines" and the response vector is Y. In addition, we require a smoothing parameter λ whose value [40] is allowed to vary from knot to knot to achieve spatial adaptiveness. Here, for the sake of simplicity, we describe a simpler version. Ruppert and Carroll [40] suggest the use of estimates $(\hat{\beta}', \hat{\gamma}') = (\hat{\beta}_0, \ldots, \hat{\beta}_p, \hat{\gamma}_1, \ldots, \hat{\gamma}_m)$ that solve the equation

$$\underset{\beta,\gamma}{\text{minimize}} \left(Y - X\begin{pmatrix}\beta\\ \gamma\end{pmatrix}\right)' \left(Y - X\begin{pmatrix}\beta\\ \gamma\end{pmatrix}\right) + \lambda\gamma'\gamma.$$

To estimate $r(\cdot)$ at an arbitrary point x_0, we just evaluate

$$\hat{r}(x_0) = \hat{\beta}_0 + \hat{\beta}_1 x_0 + \cdots + \hat{\beta}_p x_0^p + \sum_{i=1}^{m} \hat{\gamma}_i (x_0 - \tau_i)_+^p. \tag{8}$$

This shows that, like smoothing splines, penalized splines are essentially ridge regression estimators. To solve this ridge regression problem in a fast and numerical stable manner, the algorithms described in [39] and [50] can be used. The theoretical and statistical properties of penalized splines are discussed in depth in the references given above. It can be shown that the approaches in [9] and [40] are identical if the x_i's are equidistant.

A suggestion is to choose the number of knots m to be in the range 5 to 40 and to set τ_i to the $i/(m+1)$th sample **quantile** of the unique x_i's; see [40]. Another suggestion is to use $m = \min(n/4, 35)$ knots and to choose τ_i as the $(i+1)/(m+2)$th sample quantile of the unique x_i's. The question on how to choose the number of knots is further explored in [39]. However, it seems that, as long as m is large enough, the number and placement of the knots are not as important as the choice of the smoothing parameter λ.

As for smoothing splines, λ is usually chosen by optimizing some criterion such as, say, generalized cross-validation. However, it seems that there is an intrinsic relation between mixed models and smoothing procedures, as first noted in [45]. For penalized splines, this relationship is thoroughly explored in [41]. This approach relates the smoothing parameter λ to the variance of certain random effects in a mixed model and, thus, leads to a new way for automatically choosing λ, which seems promising. Details of this approach are discussed in [41] and the references given therein.

Extensions and Generalizations

We note further extensions and generalizations of spline functions. The ease with which spline functions can be extended and adapted to more complicated settings is one of the reasons why they are popular for regression smoothing.

Pseudo splines, proposed in [16] and which have not been discussed here, are related to penalized splines.

Splines can be used in multivariate smoothing problems where one would want to estimate a regression function of several parameters. Here, essentially two approaches exist – tensor splines, and thin-plate splines. Details can be found, among others, in [12, 14, 27].

Splines can be used as building blocks for more complicated models, for example, **(generalized) additive models** [17] or **semiparametric** models [41]. They can also be used to extend well-known models such as **generalized linear models**; see [13]. However, these more complicated models typically use iterative methods to calculate the final estimates and care has to be taken with the choice of convergence criteria. Problems that can arise if these convergence criteria are not stringent enough are discussed in [8] which compares three different approaches that use spline smoothing, in an ongoing study that has major implications for public health decision making.

Finally, it is also straightforward to incorporate qualitative constraints into the regression estimate, such as monotonicity (see, among others, [19] or [33]). Constraints can be incorporated in essentially two ways. Either one restricts the function space over which (5) is minimized to a suitable function space that contains only functions that have the desired

property (see, among others, [5] and [26]), or one can modify the penalty term in (5) such that the penalty term enforces the desired property onto the regression estimate (see [20] and [34]).

Notes

The figure shown in the introductory section was produced using R [32] by the following code:

```
library(sm)
provide.data(follicle)
plot(Age, log(Count))
follicle.spl <- smooth.spline(Age,
                              log(Count))
lines(follicle.spl)
```

To run this code snippet, the R installation must include the additional package `sm`.

BERWIN A. TURLACH

Split Plot Designs

The term "split plot" derives from agricultural experiments in which investigators test one treatment, such as a method of irrigation, on large plots of land referred to as whole plots. These whole plots then often can be separated into smaller subplots or split plots to test a second treatment, such as a type of fertilization, as part of the initial or primary experiment [11]. Assignment of treatments requires two stages. First, treatment A, with a levels, is assigned randomly (*see* **Randomization**) to the whole plots (there are ar whole plots or r replicates). Then, treatment B, with b levels, is assigned randomly to the split plots or subplots, so that every whole plot has a subplot receiving each of the b levels of treatment B. These investigations possess a "nested design", since the treatment applied to the subplots is "nested" within the treatment applied to whole plots. The essential feature within the agricultural context is the two-stage randomization: whole plots are assigned randomly to treatment and each whole plot receives all of the subplot treatments. This basic design is seen to have applications in areas of research, such as engineering and epidemiology, that extend beyond the agricultural framework. In these areas, some researchers have employed the term "split unit", instead of "split plot", to describe the study design [1].

We now present four examples to demonstrate the wide applicability of the split plot design. In each case, we measure some quantity (such as yield in bushels per acre) which we denote as Y_{ijk} meaning the ith replication for the kth subplot of the jth whole or main plot.

1. Three fields are selected from each of five farms to test the effects of herbicides and insecticides on yield. Each of the three fields is subdivided into four plots. Three concentrations of herbicides are assigned randomly to the three fields, and four different insecticides are assigned randomly to each of the four subplots within each field [8]. Y_{ijk} represents the yield per acre. This example demonstrates the classical split plot design as it developed within the agricultural framework [3]. The whole plots are represented by the three fields from each of the five farms. The split plots are represented by the four divisions within each field. Treatment A ($a = 3$) is the application of the three herbicide concentrations, and treatment B ($b = 4$) is the application of the four insecticides. There are five replicates ($r = 5$) represented by the five selected farms.
2. To measure the activated life of batteries, an engineer randomly assigns 18 batteries to be examined at three different temperatures. At each temperature, the battery is tested using four electrolytes [10]. Y_{ijk} represents the life of the battery under specified testing conditions. For this application, the whole plot corresponds to the particular battery, and the split plots to the four different electrolytes used in each battery tested. Treatment A becomes the temperature for testing ($a = 3$) and treatment B becomes the electrolyte applied ($b = 4$). There are six replicates ($r = 6$), representing the number of batteries tested at each temperature–electrolyte combination. Here we identify a split plot as a repeat test on the same experimental unit.
3. To study the effects of population density or crowding on the **prevalence** of upper respiratory tract infection, six families are chosen randomly from each of three neighborhoods (18 families in total) that are classified as overcrowded, crowded, or uncrowded [1]. Each family consists of a mother, father, and three children, designated 1, 2, and 3 by descending age. Y_{ijk} is the number of positive swabs for pneumococcus. For this application the whole plot is represented by the family, seen as a unit and the split plot by the family member. Treatment A ($a = 3$) becomes the level of crowding and treatment B ($b = 5$), the status within the family (mother, father, or child 1, 2, or 3). There are six replicates ($r = 6$), representing the six families from each of the different neighborhoods. Here, we replace random treatment assignment with sampling strata (*see* **Stratification**).
4. To determine sex differences in levels of insulin growth factor-one (IGF-1), an investigator selects one group of males and one group of females. Blood samples are drawn from each participant, and each sample split into two aliquots. Each of the two aliquots is assigned randomly to different laboratories, and each laboratory supplies an IGF-1 determination. Y_{ijk} is the determination of IGF-1. For this application, the whole

Table 1 IGF-1 determinations at two laboratories, by sex

Replicate	1	2	3	4	5	6	7	8	9	10
Males										
Laboratory 1	152	119	119	113	131	117	134	136	112	118
Laboratory 2	149	117	122	119	131	109	140	142	126	126
Females										
Laboratory 1	163	169	150	173	163	158	145	151	173	190
Laboratory 2	156	163	151	169	170	146	155	148	164	189

plot is represented by the blood sample, and the split plot is represented by the aliquot. Treatment A ($a = 2$) becomes gender, a stratified sampling, and treatment B ($b = 2$), the laboratory. Ten replicates ($r = 10$) are conducted for each laboratory–sex combination. The determinations presented in Table 1 will be used to demonstrate numerical calculations. (These are simulated data based on an actual experiment.)

Split Plot Analysis

We now examine data collected from a split plot design format using a split plot **analysis of variance**. The analysis owes its derivation to the split plot model, which we represent by the following equation:

$$Y_{ijk} = \mu + \rho_i + \alpha_j + \beta_k + (\rho\alpha)_{ij} + (\alpha\beta)_{jk} + e_{ijk}, \quad (1)$$

where μ is a constant depicting the "grand mean", and ρ_i, α_j and so on, are parameters representing "effects". For example, α_j represents the effect of treatment A at level j, and β_k represents the effect of treatment B at level k. The effects may be **fixed**, **random**, or a mixture of both [12]. We assume that the ρ_i and $(\rho\alpha)_{ij}$ effects are random. Some researchers refer to this as the fixed-effects model [12], while others label it the random block-effects model [9].

We make the following assumptions:

1. The ρ_i are independent $N(0, \sigma_\rho^2)$ (*see* **Normal Distribution**).
2. The $(\rho\alpha)_{ij}$ are distributed $N(0, \sigma_{\rho\alpha}^2)$, and $\sum_{j=1}^{b}(\rho\alpha)_{ij} = 0$ for every i.
3. The e_{ijk} are independent $N(0, \sigma^2)$.
4. The $\rho_i, (\rho\alpha)_{ij}$, and e_{ijk} are mutually independent.

The additional fixed effects in the model are such that:

1. The α_j are constants with $\sum_{j=1}^{a}\alpha_j = 0$.
2. The β_k are constants with $\sum_{k=1}^{b}\beta_k = 0$.
3. The $(\alpha\beta)_{jk}$ are constant with $\sum_{j=1}^{a}(\alpha\beta)_{jk} = 0$ for every k, and $\sum_{k=1}^{b}(\alpha\beta)_{jk} = 0$ for every j.

With these assumptions, $E(Y_{ijk}) = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk}$. All observations have the same **variance** $(\text{var}(Y_{ijk}) = \sigma_\rho^2 + \sigma_{\rho\alpha}^2 + \sigma^2)$. Observations within a whole plot have a constant **correlation**, $(\sigma^2 + \sigma_{\rho\alpha}^2)/(\sigma^2 + \sigma_\rho^2 + \sigma_{\rho\alpha}^2)$.

The general analysis of variance for the split plot design is presented in Table 2, and in Table 3 is presented the specific analysis of variance for the data in Table 1. The whole plots comprise $ar = 20$ units, with 19 degrees of freedom (df) for between whole-plot comparisons. These 19 df among whole plots can be partitioned further into $r - 1 = 9$ df for replicates; $a - 1 = 1$ df for treatment A; and $(a - 1)(r - 1) = 10$ df for error in whole plot comparisons. Within each whole plot, there are $(b - 1) = 1$ df associated with variation within the whole plot, giving a total of $ar(b - 1) = 20$ df for comparisons within whole plots. These 20 df are partitioned further into $b - 1 = 1$ df for treatment B, $(a - 1)(b - 1) = 1$ df for the **interaction** between treatments A and B, and $a(b - 1)(r - 1) = 18$ df for error in whole-plot comparisons.

There are three hypotheses of interest concerning the effects of treatments when using split plot designs: (i) no effect of treatment A; (ii) no effect of treatment B; and (iii) no interaction effect. When these three **null hypotheses** are true, we derive the F statistics presented in Table 2. The correctness of these tests can be seen intuitively by examining the expected mean squares provided in the table. For example, when there are no main-plot effects, all of the α_j

Table 2 Analysis of variance for a split plot design

Replicates	$ab\sum_{i=1}^{r}(\overline{Y}_{i..}-\overline{Y}_{...})^2$	$r-1$	MSR		
Error (A)	$b\sum_{i=1}^{r}\sum_{j=1}^{a}\left([\overline{Y}_{ij.}-\overline{Y}_{i..}]-[\overline{Y}_{.j.}-\overline{Y}_{...}]\right)^2$	$(a-1)(r-1)$	MSE (A)	$\sigma^2+b\sigma^2_{\rho\alpha}$	
Within whole plots (subplot comparisons)					
B	$ar\sum_{k=1}^{b}(\overline{Y}_{..k}-\overline{Y}_{...})^2$	$b-1$	MSB	$\sigma^2+\frac{ra}{b-1}\sum_{k=1}^{b}\beta_k^2$	MSB/MSE (B)
AB interaction	$r\sum_{j=1}^{a}\sum_{k=1}^{b}\left([\overline{Y}_{.jk}-\overline{Y}_{.j.}]-[\overline{Y}_{..k}-\overline{Y}_{...}]\right)^2$	$(a-1)(b-1)$	MSAB	$\sigma^2+\frac{r}{(a-1)(b-1)}\sum_{i=1}^{a}\sum_{k=1}^{b}(\alpha\beta)_{jk}^2$	MSAB/MSE (B)
Error (B)	$\sum_{i=1}^{r}\sum_{j=1}^{a}\sum_{k=1}^{b}\left([\overline{Y}_{ijk}-\overline{Y}_{.jk}]-[\overline{Y}_{ij.}-\overline{Y}_{...}]\right)^2$	$a(b-1)(r-1)$	MSE (B)	σ^2	
Total	$\sum_{i=1}^{r}\sum_{j=1}^{a}\sum_{k=1}^{b}(Y_{ijk}-\overline{Y}_{...})^2$	$abr-1$			

Table 3 Analysis of variance for data in Table 1

Source	SS	df	MS	F	P
Gender comparisons					
Gender	12 744.9	1	12 744.9	31.58	0.0003
Replicates	1 954.9	9			
Error (gender)	3 632.1	9	403.6		
Laboratory comparisons					
Lab	0.9	1	0.9	0.04	0.8420
Interaction	72.9	1	72.9	3.31	0.0854
Error (laboratory)	396.2	18	22.0		
Total	18 801.9	39			

are 0, so the MSA and MSE(A) are independent with the same expected value, $(\sigma^2 + b\sigma^2_{\rho\alpha})$. Table 3 documents a sizable gender effect ($F = 31.58$, $P = 0.0003$), but no effect due to laboratory assignment ($F = 0.04$, $P = 0.842$) or to laboratory by sex interaction ($F = 3.31$, $P = 0.0854$).

Table 2 demonstrates an important feature of the split plot design: comparisons can be made more precisely within whole plots, including comparisons of interaction effects of treatments, than between whole plots. When comparing the average IGF-1 for males with that for females in example 4, we compare the mean among males to the mean among females. Using common notation, we state the comparison as follows: $\overline{Y}_{..1} - \overline{Y}_{..2}$. The variance for the difference uses the estimator of $\sigma^2 + b\sigma^2_{\rho\alpha}$. To compare the two laboratories. we use the difference in average IGF-1 determinations, $\overline{Y}_{..1} - \overline{Y}_{..2}$. The variance of this difference uses the estimator of σ^2, which is clearly smaller than $\sigma^2 + b\sigma^2_{\rho\alpha}$. These examples demonstrate that the estimations of within-plot differences are more precise than estimations between plots. We show this theoretically by making the simple assumption that all observations have variance σ^2, and that each pair of observations within a whole plot has the correlation ρ [3]. This feature of the split plot design leads some investigators to advocate its use when the estimation of one effect takes precedence over others [10, 12].

Extensions and Related Analyses

There are many situations for which the term "split plot" is genuinely descriptive of the analyses concerned, as is the case with our examples provided above. The data fit nicely into the classical split plot design model. The design and analytic method as employed in these examples, however, have limited application. It may be advantageous to extend the use of split plot design to perform four additional types of analyses: (i) to achieve additional levels of nesting; (ii) to adjust for **covariates** using an **analysis of covariance**; (iii) to extend distributional assumptions beyond normal distributions; and (iv) to generalize assumptions concerning the correlation structure of data.

In our examples, we assume that each whole plot is split into subplots and that the subplot receiving treatment B is nested within the whole plot receiving treatment A. We can extend this concept to design studies in which each subplot is further divided into c sub-subplots. We then nest treatment C (at c levels) within treatment B. The resulting design is referred to as a split-split plot design [6]. Theoretically, the division of split plots into smaller and smaller subplots can continue indefinitely.

When conducting **observational studies**, we may find it necessary to adjust for a covariate by measuring its effects as part of the split plot design. This is accomplished by including additional terms for covariate effects in the model specified in (1) [6, 7].

To derive the F statistics in Table 2, we assume data from a normal distribution. We can however, employ (1) with the assumptions of the **generalized linear model**. Cologne et al. [4], for example, adapt a split plot analysis that assumes **Poisson** observations to a study of micronucleus frequencies and radiation sensitivity.

Finally, the requirement that the correlation between observations within a whole plot remains constant is often unreasonable. The split plot analysis of variance may be used to examine **longitudinal data** or repeated measures. For these analyses we consider measurements taken at different times to be the split plot observations. With this definition we may consider **crossover trials** to be a special type of split plot design [2]. The assumptions that we employ for (1) lead to the requirement that the data within one whole unit be equally correlated. When the split plot represents time, however, it is more realistic to assume that the correlation between measurements that are closely timed are higher than those between

measurements further apart in time. Extension of the correlation structure can be accomplished using the **generalized estimating equation** approach of Zeger and co-workers [5, 13].

S-PLUS and S

S is an interactive programming language (*see* **Computer Languages and Programs**) developed at Bell Labs, Murray Hill, NJ, for data analysis and graphics (*see* **Graphical Displays**). S-PLUS is the commercially available software implementation of S developed and marketed by the Insightful Corporation, Seattle. In 1999, the originator of S, John Chambers, was presented with the ACM Software Systems Award for his work on the S system. The name "S" is usually reserved for the language and "S-PLUS" for the interactive environment and software tools based upon it.

The original purpose of S was to provide a vehicle for technology development, testing, and transfer within the data analysis and graphics community of Bell Labs. The S-PLUS implementation has made its facilities accessible to a general data analysis community, but it remains a fully configured developmental tool for professional data analysts.

On Unix or Linux, an S-PLUS session typically uses a command-line interface with printed output displayed in the session window and graphical output on one or more graphics windows. Since S-PLUS version 4 (released March 1997) of Windows, there has been a graphical user interface available as an alternative, with an object explorer tool, a **spreadsheet**-like data browser and menu-driven commands for many standard tasks (but only on the Windows platform).

In 1999, a revision and extension of the S language was issued by Chambers and is described officially in his book [4]. This new language version forms the basis of S-PLUS on all software platforms from Release 6 for Unix, Windows, and Linux.

The main facilities provided within the environment are

1. an interpreter for an object-oriented C-like programming language, S,
2. support for a wide variety of static and dynamic, color graphics facilities,
3. software for a wide variety of basic computations, data analysis techniques, and statistical procedures, and
4. dynamic loading of routines written in C or Fortran, and hence open access to other software.

An unusual feature of S-PLUS is that the objects it creates are permanent and available in later S-PLUS sessions until the user removes them.

Data Analysis Software Available

Since S is a complete programming language, a user may, at least in principle, write a function to do any calculation. In practice, however, user-written functions in S are typically very short and for special purposes. Most standard operations are already part of the software available within the system and most large-scale computations are done using compiled code written in C or Fortran. The categories of software available in the S-PLUS implementation include:

1. **Linear regression** models, including multistratum **analysis of variance**, mixed effects and **multivariate multiple regression** models and a suite of local, smooth, or **robust regression** techniques;
2. **Generalized linear** (including some **generalized linear mixed models**) and **generalized additive models**;
3. **Nonlinear regression** models, including **random effects**, and general nonlinear **optimization**;
4. Regular and irregular **time series** with time-domain and frequency-domain analyses;
5. Parametric and nonparametric survival analysis (*see* **Parametric Models in Survival Analysis**; **Survival Analysis, Overview**; **Survival Analysis, Software**);
6. Classification and regression trees (*see* **Tree-structured Statistical Methods**), clustering algorithms (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**) and multivariate scaling (*see* **Multidimensional Scaling**).

In addition to standard built-in software, a large collection of add-on libraries exists, which offer many other, often new techniques. These are largely written by users and contributed to the user community.

In addition to libraries, S-PLUS offers "modules", which are extensive additions to the suite of functions available, which can be purchased under a separate license. These include software for financial

modeling, **wavelets**, **spatial** analysis, **environmental** statistics, **experimental design**, **sequential analysis**, and large-scale optimization.

Some Literature

What is now called "old S" was described in [1] and [2]. Release 3 of S is described in [3] and the current revision, Release 4 of S, is described in [4]. Both references are still relevant. The basic modeling software was later added and described in [5]. Third party books include [6–10].

W.N. VENABLES

Sports Medicine

The statistical methods used in sports medicine differ little from those in general clinical medicine. There is a variation in the degree of sophistication of research methods applied in different subsections of sport and exercise medicine, which reflects the development of this particular field. The earliest major research studies in sport and exercise medicine were the epidemiologic studies of the benefits of exercise by Morris [11] and Paffenbarger et al. [15]. These studies were the first to demonstrate the possible cardiovascular benefits of physical activity on mortality, but were subject to many possible **confounding** effects. They were the forerunners of many epidemiologic investigations including studies by Powell et al. [16] and Berlin & Colditz [2], who were able to confirm that regular exercise was associated with a reduction in the incidence of coronary heart disease. We now have further evidence from large observational **cohort studies** of both men and women for up to 25 years demonstrating that low physical fitness is an important precursor of mortality [3]. Scientists continue to explore the relationship between physical activity and cardiovascular risk factors and, in general, are able to provide evidence linking specific risk factors with physical activity and fitness using **cross-sectional** population studies [9]. Additional evidence of a relationship may be explored using intervention studies (*see* **Clinical Trials, Overview**), and short-term **case–control studies** [19].

Sports injuries are usually first reported as case studies or a group of injuries collected into **case series**. Observations may then be explored further in a case–control study [6]. It is difficult to establish the incidence of sports injuries in the population because of problems in defining the **denominator**. Most evidence of population sports injury is recorded in **surveys** of attendance at a hospital casualty [1] or sports injury clinic [10]. A better method of recording incidence and exploring associated factors is the prospective cohort study. The highest quality methodology is of course the **randomized** controlled trial. Unlike most clinical investigations in which it is relatively easy to undertake a randomized controlled trial and blind participants (*see* **Blinding or Masking**), it is more difficult to apply this method to investigations in sport and exercise medicine where the intervention may involve some form of activity or physical device. Recruitment is often open, or by advertisement, and few people wish to be allocated to a **control** group. Blinding is usually impossible, and with any exercise program there is always the possibility of contamination. When the randomized controlled trial is applied successfully it leads to valuable high-quality research with clinical implications [8].

Another important consideration in sport and exercise sciences is how to identify the effects of risk factors (e.g. physical inactivity, dietary composition, and smoking) on health-related fitness variables (e.g. VO_2 max, grip strength, leg power, and arterial blood pressure) in the presence of confounding effects (e.g. differences in age or body weight). One obvious solution is to use techniques such as the **analysis of covariance**. However, the **frequency distributions** of many health-related fitness variables are known to be positively skewed (*see* **Skewness**) with heteroscedastic errors (*see* **Scedasticity**) [7, 12–14], and thus deviate considerably from the **normal distribution** with constant error **variance**. In addition, the relationship between many such variables and age, for example blood pressure [14], is certainly not linear. To accommodate these characteristics and associations, a **multiplicative model** with allometric body size components has been proposed [13, 14] that can explain the known proportional relationship with body size, the nonlinear age factor, and the heteroscedastic and positively skewed errors.

Prediction of athletic performance appears to be another constant source of fascination for many statisticians. When analyzing running times recorded in the Olympic Games between the years 1900 and 1976, Chatterjee & Chatterjee [5] generated a fierce debate as to the inaccuracies in their data [17] and the lack of evidence for their claimed asymptote [20]. A recent paper by Blest [4] continues to explore the relationship between running times and distance, by fitting separate power function models to the running times taken from the Olympic Games between the years 1912 and 1992. Based on these fitted exponents, the author tries to predict the limits of future performance using a variety of nonlinear curve fitting models. An alternative approach by Royston [18] uses fractional polynomials, to model changes in running *speed* over distance rather than running *time*. An examination of the **residuals** from both models favors the latter approach, which appears more successful in removing systematic residual effects from the running performance data.

Spreadsheet

The term *spreadsheet* is derived from the sheet of paper employed by an accountant to set out financial calculations, often so large that it had to be spread out on a table. The first electronic spreadsheet, VisiCalc, was developed in 1979 by Bob Frankston and Dan Bricklin at Harvard. Originally designed as a business problem-solving tool, the remarkable versatility of the spreadsheet package has made it a popular working environment among computer users in many professions. The most commonly used spreadsheet packages include Excel, Lotus 1-2-3, Quattro Pro, and SuperCalc.

In medicine and the health sciences spreadsheets have proved useful in a wide variety of applications. For example, in resource management spreadsheets are used for scheduling [5], budgeting [10], **forecasting** [2], quality monitoring [9], "what-if" scenarios [7], and cost–benefit analysis [6]. Spreadsheet models [4] of complex systems and processes can be used to simulate behavior under varying conditions, allowing **optimization** [8] and **sensitivity analysis** [3] to be conducted. On a more mundane level the spreadsheet interface is easy to use by nontechnical personnel for data-entry and routine computation – for example, dosage calculations [1].

A basic spreadsheet comprises a rectangular array of cells with, say, columns referenced by letters A, B, C ... and rows by number $1, 2, 3 \ldots$. Thus the cell F3 would be in the third row of the sixth column. Cells may contain text, numbers, or formulas, or may be empty. Figure 1 shows the (formatted) results of a randomized block experiment (*see* **Randomized Complete Block Designs**). Cell A3 contains the text "Block 1", cell B3 contains the number 12.3, while cell F3 contains the formula = AVERAGE(B3:E3) which is calculated to be $(12.3 + 11.2 + 16.4 + 13.2)/4 = 13.275$. Formulas can be copied to other cells if a similar calculation is required. If the formula in F3 is copied into cell F4 it is automatically modified to = AVERAGE(B4:E4), it being assumed that any reference to row 3 should become row 4. In some situations this automatic modification needs to be overridden. To calculate the **residuals** $\{y_{ij} - y_{i\cdot} - y_{\cdot j} + y_{\cdot\cdot}\}$ in Figure 2 corresponding to data $\{y_{ij}\}$ in Figure 1, the required formula for cell B10 would be $= B3 - F3 - B6 + F6$. However, were we to copy this into B11, say, it would become $= B4 - F4 - B7 + F7$ – totally incorrect. Instead a \$ symbol can be used to force a row or column reference to remain unchanged during copying. Thus if the formula in B10 is written as $= B3 - \$F3 - B\$6 + \$F\$6$ it may safely be copied throughout the range B10:E12. Spreadsheets can be made more "transparent" to other users by attaching names to key cells or ranges. For example, in Figure 1, if the range B3:E3 were to be named "Block_1" then the formula in F3 could be entered as = AVERAGE(Block_1) – much more readable.

Formulas are dynamically linked to the cells from which they are calculated. Hence if any of the cells B3, C3, D3, or E3 is changed, the average in F3 is automatically recalculated. Automatic re-execution of formulas when data or model parameters are changed distinguishes the spreadsheet from a standard statistical package such as SAS (*see* **Software, Biostatistical**) where the program would need to be rerun. The spreadsheet thereby provides an interactive computing environment. Suppose, for example, that the investigator discovers that the response for Treatment II in Block 2 was actually missing and should not have been recorded as zero. The least squares estimate of the missing value can be found by trial

	A	B	C	D	E	F
1						
2	Response	Treat I	Treat II	Treat III	Treat IV	Mean
3	Block 1	12.3	11.2	16.4	13.2	13.275
4	Block 2	18.4	0	19.5	18.4	14.075
5	Block 3	12.8	11.9	14.4	12.7	12.95
6	Mean	14.5	7.7	16.766667	14.766667	13.433333
7

8						
9	Residual	Treat I	Treat II	Treat III	Treat IV	Mean
10	Block 1	−2.0417	3.6583	−0.2083	−1.4083	0.0000
11	Block 2	3.2583	−8.3417	2.0917	2.9917	0.0000
12	Block 3	−1.2167	4.6833	−1.8833	−1.5833	0.0000
13	Mean	0.0000	0.0000	0.0000	0.0000	0.0000
14						

Figure 2 Residuals from analysis of randomized block experiment (continued from Figure 1)

and error, adjusting the value in C4 until the residual in C11 is seen to be zero. An alternative solution would be to employ a circular formula $= C4 - C11$ in C4, pressing the recalculation key to obtain successive iterates. (In fact, after 17 recalculations the missing value is estimated to be 16.6833.)

AVERAGE() is an example of an inbuilt function which calculates the arithmetic mean. Most spreadsheet packages provide functions for calculating simple descriptive statistics and linear regression coefficients. Microsoft Excel is notable for its wide range of additional statistical functions. These include all the major probability distribution functions (and their inverses) used to calculate P values (or critical values) in significance tests. There have been unfortunate errors in the algorithms employed by some spreadsheet packages. For example, in Excel 5.0 it was possible to obtain negative r^2 values when fitting a regression through the origin. Such errors cast doubt on the suitability of spreadsheets for serious statistical analysis.

An impressive feature of some recent spreadsheet packages is the facility to produce high-quality charts. These may either be stored on separate sheets in the same "workbook" as their data, or pasted onto the spreadsheet itself. Charts can be customized using different styles, fonts, colors, etc. Figure 3 shows a typical example. It is important not to rely on the default settings of the various options, otherwise "chart-junk" may result – visually beautiful but totally meaningless! Like a formula, a chart is dynamically linked to the data which it portrays. Indeed, in Excel the linkage can be selected to be two-way, so that when a data point on the chart is moved (by dragging with the mouse) the corresponding cell contents change accordingly.

The statistical facilities available within a spreadsheet package can usually be extended by writing subprograms (or macros) in the spreadsheet's own

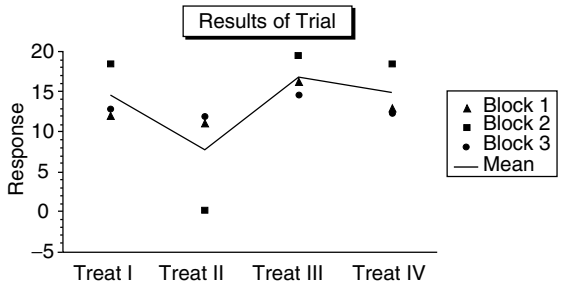

Figure 3 Spreadsheet chart of data from randomized block experiment

language – for example, Visual Basic in Excel 5. A suite of macros may even be supplied as optional "add-ins" with the software. In theory this allows even the most advanced statistical techniques to be implemented in spreadsheet form. In practice there is a danger that, unless care is taken with the algorithm and double-precision arithmetic used when appropriate, rounding errors will accumulate and numerical accuracy will suffer. Moreover the macro-output will not be dynamically linked to its input, and the spreadsheet will have lost its transparency. The proliferation of "add-ins" in spreadsheet packages, coupled with spreadsheet-like data entry facilities in statistical packages (*see* **Software, Biostatistical**), makes it likely that the distinction between the two types of package will gradually disappear. The major statistical packages such as SAS, SPSS, and Minitab already provide interface facilities with the popular spreadsheet packages, so that users can enjoy the best of both worlds.

Square Contingency Table

An $R \times C$ **contingency** table – that is, contingency table with R rows and C columns – is frequently seen in biomedical studies. When $R = C$, the contingency table is often referred to as a *square table*. Square tables usually arise in repeated measures experiments, in which a subject has his or her outcome variable observed repeatedly. Examples of repeated measures studies include longitudinal studies (observing the same subject over time); rater agreement studies (two investigators rate each subject in the study); and paired data studies (data obtained from a husband and wife, father and son, or case and control) (*see* **Matched Pairs With Categorical Data**; **Case–Control Study**).

First, we introduce some notation. Suppose that two discrete random variables, Y_{i1} and Y_{i2}, are observed on each of n independent subjects, where Y_{i1} can take on values $1, \ldots, R$, and Y_{i2} can take on values $1, \ldots, C$. Let the probabilities of the multinomial joint distribution of Y_{i1} and Y_{i2} be denoted by

$$p_{jk} = \Pr(Y_{i1} = j, Y_{i2} = k),$$

for $j = 1, \ldots, R$ and $k = 1, \ldots, C$. Since all the probabilities must sum to 1, there are $(RC - 1)$ nonredundant multinomial cell probabilities. We let $\mathbf{p}$ denote the $(RC - 1) \times 1$ probability vector of p_{jk}'s; for simplicity, we delete p_{RC}, and we take $R = C$ below. The marginal probabilities of the contingency table are $p_{j+} = \Pr(Y_{i1} = j)$ and $p_{+k} = \Pr(Y_{i2} = k)$, where the plus signs denote summing over the subscript they replace. We let n_{jk} denote the number of subjects with response level j on Y_{i1} and level k on Y_{i2}, and let $n = n_{++}$ be the total number of subjects in the study.

Models for square tables fall into three general classes – marginal models, **loglinear models**, and conditional models. Marginal models describe the similarity between the row and column marginal distributions. With loglinear models, we model the cell probabilities of the table. For example, the probabilities may be symmetric about the main diagonal, and a loglinear model can be used to describe this relationship among the cell probabilities. Conditional models model the conditional probabilities of the column variable given the row variable and are popularly used in longitudinal studies, letting the row variable represent a response at time 1 and the column variable represent the response at time 2. Often, in square tables, we are not always interested in modeling the data, but are interested in determining the association or agreement between the row and column variables.

Marginal Models

In a crossover study, a subject is given one treatment, has a washout period, and is then given a new treatment. Suppose that the response to each treatment is success, partial success, or failure. We are often interested in whether the marginal distribution of the outcome is the same for both treatments, often called *marginal homogeneity*. Under marginal homogeneity, the sum of the cell probabilities (i.e. the marginal probability) in the jth row of the contingency table equals the sum of the cell probabilities in the jth column; that is, $p_{j+} = p_{+j}$ for $j = 1, \ldots, R$. Lipsitz et al. [10] show that the maximum likelihood estimates for the p_{jk}'s under marginal homogeneity can be obtained via a linear model of the form

$$\mathbf{p} = \mathbf{X}\boldsymbol{\beta},$$

for the appropriate "design" matrix $\mathbf{X}$, which we now describe for $R = 3$, but which generalizes to any R. For $R = 3$, we can write the vector $\mathbf{p}$ in terms of the four cell probabilities, $\{p_{11}, p_{12}, p_{21}, p_{22}\}$ and the four marginal probabilities, $\{p_{1+}, p_{2+}, p_{+1}, p_{+2}\}$, as follows:

$$\begin{bmatrix} p_{11} \\ p_{12} \\ p_{13} \\ p_{21} \\ p_{22} \\ p_{23} \\ p_{31} \\ p_{32} \end{bmatrix} = \begin{bmatrix} p_{11} \\ p_{12} \\ p_{1+} - p_{11} - p_{12} \\ p_{21} \\ p_{22} \\ p_{2+} - p_{21} - p_{22} \\ p_{+1} - p_{11} - p_{21} \\ p_{+2} - p_{12} - p_{22} \end{bmatrix}.$$

Under marginal homogeneity, the row and column marginal probabilities are equal – that is, $p_{j+} = p_{+j} = p_j$ – which leads to the following linear model for the cell probabilities:

$$\begin{bmatrix} p_{11} \\ p_{12} \\ p_{13} \\ p_{21} \\ p_{22} \\ p_{23} \\ p_{31} \\ p_{32} \end{bmatrix} = \begin{bmatrix} p_{11} \\ p_{12} \\ p_1 - p_{11} - p_{12} \\ p_{21} \\ p_{22} \\ p_2 - p_{21} - p_{22} \\ p_1 - p_{11} - p_{21} \\ p_2 - p_{12} - p_{22} \end{bmatrix}$$

$$= \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ -1 & -1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & -1 & 0 & 1 \\ -1 & 0 & -1 & 0 & 1 & 0 \\ 0 & -1 & 0 & -1 & 0 & 1 \end{bmatrix} \begin{bmatrix} p_{11} \\ p_{12} \\ p_{21} \\ p_{22} \\ p_1 \\ p_2 \end{bmatrix}$$

$$= \mathbf{X}\boldsymbol{\beta}. \tag{1}$$

The **maximum likelihood estimates** (MLEs) can be obtained in any generalized linear modeling program, such as SAS *Proc GENMOD* [14], without any additional programming or iteration loops. In these programs, the outcome is the count n_{jk}, the covariates are the appropriate row of $\mathbf{X}$ in (1) without an intercept, and we specify a linear link with Poisson errors (we actually must include n_{33} as a value of the outcome, as described in [10]). Firth [7] also describes a method for obtaining the linear model for the p_{jk}s using Latin squares. Another method found in the literature for obtaining the MLE under homogeneity uses Lagrange multipliers [11].

After the estimates of the cell probabilities under marginal homogeneity have been obtained, a **likelihood ratio** statistic can be used to test whether marginal homogeneity holds. This statistic is approximately chi-square with $R-1$ degrees of freedom under the null. Alternately, a Wald statistic [3] (*see* **Likelihood**) can be used. It does not require the use of iterative techniques, since only the estimates of the cell probabilities for the saturated model are needed. The maximum likelihood estimate of p_{jk} for the saturated model (with R^2-1 nonredundant probabilities) is

$$\hat{p}_{jk} = \frac{n_{jk}}{n}, \tag{2}$$

and the MLEs of the marginal probabilities are $\hat{p}_{j+} = n_{j+}/n$ and $\hat{p}_{+j} = n_{+j}/n$. Suppose that we let the vector

$$\mathbf{U} = [\hat{p}_{1+} - \hat{p}_{+1}, \ldots, \hat{p}_{R-1,+} - \hat{p}_{+,R-1}]'$$

contain the first $R-1$ differences in the marginal probabilities (the Rth difference is redundant). Under the null of marginal homogeneity, $\mathrm{E}(\mathbf{U}) = \mathbf{0}$. If we let $\hat{\mathbf{V}}$ be the estimated covariance matrix of the vector $\mathbf{U}$ under the alternative (see [3]), then the Wald test statistic for homogeneity is the quadratic form

$$X^2 = \mathbf{U}'\hat{\mathbf{V}}^{-1}\mathbf{U}, \tag{3}$$

which will be approximately chi-square with $R-1$ degrees of freedom under the null. If, instead of estimating the variance under the alternative in (3), we let $\hat{\mathbf{V}}$ be the estimated covariance of $\mathbf{U}$ under the null of homogeneity, and if there are only two rows and columns in the table ($R = C = 2$), then (3) reduces to

$$X^2 = \frac{(n_{12} - n_{21})^2}{n_{12} + n_{21}}. \tag{4}$$

The test statistic in (4) is popularly known as *McNemar's test* for equality of correlated proportions [13].

In the crossover study discussed earlier, the outcomes "success", "partial success", and "failure" are examples of **ordered categorical data**. Suppose that we want to test for marginal homogeneity, taking this ordering into account. We can put an ordinal model on the margins, such as the **proportional-odds model** [12], and test whether the parameters of the proportional-odds models in the two margins are the same. The test statistics are similar to those given for the nominal case above. The Wald test for marginal homogeneity for proportional-odds marginal models can be obtained in SAS *Proc CATMOD* [15] using methods derived in [9]. The likelihood ratio statistic can be obtained in a generalized linear models program, but will require some additional programming. More details on marginal modeling can be found in [2, Chapter 9] and in the article on marginal models.

Loglinear Models

The models just discussed involved testing whether the marginal probabilities of the table are equal. Now, we discuss models which describe the relationship among the cell probabilities of the $R \times R$ table. One

such model for the cell probabilities is a symmetry model, in which

$$p_{jk} = p_{kj}, \quad \text{for } j \neq k. \tag{5}$$

Note that symmetry implies marginal homogeneity since, under (5),

$$p_{j+} = \sum_{k=1}^{R} p_{jk} = \sum_{k=1}^{R} p_{kj} = p_{+j}.$$

In fact, when $R = C = 2$, marginal homogeneity and symmetry are identical, and both imply that $p_{12} = p_{21}$.

For modeling purposes, symmetry is most easily written as a loglinear model. Loglinear models for contingency tables are usually written in terms of the expected cell counts

$$m_{jk} = \mathrm{E}(n_{jk}) = np_{jk}.$$

In terms of the expected cell counts, symmetry is written as

$$m_{jk} = m_{kj}, \quad \text{for } j \neq k.$$

Then, the symmetry loglinear model is

$$\log m_{jk} = \mu + \beta_j + \beta_k + \beta_{jk}, \tag{6}$$

where $\beta_{jk} = \beta_{kj}$, with the appropriate identifiability constraints on the parameters, such as $\beta_R = 0$ and $\beta_{Rj} = \beta_{jR} = 0$ for $j = 1, \ldots, R$. Since $\beta_{jk} = \beta_{kj}$, it is easy to show that $m_{jk} = m_{kj}$, and symmetry holds for (6).

The MLEs for the expected cell counts under symmetry are

$$\hat{m}_{jj} = n_{jj} \qquad \text{and} \qquad \hat{m}_{jk} = \frac{n_{jk} + n_{kj}}{2}.$$

The estimated cell probabilities are just $\hat{p}_{jk} = \hat{m}_{jk}/n$. Intuitively, since symmetry does not concern the diagonal cells, the estimated expected diagonal counts are just the observed diagonal counts. Also, an estimated off-diagonal count is just the average of the observed counts in cells jk and kj. Under the symmetry model, we only need to estimate $R(R-1)/2$ off-diagonal probabilities on one side of the diagonal, so we have placed $R(R-1)/2$ constraints on the cell probabilities under the null, and the likelihood ratio test statistic, score test statistic (*see* **Likelihood**), or Wald test statistic for symmetry are approximately chi-square with $R(R-1)/2$ degrees of freedom. The score test statistic (equivalent to Pearson's chi-square for this problem) is the simplest [1]:

$$X^2 = \sum_{j<k} \frac{(n_{jk} - n_{kj})^2}{n_{jk} + n_{kj}}. \tag{7}$$

Recall that, when $R = C = 2$, marginal homogeneity and symmetry are identical, so that (7) is also a test statistic for marginal homogeneity when $R = 2$, and is identical to the McNemar test statistic discussed earlier.

The symmetry loglinear model puts many constraints on the probabilities. A loglinear model that has fewer constraints (and more parameters) does not force the row and column main effects in (6) to be equal,

$$\log m_{jk} = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk}, \tag{8}$$

where $(\alpha\beta)_{jk} = (\alpha\beta)_{kj}$. The loglinear model in (8) is called *quasi-symmetry* [5]. If symmetry holds, then $\alpha_j = \beta_j$. The **Bradley–Terry model** [4] for **paired comparisons** is a special case of this quasi-symmetry model.

Using the identifiability constraints $\alpha_R = 0$, $\beta_R = 0$, and $(\alpha\beta)_{Rj} = (\alpha\beta)_{jR} = 0$ for $j = 1, \ldots, R$, the interaction parameter $(\alpha\beta)_{jk}$ is the log-odds ratio for the jth and Rth rows and kth and Rth columns: that is,

$$(\alpha\beta)_{jk} = \log\left(\frac{p_{jk}p_{RR}}{p_{jR}p_{Rk}}\right).$$

Then, in the quasi-symmetry model, since $(\alpha\beta)_{jk} = (\alpha\beta)_{kj}$, the log-odds ratio for the jth and Rth rows and kth and Rth columns equals the log-odds ratio for the kth and Rth rows and jth and Rth columns. In particular, these log-odds ratios are symmetric.

One last loglinear model that we discuss is a *quasi-independence* model. If the row and column variables are independent, then

$$p_{jk} = p_{j+}p_{+k},$$

or, equivalently, in terms of the loglinear model,

$$\log m_{jk} = \mu + \alpha_j + \beta_k. \tag{9}$$

In repeated measures studies, most of the agreement is often on the diagonal, so that the diagonal

elements are longer than expected under independence, with independence holding in the off-diagonal elements. A simple loglinear model that expresses such a relationship is the quasi-independence loglinear model,

$$\log m_{jk} = \mu + \alpha_j + \beta_k + \gamma_j I(j = k), \qquad (10)$$

where $I(j = k)$ equals 1 for diagonal elements $j = k$ and 0 for off-diagonal elements. For off-diagonal elements, (10) is identical to (9), and, if $\gamma_j > 0$, then the diagonal elements are longer than expected under independence.

When the rows and columns are ordered, these loglinear models can be extended by assigning **scores** to the rows and columns (see, for example, [8]). For more details on loglinear models, see [1].

Conditional Models

Often in longitudinal studies, we are interested in transitions or change in states, such as the response at time 2 given the response at time 1. In general, in crossover designs, polling studies, or employment studies (mover–stayer studies), investigators are interested in these conditional probabilities for the column variable given the row variable. When the row variable represents a response at time 1, and column variable represents the response at time 2, we model the probability of response k at time 2 given response j at time 1:

$$p_{k|j} = \Pr[Y_{i2} = k | Y_{i1} = j], \quad j = 1, \ldots, R. \quad (11)$$

Suppose that, in an arthritis clinical trial for the effectiveness of a single treatment, the subjects are observed once before treatment, then are given the new treatment, and then observed again. Suppose that the possible outcomes at the two times are "no pain", "mild pain", and "severe pain". Then, we are interested in the changes in pain, as modeled by the conditional probabilities of pain status at time 2 given the pain status at time 1. If there are two levels ($R = 2$), then we can apply logistic regression to the model given in (11), treating Y_{i1} as a covariate. If ($R > 2$) and the levels are not ordered, multinomial logistic regression can be used (*see* **Polytomous Data**); if the levels are ordered (as in this example), an ordinal logistic model such as the proportional-odds model [12] can be used.

Measures of Association and Agreement

For general ($R \times C$) tables, we are often interested in the **association** between the row and column variables (*see* **Association, Measures of**). For a (2×2) table, the odds ratio is a popular measure of association. In an ($R \times R$) square table, the log-odds ratios, as described above, can be used to measure association. For the row and column variables to be associated, you should be able to predict one from another. For example, if the odds ratio is 0, the row and column variables in a (2×2) are perfectly negatively associated. In repeated measures studies, and, in particular, inter-rater reliability studies, in which two investigators rate each subject in the study, we are interested in how well the row and column variables (the two ratings on each subject) agree. When two ratings agree, most of the observations in the contingency table will be on the diagonal (most ratings are similar). Two variables can be highly associated, but agreement between the two could be very low. Suppose that both diagonal elements in a (2×2) table are zero: then the raters completely disagree, and agreement (by any measure) is very low. However, the odds ratio is 0, and, as discussed above, the two variables are perfectly negatively associated. The kappa coefficient [6] is a popular measure of agreement corrected for chance agreement (*see* the articles on **Kappa** and **Agreement, Measurement of**).

Staggered Entry

A biostatistical survival study is said to have *staggered entry* if the study subjects are entered into the study at times which are related to their own disease history (e.g. immediately following diagnosis at a particular hospital for a specified disease, if other criteria for entry are met), but which are unpredictable from the point of view of the study. The most common method of dealing with such data, especially in the case of analysis at a single chronological time, is via the **life-table** method one ignores the chronological times of entry and treats as response variable the time from entry until event (primary endpoint, e.g. survival time, or **censoring**) together with an indicator of whether the primary endpoint is observed [27]. Implicit in this simplest method is the assumption that the probabilistic mechanism of failure changes over time only through the time since entry into the study. However, the life-table method does not (without modification) allow survival studies with staggered entry to be monitored repeatedly or sequentially over calendar time (*see* **Data and Safety Monitoring**). Occasionally, for reasons of biomedical interpretability and statistical simplicity, the investigator will choose to analyze the data using age or time from onset of some exposure or disease condition as primary time-scale [19], and here also explicit consideration of the staggered exposure times at entry is necessary. In any case, biological age or calendar time of entry can be included as **covariates** or stratifying variables in the statistical analysis (*see* **Stratification**). A crucial assumption in analyzing data with staggered entry is that the prospective time until the primary study endpoint for individual patients can be considered *stochastically* independent of the calendar time of entry, at least conditionally given some other time-scale value such as biological age at entry. In other words, one must assume that there is no (unmodeled) tendency for the patients with worse prognosis to enter the study either systematically earlier or systematically later than the patients with better prognosis.

Mathematically, the special features of a study with staggered entry arise from the presence of at least two time-scales relevant to survival, which bear an unpredictable relationship to one another for individual study subjects. For demographic or epidemiologic population studies – with **cross-sectional**, **cohort**, or mixed designs – the relation between the calendar and individual age time-scales has classically been presented in the form of a **Lexis diagram**, which plots an individual's lifetime as a vector from study entry to failure (or censoring), using calendar time as x-axis and age or study time as y-axis. See Figure 1 for an illustrative Lexis diagram concerning 15 patients from a recent clinical trial, where times are given in months. Keiding [16, 17] gives a historical perspective on Lexis's work, with many references. However, features of *multiple time-scales* exist also in many other types of failure-time data not ordinarily regarded as coming from studies with staggered entry. Other examples of such time-scale pairs include: time from diagnosis and chronological time; time since diagnosis and time since onset of some related risk factor or exposure; and chronological time and cumulative exposure. In studies of the reliability of manufactured components, times to failure collected chronologically are often also studied in terms of the *operational time* [3, 32], which can for example be the cumulative time under significant loading, or the CPU time in a computer setting.

The random data observed in a (singly right-censored) staggered entry study are generally of the form $(T, \delta, (\mathbf{Z}(t), 0 \leq t \leq T))$, where T denotes the time for a single study subject from a specified time

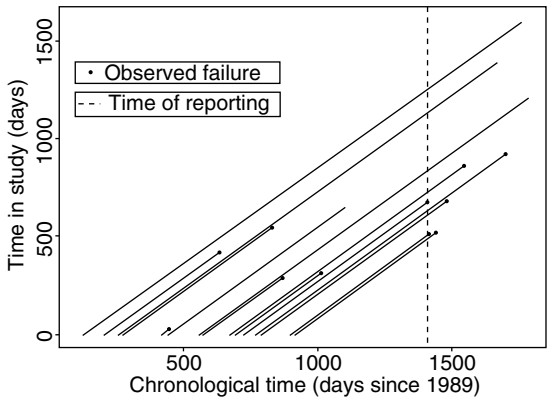

Figure 1 Lexis diagram drawn for 15 selected patients from a clinical trial. Entry time in days from the beginning of 1990 for each study subject is displayed as the initial x-coordinate for a 45° segment. At the upper-right endpoint of the segment, a dot is plotted if an observed failure occurred; otherwise, that subject's failure time was right-censored due either to loss to follow-up or to final reporting (at the time, equal to 1400, marked by the vertical dashed line) of the study results

origin (*study entry*) until the earlier of the primary endpoint and loss to follow-up; δ is the indicator variable for the event that the primary endpoint precedes loss to follow-up; and $\mathbf{Z}(t)$ denotes a vector process of *covariates*, some of which may be independent of time, observable at time $t \leq T$ after entry. There is often at least one covariate-component $Z_k(t)$ affecting survival which measures a cumulative time variable for the study subject from some time origin α until t time units following study entry. In the standard staggered entry survival study, or epidemiologic study accounting for time from onset of some condition or risk factor which never disappears, $Z_k(t) = A_k + t$ is completely determined by the time from origin α to study entry; but in studies accounting for the cumulative measurement of intermittent exposure or another *operational time*, $Z_k(t)$ may also exhibit random variation for $t > 0$. Although there are large literatures on *general* or *multiple censoring* (see [1, Chapter 3]), and on responses more complex than a single survival endpoint, we restrict attention for the rest of this article to the case described above, of right-censored survival data.

Many of the most important themes in statistical survival analysis – both theoretical and practical – are closely connected to the analysis of survival studies with staggered entry. These include: semiparametric modeling and inference for failure hazards, with a parsimonious choice of time-scale and covariates; analysis of left **truncated** and randomly right-censored data; biased sampling frames which can arise in cross-sectional designs, where some strata of the population are oversampled due to time-dependent and random entry criteria; and sequential monitoring of survival studies. In the next several paragraphs, we briefly describe the most important papers and results connecting these topics with staggered entry survival data.

Failure Models with Modified Time-Scale or Time-Dependent Covariates

Suppose that the observable data $(T, \Delta, E, \mathbf{Z})$ on each study subject consist of an event time T (time from entry until death or censoring), an observed failure indicator Δ, a biological age E at entry, and a vector of possibly time-dependent covariates $\mathbf{Z}$. The conditional failure hazard intensity $\lambda_{\mathbf{Z},E}(t|\mathbf{z}, u)$ at study-time t and entry age u, given $E = u$, $\mathbf{Z} = \mathbf{Z}(t) = \mathbf{z}$, is a general three-variable function, which one could attempt to model further by treating the age-at-entry variable as a continuous time-independent covariate or the age-at-event variable $E + T = t + u$ as a time-dependent covariate. In many clinical studies, where the age-at-entry variable E is found not to be significantly predictive of survival, one can simply drop the dependence of $\lambda_{\mathbf{Z},E}$ on E and restrict attention to the possible relationship between survival measured on the time-since-entry time-scale T and the (usually time-independent) covariates $\mathbf{Z}$.

At least in the absence of other covariates $\mathbf{Z}$, the purpose of the Lexis diagram is to help understand the dependence of λ on the two time variables T, $T + E$. A general nonparametric estimator for the corresponding two-time-variable cumulative hazard function $\Lambda(t, s) = \int_0^t \int_0^s \lambda_0(x, y)\, \mathrm{d}y\, \mathrm{d}x$ is given by McKeague & Utikal [23], who also address under minimal assumptions the basic statistical problem of testing for the presence of the covariate-adjusted relationship between a specified covariate such as *treatment* or *exposure* and the waiting time until the primary endpoint. The methodology of Cox [11], later elaborated by many authors (see [1]), applies directly when $\lambda_{\mathbf{Z},E}(t|\mathbf{z}, u)$ depends either on t alone for both values of $\mathbf{z}$ or on $t + u$ alone, in which cases we call respectively T or $T + E$ the *primary time-scale*. Another common approach [6] is to analyze data taking into account a *cohort effect* via a Cox model stratified upon (5- or 10-year groupings of) age at entry. Alternatively, Oakes [25] discusses the possibility of combining the time variables T and $T + E$ into a single time variable with respect to which survival data could be analyzed by conventional methods. The choice between the age at event, $T + E$, or time since entry, T, as the primary time-scale can be important if, for example, the covariate enters a Cox [11] proportional hazards regression model through a variable such as $\ln(E + T)$ or $(E + T)^b$ for known b. Korn et al. [19] discuss the choice of primary time-scale with special reference to examples where $T + E$ is the better choice. Here "better" means implicitly that the resulting model is simpler or more parsimonious, without the need for a time-dependent covariate involving the secondary time variable. However, it should be noted that the correctness of a "simplest" model with noticeable entry-time-dependent or cohort effects implies that any model without such effects must be misspecified.

Left Truncation and Right Censoring

Suppose that subjects of a survival study are drawn from a population who have some condition or risk factor (either the disease under investigation or some other factor), but for whom the time of onset of the condition is not known. (This can occur even in the commonest situation, where study subjects are recruited at the time of diagnosis, within population strata defined by presence or absence of some risk factor(s) at baseline.) Then the survival data are *left-truncated* in the sense that no information is collected on individuals without the condition who might otherwise have been included in the study (*see* **Delayed Entry**). It is well known that left-truncated and right-censored survival data can be analyzed via (a slight modification of) the life-table method [18]. Intuitively, this works because the life-table method infers prospective rates of failure, in terms of time since entry, from the fraction of each *risk group* of individuals under observation at specified time since entry, t, who survive to later times t'.

Random right-censoring is a characteristic feature of survival studies with staggered entry. Clinical studies are often designed to have a fixed calendar duration. If subjects were entered in a cross-sectional cohort, then those subjects without observed primary endpoints have *censoring times* from entry until analysis of the data which are identical to the (nonrandom) duration of the study. By contrast, if entry into the study is staggered, then censoring times are the waiting times from entry until the end of the study. Since recruitment into clinical studies is often assumed to be **uniformly distributed** over a specified period of calendar time, the censoring times would also be uniformly distributed. In this context, the assumption that time of entry is unrelated to survival time is equivalent to the assumption of independence between survival and right-censoring times, without which any estimation of survival-time distributions is problematic [37].

Biased Sampling for Cross-Sectional Data

Cross-sectional recruitment into survival studies at first sight seems to be the polar opposite of staggered entry. Here the subjects are entered at a single calendar time, but their biological ages, times of onset of risk factors and exposures, and times of diagnosis are still unpredictable with respect to one another. Therefore, the chronological and biological time-scales are still staggered with respect to one another, and the same considerations of modeling and analysis and multiple time-scales discussed above come into play. The papers of Keiding [16], Weldon & Potvin [41], Wang [40], and Yang & He [42] discuss various aspects of inference of disease **prevalence** and **incubation periods** as well as distributions for waiting times until medically interesting study endpoints. These papers also explicitly recognize that cross-sectional and some other sampling frames can be *biased* in the sense that study subjects are oversampled (as compared with the general patient population) in some population strata and underrepresented in others. For example, in cross-sectional studies where data on coronary risk factors are collected initially, subjects with long durations between onset of the risk factor and the study endpoint will be overrepresented. Slud & Kopylev [36] study the effect of such biased sampling in inducing dependence between death and censoring times. All of the papers mentioned in this paragraph warn that when covariate risk indicators are left-censored, as naturally happens when data are sampled cross-sectionally, straightforward regression analyses in terms of these covariates can lead to biases.

Sequential and Group-Sequential Analysis

We have described above several ways in which staggered entry affects the modeling of survival data, but staggering plays a direct role in the two-sample inference of treatment effectiveness primarily in repeated or **sequential** statistical survival analyses (*see* **Data and Safety Monitoring**). The mathematically most sophisticated work related to staggered entry has been done under this heading.

Although the early parametric sequential method of Breslow & Haug [5] did allow for random staggered entry over an accrual period, most effort has gone toward extending **nonparametric** statistics, repeated significance tests and (group) sequential procedures to the staggered setting where the calender time parameter used for repeated testing is not the same as the underlying time on test. Early work on the *group-sequential* approach to repeated significance tests in clinical trials [2, 26, 28]

advocated repeated monitoring (with possible early termination) in chronological time. Initially, the necessary asymptotic distribution theory with respect to survival-time statistics such as the **logrank** was available only for trials with *progressive censoring*, in which subjects were accrued simultaneously in a cohort or in which interim analyses would follow the termination of accrual [9, 20]. For the realistic case of trials with staggered entry, Jones & Whitehead [15] proposed – for both the logrank and Gehan-modified Wilcoxon statistics – that the asymptotic distribution theory for statistics repeatedly calculated in chronological time would be given by treating the statistics plotted against the cumulative statistical (Fisher) **information** as a **Brownian motion** process. For the logrank, this was completely substantiated: Tsiatis [39] proved it for the case of finitely many calendar times; then Sellke & Siegmund [30], with cumulative (estimated) statistical information replacing calendar time, and Slud [34], using actual calendar time, showed that the two-time-parameter normalized logrank statistic converges weakly to a continuous Gaussian process with two-dimensional time. For the modified Wilcoxon statistic in a staggered entry setting, Slud & Wei [38] showed that the asymptotic theory differed from that proposed by Jones & Whitehead, and that the repeatedly calculated statistic has dependent increments. By contrast, Slud [34, Corollary 2.4 and Proposition 2.5] (in which the functions $q(u)$ and $L(u)$ should additionally be assumed nonrandom) showed that weighted logrank statistics have uncorrelated increments (which are asymptotically jointly Gaussian, and therefore independent) if the weighting function does not depend upon calendar time.

The asymptotic distribution theory for statistics of clinical trials with staggered entry has required an understanding of the behavior of these statistics as two-time-parameter **stochastic processes** when calculated using all data available up to time on test, s, and chronological time, t. Majumdar & Sen [22] early on had the idea (further developed by Sen [31] and Sinha & Sen [33]) of using a two-time-parameter process, with time on test and number of subjects entered as the two time-scales. They provided the relevant asymptotic distribution theory, based on an assumed target sample size, for the maximum of the logrank statistic calculated at all times and numbers accrued. The more fruitful direction has been to develop the theory of clinical trial statistics as two-time-parameter processes with respect to the time on test and chronological time-scales. Sellke & Siegmund [30] and Slud [34] obtained their results on such processes via one-time-parameter martingale theory. Slud [35] represented (weighted) logrank statistics as stochastic integrals with respect to compensated two-time-parameter counting processes, using results from the theory of two-parameter (strong) martingales (see the next section) to show the weak convergence of a two-time-parameter **Kaplan–Meier estimator**. Gu & Lai [12] gave a general treatment using empirical process theory (in the case of independent and identically distributed (iid) data records for study subjects) of two-parameter weighted logrank and Kaplan–Meier statistics. This work could be used to design sequential and group-sequential clinical trial monitoring schemes based on Kaplan–Meier estimators. The empirical process approach has culminated in recent works by Gu & Ying [13] and Bilias et al. [4] on two-time-parameter analysis of Cox model estimators and **partial likelihood** score statistics under Cox-type semiparametric models with staggered entry, which could be implemented in real clinical trials if model-based group-sequential analyses were of interest.

Mathematical Tools in the Underlying Theory

It remains to describe briefly the main mathematical tools and techniques which have been used to establish the theoretical results surveyed above. To fix ideas, consider the case of iid staggered entry survival data $(E_i, T_i, \Delta_i, Z_i)$ as above, where the **binary** variables Z_i are randomized treatment-group indicators. Define

$$N_i(s,t) = I_{[E_i+T_i\le t, T_i\le s]}\cdot\Delta_i,$$
$$Y_i(s,t) = I_{[E_i+T_i\ge t, T_i\ge s]}.$$

Just as one defines a compensator for counting processes in a single time-scale, one defines a compensator for the two-time-scale process N, namely

$$A_i(s,t) = H(\min(s, C_i, t-E_i)),$$

where H is the cumulative failure hazard, assumed identical for all study subjects. Then the compensated processes $M_i(s,t) = N_i(s,t) - A_i(s,t)$ is a *two-parameter (strong) martingale* in the sense that for all t, $M_i(\cdot, t)$ is a martingale with respect to the filtration $\mathcal{F}_s^{\text{study}}$ generated by all random variables observable up to study time s, and for all fixed s, $M_i(s, \cdot)$ is a martingale with respect to the filtration $\mathcal{F}_t^{\text{chron}}$ generated by all random variables observable up to chronological time t. The two-parameter strong martingale property is a very special one, and holds in the iid staggered entry case essentially because, for each subject, after entry the two time-scales are deterministically related to one another.

Since $M(\cdot, t)$ is the usual compensated failure-counting process based upon data available up to chronological time t, the usual weighted logrank and Kaplan–Meier statistics have well-known representations as stochastic integrals with respect to

$$M(s,t) = \sum_{i=1}^{n} M_i(s,t),$$

$$M^{(1)}(s,t) = \sum_{i=1}^{n} Z_i M_i(s,t).$$

Many of the inequalities and **limit theorems** for one-parameter martingales have immediate extensions to the case of strong two-parameter martingales. The (Doob submartingale) maximal inequality has a counterpart proved by Cairoli [7]; the basic definitions and properties of stochastic integrals are due to Cairoli & Walsh [8]; the Burkholder inequalities have generalizations due to Métraux [24], Ledoux [21], and Chevalier [10]. These inequalities lead [35] to a two-parameter functional **central limit theorem** of the type of McLeish–Rebolledo–Helland [14], which Slud [35] used to obtain a two-time-parameter weak **convergence** theorem for the Kaplan–Meier statistic.

The papers of Gu & Lai cited above, beginning with [12], took a completely different and extremely productive approach to the theory of two-time-parameter weak convergence. They relied on deviation estimates and inequalities from empirical process theory [29]. These, together with functional central limit theorems for processes (derived from) $M(s,t)$, $M^{(1)}(s,t)$ above, carry over naturally to the two-time-parameter setting.

Standard Deviation

The standard deviation of a random variable X is a measure of the variable's spread or dispersion around its mean. The **mean** is the average or expected value of X, and is a measure of the center of its distribution. The mean can also be viewed as a "typical" value of X. By definition, however, the outcome of a **random variable** is unpredictable and will vary from one trial to the next; the standard deviation describes the amount of variation that can be expected around the average value. If the mean of X is represented by $\mathrm{E}(X)$, then its **variance** is defined by

$$\begin{aligned}\mathrm{var}(X) &= \mathrm{E}[X - \mathrm{E}(X)]^2 \\ &= \mathrm{E}(X^2) - [\mathrm{E}(X)]^2,\end{aligned}$$

provided that $\mathrm{E}(X)$ exists. The standard deviation is the positive square root of the variance,

$$\mathrm{sd}(X) = [\mathrm{var}(X)]^{1/2}.$$

The mean of a random variable X is often denoted by μ, its variance by σ^2, and the standard deviation by σ.

From the preceding definition, the standard deviation of X is a sort of average of the deviation of X from its mean. If X is a measurable quantity such as length or temperature, then, unlike the variance, the units of measurement for the standard deviation are the same as the units for X. If X is measured in meters, for example, then $\mathrm{sd}(X)$ is measured in meters as well. In general, a large standard deviation indicates that the outcomes of X are widely distributed around its mean, while a small standard deviation means that the outcomes are more homogeneous and cluster tightly around the center.

To calculate the standard deviation of a random variable, it is necessary to know the probability distribution of X. If X is a discrete random variable with mean $\mathrm{E}(X) = \mu$, then

$$\begin{aligned}\mathrm{var}(X) &= \sum_{i=1}^{k} (x_i - \mu)^2 \Pr(X = x_i) \\ &= \left[\sum_{i=1}^{k} x_i^2 \Pr(X = x_i)\right] - \mu^2,\end{aligned}$$

where $x_1, x_2, \ldots x_k$ are all outcomes of X such that $\Pr(X = x_i) > 0$. If X is a continuous random variable with probability density function $f(x)$ and mean $\mathrm{E}(X) = \mu$, then

$$\begin{aligned}\mathrm{var}(X) &= \int_{-\infty}^{\infty} (x - \mu)^2 f(x)\,\mathrm{d}x \\ &= \left[\int_{-\infty}^{\infty} x^2 f(x)\,\mathrm{d}x\right] - \mu^2.\end{aligned}$$

In each case, $\mathrm{sd}(X)$ is the square root of the variance.

A linear transformation of the random variable X affects the standard deviation in a straightforward manner. If a and b are constants and if the random variable $Y = aX + b$, then

$$\mathrm{sd}(Y) = |a|\mathrm{sd}(X).$$

There is no variability in a constant.

In practice, the standard deviation of a distribution can be estimated using the information contained in a sample of observations drawn from that distribution. If $x_1, x_2, \ldots x_n$ is a **random sample** of size n selected from a population with mean μ and standard deviation σ, then the sample standard deviation is represented by s and is defined by

$$\begin{aligned}s &= \left[\sum_{i=1}^{n} (x_i - \overline{x})^2 \Big/ (n-1)\right]^{1/2} \\ &= \left[\left(\sum_{i=1}^{n} x_i^2 - \left(\sum_{i=1}^{n} x_i\right)^2 \Big/ n\right) \Big/ (n-1)\right]^{1/2},\end{aligned}$$

where $\overline{x}$ is the sample mean

$$\overline{x} = \frac{\sum_{i=1}^{n} x_i}{n}.$$

Just as σ describes the dispersion of a distribution around its mean μ, s describes the spread of a sample of values around the sample mean $\overline{x}$. It can be thought of as a form of average of the deviations of the observations from the sample mean. While s^2 is an **unbiased** estimator of σ^2 over all possible random samples of size n, meaning that $\mathrm{E}(s^2) = \sigma^2$, s is *not* an unbiased estimator of σ.

Together, the sample mean $\overline{x}$ and standard deviation s are very useful for summarizing a set of measurements. The mean indicates where the observations are centered; the standard deviation quantifies the amount of dispersion around the center. More explicitly, Chebyshev's inequality states

that for any k which is greater than or equal to 1, at least $[1 - (1/k)^2]$ of the measurements lie within k standard deviations of the mean. Given $k = 2$, for example, at least $[1 - (1/2)^2] = 3/4$ of the values lie in the interval $\overline{x} \pm 2s$. Equivalently, it can be said that this interval encompasses at least 75% of the observations in the group. Similarly, the interval $\overline{x} \pm 3s$ contains at least 89% of the measurements. These statements are true no matter what the values of $\overline{x}$ and s, and regardless of the shape of the distribution from which the sample was drawn.

The summary provided by the sample mean and standard deviation can often be made more precise when the shape of the distribution of values is, in fact, known. If the data are symmetric and unimodal, for instance, then approximately 95% of the observations lie in the interval $\overline{x} \pm 2s$, and almost all of the values are contained in $\overline{x} \pm 3s$.

The sample mean and standard deviation can also be used to compare the variability of data sets representing different quantities or different types of measurements. The *coefficient of variation* is defined as

$$CV = 100\% \times \frac{s}{\overline{x}},$$

and is a measure of relative variability. Because s and $\overline{x}$ share the same units of measurement, these units cancel out and leave CV a dimensionless number. Since it is independent of measurement units, the coefficient of variation can be used to compare the amount of dispersion for any two sets of values. A larger coefficient implies that there is more variability among the measurements.

(*See also* **Mean Deviation**; **Moments**)

K. GAUVREAU

Standard Error

The term standard error (se) is used to refer to the **standard deviation** (sd) of an estimator or sample statistic. As such, it is a measure of the estimator's variability around its expected value (**expectation**) or **mean**.

More specifically, standard error often refers to the standard deviation of the sample mean $\overline{x}$. If $x_1, x_2, \ldots x_n$ is a **random sample** of size n selected from a population with mean μ and standard deviation σ, then the sample mean is defined by

$$\overline{x} = \frac{\sum_{i=1}^{n} x_i}{n}.$$

The sample mean can be used to estimate the true population mean μ. This statistic is itself a **random variable**; its value is unpredictable and will vary from one sample to the next. This variability or dispersion can be characterized by the standard deviation of the estimator $\overline{x}$, where

$$\begin{aligned} \mathrm{sd}(\overline{x}) &= \mathrm{se}(\overline{x}) \\ &= \frac{\sigma}{\sqrt{n}}. \end{aligned}$$

To illustrate this idea, suppose that we were to select repeated samples of size n from the underlying population with mean μ and standard deviation σ and calculate the mean of each one. We would end up with a set of sample means $\overline{x}_1, \overline{x}_2, \overline{x}_3$, etc. Each of these means can be treated as a unique observation; their collective distribution is called a **sampling distribution**. While σ measures the standard deviation of the original population and tells us how much variability to expect among the individual observations, $\mathrm{se}(\overline{x}) = \sigma/\sqrt{n}$ measures the standard deviation of the sampling distribution and tells us how much variability to expect among the means. Although the standard error is related to the population standard deviation σ, there is less variability among the sample means than there is among the individual observations. Even if a particular sample contains one or two extreme values, it is likely that these values would be offset by the other measurements in the group. As n increases, the amount of sampling variation – and thus the dispersion among the means – decreases.

The standard error of the sample mean $\overline{x}$ can be estimated by substituting the sample standard deviation s for σ, where

$$s = \left[\left(\frac{\sum_{i=1}^{n} (x_i - \overline{x})^2}{n-1} \right) \right]^{1/2}.$$

Therefore,

$$\widehat{\mathrm{se}}(\overline{x}) = \frac{s}{\sqrt{n}}.$$

The estimated standard error plays an important role in statistical inference on a population mean; it is vital to the construction of **confidence intervals** and the performance of **hypothesis tests**.

K. GAUVREAU

Standard Gamble Technique

In recent years the concept of **utility** has been introduced to both clinical decision making (i.e. decisions regarding the best course of action for a patient; *see* **Decision Analysis in Diagnosis and Treatment Choice**) and **program evaluation** (i.e. the best way of using available health care resources or economic evaluation of health care programs). The Standard Gamble (SG) technique is a classic method of measuring an individual's utility (i.e. preferences) under uncertainty. The measurement of individuals' preferences under uncertainty is important because decisions about health interventions at both the individual and the community levels (stemming from the unique nature of health as a nontransferable goal) are made under uncertainty [2]. It is used to measure von Neumann–Morgenstern (vNM) utility functions [20] over life-years and health states, preference weights to be used in the QALY (quality-adjusted life-years) calculations (*see* **Quality of Life and Health Status**) and the healthy years equivalent (HYEs).

The SG Technique

The SG technique is a lottery-based technique where the respondent is asked to indicate a state of indifference when comparing two lotteries or a lottery to a sure thing. The SG question is a general question. However, to be able to interpret the answers we need an underlying theory [20]. The most common one is the vNM utility theory. The SG in the context of a vNM type individual will be the focus of this article. For a review of this method and its application in general see [4], and for its use in health care see [19] or [6]. For simplicity, but without loss of generality, most of this article deals with the case of estimating a preference value for a chronic health state. In this situation an individual has a particular number of remaining life years in a given constant health state.

We use the following notations and definitions. Let Q and T denote two attributes of the outcome of concern ($Q =$ the health state of the individual, $T =$ remaining life years). Let FH represent the state of full health and D death ($D \leq Q \leq FH$). Let $U(Q, T)$ be a vNM utility function that describes the utility of being in a given health state, Q, starting now, for a period of T years, followed by death, as viewed now by the individual. For the case of chronic health state the SG technique is applied as follows (see also Figure 1):

> The subject is offered two alternatives. Alternative 1 is a treatment with two possible outcomes: either the patient is returned to normal health and lives for an additional T years (probability p), or the patient dies immediately (probability $1 - p$). Alternative 2 has the certain outcome of chronic state I (Q using the above notation) for life (T years). Probability p is varied until the respondent is indifferent between the two alternatives at which point the required preference value for state I (Q using the above notation) is simply p^* [19, p. 20].

Props and visual aids are recommended for use to help respondents understand the task.

Using the notation defined above it can be shown that $U(Q, T)$, the preference value of living T years in health state Q, is equal to p^*. More specifically, using the vNM utility theory (also known as expected utility theory) at the indifference point, the following relation holds: $U(Q, T) = p^*U(FH, T) + (1 - p^*)U(D, T)$, where p^* is the indifference probability. Denoting $U(FH, T) = 1.0$ and $U(D, T) = 0.0$, we have $U(Q, T) = p^*$.

An important question is whether one can measure the utility of a health state for a unit of time, say one year [i.e. $U(Q, 1)$]. Gafni [6] deals with this question extensively. In brief, even though in theory this is an option, it seems that in practice it will not work. For example, we can ask individuals to imagine living one year, followed by death, in each of the outcome alternatives. This is likely to be seen as threatening by participants, especially when they are evaluating less severe health states and are not very old. A common problem in many studies is that they do not incorporate any explicit statement about

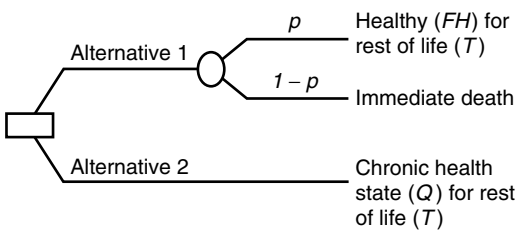

Figure 1 The Standard Gamble method for eliciting utilities for a chronic health state, Q, for rest of life T

the time period spent in the health state and what will happen after this period is over [6]. If this is not done one does not know what the respondent assumed about the length of time spent in the health state and the future states when responding to the SG question. If individuals assume different durations and future states, then their responses will embody an additional component of variation that cannot be tested out.

Interpreting the Scores

The health of an individual is unlike many other outcomes studied in **decision theory** or economics. For example, the health of an individual has a time aspect inextricably bound to it. Thus, one cannot measure only the preference value attributed by individuals to different health states while ignoring the time spent in this health state. In this sense, health is a two-dimensional phenomenon. In particular, Gafni & Torrance [5] argue that the utility (or preference value) for additional time in a given health state – measured using the SG method – depends on a quantity effect (related to the duration in the state), a time effect (reflecting time preference), and gambling effect (reflecting risk attitude). Recently, Gafni [7] added another factor – sequence effect (the order of bad and good events). Thus, observed values of $U(Q, T)$ already embody the individual's risk attitude, time preference pattern, attitudes toward additional quantities of life, and the sequences of events.

As explained, the SG technique provides an individual's preference score for living in a given health state for a given period of time, that is, $U(Q, T)$. Yet many researchers interpret this value as a "timeless" one. They define a general utility scale where a score of 1.0 represents a normal or "healthy" state and 0.0 represents the health state dead. Interpreting the values measured as "timeless" allows the development of tables in which different health states are organized in declining order from healthy (1.0) to death (0.0) (and even states worse than death), regardless of the time spent in each health state and assuming that the preference value attributed to a health state is independent of the sequence of other health states in the individual's lifetime health profile.

Another way to interpret these values is to assume, for example, that a "constant proportional trade-off" exists between quality of life (Q) and time (T), which has been shown to be a prerequisite for using the SG scores as weights in QALYs calculations (see [17]). Under this assumption, the proportion of remaining life that one would trade for a specific quality improvement is independent of the amount of remaining life. For the case of a lifetime health profile (i.e. the case where the individual can experience different health states during his or her lifetime) an additional assumption is required – that in the person's preferences, qualities of life at different times are strongly separable [3, 16]. In other words, the person's preferences about the quality of his or her life in any particular point in time are independent of the qualities of his or her life in other years.

It is important to emphasize that the constant proportional trade-off assumption and the strong separability assumption are additional assumptions to those underlying the theoretical foundation of expected utility theory (or vNM utility theory). In other words, an individual can be an expected utility maximizer without following these particular assumptions. Indeed, many who have invoked these assumptions admit that they are very restrictive and unlikely to represent individuals' behavior. Furthermore, these assumptions have no normative appeal (i.e. they do not reflect the discipline view of the world regarding how an individual should behave) nor are they supported by empirical evidence [3, 9]. Hence in treating preferences for health states as "timeless" we are thus at risk of misrepresenting the actual preferences of people (see, for example, [6]).

Aggregation of SG Scores

Until now we have concentrated on the measurement of an individual's preferences. For program evaluation (i.e. cost–utility analysis) we need a social perspective (*see* **Health Economics**). The current practice is that in cost–utility analysis "the aggregation across subjects is achieved by measuring all individual utilities on the common 0–1 dead–healthy scale and taking the arithmetic mean" [19, p. 17]. This simple (nonweighted) **mean** of individuals' responses is used to derive a "social valuation" of the weights (per unit of time) to be used in QALYs calculations. The question of aggregation of individual utilities and its validity has been

addressed by many authors (for example, [1, 11, 12, 14], and [18]). In this section I do not deal with the question of whether or not it is valid to aggregate individual utilities but assume that it can be done (albeit under a very restrictive set of assumptions).

In this section I question the meaning of aggregating individual preference scores measured using different time horizons, based on the simple arithmetic mean. As explained, each preference score represents the utility of living a period of time in a given health state [i.e. $U(Q, T)$]. For the chronic health state (which we use as an example), the time span is usually defined as the individual's expected life span (*see* **Life Expectancy**). In most health programs individuals who participate have different expected life spans. Thus, the simple aggregation rule implies subscribing to the equity criterion that the reference state of full health for the rest of the individual's life should be treated as of equal value for all individuals. However, as shown by Gafni & Birch [8], the equity criteria used to justify this method of aggregation differ from the one indicated above.

Whether a particular equity criterion is appropriate or not is a subjective issue. However, equity considerations (i.e. the relative values or weights attributed to different individuals or groups) are an intrinsic part of any evaluation. It is thus important that consideration is given to the question of whether the procedure measuring the outcome is consistent with the stated equity criteria. Gafni & Birch [8] deal with this issue extensively and derive adjustment **algorithms** based on the axioms of vNM utility theory, taking into account the different equity criteria adopted in the literature. It is important to emphasize that these adjustment algorithms add to the complexity of the measurement task.

Alternative Uses for the SG Technique

For those who do not want to subscribe to the strong assumptions of the QALY model, two alternatives exist. The first one is to use the SG technique to measure vNM utility scores directly for different potential lifetime health profiles. This can be done by asking one SG question for each lifetime health profile that we want to measure, i.e. using a holistic approach. These values can be used as measures of outcome at the endpoints of a decision tree. We can then calculate the expected utility of each treatment option and choose the one with the highest expected value. The disadvantage of this option is that it creates a communication problem. Expected utility is a theoretical notion that has no direct empirical meaning. In other words, the unit of outcome (i.e. util) has no intuitively appealing meaning to many users (e.g. clinicians or administrators). For example, it will be difficult for them to understand the meaning of cost per util.

Following the need to improve communication (i.e. to preserve the intuitively appealing meaning of the QALY measure) in a way which is consistent with the concept of utility, Mehrez & Gafni [15] suggested an alternative measure – HYE (healthy years equivalent). This measure, based on the theoretical foundation of utility theory, stems directly from the individual's utility function and thus does not require that the individual subscribes to the additional assumptions of the QALY model (or even to the underlying assumptions of the vNM utility model). It only requires that the individual's preferences should be measured under conditions of uncertainty. It combines outcomes of both quality of life (morbidity) and survival (mortality) and thus can serve as a common unit of measure for all programs, allowing comparisons across programs. It preserves the intuitively appealing meaning of the QALY by using years of life in full health as the unit of measurement.

For the case of a decision tree and a vNM type individual, the following two-stage, lottery-based procedure can be used [7, 10, 13]. In stage I, we first use the SG method to measure the utility of all potential lifetime health profiles (i.e. a holistic approach), and secondly calculate the expected utility for each treatment option. In stage II, we "convert" the expected utility of each treatment option to HYE again using the SG method but with a different type of question. In the second SG question the subject is offered two alternatives. Alternative 1 is the same lottery offered in the previous SG question with one change. The probabilities for the two outcomes are now known (i.e. $p = EU$ and $1 - p = 1 - EU$, where $EU =$ expected utility from the treatment). Alternative 2 is living H years in full health. H is varied until the individual is indifferent between the two alternatives. The indifference point H^* defines the certainty equivalent number of years in full health (HYE) that produces utility (i.e. preference value)

equal to the expected utility of the treatment. Note that this procedure illustrates the communication role of the HYE measure. By comparing the expected utility of each treatment option one can determine which treatment is preferable. However, the outcome is presented in units that are difficult to understand (i.e. utils). By adding the second stage we are able to "translate" the results to more meaningful units and thus achieve the goal of communication. For adjustment algorithms that take into account different equity criteria for the case of HYE see Gafni & Birch [8].

Debate in the literature has centered mainly around the theoretical properties of QALYs and HYEs. It seems that the theoretical superiority of the HYE has been established (e.g. in [13]); however, doubts have been raised about the feasibility of measuring HYEs. A recent paper [10] deals with this issue. In brief, the authors discuss the feasibility of measurement using the algorithm described above and the respondent burden in terms of the number and complexity of questions posed. They conclude that HYE will generally involve greater measurement burden than QALYs, but this need not always be restrictive. When the additional measurement burden on subjects is restrictive, they show how the task can be simplified and the measurement burden shared between respondents. Although the number of profiles to be assessed will make HYE infeasible for complex (i.e. very large) decision trees, analysts must view this study design issue in the broader context of the trade-off between precision of the model vs. **bias** when valuing outcome.

Standard Normal Deviate

If a **random variable** X follows a **normal distribution**, then the standard normal deviate measures the distance between a particular outcome of X and the **mean** of X in units of the **standard deviation**.

Suppose that X is a normally distributed random variable with arbitrary mean μ and standard deviation σ. While μ represents the center of the distribution of X, σ specifies the amount of dispersion or spread around the mean. Together, these two parameters completely define the shape of the normal curve.

We often wish to evaluate probabilities associated with various outcomes of the random variable X. For instance, if c is a constant, we might wish to know $\Pr(X \leq c)$. One way to determine this is to look up the probability using a table of areas calculated for this specific normal curve. Since a given normal distribution can have an infinite number of values for its mean and standard deviation, however, it is impossible to tabulate the probabilities associated with each and every curve. Instead, only a single curve is tabulated – the special case for which $\mu = 0$ and $\sigma = 1$. This curve is known as the standard normal distribution.

To use the table of the standard normal distribution to look up probabilities associated with a generic normal random variable X which has mean μ and standard deviation σ, we must rescale X to have mean 0 and standard deviation 1. The rescaled random variable is defined by

$$Z = \frac{(X - \mu)}{\sigma};$$

we take the random variable X, subtract its mean, and divide by its standard deviation. Instead of evaluating $\Pr(X \leq c)$ directly, therefore, we would evaluate

$$\begin{aligned} \Pr(X \leq c) &= \Pr\left(\frac{X - \mu}{\sigma} \leq \frac{c - \mu}{\sigma}\right) \\ &= \Pr\left(Z \leq \frac{c - \mu}{\sigma}\right). \end{aligned}$$

An outcome of this rescaled random variable – $(c - \mu)/\sigma$ in the example above – is known as a standard normal deviate or a z-score. Unlike the original outcome c, it does not have any units of measurement. It tells us how far the value c lies from the mean μ, measured in standard deviations. If $Z = -2$, for instance, then c must be two standard deviations below the mean.

K. GAUVREAU

Standardization Methods

Standardization methods are used to adjust for the effects of age and sex, and possibly other factors, in the comparison of disease **rates** between two or more populations. In what follows, adjustment for age will be described, but all the methods can be extended to adjust for other factors, such as sex.

Standardization methods have a long history, and rank among the earliest statistical tools developed. Keiding [21] has traced their origins to eighteenth century actuarial mathematicians (*see* **Actuarial Methods**), though they were reinvented a century later by Neison and **Farr**. Neison was a famous statistician of his day, writing regularly in the *Journal of the Statistical Society* on a wide variety of subjects. Farr was a government official who worked as the "compiler of abstracts" in the Office of the Registrar General for England and Wales from 1839 to 1880. These two eminent men recognized that the comparisons of crude death rates (*see* **Vital Statistics, Overview**) were not sufficient for examining mortality patterns over time (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**), or between geographic areas (*see* **Geographic Patterns of Disease**; **Mortality, International Comparisons**). They also showed that the **average age at death** was not an appropriate index for assessing differences in mortality [25].

In 1841, Farr published age-specific death rates and compared them to rates for the previous three years to show how the pattern of mortality had changed (Registrar General 1841; see [37]). Examination of age-specific rates (usually stratified by sex as well) is widely considered to be the most comprehensive way of comparing disease rates across populations. However, when many populations and types of disease are to be studied, the number of individual rates requiring scrutiny, rapidly becomes awkwardly large. A further summarization of the data is therefore required.

Farr introduced the idea of an external standard population, against which other populations could be compared (Registrar General, 1853; see [37]). His standard was the so-called "healthy counties" in England and Wales. He calculated a set of standard death rates for these counties against which those for other counties could be compared. He then took each of the age-specific rates in the "healthy counties" and multiplied them by the numbers of people of comparable age in the county of interest. In this way he derived an **expected number of deaths** in each age group.

This was not an entirely new method, as Neison had performed similar calculations on rates from two areas of London to prove that the method of comparing average ages at death was flawed [25]. Farr, however, went on to sum the age-specific expected deaths to give the total number of deaths in each county that would be expected if the mortality was the same as in the "healthy counties". The expected number could be compared with the observed number to assess how each county's mortality differed from that in the standard (*see* **Excess Mortality**). Multiplying the ratio of observed to expected deaths by the crude rate in the standard population provided a standardized rate for each county (Registrar General 1857; see [37]). This method is now known as *indirect standardization* and it has remained in widespread use to this day. Since then, other methods have been suggested, but indirect standardization is possibly still the most popular.

Rates and Ratios

Standardized rates, such as those produced by Farr, are expressed as the number of deaths (or cases of disease) per head of population. These can be compared with crude rates in the standard population and are expressed in the same units as normally used for the presentation of rates (e.g. number of deaths per 100 000 population). Possibly more often, however, standardized ratios are quoted. These compare the disease burden (*see* **Burden of Disease**) in the population of interest with that in the standard population. A ratio of 1 therefore indicates that the populations are similar in terms of the disease in question. Often, ratios are presented as percentages by multiplying them by 100, although this convention will not be used here. Some of the methods that will be described do not provide standardized rates *per se*, but multiplying the ratio by the crude rate in the standard population is a way of obtaining an adjusted rate.

Choice of Standard Population

Most methods of standardization require a standard population against which the population of interest

Table 1 Notation

Description	Index population	Standard population
Population in age group i	n_i	N_i
Total population	$n = \sum n_i$	$N = \sum N_i$
Deaths/events in age group i[a]	d_i	D_i
Total number of deaths/events	$d = \sum d_i$	$D = \sum D_i$
Death/event rate in age group i	$r_i = d_i/n_i$	$R_i = D_i/N_i$
Crude death/event rate	$r = d/n$	$R = D/N$
Number of deaths from all causes in age group i	a_i	A_i
Proportion of all deaths due to cause of interest in age group i	$p_i = d_i/a_i$	$P_i = D_i/A_i$
Number of deaths from all causes other than the specific cause of interest in age group i	$s_i = a_i - d_i$	$S_i = A_i - D_i$
Odds of death from specific cause compared to other causes	$m_i = d_i/s_i$	$M_i = D_i/S_i$
Number of years in age group i	y_i	
Mid-point of ith age group	h_i	

[a]For proportional analyses, this is the numbers of deaths from a specific cause in age group i. For all other indices, this can refer to deaths from all causes or specific causes, or to other disease rates.

(index population) is to be compared. Usually, the choice of standard is fairly obvious. Thus, for example, in trying to summarize age-specific rates for geographic regions within a country, the national population could be used as a standard. When examining rates for a variety of countries, a world population or the population of the appropriate continent would be suitable standards. Frequently, however, the sum of the set of index populations to be examined is used as the standard.

A variety of standard populations have been used in the successive volumes of *Cancer Incidence in Five Continents* [31]. These have included estimated African and European and world populations, and a truncated world population that only includes the ages 35–64 in five year age bands. The reason behind the choice of this unusual population was to avoid the examination of rates being dominated by cancers occurring at older ages; cancers at younger ages may give more clues to etiology than those occurring later in life. The most recent volume on cancer incidence [35] has, however, used only the approximate world population.

The important point to note is that different choices of standard population can give rise to different results. Thus identifying a suitable standard is a prerequisite for applying standardization methods. All standardized measures represent a comparison with a chosen standard population.

Notation

The notation used for the formulas for standardized rates and ratios varies widely. The notation used here is given in Table 1.

Indirect and Direct Standardization

Indirect and direct standardization are the two most widely used methods for standardizing rates. Other methods have been proposed, but have not achieved the same popularity.

Indirect Standardization

The information required for use of the indirect method is as follows:

1. age-specific rates in a standard population;
2. the size of the index population in each age group; and
3. the total number of deaths (or cases of disease) in the index population.

The formula for the indirectly standardized ratio is

$$\frac{d}{\sum n_i R_i}.$$

Such ratios are widely known as Standardized Mortality Ratios (SMR) when deaths have been studied. Similar names are adopted for morbidity, such as Standardized Incidence Ratios for cancer **incidence rates**. An alternate way of considering an indirectly standardized ratio is as a ratio of the observed number of events to the number expected in the index population on the basis of standard rates; in other words,

$$\text{SMR} = \frac{d}{e}, \quad \text{where } e = \sum n_i R_i.$$

One can then obtain the indirectly standardized rate by multiplying the ratio by the crude rate in the standard population:

$$\frac{dR}{\sum n_i R_i}.$$

Direct Standardization

A challenge to the indirect method of standardization came in 1883 from within the Registrar General's Office (Registrar General, 1883; see [37]). Ogle proposed the use of what is now known as the *direct method of standardization*. The method can be considered as the opposite of indirect standardization. The type of information required on the standard population for the indirect method is required for the index population in the direct method and vice versa. Thus the information needed for calculating a directly standardized ratio is:

1. age-specific rates in the index population;
2. the size of the standard population in each age group; and
3. the total number of deaths (or cases of disease) in the standard population.

The formula for the directly standardized ratio, usually termed the Comparative Mortality Figure (CMF) when deaths are being considered, is as follows:

$$\frac{\sum N_i r_i}{D}.$$

Analogous to the formula for the SMR, the CMF can be expressed as a ratio of the expected deaths in the standard population on the basis of index rates to the total number of deaths in the standard population; in other words,

$$\text{CMF} = \frac{E}{D}, \quad \text{where } E = \sum N_i r_i.$$

Multiplying by the crude rate in the standard population gives the standardized rate as follows:

$$\frac{R \sum N_i r_i}{D} = \frac{\sum N_i r_i}{N},$$

since $D/R = N$.

Discussion of Direct and Indirect Methods

The direct method is often advocated as the ideal, because it preserves consistency between different index populations. Thus if each age-specific rate in one index population is greater than the rate for the same age group in another index population, then the standardized rate in the former should be greater than in the latter. This is not necessarily true for indirect standardization. When a large number of index populations are compared to the same standard, the consistency property is important. Often, the standardized rates will be compared between index populations to make statements about differences between their disease rates. A method that may fail to preserve consistency could give rise to misleading conclusions about the disease burdens in different populations. However, it is hard to find examples in practice in which serious problems of this nature have arisen.

Direct standardization can be useful in a situation in which disease rates in the appropriate standard population are unavailable. For example, the *Cancer Incidence in Five Continents* volumes as mentioned above [31, 35] have used approximate world, African, and European populations. Since cancer registration is patchy worldwide, world cancer incidence rates are unknown. Estimating world rates by summing the numbers of cancers and population sizes in those countries with data would under-represent the cancer burden in Africa, for example. It is much easier to derive an approximate population distribution by age for the world than to estimate world cancer rates. The actual numbers in each age group need not be world figures as long as the ratios between different age groups are approximately correct. Once standard population numbers are available, directly standardized rates can be produced from the age-specific rates from the countries of interest.

Conversely, if age-specific rates in the index population are unavailable, the direct method cannot be used. It is rare to know the total number of cases of disease but not their ages. However, in such a situation, provided that the age distribution of the population is known, then the indirect method could be used.

One might wonder why the indirect method is used so widely, and indeed this question is still a subject of debate. The argument for the indirect method is that it is more stable when studying rates based on small numbers of deaths. If the age-specific rates in the index population are zero for a number of age groups, then the directly standardized rate or ratio is poorly estimated and can have a large **standard error**. Indeed, the SMR generally has a lower standard error than the CMF, no doubt in part because it is the first approximation to the **maximum likelihood** estimate of the index under the assumption that the number of deaths follows a **Poisson distribution**. These factors have led to the indirect method being widely used, particularly in Britain, for analyses of small geographic areas or occupational groups (see, for example, Office of Population Censuses and Surveys, 1986, 1990 [32, 33]; and *see* **Geographic Patterns of Disease**; **Occupational Mortality**; **Small Area Variation Analysis**). Breslow & Day [2] have pointed out that the SMR is preferred for the analysis of **cross-sectional** data according to **birth cohort** rather than calendar period. This is because the age intervals for which age-specific rates are available tend to vary for different generations, which precludes calculation of the CMF.

SMRs are widely used in analyses of **cohort studies**. The members of the study (index) population are followed through time, and the numbers of events, such as deaths or cancers, are recorded. **Person–years-at-risk** are calculated for each age group and calendar period, which provide the n_i to be multiplied by the age- and calendar period-specific rates R_i from the standard population (usually national rates). We thus obtain an expected number of events, which is compared with the observed number in the study population. The ratio of the observed to expected numbers gives the SMR. When many different causes of death or cancer sites are to be studied, many of the age-specific rates in the study population are zero and so the direct method is rarely used. Only in very large cohort studies does the use of CMFs become feasible and, even then, only for major **causes of death**.

Other Methods

A wide variety of other methods has been proposed since 1883, when the direct method was advocated. Many have been suggested for the analysis of mortality rates and thus have the word "mortality" in their name. There is no reason, though, why other forms of disease rates should not be summarized using these methods. The formulas for the various rates and ratios are given in Table 2; some methods only provide a standardized rate and no ratio, or vice versa. The origins of these methods and the reasons for them have been reviewed by Inskip et al. [19]. Most of the methods have been suggested in an attempt to circumvent problems identified in the two main methods. Sadly, nothing can circumvent the difficulty that the only reliable way of comparing disease rates is by examining age-specific data.

Few of these methods have become widely used and so they are not discussed in detail here. One that is used regularly, however, is Day's cumulative rate [7]. This has been used in the *Cancer Incidence* volumes since its proposal. It is one of the few methods ever suggested which does not require a standard population, and therefore, perhaps should not be counted as a "standardization" procedure *per se*. The principle is simple, in that it is the sum of the age-specific rates for each year to age 74. Usually, rates are only available in age bands comprising a number of years. The cumulative rate is then obtained by multiplying each age-specific rate by the number of years it spans, before summing them. The resulting rate is an approximation to the cumulative risk of acquiring the disease from birth to age 74. This gives a useful measure of the disease burden in the population and comparisons can readily be made between two populations of interest. The method does, however, assume that there is no other cause of death to be considered, and this would argue against its use for comparing two populations with widely differing all-cause mortality rates (such as comparing rates in Africa with those in Europe). No ratio is usually derived from this method, although, intuitively, two groups can be compared by taking the ratios of their cumulative rates.

Proportional Methods

Problems arise when no reliable estimates of the population at risk are available. Routine occupational

Table 2 Formulas for standardized rates and ratios

Rate		Ratio	
Name	Formula	Name	Formula
Comparative mortality rate	$\frac{1}{2}\sum\left(\frac{n_i}{n}+\frac{N_i}{N}\right)r_i$	Comparative mortality index [39]	$\frac{\sum(n_i/n+N_i/N)r_i}{\sum(n_i/n+N_i/N)R_i}$
Equivalent average death rate [44]	$\frac{\sum y_i r_i}{\sum y_i}$	Yule's index [44]	$\frac{\sum y_i r_i}{\sum y_i R_i}$
Cumulative rate [7]	$\sum y_i r_i$	Yerushalmy's relative mortality index [43]	$\frac{\sum y_i r_i/R_i}{\sum y_i}$
		Liddell's relative mortality index [24]	$\sum(N_i r_i/N R_i)$
		Relative risk index [26]	$\sum\frac{N_i n_i r_i}{(N_i+n_i)R_i}\Big/\sum\frac{N_i n_i}{N_i+n_i}$
		Kerridge's inverse method [22]	$\sum(d_i/n R_i)$
		Fisher's Ideal Index [11]	$\left(\frac{d}{\sum R_i n_i}\times\frac{\sum r_i N_i}{D}\right)^{1/2}$

mortality analyses usually suffer from this problem. This is because there are differences in the questions asked about a person's occupation in censuses and those asked of informants of a death. Indeed, the person notifying the death may be unable to give as accurate a description of the occupation as the deceased would have provided on a census form. While SMRs have been widely used for occupational mortality analyses, their weaknesses have to be acknowledged, and they are often **biased** (*see* **Occupational Epidemiology**; **Occupational Health and Medicine**).

A different approach has been adopted in many analyses of this type. In each age group, the population size in each age group is replaced by the number of all-cause deaths. Thus the rates are replaced by the proportions of all deaths due to the cause of interest. A method analogous to that for the SMR is then used to provide a **Proportional Mortality Ratio (PMR)**:

$$\frac{d}{\sum a_i P_i}.$$

Analyses of proportional mortality (although not as ratios) have a longer history than other standardization methods. As far back as 1662, **John Graunt** [16] considered the proportion of deaths due to different causes in order to assess the importance of different diseases in leading to death. However, it was not until the twentieth century that proportional methods became popular in a variety of contexts, particularly occupational analyses. The analysis of occupational mortality in England and Wales for 1931 (Registrar General, 1938; see [38]) gave some proportions of deaths due to the cause of interest, but it was not until the comparable report for 1961 (Registrar General, 1971; see [38]) that the ratios were given. They have been used ever since in the analysis of occupational mortality for England and Wales, but it was only in the latest report that they have been used exclusively (Office of Population Censuses and Surveys, 1995 [34]). Indeed, the latest volume also describes cancer incidence data by occupation, again using proportional measures, but these are Proportional Incidence Ratios (PIR), with all types of incident cancer forming the denominator of the proportions, rather than all deaths.

When suitable populations at risk are unavailable, proportional methods have to be used. Analysis of all-cause mortality does, however, become impossible, as the ratios take the value of unity. Criticisms of the method focus on the problems of bias. If the PMR is used as a proxy for the SMR, it will be biased upward when the all-cause SMR is low (and vice versa). Kupper et al. [23] and Decouflé et al. [8] have discussed the relationship between the PMR and the SMR; the PMR is approximately equal to the ratio of the cause-specific SMR to the all-cause SMR. Kupper et al. [23] termed this ratio the relative SMR (RSMR). In the absence of standardization for any factors, the RSMR and PMR are identical. Since the aim is to standardize, this is unhelpful, but empirical studies have shown that the PMR is a useful proxy for the RSMR [40]. If one is only interested in disease rates in comparison with the standard population, this presents problems for the analysis of groups with very low or high all-cause mortality. However, changes in the distribution of disease within groups should not be ignored, and so the PMR is of value in its own right. PMRs may well lead to useful etiologic clues, particularly in occupational groups with low overall mortality. In such groups, diseases with rates comparable to those in the standard population would be missed by an SMR analysis but would be identified by an elevated PMR.

PMRs can also be biased by abnormally low or high mortality from causes other than that of interest. This problem has been examined by McDowall [29]. He pointed out that it is only the largest causes that seriously influence the PMR for other causes. This led him to suggest recalculations of the PMR, successively excluding the major causes of death from both the standard and index proportions.

The method of calculation of the PMR is similar to that for the SMR, as it employs an indirect standardization approach, albeit of proportions instead of rates. In 1983, Zeighami & Morris [45] proposed an alternative to the PMR which is analogous to a direct standardization method, the formula being

$$\frac{\sum A_i p_i}{D},$$

but this does not appear to have been widely used.

Mortality Odds Ratio

A different approach to proportional mortality analyses was proposed by Miettinen & Wang [30]. Their ratio is equivalent to the **odds ratio** used in the analysis of **case–control studies**. The "cases" are deaths from the cause of interest and the "controls" are deaths from all other causes. "Exposure" is then membership of the study group of interest (e.g. a particular occupational group, or residence in a specific geographic area), and the "unexposed" are all those not in the group of interest and form the "standard" for this method. The formula for the Mortality Odds Ratio is

$$\frac{d}{\sum s_i M_i}.$$

This index is attractive, as it can be interpreted in a similar way to a case–control study, although the choice of other deaths as controls is not necessarily ideal. It is straightforward to show that the unadjusted PMR is always more conservative than the MOR. When such methods are being used for screening large amounts of data, such as in routine occupational mortality statistics, many **false positives** are identified. The use of a more conservative index may be an advantage. With the current speed of computers, the fact that the PMR is simpler to calculate is a minor point, but may still be a consideration if large data sets are to be analyzed (*see* **Proportional Mortality Study**).

Person-Years-of-Life Lost

One concern about most standardization methods is that they give most weight to the age groups that contain the largest numbers of events. In most mortality or morbidity analyses, the elderly therefore receive most emphasis. Restriction of the age groups under study can help, and indeed Yule's method [44] (see Table 2) and Day's cumulative rate [7] require an upper age limit for their calculation. However, for certain analyses, deaths occurring at younger ages may be of greatest interest.

In the early 1950s, there was considerable discussion about this problem [10, 17, 27, 28]. Whether examining changes in mortality over time, or comparing occupational groups, it is often of interest to know whether there are differences at younger ages that are missed by analyses dominated by many events among the elderly. Haenszel [17] loosely defined **person–years of life lost** as "the total number of years lost through the failure of individuals to live some allotted life span", and pointed out that

working-years lost "refer to those falling between the productive ages between 20 and 65". He went on to point out that "it has long been recognized that a count of deaths alone did not give a complete picture of mortality, and measures have been sought which would make some allowance for the widely held intuitive idea that a death at age 70, for example, does not represent as great a loss to society as death at age 35".

While standardized rates of years of life lost can be calculated and used for comparison of groups, ratios are usually more readily understood. To obtain either rates or ratios, the deaths in each age group in the index and standard population are multiplied by the years of life lost in each age group.

Two different forms of years of life lost factors have been suggested. The first is simply to choose an upper age limit of interest and subtract from it the mid-age of each age group. Thus, if years to age 70 were of interest, the years-of-life lost in age group 35–39 would be 33. The formula for the standardized ratio is therefore

$$\frac{\sum d_i(70 - h_i)}{\sum n_i R_i(70 - h_i)}$$

This is equivalent to a weighted indirectly standardized ratio, and by analogy the directly standardized form is

$$\frac{\sum N_i r_i(70 - h_i)}{\sum D_i(70 - h_i)}.$$

Upper age limits other than 70 can be used and, indeed, a lower age limit such as 15 or 20 for occupational mortality can be incorporated by ignoring deaths in childhood.

The other form of weights to represent years of life lost are obtained from **life table** estimates of **life expectancy**. The number of years that a person at the mid-age of each age group can be expected to live is estimated from life tables derived from death rates for the standard population. These weights can then be used in the above formulas replacing $70 - h_i$.

Variances and Standard Errors

In estimating **standard errors**, we usually assume that the standard rates and populations are stable and their sampling errors can be ignored. This is not always true, but, rightly or wrongly, the assumption is usually made. We also assume that the populations in the index population are fixed. Therefore, the only **random variables** to consider are the age-specific rates in the index population, or, more simply, the numbers of events in each age group in the index population. The events in each age group are also assumed to be independent of each other.

It is worth noting that almost all the formulas for standardized rates and ratios can be written as a weighted sum of the age-specific rates in the index population:

$$\sum w_i r_i,$$

where the w_i are the weights.

Thus, for the directly standardized rate, the weights are

$$w_i = \frac{N_i}{N},$$

while for the indirect method they are

$$w_i = \frac{n_i R}{\sum n_i R_i}.$$

Similar formulas exist for the ratios. Most of the ratios can be written as a weighted average of the age-specific ratios in the form

$$\frac{\sum (w_i r_i / R_i)}{\sum w_i}$$

or, sometimes more conveniently, as a ratio of the weighted age-specific rates:

$$\frac{\sum w_i r_i}{\sum w_i R_i}.$$

Using the first form, the weights for the Comparative Mortality Figure (directly standardized ratio) are D_i and for Standardized Mortality Ratio (indirectly standardized ratio) are $n_i R_i$. All the other rates and ratios in Table 2 can be written in this form with differing values of w_i, the only exception being Fisher's Ideal Index [11].

The next step is therefore to consider the standard error of the r_i (or d_i). There are two approaches to this.

Use of the Binomial Distribution

Chiang [6] developed an approach based on the **binomial distribution**. He noted that rates r_i are not proportions, but derived a formula for each rate as a function of the proportions of deaths d_i in the hypothetical population from which the deaths were drawn. This requires knowing the distribution of the ages of the events within each age group. As an approximation it is reasonable to assume that all events occur in the middle of the age range. Chiang's formula for the **variance** of the r_i then becomes

$$\frac{r_i(2 - y_i r_i)}{n_i(2 + y_i r_i)}.$$

This leads to the variance of the standardized rate being

$$\sum w_i^2 \text{var}(r_i),$$

and that of the ratio being

$$\frac{\sum \left[\frac{w_i^2}{R_i^2} \text{var}(r_i) \right]}{\left(\sum w_i \right)^2}.$$

The standard errors are then the square roots of the variances.

Use of the Poisson Distribution

The alternate approach to estimating the standard errors is to assume that the numbers of events in each age group follow a **Poisson distribution**. (It is worth nothing, however, that this assumption may not be valid and that extra-Poisson variability (*see* **Overdispersion**) may need to be investigated [3]. The variance of a Poisson variable is equal to its **expectation**, for which the observed number of events is the best approximation available. The denominators of the rates (the n_i) can be absorbed into the weights and so the formulas for the variances of the rates and ratios become

$$\frac{\sum w_i^2 r_i}{n_i}$$

and

$$\frac{\sum \frac{w_i^2 r_i}{R_i^2 n_i}}{\left(\sum w_i \right)^2},$$

respectively.

Table 3 Variances of directly and indirectly standardized rates and ratios

Method	Rate	Ratio
Direct	$\sum(N_i^2 r_i / N^2 n_i)$	$\sum(N_i^2 r_i / D^2 n_i)$
Indirect	$\frac{\sum R_i^2 d_i}{\left(\sum n_i R_i\right)^2}$	$\frac{d}{\left(\sum n_i R_i\right)^2} = \frac{d}{e^2}$

Note that when SMRs are under discussion alone, the variance is usually given as O/E^2, although the use of upper case letters and O for the total number of (observed) deaths is not consistent with the notation used here for index and standard populations.

These formulas reduce to fairly simple forms for direct and indirect standardization, and these are given in Table 3.

The formulas for the standard errors of Proportional Mortality Ratios (indirectly and directly obtained) are similar to those in Table 3. The numbers in the populations are replaced by the numbers of all-cause deaths, and the rates are replaced by the proportions of deaths. However, it is worth noting that the proportions of deaths due to the cause of interest are true proportions, unlike rates, and so the binomial distribution could be used in the derivation of the standard errors.

Confidence Intervals

In deriving **confidence intervals** for rates and ratios, similar assumptions are made as for the estimation of standard errors (se). Again, we have to make assumptions about the distribution of the rates and ratios.

Confidence Intervals for Rates

Confidence intervals for rates can be derived by assuming that the rates follow a **normal distribution**. The method, therefore, is to add and subtract 1.96 times the standard error from the rate. If rates are small, this leads to problems, as negative values can occur. In such cases, it is preferable to consider the standard error of the logarithm of the rate. Using the standard approximation

$$\text{var}(\log x) = \frac{\text{var } x}{x^2},$$

the standard error of the logarithm of a standardized rate can be obtained as

$$\text{se (log(rate))} = \frac{\text{(se (rate))}}{\text{rate}}.$$

Using this, a 95% confidence for the logarithm of the rate can be obtained, and taking exponentials gives the 95% confidence interval for the rate itself.

Such estimates of confidence intervals rely on the adequacy of the normal assumption, either for the rate or its logarithm. The assumption tends to be poor when the rates are low. This is particularly a problem when we are calculating weighted sums of the age-specific rates, each of which may be small. Dobson et al. [9] have addressed this issue. They have discussed a number of alternate methods for estimating the confidence interval for a Poisson parameter, and derived an improved estimate for the confidence interval for a weighted sum of the events in each age group.

The lower point and upper point of the interval are

$$\text{standardized rate} + \left(\frac{V}{d}\right)^{1/2}(d_{\mathrm{L}} - d)$$

and

$$\text{standardized rate} + \left(\frac{V}{d}\right)^{1/2}(d_{\mathrm{U}} - d),$$

where

$$V = \sum w_i^2 r_i,$$

and d_{L} and d_{U} are the lower and upper confidence interval for the total number of observed deaths, d. Various tables of confidence intervals for Poisson variables exist, usually for a number of levels of confidence. Those given by Gardner [14] provide 90%, 95%, and 99% confidence intervals. Alternatively, Dobson et al. [9] provide a list of approximate methods for obtaining d_{L} and d_{U}.

Recently, there has been considerable research into improved methods for obtaining confidence intervals for standardized rates. As Swift [42] has noted, most of these have been computer intensive methods, and none appears to have been used routinely. Swift himself suggested an approximate **bootstrap method** which he compared with other methods using **simulation** studies. It appears that the debate on calculation of confidence intervals has not yet run its course. Since all methods are approximate, a sensible approach might be to produce a number of confidence intervals calculated in different ways to see how they vary.

Confidence Intervals for Ratios

Similar considerations apply to the confidence interval for a ratio. Ratios are decidedly nonnormal and often the logarithm is considered, with its approximate standard error being calculated as described above. The formula for standard error of the logarithm of the directly standardized ratio (CMF) is

$$\frac{\left(\sum N_i^2 r_i / n_i\right)^{1/2}}{\sum N_i r_i},$$

whereas that for the logarithm of the indirectly standardized ratio (SMR) reduces to

$$\frac{1}{\sqrt{d}}.$$

An alternate method for the calculation of confidence intervals for the SMR (and for the indirectly standardized PMR) requires us to assume that the total number of observed deaths in the index population, d, is a Poisson variable. d_{L} and d_{U}, the lower and upper points of the confidence interval for d, are first obtained from tables or approximations and then the corresponding confidence interval for the SMR is

$$\frac{d_{\mathrm{L}}}{E} - \frac{d_{\mathrm{U}}}{E}.$$

These formulas are now widely used for the calculation of confidence intervals, and it is unusual to derive confidence intervals for SMRs using the standard errors. Computationally intensive methods could also be used, but the above formula is considered appropriate for most needs.

Regression Models

Increasingly, mortality rates are being modeled using **regression** techniques. Keiding [21] discusses some of these approaches at the end of his historical review paper. **Generalized linear modeling** can be used to analyze rates, and a number of papers have explored the issues relating to such analyses [12, 13]. More recently, there has been increasing interest

in **Bayesian** approaches using **Monte Carlo methods** [1] and **generalized estimating equations**.

Recurrent Outcomes

An important new development in the standardization of rates is the consideration of recurrent outcomes. Most of the methods described above have been developed with a single outcome per person in mind, notably death. Even when cancer has been of interest, the number of people with multiple cancers is so small that the cancers have been assumed to be independent. Epidemiology has moved on from there, to deal with outcomes that can occur more than once within an individual. Examples are admission to hospital, episodes of back pain, and attacks of asthma.

Although the standardized rates can be calculated as for nonrecurrent events, the standard errors are larger because of the lack of independence of recurrent events. Glynn et al. [15] used the **negative binomial distribution** to account for departures from the assumption, inherent in the use of the Poisson distribution, that the recurrent events occur randomly. The variance of each age-specific rate in the index population is then

$$\frac{(r_i + r_i^2/k)}{n_i},$$

where k is an index of extra-Poisson variation in the rate, with smaller values of k indicating larger departures from the Poisson distribution. k has to be estimated from the data and Glynn et al.suggest use of the **method of moments** estimator.

The variance of the standardized rate is then

$$\sum (w_i^2)\mathrm{var}(r_i),$$

from which the standard error can be obtained by taking the square root. Again, to obtain confidence intervals, taking logarithms as described above is recommended.

Often one wishes to compare a number of standardized rates (for recurrent or single events). Carriere & Roos [5] have developed a simple test for the comparison of H standardized rates against a standard rate that can be compared with the **chi-square distribution** on H **degrees of freedom**. If S_h is the standardized rate in the hth index population, and R is the crude rate in the standard population, then the test statistic is

$$\frac{\sum (S_h - R)^2}{\mathrm{var}(S_h)},$$

where the summation is over the H populations of interest. If the standard rate is simply the overall rate obtained from the combined index populations, then the test statistic should be compared with the chi-square distribution on $H - 1$ degrees of freedom.

More complex approaches are recommended when the data are available for each individual followed up over time. In this way, the events occurring for each person are known. The analysis of such outcomes requires approaches used for the analysis of **longitudinal data**. Methods mentioned above such as generalized estimating equations, Bayesian approaches using **Markov chain Monte Carlo methods**, and other methods for **multilevel modeling** could be applied. These are, however, computationally intensive and analysis of large data sets can be very time-consuming.

Computation

Despite the long history of standardization methods, few standard statistical packages allow for their use. Many users write their own procedures and link their data to the standard rates. STATA [41] is one package that now incorporates procedures to perform direct and indirect standardization, and Immonen-Räihä et al. [18] published a macro for use in SAS (*see* **Software, Biostatistical**). Spreadsheets are probably the most common computational method used to derive standardized rates/ratios; the columns of the spreadsheet hold the events/population numbers by age for the index and standard populations respectively, and the appropriate calculations performed.

For modeling approaches (*see* **Model, Choice of**) to the analysis of rates, many packages are available and will not be outlined here.

Discussion of Methods

Over the years, many methods of standardization have been proposed. No single method has emerged on top and a variety are in use. Direct and indirect standardization are undoubtedly the most popular, but other methods such as PMRs have to be employed in

certain circumstances. A recent report of occupational mortality in Italy [20] gave a table summarizing occupational mortality analyses from many countries worldwide in recent years. The method used for obtaining standardized ratios in each analysis was listed, and four different methods had been employed. None used a direct method, whereas this is commonly used in cancer studies (see, for example, Parkin et al. [35]) and in many geographic analyses (see, for example, Pickle et al. [36]).

Estimating standard errors and deriving confidence intervals are not straightforward, and many methods are in widespread use. The final verdict has not yet been reached as to which methods are best, and the debate is likely to continue for many years.

As a final note, and to return to where we began, we must be aware that in any standardization procedure we lose something. Much of the debate about which methods to use is due to the fact that no standardized measure can replace the analysis of the age-specific rates themselves. We should understand that summaries can be distorted by patterns in particular age groups. Before one employs any standardization, one should scrutinize the individual age groups. Burack et al. [4] have argued forcibly for examining the age-specific rates, but it has to be acknowledged that in large-scale studies of routine data, even examining the standardized rates or ratios for each subset of the population (such as each occupational group) is an unwieldy task. Scrutiny of the age-specific rates for every group would be impossible. However, perhaps we should take the advice of Burack et al., at least in part, and before commenting on any particular standardized rate or ratio as being particularly high or low we should be more prepared to examine the original age-specific data.

HAZEL INSKIP

Standardized Coefficients

A **linear regression** model relates a response variable to a linear predictor

$$\alpha + \beta_1 X_1 + \cdots + \beta_k X_k,$$

where the Xs correspond to **explanatory variables** and the βs are termed the regression coefficients. The regression coefficient β_i represents the change in the linear predictor corresponding to a one unit shift in the variable X_i, if all other variables remain the same. Thus direct comparison of the size of regression coefficients is usually meaningless, since their interpretation depends on the specific explanatory variable.

Standardized regression coefficients represent an attempt to circumvent this problem. If all the explanatory variables are standardized to have a mean of zero and a variance of one, then the coefficients corresponding to these standardized variables are termed standardized regression coefficients. Because unit shifts in these transformed variables are more comparable, then so are the corresponding regression coefficients. Note that the mean standardization is not essential, since it is reflected only in α.

VERN T. FAREWELL

Stationarity

The concept of stationarity of a time series is concerned with the series being in statistical equilibrium; the equilibrium behavior may exhibit a rich variety of features but the features themselves must not be evolving over time. This lack of evolvement is at the heart of stationarity. From practical and visual points of view the behavior of the series, in stretches of sufficient length, must appear statistically identical. A qualification about sufficient length is needed since apparently nonstationary features over the short term are not precluded from a stationary series; they must, however, be nonunique and be a repeatable feature over the long term. This aspect makes stationarity a rather slippery concept to verify in practice. Most analysts would only regard a series as stationary if there were some clear evidence of repeatability in its features. Evidence against stationarity would include cyclic behavior (*see* **Seasonal Time Series**) and the values trending over time; in the latter case, the local level or average of the series would indicate a clear pattern over the length of the series. The nonstationarity might be not in a level, but in the variability about a level; extremes, say, might become more or less frequent as time passes, and, more generally, the distribution of fluctuations of the values could be changing. A more subtle type of behavior ruling out stationarity would be a change in dependency, such as autocorrelation. Other simpler features, such as a sudden and sustained change in level, are absent from stationary series but would present little difficulty in identification. There are no particularly biostatistical aspects to stationarity, or to much of time series analysis in general, most existing methods being readily applicable. One text orientated towards biostatistics is Diggle [4]. Classical texts include Box & Jenkins [1], Priestley [5], Brillinger [2], and Brockwell & Davis [3].

Technical Definitions

Time series are usually measured either at discrete evenly-spaced time-points or continuously over time. This makes a considerable difference to their specification or modeling as **stochastic processes**, but little difference as far as definitions of stationarity are concerned. In definitions, time series are represented by random variables $X(t_1), X(t_2), \ldots, X(t_n)$ at a series of times $(t_1, t_2, \ldots, t_n), n \geq 1$, and the invariance of their joint distribution to a common translation in time is the key aspect of stationarity. Thus, the requirement of the strongest form of stationarity, called *strict* or *full stationarity*, is that the joint distribution of $[X(t_1), X(t_2), \ldots, X(t_n)]$ should be identical to that of $[X(t_1 + t), X(t_2 + t), \ldots, X(t_n + t)]$ for all integers n and all allowable $t, -\infty < t < \infty$. This form of stationarity is often unnecessarily rigorous and would be impossible to investigate practically in its entirety. It is, however, satisfied by independent and identically distributed random variables, although such a time series structure is usually no more than a useful null hypothesis model. Simpler forms of stationarity are employed in practice, beginning with stationarity in mean, which requires that $\mathrm{E}[X(t)]$ does not depend on t. A generalization would be to *marginal stationarity*, in which the marginal distribution of $X(t)$ does not depend on t. The most used form of stationarity, *second-order* or *weak stationarity,* requires that the moments up to the second-order, $\mathrm{E}[X(t)]$, $\mathrm{var}[X(t)]$ and $\mathrm{cov}[X(t_i + t), X(t_j + t)]$, $1 \leq i, j \leq n$, do not depend on translation time.

These definitions, and the main discussion here, are limited to univariate time series; with several time series considered simultaneously, there will be straightforward generalizations involving vector time series quantities.

Stationarity of Linear Time Series Models

In discrete time, $t = 0, \pm 1, \pm 2, \ldots$, a linear time series model is usually given in the form:

$$X(t) = c_0\varepsilon(t) + c_1\varepsilon(t-1) + c_2\varepsilon(t-2) + \cdots,$$

where $\varepsilon(t), t = 0, \pm 1, \pm 2, \ldots$, is an independent and identically distributed sequence of random variables, and $c_0, c_1, c_2, \ldots$ is a sequence of constants. For the model to be strictly stationary, the sequence of constants must be such that $c(x) = \sum_{i=0}^{\infty} c_i x^i$ converges for $|x| \leq 1$. A practically useful class of linear models, having a finite number of parameters, are autoregressive and moving-average processes (*see* **ARMA and ARIMA Models**) of the form

$$X(t) = a_1 X(t-1) + a_2 X(t-2) + \cdots + a_p X(t-p) + \varepsilon(t) + b_1\varepsilon(t-1) + \cdots + b_q\varepsilon(t-q),$$

where $p, q \geq 0$ and $a_1, a_2, \ldots, a_p$ and $b_1, b_2, \ldots, b_q$ are constants. The stationarity condition just mentioned is now equivalent to requiring that the roots of the pth-order polynomial equation,

$$1 - a_1 x - a_2 x^2 - \cdots - a_p x^p = 0,$$

lie outside the unit circle in the complex plane. This type of exposition was first simply set out by Box & Jenkins [1].

Statistical Analysis of Stationarity

Most series will not be stationary, and yet the statistical repeatability implied by stationarity is central to much statistical analysis of time series data. This is because the identification and elimination of nonstationary features, such as trend and seasonality, as often required, is supposed to leave a stationary series. For trend in mean, differencing of successive data values, producing the series $[X(t) - X(t-1)]$ is suggested, with iterative differencing when necessary; subtraction of a smoothed version of the series from itself is another method. Transformation by logarithms has been suggested to eliminate trend in seasonality.

Statistical Consulting

Statistical consulting, the provision of statistical advice and/or services to those who request it, applies statistical methodology to problems in other disciplines. Consultants assist with design and conduct of the study, including **randomization** of subjects, data collection, and data analysis. They help to report the results of the study and to ensure that conclusions reached are supported by the data. The consultation may range from a five-minute chat in a hallway, involving only advice about some aspect of the study, to a many years' collaboration on a project. Although the terms *consulting* and *collaboration* are often used interchangeably, a collaboration implies more responsibility and involvement, both intellectual and time, by the statistician. In a collaborative relationship, a statistician is a full-fledged member of the team of investigators conducting the study, has more authority, receives credit for contributions made, and coauthors the research paper reporting the project. This is a relationship most conducive to statistical contribution. To connote a broad range of services, some statisticians now refer to the *practice* of statistics, meaning the communication of statistical information across disciplinary boundaries by persons who have training in statistics and related quantitative fields.

Biostatistical consulting is the application of statistical expertise in the biological or health sciences. Within the arenas of medicine, dentistry, and public health, biostatisticians work with physicians, basic scientists, dentists, nurses, pharmacists, epidemiologists and other health professionals. A biostatistician may be a faculty member in a school of public health or a professor in a quantitative sciences department in a medical or dental school or at a medical research center [4]. In this capacity, they teach graduate courses in biostatistics while working collaboratively on research grants, jointly with medical colleagues. In addition, the biostatistician might perform analyses for reports, manuscripts, and presentations for medical clients. In many universities, consulting biostatisticians belong to a statistical consulting unit [14], often within a biostatistics department that offers statistical and computing services. Some universities and schools of public health have statistical or clinical trials centers in which biostatisticians have a primary role [1]. Some biostatisticians work in cancer centers or other disease-specific research centers that may be part of a larger network [25]. Such centers are usually in a university setting; others may be independent entities. State and federal governmental agencies in the US, such as the **Food and Drug Administration** (FDA), the **National Institutes of Health** (NIH), the **National Center for Health Statistics** (NCHS), and the **Centers for Disease Control** (CDC), employ many biostatisticians in a variety of capacities. Pharmaceutical companies usually have a biostatistics unit that works with a team of research investigators in designing and analyzing **clinical trials** [10] (*see* **Statisticians in the Pharmaceutical Industry (PSI)**). Other biostatisticians might be employed in a contract research organization (CRO) (*see* **Proprietary Biostatistical Firms**) that provides statistical and other services to pharmaceutical or biotechnology companies. Finally, some biostatisticians work independently as consultants and contract individually with clients or sponsors.

Role of a Biostatistical Consultant

The role that a biostatistical consultant plays is determined by the type of organization in which they work [9, 20]. The several roles described below demonstrate the variety of circumstances in which biostatisticians are engaged.

Biostatistician in a Medical School

Kerry is the senior of four faculty biostatisticians employed in a clinical trials center at a medical school in a major university in the south east of the US. Having worked closely with physicians for more than 20 years to build and develop the center, he has had years of experience, primarily in cardiovascular clinical trials (*see* **Cardiology and Cardiovascular Disease**). Working with physicians and other medical investigators within a collaborative setting, he offers advice and provides statistical input for the design and analysis of trials of cardiovascular disease. When the trials are being designed, the medical school cardiologists meet with Kerry and investigators from pharmaceutical companies. In designing the trials, Kerry considers both statistical and clinical factors. He seeks to understand the clinical issues in these studies; he provides sample size calculations (*see* **Sample Size Determination for Clinical**

Trials), input on study design, advice on interim analyses, and **randomization** schedules (*see* **Randomized Treatment Assignment**). He usually writes the statistical portions of the study protocol (*see* **Clinical Trials Protocols**). As the trial progresses, he works with junior statisticians to monitor the trial (*see* **Data and Safety Monitoring**) and supervises the analysis. When the trial has been completed, many manuscripts reporting various aspects of the study are produced, for which Kerry specifies the appropriate statistical methods and supervises the analysis by junior biostatisticians. In addition, he is the principal investigator of three clinical trials.

Kerry's greatest strengths as a consultant are his ability to listen intently and to explain statistical design and methodology principles to physicians clearly (*see* **Teaching Statistics to Physicians**). In addition, he often conducts research conferences for a mixed audience of physicians, statisticians, trial coordinators, and other team members in the organization. His ability to speak systematically and to present statistical ideas simply make him sought after as a lecturer. He also teaches a class of physicians and other health professionals who are enrolled in a biostatistics training program to obtain a master's degree. In all aspects of Kerry's varied role, he communicates effectively with physicians, health professionals, and other statisticians, in a group setting or individually.

Biostatistician in a Pharmaceutical Company

Ellen is a doctoral-level biostatistician in the Clinical Biostatistics Department of a major pharmaceutical company on the East Coast of the US. As the lead statistician for all of the clinical trials of ophthalmic preparations that are in development or are currently manufactured by the company, she collaborates with clinical researchers to plan and design clinical trials for protocols to study new chemotherapeutic treatments. She writes the statistical sections, including plans for the designs and the analyses of the studies that will be part of a New Drug Application (NDA) (*see* **Drug Approval and Regulation**). She analyzes clinical trial data; she writes the results sections of clinical study reports and statistical technical sections of regulatory submissions; she coauthors manuscripts submitted to medical journals. Ellen attends and often presents the statistical aspects of the clinical trial at meetings with regulatory agencies and responds to queries, verbal or written, concerning the statistical aspects of the study. She serves as the statistical liaison for studies subcontracted to CROs and she organizes work for a team of masters and doctoral statisticians and statistical programmers. As the lead statistician for ophthalmic preparations, she compiles periodic reports to inform the upper management of the activities of her department concerning the status of projects, resource requirements, and important technical and regulatory issues. As the lead statistician, she is an integral member of the project team for ophthalmic preparations, a cross functional team made up of people in various areas of the company, including Basic Research, Biostatistics, Clinical Pharmacology, Clinical Research, Data Coordination, Drug Metabolism, Epidemiology, Marketing, Manufacturing, Project Planning, Regulatory Affairs, and Safety Assessment. The project team meets regularly to coordinate activities concerning the approval and promotion of ophthalmic products, to communicate new information to its members, and to make recommendations to the senior management of the company about key decisions. On the ophthalmic project team, she represents her department, participates in discussions that require statistical input and thinking, submits a time schedule of work to be accomplished, reports on the progress of projects, and presents clinical trial results to the project team.

Biostatistician in a Dental School

Stuart, a member of the biostatistics faculty of a dental school on the west coast of the United States, acts primarily as a collaborative researcher but also works on relevant methodological problems in biostatistics, teaches research methods courses, and mentors master's degree students. In most situations, he is a consultant, which always has a teaching component. He consults with clinical faculty members (dentists and hygienists), postgraduate residents, basic scientists, including basic laboratory researchers, oral epidemiologists, and public health dentists. He works on many studies including clinical trials of caries risk management, community intervention trials for spit tobacco cessation, **observational studies** of periodontal disease and temporomandibular disorders, and **case–control studies** of early childhood caries. Stuart also helps to write grant proposals, refines study designs, performs **power** analyses and **sample size determinations**, develops analysis plans, coordinates data management activities (*see* **Data**

Management and Coordination), and conducts data analyses.

Dental studies present particular statistical structures, most notably clustered observations (e.g. jaws, teeth, tooth surfaces, and periodontal probing sites) (*see* **Clustering**) within people. In addition, the variability of dental disease, both for sites within and among individuals, and lack of consistency over time (areas can heal and later relapse) create challenges for epidemiologic studies and sample surveys designed to estimate, for example, incidence and **prevalence**. Appropriate modifications are needed in sample size calculations and analyses. Issues of reliability (*see* **Agreement, Measurement of**) and validity often arise since many responses are measured on categorical scales. In all these activities, Stuart consults with colleagues, asks probing questions about the subject matter, refines study research questions, explains possible design and analysis options, and resolves the problems with clients in a partnership to develop statistically appropriate solutions based on goals and available resources.

Biostatistician in a Governmental Agency

Debby leads a biostatistical group in one of the Institutes at the National Institutes of Health in the US. Because her Institute recognizes the value of statistics in the design, analysis, and interpretation of medical studies, the group of biostatisticians finds itself in constant demand. Debby sees her consulting role divided into three very different functions – intramural consulting, participation in discussions on issues related to funding, and collaboration with non-government investigators. For the intramural scientists within the Institute, she serves as an *ad hoc* statistical consultant, with all the excitement and frustration that role entails. The investigators, often postdoctoral fellows, look to statisticians as the purveyors of small ***P*** **values**, those precious tickets to publication. Debby's first contact with an investigator may be a frantic call demanding immediate statistical input for an abstract that is complete "except for a few numbers". She recognizes that these encounters afford an opportunity for teaching young researchers about the value of statistical collaboration. Moreover, a fruitful short-term statistical fix may lead to long-term collaboration with an investigator who has become convinced that statistical thinking enhances scientific research.

In her second consultative role, Debby's activities have broad influence on public health. The NIH, as one of the primary sponsors of clinical studies, establishes priorities for funding of types and fields of studies. In her capacity as an Institute biostatistician, Debby helps to formulate the statistical aspects of research programs. Her medical colleagues at the Institute have sophisticated understanding of statistical ideas, and the biostatisticians understand the medical problems. Thus, the joint medical and statistical collaboration allows rigorous formulation of the scientific basis of scopes of work for contracts or broad areas to fund for grants. This aspect of Debby's consultation, although perhaps her most anonymous activity, is the one she finds most rewarding.

Debby's third role has one foot in government and one in academe. Her Institute funds many long-term clinical trials and epidemiologic studies and she, along with other members of the Institute, serves on committees for these studies. As a committee member, she acts just like everyone else. In some capacities she plays a role distinct from the academic researchers. As a government employee, she sits as an observer on many **data and safety monitoring boards**. Thus she brings to data monitoring a wealth of experience. Investigators, both within NIH and outside, call upon her to consult on forming data monitoring boards, planning interim analyses, and helping coordinating centers prepare statistical reports.

Debby's consulting spans a wide range of activities. Like any effective biostatistical consultant, she must understand the studies with which she is involved; she must be aware of new biostatistical methodology, and she must be poised to develop new techniques. What distinguishes her role from that of other biostatistical consultants is the perception that when she expresses an opinion, she is speaking for the government.

Biostatistician in a Department of Biostatistics and Director of a Consulting Unit

Gary, a professor in a department of biostatistics at a major university in the south east of the US, teaches two **categorical data** courses, mentors numerous doctoral dissertations, and directs a biostatistical consulting laboratory staffed by students in the department (*see* **Teaching Medical Statistics to Statisticians**). The role of the laboratory, which provides statistical consultation primarily

to investigators from the university's Schools of Medicine, Dentistry, and Public Health, is to provide funding and training for students in academic biostatistics programs and to encourage practice-oriented statistical research, particularly for master's degree papers and doctoral dissertations – and, of course, the investigators benefit by having the statistical aspects of their research problems solved. In addition to clients within the university, Gary also arranges cooperative agreements between the laboratory and sponsors in the biopharmaceutic industry.

Gary has created a structure for consultation that fosters learning and teaches team work. The doctoral students have a direct liaison with him, delegate projects to master's and undergraduate students, and mentor them. The doctoral students are responsible for meeting deadlines and writing and reviewing statistical reports. The master's students work with the doctoral students for large projects and manage databases (*see* **Database Systems**), write programs and reports, and learn to handle smaller projects directly with clients. They also mentor the undergraduates. The undergraduates perform support services including data entry, word processing, and basic programming. The benefits for students of this arrangement include mentoring by Gary, reinforcement of course work, practice in communication skills and report writing, publications, and thesis topics.

A wide variety of projects are available to students in the consulting laboratory. One example is a longitudinal periodontal study for the university's Department of Dental Ecology. Patients were examined at baseline and at three other time points. Attachment loss was measured at multiple sites on each tooth and for multiple teeth per person. There were also numerous other site-level, tooth-level, and person-level variables. The primary question was whether attachment loss during one period in time was associated with higher risk for attachment loss at a subsequent period. Analysis of these data involved using special software (*see* **Software, Biostatistical**) to adjust for the clustering of observations within each person. Three journal publications and two master's papers resulted from this investigation.

Another example is a study of Alzheimer's disease for the university's Department of Family Medicine. Data were collected from a sample of specialized dementia care units and traditional care units in five states. A **case–control** matched pair design was used, in which 307 residents from 31 specialized units and 318 patients from 32 traditional units were randomly selected. Data were obtained from questionnaires, medical record review, and direct observation. The key question was whether the use of physical restraints or pharmacologic restraints was different based on whether the individual was in a traditional or specialized care unit. **Logistic regression**, which accounted for clustering of individuals within the same unit, was used to adjust for other factors in modeling use of physical or pharmacologic restraints. A manuscript was published in a prominent medical journal.

Gray has many strengths as a consultant, including his ability to listen discerningly as clients explain their investigations. He has a great ability, based on years of experience, to assess problems and determine the appropriate statistical methodology for the situation. As he involves students in many facets of the work, he allows them to observe his interactions with clients and the development of solutions to research problems both during and after the consultation. He also explains his ideas to the students, and why he is using certain statistical techniques. Contact and coaching with real research problems in this way is excellent training for the students. Gary is a caring mentor and is highly regarded by students, faculty, and clients for both his insightful use of statistics and his ability to teach these skills to others.

Characteristics of a Successful Biostatistical Consultant

A successful biostatistical consultant possesses many skills [13, 16, 18]. The consultant must have a solid technical background in biostatistics, good knowledge of the subject matter area, excellent computing skills, and the ability to apply – or develop if necessary – statistical methods innovatively in a variety of settings. A successful biostatistical consultant should be aware of his or her limitations and know when to ask for assistance from a statistical or subject matter colleague or to learn about the appropriate statistical methodology in the literature. Other important characteristics are: enthusiasm in participating as a member of a team of research investigators; the capability of formulating problems in statistical terms; a

proclivity for problem-solving; and excellent communication skills, both oral and written.

Being a good consultant requires skills beyond ability in mathematics and knowledge of the theory and methods of statistics. Any investigation requires high-quality data, so the successful consulting biostatistician should become familiar with data collection procedures and methods for assuring the quality of the data. He or she should be genuinely interested in the subject matter area in order to become aware of issues that may have important statistical implications. Many clients fear mathematical and statistical ideas, but it is crucial that the client understand the statistical aspects that the consultant is discussing. Thus, a successful biostatistical consultant should be a good teacher who is willing to explain the statistical aspects of design and analysis in terms that a client can understand.

Working effectively on several research projects simultaneously means that the consultant should manage time efficiently and meet appropriate deadlines. Sometimes, the consultant should aim to achieve an acceptable solution to a problem when an ideal solution would require too much time, effort, and expense. Having good interpersonal skills is essential, since many personalities are encountered; sometimes the biostatistical consultant functions as an expert, while at other times he or she is a strategist or confidant. A willingness to admit mistakes and learn from failures helps a consultant in working on subsequent projects with clients.

Challenges of Consulting

Consultations are complex interactions in which the biostatistician may use many skills simultaneously. The successful biostatistical consultant often listens to the client's problem and constructs a statistical formulation. If the client brings data to be analyzed, the consultant should assess the statistical design of the project, explore the assumptions of statistical tests, discuss limitations of the analyses, and suggest appropriate solutions. After arriving at a statistical solution, the consultant should write a coherent report that is understandable to the client. Delivery of raw computer output or an uninterpreted set of tables does not serve either medicine or statistics. The consultant biostatistician should be aware that the nontechnical aspects of consulting may be at least as important as the technical aspects [2, 27]. Projects often have deadlines and budgetary constraints. Some clients apply pressures to achieve a favorable outcome, but the biostatistician must deal ethically and provide an honest report of the study. The best clients are those who understand that an honest report of the project is in the highest interest of science.

Excellence in communication is another essential skill for the consulting biostatistician. Adequate technical knowledge is simply not sufficient if the biostatistician is poor at communicating ideas to clients. Often, biostatisticians have to learn to listen and to ask questions that gradually lead to a revelation of the client's problem. This is especially important when the client is unfamiliar with statistics. Being able to discuss problems in the language of the client is a definite aid to communication. Being knowledgeable in the client's discipline, and being supportive and willing to educate the client, are attitudes that are most helpful in establishing good client–biostatistician relationships. Therefore, while a basic technical knowledge is necessary and presumed for consulting, the nontechnical aspects of consulting are often the most challenging.

Consultation may have a negative side, for the biostatistician may not receive sufficient recognition by the client and by the institution or organization in which the consultant is employed. In universities, promotions and tenure are based primarily on research, followed by teaching and service or practice-oriented research. Consulting, which usually falls into the category of supportive practice-oriented research, often is not valued greatly. Extremely active consultants who are consulting with a variety of disciplines simultaneously may not publish enough methodological research in peer-reviewed statistical journals [26]. The biostatistician spends a lot of time learning the discipline of the investigators and communicating with them regularly, particularly in large, long-term projects. The lack of recognition of consulting activities by academic departments when discussions are held about promotions and tenure, coupled with the lack of time for methodological research, compounds the frustration of an academic consultant. In addition, some clients believe that payment for services is sufficient recognition for a consultant's efforts. When the biostatistician has devoted substantial time and energy to a project, the client's failure to acknowledge the intellectual contribution,

in the form of authorship, also frustrates the consultant. Even when consultants are authors, rarely are they first authors. Since first authorship is given greater emphasis during reviews for promotion, consulting contributions tend to be undervalued. Some frustrations may be eliminated when there is a discussion with the client prior to the initiation of the project concerning authorship of papers and charges for statistical services. Some academic institutions realize that consulting biostatisticians contribute substantively to publications and subject matter areas, and consider this during reviews for promotions. Many contributions to statistical methodology have arisen through consulting projects. Also, as more attention is given to utilization of appropriate statistical methodology in research papers (e.g. the *Journal of the National Cancer Institute* has 20 consulting statistical editors), perhaps academic institutions will award more credit when a biostatistician is the coauthor of a medical paper.

Challenges may be different in other settings. In an organization in which consultation constitutes the primary role of the biostatistician, it may be difficult to satisfy the requests of several clients simultaneously in a manner consistent with the priorities of the organization. Often, the ideal analysis of a set of data may require more time and money than has been allocated to the project. The challenge to the biostatistician is to set priorities firmly and complete projects in a timely manner, subject to budgetary constraints.

Whatever the setting, biostatistical consultants must stay current with the statistical literature while maintaining their other responsibilities. In addition, they must maintain their computing skills in the face of evolving technology and a plethora of software packages. It is challenging to stay abreast of these developments in the field while simultaneously meeting work demands.

Special Challenges of Consulting with Physicians

A biostatistician working with physicians faces many challenges. Some problems are universal issues that occur with clients from all fields, and others seem to derive from differences in mind-set, approach, or inherent differences in the nature of physicians and statisticians. Physicians are trained to produce quick responses when presented with a set of patient characteristics; indeed, the patient usually expects an immediate assessment. In some clinical specialties, these decisions are made in a life-threatening situation. Physicians may weigh the results of a number of tests or factors as they make the decision. If most of the evidence leads to a certain conclusion, they often do not quibble over slight vagaries. In the clinical setting, physicians need and want the best answer in the shortest length of time. On the other hand, biostatisticians tend to be meticulous. They examine the data, check for discrepancies and **outliers**, test assumptions, and often approach questions from several angles. They like to do a thorough job. When physicians bring their clinical mind-set to the statistical consultation, they sometimes complain that biostatisticians are overly conscientious. And biostatisticians frequently complain that physicians want conclusions before the relevant data have been fully analyzed and interpreted! Each party should recognize the inherent differences in style and modify their approaches somewhat, moving toward a more "central" position. "Differences" seen in this light allow better understanding between physicians and biostatisticians.

Another complication that often surfaces when biostatisticians work with physicians is the psyche of the physician. Physicians are used to being "in charge". When coming to a biostatistician for assistance, they can feel either a lack of control because of a lack of familiarity with biostatistics or a need to dominate the biostatistician about what "statistics" should be done. Sometimes, physicians who do not understand the statistical arguments adopt a passive–aggressive stance, accepting with question the results presented by the biostatistician. This situation is usually stressful for the biostatistician and physician alike. Often this can be alleviated by a frank characterization of the situation and a statement by the biostatistician of their commitment to work with the physician, perhaps suggesting an ongoing collaboration. This, combined with some respectful coaching of the physician on statistical terms and practice by the consultant, can mollify the situation.

Many physicians and biostatisticians develop extremely productive collaborations that continue for years. This occurs most often when the physician has come to value the impact that the biostatistician has had on their work in terms of efficiency and accuracy of methodology, leading to an increase in the number of grants or papers accepted for publication. And

that usually occurs when the biostatistician has taken the time to become educated in the discipline of the physician and has fostered the relationship. In these long-term relationships, biostatisticians often have concentrated their consulting efforts in a particular area of medicine and become "experts" in the analyses that are used most often in that area.

Biostatistical Consultants as Ambassadors

The relationships that a biostatistician establishes with people in other fields can have an important impact on how those collaborators view statistics as a discipline. Often, the only contact that investigators have with statistics is through their consultant. By seeking out opportunities to demonstrate the usefulness and the power of statistics, the consultant can enhance the image of statisticians both locally and on a broader scale [3]. Locally, they can give a talk, a short course, or a workshop to a client's department or unit. Making use of actual data from designed studies in the client's field is an effective method to illustrate statistical principles. In a consulting practice, the biostatistician can also reflect interest in the client's projects by visiting the client's laboratory or office to learn about the conduct of the research project. Suggestions for improving the consulting process can come by soliciting feedback from the client directly. Feedback questionnaires administered anonymously can also elicit useful suggestions.

A biostatistician can enhance the image of statistics both nationally and internationally. For example, many biostatisticians participate in the review process for scientific manuscripts and research proposals [6]. They can serve on a journal's editorial board and develop standards for statistical review [12, 17] (*see* **Statistical Review for Medical Journals**). Numerous research journals have supported commentaries or tutorial articles on statistical issues relevant to the journal's readers [7]. All of these activities have a far-reaching impact on how clients view statisticians.

Another emissary role of a biostatistician is service on advisory committees for state or federal agencies. In particular, biostatisticians serving the Food and Drug Administration (FDA) or the National Institutes of Health (NIH) and other governmental agencies not only represent the profession, but also have an opportunity to shape decisions and make policy that may have a major impact in the health and medical sciences. Besides the statistical input, they can provide for the process of decision-making, and they can also raise awareness of the need for statistical thinking about research projects at the highest levels of these organizations.

Training of Biostatistical Consultants

Most practicing biostatisticians have graduate degrees, often from a school of public health. Undergraduate degrees are often in mathematics, statistics, or biostatistics. However, many biostatisticians have their first degree in a field such as biology, psychology, or pharmacy. Graduate training includes the usual theoretical and applied courses for a statistician as well as courses in epidemiology and other public health fields. In the past, most of the students' practical consulting experience obtained in graduate programs came from apprenticeship participation on projects with faculty advisors or from working in consulting centers, usually under faculty direction. However, the past 10–15 years has seen a growing interest in the design and development of courses in consulting to teach the specific skills needed; some of these courses have been implemented in departments of biostatistics. Although most people agree with the list of skills needed by statistical and biostatistical consultants, and many articles in the statistical literature attest to them [5, 11, 13, 15, 21], only a few people have actually designed courses to model these skills and to cultivate them in students. Most biostatisticians have not been simultaneously trained in psychological or communication skills. Even if a biostatistician does naturally possess the traits necessary for consulting, he or she may not know how to transmit these characteristics to others systematically. In addition, a university may not reward spending time in such an endeavor.

A variety of approaches have been taken to educate students about consulting. They usually include some analysis of "real" data, which most consider the main skill needed for consultation, and report writing. Other courses focus mainly on the psychological and communication aspects of consulting [19, 24]. More and more, though, the courses take a broad approach and incorporate the skills needed to carry out an entire project from start to finish. These courses offer exercises and discussions to develop and improve skills in communication, organization, analysis, and presentation of oral and written results [8,

22, 23]. Often using videotaped consultations, students are shown how to elicit information from and deliver technical information to clients as well as how to manage a consulting session. Students are often videotaped in mock or actual consultations. Carrying out a full-fledged project during the class provides experience with time management, organization and documentation of project materials, discussion of appropriate analysis approaches, writing of statistical reports, and opportunities to discuss budgets and the billing of clients. Courses such as this are usually prerequisites or adjuncts to the actual consulting experience.

Many students find additional ways to gain practical experience during their graduate programs. They either work part-time or participate in internship programs. This experience gives both parties a chance to assess potential future relationships. However, on-the-job training is perhaps the primary method for learning consulting. Being aware of what works and what does not work, and changing one's procedures accordingly, is the ultimate strategy for success in consulting. Add years of experience and you will have a seasoned consultant.

Incentives for Biostatistical Consulting

Consultation has many rewards for a biostatistician. The skills required may match those of the individual, whereas a career spent entirely in teaching and research may be less rewarding. A biostatistical consultant will almost surely design an experiment and analyze data, whereas many academic biostatisticians may have no real experience in these areas. In addition, many problems encountered in consulting relationships are challenging. Since most new statistical methodology arises from realistic problems, being a consulting biostatistician is a way to learn about new projects requiring advances in statistical methodology. Also, there is the excitement of participating as a collaborating member of a team on a research project that is addressing an important scientific or health related question. Another incentive is that financial benefits accruing to the biostatistical consultant are often greater than for those participating only in academic work. Additional benefits derive from being coauthors on medical publications, making presentations at scientific meetings, and contributing generally to the betterment of society.

Statistical Dependence and Independence

Statistical dependence is a type of relation between any two features of units under study. These units may, for instance, be individuals, objects, or various aspects of the environment. Deterministic dependence and statistical independence can be regarded as the two opposite extreme types of relation, but also as being qualitatively distinct from the possible other forms of relation. If deterministic dependence and independence are excluded, then the remaining intermediate types of statistical dependence involve both features as proper variables such that there are differences in the distributions of one variable for at least some of the levels of the other.

If proper variables are statistically independent, then the distribution of one of them is the same no matter at which fixed levels the other variable is considered and observations for such variables will lead correspondingly to nearly equal frequency distributions. If there is deterministic dependence, then the levels of one of the variables vary in an exactly determined way with changing levels of the other. In other words, under independence, knowledge about one feature remains unaffected by information provided about the other, while under deterministic dependence it follows with certainty which level of one variable occurs as soon as the level of the other variable is known.

The definition of these opposite extreme types of relation is symmetrical between the two features involved, but in its intermediate forms, statistical dependence may or may not be considered in a symmetric way, depending on the substance matter context. A symmetrical type of dependence will be appropriate if the variables involved are considered to be on an equal footing, such as symptoms of a disease, or as length, height and depth of produced objects, or as personality characteristics of individuals. By contrast, an asymmetrical form of dependence is of main interest if, instead, one of the variables is considered as a possible **response** to the other, such as weight to caloric intake, or as depression to anxiety. The terms symmetric **association** and directed association are often used to capture this distinction.

Given observations on independent units, statistical dependence shows in a number of different ways depending on several aspects. Important are, in particular, the types of variable involved, the conditions under which the relation is recorded, and the type of association measures used to summarize the data. These issues are addressed next, in turn.

Relations Depending on Types of Variable

One important distinction for variables is whether they are qualitative or quantitative. Quantitative variables have levels that are numerical values with a substantive meaning, such as kilograms, as ranks, or as sumscores of questionnaires. Qualitative variables have, instead, categories as possible levels. With a nominal scale the categories are just of a qualitatively similar kind such as **blood groups**; numbers possibly assigned to them play the role of codes; that is, of mere labels. In the case in which levels of a qualitative variable can be ranked, the scale becomes ordinal. This information may sometimes be exploited to improve formal analysis (*see* **Measurement Scale**).

First, data summaries appropriate to detect the form of **pairwise dependence** change with the types of variable involved. They are, typically, **contingency tables** for qualitative or discretized quantitative variables, scatter plots for quantitative variables and frequency distributions (or at least selected characteristics of the distributions) of the quantitative variable displayed within each category of the qualitative variable (*see* **Graphical Displays**).

Accordingly, a great variety of more formal techniques is available. In the case of symmetric associations examples are **loglinear models** for qualitative variables, covariance selection for quantitative variables (*see* **Variable Selection**), and mixed **interaction** models for both qualitative and quantitative variables. In the case of directed associations examples are logistic [2] and probit [6] regression for discrete responses (*see* **Quantal Response Models**), **linear regression** for quantitative responses, and combinations of these for mixed joint responses. In any case it is essential to check systematically [4] for more complex dependencies involving several variables or, possibly, nonlinear relations among quantitative variables.

Relations Depending on the Conditioning Set

Every statistical dependence among observed variables is a conditional relation, since there is always some conditioning, at least implicitly on time and location of the study. A more explicit form of conditioning may result by design or by statistical analysis involving several recorded variables. In that case the distinction between conditional and marginal dependence and conditional and marginal independence becomes relevant. Both may convey different information. A marginal dependence of a response on a potential explanatory variable may, for instance, be completely explainable in terms of a corresponding conditional independence statement given an intermediate variable, which itself is strongly related to both.

One example from the German labor market in 1986 is shown here with the following 2^3 contingency table, adapted from job placement statistics [1]. The response is successful job placement, A, the intermediate variable is field of study, B, and the potential explanatory variable is gender of the applicant, C. If the marginal dependence of job placement on gender is considered, i.e. the overall association of pair (A, C), shown on the right-hand side of Table 1, it appears as if there were discrimination against women, since females have a much lower chance than men of obtaining a job.

This dependence can, however, be explained in the following way: home economics was a preferred field of qualification for women, while mechanical engineering was strongly preferred by men. At the same time there were many more successful job placements for mechanical engineers than for home economists, simply because many more job openings were available for the former. Within each of the two fields of qualification there was the same percentage of successful job placements for both, women and men. In other words, A is conditionally independent of C given B (*see* **Simpson's Paradox**).

This conditional independence, together with the strong marginal associations for pairs (A, B) and (B, C) both having variable B in common, imply the observed dependence for (A, C); that is, this dependence is generated by the intermediate variable B. The data are also an example of a simple **Markov chain** [8] and, more generally, of a graphical Markov model, a general framework (see [4, 5], and [7]) within which sequences of response, intermediate and **explanatory** variables, both types of variables, qualitative and quantitative, distinct levels of conditioning and interactive as well as nonlinear relations, may be modeled explicitly.

Judgment of Relations as Dependent on Measures of Association

In many contexts it is possible to summarize dependencies concisely with a few carefully chosen measures of association (*see* **Association, Measures of**). One example for a quantitative response and equally spaced levels of a quantitative explanatory variable is the set of coefficients of a **polynomial regression**. If, for instance, the dependence can be well captured by an orthogonal polynomial in three coefficients, then the dependence is additively decomposed into an overall mean, a linear, and a quadratic effect. A direct extension is, conceptually though not technically, the decomposition of a time dependence into a general level, a linear trend, and seasonal effects.

Some measures of association arise as parameters in multivariate distributions. In such distributions, it is typical that discrete random variables model

Table 1 Overall dependence in spite of conditional independence

	B, field of qualification				Overall; that is, summed over B	
	Home economics		Mechanical engineering			
	C, gender		C, gender		C, gender	
A, successful job placement	Female	Male	Female	Male	Female	Male
Yes	15 (3.61%)	2 (3.64%)	4 (20.0%)	95 (21.1%)	19 (4.4%)	97 (19.2%)
No	400	53	16	355	416	408
Sum	415	55	20	450	435	505

qualitative features and continuous random variables model quantitative features. For symmetric associations one prominent example is the **exponential family** called the conditional Gaussian (CG) distribution, in which the continuous variables have a joint Gaussian distribution for each level combination of the discrete variables.

In the bivariate versions of the CG distribution, the canonical association parameters are log **odds ratios** for two discrete variables, multiples of the simple **correlation** coefficient for two continuous variables, and a weighted difference in means for the mixed case. In higher dimensions these association parameters are generalized in such a way that null values of all terms involving a particular pair of variables imply conditional independence of the pair given all remaining variables: the measures of association are then conditional log odds ratios, multiples of partial correlation coefficients, and weighted differences of means, corrected for effects of the remaining variables.

The obvious danger in using measures of association which are part of a well studied joint distribution is that the true distribution of the features under study may be quite different. For instance, if the judgment of dependencies among quantitative variables were based only on simple and partial correlation coefficients, then substantial misjudgments of the actual relations might result. If the simple correlation is zero, then strong nonlinear relations of a particular type may still be present, but at least, if the simple correlation is nonzero, the variable pair will always be marginally dependent. The situation is much worse with partial correlations.

Every partial correlation coefficient is a simple correlation coefficient for **residuals** obtained after linear regression on some common set of further variables. As for the simple correlation, there may be strong nonlinear conditional associations even if a partial correlation coefficient is zero. However, the reverse may happen as well; that is, the partial correlation coefficient may be high in spite of conditional independence. This is best illustrated with an example.

Let Z, U, and V be mutually independent variables, each having a standardized Gaussian distribution; that is, in particular, each having mean zero and variance one. Define Y and X as follows:

$$Y = (Z^2 - 1) + U, \qquad X = (Z^2 - 1) + Z + V.$$

Then Y is conditionally independent of X given Z, written as $Y \perp\!\!\!\perp X|Z$, because given Z only U and V are variable, and they are independent by assumption. But the simple correlation between the residuals from linear regression is 2/3; that is, the partial correlation coefficient $\rho_{xy.z}$ is sizeable.

To see this, note that linear – instead of the appropriate nonlinear – regression of Y on Z and of X on Z would give as conditional means

$$\mathrm{E}_{\mathrm{linear}}(Y|Z) = 0, \qquad \mathrm{E}_{\mathrm{linear}}(X|Z) = Z,$$

and hence as residuals from these linear regressions

$$R_{Y.Z} = (Z^2 - 1) + U, \qquad R_{X.Z} = (Z^2 - 1) + V.$$

Since the square of a standardized Gaussian variable has a **chi-square distribution** on one **degree of freedom**, the variable Z^2 has mean 1 and variance 2 and the residuals both have zero means. Furthermore, both residuals have variance 3 and their covariance is

$$\mathrm{cov}(R_{X.Z}, R_{Y.Z}) = \mathrm{var}(Z^2 - 1) = 2,$$

so that $\rho_{xy.z} = \mathrm{cov}(R_{X.Z}, R_{Y.Z})\{\mathrm{var}(R_{X.Z})\mathrm{var}(R_{Y.Z})\}^{-1/2} = 2/3$ even though the corresponding conditional independence statement $Y \perp\!\!\!\perp X|Z$ holds. Of course, if for corresponding observations systematic checks for nonlinearities and interactions were used [3], then it would certainly be detected that nonlinear associations are present and hence it would be noticed that correcting for only linear relations of Y on Z and of X on Z is inadequate.

An alternative to assuming that a set of variables has a particular distribution is to define the joint distribution only implicitly via a sequence of recursive conditional distributions. This is typical for graphical Markov models corresponding to so-called chain graphs. In that case, conditional dependencies of potential explanatory variables are modeled separately for each response in accordance with available substance matter knowledge [4, 9]; nonlinear relations and interactions among continuous variables may be part of the model. In addition, for a given model it may often be deduced which independencies and associations are implied under other conditioning sets than those specified with the given model [10].

Another important additional advantage of such conditional modeling is that issues such as **censoring**, measurement error (*see* **Errors in Variables**), missing values, time dependencies, and effects of hidden random variables may in principle be directly

integrated into the modeling process. To date, however, the actual implementation might for some combinations still require substantial further theoretic and technical developments.

Statistical Forensics

When genetic evidence is used for individual identification, there are generally competing explanations for the observations. A typical forensic situation arises when biological material at the scene of a crime is typed, found to have some profile A, and the circumstances of the crime suggest that the material was left by the perpetrator P. A person S suspected of having committed the crime is also typed, and is found to have the same profile. The evidence E is that the two profiles are of type A.

The competing explanations are:

H_p: the crime sample is from S
H_d: the crime sample is not from S

and the relative merits of these two explanations are compared by means of a **likelihood ratio**. This compares the probability of the evidence under the two explanations:

$$L = \frac{\Pr(E|H_p)}{\Pr(E|H_d)}. \tag{1}$$

Values of L greater than 1 favor the explanation H_p over H_d. If there are prior odds $\Pr(H_p)/\Pr(H_d)$ on S being the contributor, then the posterior odds $\Pr(H_p|E)/\Pr(H_d|E)$ follow from **Bayes' Theorem** as

$$\text{posterior odds} = L \times \text{prior odds}.$$

One of the most common errors in interpreting genetic evidence is to confuse the posterior odds with the likelihood ratio. This transposition of the conditional is more commonly made by prosecutors, giving rise to the term "prosecutor's fallacy". It is generally the case that $\Pr(E|H_p) = 1$, and the value of $\Pr(E|H_d)$ might be 10^{-6}. The likelihood ratio is then one million, but the posterior odds depend on the prior odds. They are not a million to one on guilt. Although odds on guilt is very much the kind of information desired by courts, it cannot be found from genetic evidence alone.

Conditional Probabilities

Eq. (1) can be modified by the rules of **conditional probability**. If S_A and P_A mean that S and P, respectively, have genetic profile A, then

$$\begin{aligned} L &= \frac{\Pr(S_A, P_A|H_p)}{\Pr(S_A, P_A|H_d)} \\ &= \frac{\Pr(P_A|S_A, H_p)\ \Pr(S_A|H_p)}{\Pr(P_A|S_A, H_d)\ \Pr(S_A|H_d)}. \end{aligned}$$

It may generally be assumed that the profile type of S does not depend on either explanation of the matching profiles, so $\Pr(S_A|H_p) = \Pr(S_A|H_d)$, and that a match is certain under H_p, so $\Pr(P_A|S_A, H_p) = 1$, and then

$$L = \frac{1}{\Pr(P_A|S_A, H_d)}.$$

The focus on conditional probabilities greatly simplifies the interpretation of matching profiles. The question is clearly seen to be "What is the probability that the perpetrator of the crime is of type A given that S is of type A, when these two people are not the same?" The smaller this probability, the stronger the evidence against S. By emphasizing that L depends on the probability of an event, comparisons between L and the size of the population are avoided. There is no inconsistency between an L of one million and a population size of one thousand. One has nothing to do with the other.

In the special case that profile probabilities of different people S and P are independent, the likelihood ratio reduces to the reciprocal of the profile probability ("profile frequency")

$$L = \frac{1}{\Pr(P_A)}. \tag{2}$$

This equation will not hold if S and P are related, or if they both belong to the same subpopulation. In one case the two people are related by virtue of being in the same family, and in the second they are related in an evolutionary sense. Although the second dependence cannot be zero for two humans (see **Inbreeding**), it is usually negligible.

The Product Rule

If dependencies between profile probabilities can be ignored, (2) shows that what is needed is the probability with which an unknown (or untyped) person has a specific profile. These profiles are the joint genotypes at several loci. If a_{li} is allele i for locus l,

and has frequency p_{li}, the probability P_A of m-locus **genotype** $A = \prod_{l=1}^{m} a_{li}a_{li'}$ is

$$P_A = \prod_l 2^{h_l} p_{li} p_{li'},$$

where $h_l = 0$ if the profile is homozygous at the lth locus, $a_{li} = a_{li'}$, and $h_l = 1$ if it is **heterozygous**, $a_{li} \neq a_{li'}$. This result holds only if independence of all alleles can be assumed (*see* **Hardy–Weinberg Equilibrium**; **Linkage Disequilibrium**).

Independence of alleles among loci is usually a reasonable assumption for unlinked loci, but dependence within loci may exist. For a population with departures from Hardy–Weinberg equilibrium characterized by inbreeding F_l at locus l, the profile probability would need to be modified to

$$P_A = \prod_l \left\{(1 - h_l)[p_{li}^2 + F_l p_{li}(1 - p_{li})] + h_l 2 p_{li} p_{li'}(1 - F_l)\right\}.$$

This increase for homozygotes and decrease for heterozygotes is appropriate for departures from Hardy–Weinberg equilibrium due to inbreeding. A more likely cause of Hardy–Weinberg departures for human populations, however, is admixture (*see* **Admixture in Human Populations**). For genes with multiple alleles, admixture increases the frequency of homozygotes in the total population over the squared total allele frequency, but the frequency of any particular heterozygote may be increased or decreased over twice the product of total allele frequencies. Such doubts as to the proper adjustment for one-locus frequencies could be avoided by using observed genotype frequencies at each locus, instead of the product rule, and then multiplying genotype frequencies over loci. This procedure has difficulties for highly variable loci, when specific genotypes may not be present in population samples. A better way of avoiding doubts is to return to the conditional probabilities instead of approximating them by unconditional profile probabilities.

Relatives

A plausible defense for a suspect whose genetic profile matches that found in a crime scene sample is that he may be related to the true perpetrator, so that the match has little probative value. Unless the suspect's relatives are typed, this claim must be met by calculating the conditional probability of two relatives having the same profile. A full treatment of this issue, allowing either relative to be inbred, requires the full set of four-allele **identity coefficients**. For noninbred relatives, however, calculations are fairly simple, and involve considering whether or not the relatives share alleles. Results for some common cases are given in Table 1 [2].

Table 1

Genotype A	Relationship	$\Pr(P_A \mid S_A)$
$a_i a_j$ $(i \neq j)$	Full brothers	$(1 + p_i + p_j + 2p_i p_j)/4$
	Father and son	$(p_i + p_j)/2$
	Half brothers	$(p_i + p_j + 4p_i p_j)/4$
	Uncle and nephew	$(p_i + p_j + 4p_i p_j)/4$
	First cousins	$(p_i + p_j + 12p_i p_j)/8$
	Unrelated	$2p_i p_j$
$a_i a_i$	Full brothers	$(1 + p_i)^2/4$
	Father and son	p_i
	Half brothers	$p_i(1 + p_i)/2$
	Uncle and nephew	$p_i(1 + p_i)/2$
	First cousins	$p_i(1 + 3p_i)/4$
	Unrelated	p_i^2

Population Structure

Another plausible defense for a suspect found to have a profile matching that in a crime scene sample is that he and the true perpetrator both belong to a particular subpopulation in which the profile is more common than in the population at large, but that probability calculations have been performed with data taken from the whole population.

To address this question completely the conditional probability would need to be estimated for that subpopulation. This will not be feasible in general, and not even possible if the subpopulation is not well-defined. However, there is a framework for addressing the issue. The article on **Inbreeding** discusses conditional allelic probabilities, and gives the result for allele a_i,

$$\Pr(a_i \mid a_i) = p_i + \theta(1 - p_i). \tag{3}$$

This is the probability that two people in the same subpopulation share allele a_i, with the answer being

given as an average over all subpopulations. The allele frequency p_i applies to the total population, and may be estimated from a population-wide sample. The coancestry (or kinship) coefficient θ cannot be estimated directly without data from these subpopulations, but may be given an appropriate value from other studies or from some value considered to be a plausible upper bound.

For matching profiles, an expression equivalent to (3), but for genotypes, is needed. Such expressions require relationships among four alleles, two per person, but adequate approximations derived from evolutionary-equilibrium theory have been proposed [1]. They are:

$$\Pr(a_i a_i | a_i a_i) = \frac{[p_i + \theta(2 - p_i)][p_i + \theta(3 - p_i)]}{(1 + \theta)(1 + 2\theta)} \geq p_i^2$$

and

$$\Pr(a_i a_j | a_i a_j) = \frac{2[p_i + \theta(1 - p_i)][p_j + \theta(1 - p_j)]}{(1 + \theta)(1 + 2\theta)}.$$

Provided $\theta \geq 0$, the conditional probabilities always exceed the total probabilities for homozygotes and usually for heterozygotes. The same approach is therefore valid for all genotypes, and it is necessary only to select an appropriate value of θ. It is unlikely that θ would be as great as 0.05 for human populations (it is 0.0625 for first cousins), and so these conditional probabilities are very close to the Hardy–Weinberg probabilities when allele frequencies are 0.1 or higher.

Mixtures

Some crime-scene samples contain genetic material from more than one person. This is the case for vaginal swabs from a rape victim, for example. Unless the typing procedure indicates that some elements of the mixture necessarily come from the same person, interpretation of mixed samples proceeds very much as for single stains. Suppose the crime sample has a set $\{e\}$ of alleles for a gene. Explanation H_p is that some specified people contributed to the sample, and that p unknown people must have contributed alleles $\{u\}$ of that set, but did not have any alleles not in $\{e\}$ between them. The probability of this event is written as $P_p(u|e)$. Similarly, $P_d(v|e)$ is the probability of the event specified by explanation H_d: a number d of unknown people must have contributed alleles $\{v\}$ but did not carry any alleles not in $\{e\}$ between them. The likelihood ratio is

$$L = \frac{P_p(u|e)}{P_d(v|e)}.$$

As an example, consider the case where a woman has been raped by two men. A vaginal swab reveals alleles *abcde* for a gene. The victim is of type *ab*, and the type of a single suspect is *cd*. The prosecution explanation is that the victim, the suspect, and one unknown man were the contributors to the sample. The defense explanation may be that the victim and two unknown men were the contributors. The likelihood ratio is

$$L = \frac{P_1(e|abcde)}{P_2(cde|abcde)}.$$

Assuming allelic independence, and the absence of effects of relatives, inbreeding or population structure,

$$P_x(u|e) = T_0^{2x} - \sum_i T_i^{2x} + \sum_i \sum_{j \neq i} T_{ij}^{2x} - \cdots,$$

where T_0 is the sum of frequencies of all the alleles in $\{e\}$, T_i is T_0 minus the frequency of the ith allele in $\{u\}$, T_{ij} is T_i minus the frequency of the jth allele in $\{u\}$, and so on [3].

Conclusion

This discussion has focused on the probabilities of coincidental matches of genetic profiles from two people. It has ignored nongenetic issues, such as the possibility that a match has been declared falsely, whether by error or fraud. The discussion may be of temporary relevance because of the increasingly discriminatory power of genetic profiles. The technology has advanced to the point where it may no longer be reasonable to believe that any two people, identical twins excepted, could have the same profile. At that point, the term "genetic fingerprint" would be appropriate.

Statistical Map

A map can be defined as "a collection of spatially defined objects" [13, 14].

As such, a map is simply a display of the spatial properties of an object set. This usually implies a two-dimensional display of the Cartesian or polar coordinate locations of objects and also their attributes, e.g. a street map displays the locations of streets and houses on these streets (if the *resolution* of the map is high enough). In addition, the houses may have attributes that relate to the population of each household. Hence a variety of maps could be constructed even from this simple example. We could have a simple street map, a more detailed house map, and a map of household attributes at the highest resolution. The display of such varied information in a graphical form has been the concern of *cartography* for a considerable time [13]. Many of the concerns of those within statistics about the representation of data in graphical forms have also been explored within geography for mapped displays. The psychological/visual perceptual implications of chosen mapping methods has been studied extensively [14, Chapters 3– 6], and these issues also apply to the construction of maps of statistical information. Walter [22] has examined visualization issues related to medical mapping. The stages of map construction can each be associated with some form of processing of spatial information and hence can be of concern to anyone wishing to use such methods of presentation.

The main stages are:

1. choice of scale
2. choice of symbolization or representational processing
3. further processing required to construct a suitable map.

In stage 1, a suitable scale for the map must be chosen. Any choice of scale, however, inevitably leads to a process of *averaging* of spatial information from higher levels of resolution. For instance, a street map of a city will usually be represented as sets of linear features depicting street locations, but if a larger country scale was to be used, within which the city was but a small part, then the city streets could be represented by a dot. Hence in this case, the scale change has resulted in averaging of the spatial information. Stage 2 is also represented in the street map example. At the detailed scale, linear features represent the streets, while at the country scale the whole city is represented by a dot. This represents a change in symbolic representation as well as scale change. This can both have a visual perceptual effect for the map user and represent an averaging of spatial information. Stage 3, that of further processing, can occur when information on the spatial structure of the objects and/or attributes is not available in the form required by the representational system. For example, often one needs to compute a map representation from a set of sampling points that are predefined, whereas we need to have measurements at the intersections of a fixed grid which do not correspond to the sampling points. This arises in many statistical mapping problems and leads to the use of *interpolation* or smoothing of data. Another example of further processing is the use of **transformations** of the mapped data to represent some feature of the spatial structure. Map projections [14, Chapter 2] are a classic example of transformation. Schulman et al. [17] give an example of using projection and transformation in a medical statistical application.

Hence, in two of the three stages of map production, some form of statistical processing of the spatial information usually occurs. This applies in most forms of mapping exercise and hence it can be claimed that map construction is, to a large extent, a statistical processing task. Figures 1 and 2 display the transition between street and city level representations.

Statistical Maps and Mapping

The three stages of map production discussed above map easily onto the data types that are often the basic ingredients for mapped representation. Within the subject of spatial statistics a spectrum of spatial information and data formats is found. This spectrum ranges from the locations of points or objects (point and object processes; *see* **Point Processes**) to the measurements made on random variates at specific spatial locations (random fields). In the former case, the subject area of stochastic geometry concerns the probabilistic modeling of the locations of objects [19]. In the latter case, the subjects of geostatistics and image processing (*see* **Image Analysis and Tomography**) deal with observations made on random fields [2]. Image processing characteristically studies random fields observed on a grid mesh of regular sampling points (pixels), and its task is usually restricted to the processing of the pixel data to obtain the underlying "ground truth" or noise-free image. Hence, this form of processing is not closely akin to mapping as there is usually no need for interpolation or scale averaging. However, the subject of geostatistics does involve smoothing and interpolation and can involve the estimation of areas or blocks of information that are averages of underlying sampling point data. In addition, the analysis of object processes often involves the averaging and scale change from locational data to localized intensity data, i.e. the locations of objects are converted into a continuous surface describing the local density/intensity of objects. Both of these data types lead to scale change and interpolation/smoothing operations that are integral to the mapping process.

As image processing can be considered a special case of geostatistics, for brevity we will consider here the construction of maps and map interpretation and properties for object processes and for geostatistical data only. A review of map construction issues for disease atlases can be found in [3] (*see* **Mapping Disease Patterns**).

Object Process Mapping

An object process map is a presentation of the spatial locations of objects, usually in two dimensions. Define $\mathbf{x}_i, i = 1, \ldots, n$, to be the locations of the objects within a spatial window T. The area of T is denoted $|T|$. Usually objects are mapped at a specified point (the associated point), which can be uniquely identified for each object. For example, a process of circles could have the circle centers as associated points. Hence to construct a map of such a process it suffices to plot the locations of such points and then to construct circles with given radii. For this example, the locations of the circles could follow a **stochastic process** and the circle radii could be the realization of a **random variable**. A simpler example of this idea is the **point process**, which simply has a point location as its observation unit and the realization of point locations are the objects. For example, the address locations of cases of a disease form a point process and a map of all addresses of disease within T would be a mapping of the process. Figure 3 depicts a case address map for respiratory cancer in a small Scottish town for the period 1966–1976.

Often it is important to transform an object map by converting the object locations into a continuous surface representation of the objects. This kind of transformation can be achieved by computing the local density of objects. **Density estimation** [18] can be used to provide such local densities and the resulting density surface can be mapped over the study window. Usually such a surface is displayed as a contour plot or, in three dimensions, as a surface perspective view. The contour plot is often preferred, as some spatial information is hidden in perspective views. To demonstrate how scale and symbolization affect such mapping, the contour plot of a density estimate of the case event data in Figure 1 has been drawn for two different

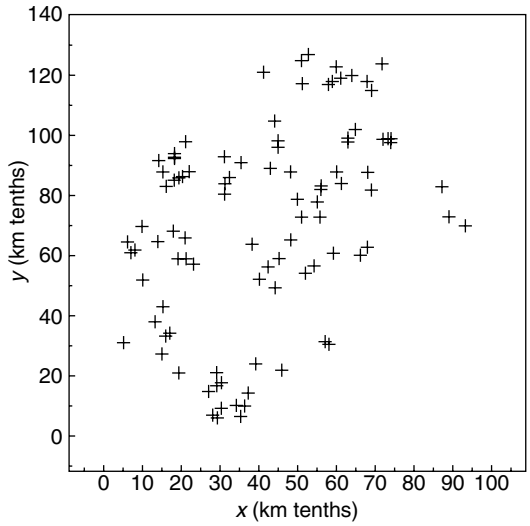

Figure 3 Arbroath: central Scotland: object map of cases of respiratory cancer within a fixed time period. Map made with Mapinfo Professional®. © 1997 Mapinfo Corporation

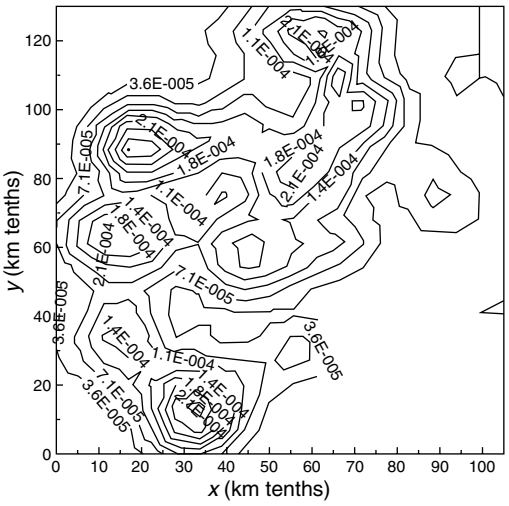

Figure 4 Contour map of case events in Figure 3: 10 contour heights. Map made with Mapinfo Professional®. © 1997 Mapinfo Corporation

contour densities (10 and five heights) in Figures 4 and 5. Note that the arbitrary choice of fewer contours effectively produces a smoother surface and can change the perception of the object map. In addition, the derivation of these contour maps has proceeded through a number of stages that may affect the final

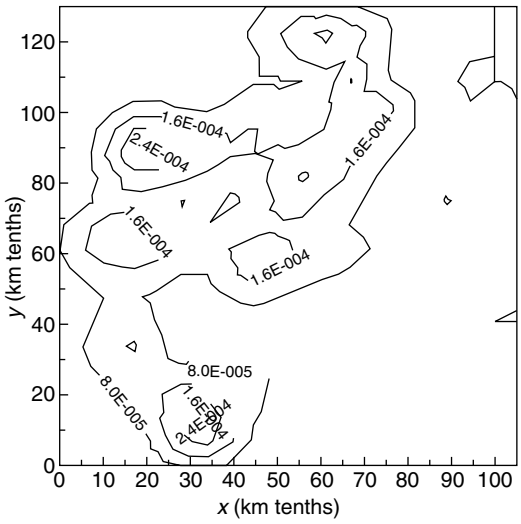

Figure 5 Contour map of case events in Figure 3: five contour heights. Map made with Mapinfo Professional®. © 1997 Mapinfo Corporation

visualization. First, the process of density estimation involves the production of estimates in a grid mesh (interpolation) and the choice of a smoothing constant (bandwidth) that controls the smoothness of the gridded data. Then a graphic package has constructed contours using a further interpolation/smoothing step.

Geostatistical Mapping

Geostatistical data differ from the above in that a network of sites is usually used to sample or measure some spatially distributed variate. For example, the early geostatistical work related to estimation of geological structures in mining applications where concentrations of particular minerals were sampled at fixed locations [2, 21]. Within biostatistics, many examples can be found where data are sampled at spatial sites. One common example is the mapping of disease rates located at the centroids of small geographic areas (*see* **Geographic Patterns of Disease**), such as census tracts. While the rate represents an average over the whole region, the approximation of allocating the rate to a centroid is often made. In this case the rate (e.g. a standardized mortality ratio (SMR) [7]; *see* **Standardization Methods**) is regarded as being associated with a fixed spatial location. Another application arises when a

spatially distributed covariate must be interpolated to a set of locations within an ecologic study. An example of this would be the use of interpolated pollution measurements as a covariate in a study of the distribution of respiratory disease morbidity (e.g. asthma). In principle, the basic mapping considerations apply in this case also: for visualization, the data can be displayed as an object map with each sample site becoming the location of an object representing the measurement at that site. For example, a circle of radius equal to the measurement could depict the distribution. Other display forms are available, such as needle plots where vertical lines of length scaled to represent the measurement are drawn at the sites [15]. Often a surface interpolated from the measured data is to be constructed. This surface also requires an interpolation or smoothing step to provide a gridded data set, which can be subsequently contoured. Such interpolation can be achieved by a wide range of smoothing techniques. The method of *Kriging* was developed within geostatistics to provide such processing. This method is not directly applicable to data that have a positivity constraint (e.g. SMRs or counts), but can be modified [10, 12].

Other notable forms of smoothing available for such data are: **nonparametric regression** or *kernel smoothing* [6], and *thin plate* **splines** [5, Chapter 7]. A wide variety of mathematical interpolation methods are available also, e.g. finite element methods [8].

Statistical Accuracy

Any step of map production which requires statistical **estimation** will have associated with it a measure of the reliability or variability of that estimation. Hence any map of estimated values (such as interpolated or smoothed data) should have a variance estimate available at the estimation points. The variance estimate can also be represented as a surface, or a pointwise **confidence interval** for the estimated surface can be produced. The visualization of such surfaces can cause some problems as there are no simple clear methods of displaying multiple surfaces without losing spatial information. If areas of the estimated surface that exceed limits of variability are of interest, then it may be possible to construct a **Monte Carlo *P*-value** surface [4] (*see* **Markov Chain Monte Carlo**).

Edge Effects

In most mapping exercises where statistical data are to be represented, edge effects are present and may require to be accommodated in the analysis. When spatial data are spatially **autocorrelated** then observations made within a study window will relate to unobserved data outside the window. This is a form of spatial **censoring**. Even when data are not autocorrelated, the method used to estimate the smoothed surface representation of the data will have greater variability at the edges. This is because such smoothing operators use neighboring data observations to compute estimates and at edges these neighborhoods are censored. Also, if only data *within* the window are used to estimate edge values, then a bias will appear in this edge estimation. The use of *guard areas* or *data augmentation* at the edges of maps may be useful [16, 20]. An example of a disease mapping application where edge effects may have a significant impact is given in [1].

Aggregation

Finally, it is important to consider the interconnection between some mapping concepts and the related statistical issue of aggregation. The effect of aggregation of data into spatially larger areas has a variety of effects on the subsequent interpretation. First, aggregation is a scale change; by accumulating observations into larger spatial units the scale of analysis is changed. In addition, aggregation acts as a smoothing operation. That is, by accumulation of data detailed variation in the data will be lost and will not be retrievable. A classic example of this is the arbitrary regionalization of case events into **census** tracts in medical small area studies. In that case the detailed spatial variation of cases is lost within the census tract count (for discussion see [9] or [11]). This type of averaging of spatial effects is inherent in scale changes, and it is important that any spatial structural effects observed in data at one scale are scale labeled, i.e. the scale at which the effect is found is permanently associated with the effect. For example, clustering of disease data in space may occur on a case event map, but when aggregated into census tract counts this effect may disappear.

Statistical Methods in Medical Research

Statistical Methods in Medical Research is an international review journal that was first published in 1992. Its aim is to provide medical statisticians and others with up-to-date reviews of those areas of statistics that are most important in medical and health investigations. The journal is published six times a year, with four of the issues consisting of four or five commissioned review papers on a particular topic, and the other two papers submitted and refereed in the usual way. Each issue also contains an editorial either by one of the editors (B.S. Everitt and T. Holford) or by a guest editor, most often chosen from the 25 or so members of the editorial board, and a number of book reviews.

Some recent issues of the journal have dealt with

1. Multi-state models
2. Nonparametric longitudinal data analysis
3. Ethics, Statistics and Statisticians

The content of the issue on Ethics was as follows:

1. On the ethical aspects of the testimony of statisticians in court, E.A. Gehan.
2. The ethics of consulting for the tobacco industry, D.R. Rubin.
3. Ethics, data-dependent designs, and the strategy of clinical trials: time to start learning as we go? C.R. Palmer.
4. Ethical considerations concerning treatment allocation in drug development trials, S. Senn.
5. Placebos that harm: sham surgery controls in clinical trials, A.J. London and J.B. Kadane.
6. Ethical issues in oncology biostatistics, P.F. Thall.

The journal is published by Edward Arnold, London.

BRIAN S. EVERITT

Statistical Review for Medical Journals, Guidelines for Authors

In 1978, a panel of statisticians, practicing physicians, and medical editors convened at a statistical conference and concluded that medical articles often contained incomplete reporting of statistical results and methods, and that this problem was associated with the use of faulty statistical designs and analyses in published medical studies [11]. The panelists recognized the need for complete statistical reporting, to make medical studies both interpretable and convincing, and the role of medical journals in enforcing good statistical practice and reporting. The panel proposed the development of standards governing the format and content of reports of statistical methods and results in medical articles.

In 1980, Mosteller et al. [10] reviewed the original reports of 147 cancer trials cited in a comprehensive clinical anthology, and they found that important statistical issues, in particular the statistical methods used, were reported only 25% of the time, with statistical **power** and intended sample size (*see* **Sample Size Determination**) almost never reported. DerSimonian et al. [5] reviewed the reports of a chronological sample of 67 **clinical trials** appearing in four leading British and American medical journals, in 1979 and 1980, and found that patient eligibility (*see* **Eligibility and Exclusion Criteria**), method of **randomization**, loss to follow-up, statistical methods, and statistical power were reported ambiguously, or not at all, on average 44% of the time. Other surveys focused on individual issues. Schulz et al. [13] found that ambiguous reporting of the method of concealment of the treatment allocation (*see* **Blinding or Masking**) was associated with larger estimates of treatment effect, suggesting that inadequate methods might lurk behind inadequate reporting. Pocock et al. [12] found poor reporting of prioritization of **multiple endpoints** and statistical comparisons, of whether subgroup analyses or strategies for multiple testing over time were pre-defined (*see* **Multiple Comparisons**), and of whether sample size and interim stopping rules (*see* **Sequential Analysis**) were defined prior to the start of the study (*see* **Treatment-covariate Interaction**). They indicated that, without such provisions, multiple testing leads to serious problems of interpretation, since the nominal significance levels no longer reflect the true significance levels. For repeated interim monitoring, in particular, this was dramatically demonstrated by the simulations of Green & Fleming [7]. Moher et al. [9], in a comprehensive review of the negative trials published in three leading British and American medical journals in 1975, 1980, 1985, and 1990, found that the majority failed to report an intended sample size. A related finding was that 64% of the trials failed to have at least 80% power to detect a 50% relative improvement. Finally, George [6], in a survey of 98 medical journals (with 83 respondents), found only 16% to have a policy guaranteeing statistical review.

There have been a series of efforts by statisticians and clinicians to address the above issues. Altman et al. [1] published a detailed and comprehensive set of statistical guidelines for medical journals. Bailar & Mosteller [3], expanding on the concise guidelines adopted by the International Committee of Medical Journal Editors [8], produced a similarly comprehensive set. Zelen [17] and Simon & Wittes [14] focused their detailed guidelines on the particular issues of clinical trial reporting, as did Baar & Tannock [2] in the annotations of their whimsical twin examples of a well executed trial report and a poorly executed one. Recently, a working group of statisticians and clinicians [4], made up of representatives of two previous such groups [15, 16], issued the "CONSORT Statement", a proposal for the structured reporting of clinical trials, following a detailed list of statistical guidelines.

The following is a melding of the above sets of guidelines, structured according to and closely following the CONSORT proposal, but expanded to include additional stipulations made by the other authors. It is not meant to be either definitive or all-inclusive. Each statement is referenced to allow the reader to refer to the original sources for further explanation.

Structured Statistical Guidelines for Medical Journals

Introduction

State prospectively defined hypotheses and planned subgroup or **covariate** analyses [1, 4].

Methods: Protocol Design

Describe the planned study population, together with inclusion/exclusion criteria [1–4, 14, 17].

Give the primary and secondary **outcome measure(s)** and the minimum important difference(s), and indicate how the target sample size was projected [2, 4, 14].

Describe the rationale and methods for statistical analyses, giving the main comparative analyses and whether they were completed on an **intention-to-treat** basis, with enough detail to permit replication [1, 3, 4, 14]. Give assumptions concerning the distribution of the variables which underly the statistical methods used [1]. For randomized studies, an intent-to-treat comparison should be included for major endpoints [14].

Give the prospectively defined stopping rules [4, 14, 17].

For observational studies, explain the design, describing the selection of **controls** and the **matching** procedures, whether the study is **case–control**, **cross-sectional**, or **cohort**, and what was the participation rate [1].

Methods: Treatment Assignment

Give the unit of randomization (e.g. individual, cluster, or geographic) (*see* **Unit of Analysis**) [3, 4].

Describe the method used to generate the allocation schedule (*see* **Randomization**; **Randomized Treatment Assignment**) [1, 3, 4, 17].

Describe the method of allocation concealment and the timing of assignment [4, 17].

Give the number of eligible patients not entered or not randomized, and the reasons [2, 4, 17].

Methods: Treatment Blinding

Describe the mechanism of treatment blinding, if used, and the evidence for successful blinding of subjects and investigators, as appropriate [1, 3, 4].

Methods: Quality Control

Briefly describe the methods used to ensure that the data are complete and accurate, that all patients entered on study are reported, and that the assessment of major endpoints is reliable [14, 17]. The study should not have an inevaluability rate for major endpoints in excess of 15% [14] (*see* **Missing Data in Clinical Trials**).

Results: Follow-up Schedule and Loss to Follow-up

For each randomized group, give the timing of follow-up and the number of patients withdrawn or lost to follow-up [3, 4, 14, 17]. Not more than 15% of eligible patients should be lost to follow-up [14].

Results: Analysis

State the estimated effect of treatment on primary and secondary outcome measures, including the point estimate (*see* **Estimation**) and **confidence interval** [1, 3, 4, 14]. Give precise ***P* values**, but not to more than two or three decimal places [1, 3].

Claims of therapeutic efficacy should be based upon comparisons with a control group, except in special circumstances, such as when each patient is his own control [14]. Where historical controls are used, patient characteristics should be compared in detail with those of the experimental group, and potential sources of **bias** should be discussed [14, 17]. Comparison of survival between responders and nonresponders can not be used to establish efficacy [2, 14].

Significance tests not relating to pre-specified hypotheses must be considered exploratory [1] (*see* **Hypothesis Testing**). Claims of subset-specific treatment differences must be documented to be based on more than the random results of multiple-subset analyses [14].

Present summary data and appropriate descriptive and inferential statistics (*see* **Inference**) in sufficient detail to permit alternative analyses and replication [1, 14, 17].

Cite statistical software packages used [1, 3] (*see* **Software, Biostatistical**).

Do not use technical statistical terms, such as significance and **correlation**, in a general fashion [1, 3].

Describe **prognostic factors**, by treatment group, and any attempt to adjust for them [1, 4, 17].

Describe protocol deviations (*see* **Clinical Trials Protocols**), including the number of randomized patients subsequently found ineligible or not treated as assigned, together with the reasons [1, 4, 14]. In general, observations that appear to be inconsistent with the main body of data should not be excluded unless there are additional reasons to doubt

their credibility, and any such exclusion should be reported [1].

Comment

State specific interpretation of study findings, including sources of **bias** and imprecision [4].

State general interpretation of the data in light of the totality of the available evidence [4].

LAWRENCE V. RUBINSTEIN

Statistical Review for Medical Journals, Journal's Perspective

Recently I met a woman doctor who had just read the medical journal I edit – the *British Medical Journal* (*BMJ*) – for the first time in 25 years. "It doesn't have any medicine in it any more. It's full of statistics," she complained. To begin an article in a biostatistical encyclopedia with a study that has a sample of one may seem ingenuous in the extreme, but such Rip van Winkle characters are rare: most doctors who stopped reading medical journals 20 years ago have never started again. And I am fascinated that her first observation should be the predominance of statistics. It could have been the appearance of molecular biology or references to computers or the increase in sociological, economic, and political material. Perhaps the biggest change in medical journals in the past 25 years has been the dramatic increase in the amount of statistical material they contain.

Medical journals of 25 years ago did, of course, contain some statistics. **Austin Bradford Hill** published a ground-breaking series of articles on statistics in the *Lancet* in 1937, [14]. Hugh Clegg, the editor of the *BMJ* from 1947 to 1965, was a personal friend of Bradford Hill and was persuaded by him of the importance of statistics for medicine and medical journals. The *BMJ* carried one of the first randomized controlled trials (*see* **Clinical Trials, Overview**) in 1948 (*see* **Medical Research Council Streptomycin Trial**), and in 1976 the journal published a book on elementary statistics written not by a statistician but by the deputy editor, Dougal Swinscow [18]. The book, *Statistics at Square One*, has remained in print ever since and sold almost 100 000 copies – three times as many copies as any other book published by the *BMJ* Publishing Group. Many other journals have also published educational articles on statistics, and the *BMJ* has published further books.

But a survey of all papers published during 1978–79 in the *New England Journal of Medicine (NEJM)*, the world's leading general medical journal, showed that 58% included no statistical method or descriptive statistics only [8]. Three-quarters of the original papers did, however, include statistical methods. By 1990 this proportion had increased to 89%, and there was a marked increase in the use of more advanced methods of analysis [3]. Generally, medical journals have moved away from the case reports and accounts of series of patients (*see* **Case Series, Case Reports**) that were once their staple fare to experimental studies, particularly randomized controlled trials, and epidemiologic studies that use increasingly complex statistical methods. Medical journals have, however, moved at different rates. The leading general medical journals – the *Annals of Internal Medicine, BMJ, Journal of the American Medical Association (JAMA), Lancet*, and *NEJM* – increased the proportion of papers that depended on statistical analysis much more rapidly than specialist medical journals.

The appearance of statistical methods in medical journals was quickly followed by a realization that the methods were commonly misused. A great many studies have now shown that basic statistical errors – in design, analysis, and presentation – are common in medical journals [3]. A particular problem has been many studies too small to reach a confident conclusion of the absence of an effect. Many of the statistical errors found in medical papers were so serious that the conclusions of the papers were not supported by the evidence they contained (*see* **Statistical Review for Medical Journals**).

The Story of Statisticians Moving to the Heart of the *BMJ*

The appearance of studies on poor statistics in medical journals led editors, most of whom had little or no training in statistics, to recognize that they needed help. From the late 1970s medical journals began to recruit statistical advisers, although there are still many medical journals that have no regular statistical advice. I arrived at the *BMJ* in May 1979, and I have lived through the incorporation of medical statisticians into the heart of the editorial process. I want to describe the path taken by the *BMJ* – partly because I know it so well, and partly because it is, I know, very similar to the path taken by most medical journals and still being followed by many.

We began in the 1970s by recruiting a statistical adviser, the late **Martin Gardner**. He assembled a small group of statisticians who agreed to review *BMJ* papers. We thought it essential from the beginning to work with statisticians who had practical experience of medical research. We were having to

learn each other's way of thinking, and we worried that the gulf between medical editors and statisticians with no knowledge of medical research would be unbridgeable. In the early days we made the mistake of thinking that statistics was a much more exact science than clinical research and that we had to go along with exactly what the statisticians advised. Eventually we learnt that there was room for negotiation over what was acceptable. We, as editors, always did – and still do – feel vulnerable when caught in the middle of statisticians arguing with each other.

In the early days we sent our statistical advisers only those papers where we were worried about the statistics. This usually meant that we sent papers that had complex statistics, but we gradually learnt that some of the most egregious errors occurred in papers that used only simple statistical tests. There might be errors in design, sampling, and data collection. We sent only some papers because the statisticians were seen as a limited resource. But slowly over 5–10 years we moved to the point that all research papers with any statistical content at all, which is virtually all of them, were sent for a statistical opinion before publication. Statisticians are, however, usually involved towards the end of our peer review process. We reject 85% of papers (a figure that is roughly the same for the main general journals), and about 60% are rejected without ever having had a statistical opinion. Letters – which in the case of the *BMJ* are all in response to material already published in the journal – are still published without a routine statistical opinion, although we ask for one if we are worried.

A very important step for us was when we began to involve statisticians in our "hanging committee" – the committee of two editors and two outside doctors that takes the final decision on whether to publish research papers. This committee meets every week, and from the mid-1980s we began to include a statistician on some occasions and from the early 1990s on every occasion. The beauty of this arrangement is that it means that the editors, doctors, and statistician can discuss all aspects of a paper together – recognizing the inevitable trade-offs between statistical purity, what can actually be done in clinical research, and what matters to doctors treating patients. My experience is that being able to discuss a paper with a statistician is much preferable to simply having a written report. This is particularly because peer review is in my mind more about improving the papers we do publish than simply deciding which to publish. Another advantage of being able to discuss papers is that it is highly educational for those attending: we learn from each other in a way that is not possible if everything is done on paper. After moving to a system of having a statistician present at every meeting, none of the editorial team could imagine moving back to a system where they were not present.

Statistical Policies

One of the first jobs of our statistical advisers was to develop published advice to authors on statistics and to produce checklists that could be used when assessing papers. They also advised us on statistical policy. In 1983 we published "for debate" comprehensive guidelines on statistical aspects of manuscripts [5]; these were soon recommended in our Instructions to Authors (*see* **Statistical Review for Medical Journals, Guidelines for Authors**). In 1986 we published checklists used by statistical referees [12] and began to require **confidence intervals** whenever appropriate (see [11]). From the early 1990s we have not published controlled trials in which patients are allocated to different interventions in any way other than randomly (unless an acceptable argument is given on why random allocation was not possible; *see* **Randomized Treatment Assignment**) [2]. Currently we are moving towards policies on publishing **absolute risks** as well as **relative risks** and including the "**number needed to treat**" in appropriate studies. A debate is beginning on including much more **Bayesian** statistics in medical journals [10]. And medical journals have also become increasingly interested in **meta-analyses** and publish more and more [7].

Standards Across Journals

The result of these moves is that statisticians have become central to the peer review process of the *BMJ*. The same is true of other leading journals, but not of all journals. George [13] and Altman [1] have produced recommendations on the statistical aspects of medical journals:

1. All papers should be reviewed by a statistician prior to publication (perhaps only after a favorable subject-matter review).

2. Journals should recruit statistical reviewers.
3. The statistical reviewers should at least be offered the option to see the revised manuscript.
4. Journals should publish their policy on statistical review.
5. Journals should adopt written standards or guidelines for statistical reporting (usually previously published guidelines).

Altman observed some years ago that few journals meet more than two of these five recommendations [3], but my impression is that more and more are moving towards fulfilling all five. I sit on the editorial boards of the 25 specialist journals of the *BMJ* Publishing Group, and most are beginning to follow all five recommendations.

Another important move is that statisticians who advise different journals are coming together to produce advice that will be useful to all medical researchers and journals. A good example is the CONSORT proposals on how to present randomized controlled trials, [6]. These have already been adopted by more than 20 journals and will certainly be accepted by many more. Statisticians have also persuaded the International Committee of Medical Journal Editors to produce general guidelines on the use of statistics in medical journals [15].

All this activity should be raising the quality of statistics in medical journals, but there is so far little hard evidence that this is the case. I think that we urgently need to study whether the standard of statistics has improved.

Statisticians: A Fundamental Influence on Medicine

The influence of statisticians on medical journals – and medicine – has, I believe, been fundamental, and we are only just becoming aware of their full impact. Medicine is currently experiencing an intense debate over the need to move towards **evidence-based medicine** [17], and statisticians have been key in this debate [4]. Evidence-based medicine is a movement that encourages doctors to base their practice on the best evidence available. All doctors know that much medical practice is based on opinion and experience rather than on scientifically sound evidence, but they also recognize that good scientific evidence is not available on whether much of medical practice is effective. Those who are encouraging the move to evidence-based medicine are trying to work out what doctors know and what they do not know; promote research into what is not known; extract from medical journals the small proportion of studies that are scientifically sound and disseminate them; produce evidence-based guides to practice; and interest practitioners in critically appraising the evidence presented to them. All of this activity is based on statistical ideas of what constitutes good evidence. This movement will, many predict, transform medical practice.

Another important area where statisticians have had a great influence is in identifying and managing the problem of scientific fraud. Editors of medical journals – and other scientific journals – are learning that some of the papers submitted to them are fraudulent [16]. Researchers may have invented data, stolen them, or manipulated them in dishonest ways. Peer review does not easily detect fraud, but statisticians are able to help. Some statisticians, for instance, have developed tests that will help identify "the fingerprint" of invented data [9].

Statisticians have also raised consciousness of more minor scientific dishonesty. Since doctors have had access to computer programs to help them analyze data they have learnt that they can "torture the data until they confess". For instance, if doctors do not find a significant difference between placebo and a treatment in a randomized controlled trial they may keep doing subgroup analyses until they find a significant difference. Statisticians have taught us that we must declare the hypotheses we are going to test in advance, and the *post hoc* analyses are suspect. There are many other similar concerns.

My conclusion has to be that statisticians have become central to medical journals and to medical practice. There is still much room to raise statistical standards in medical journals, but statisticians have done more than simply improve statistical design, analysis, and presentation in medical journals. They have played an important part in what is looking increasingly like a paradigm shift in medicine – from opinion to evidence-based medicine.

RICHARD SMITH

Statistical Review for Medical Journals

The statistical content of medical and epidemiologic journals has undergone a radical transformation over the past 25 years. As recently as the 1960s, articles in the major medical [13] and epidemiology [14] journals employed only the most rudimentary statistical methods. Most papers reported only **means** and **standard deviations**, while an author would occasionally use simple **linear regression**. By the end of the 1980s, however, the statistical content of articles published in the leading journals had changed dramatically. Emerson & Colditz [6] found that, of 115 Original Articles published in the *New England Journal of Medicine* in 1989, 33% employed one or more advanced statistical methods. An equally dramatic shift occurred in the design and size of studies [14]. While most studies published in the 1960s were laboratory investigations or small observational studies, often uncontrolled, the majority of today's investigations of human populations are of two major types, controlled epidemiologic studies with explicit and carefully crafted designs (*see* **Analytic Epidemiology**) and randomized **clinical trials**.

In response to this shift in the statistical and epidemiologic character of submissions, many clinical and epidemiologic journals have increased the intensity of their statistical reviews. For more than a decade, *The New England Journal of Medicine* has retained a team of statistical consultants who attend weekly editorial meetings and review every potential publication with statistical or epidemiologic content. *The Journal of the National Cancer Institute* has a total of 20 statistical editors! All articles with statistical content receive statistical review. Other leading medical journals have made similar arrangements.

The move toward increased emphasis on statistical review has been stimulated in part by periodic controversies about the design or analysis of studies that subsequently play an important role in drug approval (*see* **Drug Approval and Regulation**) (for one example, see Groothuis et al. [7], McIntosh [11], or Ellenberg et al. [5]) or national biomedical policy (for one example, see Berkel et al. [1] and Bryant & Brasher [2]). Although no review process can be completely successful in identifying weaknesses in the design, conduct, or analysis of scientific studies, the increasing intensity of statistical review has improved the quality and clarity of presentation of statistical methods employed in articles published in major medical journals. This article discusses the role of the statistical reviewer and reflects on the boundaries and limitations of statistical review.

The nature and complexity of a statistical review depends to a great degree on the design of the study under review. Review of randomized clinical trials is often straightforward because the methodologic paradigm is both well established and achievable. Review of epidemiologic studies can be more challenging for statisticians, because such reviews frequently require a deeper understanding of the biological question and its implications for design and analysis. We discuss some of the issues in each type of review in subsequent paragraphs, then conclude by mentioning some study designs and methods of analysis that are growing in importance and which present new challenges to the reviewer.

Randomized Clinical Trials

Statistical review of randomized clinical trials is often straightforward, at least when the responsibilities of a statistical reviewer are interpreted narrowly, because the standards for design and analysis of clinical trials are so clear. DerSimonian et al. [3] identified 11 aspects of the design and analysis of clinical trials that they considered important to assessing the quality of a study. They were:

1. **eligibility criteria**;
2. admission decision preceding treatment assignment;
3. random allocation to treatment;
4. the method of **randomization**;
5. patients' blindness to treatment (*see* **Blinding or Masking**);
6. blinded assessment of outcome;
7. information about treatment complications;
8. loss to follow-up data;
9. quality of statistical analysis;
10. complete description of statistical methods;
11. **power**.

Criteria for selection of patients bear primarily on the generalizability of the study. Consistent application of those criteria, however, including evidence

that all patients seen during a specified time period were screened for eligibility, insures that the study sample reflects the stated criteria, thus providing a firm basis for generalization (*see* **Validity and Generalizability in Epidemiologic Studies**).

Procedures for randomizing patients are now well standardized (*see* **Randomized Treatment Assignment**). The sequence of treatment assignments should be derived from computer-based randomization, and no aspect of the assignment procedure should enable investigators to anticipate assignments before they are revealed. These assignments should be revealed only after the decision to enroll a patient has been made. Problems associated with randomization usually result from failures of implementation rather than failures of design. There have been a number of well-publicized examples of breaches of procedure by study personnel who had access to envelopes or other insufficiently secured information about treatment assignments.

Randomization is not always ethical or feasible. In studies of, for example, survival after lung or heart transplantation, the high level of risk and ethos surrounding care of the transplant candidate have prevented consideration of randomized trials. In those settings, the reviewer must judge whether unblinding of patients or study personnel could have introduced **bias** into the comparison of treatment groups. This assessment depends in part on the degree to which the endpoints are objective (*see* **Outcome Measures in Clinical Trials**).

In the ideal trial, patients, caregivers, and evaluators are blind to treatment assignment. Knowledge of treatment assignments should be concealed from all three groups to the maximal extent feasible and ethically defensible (*see* **Ethics of Randomized Trials**). Again, in the ideal design, every patient should be followed throughout the trial and measured on every scheduled occasion. This ideal is never met in clinical research. Losses to follow-up are an unavoidable part of clinical trials involving extended follow-up. The statistical reviewer should be aware that loss to follow-up threatens the integrity of a randomized trial, and that no statistical method for analysis of incomplete data can protect against bias if losses to follow-up are informative [10]. Thus, the reviewer must judge whether (i) the investigators have achieved the best possible follow-up rate in the particular study setting, and (ii) whether the extent and nature of **missing data** have the potential to produce bias in treatment group comparisons comparable in magnitude to the treatment effects under investigation.

The statistical methods used by authors of reports of clinical trials are usually sound in their fundamentals, both because the design suggests the appropriate comparisons and because trialists tend to be experienced investigators. It is common, however, for statistical reviewers to find problems of emphasis or selection. Investigators may, for example, emphasize results in a subgroup (*see* **Treatment-covariate Interaction**) or for an endpoint that was not identified a priori as the primary hypothesis without appropriate statistical adjustment in the analysis. Simon [12] discuss statistical methods for analysis of subsets in clinical trials.

Given the importance of the distinction between a priori and a posteriori hypotheses in the interpretation of randomized trials, as well as the frequent difficulty of evaluating statistical methods from the brief synopses provided in typical submissions to medical journals, it would be helpful for statistical reviewers to receive copies of the statistical methods sections of study protocols, yet this is rarely done on a routine basis. When the study employed a less commonly used design, such as repeated measures, the reviewer must be more vigilant about the validity of the analytic approach.

Serious deficiencies of design or analysis of clinical trials are not always apparent from the manuscript submitted for review. Review of primary data has sometimes uncovered problems or discrepancies in study results that would not be detectable from a careful review of the scientific article. The risk of hidden deficiencies is unavoidable, because it will not be possible for reviewers to examine the details of every study submitted for publication. The statistical reviewer can address this concern to some degree by asking probing questions of the authors that require more detailed discussion of study procedures.

One challenging aspect of statistical review for this writer has been the judgment about whether a small, preliminary clinical trial is worthy of publication. This judgment can depend not only on the size of a trial and the strength of its evidence, but also on the degree to which the therapeutic strategy is innovative, and upon the urgency of the public health problem it addresses. When one has difficulty

making that judgment in an area in which one is not fully acquainted with the state of the field, it can be helpful to acknowledge the issue and provide clear information to the editor about the strength of the study.

Epidemiologic Studies

Epidemiologic studies are intrinsically more challenging than randomized trials for most statistical reviewers, because interpretation of an epidemiologic study often requires a high level of understanding of the scientific issues. One helpful concept is the assertion that epidemiologic studies should be conducted according to scientific principles governing the design and conduct of randomized trials in every respect save the use of randomization for assignment of treatments. Thus, epidemiologic studies should be based on a written scientific protocol, hypotheses should be stated a priori, subjects should be completely enumerated, losses to follow-up should be minimized, and so on. Several individuals and groups have prepared guidelines for the design, conduct, or evaluation of epidemiologic studies.

Even when this principle is honored, however, **observational studies** have pitfalls. Both patient selection and control of potential **confounders** are important issues in most epidemiologic studies. Statistical reviewers for medical journals must be conversant with the criteria for evaluation of such designs. Most contemporary epidemiologic studies employ either the **cohort** or **case–control** design, and thus include concurrent **controls**. The evaluation of such studies, especially case–control studies, requires special expertise and understanding of the issues involved in selection of controls, measurement of confounders, and the implications of **matching** (*see* **Bias in Case–Control Studies**; **Bias in Cohort Studies**; **Bias in Observational Studies**).

The parallels in data analysis between epidemiologic studies and randomized trials are much closer than those in design. Statistical reviewers should be knowledgeable about statistical methods for the analysis of cohort and case–control studies, including the effects of matching (*see* **Matched Analysis**) and **stratification** on the analysis. In practice, epidemiologic studies are less likely than randomized trials to follow a written protocol that specifies the primary and secondary study hypotheses. Thus, the reviewer should attend to whether the endpoints and hypotheses emphasized in the report are the natural primary questions that motivated the study.

New Challenges to Statistical Reviewers

The use of multivariate methods in biomedical research has developed sporadically (*see* **Multivariate Analysis, Overview**). **Logistic regression** analysis emerged as an important analytic tool in the 1960s, multivariate survival analysis was popularized in the 1970s, and methods for the analysis of longitudinal and clustered data (*see* **Cluster Analysis, Variables**) became increasingly important in the 1980s. In part, this reflected the maturation of research on chronic diseases. While early studies focused on survival and severe morbidity, more recent studies have focused on changes in **quality of life** over time and in the development of risk factors for chronic disease. Both of these questions require study designs that employ repeated measures. Unfortunately, there is at present no easy introduction to the principles of **longitudinal data analysis**. The landmark book by Diggle et al. [4] is comprehensive but challenging. A recent SAS publication on mixed effects models [9] provides some helpful illustrations of the use of mixed linear and **nonlinear** models for analysis of repeated measures.

Perhaps the 1990s will be remembered for the growing importance of investigations based on genetic and molecular data. Some studies can be classified as examples of either **molecular epidemiology** or **population genetics**. In a molecular epidemiology study, a classifiable genetic trait of an individual is used as either a risk factor or an **effect-modifier** for a disease outcome. Although such studies require sophisticated molecular methods for patient characterization, the principles of study design and data analysis are identical to those encountered in epidemiologic studies using other types of risk factors. Thus, they present no fundamentally new challenges to the statistical reviewer.

The same cannot be said of studies involving **linkage analysis**, **segregation analysis**, and investigation of **polygenic inheritance** of disease. Such studies require new study designs [8] and new methods for quantifying relationships at the molecular level. Statisticians wishing to be broadly knowledgeable about statistical issues in biomedical research should master these ideas.

Statisticians in the Pharmaceutical Industry (PSI)

PSI (Statisticians in the Pharmaceutical Industry Limited) is a nonprofit organization, which converted to a limited company early in 2003. Though primarily UK-based, currently around 20% of PSI members reside outside of the United Kingdom, and further members from all over the world are welcomed. PSI is open to all people interested in the application of statistics in the **pharmaceutical industry**. Its major objectives are:

1. To promote professional standards in the application of statistics in matters pertinent to the pharmaceutical industry
2. To provide a forum for regular discussion on statistics and matters relating to the practice of statistics in the pharmaceutical industry
3. To influence regulatory direction and scientific methodologies that are applied to drug development
4. To contribute to the development of statistics as a profession.

PSI was founded in 1977 with around 50 members. The organization has grown rapidly, with the development of the role of statistics in the highly regulated pharmaceutical industry (*see* **Drug Approval and Regulation**) and now has over 1000 members. The majority of members are statisticians and statistical programmers working within sponsor pharmaceutical and biotechnology companies or Contract Research Organizations (*see* **Proprietary Biostatistical Firms**), in all areas of the drug development process, including research, **preclinical** and clinical development (*see* **Clinical Trials, Overview**), production, **quality control**, marketing, and market research. Further members include independent statisticians and statistical programmers, academic statisticians, teachers, students and nonstatisticians from within the industry.

PSI arranges regular scientific meetings, with a view to creating an environment where members have the opportunity to exchange scientific information. A three-day conference and a number of one-day scientific meetings are held each year. In addition, special interest groups (SIGs) communicate regularly on topics of particular interest (e.g. the Statistical Computing SIG often runs half-day meetings on topics of current interest). From time to time, working parties are established to investigate particular statistical issues, and members are actively encouraged to participate. One such group is the Clinical Research Computer Systems Validation Working Party (jointly sponsored by PSI and the Association of Clinical Data Management, ACDM), which has recently published the second edition of the "Computerised Systems Validation in Clinical Research" Guideline. The guideline can be purchased via the ACDM website (see `http://www.acdm.org.uk`).

PSI runs a program of training courses, with the aim of bringing members up-to-date in a particular area without having to commit to a lengthy period away from the office or to extensive follow-up reading. An "Introduction to Industry" course is run each year for new entrants to the pharmaceutical industry, as well as three or four short courses on statistical topics, each usually lasting two to three days (*see* **Teaching Medical Statistics to Statisticians**).

Contact is maintained with academic statistical groups and professional organizations (such as the **Royal Statistical Society**, (RSS)), as well as other pharmaceutical bodies (such as the Pharmaceutical Research and Manufacturers of America, PhRMA), thereby promoting the public image of PSI, both within and outside the pharmaceutical industry. Together with other European statistical organizations, PSI is a member of the **European Federation of Statisticians in the Pharmaceutical Industry (EFSPI)**, in which capacity PSI monitors and responds to appropriate regulatory statistical issues within the pharmaceutical industry. PSI organizes occasional workshops to discuss important regulatory issues, and invites an expert statistical group to provide comments on draft regulatory documents. Feedback from members is coordinated in conjunction with the Association of the British Pharmaceutical Industry (ABPI) and EFSPI to ensure appropriate input to regulatory authorities and industry organizations.

In 2002, PSI launched the statistical journal, *Pharmaceutical Statistics*, in conjunction with the publishers John Wiley and Sons (`http://www3.interscience.wiley.com/cgi-bin/jhome/93012805`). This international journal, sponsored by PSI, is issued electronically on a quarterly basis to

all PSI members as part of their annual PSI subscription. The journal aims to disseminate information and practical examples of the use of statistics in all stages of drug development, from discovery to production. Also, in 2002, PSI redesigned its website (`http://www.psiweb.org`) to include a resource center, membership discussion forums, and job/service advertisements in addition to electronic journal access. PSI continues to publish a quarterly newsletter, *SPIN*, to keep its members informed about PSI activities and other relevant events.

PSI promotes careers within the industry by publishing careers material and arranging a program of talks for universities. More recently, PSI has collaborated with the RSS and other organizations in attempts to nurture statistical interest in schools. A Grants Fund is available to subsidize student attendance at relevant PSI scientific meetings.

PSI employs a professional executive secretary in order to ensure efficient administration. For further information please contact: PSI Executive Office, Resources for Business, Association House, South Park Road, Macclesfield, Cheshire SK11 6SH, UK. Tel: +44 (0) 1625 267882; Fax: +44 (0) 1625 267879; e-mail: admin@psiweb.org.

DAVID MORGAN & KERRY GORDON

Statistics in Medicine

Statistics in Medicine is among the leading journals of medical statistics and epidemiology. It publishes papers on the practical applications of statistics and other quantitative methods to medicine and its allied sciences. It embraces all aspects of the collection, analysis, presentation, and interpretation of medical data, including areas such as **clinical trials**, diagnostic studies, quality control, laboratory experiments, epidemiology, and **health services research**.

The journal emphasizes the relevance of statistical techniques and aims to communicate statistical and quantitative ideas in a medical context. Examples of applications of statistics to specific projects, articles explaining new statistical methods, and reviews of general topics are published.

The ultimate goal of *Statistics in Medicine* is to enhance communication between statisticians, clinicians, and medical researchers with the common purpose of advancing knowledge and understanding of quantitative aspects of medicine. It is intended that both the readers and authors of the journal include statisticians, clinicians, epidemiologists, health researchers, mathematicians, and computer scientists interested in medicine.

Statistics in Medicine was launched as a quarterly journal in 1982, under the editorship of T. Colton (Boston), and L. Freedman and A. Johnson (Cambridge); the first volume included 40 papers in 380 pages. It progressed to six issues in 1986 with 64 papers in 678 pages; to eight in 1987, and to 12 in 1988, when L. Freedman emigrated to Bethesda, and the original editors were joined by D. Machin (Cambridge). Further expansion to 16 issues occurred in 1992, and, ultimately, to 24 in 1993; in 2003, the journal published 83 papers in 3914 pages. L. Freedman retired as an editor in 1993, an occasion marked by an account of the foundation and early development of the journal (**13**(1), 1–2 (1994)). He was succeeded by R. D'Agostino (Boston) Deputy editors R. Glynn (Boston) and J. Greenhouse (Pittsburgh) were appointed in the US at the beginning of 1995, and C. Palmer and S. Stenning (Cambridge) in the UK in September 1996. Tony Johnson stepped down in June 1999. The journal has an editorial board of over 70 eminent statisticians and epidemiologists in many centers of excellence throughout the world.

In addition to papers that are peer reviewed by the editorial board and other advisory referees, the journal welcomes letters commenting on published papers, as well as those embracing more general issues. It also includes reviews of books and reports of general interest to medical statisticians under the guidance of the book reviews editor [P. Macaskill, Sydney) The position of deputy editor was abolished at the end of 2001 when four editors-in-chief (D'Agostino, Greenhouse, Machin and Campbell) were appointed. Machin retired at the end of 2002, to be succeeded by J. Matthews (New castle). In 1995, the journal launched two further topical features: first, a series of expository articles on the application of specific biostatistical techniques, including those introduced comparatively recently, under the title of Biostatistical Tutorials, with R. D'Agostino (Boston) as editor; and, secondly, a series of occasional articles under the title Statistics in the Medical Literature formerly the editorship of D. Altman (Oxford) and now S. Evans (London) drawing attention to specific publications dealing with some aspect of biostatistics or epidemiology, and published in the biomedical literature.

Apart from the regular papers submitted to the journal, a major feature is the publication of special issues, many under the directorship of invited guest editors. Four of these have honored eminent colleagues whose work has been of fundamental importance in the foundation and development of medical statistics. **Sir Austin Bradford Hill** (**1**(4), October 1982), P. Armitage (**9**(6), June 1990), D. Newell (**14**(2), January 1995) and **Sam Greenhouse** (22(21) November 2003). Several more have been devoted to workshops on statistical methodology organized by the **National Institutes of Health**, **Centers for Disease Control**, Johns Hopkins University, United Kingdom Coordinating Committee on Cancer Research, and others. It also publishes the proceeding of the annual conference of the International Society for Clinical Biostatistics.

In 1991, a decade of publication was celebrated by a special anniversary issue which included overviews of advances over the previous ten years in clinical trials, epidemiology, diagnosis and **quality of life**, and a competition for younger medical statisticians in the US (**10**(12), December 1991).

The journal is published by John Wiley in Chichester, UK, and operates from one editorial office at Boston University School of Public Health, 80

East Concord Street, Boston, Massachusetts 02118, USA (editorial assistant, S. Thompson), since January 2004 the journal runs under an electronic system `www.sim-wiley.manuscriptcentral.com` from which submission details are available. Most papers are peer reviewed, usually by two expert referees.

THEODORE COLTON, ANTHONY L. JOHNSON &
DAVID MACHIN

Statistics, Overview

This article is an inevitably personal view of the general position of statistical science, as seen in the mid-1990s, a period of rapid development. Even within medical statistics the range of applications is great, and in statistics more broadly the variety is even more extreme, making sweeping statements about the relative importance of, for example, different techniques and different approaches difficult to substantiate in any generality.

The term *statistical science* is sometimes used for statistical theory and its applications to the natural and social sciences and to science-based technology and this roughly corresponds to the scope of the present article.

The interlinked pillars of statistics as a field of study are

1. The mathematics of probability.
2. The general principles for the design, analysis and interpretation of investigations. Formal principles of statistical **inference** are a part, but only a part, of this.

It may be tempting to add a third pillar, which gave the subject its name, namely the collection and study of economic and social statistics for government, so-called official statistics, and the closely related issues concerning large enterprises. While this aspect of the subject has indeed developed rather separately over many years, at some level the general principles seem unlikely to be different from those involved with applications to science and science-based technology. For medical statisticians official statistics connected with health have always been important (*see* **Vital Statistics, Overview**), and if the term biostatistics is interpreted more widely to include, for example, agricultural statistics, then there are other links with official statistics.

Probability

The first part of the article thus concerns the mathematics of probability; that is, issues concerned with the meaning and philosophy of probability are excluded.

Historically and, often but not always, in introductory teaching, probability starts from combinatorial problems, i.e. from the counting of the proportion of "favorable" cases in the enumeration of a set of possibilities assumed equally likely a priori. Modern **probability theory** has blossomed from that into a rich chapter of modern mathematics with links to other areas of pure mathematics. Some of the modern developments are, at the moment, fairly remote from statistical applications although study at a relatively advanced level is required:

1. To derive and underpin various statistical methods. Instances where mathematically elaborate methods have been deployed include the use of martingale theory in connection with survival data [1] (*see* **Counting Process Methods in Survival Analysis**) and more generally the rigorous derivation of limiting results in semiparametric inference (*see* **Semiparametric Regression**).
2. To derive special stochastic models for phenomena, usually systems developing in time (*see* **Stochastic Processes**; **Epidemic Models, Stochastic**).

We deal here with the second of these.

Stochastic models supply an important route for developing mathematical models of systems involving a nontrivial random element, both for the insight that the models themselves can supply and as a basis for introducing a substantive base into the interpretation of empirical data.

Among the fields in which such work has a solid history combined with much current activity are

1. Epidemic theory, again with a long history, with developments up to 1970 summarized by Bailey [4], and with major recent developments [26] stemming largely but not entirely from the study of **AIDS** [10, 2]. For an application to **BSE** (bovine spongiform encephalopathy), see [3].
2. The study of congestion and more broadly in **operational research**, dating back to the work of A.K. Erlang at the Copenhagen Telephone Company and congestion theory being stimulated nowadays by the study of complex networks.
3. Finance theory.
4. Genetics, for example, in particular, phylogenetics and **genetic epidemiology**.
5. A number of other areas of **mathematical biology**, such as competition processes, including predator–prey models.
6. Geomorphology and hydrology.

7. Statistical physics, with a very long history of the use of probabilistic ideas, often in a way that seems idiosyncratic from the viewpoint of other developments in probability theory. More recently, however, there has been rather more contact between statistical physics and the mainstream of work in stochastic processes. Two fundamental problems in physics, i.e. the foundations of quantum theory and the nature of the process generating turbulence, both seem likely to have some stochastic element to them.

In the present context, it is helpful to draw a rough distinction between four types of probability model:

1. Purely empirical models.
2. "Toy" models.
3. Intermediate models.
4. Quasi-realistic models.

Models for rainfall provide a convenient illustration. A purely empirical model for, say, daily rainfall at a single site [41] might specify the binary sequence of (no rain, rain) as an m-dependent **Markov chain** with seasonally varying transition matrix and the amount of rain, conditionally on its being nonzero, as having a **lognormal distribution** or **gamma distribution** with seasonally varying parameters. This might provide a valuable and accurate representation of the frequency properties of the rainfall process, but there would be no direct link with the underlying physical process or corresponding interpretation of the parameters.

A "toy" model is one in which a highly idealized representation is used to explore the particular circumstances under which a phenomenon of interest could be generated from simple starting assumptions. Examples are the use of idealized cascade models (clusters of clusters of ...) to show some conditions under which scaling, i.e. self-similarity, of the rainfall spatial field can occur [21], and simple models showing conditions for the explosion or extinction of epidemics, or the extinction of species by competition. Elaborate fitting to empirical data is often inappropriate.

An intermediate model is one in which some aspects of a complex physical or other process are represented with the objective of obtaining a form that can be fitted to empirical data in such a way that the resulting parameter estimates do have a link with the underlying generating process. An example with rainfall is the use of models in which there is a **Poisson process** of storms. Each storm consists of a random number of rain cells, displaced from the storm origin, each cell being of random duration and depth, the total rainfall depth consisting of the sum of all contributing cells. The notion of a rain cell has a physical interpretation and the resulting process can produce a reasonable fit to the rather complicated time series of say five-minute rainfalls, in which within periods of rain there is a large highly non-Gaussian distribution of intensity interspersed with short periods of zero rainfall. The models [36] also have the major advantage that they can be generalized to spatial–temporal form [14].

A corresponding quasi-realistic model would be a global circulation model in which the nonlinear partial differential equations representing the physical processes involved are solved numerically [30]. Similar models involving complex processes are used in studying global warming [24] and many other types of system, physical, biological, or economic. The models are frequently, although not inevitably, deterministic rather than having an explicit stochastic element.

A few general issues in this broad area of work are as follows.

1. When is the introduction of a stochastic element into a model likely to be crucial, i.e. when are deterministic models broadly adequate?
2. The relationships between a deterministic model and a roughly corresponding stochastic model [44, 25] are important in settling the kind of formulation suitable. For models consisting of linearly superimposable components the deterministic model gives the corresponding stochastic mean, but even then the mean may, for small systems, give a poor idea of the behavior of sample paths. For nonlinear systems, such as epidemic models, the deterministic model gives an approximation to the stochastic mean valid in large systems (*see* **Epidemic Models, Deterministic**).
3. "Toy" models can be highly enlightening. (The term "toy" should not be taken pejoratively!) How can they best be used in combination with more realistic and elaborate models? One route is in the interpretation of results from a complex **simulation** model by examining the ratio of relevant response variables as simulated

to those predicted by a "toy" model. This ratio, or correction factor, may be expected to vary much more slowly with relevant parameters than the response itself [12].

4. Issues arise over the fitting of intermediate models in that **likelihood** functions may be hard to compute and, not always relevant and **estimating functions** constructed by equating observed and fitted features may have a strong element of arbitrariness.

The study of deterministic models, of stochastic models and of the analysis of empirical data has often been undertaken by separate groups of investigators. While the reasons for this may be clear the separation is to be regretted.

Design, Analysis, and Interpretation

Preliminaries

The remainder of the article is concerned with the design, analysis, and interpretation of investigations. In a broad sense the same principles apply to experiments, **observational studies**, and the secondary analysis of data collected for some not very specific research purpose, for example a large family expenditure survey or a cancer registry. We assume that the starting point is a question or issue or research hypothesis of interest, although sometimes preliminary analysis may be needed to clarify the issue involved. In all types of study the key initial questions of design are

1. What individuals should be studied?
2. What properties should be measured and what do the measurements really mean?
3. What **contrasts**, including **interactions**, should be examined?

The broad requirements are

1. The avoidance of **systematic error**.
2. The control of **random error**.
3. The exploitation of the factorial structure of contrasts (*see* **Factorial Experiments**).
4. The formulation of special objectives.

So far as the last point is concerned we can for the most part regard the purpose to be the **estimation** of relevant parameters and corresponding **standard errors**, but a specific decision or prediction objective may alter the whole focus of the study. For example, the design of a plant-breeding programme for varietal selection would involve quite different considerations from that for the comparison of a small number of specific varieties. In the former, emphasis is to be placed on the properties of the small number of varieties ultimately chosen for intensive investigation rather than on specific internal comparisons among a small number of varieties.

The differing relative emphasis on the above requirements, especially the first three, explains why the literature on design appears so different in the **clinical trial** context from that in, say, the chemical engineering field. In the former, but not the latter, avoidance of systematic error is of key importance. In the design and analysis of observational studies too, attempts to eliminate systematic error are often of central importance.

It is disappointing that awareness of some of the basic principles of design has not percolated more widely into the laboratory sciences. Even in physics, where investigations of great subtlety are common, the widely held view that refinement of laboratory technique is always to be preferred to statistical technique as a base for error control is probably much less valid than it used to be.

The reason for neglect of the statistical aspects of the design of investigations may partly be that the theory of statistical design is quite widely identified with the use of complex designs. These have their place, but they are often not appropriate, key issues more commonly being simple techniques for methodical **bias** elimination and error control.

Measurement Issues

The techniques of analysis connected with **variance components** were developed in the 1930s and 1940s tied to balanced data and continuous roughly **normally distributed** data. The restriction to balanced data was removed in pioneering work by C.R. Henderson in connection with animal breeding and synthesized most satisfactorily in the residual (or **restricted) maximum likelihood** (REML) method of Patterson and Thompson [32]. Systematic extensions to **Poisson**, ordinal, and **binomial** data are the focus of current work [29].

Such techniques provide the basis for the design and analysis of interpersonal and interlaboratory

studies of measuring techniques, common in some fields of study, especially connected with the physical sciences, but regrettably less common in a medical context.

They also are in principle appropriate in instrument development. The psychometric notions of reproducibility, and of face, criterion, and concept validity and of comparison with a **gold standard** are not normally presented in terms of components of variance but would probably be better done so (*see* **Psychometrics, Overview**). Systematic techniques for the more detailed analysis of instruments consisting of many relatively similar items are needed. This is especially relevant in connection with **quality of life,** i.e. health status [13].

Classical work on error assessment in experiments and surveys emphasized the often **multilevel** or **time series** structure of error. Treating error variables as independent and identically distributed typically leads to an underestimate of the standard error of contrasts of primary interest. A more empirical adjustment for such **overdispersion** may be via the direct estimation of correction factors to apply to standard errors [6, 31, 19].

Methods of Analysis

Some methods of analysis do not depend on an explicit probability model and recent developments, especially in computer graphics, are of interest both for exploratory work and also in presenting the conclusions of more elaborate analyses; indeed, as in very elaborate analyses the connection between the data and the conclusions may get rather remote, the need for insightful methods of presentation increases.

Nevertheless the rest of this section concentrates on methods that depend at least in part on an explicit probabilistic base.

Some requirements for a probabilistic model are as follows, although not all are relevant in every application.

1. The model should establish a link with underlying substantive knowledge or theory.
2. The model should allow comparisons with previous related studies of the topic.
3. The model should be consistent with or suggest a possible process that might have generated the data.
4. Parameters defining primary features of the system should have individually clear substantive interpretations.
5. The error structure should be represented sufficiently realistically that meaningful measures of precision are obtained for the primary comparisons.
6. The fit to data should be adequate.

We comment here on only some of these points.

The first three items are related to the general issue of preferring what we previously called intermediate models to purely empirical models. Such a preference was indicated in much of the applied work of J. **Neyman**; it can have the disadvantage of making the analysis of fairly simple sets of data overcomplicated and there is a difficult broad strategical issue to be faced in each application concerning the weight to be placed on substantive vs. purely empirical models.

In fields with a quantitative theoretical base this will typically provide a key to a suitable model. In the **social sciences** and in some areas of biology there is often the problem of incorporating background knowledge that is essentially qualitative. Here the ideas of chain graphs, expressing directional relationships between variables and of substantive research hypotheses [43] expressing some conditional independencies and some strong dependencies provide a route to insertion of such knowledge. The graph theory ideas are a development from Sewell Wright's **path analysis**. For accounts with a strong statistical focus, see [18, 15] and [16], and for a more theoretical account see [28]. Spiegelhalter et al. [39] discuss applications to probabilistic expert systems.

The need to connect to previous work is in superficial conflict with the Fisherian notion that investigations provide their own estimate of error. However, the need to relate the primary conclusions in different studies is clear; this includes the examination of consistency of the conclusions. There is a broad connection with overviews, or so-called **meta-analysis**, of much current interest in medical research. The statistical principles were set out by Yates and Cochran [45] and developed further by Cochran [11]. The most challenging issues there, however, concern the choice of material for synthesis.

Models suggesting or consistent with a data-generating process provide some possible link with a causal interpretation; see the further discussion

below. While the term *causal* has a number of interpretations, a very cautious usage tends to be favored in statistical discussions, in particular that strong evidence for causality can only come from the synthesis of different kinds of data. Analysis that points towards a potentially causal interpretation can, however, be valuable; this is one reason for the importance of chain graph representations (*see* **Causation**).

The preference for primary parameters that have individual interpretations links to the previous point and to the Fisherian notion that in **analysis of variance** "treatment" sums of squares should if possible be split into single **degrees of freedom**.

Detailed Techniques

Specific developments in methods of analysis are described throughout this *Encyclopedia*. Among some predominant themes in current research are the following:

1. Nonlinearity is a widely occurring theme, as in so many areas of modern mathematical science. **Nonlinear time series** models provide one important example;
2. **Nonparametric regression** and **density estimation** have been intensively studied in their theoretical aspects. The main value in applications is likely to be in the preliminary stages of analysis.
3. Semiparametric methods in which the primary aspects of the model are represented by parameters, and such issues as distributional form are left nonparametric, raise very interesting theoretical issues. It is, of course, for consideration in each case whether the greater complication and loss of transparency involved as compared with fully parametric formulations is really justified.
4. **Markov chain Monte Carlo** methods provide a powerful general tool for the fitting of relatively complex models.
5. Computer **simulation** methods, **cross-validation**, and the **bootstrap**, provide fairly general methods of assessing precision without elaborate theoretical analysis, although some underlying assumed simple structure is needed (*see* **Computer-intensive Methods**).
6. Methods for addressing data imperfections, such as missing data, including selective **nonresponse**, and for the analysis of nonstandard sampling schemes, are important in many fields.
7. Higher-order asymptotic theory [5] aims to provide a basis for choosing between procedures equivalent to the first order of asymptotic theory and of providing more refined distributional approximations (*see* **Large-sample Theory**).

Interpretation

Design, analysis, and interpretation might suggest a sequence in which narrowly statistical considerations stop at analysis, for example ending with the estimation of relevant parameters, whereas interpretation involves essentially subject-matter considerations not specifically statistical. While, of course, there is some truth to this distinction, the emphasis on model formulation, in particular some of the criteria listed under Methods of Analysis, and the considerations of the section on Probability, are aimed, in line with current thinking, to break down that barrier.

For example, there has been increasing discussion in statistical circles of the conditions under which conclusions can be said to be causal; see, for example, [23, 38] and [16], Section 8.7. The discussion is prompted in part by developments in the computer science and philosophical literature in which a weaker definition of causality tends to be employed [33, 34, 40], much less cautious than the traditional statistical and epidemiological view summarized in **Hill's criteria** [22] (*see* **Causation**).

Closely connected with this are the issues of generalizability and specificity and the importance of absence of interaction. For example, in the light of a well-conducted randomized clinical trial showing evidence of the superiority of treatment A over treatment B, what is the basis for hoping that the conclusions generalize to a new population of patients and what is the basis for thinking that A rather than B will be beneficial for a specific new patient? (*See* **Validity and Generalizability in Epidemiologic Studies**.)

Decision Analysis

Wald [42], in effect continuing in the Neyman–Pearson tradition, proposed that all statistical problems could be formulated as a choice between possible decisions (*see* **Decision Theory**). In Wald's formulation a **utility** (or **loss**) function was assumed known but **prior distributions** enter only as technical devices to produce a complete class of decision functions.

The qualitative ideas that one should consider the objectives of the study, the possible actions that might be taken on the basis of the results and their potential consequences are clearly important. In fields such as sampling inspection and control theory, or where specific point forecasting is involved, a full specification of utilities and prior distribution will yield the preferred solution, but for most purposes summarization of evidence via the estimation of relevant parameters seems a more suitable objective. Thus formulations of clinical trials as decision making procedures, while giving valuable qualitative insights, have not been widely accepted as a realistic model of how trials are used.

Formal Theories of Inference

Much discussion in the more theoretical literature has for many years focused on the formal theory of statistical inference, in particular on the meaning of probability when used to assess the uncertainty in conclusions. The issues are important partly in setting the broad approach to specific problems and partly in detail in developing particular methods of analysis and interpretation.

There are many different approaches but, leaving aside a pure decision-theoretical approach, they can be broadly classified as

1. Pure likelihood [17].
2. Fisherian, putting emphasis on likelihood, **sufficiency**, **conditionality**, **ancillarity**.
3. Neyman–Pearson, reaching many of the same conclusions as 2 but emphasizing operational criteria such as **power**.
4. A Bayesian approach based on standardized impersonal priors [27], now often called reference priors [8, 7] (*see* **Bayesian Methods**).
5. An emphasis on personalistic (or **subjective**) **probability** leading to a wholly Bayesian analysis and rejecting the above approaches as incoherent, or at best as approximations to something else [9].

This is a controversial area on which it seems improbable (in any sense!) that unanimity will be reached. There are, however, some signs of a fairly broad agreement perhaps along the following eclectic lines:

1. Many of the issues addressed in this article, and of direct concern in applied statistical work, do not depend critically on the choice of approach to formal inference.
2. Likelihood, or some adaptation thereof, is of key importance but typically needs calibration into posterior intervals, **confidence intervals** or whatever.
3. Probability, as representing idealized properties of the real world, has to be distinguished from probability as measuring a state of an individual's knowledge.
4. Problems with many similar parameters are usually best formulated in **empirical Bayes** form, powerful numerical methods now being available for their solution.
5. Reference priors in a small number of dimensions usually produce answers with good properties also from the confidence interval viewpoint.
6. It is necessary to have some notion that one's methods of analysis have good properties, or at least are not systematically misleading, when hypothetically they are used repeatedly.
7. To the extent that the previous notion is formalized, some element of conditioning is needed, although overconditioning must be avoided, for example to escape the C.R. Rao paradox of sampling theory [35].
8. The Bayesian formalism provides a valuable representation of the merging of "prior" knowledge with new knowledge from data under analysis, although it does not deal adequately with the possibility of conflict between the two sources.
9. The Bayesian axioms of coherent personalistic probabilities are a valuable guide to opinion formation by individuals, but are not compelling as a basis for public discussion, partly because they put weight on internal consistency rather than on consistency with the real world.
10. While the importance of formal statistical significance is commonly overstated, some such notion, with a **null hypothesis** and **alternatives** (usually not formalized probabilistically), is needed partly to formalize an escape route from an initial unsatisfactory formalization.

Statistics and Public Affairs

The primary emphasis in this article has been on statistics in science and science-based technology. The organization of government statistics varies between countries with somewhat differing emphasis placed on the one hand on the provision of information and advice for direct use by government, somewhat akin to the provision of such information in a business context, and on the other hand on the provision of information to society at large and to social science research workers in particular. For both purposes independence is crucial; in the provision of advice one would hope for government statisticians to be the firm voice of reason in the face of political and economic dogmatism. In the second role, collaboration between government statisticians and social science research workers, including statisticians, is important.

One important area of social policy concerns **risk assessment** and management, i.e. especially as concerns extremely small or maybe even nonexistent risks. This has been discussed extensively by engineers, toxicologists, epidemiologists, psychologists, social anthropologists, sociologists, economists, and political scientists [37], but surprisingly little has appeared in the statistical literature. The role of judgmental probabilities in such situations is central.

The importance of appreciation by the general public of central principles of the interpretation of evidence shows itself in many aspects of material appearing in newspapers and presented on radio or television. For sample surveys, issues like the sample size, the sampling scheme, the response rate, and limits of error, are probably reported rather more often nowadays than in the past. Sensible interpretation of so-called league tables of the performance of schools, hospitals, and the like [20] depends crucially on a critical attitude to empirical data. The reporting, sometimes rather sensationally, of the results of often badly designed small medical studies is of particular concern.

Conclusion

The years 1925–1960 can be regarded as a golden era of statistical thought. For example, in terms of issues of formal inference, the period embraces most of the work of R.A. **Fisher**, of **Neyman** and E.S. **Pearson**, and of **Wald**, the objectivist Bayesian contributions of Jeffreys and the personalistic approach of F.P. Ramsey, **de Finetti**, and **Savage**. Aspects of the design of experiments and sample surveys were developed to a high pitch of elaboration; many of the key ideas of **time series** analysis and **multivariate analysis** were formulated. Statistical quality control and randomized clinical trials were firmly established.

While further important developments took place between 1960 and 1985, these years may best be seen as primarily a period of consolidation. At the beginning of that time most statisticians had access to an electronic computer but obtaining useful results could be a lengthy chore. By the end of the period all the "standard" methods, and more, were fairly readily available to a wide spectrum of users.

Encouraging features of the last 10 years or so are that while a massive educational job remains, the appreciation of statistical ideas is more widely spread among research workers in many disciplines, as shown by the relative sophistication of statistical ideas in subject-matter journals, and by an increase in the amount of substantial collaborative work involving statisticians, in contrast to short-term "consulting" on very specific and often minor details.

Viewed over a rather longer period, there has been a massive growth in the subject, as indicated by the amount of work published per year, by the introduction of new journals, by the number of people employed and by the career prospects for new graduates.

There is currently no shortage of interesting new ideas and challenging problems, many stemming from the relatively large sets of data now so common. For individual research workers freedom to follow one's own judgment of topics likely to be important and to which one is equipped to contribute is needed and is under threat from the short-term policies of many of the sources of financial support. Nevertheless, if statisticians as a group become increasingly involved in important issues in science, technology, and public affairs, if imaginative new ideas can be encouraged, and if fragmentation of the subject can be avoided, then the prospects for an important new period of major development are strong.

D.R. COX

StatXact

StatXact is a specialized software package for the exact analysis of small-sample **categorical** and **nonparametric** data with special emphasis on data in the form of **contingency** tables. The term "small-sample" applies equally to datasets with only a few observations, to large but unbalanced datasets, or to contingency tables with zeros and small cell-counts in some of the cells but large cell-counts in other cells (*see* **Structural and Sampling Zeros**). In these settings, StatXact produces exact ***P* values** and exact **confidence intervals** instead of relying on possibly unreliable **large-sample theory** for its inferences. The inference is based on generating permutation distributions of the appropriate test statistics in a conditional reference set (*see* **Randomization Tests**). For a discussion of the theory underlying exact inference, references to numerical **algorithms** that perform the computations, and several examples involving the analysis of biomedical data by StatXact, (*see* **Exact Inference for Categorical Data**). Different reviews of StatXact were published by Lynch, Landis and Localio [2], Wass [5], and Oster [4].

The current version, StatXact-6, offers exact P values for one, two, and K-sample problems, **2 × 2**, $2 \times c$, and $r \times c$ contingency tables, and measures of **association**. The data may be either unstratified or **stratified**. Both independent and blocked samples are accommodated. StatXact-6 computes the exact confidence intervals of odds ratio in case of 2×2 and $2 \times c$ contingency tables and exact confidence interval of median shift in ordered $2 \times c$ contingency tables. StatXact-6 has inference procedures that cater explicitly to **binomial** data, **nominal** categorical data, **ordered categorical data**, ordered correlated categorical data, continuous complete data, and continuous right-**censored** data. StatXact-5 also offers analysis of data that follow **Poisson distributions**. In case the computation of exact P value becomes infeasible due to lack of time and memory, StatXact produces exact P values with at least two decimal digits accuracy using efficient Monte Carlo simulation strategies. Changing the number of Monte Carlo simulations can change the accuracy.

StatXact-6 also computes the exact unconditional confidence interval for a difference or ratio of two independent as well as related binomial proportions and computes exact P values for tests of **equivalence** and noninferiority of two binomial proportions (*see* **Proportions, Inferences, and Comparisons**).

In addition to all the tests mentioned above, StatXact-6 also provides exact **power** and **sample size** calculations for different tests on 2×2 and ordered $2 \times c$ tables.

StatXact-6 runs on Microsoft Windows NT/2000/XP as a stand-alone product. In addition, a special version, StatXact PROCs for SAS users, is available as external SAS procedures for both the Microsoft Windows and Unix operating systems.

LogXact is a companion product to StatXact featuring exact inference for **binary data** in the presence of **covariates**. An underlying **logistic regression** model is assumed. Both exact and asymptotic inferences are provided. The current version of LogXact-5 uses powerful Monte Carlo procedures that enable fast exact inference for much larger data sets. LogXact handles matched case–control data under general M:N matching, by conditional likelihood inference. Asymptotic inference is based on maximizing the unconditional likelihood function for unstratified data and on maximizing the conditional likelihood function for stratified data *see* **Maximum Likelihood**; **Logistic Regression, Conditional**). Exact inference is based on generating the conditional distributions of the **sufficient statistics** for the coefficients of interest, **nuisance parameters** being eliminated by fixing their respective sufficient statistics at the observed values. For a detailed discussion of the theory underlying exact logistic regression, references to numerical algorithms that perform the computations, and several examples involving the analysis of biomedical data by LogXact, refer to [3].

LogXact also provides exact and asymptotic inference for **Poisson regression**. Reviews of LogXact were published by Lemeshow [1] and Oster [4].

LogXact runs on Microsoft Windows NT/2000/XP as a stand-alone product. In addition, a special version, PROC-LogXact for SAS users, is available as external SAS procedures for Microsoft Windows.

Stereology

Stereology is the science of inference about three-dimensional structures based on two-dimensional sections or one-dimensional probes. The name was coined at a meeting of scientists from various disciplines in 1961. This was the first recognition that scattered results in geometrical probability could constitute a coherent field of study.

The subject has important applications in mineralogy, petrology, and metallurgy. In medical and biological research, microscope slides are thin slices through specimens of material. They can give information about the volume of different types of tissue in the specimen, about the area of membranes, and about the length of capillaries. An example of a linear probe is given by a microelectrode penetrating nervous tissue. It allows inference about the size and distribution of nerve cells and their cell membranes.

Inference is also possible about geometrical and topological properties of structures in the specimen. The curvatures of one- and two-dimensional objects may be of interest. Connectivity between structures is often important, and some progress is possible in investigating these features.

Early Results

The first stereological result to be published was the "Delesse Principle", in 1849 [17]. It states that the proportion of *area* occupied by a particular substance or "phase" in a random section of a specimen is an **unbiased** estimate of the proportion of *volume* of that phase in the specimen.

"Buffon's needle" gives the mean number of intersections between two systems of lines in a plane. The result dates from 1733, but was not published until 1777 [2]. Barbier [1], in 1860, gave the three-dimensional extension of the problem. It makes it possible to estimate the length of linear systems from counts of their intersections with a section.

The theory of geometrical probability was first seriously investigated by Crofton. In 1869, his first paper on the subject appeared [7], and his Encyclopedia Britannica article in 1885 [8] summarizes the theory.

In 1925, Wicksell [46] published a paper on the "corpuscle problem", discussing how to estimate the size distribution of spherical particles from their circular intersections with a plane. In 1926 [47], he investigated the much more difficult problem of ellipsoidal objects. These were the first statistical papers in the field of stereology, and they were followed by a number of related studies; see [23].

Sampling

If the aim of a study is to estimate the volume fractions of different phases in an object, the sampling problem is straightforward. Parallel section may be selected by any of the standard sampling procedures; see [4]. Usually, systematic sampling is preferred. Estimates of the volume ratio can then be made from each section, and combined, either by weighting according to the area of the section of the object, or by subsampling proportionally to this area.

Other stereological formulae, however, depend on the orientation of the section. For them to be valid, the section must be random in direction, as well as in position. Isotropic sampling of biological specimens for microscope slides is virtually impossible. In petrology, it may be an option if sufficiently large specimens are available, and isotropic linear sampling may be feasible. Otherwise, no statistical analysis is possible except on slides from different specimens unless it is assumed that the specimen is isotropic – generally highly implausibly for biological material.

For discussions of the sampling problem, see [13, 14, 28, 29], and [30]. The two basic types of sample that give unbiased estimates are *isotropic uniform random* and *area weighted*.

For discussions of the errors that can arise from misuse of statistics in the stereological analysis of biological material, see [34] and [43].

Fundamental Formulae of Stereology

The basic results of stereology can be expressed in terms of ratios. In the original three-dimensional specimen, interest may center on the volume of a particular phase, the area of an interface or membrane, the length of some linear feature, or the number of particles; these can all be expressed *per unit volume*. They are estimated from measurements of area, or length, or from counts on sections or linear probes, expressed per unit area, or per unit length.

A standard notation is used for these formulae. The subscripts V, A, and L refer to the divisor in the specimen, in sections, and in probes, respectively. The letters V, A, L, and N refer to volume, area, length, and count. Thus, A_V means the area of some feature per unit volume in the original specimen.

One other concept is required; $\overline{H}$ is the *mean caliper length* of a set of particles. This is defined as the mean projected length of the particles on a line normal to the section. If the sections are isotropic, or if the particles are spherical or randomly orientated, the value of $\overline{H}$ is taken to be the same for all sections.

Table 1 shows the fundamental formulae. The first line shows the Delesse principle, relating the volume ratio, the area ratio, and the length ratio. These results do not depend on isotropic sampling or structures. The second line shows estimates of area per unit volume; note that the relationship between the two estimates corresponds to the ordinary two-dimensional Buffon's needle. The third line gives the estimate, from a section, of the length per unit volume of some linear feature of the specimen. The fourth line is a possible way of estimating the number of particles or cells; it depends on a knowledge, or a separate estimate, of mean caliper length. This traditional estimate is not necessarily the best; for a discussion of it and other approaches, see [12].

Curvature

Given an interface I between two phases, there are various measures of average curvature of the surface; see [31]. At the center of an element $\mathrm{d}S$, the *principal curvatures* κ_1, κ_2 are defined as the reciprocals of the minimum and maximum radii of curvature (which are orthogonal). The radii and the curvatures are signed; they are usually taken to be positive for elements that are convex toward the bounding phase. The *integral of mean curvature* is defined as

$$K = \int_I \frac{1}{2}(\kappa_1 + \kappa_2)\,\mathrm{d}S \tag{1}$$

If the surface I is imbedded in a volume V, a possible measure of average curvature is $K_V = K/V$. DeHoff [15] (see also [6]) introduced a method of estimating K_V for a phase boundary from sections. This is based on the *area tangent count*. Given an area A, a section of an isotropic uniform specimen with a phase bounded by I, choose a fixed direction. As a line with this direction is moved across the area, it is sometimes tangential to the boundary. The tangent count is divided into two parts. T_+ is the number of times the line is tangential to a convex element of the interface, T_- the corresponding count for concave elements (see Figure 1). Now define

$$T_{\mathrm{Anet}} = \frac{T_+ - T_-}{A}. \tag{2}$$

DeHoff has shown [16] that

$$\hat{K}_V = \pi T_{\mathrm{Anet}} \tag{3}$$

is a consistent measure of the integral mean curvature per unit volume.

Table 1 Fundamental formulae of stereology

Specimen	Section	Probe
V_V	A_A (Delesse)	L_L
A_V	$\frac{4}{\pi}L_A$	$2N_L$ (Buffon)
L_V	$2N_A$ (Barbier)	
N_V	$\frac{1}{\overline{H}}N_A$	

The Spherical Particle Problem

The problem first studied by Wicksell [46] is that of estimating the distribution of the radii of spherical particles from the observed distribution of the radii of the circular sections in a random section. Suppose the sphere radii have density function $f(r)$, with **moments** μ'_k, and the radii of the sections have density $g(x)$, with moments ν'_k. The density of the radii of spheres cut by a random plane has the form

$$\frac{rf(r)}{\int_0^{R_m} rf(r)\,\mathrm{d}r} = \frac{rf(r)}{\mu'_1} \tag{4}$$

where R_m is the maximum value of r. The conditional density of x is given by

$$g(x|r = R) = \frac{x}{R(R^2 - x^2)^{1/2}} \tag{5}$$

and finally

$$g(x) = \frac{x}{\mu'_1}\int_x^{R_m} \frac{f(r)}{(r^2 - x^2)^{1/2}}\,\mathrm{d}r. \tag{6}$$

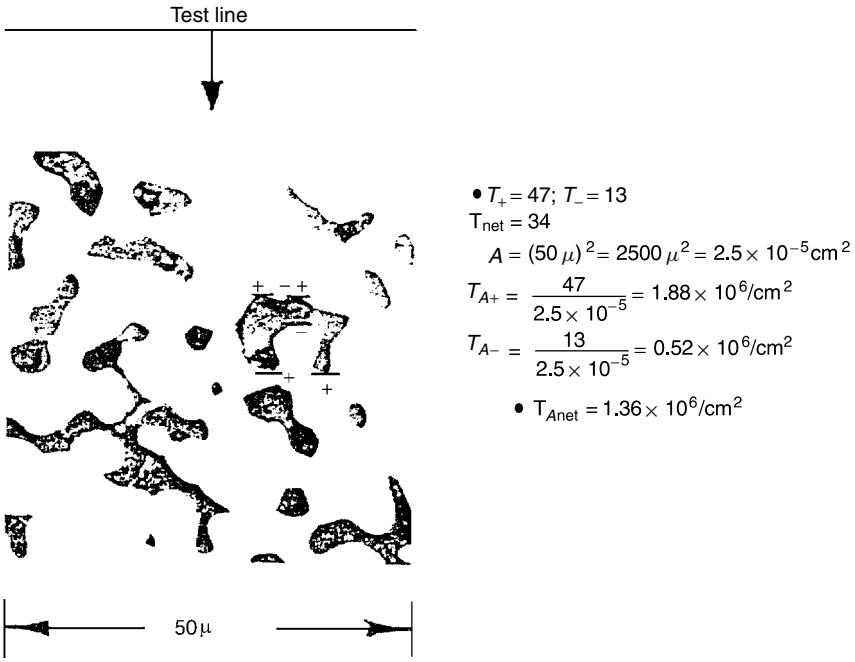

Figure 1 Procedure for measuring the net area tangent count (From DeHoff [15])

This is known as Wicksell's integral equation. The values of x are observed, and the problem is the estimation of $f(r)$. There are two difficulties with the solution. First, small values of r are underrepresented, and in theory, there might be large numbers of particles so small that they almost never appear in sections. This is not a real difficulty in biological applications, as extremely small cells or similar structures are not viable. Secondly, if the spheres are all virtually the same size, the solution may not give a density, as the **variance** of x may be lower than that arising from a homogeneous population of spheres.

Wicksell [46] himself suggested the following two approaches:

1. The moments of r and x are related by the equations

$$\mu'_{k+1} = \frac{1}{h_k}\mu'_1\nu'_k \quad k \geq -1, \tag{7}$$

where

$$h_k = \frac{1}{2}B\left(\frac{k+2}{2}, \frac{1}{2}\right). \tag{8}$$

These equations are valid for $k = 0$ and $k = -1$, with $\nu'_0 = 1$ and $1/\nu'_{-1}$ the harmonic **mean** of the section radii, so that $\mu'_1 = (\pi/2)/\nu'_{-1}$. It is then possible to estimate the moments of the sphere radii, and approximate the density by fitting a member of some family of curves, such as the Pearson family (*see* **Pearson Distributions**). This method is not satisfactory because of the problem of very small values of x. These may often be missed, and their influence on the harmonic mean is large.

2. Wicksell [46] also suggested a **nonparametric** approach, based on an approximate numerical solution of the integral equation. Suppose the observed data – the x values – are grouped in a histogram (*see* **Frequency Distribution**), and suppose R_m, the maximum radius of the spheres, is known or assumed. Then it is easy to calculate the probability that a value of r in a short range gives rise to a value of x in each cell of the histogram. This gives a set of linear equations relating the probabilities of the cells in a histogram of r values to the observed frequencies in the histogram of xs. Solving these equations, described as "unfolding" the observed histogram, gives an estimated histogram for r.

This method works well, provided the histogram intervals are well chosen and the underlying distributions are well behaved. There is no guarantee that the estimated probabilities will be positive; a gap in the distribution of r may give small negative estimates. A number of authors have used this numerical procedure modified in various ways; see [44]. For details of the numerical procedure, see [10].

Particles of Other Shapes

Wicksell [47] also studied the problem of estimating the distribution of the properties of a population of general ellipsoidal particles from a section showing elliptical sections. This is much more difficult; there are obviously problems of **identifiability**. The general problem is that of inference about the joint distribution of three variables (the three axes of the ellipsoids) from the joint distribution of two. Further assumptions are needed. These depend on the material examined, and the solutions are mathematically quite difficult. Cruz-Orive [9, 11] has solved the problem for spheroids. He shows how to estimate the distribution of measurements on particles assumed to be oblate spheroids, or prolate spheroids, and shows that there is no way, from the distribution of the properties of elliptical sections, of discriminating between the two cases.

Other particle shapes have been investigated. Nicholson [32] gives a general mathematical discussion, and illustrates, in particular, the possible sections of cylindrical particles. Sections of polyhedra are important in crystallography, but probably not in biological applications. Coleman [5] deals with sections of two-phase particles, such as cells with nuclei.

Effects of Section Thickness

Sections are usually thin slices. If a specimen has two phases, one opaque and one translucent, and a slide is examined by transmitted light, the finite thickness of the slice can cause bias in standard stereological estimates. The interface is not, in general, normal to the section, and the area ratio of the opaque phase is an overestimate of the volume ratio. This bias was first recognized by Holmes [21], and is known as the Holmes effect.

The appropriate correction in the isotropic case was given by Cahn and Nutting [3]. For a section of thickness t, the adjusted estimate is given by

$$\hat{V}_V = A_A - \frac{1}{4} A_V t, \tag{9}$$

where A_V is the volume fraction of the interface. This, of course, is not observable, and must be estimated from

$$\hat{A}_V = 4\pi L_A, \tag{10}$$

where L_A is the area fraction of the interface in the section. This gives, finally,

$$\hat{V}_V = \frac{1}{\pi} L_A t. \tag{11}$$

This is not an unbiased estimate, since the Holmes effect also implies that L_A is reduced in sections of finite thickness, but for thin sections the effect is small. If the assumption of isotropy is false, the adjustment can be seriously misleading; see [45] for a discussion of the anisotropic case, with application to the structure of trabecular bone.

Finite section thickness also affects the estimation of particle size distributions. For spherical particles, Wicksell's integral (6) becomes

$$g(x) = \frac{t f(r)}{\mu_1' + t} + \frac{x}{\mu_1 + t'} \int_x^{R_m} \frac{f(r)}{(r^2 - x^2)^{1/2}} \, \mathrm{d}r. \tag{12}$$

The solution to this equation, with the further modification of a truncation point – a minimum observable section radius – is discussed by Coleman [6]; see also [40] and [22].

Tessellations

A tessellation is a subdivision of p dimensions into closed subsets, divided by edges of dimension $p - 1$. In stereology, we are concerned with tessellations of $\mathcal{R}^3$, and tessellations in $\mathcal{R}^2$ produced by sectioning them.

The Dirichlet tessellation of a **point process** subdivides the space into those sets nearest to each point of the process. This gives convex polyhedra in $\mathcal{R}^3$, or convex polygons in $\mathcal{R}^2$. (These are sometimes known

as Voronoi polygons or polyhedra). The particular case when the underlying point process is Poisson (*see* **Poisson Processes**) has been widely studied under the name of the *cell model*. "Seed" are randomly scattered, and grow at the same rate until the circles or spheres meet, and eventually fill the complete space. The model has been used in studies of crystal growth, and in various ecological applications, such as ground cover by plants, and territories of animals.

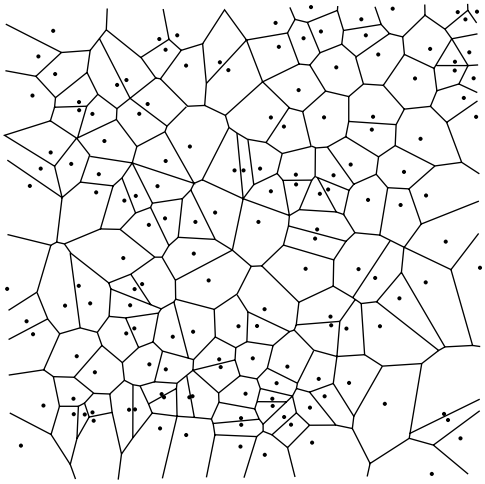

Figure 2 A two-dimensional cell model (the Dirichlet tessellation of a Poisson process). The points show the seeds. From Okabe et al. [33]

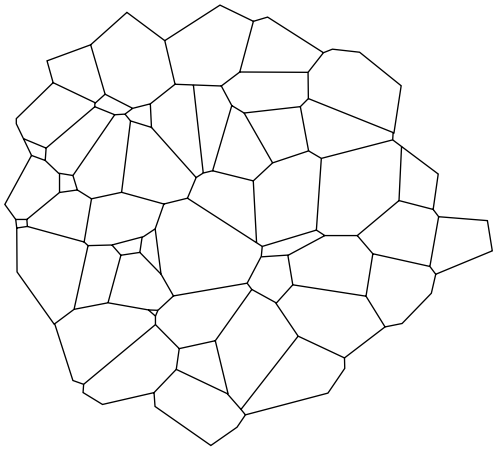

Figure 3 A two-dimensional section of a three-dimensional cell model. From Lorz [24]

The two-dimensional cell model consists of convex polygons, with an average of six edges. (This applies to all Dirichlet tessellations of random processes; it is simply a consequence of the fact that three or more boundaries meet in a point with zero probability). A two-dimensional section of the three-dimensional cell model has similar properties. In fact, Miles [29] has shown that it is a Dirichlet tessellation of a point process, but not of a Poisson process of constant intensity. The main visual difference is that the section has more cells much smaller than the average. Figures 2 and 3 show an example of a two-dimensional cell model, and of a section of a three-dimensional cell model. Table 2 lists some of the more important properties of the models. Notice that the number of vertices and the perimeter, in terms of μ, both show higher variance for the section than for the two-dimensional model.

Another model proposed for crystal growth, the Johnson–Mehl model, has seeds generated by a Poisson process in space *and time*, which then grow at a constant rate. The resulting tessellation has edges that are quadratic curves or surfaces. The cells are not convex, but have the property that all lines through the seed cut the surface twice only. Sections of this model are difficult to interpret, since a single cell may

Table 2 Some properties of the cell model in $\mathcal{R}^2$ and $\mathcal{R}^3$, and of two-dimensional sections of the $\mathcal{R}^3$ model. The intensity of the Poisson process of seeds is represented by λ, and the intensity of centroids in the section by μ. Entries with an asterisk were obtained by **Monte Carlo** simulation

Cell model in $\mathcal{R}^2$			
Vertices/cell	$E(N)$	6	
	$E(N^2)$	37.781	
Perimeter/cell	$E(P)$	$4\lambda^{1/2}$	
	$E(P^2)$	$16.945\lambda^{-1}$	
Cell model in $\mathcal{R}^3$			
Vertices/cell	$E(M)$	27.071	
Edges/cell	$E(E)$	40.606	
Faces/cell	$E(F)$	15.535	
Cell model in $\mathcal{R}^3$; 2-D section			
Intensity of centroids		$1.458\lambda^{2/3}$	μ
Edges/cell	$E(N)$	6	
	$E(N^2)$	38.827*	
Perimeter/cell	$E(P)$	$3.136\lambda^{-1/3}$	$3.79\mu^{-1/2}$
	$E(P^2)$	$11.308\lambda^{-2/3}$	$16.49\mu^{-1}$*

be represented by more than one area in the section. Properties have been studied mainly by simulation.

Early work on these models [19, 26] established the main properties, and Miles [27, 29] derived further results. Many variations are possible, by changing the underlying process, the definition of distance, or the rate of growth. For details, see [33].

Mathematical Morphology

Mathematical morphology was developed for the study of properties of three-dimensional structures from sections, particularly in the context of petrology and the porosity of rocks; see [25]. Properties of interest (porosity, the strength of bones, the healthiness of lungs) may not depend in a simple way on the standard stereological measurements, such as the area ratio. More complicated measurements on the sections might be used; an alternative is to apply transformations to the image, and investigate the relationships between the properties and measurements on the transformed images.

An image is represented by a pixel map on a regular lattice. The work of Matheron [25] and Serra [38] is based on a hexagonal lattice, but computer graphics is more often referred to a square lattice. Each pixel has an associated value z. For a black and white image, z is binary. The original theory was concerned with binary images; later work extends it to grey-level images.

Consider a binary image in which black objects ($z = 1$) appear on a white background ($z = 0$). There are now two basic operations in the calculus:
Erosion consists in peeling a layer, one or more pixels deep, off each object.
Dilatation adds a layer of one or more pixels to each object.

These operations may be combined:
Opening is erosion followed by dilatation.
Closure is dilatation followed by erosion.

Notice that changing the coding, so that white objects ($z = 1$) lie on a dark background ($z = 0$) simply interchanges erosion and dilatation, and opening and closure.

Opening has no effect on large, regular objects; dilatation simply restores the layer removed by erosion. Small and thin objects, and small irregularities on the surface of larger objects, are removed by erosion and not restored by dilatation. Opening thus gives a "smoothed" image, with a lower area ratio than the original. Closure operates in the same way on background irregularities, and gives an image with higher area ratio. Note, however, that edge effects must be considered separately.

A more formal treatment, allowing generalizations and extensions to the simple operations, was given by Serra [38, 39]. Denote by X the lattice with elements $\boldsymbol{x}$, by A the object defined by $Z(\boldsymbol{x}) = 1$, and suppose B is a *structuring element*. B is typically an approximation to a disk, defined on the lattice. On a triangular lattice, B may be hexagonal, the smallest structuring element consisting of a central point and six surrounding points. On a square lattice, it is less easy to approximate circular disks with small pixel patterns; the smallest suitable structuring elements are a point with its four nearest neighbors, or a nine-point square. The structuring element has an origin, the central point in these simple examples.

Table 3, from [37], shows the basic operations defined in terms of the structuring element B.

Minkowski addition gives a score of 1 whenever a point of A scores 1, or when a point not in A is covered by B with its origin on a point of A.

The reflection of B in the origin is $\check{B}$; for the simple structures described above, $\check{B} = B$.

Dilatation and erosion are defined in terms of the structuring element; different structuring elements give different interpretations to the idea of adding or peeling off a layer.

Table 3 Basic operations of Serra's set calculus

Minkowski addition	$A \oplus B = \{\boldsymbol{x} + \boldsymbol{y} \mid \boldsymbol{x} \in A, \boldsymbol{y} \in B\} = \cup_{\boldsymbol{y} \in B}(A + \boldsymbol{y})$
Reflection	$\check{B} = \{-\boldsymbol{x} \mid \boldsymbol{x} \in B\}$
Subtraction	$A \ominus B = (A^c \oplus B)^c = \{\boldsymbol{x} \mid (\boldsymbol{x} - B) \subset A\}$
Dilatation of A by B	$A^B = A \oplus \check{B} = \{\boldsymbol{x} \mid (B + \boldsymbol{x}) \cap A\}$
Erosion of A by B	$A_B = A \ominus \check{B} = \{\boldsymbol{x} \mid (B + \boldsymbol{x}) \subset A\}$
Opening of A by B	$A\omega B = (A \ominus \check{B}) \oplus B = \cup\{B + \boldsymbol{x} \mid (B + \boldsymbol{x}) \subset A\}$
Closure of A by B	$AfB = (A \oplus \check{B}) \ominus B = \cap\{B + \boldsymbol{x} \mid (B + \boldsymbol{x}) \cap A \neq \emptyset\}$

Opening and closure are erosion followed by dilatation, and dilatation followed by erosion respectively, as discussed above.

The extension of the set calculus to grey-level images is straightforward. An image in $\mathcal{R}^2$ can be represented by a three-dimensional plot in which the axis normal to the plane of the image indicates the grey level. This plot is known as the *umbra*. A structuring element B is defined as before in the plane, and its origin is moved to each pixel of the image. *Erosion* then reduces the grey level at the origin to the minimum level in any point of the image covered by B, and *dilatation* raises it to the maximum. Opening and closure are defined as before. Both effect a smoothing of the image, the former by flattening the peaks and the latter by filling in the troughs in the umbra.

Figure 4 illustrates, in section, the opening and closure of a grey-level function.

This section covers only the most basic functions of mathematical morphology. For further details, see [38] and [39]. Many of the extensions are of more importance in the field of **pattern recognition** than in the analysis of two-dimensional sections or projections.

Computation and Software

Devices for taking measurements on two-dimensional images have been available since the 1960s. The *Quantimet* was the earliest practical instrument; it could scan black and white images, record the areas of the two phases, and, using the principle of Buffon's needle, measure the length of an irregular curve. It was first described in 1963, and became commercially available in 1967. For details about the early developments, see [43], Chapter 7. For a more recent account of image processing software, see [36] (*see* **Image Analysis and Tomography**).

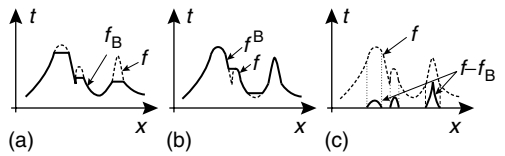

Figure 4 Grey-level morphology. (a) and (b) show respectively the opening and closure of a function by a compact convex set. (c) shows the difference between the function and its opening – the peaks smoothed off by opening. (From Serra [38])

Software for image processing is available, and is being developed and elaborated all the time. SCILAIM is a package developed by a group in Amsterdam; see [20]. The KHOROS system contains a large number of algorithms for image processing. The TargetJr software was initiated in the General Electric Corporate Research and Development department. It was originally designed primarily for photointerpretation and X-ray image analysis. Image Understanding Environment (IUE) is a project started in the United States in 1989 and still under development there and in Europe.

Bibliography

A number of books have been written on stereology; unfortunately, many are out of print or difficult to obtain. They include [6, 10, 18, 35, 41, 42, 44]. The Buffon Bicentenary meeting was influential in bringing practical stereologists and statisticians together. The Proceedings volume has been cited repeatedly, for example, [28].

There have been regular congresses on stereology, and the proceedings, usually special publications not readily available, contain many valuable papers. International Congresses for Stereology have been held at four-yearly intervals since 1963. European Congresses for Stereology have been held, also at four-yearly intervals, since 1973. International Conferences on Stereology and Stochastic Geometry were held in 1981, 1983, 1985, and 1987. Papers presented at these meetings are often published in the *Journal of Microscopy*, which regularly devotes one or more special issues to stereological topics. This journal is the main English language journal publishing papers on stereology.

Image analysis and mathematical morphology is an ever-growing subject. Serra [38] gives the basic calculus developed by Matheron and Serra. Serra [39] is more specialized. A third volume containing algorithms for image analysis has not yet appeared in English.

Stimulus–Response Studies

Introduction

Exposure of individuals to environmental stress, such as heat or noise, can be damaging to health. A psychologist wishing to investigate the effect of heat on concentration, for example, might give a number of human subjects a recognition task, which proceeds as follows:

At each of a number of trials, the subjects are either presented with a signal or not, where the signal could, for example, be a light flashing on a screen. In cool conditions, each subject records his/her impression of whether the signal was present or not, and the experiment is then repeated in heat. A "hit" corresponds to a positive response to a signal, while a "false alarm" results from a positive response when no signal is present. For each subject, the overall responses to the experiment may be summarized by the proportions of hits and of false alarms recorded, for each of the two conditions.

A simple probability model for the behavior of the subject in such a stimulus–response situation is to suppose that the stimulus induces a latent random variable, X, from one of two distributions (*see* **Latent Class Analysis**). If the signal was present, then X is supposed to be a **random variable** with cumulative distribution function $F_P(x)$, and if the signal was absent, then X is supposed to be a random variable with the cumulative distribution function $F_A(x)$. The subject's response is then governed by the value of the latent variable; the subject's response is positive (the signal was present) if and only if $X > c$, where c is some cut-off value determined by the subject's natural level of performance. In this case, we can see that the probabilities of a hit and of a false alarm are given as

$$\Pr(\text{Hit}) = 1 - F_P(c); \quad \Pr(\text{False alarm}) = 1 - F_A(c). \tag{1}$$

It is usual to assume that $F_P(x) = F(x - d')$, and $F_A(x) = F(x)$, for some cumulative distribution $F()$, which is the case illustrated in Figure 1. Typically, a **normal** or **logistic** form is adopted for $F()$. The value of c varies between subjects, and may also be manipulated artificially by means of suitable reward schemes. Changing c, but without varying d', produces different points on the **receiver operating characteristic (ROC) curve** illustrated in Figure 2.

The transformation of hit and false alarm rates into a single measure d', to represent the separation of the signal from noise (when no signal was present) is very attractive, and the tables of Freeman [8], providing estimates of d' from empirical proportions of hits and false alarms, have proved very popular. Thus, for example, the effect of heat on performance may be examined by comparing two ROC curves, or equivalently, the two corresponding estimates of d'. A latent **bivariate normal** model was proposed by Metz et al. [16], for the case when the same subjects are used in both conditions, and De Long et al. [5] use the theory of generalized ***U*-statistics** to provide a **nonparametric** approach for comparing correlated ROC curves.

Designed originally for engineering problems, ROC curve methodology now has wide application, not just in psychology, but also in areas such as medicine and ecology; see [10]. An introduction is given by McNicol [15], and reviews are provided in [1, 12, 21, 23].

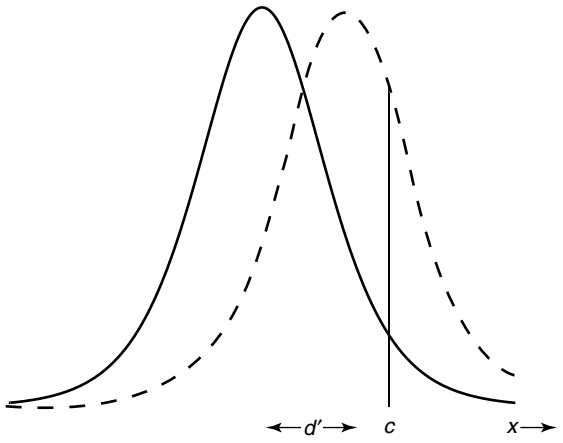

Figure 1 The basic model for the Yes–No signal-detection experiment. A subject responds "Yes" if and only if the latent variable $X > c$. The latent variable has cumulative distribution function $F(x)$ when only noise is presented (probability density function shown by ——) and cumulative distribution function $F(x - d')$ when signal is present (probability density function shown by - - - -)

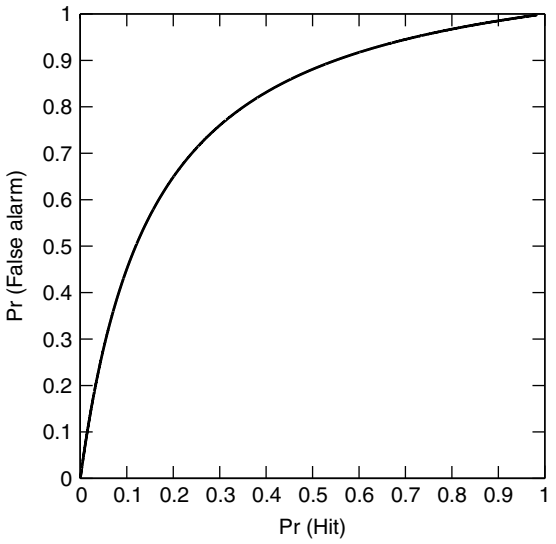

Figure 2 The ROC curve that results from varying c in Figure 1

Extensions

The simple experimental paradigm and model described above may be varied in various ways. In a forced-choice experiment [15, 8], a subject is told that on one of two trials a signal is present, and the task is to decide which of the trials contained the signal. A rating-method experiment is a natural extension of the basic stimulus–response experiment, allowing a subject to express a degree of uncertainty, rather than simply stating "Yes" or "No". The model for this experiment simply extends that of Figure 1, by increasing the number of cut-offs. For example, if there are two cut-offs, c, and c_2, then if $c_1 \leq X < c_2$, the response "maybe" would result. **Maximum likelihood** model-fitting for the rating-method experiment is described in [11]. For the case of two or more cut-offs, the two underlying distributions are not required to have equal variances, though typically, the same distributional form would be assumed. The two cut-off example is then saturated, and explicit maximum likelihood estimates result for the full set of parameters (including the cut-offs).

This model is generally useful for **contingency tables** with **ordered categories** ([14]) and also for **quantal response models** with intermediate categories of response, such as when embryos, say, are classified as deformed, as well as dead or alive; see [17]. Usually, the cut-off values are regarded as **nuisance parameters**, but in some cases, they are also of interest; see [4]. If the underlying distribution is logistic, we have a **proportional-odds** model, while if it is **extreme value**, we obtain a **proportional hazards** model; see also [18].

Applications

Applications to diagnostic medicine (*see* **Diagnostic Tests, Evaluation of**) use the terms "**specificity**", for 1− Pr(False alarm), and "**sensitivity**", for Pr(Hit). The latent variable of engineering and psychology applications is *explicit* when it plays the role of a disease indicator, which may be measured. Murtaugh [19] investigated ROC curve methodology for the case when several such markers are measured on each subject. Such data may alternatively be measured through space, rather than time, and this typically occurs in ecological monitoring studies.

The area, A, under the ROC curve is used as a measure of accuracy of a diagnostic test, for example, in radiology [1], and of discrimination in **discriminant analysis**. The Gini coefficient is defined as 2(A-1/2). A shrinkage correction for both A and the ROC curve is given in [3]; see also [7]. The nonparametric area estimator of [13] is equivalent to a ***Wilcoxon test*** for comparing diseased and normal subjects; however, this assumes exact diagnosis. When diagnosis is imperfect, it is necessary to examine the effect of verification bias. This was done by Gray, Begg, and Greeves [9] in the case of a maximum likelihood estimator of area; Zhou [22], obtained a nonparametric maximum likelihood estimate after formulating the problem in the framework of **missing data**, and making the missing-at-random assumption.

If X and Y denote the ranks of two observations, one from each of two independent populations, it is frequently important to evaluate $\Pr(X < Y)$ and $\Pr(X < Y) - \Pr(Y < X)$; see [6, 20]. Brownie [2] showed how ROC analysis may be used in this context.

Stochastic Approximation

In the mathematical sciences, iterative methods to find roots of equations have a long and honored history dating back, of course, to Sir Isaac Newton (*see* **Optimization and Nonlinear Equations**). Stochastic approximation, which is concerned with the same problem when these roots are observable in the presence of statistical variation, has been available for less than half a century. The seminal paper by Robbins & Monro [26] appeared in 1951. Applications of stochastic approximation have been primarily in the areas of adaptive control, statistical **simulation** and sequential estimation. Biomedical areas that have used stochastic approximation include quantal response, evolution and survival analysis.

Sampson [29] provides an excellent overview of stochastic approximation from a statistical viewpoint.

Theoretical Development and Overview

Suppose an experimenter is concerned with obtaining the (unique) root of $M(x)$; that is, the value θ such that $M(\theta) = m_0$. However, $M(x)$, a real-valued, differentiable function of x, is not directly observable. What one does observe is a **random variable** $Y(x)$ with cumulative distribution function (cdf) $F(y|x)$, where the expected value of $Y(x)$ is $M(x)$. That is,

$$\mathrm{E}(Y|x) = \int_{-\infty}^{\infty} y(x)\,\mathrm{d}F(y|x) = M(x) < \infty, \quad (1)$$

for all x. The principal idea is to determine the value of θ by successive approximation.

To this end, suppose $\{X_n\}$, $n \geq 1$ is a sequence of random variables wherein X_1 is selected arbitrarily and, upon its selection, the succeeding values are defined by

$$X_{n+1} = X_n - a_n[Y(X_n) - m_0], \quad (2)$$

where $\{na_n\}$ is a sequence of bounded, positive constants. Robbins & Munro [26] proved that X_n converges to θ, stochastically, $(X_n \xrightarrow{\mathrm{p}} \theta)$ as $n \to \infty$ provided the following conditions hold:

1. there exists a θ, such that $M(\theta) = m_0$,
2. $Y(x)$ is uniformly bounded for all x, almost surely,
3. var $X_1 < \infty$,

and

4. $M(x)$ is nondecreasing and $M'(\theta) > 0$.

Since the original development by Robbins & Munro [26], there has been a myriad of refinements, improvements and significant advances in stochastic approximation. While not an all-inclusive list, the following synopsis provides some of the more important results that have accrued since 1952.

1. Wolfowitz [35] shows that condition 2 can be replaced with the weaker conditions that $M(x)$ is uniformly bounded for all x as is $\mathrm{E}[Y - M(x)]^2$. He also gives conditions under which condition 4 can be relaxed.
2. Kiefer & Wolfowitz [18], using ideas of both Robbins & Munro [26] and Wolfowitz [35], obtain a stochastic approximation procedure for finding the maximum of a regression function.
3. In 1954, Blum [1] is able to weaken, further, conditions that were considered in [18] and [35]. He also solves a similar problem when $M(x)$ is the median rather than the mean of the cdf $F(y|x)$. Further, Kallianpur [16] obtains an estimate of the order of magnitude of the nth iteration x_n in terms of $\mathrm{E}(x_n - \theta)^2$. Finally, Blum [2] considers multivariate stochastic approximation procedures.
4. Subsequently, Dvoretzky [7] develops a more general stochastic approximation scheme that includes both the Robbins–Munro and Kiefer–Wolfowitz procedures as special cases. Blum [1] also obtains a generalized version of the Robbins–Monro process that is related to the Dvoretzky procedure.
5. Issues, such as stopping rules, constrained optimization, and asymptotic normality, have been considered by several authors. Further information, including relevant references, can be obtained in [29].

Applications

Stochastic approximation has been used, to some extent, in the biomedical sciences. In particular, **neural network** research has been the focus of many of these applications.

Table 1 provides a selection of some of the biomedical studies that have used stochastic

Stochastic Limit and Order Relations

The O and o notation for nonstochastic functions and sequences (*see* **Orders of Magnitude**) can be generalized to stochastic **random variables**, leading to the O_p and o_p notation. The stochastic order relations were derived originally by Mann & Wald [2], and discussed by Chernoff [1] and Pratt [3].

Assume that $\{X_n\}$ is a sequence of random variables on the extended real line $[-\infty, \infty]$, with probability distribution $\{P_n\}$. Let a_n denote a sequence of points on $[-\infty, \infty]$.

Definition 1. We write $X_n = o_p(a_n)$ if, for every $\eta > 0$,

$$P_n\left\{\left|\frac{X_n}{a_n}\right| \leq \eta\right\} \to 1 \text{ as } n \to \infty.$$

That is, the sequence $\{|X_n/a_n|\}$ approaches zero in probability. Note that $X_n = o_p(1)$ is also written: $X_n \xrightarrow{\text{p}} 0$.

Definition 1 is equivalent to Definition 1′ as follows.

Definition 1′. $X_n = o_p(a_n)$ if, for every positive ε and η, there exists an N such that

$$P_n\left\{\left|\frac{X_n}{a_n}\right| \leq \eta\right\} \geq 1 - \varepsilon, \quad \text{for } n > N.$$

Definition 1′ has a suitable analog for the O_p notation as follows.

Definition 2. We write $X_n = O_p(a_n)$ if, for every positive ε, there exist N and $\eta > 0$ such that

$$P_n\left\{\left|\frac{X_n}{a_n}\right| \leq \eta\right\} \geq 1 - \varepsilon, \quad \text{for } n > N.$$

That is, the sequence $\{X_n/a_n\}$ is *bounded in probability*.

The following theorems, derived by Pratt [3], are useful in derivations of large sample theory and rate of convergence for approximations.

Theorem. If $Y_n - Z_n = o_p(1)$, $Z_n = O_p(1)$, and g is a continuous function, then $g(Y_n) - g(Z_n) = o_p(1)$.

Theorem. If $Y_n - Y = o_p(1)$ and $Z_n - Z = o_p(1)$, and $f(y, z)$ is jointly continuous, then $f(Y_n, Z_n) - f(Y, Z) = o_p(1)$.

Example: Normal Approximation for the Binomial Distribution

Assume that $X \sim \text{Bin}(n, \pi)$ is a **binomial** random variable with index n and probability π. Then all cumulants of X (*see* **Characteristic Function**) are $O(n)$ and

$$\frac{X - n\pi}{[n\pi(1-\pi)]^{1/2}} \sim \text{N}(0, 1) + O_p(n^{-1/2}).$$

MEI-LING TING LEE

Stochastic Processes

Time, life, and risks are three basic elements in empirical processes studied in biostatistical research. Risks of birth, risks of illness, risks of death, and other risks continuously act on human beings with varying degrees of intensity and varying degrees of frequency. Recent advances in stochastic processes have made it possible to study systematically these risks in the human population from a probabilistic point of view. Many have contributed to the theoretical development of stochastic processes to the high level of sophistication they enjoy today. Among them we mention Markov, **Kolmogorov** [22, 23], Feller [17], Doob [13, 14], and Chung [12]. The purpose of this article is to review various processes which have applications in biostatistical and epidemiologic research. Solutions are given for most problems described here, but theoretical justifications may not always be adequate. For the reader who will not take a formula or a theorem at face value without a formal proof, further references are given.

The order of presentation in this article is from discrete processes to continuous processes. The major form of discrete process is the **Markov chain**. In continuous processes, we proceed from a general birth process through the birth–death processes to the finite **Markov process**. A few special topics of interest are discussed in the sections between these on the birth processes and the birth–death processes. We end this brief introduction with a definition:

A stochastic process $\{X(t); t \in [0, \infty)\}$ *is a family of random variables describing an empirical process, whose development is governed by probability laws.* The parameter t, which is often interpreted as time, is real-valued, but it may be either discrete or continuous. The **random variable** $X(t)$ may be real- or complex-valued, or it may take the form of a vector. In diffusion processes, for example, both t and $X(t)$ are continuous variables, whereas in Markov chains, t and $X(t)$ take on discrete values. In the processes of **population growth**, time t is a continuous parameter, but the random variable $X(t)$, the population size at time t, has a discrete set of positive integers.

In some stochastic processes the one-dimensional time parameter is replaced by a multidimensional parameter, such as the coordinates of a point in multidimensional space. These are called *random fields*. A simple example would be a process describing the random fluctuations in some variable observed at points on a two-dimensional surface. The term may be applied also to more complex generalizations (see [1]).

Random Walk

The one-dimensional random walk is an extension of Bernoulli trials (*see* **Binary Data**). It is closely related to **branching processes** and to gambler's ruin in probability theory (see, for example, [27] and [17]), to **Brownian motion and diffusion processes**, to **sequential analysis** [28], and to sequential clinical trials [2] (*see* **Data and Safety Monitoring**). It is presented here as a prelude to the discrete-time Markov chains.

Position of Particle

In a one-dimensional random walk of a particle starting from the origin, the position of the particle is designated by $\pm 1, \pm 2, \ldots$. Let X_i be the outcome of the ith move, with $\Pr\{X_i = +1\} = p$ and $\Pr\{X_i = -1\} = q$, where $p + q = 1$. The expectation of X_i is $\mathrm{E}[X_i] = p - q$, and the variance of X_i is $\mathrm{var}(X_i) = 4pq$. The probability **generating function** of X_i is

$$g_i(s) = ps + qs^{-1}.$$

Let $Z_n = X_1 + \cdots + X_n$ be the position of the particle after n moves. We need the probability $\Pr\{Z_n = k\}$. The probability generating function of Z_n is

$$G_{Z_n}(s) = [ps + qs^{-1}]^n = s^{-n}[ps^2 + q]^n$$
$$= \sum_{i=0}^{n} \binom{n}{i} p^i q^{n-i} s^{2i-n}.$$

Substituting $k = 2i - n$ so that $i = (n + k)/2$, we find

$$\Pr\{Z_n = k\} = \binom{n}{\frac{n+k}{2}} p^{(n+k)/2} q^{(n-k)/2},$$

with expectation $\mathrm{E}(Z_n) = n(p - q)$ and variance $\mathrm{var}(Z_n) = 4npq$. The values that Z_n assumes may be odd numbers or even numbers depending on whether n is odd or even. When n is an odd number, the probability that Z_n will assume even values

is zero. When n is an even number, the probability that Z_n will take on odd values is zero. For Z_n to assume a value k, the particle must take $(n+k)/2$ steps to the right and $(n-k)/2$ steps to the left so that $[(n+k)/2-(n-k)/2]=k$ is the net displacement to the right of the origin. Of course, k can be either positive or negative. When $Z_n=0$, the particle returns to the origin. When n is odd, the probability of the particle returning to the origin is zero. When n is even,

$$\Pr\{Z_n=0\}=\binom{n}{\frac{n}{2}}p^{n/2}q^{n/2}.$$

We now consider two extensions of the simple random walk.

Limiting Case of a Diffusion Process

The notion involved in the random walk is clear and the mathematics is simple. It is therefore quite helpful to use the random walk to explain rather more subtle concepts of Brownian movement and diffusion processes. When both the size of step and the time needed to make a move are infinitesimal, the density function of the total displacement up to time t is continuous and satisfies a partial differential equation, known as the Fokker–Planck diffusion equation. While a direct approach to establishing the differential equation from the viewpoint of diffusion processes is somewhat difficult, as a limiting case of the random walk the differential equation becomes logical (*see* **Brownian Motion and Diffusion Processes**).

Two-Dimensional Random Walk

The one-dimensional random walk presented in this section can be extended to a random walk in a two-dimensional plane or in a high-dimensional space. In a two-dimensional random walk, let X_{ij} be the outcome of the jth move in the ith coordinate, with $\Pr\{X_{ij}=+1\}=p_i$ and $\Pr\{X_{ij}=-1\}=q_i$, where $p_i+q_i=1$, for $i=1,2$ and $j=1,2,\ldots$. Let $Z_{in}=\sum_j^n X_{ij}$ be the total displacement on the ith axis after n moves. The probability $\Pr\{Z_{in}=k_i\}$ is computed separately for each coordinate i. The total displacements in the two coordinates are represented by the vector $\mathbf{Z}_n=(Z_{1n},Z_{2n})$. Therefore, the whole extension process is quite simple, and can carry over to a random walk in any high-dimensional space.

The components Z_{1n} and Z_{2n}, however, should not be treated as independent random variables in a bivariate vector. They are merely the coordinates of the particle after n moves. Furthermore, the particle will not reach everywhere in the two-dimensional plane. It will reach only those positions where the sum, in absolute values, of Z_{1n} and Z_{2n} is zero or a multiple of 2. For example, the particle could be in a position with coordinates (3, 5), or (−3, 5), but not in a position with coordinates (4, 5), or (3, 6).

Combining the above two extensions, we see that a continuous-time random walk in a three-dimensional space will be a close description of Brownian movement, since that describes phenomena in three-dimensional space.

Gambler's Ruin

Two players A and B, with their initial a and b, play a series of games. Their respective probabilities of winning a game are p and q. We seek to determine the probability, R_a, that the ruin of player A will eventually occur and the probability, R_b, that the ruin of player B will eventually occur, if the game is to be played until one of them becomes bankrupt. In the language of the random walk, these are the probabilities that a particle will be absorbed at the barriers $x=0$ and $x=a+b$, respectively.

To determine the probability of A's ruin, R_a, we first establish, and then solve, a system of difference equations. Consider more generally R_x, the probability of A's ruin when his capital is x, and establish a difference equation as the result of the first subsequent move. Gambler A may win the game with a probability p and then his probability of ruin will be R_{x+1}, or he may lose the game with a probability q and then his ruin probability will be R_{x-1}. It follows that

$$R_x=pR_{x+1}+qR_{x-1},\quad x=1,2,\ldots,a+b-1,$$

which has the general solution

$$R_x=c+d\left(\frac{q}{p}\right)^x.$$

The constants c and d are to be determined by the boundary conditions. If $x=0$, then A's ruin is certain; if $x=a+b$, then A's ruin is impossible.

Therefore the boundary conditions are $R_0 = 1$ and $R_{a+b} = 0$. Using these conditions, we find

$$R_x = \frac{(q/p)^x - (q/p)^{a+b}}{1 - (q/p)^{a+b}}.$$

When $x = a$, the probability of A's ruin is

$$R_a = \frac{(q/p)^a - (q/p)^{a+b}}{1 - (q/p)^{a+b}}.$$

Similarly, the probability of B's ruin is

$$R_b = \frac{1 - (q/p)^a}{1 - (q/p)^{a+b}}.$$

Since $R_a + R_b = 1$, it is certain that either A or B will eventually lose all his initial capital. An infinite series of games should not be expected.

When $p = q = 1/2$, we use L'Hôpital's rule to obtain the probabilities

$$R_a = \frac{b}{a+b} \quad \text{and} \quad R_b = \frac{a}{a+b}.$$

Expected Gain

R_a and R_b are the probabilities of A's gain of $-a$ and $+b$, respectively. Hence, his expected gain is:

$$\mathrm{E}(G) = -aR_a + bR_b.$$

When $a = b$,

$$\mathrm{E}[G] = a\frac{1 - (q/p)^a}{1 + (q/p)^a}.$$

In this case $\mathrm{E}[G] > 0$ if $q < p$, and $\mathrm{E}[G] < 0$ if $p < q$. When $p = q = 1/2$, $\mathrm{E}[G] = 0$.

The probabilities R_a and R_b depend not only on the probability of losing or winning a single game, but also on the amount of a player's initial capital. Suppose B is so enormously rich that $b = \infty$. Taking the limit in the formula of R_a as $b \to \infty$ yields the probability of A's eventual ruin:

$$R_a = \begin{cases} 1, & \text{if} \quad p < q, \\ 1, & \text{if} \quad p = q, \\ \left(\dfrac{q}{p}\right)^a, & \text{if} \quad p > q. \end{cases}$$

The second case above is interesting. Even if the game is fair ($p = q$), A's eventual ruin is certain simply because B is much richer than he is.

Expected Number of Games (Duration of Play)

Suppose that player A has an initial capital of x; the series of games ends as soon as either A loses all his capital or his capital becomes $a + b$. Let D_x be the expected number of games to be played. It is easy to show that D_x satisfies the following difference equation:

$$D_x = pD_{x+1} + qD_{x-1} + 1, \quad x = 1, 2, \ldots, a + b - 1.$$

The series terminates when $x = 0$ or $x = a + b$. Therefore the boundary conditions are $D_0 = 0$ and $D_{a+b} = 0$. The above difference equation is almost the same as the equation for R_x, except for the addition of unity. This addition makes the equation nonhomogeneous. Clearly, $D_x = x/(q - p)$ is a solution. The general solution of the equation is the sum:

$$D_x = \frac{x}{q-p} + \left[c + d\left(\frac{q}{p}\right)^x\right].$$

Using the boundary conditions $D_0 = 0$ and $D_{a+b} = 0$ to determine the constants c and d, we find the solution

$$D_x = \frac{x}{q-p} - \frac{a+b}{q-p}\left[\frac{1 - (q/p)^x}{1 - (q/p)^{a+b}}\right].$$

The expected number of games depends on the values of p and q. For given $a + b$ and x, D_x increases as p (and q) approaches 1/2. When $p = q = 1/2$, the expected number of games is $D_x = x(a + b - x)$. The expected number takes a maximum value of $D_x = [(a + b)/2]^2$ when $x = (a + b)/2$. If $a = \$100$ and $b = \$100$, and A and B play a series of fair games at a stake of \$1 per game, they will, on average, be expected to play 10 000 games before either one of them loses his entire capital.

Markov Chains

Most statistical and probability theory has been developed for cases where the random variables involved are independent. The classical **central limit theorem** and the **law of large numbers** are prominent examples. In many practical situations, however, the random variables involved are neither independent nor identically distributed. Such phenomena are especially prevalent when the observations are made in sequence.

For example, in sampling without replacement from a dichotomous population consisting of "successes" and "failures", the probability of choosing a "success" is a function of the previous elements sampled. In the random walk discussed in the previous section, the location of a particle after a given move depends on the previous moves. In the Markov chain, we study dependence of a particular kind. When random variables are observed in sequence, the distribution of a random variable is dependent on only the immediately preceding observed random variable and not on those that came before it.

The theory of Markov chains, or discrete-time Markov processes, is named after A.A. Markov, who in 1907 introduced the concept of chains with a discrete parameter and finite number of states. Kolmogorov [23] extended the theory for the denumerable case; Doob [13] and Paul Levy in 1951 introduced continuous-parameter chains. While many others have contributed to the advancement of Markov theory, W. Feller and K.L. Chung are among those responsible for the present status in probability theory that the Markov chain enjoys. Chung [12] gave a comprehensive theoretical treatment of the subject, and Feller [17] gave a most lucid account of both theoretical and practical aspects of Markov chains.

The purpose of this section is to introduce the Markov chain from a practical point of view. Included are the essentials necessary for an understanding and appreciation of the topic. A good reference is [17]; see also [10]. For further discussion, see the article on **Markov Chains**.

Definition 1. A sequence of random variables $\{X_\alpha, \alpha = 0, 1, \ldots\}$ is called a Markov chain if, for every collection of integers, $\alpha_0 < \alpha_1 < \cdots < \alpha_n < \beta$, the conditional distributions of X_β satisfy the relation:

$$\Pr\{X_\beta = i_\beta | X_{\alpha_0}, \ldots, X_{\alpha_n}\} = \Pr\{X_\beta = i_\beta | X_{\alpha_n}\}, \quad \text{for all } i_\beta. \tag{1}$$

Thus, given a knowledge of the present state (X_{α_n}), the outcome in the future $(X_\beta = i_\beta)$ is no longer dependent upon the past $(X_{\alpha_0}, \ldots, X_{\alpha_{n-1}})$.

Absolute Probabilities and Transition Probabilities

We denote for each X_α the absolute probability by

$$\Pr\{X_\alpha = i_\alpha\} = a_{i_\alpha}, \tag{2}$$

and for every pair of random variables X_α and $X_\beta, \alpha < \beta$, the transition (conditional) probability by

$$\Pr\{X_\beta = i_\beta | X_\alpha = i_\alpha\} = P_{i_\alpha, i_\beta}, \tag{3}$$

with the conditions that

$$\sum_{i_\alpha} \Pr\{X_\alpha = i_\alpha\} = \sum_{i_\alpha} a_{i_\alpha} = 1 \quad \text{and}$$

$$\sum_{i_\beta} P_{i_\alpha, i_\beta} = 1.$$

Therefore, the joint probabilities of $X_\alpha, X_\beta, X_\gamma$, for $\alpha < \beta < \gamma$, are given by

$$\Pr\{X_\alpha = i_\alpha, X_\beta = i_\beta, X_\gamma = i_\gamma\} = a_{i_\alpha} P_{i_\alpha, i_\beta} P_{i_\beta, i_\gamma}.$$

Generally, for any collection of integers $\alpha < \beta < \cdots < \delta < \varepsilon$ the joint probabilities are

$$\Pr\{X_\alpha = i_\alpha, X_\beta = i_\beta, \ldots, X_\delta = i_\delta, X_\varepsilon = i_\varepsilon\} = a_{i_\alpha} P_{i_\alpha, i_\beta} \ldots P_{i_\delta, i_\varepsilon}. \tag{4}$$

An important feature of the Markov chain, and indeed of stochastic processes in general, is that the random variables are observed in sequence and the order of the sequence, such as the one in (4), should not be disturbed. In a Markov chain describing a stochastic process, the totality of possible values of random variables X_α constitute the state space of the system. The event associated with the absolute probability in (2) is that the system is in state i_α at time α (or the αth step). The conditional probability in (3) describes a transition from state i_α at α to state i_β at β. A Markov chain with state space being the set of all the nonnegative integers is completely determined by the initial absolute probability distribution

$$\Pr\{X_0 = i_0\} = a_{i_0}, \quad i_0 = 1, 2, \ldots$$

and the transition probabilities

$$\Pr\{X_{\alpha+1} = i_{\alpha+1} | X_\alpha = i_\alpha\} = P_{i_\alpha, i_{\alpha+1}}, \quad i_\alpha, i_{\alpha+1} = 1, 2, \ldots \text{ for } \alpha = 0, 1, \ldots.$$

Example 1. Life Table Urns

Balls are drawn with replacement from an infinite sequence of urns numbered $0, 1, \ldots$. In the αth urn, there is a proportion p_α of white balls and a proportion q_α of black balls with $0 < p_\alpha < 1$ and $p_\alpha + q_\alpha = 1$. Beginning with the 0th urn, $X_0 = i_0$ balls are drawn of which $X_1 = i_1$ are white; a total of i_1 balls is drawn from the first urn of which $X_2 = i_2$ are white; i_2 balls are then drawn from the second urn of which $X_3 = i_3$ balls are white, and so on. In general, the number $X_{\alpha+1} = i_{\alpha+1}$ of white balls drawn from the αth urn is the number of balls to be drawn from the $(\alpha + 1)$th urn. The experiment terminates as soon as the number of white balls drawn from an urn is zero. Clearly, X_1, the number of white balls drawn from the 0th urn, has a **binomial distribution**:

$$\Pr\{X_1 = i_1 | i_0\} = \binom{i_0}{i_1} p_0^{i_1} q_0^{i_0 - i_1}, \quad i_1 = 0, \ldots, i_0.$$

The number of white balls drawn (X_2) from the first urn depends only on the number of drawings (X_1) from that urn but not on i_0. Therefore, given $X_0 = i_0$, $X_1 = i_1$, the probability of X_2 is

$$\begin{aligned} \Pr\{X_2 = i_2 | i_0, i_1\} &= \Pr\{X_2 = i_2 | i_1\} \\ &= p_{i_1, i_2} = \binom{i_1}{i_2} p_1^{i_2} q_1^{i_1 - i_2}, \\ & \quad 0 \le i_2 \le i_1 \le i_0. \end{aligned}$$

Generally,

$$\begin{aligned} &\Pr\{X_\beta = i_\beta | i_0, \ldots, i_\alpha\} = \Pr\{X_\beta = i_\beta | i_\alpha\} = P_{i_\alpha, i_\beta}, \\ &\quad i_\alpha > 0; i_\beta = 0, \ldots, i_\alpha. \end{aligned}$$

This urn model was devised to describe the **life table** where X_0 was the size of the original cohort with which a life table starts. The number X_α is the number of people of exact age α, and $X_{\alpha+1}$ is the number surviving to the end of the αth age interval.

Time-Homogeneous Markov Chains

A Markov chain is homogeneous with respect to time if the transition probabilities

$$\Pr\{X_{\alpha+1} = j | X_\alpha = i\} = p_{ij} \tag{5}$$

are independent of α. We shall be studying mainly time-homogeneous Markov chains in this section. A chain is a finite chain if there are a finite number of states, an infinite chain if there are an infinite number of states. In any case, the transition probabilities p_{ij} can be arranged in the form of a matrix

$$\mathbf{P} = \begin{pmatrix} p_{11} & p_{12} & p_{13} & \cdots \\ p_{21} & p_{22} & p_{23} & \cdots \\ . & . & . & \cdots \\ . & . & . & \\ . & . & . & \cdots \end{pmatrix} \tag{6}$$

if the state space contains $1, 2, \ldots$, or

$$\mathbf{P} = \begin{pmatrix} p_{00} & p_{01} & p_{02} & \cdots \\ p_{10} & p_{11} & p_{12} & \cdots \\ . & . & . & \cdots \\ . & . & . & \cdots \end{pmatrix}$$

if the state space contains nonnegative integers. These matrices are known as *stochastic matrices* with transition probabilities p_{ij} as their elements. The subscripts of each probability are the states associated with a transition from i to j. Given $X_\alpha = i$,

$$\sum_j \Pr\{X_{\alpha+1} = j | X_\alpha = i\} = \sum_j p_{ij} = 1,$$

so that each row sum in a stochastic matrix is unity.

When a system has only two states, denoted by (1,0), they may represent occurrence and nonoccurrence of an event E. In this case, p_{01} is the passage probability to the occurrence of E, and p_{11} is the recurrence probability of event E. The process becomes a **renewal**, or recurrence, process.

Example 2. Gambler's Ruin

The possible states of the system, which range from 0 to $a + b$, represent the amount of money that player A may possess during the course of the game. For $0 < i < a + b$, $p_{i,i+1} = p$ and $p_{i,i-1} = q$; and the game ends at 0 or $a + b$. The $(a + b + 1) \times (a + b + 1)$ transition probability matrix is

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 & 0 & \ldots & 0 & 0 & 0 \\ q & 0 & p & 0 & \ldots & 0 & 0 & 0 \\ 0 & q & 0 & p & \ldots & 0 & 0 & 0 \\ . & . & . & . & \ldots & . & . & . \\ . & . & . & . & \ldots & . & . & . \\ . & . & . & . & \ldots & . & . & . \\ 0 & 0 & 0 & 0 & \ldots & q & 0 & p \\ 0 & 0 & 0 & 0 & \ldots & 0 & 0 & 1 \end{pmatrix}.$$

Example 3. The Ehrenfest Model of Diffusion

This model has $s+1$ states: $0, 1, 2, \ldots, s$. Transitions are possible only for one step to the right or one step to the left, with the respective probabilities $p_{j,j+1} = 1 - j/s$ and $p_{j,j-1} = j/s$, for $j = 0, 1, \ldots, s$. The transition probability matrix is:

$$\mathbf{P} = \begin{pmatrix} 0 & 1 & 0 & 0 & \ldots & 0 & 0 \\ \frac{1}{s} & 0 & \frac{1-1}{s} & 0 & \ldots & 0 & 0 \\ 0 & \frac{2}{s} & 0 & \frac{1-2}{s} & \ldots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \ldots & \cdot & \cdot \\ 0 & 0 & 0 & 0 & \ldots & 0 & \frac{1}{s} \\ 0 & 0 & 0 & 0 & \ldots & 1 & 0 \end{pmatrix}.$$

This model originally was described by P. & T. Ehrenfest [15] as a conceptual urn experiment where s molecules are distributed in two containers A and B. At each trial a molecule is chosen at random and moved from its container to the other. The state of the system is the number of molecules in A. Feller [17] interpreted the Ehrenfest experiment as a diffusion process with a central force in the sense that the transition probability $p_{j,j+1}$ is greater than or less than 1/2 depending on whether j is less than or greater than 1/2.

Example 4. The Bernoulli–Laplace Model of Diffusion

This model was proposed by D. Bernoulli in 1769 and analyzed by Laplace in 1812 as a probabilistic analog for the flow of two incompressible liquids between two urns. There are $2s$ particles in total, of which s are white and s are black. The system is in state k if there are k white particles in the first urn. At each trial one particle is taken from each urn and they are interchanged. The transition probabilities are:

$$p_{j,j-1} = \left(\frac{j}{s}\right)^2, \qquad p_{j,j} = \frac{2j(s-j)}{s^2},$$

$$p_{j,j+1} = \left(\frac{1-j}{s}\right)^2,$$

so that $p_{j,j-1} + p_{j,j} + p_{j,j+1} = 1$, for $j = 0, 1, \ldots, s$. The corresponding transition probability matrix $\mathbf{P}$ is $(s+1) \times (s+1)$. With the exception of the 0th row and the sth row, the matrix $\mathbf{P}$ has the probabilities $p_{j,j}$ on the diagonal line, $p_{j,j+1}$ on the upper diagonal line, and $p_{j,j-1}$ on the lower diagonal line, and zeros elsewhere. The 0th row is $(0, 1, 0, \ldots, 0)$ and the sth row is $(0, 0, \ldots, 0, 1, 0)$. For details, see [17].

High-Order Transition Probabilities $p_{ij}(n)$

The transition probability p_{ij} defined in (5) is associated with a transition taking place in one step, from $X_\alpha = i$ to $X_{\alpha+1} = j$. When a transition from i to j takes place in n steps, we have an n-step transition probability:

$$\Pr\{X_{\alpha+n} = j | X_\alpha = i\} = p_{ij}(n).$$

The matrix $\mathbf{P}(n)$, with $p_{ij}(n)$ as its elements, is related to $\mathbf{P}(1)$ by

$$\mathbf{P}(n) = [\mathbf{P}(1)]^n.$$

Classification of States

Transition from one state to another is not always possible, depending upon the type of states. The state j is said to be *reachable* from state i if there exists some positive integer n such that the probability $p_{ij}(n) > 0$, and we write $i \to j$. For $n = 0$, we define $p_{ii}(0) = 1$ and $p_{ij}(0) = 0$ for $j \neq i$. If state j is reachable from state i and state i is reachable from state j, the two states are said to be *communicative*, and we write $i \leftrightarrow j$. If state k is reachable from state j and state j is reachable from state i, then state k is reachable from state i. It is clear that the communication relation has the following properties:

1. Reflexivity: $i \leftrightarrow i$, as $p_{ii}(0) = 1$.
2. Symmetry: if $i \leftrightarrow j$, then $j \leftrightarrow i$.
3. Transitivity: if $i \leftrightarrow j$ and $j \leftrightarrow k$, then $i \leftrightarrow k$.

Therefore, the communication relation is an equivalence relation.

For every two states i and j, $p_{ij}(n)$ is the probability that, starting from state i, the system will enter

state j at the nth step, regardless of the number of entrances into j prior to n. Now we introduce the probability that state j is reached for the first time at the nth step, or the *first passage probability*:

$$f_{ij}(n) = \Pr\{X_n = j \quad \text{and} \quad X_m \neq j; \\ m = 1, \ldots, n-1 | X_0 = i\}.$$

The two types of probability are related as follows:

$$p_{ij}(n) = \sum_{\ell=1}^{n} f_{ij}(\ell) p_{jj}(n-\ell) \quad \text{and}$$

$$f_{ij}(n) = p_{ij}(n) - \sum_{\ell=1}^{n-1} f_{ij}(\ell) p_{jj}(n-\ell).$$

The sum

$$\sum_{n=1}^{\infty} f_{ij}(n) = f_{ij}$$

is the probability that, starting from state i, a system will enter j eventually. If $f_{ij} = 1$, the sequence $\{f_{ij}(n)\}$ is the probability distribution of the first passage time to state j. In this case, the expectation

$$\mu_{ij} = \sum_{n=1}^{\infty} n f_{ij}(n)$$

is the mean passage time from state i to state j.

When $j = i$, we have the first return (recurrence) probability at the nth step,

$$f_{ii}(n) = \Pr\{X_n = i \quad \text{and} \quad X_m \neq i; m = 1, \ldots, \\ n-1 | X_0 = i\}, \quad n = 1, 2, \ldots.$$

The probabilities $p_{ii}(n)$ and $f_{ii}(n)$ are related by the following two formulas:

$$p_{ii}(n) = \sum_{\ell=1}^{n} f_{ii}(\ell) p_{ii}(n-\ell) \quad \text{and}$$

$$f_{ii}(n) = p_{ii}(n) - \sum_{\ell=1}^{n-1} f_{ii}(\ell) p_{ii}(n-\ell).$$

The sum

$$\sum_{n=1}^{\infty} f_{ii}(n) = f_{ii}$$

is the probability of eventual return to the original state i.

Now we introduce various types of state in terms of the passage probabilities and the return probabilities.

1. *Transient state*. A state i is called a transient state if $f_{ii} < 1$. In this case there is a positive probability $1 - f_{ii}$ that, starting from state i, a system will not return to state i in a finite number of steps.
2. *Recurrent state*. A state i is called a recurrent state if $f_{ii} = 1$. In this case, the sequence $\{f_{ii}(n)\}$ represents the probability distribution of the first return (recurrence) time. The expectation
$$\mu_{ii} = \sum_{n=1}^{\infty} n f_{ii}(n)$$
is the mean recurrence time for state i.
3. *Recurrent null state and recurrent nonnull state*. A recurrent state i is called a null state if the expectation $\mu_{ii} = \infty$, and a nonnull state if $\mu_{ii} < \infty$.
4. *Periodic state and aperiodic state*. A state i is periodic with period $t > 1$ if $p_{ii}(n) = 0$ except for $n = t, 2t, \ldots$, where t is the largest integer with this property. In the gambler's ruin problem, the event that a player will break even has a period of $t = 2$: his winnings can only be zero at the nth game for $n = 2, 4, \ldots$. The number of white balls drawn from an urn in the life table example is aperiodic.
5. *Ergodic state*. An aperiodic recurrent state with a finite recurrence time is an ergodic state.
6. *Absorbing state*. A state i is an absorbing state if and only if $f_{ii}(1) = 1$. Clearly, if i is an absorbing state, $f_{ii} = 1, \mu_{ii} = 1$.

The types of state may be defined also in terms of the probabilities $p_{ii}(n)$ and $p_{ij}(n)$. The following theorems in effect further express the relations between $f_{ii}(n)$ and $p_{ii}(n)$ by way of these definitions.

Theorem 1. State j can be reached from state i if and only if $f_{ij} > 0$; states i and j communicate if and only if $f_{ij} f_{ji} > 0$.

Theorem 2. State i is transient if and only if $\sum_{n=0}^{\infty} p_{ii}(n) < \infty$, and is recurrent if the infinite sum diverges.

Theorem 3. If state j is transient, then $\sum_{n=1}^{\infty} p_{ij}(n) < \infty$, and in this case $\lim_{n\to\infty} p_{ij}(n) = 0$.

Closed Sets and Irreducible Markov Chains

Closed Set. A set C of states is closed if for every i in C

$$\sum_{j\in C} p_{ij} = 1,$$

where the summation is taken over all states j belonging to the set C. Generally, for every $n \geq 1$

$$\sum_{j\in C} p_{ij}(n) = 1.$$

Therefore, any closed subset of a system can be studied independently of all other states.

The totality of all states that can be reached from a given state i form a closed set. A closed set may contain states which do not communicate. A closed set of communicating states is a *class*. If C is a class, then for every pair i and j in C, there exists a positive integer n for which $p_{ij}(n) > 0$. An absorbing state is considered a class.

Irreducible Chain. A Markov chain is called an irreducible chain if there exists no closed subset other than the set of all states.

Theorem 4. In an irreducible Markov chain every state can be reached from every other state.

Theorem 5. The states in a class are of the same type; they are either all transient or all recurrent null or all ergodic.

Corollary. The states in an irreducible Markov chain are of the same type.

Theorem 6. All states of a class have the same period.

Corollary. All states in an irreducible Markov chain have the same period.

Ergodic Chain. An irreducible Markov chain with ergodic states is called an ergodic chain.

The above concepts are illustrated by an example.

Example 5

The stochastic matrix $\mathbf{P}$ is given by

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{3}{8} & \frac{1}{6} & \frac{11}{24} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{3}{8} & \frac{1}{2} & \frac{1}{8} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \frac{1}{3} & \frac{2}{3} \\ 0 & 0 & 0 & 0 & 0 & 0 & \frac{2}{4} & \frac{1}{4} & \frac{1}{4} \\ 0 & 0 & 0 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2} & 0 \end{pmatrix}.$$

describes transitions in a system of nine states numbered from 1 to 9. We divide these states into four subsets: $C_1 = \{1\}$; $C_2 = \{2, 3\}$, $C_3 = \{4, 5, 6\}$; and $C_4 = \{7, 8, 9\}$. The set C_1 consists of a single absorbing state 1; it is a closed set and a class. In set C_2 states 2 and 3 communicate and both have a period $t = 2$; C_2 is closed and is a class. C_3 is also a closed set but not a class since neither states 5 nor state 6 can be reached from state 4. State 4 is a class and is a proper closed subset of C_3; the subset $\{5, 6\}$ is not a class because it is not closed. Finally, the set C_4 is closed and is a class where states 7, 8, and 9 communicate.

It is clear, then, that a Markov chain corresponding to subset C_2 is an irreducible chain with period $t = 2$, while a chain corresponding to subset C_3 is not an irreducible chain since C_3 contains a proper closed subset; neither is a chain corresponding to subset $\{5, 6\}$ is irreducible chain since the subset is not closed. A Markov chain corresponding to set C_4 obviously is irreducible.

To summarize, we have considered examples of the following types:

1. irreducible periodic chains – C_2;
2. chains which are not irreducible, because
   (i) the corresponding state set contains a proper closed subset – C_3, or
   (ii) the state set is not closed – $\{5, 6\}$;
3. irreducible and aperiodic chains – C_4.

The matrix $\mathbf{P}$ can be decomposed into four submatrices corresponding to these four subsets:

$$\mathbf{P} = \begin{pmatrix} \mathbf{P}_1 & 0 & 0 & 0 \\ 0 & \mathbf{P}_2 & 0 & 0 \\ 0 & 0 & \mathbf{P}_3 & 0 \\ 0 & 0 & 0 & \mathbf{P}_4 \end{pmatrix}, \tag{7}$$

where the zeros are matrices of various dimensions. The zeros in the first row, for example, (from left to right) are 1×2, 1×3, and 1×3 matrices (or row vectors), respectively. The nonzero submatrices are:

$$\mathbf{P}_1 = [1], \quad \mathbf{P}_2 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

$$\mathbf{P}_3 = \begin{pmatrix} 1 & 0 & 0 \\ \frac{3}{8} & \frac{1}{6} & \frac{11}{24} \\ \frac{3}{8} & \frac{1}{2} & \frac{1}{8} \end{pmatrix},$$

$$\mathbf{P}_4 = \begin{pmatrix} 0 & \frac{1}{3} & \frac{2}{3} \\ \frac{2}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{2} & \frac{1}{2} & 0 \end{pmatrix}.$$

each corresponds to a sub-Markov chain.

The matrix on the right-hand side of (7) having submatrices on the diagonal line and zeros elsewhere is known as a *quasi-diagonal matrix*. Direct computations show that the square of the matrix $\mathbf{P}$ is also a quasi-diagonal matrix with the squares of the submatrices on the diagonal line. In general, the nth power of a quasi-diagonal matrix $\mathbf{P}$ is also a quasi-diagonal matrix with the nth power of the submatrices on the diagonal line. In the present example,

$$\mathbf{P}^n = \begin{pmatrix} \mathbf{P}_1^n & 0 & 0 & 0 \\ 0 & \mathbf{P}_2^n & 0 & 0 \\ 0 & 0 & \mathbf{P}_3^n & 0 \\ 0 & 0 & 0 & \mathbf{P}_4^n \end{pmatrix}. \tag{8}$$

Relation (8) reveals interesting properties of transitions of a Markov chain. First, the states in different classes do not communicate: $p_{ik} = 0$ whenever i and k belong to two different classes. Second, for every i and j belonging to the same class C_α, the transition probabilities $p_{ij}(n)$ are computed from the corresponding submatrix only and are independent of the other matrices. This is true even if C_α is not a class (such as C_3) and the corresponding Markov chain is reducible. Therefore, a Markov chain may be studied in terms of individual subchains, each corresponding to a closed set of states.

Asymptotic Behavior of Transition Probabilities $p_{ij}(n)$

We have seen in the preceding section that the transient probabilities $p_{ij}(n)$ behave differently for different types of state. The following theorem describes the limiting probability of $p_{ij}(n)$ as $n \to \infty$.

Theorem 7. If state i is either transient or recurrent null, then $\lim_{n\to\infty} p_{ii}(n) = 0$. If state i is recurrent with period t, then $\lim_{n\to\infty} p_{ii}(n) = t/\mu_{ii}$, where μ_{ii} is the mean recurrent time for state i. If state i is ergodic, then $\lim_{n\to\infty} p_{ii}(n) = 1/\mu_{ii}$.

Theorem 8. If state j is either transient or recurrent null, then for all i $\lim_{n\to\infty} p_{ij}(n) = 0$; if state j is ergodic, then for all i $\lim_{n\to\infty} p_{ij}(n) = 1/\mu_{jj}$.

Stationary Distribution

Definition 2. A probability distribution $\{\pi_i\}$ is called *stationary* for a given Markov chain if it satisfies the relation

$$\pi_j = \sum_i \pi_i p_{ij}.$$

For a stationary distribution, we have, for any integer n,

$$\pi_j = \sum_i \pi_i p_{ij}(n).$$

Theorem 9. If all the states in an irreducible Markov chain are ergodic, then the limits

$$\lim_{n\to\infty} p_{ij}(n) = \pi_j$$

exist and are independent of the initial state i. Furthermore, $\pi_j > 0$,

$$\sum_j \pi_j = 1, \tag{9}$$

and the limiting distribution $\{\pi_j\}$ is stationary so that

$$\sum_i \pi_i p_{ij} = \pi_j. \tag{10}$$

Conversely, if a stationary distribution of an irreducible Markov chain exists and satisfies (9) and (10) then all the states of the Markov chain are ergodic and the stationary distribution is the limiting distribution of the chain.

It is easy to deduce from Theorems 8 and 9 that for each state j in an ergodic Markov chain,

$$\mu_{jj} = \frac{1}{\pi_j}. \tag{11}$$

Formulas for High-Order Transition Probabilities $p_{ij}(n)$

For a finite Markov chain having states $1, 2, \ldots, s$, and a stochastic matrix

$$\mathbf{P} = \begin{pmatrix} p_{11} & p_{12} & \cdots & p_{1s} \\ p_{21} & p_{22} & \cdots & p_{2s} \\ \vdots & \vdots & \cdots & \vdots \\ p_{s1} & p_{s2} & \cdots & p_{ss} \end{pmatrix}, \tag{6a}$$

with

$$\sum_{j=1}^{s} p_{ij} = 1, \quad i = 1, \ldots, s,$$

we introduce a characteristic matrix

$$\mathbf{A}(\lambda) = (\lambda \mathbf{I} - \mathbf{P}) = \begin{pmatrix} \lambda - p_{11} & -p_{12} & \ldots & -p_{1s} \\ -p_{21} & \lambda - p_{22} & \ldots & -p_{2s} \\ \vdots & \vdots & \ldots & \vdots \\ -p_{s1} & -p_{s2} & \ldots & \lambda - p_{ss} \end{pmatrix}, \tag{12}$$

where $\mathbf{I}$ is an $s \times s$ unit matrix. The determinant $|\mathbf{A}(\lambda)|$ is an s-degree polynomial in λ. The characteristic equation

$$|\mathbf{A}(\lambda)| = 0 \quad \text{or} \quad |\lambda \mathbf{I} - \mathbf{P}| = 0 \tag{13}$$

has s roots: $\lambda_1, \lambda_2, \ldots, \lambda_s$. These are known as the characteristic roots, or **eigenvalues**, of the matrix $\mathbf{P}$. The magnitude of these roots is given in the following theorem.

Theorem 10. The eigenvalues of the stochastic matrix $\mathbf{P}$ are not greater than unity in absolute value and one of the eigenvalue is $\lambda = 1$.

The cofactor of the (i, j)th element of the matrix $\mathbf{A}(\lambda)$, $A_{ij}(\lambda)$, is an $(s-1) \times (s-1)$ determinant after the ith row and the jth column are deleted from $\mathbf{A}(\lambda)$ and multiplied by $(-1)^{i+j}$.

When $\lambda = 1$, the cofactors of the elements in the same row of $\mathbf{A}(1)$ are equal:

$$A_{ij}(1) = A_{ii}(1), \quad i, j = 1, 2, \ldots, s.$$

The adjoint matrix of $\mathbf{A}(\lambda)$ is a matrix whose elements are the cofactors of $\mathbf{A}(\lambda)$, with the indices transposed: the element in the ith row and the jth column is $A_{ji}(\lambda)$, for $i, j = 1, 2, \ldots, s$.

Theorem 11. If the stochastic matrix $\mathbf{P}$ in (6) of a Markov chain has distinct eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_s$, then the nth-order transition probabilities are given by

$$p_{ij}(n) = \sum_{\ell=1}^{s} A_{ji}(\lambda_\ell) \lambda_\ell^n \frac{1}{\prod_{\substack{m=1 \\ m \neq \ell}}^{s} (\lambda_\ell - \lambda_m)}$$
$$i, j = 1, \ldots, s; n = 1, 2, \ldots. \tag{14}$$

Furthermore, the right-hand side of formula (14) is a real function of p_{ij} even if (13) has complex roots.

For the derivation of formula (14) and those in Theorem 11, see [10].

Limiting Probability Distribution

We have shown in Theorem 9 that the limiting probability distribution $\{\pi_j\}$ of an irreducible ergodic Markov chain exists and is stationary. We now provide explicit formulas for the limiting probabilities.

Theorem 12. Let $\mathbf{P}$ defined in (6) be the stochastic matrix of a finite ergodic Markov chain. The limiting probabilities

$$\lim_{n \to \infty} p_{ij}(n) = \pi_j, \quad i, j = 1, \ldots, s,$$

are given by

$$\pi_j = \frac{A_{jj}(1)}{\sum_{k=1}^{s} A_{kk}(1)}, \quad j = 1, \ldots s,$$

and the mean recurrence time by

$$\mu_{jj} = \frac{\sum_{k=1}^{s} A_{kk}(1)}{A_{jj}(1)}, \quad j = 1, \ldots, s,$$

where $A_{jj}(1)$ is the (j, j)th cofactor of the matrix $\mathbf{A}(1) = \mathbf{I} - \mathbf{P}$.

Theorem 12 also confirms the relation between the mean recurrence time μ_{jj} and the limiting probability π_j in formula (11).

Example 6

In a two-state Markov chain with the stochastic matrix:

$$\mathbf{P} = \begin{bmatrix} 1 - p_1 & p_1 \\ p_2 & 1 - p_2 \end{bmatrix},$$

where $0 < p_1 < 1$ and $0 < p_2 < 1$, the equation $|\lambda\mathbf{I} - \mathbf{P}| = 0$ admits two eigenvalues: $\lambda_1 = 1$ and $\lambda_2 = 1 - p_1 - p_2$. The differences between the eigenvalues are $\lambda_1 - \lambda_2 = p_1 + p_2$ and $\lambda_2 - \lambda_1 = -(p_1 + p_2)$, and the corresponding characteristic matrices are

$$\mathbf{A}(\lambda_1) = \begin{bmatrix} p_1 & -p_1 \\ -p_2 & p_2 \end{bmatrix},$$

$$\mathbf{A}(\lambda_2) = \begin{bmatrix} -p_2 & -p_1 \\ -p_2 & -p_1 \end{bmatrix}.$$

Substituting these values in formula (14) yields the final formula:

$$\mathbf{P}(n) = \begin{bmatrix} p_{11}(n) & p_{12}(n) \\ p_{21}(n) & p_{22}(n) \end{bmatrix} = \frac{1}{p_1 + p_2} \times \begin{bmatrix} p_2 + p_1(1 - p_1 - p_2)^n & p_1 - p_1(1 - p_1 - p_2)^n \\ p_2 - p_2(1 - p_1 - p_2)^n & p_1 + p_2(1 - p_1 - p_2)^n \end{bmatrix}.$$

Since $\lambda_1 = 1$, we find from $\mathbf{A}(\lambda_1) = \mathbf{A}(1)$ the limiting probabilities:

$$\pi_1 = \frac{p_2}{p_1 + p_2} \quad \text{and} \quad \pi_2 = \frac{p_1}{p_1 + p_2},$$

which can be obtained from $\mathbf{P}(n)$ as $n \to \infty$. Therefore the mean recurrence times for the two states are

$$\mu_{11} = \frac{p_1 + p_2}{p_2} \quad \text{and} \quad \mu_{22} = \frac{p_1 + p_2}{p_1}.$$

Example 7. An Application in Genetics

To describe the heredity process in a given locus (*see* **Mendel's Laws**) in terms of Markov chain, the number of A genes in the population is denoted by p and the number of a genes by q, with $p + q = 1$. The possible **genotypes**, AA, Aa and aa, are identified with the numbers 1, 2, and 3, respectively. The transition probability p_{ij} denotes the probability that an offspring will have genotype j given that a specific parent has a genotype i. Using a mother–son pair as an example, and when $i = 1$ and $j = 2$,

$$p_{12} = \Pr\{\text{the son will have genotype Aa}|\text{the mother has genotype AA}\} = q.$$

For the son to have the genotype Aa, he must inherit one A gene from his mother with probability one and acquire one a gene from the male population, through his father, with probability q. And this gene selection is the only possibility for the child to have the genotype Aa. Therefore $p_{12} = q$. Using a similar calculation, we find the other transition probabilities, and the following one-step transition probability matrix:

$$\mathbf{P}(1) = \begin{bmatrix} p_{11} & p_{12} & p_{13} \\ p_{21} & p_{22} & p_{23} \\ p_{31} & p_{32} & p_{33} \end{bmatrix} = \begin{bmatrix} p & q & 0 \\ \left(\frac{1}{2}\right)p & \frac{1}{2} & \left(\frac{1}{2}\right)q \\ 0 & p & q \end{bmatrix}$$

which is well known in **population genetics**. The matrix $\mathbf{P}(1)$ also shows that the corresponding Markov chain is an irreducible ergodic chain.

To find the n-step transition probabilities $p_{ij}(n)$, we first formulate a characteristic matrix:

$$\mathbf{A}(\lambda) = [\lambda\mathbf{I} - \mathbf{P}] = \begin{bmatrix} \lambda - p & -q & 0 \\ -\left(\frac{1}{2}\right)p & \frac{\lambda - 1}{2} & -\left(\frac{1}{2}\right)q \\ 0 & -p & \lambda - q \end{bmatrix}$$

From $|\mathbf{A}(\lambda)| = 0$, we find the eigenvalues: $\lambda_1 = 1, \lambda_2 = 1/2, \lambda_3 = 0$, so that $(\lambda_1 - \lambda_2)(\lambda_1 - \lambda_3) =$

$1/2$, $(\lambda_2 - \lambda_1)(\lambda_2 - \lambda_3) = -(1/2)^2$ and $(\lambda_3 - \lambda_1)(\lambda_3 - \lambda_2) = 1/2$.

For each eigenvalue, we formulate the corresponding characteristic matrix, compute the cofactors, and find the adjoint matrix. For $\lambda_1 = 1$,

$$\mathbf{A}(\lambda_1) = \mathbf{A}(1) = \begin{bmatrix} 1-p & -q & 0 \\ -\left(\frac{1}{2}\right)p & \frac{1-1}{2} & -\left(\frac{1}{2}\right)q \\ 0 & -p & 1-q \end{bmatrix},$$

and the adjoint matrix:

$$\|A_{ji}(1)\| = \begin{bmatrix} \left(\frac{1}{2}\right)p^2 & pq & \left(\frac{1}{2}\right)q^2 \\ \left(\frac{1}{2}\right)p^2 & pq & \left(\frac{1}{2}\right)q^2 \\ \left(\frac{1}{2}\right)p^2 & pq & \left(\frac{1}{2}\right)q^2 \end{bmatrix},$$

For $\lambda_2 = \dfrac{1}{2}$,

$$\mathbf{A}(\lambda_2) = \mathbf{A}\left(\frac{1}{2}\right) = \begin{bmatrix} \left(\frac{1}{2}\right)-p & -q & 0 \\ -\left(\frac{1}{2}\right)p & 0 & -\left(\frac{1}{2}\right)q \\ 0 & -p & \left(\frac{1}{2}\right)-q \end{bmatrix},$$

and the adjoint matrix:

$$\|A_{ji}\left(\frac{1}{2}\right)\| = \begin{bmatrix} -\left(\frac{1}{2}\right)pq & \left(\frac{1}{2}\right)q(p-q) & \left(\frac{1}{2}\right)q^2 \\ -\left(\frac{1}{2}\right)^2 p(p-q) & -\left(\frac{1}{2}\right)^2 (p-q) & -\left(\frac{1}{2}\right)^2 q(p-q) \\ \left(\frac{1}{2}\right)p^2 & -\left(\frac{1}{2}\right)p(p-q) & -\left(\frac{1}{2}\right)pq \end{bmatrix}.$$

In this problem, $\lambda_3 = 0$, so there is no contribution to $p_{ij}(n)$.

Now substituting the eigenvalues, the cofactors, and the products of the differences of eigenvalues in formula (14) for $p_{ij}(n)$, we find

$$\mathbf{P}(n) = \begin{bmatrix} p^2 + \frac{pq}{2}^{n-1} & 2pq + q(q-p)/2^{n-1} & q^2 - q^2/2^{n-1} \\ p^2 + p(q-p)/2^n & 2pq + (p-q)^2/2^n & q^2 + q(p-q)/2^n \\ p^2 - p^2/2^{n-1} & 2pq + p(p-q)/2^{n-1} & q^2 + pq/2^{n-1} \end{bmatrix}.$$

This formula has appeared in [17] and [24] from different approaches.

As $n \to \infty$, the limiting transition probability matrix is:

$$\lim_{n\to\infty} \mathbf{P}(n) = \begin{bmatrix} p^2 & 2pq & q^2 \\ p^2 & 2pq & q^2 \\ p^2 & 2pq & q^2 \end{bmatrix}$$

and the limiting probability distribution

$$(\pi_1 \quad \pi_2 \quad \pi_3) = (p^2 \quad 2pq \quad q^2),$$

is stationary, since

$$(p^2\ 2pq\ q^2)\begin{bmatrix} p^2 & 2pq & q^2 \\ p^2 & 2pq & q^2 \\ p^2 & 2pq & q^2 \end{bmatrix} = (p^2\ 2pq\ q^2).$$

The mean recurrence times are $\mu_{11} = 1/p^2$, $\mu_{22} = 1/2_{pq}$, and $\mu_{33} = 1/q^2$.

A General Birth Process

In this general birth process, the time scale t is continuous. For every $t \in [0, \infty)$, the random variable $X(t)$ is defined as the number of births occurring at or before time t, so $X(t)$ takes on discrete values. The term "the number of births" is used here quite loosely. It refers to the number of "events" occurring up to t, whatever the "event" may happen to be in a particular study. The "event" may be an accident, an incoming telephone call, a new species in a genus, a new infected case during an epidemic, or even a death. If a birth process is regarded as an "increasing" process and a death process as a "decreasing" process, the general birth process described here applies to both increasing processes and decreasing processes.

As the number of events occurring increases with time, the distribution of $X(t)$ is a increasing function of time. The purpose in this section is to review the general formula for the transition probability from which a desired transition probability for a particular process can be derived.

Let

$$p_{i,k}(0,t) = \Pr[X(t) = k | X(0) = i\}$$

be the transition probability from $X(0) = i$ at time $t = 0$ to $X(t) = k$ at time t, for $k = i, i+1, \ldots$. Given $X(t) = k$, let the probability of having a birth during $(t, t+\Delta)$ be $\lambda_k \beta(t)\Delta + o(\Delta)$. The product $\lambda_k \beta(t)$ is the birth intensity function, which plays a major role in determining the process. Here $\beta(t)$ is an integrable function of t such that the integral

$$\int_0^t \beta(\tau)\,\mathrm{d}\tau \to \infty \quad \text{as} \quad t \to \infty,$$

and λ_j is an arbitrary function of j subject to the condition that $\lambda_i \neq \lambda_j$, for $i \neq j$. Under these conditions, the transition probabilities satisfy the following differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,i}(0,t) = -\lambda_i \beta(t) p_{i,i}(0,t) \tag{15a}$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,k}(0,t) = -\lambda_k \beta(t) p_{i,k}(0,t) + \lambda_{k-1}\beta(t) p_{i,k-1}(0,t), \tag{15b}$$

for $k = i, i+1, \ldots$. Eq. (15a) has the solution

$$p_{i,i}(0,t) = \exp\left[-\lambda_i \int_0^t \beta(\tau)\,\mathrm{d}\tau\right]. \tag{16}$$

Using (16) and solving (15b) successively beginning with $k = i+1$ yields the general formula:

$$p_{i,k}(0,t) = (-1)^{k-i}\lambda_i \ldots \lambda_{k-1} \times \left[\sum_{j=1}^{k} \frac{\exp\left[-\lambda_j \int_0^t \beta(\tau)\,\mathrm{d}\tau\right]}{\prod_{\substack{\ell=i \\ \ell\neq j}}^{k} (\lambda_j - \lambda_\ell)}\right], \tag{17}$$

for $k = i, i+1, \ldots$. An inductive proof of (17) is given in [10].

Now we use (17) to deduce the formulas of the transition probability $p_{i,k}(0,t)$ in some well-known processes.

Yule Processes

The intensity functions are:

$$\lambda_j = j\lambda \quad \text{and} \quad \beta(t) = 1$$

(*see* **Yule Process**). Substituting these values in formula (17) yields:

$$p_{i,k}(0,t) = (-1)^{k-i}[i\lambda]\ldots[(k-1)\lambda] \times \left[\sum_{j=1}^{k} \left(\frac{\exp(-j\lambda t)}{\prod_{\substack{\ell=i \\ \ell\neq j}}^{k} (j\lambda - \ell\lambda)}\right)\right], \tag{18}$$

where

$$[i\lambda]\ldots[(k-1)\lambda] = \lambda^{k-i}\binom{k-1}{k-i}(k-i)!$$

and

$$\prod_{\substack{\ell=i \\ \ell\neq j}}^{k} (j\lambda - \ell\lambda) = \lambda^{k-i}(-1)^{k-j}\binom{k-i}{j-i}^{-1}(k-i)!.$$

Therefore (18) can be rewritten as

$$\begin{aligned} p_{i,k}(0,t) &= \binom{k-1}{k-i}\exp(-i\lambda t) \times \left[\sum_{j=i}^{k}\binom{k-i}{j-i}\exp(-\lambda t)^{j-i}\right] \\ &= \binom{k-1}{k-i}\exp(-i\lambda t)[1-\exp(-\lambda t)]^{k-i}, \end{aligned}$$

for $k = i, i+1, \ldots$, a familiar formula in the Yule process.

If the intensity function $\beta(t)$ remains a function of t, then we have the time-dependent Yule process:

$$p_{i,k}(0,t) = \binom{k-1}{k-i}\left\{\exp\left[-\lambda\int_0^t \beta(\tau)\,d\tau\right]\right\}^i \times\left\{1-\exp\left[-\lambda\int_0^t \beta(\tau)\,d\tau\right]\right\}^{k-i}$$

for $k = i, i+1, \ldots$.

Pólya Process

The **Pólya process** usually records the events occurring during the interval $(0, t]$, so the initial value at $t = 0$ is $X(0) = 0$. The intensity function is:

$$\lambda_k = (1+\lambda k) \quad \text{and} \quad \beta(t) = (1+\lambda t)^{-1}.$$

Using these intensity functions and with reference to formula (17) for $p_{0,k}(0,t)$, we evaluate

$$\exp\left[-(1+j\lambda)\int_0^t (1+\lambda\tau)^{-1}\,d\tau\right] = (1+\lambda t)^{-(1/\lambda+j)},$$

$$(1+\lambda)(1+2\lambda)\ldots[1+(k-1)\lambda] = \binom{\frac{1}{\lambda}+k-1}{k}\lambda^k k!,$$

and

$$\prod_{\substack{\ell=0\\ \ell\neq j}}^{k}[(1+j\lambda)-(1+\ell\lambda)] = \lambda^k\binom{k}{j}^{-1}k!(-1)^{k-j},$$

and substitute these formulas in (17). As a result,

$$p_{0,k}(0,t) = \binom{\frac{l}{\lambda}+k-1}{k}\sum_{j=0}^{k}\binom{k}{j} \times(-1)^j(1+\lambda t)^{-(1/\lambda+j)} = \binom{\frac{l}{\lambda}+k-1}{k}(1+\lambda t)^{-1/\lambda}\left(\frac{\lambda t}{1+\lambda t}\right)^k$$

for $k = 0, 1, \ldots$, which is the formula of the transition probability in the Pólya process.

Birth Process with Immigration

Another plausible function for λ_j is linear:

$$\lambda_j = j\lambda+\eta \quad \text{and} \quad \beta(t) = 1.$$

Here the linear term $j\lambda$ corresponds to birth and the constant term η corresponds to immigration (*see* **Migration Processes**). With reference to (17), we compute

$$[i\lambda+\eta][(i+1)\lambda+\eta]\ldots[(k-1)\lambda+\eta] = \lambda^{k-i}\binom{k+\left(\frac{\eta}{\lambda}\right)-1}{k-i}(k-i)!$$

and

$$\prod_{\substack{\ell=i\\ \ell\neq j}}^{k}[(j\lambda+\eta)-(\ell\lambda+\eta)] = \lambda^{k-1}(-1)^{k-j}\binom{k-i}{k-j}^{-1}(k-i)!$$

As a result,

$$p_{i,k}(0,t) = \binom{k+\left(\frac{\eta}{\lambda}\right)-1}{k-i}[\exp(-\lambda t)]^{i+\left(\frac{\eta}{\lambda}\right)} \times[1-\exp(-\lambda t)]^{k-i}, \tag{19}$$

for $k = i, i+1, \ldots$. If $\beta(t)$ remains a function of time t, the transition probability $p_{i,k}(0,t)$ will be the same as in formula (19) but with t being replaced by the integral $\int_0^t \beta(\tau)\,d\tau$.

From (19) we see that the difference $X(t) - i$ has a **negative binomial** distribution with parameters $i + \eta/\lambda$ and $\exp(-\lambda t)$. (*see* **Accident Proneness**).

Death Process

Let i individuals alive at $t = 0$ be subject to the same force of mortality, or **hazard**, $\mu(t)$, and let the random variable $X(t)$ be the number of deaths occurring during the interval $(0, t]$, with $X(0) = 0$. The transition probability is defined by

$$p_{0,k}(0,t) = \Pr\{X(t) = k | X(0) = 0\}.$$

Under the assumption of independence of mortality, the intensity functions are

$$\lambda_j = i - j \quad \text{and} \quad \beta(t) = \mu(t).$$

Substituting these functions in (17), we find

$$\exp\left[-(i-j)\int_0^t \mu(\tau)\,d\tau\right] = \left\{\exp\left[-\int_0^t \mu(\tau)\,d\tau\right]\right\}^{i-k} \times \left\{\exp\left[-\int_0^t \mu(\tau)\,d\tau\right]\right\}^{k-j},$$

$$(i-0)(i-1)\dots(i-k+1) = \binom{i}{k} k!$$

and

$$\prod_{\substack{\ell=0\\ \ell=j}}^{k} [(i-j)-(i-\ell)] = (-1)^j \binom{k}{j}^{-1} k!.$$

Therefore,

$$p_{0,k}(0,t) = \binom{i}{k}\left\{\exp\left[-\int_0^t \mu(\tau)\,d\tau\right]\right\}^{i-k} \times \left\{1-\exp\left[-\int_0^t \mu(\tau)\,d\tau\right]\right\}^{k}$$

for $k = 0, 1, \dots, i$, which is the binomial distribution, with the exponential function being the survival function (*see* **Survival Distributions and Their Characteristics**).

A Divergent Process

This process was mentioned in [17]; in it $\lambda_j = j^2$ and $\beta(t)$ is a function of t. The probability derived from (17) is

$$p_{i,k}(0,t) = \binom{k-1}{k-i}^2 \sum_{j=i}^{k} (-1)^{j-i} \times \binom{k-i}{k-j}^2 \binom{2j-1}{j-1}^{-1} \binom{k+j}{k-j}^{-1} \times \exp\left[-j^2\lambda \int_0^t \beta(\tau)\,d\tau\right],$$

$k = i, i+1, \dots$. According to this model, the rate of population growth is proportional to the square of the population size j within each time element $(t, t+\Delta)$, and for every given t there is a positive probability,

$$1 - \sum_{k=i} p_{i,k}(0,t) > 0,$$

that the population will become infinitely large. This model may not be an accurate description of human population growth, but it may be applicable to the growth of microorganisms or to nuclear fission.

Poisson Process

While formula (17) holds for cases where $\lambda_i \neq \lambda_j$, for $i \neq j$, the transition probability in the **Poisson process** may be derived from the general birth process as a limiting case as $\lambda_j \to \lambda$. That is,

$$\lim_{\lambda_j \to \lambda} (-1)^k \lambda_0 \dots \lambda_{k-1} \sum_{j=0}^{k} \frac{\exp(-\lambda_j t)}{\prod_{\substack{\ell=0\\ \ell\neq j}}^{k} (\lambda_j - \lambda_\ell)} = \frac{\exp(-\lambda t)(\lambda t)^k}{k!}.$$

A description of the limiting process may be found in [10, pp. 255–256].

An Equality in Stochastic Processes

Transition probabilities $p_{i,k}(0,t)$ are the basic elements in stochastic processes. Explicit formulas for the probabilities are needed not only for an appreciation of stochastic processes as an analytic tool, but also for a better understanding of the problems on hand through analyses of the data. Generally, efforts are made to obtain explicit solutions, but these are not always successful. The equality presented in this section is a general property of (increasing) stochastic processes, but it is useful for derivation of explicit formulas when other methods have failed.

Let $X(t)$ be the number of "births" up to time t, with birth intensity function $\lambda_j\beta(\tau)$ and transition probabilities

$$p_{i,k}(0,t) = \Pr\{X(t) = k | X(0) = i\}, \qquad (20)$$

as defined in the general birth process. Let j be an arbitrary but *fixed* integer between i and k and

consider the transition $j \to j+1$. Instead of a simple transition from i to k, there is now a sequence of transitions: $i \to j \to j+1 \to k$. The transition $j \to j+1$ must take place somewhere between 0 and t; let it take place in $(\tau, \tau + d\tau)$. The probability for the sequence $i \to j \to j+1 \to k$ is

$$p_{i,j}(0,\tau)\lambda_j\beta(\tau)\,d\tau p_{j+1,k}(\tau,t).$$

For different values of τ, the corresponding sequences of transitions $i \to j \to j+1 \to k$ are mutually exclusive; the integral

$$\int_0^t p_{i,j}(0,\tau)\lambda_j\beta(\tau)p_{j+1,k}(\tau,t)\,d\tau \qquad (21)$$

is the probability that the sequence $i \to j \to j+1 \to k$ will occur during the interval $(0,t)$. Since the process must admit state j and the transition $j \to j+1$ before arriving at the value k at time t, the integral in (21) is equal to the expression in (20). That is,

$$p_{i,k}(0,t) = \int_0^t p_{i,j}(0,\tau)\lambda_j\beta(\tau)p_{j+1,k}(\tau,t)\,d\tau. \qquad (22)$$

Formula (22) was proposed in [8]; a formal proof using the Riemann integral is given in [10]. It is easy to verify that the Yule processes and others in the section on the general birth process all satisfy (22).

Example 8. The Poisson process with $i = 0$, $\lambda_j\beta(\tau) = \lambda$, has transition probability

$$p_{0,k}(0,t) = \frac{\exp(-\lambda t)(\lambda t)^k}{k!},$$

which is the left-hand side of (22). The right-hand side is

$$\begin{aligned}
&\int_0^t \left[\frac{\exp(-\lambda\tau)(\lambda\tau)^j}{j!}\right]\lambda\,d\tau \\
&\quad\times\left[\frac{\exp\{-\lambda(t-\tau)\}[\lambda(t-\tau)]^{k-j-1}}{(k-j-1)!}\right] \\
&\quad= \frac{\exp(-\lambda t)(\lambda t)^k}{j!(k-j-1)!}\int_0^1 \theta^j(1-\theta)^{k-j-1}\,d\theta \\
&\quad= p_{0,k}(0,t),
\end{aligned}$$

where $\theta = \tau/t$, and the beta function in the last integral is equal to $j!(k-j-1)!/k!$, justifying the last equality.

Equality (22) can be extended to any number of intermediate values between $X(0)$ and $X(t)$. Suppose there are two intermediate fixed values j and k, such that $i < j < k < l$; the transition probability

$$\Pr\{X(t) = l | X(0) = i\} = p_{i,l}(0,t)$$

satisfies the equality

$$\begin{aligned}
p_{i,l}(0,t) = \int_0^t \int_0^{\tau_2} &p_{ij}(0,\tau_1)\lambda_j(\tau_1)p_{j+1,k}(\tau_1,\tau_2) \\
&\times \lambda_k(\tau_2)p_{k+1,l}(\tau_2,t)\,d\tau_1\,d\tau_2.
\end{aligned}$$

An Application: Simple Stochastic Epidemic

In a simple stochastic model, a population consists of two categories of individuals: susceptibles and infectives (*see* **Epidemic Models, Stochastic**). There are no removals, no deaths, no immunes, and no recoveries from infection. Suppose that at the initial time $t = 0$, there are N susceptibles and 1 infective. Let $X(t)$ be the number of infectives at time t, so that there are $N + 1 - X(t)$ susceptibles. The primary purpose is to derive an explicit formula for the transition probability

$$p_{1,n}(0,t) = \Pr\{X(t) = n | X(0) = 1\}. \qquad (20a)$$

Under the assumption of homogeneous mixing of infectives and susceptibles, the intensity functions in the general birth process are:

$$\lambda_j = j(N+1-j) = a_j$$

and

$$\int_0^t \beta(\tau)\,d\tau = \theta(t),$$

where $\beta(t)$ is known as the *infection rate* and is a function of t, the "age" of an epidemic, and $\theta(t)$ tends to infinity as $t \to \infty$.

For $n < (N+1)/2$, $a_j \neq a_i$, for $i \neq j$, formula (17) in the general birth process applies. This means

that the solution is

$$p_{1,n}(0,t) = (-1)^{n-1} a_1 \dots a_{n-1} \times \left[\sum_{i=1}^{n} \left(\frac{\exp[-a_i \theta(t)]}{\prod_{\substack{\alpha=1 \\ \alpha \neq i}}^{n} (a_i - a_\alpha)} \right) \right], \tag{17a}$$

for $n = 1, 2, \dots, [(N+1)/2]$.

Formula (17) no longer applies for $n > (N+1)/2$, since in this case, $a_1, a_2, \dots, a_n$ are not all distinct. In particular,

$$a_j = j(N+1-j) = a_{N+1-j}.$$

However, an explicit formula for the probability $p_{1,n}(0,t)$ can be obtained by applying formula (22):

$$p_{1,n}(0,t) = \int_0^t p_{1,k}(0,\tau) a_k \beta(\tau) p_{k+1,n}(\tau,t)\, \mathrm{d}\tau. \tag{22a}$$

The integer k must be so chosen that the a_js in the probability $p_{i,k}(0,\tau)$ are distinct and the a_js in $p_{k+1,n}(\tau,t)$ are also distinct. When N is even, $k = N/2$; when N is odd, $k = (N+1)/2$. With these values of k, we apply (17) to the two probabilities $p_{1,k}(0,\tau)$ and $p_{k+1,n}(\tau,t)$ to obtain

$$p_{1,k}(0,\tau) = (-1)^{k-1} a_1 \dots a_{k-1} \times \left[\sum_{i=1}^{k} \left(\frac{\exp[-a_i \theta(\tau)]}{\prod_{\substack{\alpha=1 \\ \alpha \neq i}}^{k} (a_i - a_\alpha)} \right) \right] \tag{17b}$$

and

$$p_{k+1,n}(\tau,t) = (-1)^{n-k-1} a_{k+1} \dots a_{n-1} \times \left[\sum_{j=k+1}^{n} \left(\frac{\exp\{-a_j[\theta(t) - \theta(\tau)]\}}{\prod_{\substack{\beta=k+1 \\ \beta \neq j}}^{n} (a_j - a_\beta)} \right) \right]. \tag{17c}$$

Substituting (17b) and (17c) in (22a) and simplifying the resulting expression, we find.

$$p_{1,n}(0,t) = (-1)^{n-1} a_1 \dots a_{n-1} \times \left[-\sum_{j=k+1}^{n} \left(\frac{\theta(t) \exp[-a_j \theta(t)]}{\prod_{\substack{\beta=1 \\ a_\beta \neq a_j}}^{n} (a_j - a_\beta)} \right) + \sum_{\substack{i=1 \\ a_i \neq a_j}}^{k} \sum_{j=k+1}^{n} \left(\frac{\exp[-a_i \theta(t)] - \exp[-a_j \theta(t)]}{(a_i - a_j) \prod_{\substack{\alpha=1 \\ \alpha \neq i}}^{k} (a_i - a_\alpha) \prod_{\substack{\beta=k+1 \\ \beta \neq j}}^{n} (a_j - a_\beta)} \right) \right],$$

for $n = k+1, k+2, \dots, N+1$, where $k = N/2$ when N is even and $k = (N+1)/2$ when N is odd.

Infection Time and the Duration of an Epidemic

The length of time elapsed up to the occurrence of the nth infection is a continuous random variable taking nonnegative real values. Let it be denoted by T_n, for $1 \le n \le N+1$, with $T_1 = 0$. The duration of an epidemic is T_{N+1}, the length of time elapsed up to the infection of the last number of the population. The purpose of this section is to derive explicit formulas for the density function $f_n(t)$, the distribution $F_n(t)$, and the expectation and variance of T_n.

The density function $f_n(t)$ has a close relationship with the probability $p_{1,n}(t)$. By definition, $f_n(t)\,\mathrm{d}t$ is the probability that the random variable T_n will take values in $(t, t+\mathrm{d}t)$. This means that at time t there are $n-1$ infectives, and the nth infection takes place in the interval $(t, t+\mathrm{d}t)$. Therefore,

$$f_n(t)\,\mathrm{d}t = p_{1,n-1}(0,t) a_{n-1} \beta(t)\,\mathrm{d}t,$$

and the distribution function

$$F_n(t) = \int_0^t p_{1,n-1}(0,\tau) a_{n-1} \beta(\tau)\,\mathrm{d}\tau, \quad \text{for } n = 2, \dots, N+1.$$

Using the formulas for the probabilities in the preceding section, we can write down explicit functions for $f_n(t)$ and $F_n(t)$ for each n. For example, for

$n \le (N+1)/2$, we use formula (17a) to obtain the density function

$$f_n(t)\,\mathrm{d}t = (-1)^{n-2}a_1 \ldots a_{n-1} \times \left[\sum_{i=1}^{n-1} \left(\frac{\beta(t)\exp[-a_i\theta(t)]}{\prod_{\substack{\alpha=1 \\ \alpha\neq i}}^{n-1}(a_i - a_\alpha)} \right) \right] \mathrm{d}t$$

and the distribution function

$$F_n(t) = (-1)^{n-2}a_1 \ldots a_{n-1} \times \sum_{i=1}^{n-1} \frac{1-\exp[-a_i\theta(t)]}{\prod_{\substack{\alpha=1 \\ \alpha\neq i}}^{n-1}(a_i - a_\alpha)a_i}.$$

As t approaches infinity,

$$\lim_{t\to\infty}\theta(t) = \lim_{t\to\infty}\int_0^t \beta(\tau)\,\mathrm{d}\tau = \infty,$$

$$F_n(\infty) = (-1)^{n-2}a_1 \ldots a_{n-1} \times \sum_{i=1}^{n-1} \frac{1}{\prod_{\substack{\alpha=1 \\ \alpha\neq i}}^{n-1}(a_i - a_\alpha)a_i} = 1.$$

A proof of $F_n(\infty) = 1$, for $1 < n \le N+1$, is given in [10].

The expectation and variance of T_n can be computed directly from the definitions

$$\mathrm{E}(T_n) = \int_0^\infty t f_n(t)\,\mathrm{d}t$$

and

$$\mathrm{var}(T_n) = \int_0^\infty [t - \mathrm{E}(T_n)]^2 f_n(t)\,\mathrm{d}t.$$

Explicit formulas depend on the function $\beta(t)$. However, when the infection rate is independent of time, with $\beta(t) = \beta$, there is an alternative approach which is simpler.

The length of time elapsed until the occurrence of the nth infection may be divided into two periods: a period of length T_{n-1} up to the occurrence of the $(n-1)$th infection; and a period of length t_n between the occurrences of the $(n-1)$th and nth infections. The sum of the two periods is equal to the entire length of time:

$$T_n = T_{n-1} + t_n, \tag{23}$$

where T_{n-1} and t_n are independently distributed non-negative random variables, with respective density functions

$$f_{n-1}(t) = p_{1,n-2}(0,t)a_{n-2}\beta$$

and

$$g_n(t) = p_{n-1,n-1}(0,t)a_{n-1}\beta. \tag{24}$$

According to (23), the distribution of T_n is the convolution of the distributions of T_{n-1} and t_n, and the density functions satisfy the equation

$$f_n(t) = \int_0^t f_{n-1}(\tau)g_n(t-\tau)\,\mathrm{d}\tau.$$

Now, the density function in (24) is exponential,

$$g_n(t) = a_{n-1}\beta\exp\{-a_{n-1}\beta t)\},$$

with expectation and variance

$$\mathrm{E}(t_n) = \frac{1}{a_{n-1}\beta} \quad \text{and} \quad \sigma_{t_n}^2 = \frac{1}{a_{n-1}^2\beta^2}.$$

However, (23) can be extended so that

$$T_n = t_2 + t_3 + \ldots + t_n,$$

where $t_2, t_3, \ldots, t_n$ are independently distributed **exponential** random variables. It follows that the expectation and the variance of T_n are, respectively,

$$\mathrm{E}(T_n) = \frac{1}{\beta}\sum_{i=1}^{n-1}\frac{1}{a_i}$$

and

$$\sigma_{T_n}^2 = \frac{1}{\beta^2}\sum_{i=1}^{n-1}\frac{1}{a_i^2}, \quad n = 2, \ldots, N+1.$$

This epidemic model was originally formulated by Kermack and McKendrick [21, 26]. It has since been extensively studied; see, for example, [3], [4], [5] and [20]. An important feature of this model is that the coefficients a_n are quadratic functions of n, and the differential equations of the transition

probabilities are of second order and cannot be easily solved. The Laplace transform does not provide an explicit formula for the transition probability either. The present method, relying on the general birth process formula (17) and the equality (22), is based on [29].

Death Processes and Survival Distributions

In the death process deduced from the general birth process in the preceding section, the time interval $[0, t)$ was fixed and the number of deaths occurring in $[0, t)$ was a random variable. In this section, the survival time of an individual is treated as a random variable and the purpose is to derive its distribution.

Let a random variable T be the survival time, or lifetime, of an individual with mortality intensity function, or force of mortality, $\mu(t)$, so that, the sum $\mu(t)\Delta + o(\Delta)$ is the probability that an individual alive at time t will die in the time interval $(t, t + \Delta)$. The distribution function of T at t, $F_T(t) = \Pr\{T \leq t\}$, is the probability that an individual will die at or before time t. The complement $1 - F_T(t)$ is the survival function of T at t.

Consider now the distribution function of T at time $t + \Delta$, $F_T(t + \Delta) = \Pr\{T \leq t + \Delta\}$. For an individual to die before $t + \Delta$, either he dies before t, or else he must survive to t and die during the interval $(t, t + \Delta)$. Symbolically,

$$F_T(t + \Delta) = F_T(t) + [1 - F_T(t)][\mu(t)\Delta + o(\Delta)],$$

which leads to the differential equation:

$$\frac{\mathrm{d}}{\mathrm{d}t} F_T(t) = [1 - F_T(t)]\mu(t)$$

or

$$\frac{\mathrm{d}}{\mathrm{d}t} \ln[1 - F_T(t)] = -\mu(t). \tag{25}$$

Clearly at $t = 0$, $F_T(0) = 0$. The solution of the differential equation (25) is:

$$1 - F_T(t) = \exp\left[-\int_0^t \mu(\tau)\,\mathrm{d}\tau\right]$$

and

$$F_T(t) = 1 - \exp\left[-\int_0^t \mu(\tau)\,\mathrm{d}\tau\right]. \tag{26}$$

The survival function and the distribution function in (26) are the same as those in the death process in the section on the general birth process. The density function of T is

$$f(t) = \mu(t) \exp\left[-\int_0^t \mu(\tau)\,\mathrm{d}\tau\right]. \tag{27}$$

Formulas (26) and (27) both depend on $\mu(t)$, and are the basic functions in a survival analysis. One can derive formulas for a particular survival distribution by making assumptions about the mortality intensity function $\mu(t)$. The following are a few examples.

Gompertz Distribution

In a celebrated paper on the law of human mortality, Benjamin Gompertz [18] attributed death to either one of two causes: chance or deterioration of the power to withstand destruction (*see* **Aging Models**). In deriving his law of mortality, however, Gompertz considered only deterioration, and assumed that a person's power to resist death decreases at a rate proportional to the power itself. Since the force of mortality $\mu(t)$ is a measure of a person's susceptibility to death, Gompertz used the reciprocal $1/\mu(t)$ as a measure of a person's resistance to death and thus arrived at the formula:

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{\mu(t)}\right) = -h\left(\frac{1}{\mu(t)}\right)$$

or

$$\frac{\mathrm{d}}{\mathrm{d}t}\mu(t) = -h\mu(t),$$

from which he found the force of mortality $\mu(t) = Bc^t$. The distribution function and the density function are, respectively,

$$F_T(t) = 1 - \exp\left\{\frac{-B(c^t - 1)}{\ln c}\right\}.$$

and

$$f_T(t) = Bc^t \exp\left\{\frac{-B(c^t - 1)}{\ln c}\right\}.$$

Makeham Distribution

Makeham [25] suggested the modification $\mu(t) = A + Bc^t$ to restore the missing component "chance" in the Gompertz formula (*see* **Aging Models**). The corresponding distribution function is

$$F_T(t) = 1 - \exp\left\{-\left[At + \frac{B(c^t - 1)}{\ln c}\right]\right\}$$

and the density function is

$$f_T(t) = (A + Bc^t) \exp\left\{-\left[At + \frac{B(c^t - 1)}{\ln c}\right]\right\}.$$

Weibull Distribution

When the force of mortality is assumed a power function of t, $\mu(t) = ct^{c-1}$, the distribution function and the density function are:

$$F_T(t) = 1 - \exp\{-t^c\}$$

and

$$f_T(t) = ct^{c-1} \exp(-t^c).$$

This distribution, proposed by Weibull in 1939 for studies of the lifespan of materials, is used frequently in survival analysis (*see* **Weibull Distribution**).

Exponential Distribution

If $\mu(t) = \mu$ is a constant, then the distribution function and the density function are:

$$F_T(t) = 1 - \mathrm{e}^{-\mu t}$$

and

$$f_T(t) = \mu \mathrm{e}^{-\mu t},$$

which were used for illustration of the theory of life testing [16] (*see* **Exponential Distribution**).

A Staging Process and Stages of Disease

Development of many chronic conditions is characterized by stages. Generally, diseases advance with time from a mild stage through intermediate and severe stages to death. The process often is irreversible, but a patient may die while being in any of the stages. In the natural progression of cancer, for example, there are stages of the disease determined by the size of tumor and metastasis of cancer. **AIDS**, too, can be classified by stages.

Birth order and child spacing are another example of a staging process. Here the process begins when the couple decides to start a family; stages are defined by the parities of the woman, from parity zero (no children) to parity one (one child), to parity two (two children), and so on. The process is clearly irreversible, and it terminates when the couple decides to stop reproducing. We can find staging phenomena in many other areas, such as metamorphosis in biology, foraging processes in wildlife, and cascade processes in nuclear physics. Since this process was originally proposed in [9] for statistical studies of chronic illnesses, we shall use chronic diseases as an example for illustration.

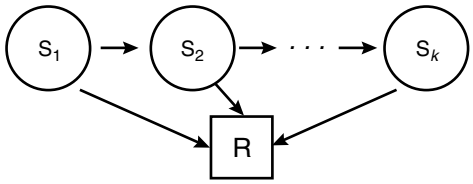

Figure 1 The stages of a disease

Denote the stages of a disease by $\mathrm{S}_1, \mathrm{S}_2, \ldots, \mathrm{S}_k$, and the death state by R. We can describe the disease process schematically as in Figure 1. The arrows indicate the directions in which that transitions take place. From each stage S_i, for $i = 1, 2, \ldots, k-1$, the disease process may enter the next stage S_{i+1}, or enter the death state R. From the final stage S_k, the process enters the death state R. We shall derive the distribution function of the survival time T of an individual who is in stage S_1 at the initial time $t = 0$.

The following identities are needed in deriving the formulas for the distribution function, expectation and variance of the survival time T. For proofs of these identities, see [9] and [10].

Lemma 1. For distinct numbers $\lambda_1, \lambda_2, \ldots, \lambda_n$,

$$\sum_{i=1}^{n} \frac{1}{\prod_{\substack{j=1 \\ j \neq i}}^{n} (\lambda_i - \lambda_j)} = 0, \tag{A}$$

$$\sum_{i=1}^{n} \frac{1}{\prod_{\substack{j=1 \\ j \neq i}}^{n} (\lambda_i - \lambda_j)\lambda_i} = (-1)^{n-1} \frac{1}{\prod_{i=1}^{n} \lambda_i}, \tag{B}$$

$$\sum_{i=1}^{n} \frac{1}{\prod_{\substack{j=1 \\ j \neq i}}^{n} (\lambda_i - \lambda_j)\lambda_i^2} = (-1)^{n-1} \frac{1}{\prod_{i=1}^{n} \lambda_i} \left(\sum_{i=1}^{n} \frac{1}{\lambda_i}\right), \tag{C}$$

and

$$\sum_{i=1}^{n} \frac{1}{\prod_{\substack{j=1 \\ j\neq i}}^{n} (\lambda_i - \lambda_j)\lambda_i^3} = (-1)^{n-1} \frac{1}{\prod_{i=1}^{n} \lambda_i} \times \left(\sum_{j\geq i}^{n} \sum_{i=1}^{n} \frac{1}{\lambda_i \lambda_j} \right). \quad \text{(D)}$$

Intensity Functions

For an individual in stage S_i a time $\tau, 0 \leq \tau < \infty$, let

$$\nu_{i,i+1}\beta(\tau)\,d\tau = \Pr\{\text{the individual will enter stage } S_{i+1} \text{ in } (\tau, \tau + d\tau)\},$$

and

$$\mu_i \beta(\tau)\,d\tau = \Pr\{\text{the individual will enter R in } (\tau, \tau + d\tau)\}$$

and let

$$\nu_{ii}\beta(\tau) = -[\nu_{i,i+1}\beta(\tau) + \mu_i\beta(\tau)], \quad i = 1, \ldots, k-1.$$

For an individual in the final stage S_k at time τ, we let

$$\mu_k \beta(\tau)\,d\tau = \Pr\{\text{the individual will enter R in } (\tau, \tau + d\tau)\}$$

and

$$\nu_{kk}\beta(\tau) = -\mu_k\beta(\tau).$$

The function $\beta(t)$ is such that

$$\theta(t) = \int_0^t \beta(\tau)\,d\tau$$

tends to infinity as $t \to \infty$.

While diseases develop continuously, the time of transition from one stage to the next follows a definite order. Suppose the transition from stage S_i to stage S_{i+1} takes place during the time interval $(\tau_i, \tau_i + d\tau_i)$, for $i = 1, 2, \ldots, k-1$, and that $0 < \tau_1 < \tau_2 < \ldots < \tau_{k-1}$.

Density Function of Survival Time T

When death occurs during the interval $(t, t + dt)$, the individual must be in one of the states $S_1, S_2, \ldots, S_k$ at time t. By definition, $f_T(t)\,dt$ is the probability that the individual who is in stage S_1 time $t = 0$ will die in $(t, t + dt)$. Since he may enter the death state R from any one of the k states $S_1, S_2, \ldots, S_k$, the product $f_T(t)\,dt$ is the sum of k terms:

$$f_T(t)\,dt = f_1(t)\,dt + f_2(t)\,dt + f_3(t)\,dt + \cdots + f_k(t)\,dt. \quad (28)$$

Each $f_j(t)\,dt$ in (28) corresponds to the sequence of transitions. $S_1 \to S_2 \to \ldots \to S_j \to R$. The first term $f_1(t)\,dt$, for example, is the probability of transition $S_1 \to R$ occurring in $(t, t + dt)$,

$$f_1(t)\,dt = \exp\{\nu_{11}\theta(t)\}\mu_1\beta(t)\,dt. \quad (29)$$

The function $f_2(t)\,dt$ represents the sequence of transitions $S_1 \to S_2 \to R$. For the transition $S_1 \to S_2$ to take place during a particular interval $(\tau_1, \tau_1 + d\tau_1)$, the probability of the sequence $S_1 \to S_2 \to R$ is

$$\exp\left\{\nu_{11}\int_0^{\tau_1} \beta(\tau)\,d\tau\right\} \nu_{12}\beta(\tau_1)\,d\tau_1 \times \exp\left\{\nu_{22}\int_{\tau_1}^{t} \beta(\tau)\,d\tau\right\} \mu_2\beta(t)\,dt. \quad (30)$$

Integrating (30) from $\tau_1 = 0$ to $\tau_1 = t$ yields

$$f_2(t)\,dt = \nu_{12}\mu_2\beta(t)\left[\frac{1}{\nu_{11} - \nu_{22}} \exp\{\nu_{11}\theta(t)\} + \frac{1}{\nu_{22} - \nu_{11}} \exp\{\nu_{22}\theta(t)\}\right] dt. \quad (31)$$

Generally, for the sequence $S_1 \to S_2 \to \cdots \to S_j \to R$,

$$f_j(t)\,dt = \nu_{12}\ldots\nu_{j-1,j}\mu_j\beta(t) \sum_{i=1}^{j} \frac{1}{\prod_{\substack{\ell=1 \\ \ell\neq i}}^{j} (\nu_{ii} - \nu_{\ell\ell})} \times \exp\{\nu_{ii}\theta(t)\}\,dt, \quad j = 2, \ldots, k. \quad (32)$$

Substituting (29), (31) and (32) in (28) gives the density function of the survival time T:

$$f_T(t) = \exp\{\nu_{11}\theta(t)\}\mu_1\beta(t) + \sum_{j=2}^{k}\left\{\nu_{12}\ldots\nu_{j-1,j}\mu_j\beta(t) \times \sum_{i=1}^{j}\left(\exp[\nu_{ii}\theta(t)] \Big/ \prod_{\substack{\ell=1\\ \ell\neq i}}^{j}(\nu_{ii}-\nu_{\ell\ell})\right)\right\}. \quad (33)$$

Expectation and Variance of Survival Time T

When $\beta(t) = 1$, $\theta(t) = t$. In this case the density function of T is

$$f_T(t) = \mu_1\exp\{\nu_{11}t\} + \sum_{j=2}^{k}\left\{\nu_{12}\ldots\nu_{j-1,j}\mu_j \times \sum_{i=1}^{j}\left(\exp\{\nu_{ii}t\} \Big/ \prod_{\substack{\ell=1\\ \ell\neq i}}^{j}(\nu_{ii}-\nu_{\ell\ell})\right)\right\}, \quad (34)$$

and the distribution function is

$$F_T(t) = \frac{\mu_1}{\nu_{11}}(\exp\{\nu_{11}t\}-1) + \sum_{j=2}^{k}\left\{\nu_{12}\ldots\nu_{j-1,j}\mu_j \times \sum_{i=1}^{j}\left((\exp\{\nu_{ii}t\}-1) \Big/ \prod_{\substack{\ell=1\\ \ell\neq i}}^{j}(\nu_{ii}-\nu_{\ell\ell})\nu_{ii}\right)\right\}.$$

As $t \to \infty$, the distribution function $F_T(\infty) = 1$, which can be proven using (B) in Lemma 1. Therefore, the distribution is proper.

Using the density function in (34) we find the formula for the expectation $\mathrm{E}(T)$, and then using formula (C) in the lemma we simplify the formula to the following:

$$\mathrm{E}[T] = \frac{1}{-\nu_{11}} + \frac{\nu_{12}}{-\nu_{11}}\left(\frac{1}{-\nu_{22}}\right) + \frac{\nu_{12}}{-\nu_{11}}\frac{\nu_{23}}{-\nu_{22}}\left(\frac{1}{-\nu_{33}}\right) + \cdots + \prod_{i=1}^{k-1}\frac{\nu_{i,i+1}}{-\nu_{ii}}\left(\frac{1}{-\nu_{kk}}\right). \quad (35)$$

Each factor

$$\frac{\nu_{i,i+1}}{-\nu_{ii}} = \frac{\nu_{i,i+1}}{\nu_{i,i+1}+\mu_i}.$$

in (35) is the conditional probability of transition $\mathrm{S}_i \to \mathrm{S}_{i+1}$ given that a transition out of S_i takes place, while the factor $(-1/\nu_{i+1,i+1})$ is the expected duration of stay in stage S_{i+1}. In other words, the expectation $\mathrm{E}(T)$ in (35) is the sum of expected durations of stay in $\mathrm{S}_1, \mathrm{S}_2, \ldots, \mathrm{S}_k$, as it should be.

The variance of the survival time T is:

$$\mathrm{var}(T) = 2\left[\left(\frac{\mu_1}{-\nu_{11}}\right)\frac{1}{\nu_{11}^2} + \frac{\nu_{12}\mu_2}{\nu_{11}\nu_{22}}\sum_{j\geq i}^{2}\sum_{i=1}^{2}\frac{1}{\nu_{ii}\nu_{jj}} + \cdots + (-1)^k\left(\prod_{i=1}^{k-1}\frac{\nu_{i,i+1}}{\nu_{ii}}\right) \times \frac{\mu_k}{\nu_{kk}}\sum_{j\geq i}^{k}\sum_{i=1}^{k}\frac{1}{\nu_{ii}\nu_{jj}}\right] - [\mathrm{E}(T)]^2.$$

The staging process described in this section is a special case of the *illness – death process*, in which transitions between states of illness may be reversible. Another particular case is the **Fix–Neyman process**.

Birth–Death Processes

The stochastic processes presented so far in this article have been either increasing processes like the Yule processes, or decreasing processes like the death processes. We now consider processes that allow a population to grow as well as to decline, which are more relevant to the biological and the human populations in which both births and

deaths occur. The concept of birth–death processes existed before the theory of stochastic processes. Kendall [19] was among the first to seek a general solution of the processes. Methods of solving the differential equations have since been revised and refined. In this section, explicit solutions for two cases are presented.

Again, we let $X(t)$ be the population size at time t, for $0 \le t < \infty$, and the transition probability

$$p_{i,k}(0,t) = \Pr\{X(t) = k | X(0) = i\}, \quad \text{for } k = 0, 1, \ldots.$$

Given $X(t) = k$, let $\lambda_k(t)$ and $\mu_k(t)$ be the birth intensity and death intensity functions, respectively. The transition probabilities satisfy the following differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,0}(0,t) = -[\lambda_0(t) + \mu_0(t)] p_{i,0}(0,t) + \mu_1(t) p_{i,1}(0,t), \tag{36a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,k}(0,t) = -[\lambda_k(t) + \mu_k(t)] p_{i,k}(0,t) + \lambda_{k-1}(t) p_{i,k-1}(t) + \mu_{k+1}(t) p_{i,k+1}(t). \tag{36b}$$

The system of differential equations in (36) and the initial conditions,

$$p_{i,i}(0,0) = 1 \quad \text{and} \quad p_{i,k}(0,0) = 0 \text{ for } k \ne i,$$

completely determine the probability distribution $\{p_{i,k}(0,t)\}$. Since the differential equations are dependent on the intensity functions $\lambda_k(t)$ and $\mu_k(t)$, two specific forms of the intensity functions are assumed in the following discussion.

Linear Growth

Suppose both $\lambda_k(t)$ and $\mu_k(t)$ are independent of time but proportional to k,

$$\lambda_k(t) = k\lambda \quad \text{and} \quad \mu_k(t) = k\mu,$$

where λ and μ are constant. In this case, the differential equations (36) become:

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,0}(0,t) = \mu p_{i,1}(0,t) \tag{37a}$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{i,k}(0,t) = -k(\lambda+\mu) p_{i,k}(0,t) + (k-1)\lambda p_{i,k-1}(0,t) + (k+1)\mu p_{i,k+1}(0,t), \quad k = 1, 2, \ldots. \tag{37b}$$

Each of differential equations in (37b) has three unknown probabilities, $p_{i,k-1}(0,t)$, $p_{i,k}(0,t)$, and $p_{i,k+1}(0,t)$, and cannot be solved with the methods used in the general birth process. We resort to the method of probability generating functions (pgfs). The pgf of $X(t)$ is defined by

$$G_X(s;t) = \sum_{k=0}^{\infty} s^k p_{i,k}(0,t),$$

which is a polynomial in s, the coefficient of s^k being the transition probability $p_{i,k}(0,t)$, for $k = 0, 1, \ldots$. Therefore, when an explicit formula for the pgf is derived, one can obtain the desired transition probability by identifying the coefficient of the corresponding s^k.

In addition to the probabilities, the pgf also generates the expectation and the variance of $X(t)$.

Using the differential equations (37) we find that the generating function satisfies the partial differential equation,

$$\frac{\partial}{\partial t} G_X(s;t) + (1-s)(\lambda s - \mu)\frac{\partial}{\partial s} G_X(s;t) = 0,$$

with the initial condition at $t = 0$ given by $G_{X(0)}(s;0) = s^i$. The solution of the partial differential equation is:

$$G_X(s;t) = \left\{ \frac{\alpha(t) + [1 - \alpha(t) - \beta(t)]s}{1 - \beta(t)s} \right\}^i, \tag{38}$$

where

$$\alpha(t) = \mu \frac{1 - \exp\{(\lambda-\mu)t\}}{\mu - \lambda \exp\{(\lambda-\mu)t\}} \text{ and } \beta(t) = \frac{\lambda}{\mu}\alpha(t).$$

Now it is a simple matter of expanding the pgf as a polynomial in s, and identifying the coefficient of s^k to obtain the formula for the probability $p_{i,k}\ (0,t)$.

The numerator on the right-hand side of (38) is a binomial function:

$$\{\alpha(t) + [1 - \alpha(t) - \beta(t)]s\}^i = \sum_{j=0}^{i} \binom{i}{j} [\alpha(t)]^{i-j} [1 - \alpha(t) - \beta(t)]^j s^j.$$

For the denominator, since clearly $|\beta(t)s| < 1$,

$$\{1 - \beta(t)s\}^{-i} = \sum_{j=0}^{\infty} \binom{-i}{j} (-1)^j [\beta(t)]^j s^j = \sum_{j=0}^{\infty} \binom{i+j-1}{j} [\beta(t)]^j s^j.$$

Hence the probability

$$p_{i,k}(0,t) = \sum_{j=0}^{\min[i,k]} \binom{i}{j} \binom{i+k-j-1}{k-j} [\alpha(t)]^{i-j} \times [\beta(t)]^{k-j} [1 - \alpha(t) - \beta(t)]^j, \qquad (39)$$

for $k = 1, 2, \ldots$. For $k = 0$,

$$p_{i,0}(0,t) = [\alpha(t)]^i$$

is the probability that the population will become extinct at time t.

When $i = 1$, formula (38) is the pgf of the population size at time t when the initial population is $X(0) = 1$. This means that the random variable $X(t)$ discussed above is the sum of i independent and identically distributed random variables, each having the pgf defined in (38) with $i = 1$. In other words, the i populations reproduce and perish independent of each other, but their growth is subject to the same probability law $\{p_{1,k}(0,t)\}$.

Differentiating the pgf in (38) with respect to s yields the expectation of $X(t)$,

$$\mathrm{E}[X(t)] = i \exp\{(\lambda - \mu)t\},$$

and the variance of $X(t)$,

$$\sigma^2_{X(t)} = i \left(\frac{\lambda + \mu}{\lambda - \mu}\right) \exp\{(\lambda - \mu)t\} \times [\exp\{(\lambda - \mu)t\} - 1].$$

Two terms had been suggested for the birth–death processes, depending upon the relative values of the birth parameter λ and the death parameter μ. If $\lambda > \mu$, then the birth–death process is called supercritical; if $\lambda < \mu$, then the process is subcritical.

When $\lambda = \mu$, the probabilities are

$$p_{i,k}(0,t) = \sum_{j=0}^{\min[i,k]} \binom{i}{j} \binom{i+k-j-1}{k-j} (\lambda t)^{i+k-2j} \times (1 - \lambda t)^j (1 + \lambda t)^{-i-k+j}, \quad k > 1,$$

and

$$p_{i,0}(0,t) = \left\{\frac{\lambda t}{1 + \lambda t}\right\}^i.$$

The expectation and the variance of $X(t)$ are

$$\mathrm{E}[X(t)] = i \quad \text{and} \quad \sigma^2_{X(t)} = 2i\lambda t.$$

Thus, when the birth rate λ is equal to the death rate μ, the population size has a constant expectation but an increasing variance with time t.

As t approaches infinity, the limiting behavior of the birth–death process depends on the relative values of the birth rate λ and the death rate μ. The following are the asymptotic values of the probability generating function.

$$\lim_{t\to\infty} G_{X(t)}(s,t) = \begin{cases} 1, & \text{if} \quad \lambda \le \mu, \\ \left(\frac{\mu}{\lambda}\right)^i, & \text{if} \quad \lambda > \mu. \end{cases} \qquad (40)$$

Now when $s = 0$, $G_X(0;t) = p_{i,0}(0,t)$ is the probability that the population will become extinct at time t. According to (40), if the birth rate λ is smaller than or equal to the death rate μ, then the probability of extinction tends to unity as $t \to \infty$, and the population is certain to die out eventually. On the other hand, if the birth rate λ is greater than the death rate μ the probability of ultimate extinction is $(\mu/\lambda)^i$. Furthermore, since the limiting pgf is a constant, the population will either die out with probability $(\mu/\lambda)^i$, or increase without bound with probability $1 - (\mu/\lambda)^i$; no intermediate course is possible.

The relative values of λ and μ also influence the asymptotic values of the expectation and the variance of $X(t)$. As t approaches infinity,

$$\lim_{t\to\infty} \mathrm{E}[X(t)] = \begin{cases} 0, & \text{if} \quad \lambda < \mu, \\ i, & \text{if} \quad \lambda = \mu, \\ \infty, & \text{if} \quad \lambda > \mu, \end{cases}$$

and

$$\lim_{t\to\infty} \text{var}[X(t)] = \begin{cases} 0, & \text{if } \lambda < \mu, \\ \infty, & \text{if } \lambda \geq \mu. \end{cases}$$

When $\lambda = \mu$, we have an interesting case in which the probability of extinction tends to unity, yet the expected population size tends to i. These seemingly contradictory facts may be intuitively explained by the large value of the variance. Although most populations will eventually become extinct, a few will attain huge sizes, so that the average size will be i.

Time-Dependent Birth–Death Process

We may generalize the birth–death process presented above by letting both the birth intensity function $\lambda(t)$ and the death intensity function $\mu(t)$ be functions of time t. In this case the differential equations for the transition probability $p_{i,k}(0,t)$ assume the same general form as those in formulas (37a) and (37b) with the functions $\lambda(t)$ and $\mu(t)$ replacing the constants λ and μ, respectively.

Again we derive the formulas for the transition probabilities $p_{i,k}(0,t)$ by way of the probability generating function, Which turns out to be

$$G_X(s;t) = \left\{ \frac{\alpha(t) + [1 - \alpha(t) - \beta(t)]s}{1 - \beta(t)s} \right\}^i, \quad (38a)$$

where

$$\alpha(t) = 1 - \frac{1}{\exp[\gamma(t)] + \displaystyle\int_0^t \lambda(\tau)\exp[\gamma(\tau)]\,d\tau},$$

$$\beta(t) = 1 - \exp[\gamma(t)][1 - \alpha(t)],$$

$$\gamma(t) = -\int_0^t [\lambda(\tau) - \mu(\tau)]\,d\tau.$$

Except for the definitions of $\alpha(t)$ and $\beta(t)$, the pgf is of the same general form as in (38). Consequently, the formulas for the transition probabilities $p_{i,k}(0,t)$ assume the same form as those in (39).

The expectation of $X(t)$ is

$$\text{E}[X(t)] = i \exp\left\{ \int_0^t [\lambda(\tau) - \mu(\tau)]\,d\tau \right\}.$$

Thus $\text{E}[X(t)] \to \infty$ if the integral diverges, $\text{E}[X(t)] \to 0$ if the integral approaches minus infinity, and $\text{E}[X(t)] \to i$ if $\lambda(\tau) = \mu(\tau)$, whatever the value of τ, $0 \leq \tau < \infty$.

The probability of population extinction can be obtained directly from the pgf by setting $s = 0$,

$$p_{i,0}(0,t) = \left\{ \frac{\displaystyle\int_0^t \mu(\tau)\exp[\gamma(\tau)]\,d\tau}{1 + \displaystyle\int_0^t \mu(\tau)\exp[\gamma(\tau)]\,d\tau} \right\}^i,$$

which approaches unity if and only if the integral

$$\int_0^t \mu(\tau)\exp\left\{ -\int_0^\tau [\lambda(\xi) - \mu(\xi)]\,d\xi \right\} d\tau$$

diverges as $t \to \infty$. Obviously, the divergence occurs if and only if $\mu(\tau) > \lambda(\tau)$ for every $\tau > 0$. This conclusion is consistent with that reached in the consideration of $\text{E}[X(t)] \to 0$.

Finite Markov Processes

In a finite Markov process, a system has a finite or denumerable number of states: $1, 2, \ldots$. The state of a system at time t is identified by the value of a discrete random variable $X(t)$. "The system is in state j at time t" is the same as "$X(t) = j$". In the birth–death processes, for example, the state of the system at time t was the population size at t, and was identified by the value $X(t) = k$. But there was a rather restrictive assumption that, within a small time interval $(t, t + \Delta t)$, the population size may increase, or decrease, by only one. We now remove this restriction and allow a system to move from any state in the system to any other state in the system. And we assume that the set of states is closed and contains no proper closed subset in the set but itself. For a time interval (τ, t), for $\tau < t$, $\tau, t \in [0, \infty)$, we let

$$p_{ij}(\tau, t) = \Pr\{X(t) = j | X(\tau) = i\}, \quad \text{for } i, j = 1, 2, \ldots \quad (41)$$

be the transition (conditional) probabilities, with sum $\sum_j p_{ij}(0,t) = 1$, for every i. Formula (41) shows the stochastic dependence of $X(t)$ on $X(\tau)$. Two important forms of dependence are defined below:

Definition 3. A discrete-valued stochastic process $\{X(t) : t \in [0, \infty)\}$ is a Markov process if,

for any $t_0 < t_1 < \ldots t_i \ldots < t_j$ and any integers $k_0, k_1, \ldots, k_i, \ldots, k_j$,

$$\Pr\{X(t_j) = k_j | X(t_0) = k_0, X(t_1) = k_1, \ldots, X(t_i) = k_i\} = \Pr\{X(t_j) = k_j | X(t_i) = k_i\}. \quad (42)$$

Thus, in a Markov process, given $X(t_i)$ (present), the conditional probability of $X(t_j)$ (future) is independent of $X(t_0), \ldots, X(t_{i-1})$ (past).

Definition 4. A Markov process $\{X(t); t \in [0, \infty)\}$ is homogeneous with respect to time, or time-homogeneous, if the transition probability in (41) depends only the difference $t - \tau$ and not on τ or t separately. In such a case we may write

$$\Pr\{X(t) = j | X(\tau) = i\} = P_{ij}(0, t - \tau\}, \quad i, j = 1, 2, \ldots. \quad (43)$$

The simple Poisson process is an example of a time-homogeneous process.

Chapman–Kolmogorov Equations

Let ξ be a fixed point in the interval (τ, t), so that $\tau < \xi < t$, and let $X(\tau)$, $X(\xi)$, and $X(t)$ be the corresponding random variables. According to the assumption in (42),

$$\Pr\{X(t) = k | X(\tau) = i \text{ and } X(\xi) = j\} = \Pr\{X(t) = k | X(\xi) = j\} = P_{jk}(\xi, t)$$

and

$$\Pr\{X(\xi) = j \text{ and } X(t) = k | X(\tau) = i\} = P_{ij}(\tau, \xi) p_{jk}(\xi, t). \quad (44)$$

Formula (44) is the probability of a passage from $X(\tau) = i$ to $X(t) = k$ by way of a particular state j at time ξ. At time ξ, the system must be in one of the states $[1, 2, \ldots]$, and the set of the states is closed, $Pr\{X(\xi) = 1 \text{ or } X(\xi) = 2 \text{ or } \ldots\} = 1$. Therefore,

$$p_{ik}(\tau, t) = \sum_j p_{ij}(\tau, \xi) p_{jk}(\xi, t) \quad i, j, k = 1, 2, \ldots, \tau < \xi < t, \quad (45)$$

which is known as the *Chapman–Kolmogorov equation*. In the case of a time-homogeneous process, (45), may be replaced by

$$p_{ik}(0, \tau + t) = \sum_j p_{ij}(0, \tau) p_{jk}(0, t), \quad i, j, k = 1, 2, \ldots. \quad (46)$$

Kolmogorov Differential Equations

Kolmogorov [22] derived two systems of differential equations for the transition probabilities $p_{ij}(\tau, t)$: the *forward differential equations*, where the differentiation of $p_{ij}(\tau, t)$ is taken with respect to t; and the *backward differential equations*, where the differentiation is taken with respect to τ. When the transition probabilities $p_{ij}(\tau, t)$ satisfy certain regularity conditions, both systems may be derived from the Chapman–Kolmogorov equation (45). Following Kolmogorov, Chung [12], Doob [14], Feller [17], and others have discussed in detail theoretical aspects of these differential equations. Feller, for example, has shown that, if $\sum_j p_{ij}(\tau, t) = 1$, then there always exists a unique solution $p_{ij}(\tau, t)$ that satisfies both the forward and the backward differential equations. In this article we shall present explicit solutions for the individual transition probabilities $p_{ij}(0, t)$ for the time-homogeneous Markov processes. Reference may be made to [7] and [11].

Let the transition intensity functions be defined as follows:

$$\nu_{ij} \Delta + o(\Delta) = \Pr\{X(t + \Delta) = j | X(t) = i\}, \quad \text{for } j \neq i; i, j = 1, 2, \ldots, s,$$

and

$$\nu_{ii} = -\sum_{\substack{j=1 \\ j \neq i}}^{s} \nu_{ij}, \quad i = 1, 2, \ldots, s.$$

Denote the intensity function matrix $||\nu_{ij}||$ by $\mathbf{V}$.

In the time-homogeneous Markov processes, the forward Kolmogorov differential equations are

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{ik}(0, t) = \sum_{j=1}^{s} p_{ij}(0, t) \nu_{jk}, \quad (47)$$

and the backward differential equations are

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{ik}(0, t) = \sum_{j=1}^{s} \nu_{ij} p_{jk}(0, t), \quad (48)$$

with common initial condition

$$p_{ik}(0,0) = \delta_{ik}; \tag{49}$$

δ_{ik} is the Kronecker delta, i.e. $\delta_{ik} = 1$ if $k = i$ and $\delta_{ik} = 0$ if $k \neq i$.

Formulas for Transition Probabilities $p_{ij}(0, t)$

Derivation of the formulas for the transition probabilities requires the following result:

Lemma 2. For distinct numbers $\rho_1, \rho_2, \ldots, \rho_s$,

$$\sum_{i=1}^{s} \frac{\rho_i^r}{\prod_{\substack{j=1 \\ j\neq i}}^{s} (\rho_i - \rho_j)} = \begin{cases} 0, & \text{for } 0 \leq r < s-1, \quad (50) \\ 1, & \text{for } r = s-1. \quad (51) \end{cases}$$

See [6] for proof of (50) and (51).

Formulas (47) are first-order ordinary differential equations with constant coefficients; the solution should be exponential functions of t, $p_{ij}(0, t) = c_{ij} \exp\{\rho t\}$. Substituting the suggested solution in (47) and canceling out the nonvanishing exponential functions yields a system of $s \times s$ simultaneous homogeneous equations in c_{ij}. In order for the system to have nontrivial solution for c_{ij}, the matrix of the coefficients must be zero. That is, $\mathbf{A}'(\rho) = |\mathbf{I}\rho - \mathbf{V}'| = 0$, with roots $\rho_1, \rho_2, \ldots \rho_s$. This means that these roots are the only values of ρ for which the suggested solution is a valid solution for $p_{ij}(0, t)$.

For each root, say $\rho = \rho_\ell$, there is be a system of $s \times s$ simultaneous homogeneous equations for the unknown $c_{ij\ell}$. Since the simultaneous equations are homogeneous, $c_{ij\ell}$ are proportional to the cofactors of the matrix $\mathbf{A}'(\rho_\ell)$, or $c_{ij\ell} = k_{i\ell} A'_{ij}(\rho_\ell)$, for each ℓ. When the roots $\rho_1, \rho_2, \ldots, \rho_s$ are distinct, the general solution of the differential equation (47) is the following sum:

$$p_{ij}(0, t) = \sum_{\ell=1}^{s} k_{i\ell} A'_{ij}(\ell) e^{\rho_\ell t}, \; i, j = 1, \ldots, s. \tag{52}$$

At the initial time $t = 0$, $p_{ii}(0, 0) = 1$ and $p_{ij}(0, 0) = 0$. These initial conditions impose restrictions on $k_{i\ell}$ in (52). Expanding each cofactor $A'_{ij}(\ell)$ as a polynomial in ρ_ℓ, and using the identities (50) and (51) in the lemma, we find

$$k_{i\ell} = \left[\prod_{\substack{m=1 \\ m\neq\ell}}^{s} (\rho_\ell - \rho_m) \right]^{-1}.$$

Substituting these values of k_i in (52) yields the solution:

$$p_{ij}(0, t) = \sum_{\ell=1}^{s} \frac{A'_{ij}(\rho_\ell) \exp\{\rho_\ell t\}}{\prod_{\substack{m=1 \\ m\neq\ell}}^{s} (\rho_\ell - \rho_m)}, \quad i, j = 1, \ldots, s. \tag{53}$$

The limiting probabilities can be obtained from (53), as t approaches infinity:

$$\lim_{t\to\infty} p_{ij}(0, t) = \frac{V_{jj}}{\sum_{\ell=1}^{s} V_{\ell\ell}}, \quad i, j = 1, \ldots, s, \tag{54}$$

where V_{jj} are the principal minors of matrix $\mathbf{V}$.

The proof of this result is as follows: Since $\rho_k < 0$ for $k = 2, \ldots, s$, $\exp\{\rho_k t\}$ tends to zero as $t \to \infty$. From (53),

$$\lim_{t\to\infty} p_{ij}(0, t) = \frac{A'_{ij}(\rho_1)}{\prod_{m=2}^{s} (\rho_1 - \rho_m)}. \tag{55}$$

Here $\mathbf{A}'(\rho_1) = \rho_1 \mathbf{I} - \mathbf{V}'$ and $\rho_1 = 0$; therefore,

$$A'_{ij}(\rho_1) = (-1)^{s-1} V'_{ij} = (-1)^{s-1} V_{ji} = (-1)^{s-1} V_{jj}, \tag{56}$$

since $V_{ji} = V_{jj}$. For the denominator in (55), we write

$$(-1)^{s-1} \rho_2 \ldots \rho_s = (-1)^{s-1} [V_{11} + \ldots + V_{ss}]. \tag{57}$$

Substituting (56) and (57) in (55) yields (54).

Solution of Backward Differential Equations

Formula (53) for the transition probability also satisfies the backward Kolmogorov differential equations (48). Substituting (53) in (48) yields the equation

$$\sum_{\ell=1}^{s} \frac{A'_{ik}(\rho_\ell)}{\prod_{\substack{m=1\\m\neq l}}^{s}(\rho_\ell - \rho_m)} \rho_\ell \exp\{\rho_\ell t\}$$

$$= \sum_{j=1}^{s} \nu_{ij} \sum_{\ell=1}^{s} \frac{A'_{jk}(\rho_\ell)\exp\{\rho_\ell t\}}{\prod_{\substack{m=1\\m\neq \ell}}^{s}(\rho_\ell - \rho_m)}, \qquad (58)$$

which holds if, for each ℓ,

$$\rho_\ell A'_{ik}(\rho_\ell) = \sum_{j=1}^{s} \nu_{ij} A'_{jk}(\rho_\ell)$$

or

$$\rho_\ell A_{ki}(\rho_\ell) - \sum_{j=1}^{s} \nu_{ij} A_{kj}(\rho_\ell) = 0. \qquad (59)$$

The left-hand side of (59) is an expansion of the determinant $|\mathbf{A}(\rho_\ell)|$ using the kth row cofactors and the ith row elements. It is equal to zero for $i \neq k$, and is equal to the determinant $|\mathbf{A}(\rho_\ell)| = 0$ for $i = k$, since ρ_ℓ is a root of the equation $|\mathbf{A}(\rho)| = 0$. Therefore, equation (59) is true. This implies (58), which means that (48) is satisfied.

A Time-Dependent Markov Process

When the transition intensity is a product of two functions, one being a function of the states involved in the transition and the other a function of the time at which the transition takes place, we have a time-dependent Markov process. Specifically,

$$\Pr\{X(t+\Delta) = j | X(t) = i\} = \nu_{ij}\beta(t)\Delta + o(\Delta).$$

The corresponding differential equations are

$$\frac{\mathrm{d}}{\mathrm{d}t} p_{ik}(0,t) = \sum_{j=1}^{s} p_{ij}(0,t)\nu_{jk}\beta(t),$$

$$i, k = 1, 2, \ldots, s,$$

and the formulas for the transition probabilities are

$$p_{ij}(0,t) = \sum_{\ell=1}^{s} \frac{A'_{ij}(\rho_\ell)\exp[\rho_\ell \int_0^t \beta(\tau)\,\mathrm{d}\tau]}{\prod_{\substack{m=1\\m\neq\ell}}^{s}(\rho_\ell - \rho_m)}$$

for $i, j = 1, 2, \ldots, s$, where $A'_{ij}(\rho_\ell)$ and ρ_ℓ have the same meaning as those in (53).

CHIN LONG CHIANG

Stocks, Percy

Born: November 5, 1899.
Died: December 18, 1974.

After qualification in medicine and public health, Stocks joined the public health service in Bristol, before moving to **Karl Pearson's** department at University College London (UCL) in 1921, where, in 1926, he became Reader in Medical Statistics. He became Chief Medical Statistician at the General Register Office (GRO) from 1933 until retirement in 1950. At UCL and at the GRO he conducted epidemiologic studies, and at the GRO he played a leading part in revising the **International Classification of Diseases**. After retirement, he was a research fellow in cancer until 1957, and published studies on cancer epidemiology. In an obituary notice in the ***Journal of the Royal Statistical Society***, **A. Bradford Hill** wrote "Percy Stocks will be remembered, nationally and internationally, as one of the great contributors to the development and use of medical statistics".

PETER ARMITAGE

Stratification

Stratification refers in epidemiology to a design that improves the efficiency of analytical procedures to control for **confounding** by causing **controls** to have the same distribution over strata defined by levels of potential **confounders** as cases in a **case–control study** or as the exposed cohort in a **cohort study** (*see* **Matching**; **Frequency Matching**). Stratification (or stratified analysis) also refers to the analytical strategy that controls for confounding by estimating the **association** between exposure and disease status within strata defined by categorized levels of potential confounders and then combining stratum-specific results to obtain an overall estimate of exposure effect (*see* **Mantel–Haenszel Methods**; **Matched Analysis**).

In the context of survey sampling, stratification is an efficient design that usually allocates larger samples to strata of the population within which the estimate has a large **variance** (*see* **Stratified Sampling**).

MITCHELL H. GAIL

Stratified Sampling, Allocation in

Allocation describes the size of the sample to be selected in each stratum. The fact that a fixed sample size can be selected from each stratum is due to the two defining characteristics of a stratified design: (i) all members of the population can be partitioned into strata and (ii) samples of these members can be selected independently among strata (*see* **Stratified Sampling**).

Whether the total sample allocation is constrained by fixed sampling costs or whether an estimate with a specific **variance** is needed at any cost, a judicious allocation of sample size to strata can result in significant survey gains. If costs are fixed, then a good sample allocation can produce estimates with a smaller variance than other estimates sampled at equal costs. If a target variance is specified for an estimate, then a good allocation will produce estimates with variance equal to costlier alternatives. Gains in allocation are greatest when either the stratum variances or differential stratum sampling costs vary widely. To achieve a gain, only knowledge of the relative values of stratum variances is needed. Rough guesses of stratum variances and costs, possibly using related data and surveys, may even be enough to achieve large gains. Lastly, although the allocation of sample will influence the precision of an estimate and can reduce the cost of a sample, there is no wrong allocation in the sense that **unbiased** estimates of linear population parameters can always be made from any allocation in which each stratum is sampled.

When estimates of the population **mean** or population total are needed, proportional allocation or the all-encompassing optimal allocation is usually used. When individual strata estimates or estimates of strata differences are needed, equal allocation is most commonly used. Note that the population mean is defined as $\overline{Y} = \sum_{j=1}^{L} N_j \overline{Y}_j / N_\cdot$, where L is the number of strata, N_j is the number of elements in stratum j, $\overline{Y}_j = \sum_{k=1}^{N_j} Y_{jk}/N_j$ is the stratum mean and $N_\cdot = \sum_{j=1}^{L} N_j$ is the total population size. The (unbiased) estimator of the population mean, considered here, is $\overline{y} = \sum_{j=1}^{L} N_j \overline{y}_j / N_\cdot$, where $\overline{y}_j = \sum_{k\in s}^{N_j} Y_{jk}/n_j$ is the stratum mean based on a sample of size n_j. The population total is defined as $Y = \sum_{j=1}^{L} N_j \overline{Y}_j$ with an estimator: $\hat{y} = \sum_{j=1}^{L} N_j \overline{y}_j$.

As its name implies, proportional allocation involves allocating the total sample size proportionally to strata size. Given that a total sample of size n will be selected and that the number of individuals in stratum j is N_j, the proportional allocation of sample to stratum j is

$$n_j = n\frac{N_j}{N}.$$

Even though proportional allocation is most appropriate when both the variability of individuals within each stratum and sampling costs are constant across strata, it is often employed when little is known about the strata variances or collection costs. This is because it is believed that a good stratification, in producing homogeneous strata, may also produce strata having similar variances.

An optimal allocation is the sample allocation that produces an estimate with the smallest variance among all sample allocations under consideration. Note that for any allocation:

$$\mathrm{var}\overline{y} = \sum_{j=1}^{L} \left(\frac{N_j}{N}\right)^2 \left(1 - \frac{n_j}{N_j}\right) \frac{S_j^2}{n_j},$$

where

$$S_j^2 = \sum_{k=1}^{N_j} \frac{(Y_{jk} - \overline{Y}_j)^2}{(N_j - 1)} \quad \text{and} \quad \mathrm{var}\hat{y} = N^2 \mathrm{var}\overline{y}.$$

If there are L strata and the variance within stratum j is S_j^2, then the optimal allocation to stratum j, when the total sample is of size n is

$$n_j = n\frac{N_j S_j}{\sum_{k=1}^{L} N_k S_k}.$$

This type of allocation is also referred to as Neyman allocation, after **J. Neyman**, who showed in 1934 that it is optimal among all fixed-sized samples [6].

Costs may vary widely when the strata utilize different sampling methods. For example, one stratum may contain households with a telephone and another stratum households without a telephone. Here the cost of sampling a household with a telephone is generally cheaper than a nontelephone household since it involves making a telephone call instead of a face-to-face interview. If the cost per element in stratum j is c_j, and only allocations of cost, c,

are allowed, i.e. $c = \sum_{j=1}^{L} n_j c_j$, then the optimal allocation to stratum j is

$$n_j = c \frac{N_j S_j / \sqrt{c_j}}{\sum_{k=1}^{L} N_k S_k / \sqrt{c_k}}.$$

This allocation finds the sample $n_1, \ldots, n_L$ that minimizes $\mathrm{var}\overline{y}$ (or, equivalently $\mathrm{var}\hat{y}$), subject to the cost constraint $c = \sum_{j=1}^{L} n_j c_j$. An estimator based on this allocation will have a variance smaller than one based on any other allocation of equal cost.

A number of facts can be observed by viewing the sample allocation formula listed above. Given equal strata costs, the optimum allocation selects relatively more units from strata with large variances and, given equal strata variances, the optimal allocation selects relatively more units from the cheaper strata. Comparing the optimal allocation with proportional allocation, it can be seen that proportional allocation is, itself, optimal when the within-strata variance is proportional to the cost. (The most common case is when both collection costs and variances are constant across strata.) Neyman allocation can be seen to be optimal for a fixed cost design when strata collection costs are constant.

Instead of a fixed cost design, an allocation may be needed to obtain an estimate with fixed variance. Given the same linear cost structure, the optimal allocation with fixed variance takes the same form as the optimal fixed cost allocation except that the cost c is unknown and must be solved. The minimal cost to achieve a fixed variance V is

$$c = \frac{\left(\sum_{k=1}^{L} N_k S_k \sqrt{c_k}\right)^2}{N^2 V - \sum_{k=1}^{L} (N_k S_k)^2}.$$

Detailed derivations of all the above allocation formulas are in most sampling books (see, for example, Cochran [1] or Sarndal et al. [7]).

Equal allocation is used if estimates for individual strata or strata differences are needed. Generally, this will not be a good allocation for estimating the population mean or total unless sampling costs, stratum variances, and stratum sizes are all constant across strata (in this case equal, proportional, and optimal allocations are identical). Allocation for strata means (or differences of means) is an example of multipurpose design since the objective, now, is to lower more than one variance. More on multipurpose allocation will be given below.

The allocations described above apply to **unbiased**, linear estimates (estimates consisting of weighted averages of sampled values) with a linear cost (when applicable). In reality, estimates may be nonlinear (e.g. **ratio or regression estimators**) as may be the costs. In practice, allocations for nonlinear estimators and nonlinear costs usually are determined by first replacing estimates and costs by their approximate, linearized versions.

Using the basic formulas given above, a few minor problems can arise. The allocations may not be integral valued. Also, the allocation to a stratum can sometimes be larger than the stratum population size, or it may be less than one. The nonintegral problem can be bypassed by using integer programming techniques that will only find optimal integral solutions. However, rounding the allocations to their nearest integer will give nearly optimal results. Allocations that are out of bounds can be avoided by using **linear programming** techniques. This approach is not commonly employed because it does not provide an easy-to-use formula and the following quick fix is usually adequate. When an allocation in stratum j is above N_j, just select N_j from that strata and reallocate the remaining $n - N_j$ to the remaining $L - 1$ strata using as before. This procedure can also be applied for sample sizes smaller than one. That is, a sample size of one is allocated to a stratum with allocation less than one. The stratum is then removed from the variance formula and the remaining sample is allocated to the remaining strata. Note that since unbiased estimates of variance require a sample size of at least two, only allocations that include at least two sample units per stratum are usually considered. A more detailed explanation of correcting for allocations out of bounds can be found in [1, p. 104] or [7, Section 12.7].

Owing to high costs per sampling unit, most surveys collect many items. In such a situation, an allocation is needed to provide precise estimates for every item. An allocation that provides the minimal variance for estimates of all items is clearly impossible, unless each item exhibits the same relative strata variances. Since only one allocation can actually be fielded, no allocation will be optimal for all items.

There are, however, several compromise methods used in practice. For example, if it is important to measure one item with as much precision as possible, then the allocation should be based solely on that item. Proportional allocation is also used in this context because, if subpopulations are not of interest, strata variances may be relatively constant for most items. If a fixed precision is required for each estimate, then the solution is clear: determine the minimal cost sample size in which all minimum precisions are obtained. Numerical solutions requiring linear programing methods are available to do this (see, for example, [4]).

Fixed cost multipurpose design places a further constraint on allocation. The concept of an admissible allocation can be used to determine a subset of acceptable allocations. An admissible allocation, with respect to multiple estimators, is one which cannot be uniformly improved on. For example, denote a possible allocation by $\underline{n}$. Given R estimators, denote the variance of the rth estimator using allocation $\underline{n}$ by $\text{var}(\overline{y}^{(r)}|\underline{n})$. An allocation $\underline{n}_0$ is admissible if there is no allocation, $\underline{n}$, such that $\text{var}(\overline{y}^{(1)}|\underline{n}) \leq \text{var}(\overline{y}^{(1)}\,|\,\underline{n}_0), \ldots, \text{var}(\overline{y}^{(R)}\,|\,\underline{n}) \leq \text{var}(\overline{y}^{(R)}\,|\,\underline{n}_0)$ and $\text{var}(\overline{y}^{(r)}|\underline{n}) < \text{var}(\overline{y}^{(r)}|\underline{n}_0)$ for at least one r, $1 \leq r \leq R$. Folks & Antle [3] give the solution for all admissible strata allocations based on R responses. When both individual strata means and an overall population mean are needed for one item, Bankier [2] advocates power allocations. This method provides a subset of admissible allocations ranging between proportional allocation (good for populations mean) and equal allocation (good for strata means). Graphs of the tradeoffs in precision can be viewed to determine an acceptable compromise.

If the measurements are all on the same scale, an allocation that minimizes the maximum variance (**minimax**) can be useful. For example, suppose that an allocation is needed to estimate each stratum mean. The minimax allocation that will produce estimates of equal precision is the solution to

$$\left(1 - \frac{n_1}{N_1}\right)\frac{S_1^2}{n_1} = \cdots = \left(1 - \frac{n_j}{N_j}\right)\frac{S_j^2}{n_j} = \cdots = \left(1 - \frac{n_L}{N_L}\right)\frac{S_L^2}{n_L}.$$

This solution can be determined by a numerical search procedure. Note that if all N_i are large, then an approximate minimax allocation is the solution to

$$\frac{S_1^2}{n_1} = \cdots = \frac{S_j^2}{n_j} = \cdots = \frac{S_L^2}{n_L}.$$

For a fixed sample size, the minimax solution is seen to be

$$n_j = n\frac{S_j^2}{\sum_{k=1}^{L} S_k^2},$$

giving equal allocation when all variances are equal.

Minimax allocations are very useful for all types of multiple objective surveys, as was shown by Malec [5], who employs the concept of admissible designs to find minimax designs.

Stratified Sampling

Stratified sampling is a **probability sampling** method that is frequently implemented in sample surveys. In general, a population's elements (or in practice the **sampling frame** members) are divided into distinct groups or strata based upon the similarity of selected characteristics important to the survey. Typically, each stratum is independently sampled using a method for which an **unbiased** estimator of stratum total or stratum mean can be computed. These estimated stratum totals may then be added to obtain an estimator for the population total. Similarly, a stratum-weighted average of the estimated stratum means may be computed to estimate the overall population **mean** (*see* **Estimation**). **Stratification** is used to increase the efficiency of a sample design with respect to cost and estimator precision.

In this article we discuss the theoretical foundations of stratified sampling. For simplicity, we focus on the most elementary sampling structure, *stratified random sampling*. Here, the population elements are sampled by **simple random sampling**. "Real-life" surveys tend to use stratified multistage cluster sampling (*see* **Cluster Sampling**; **Multistage Sampling**), but most of the elementary foundations presented here can be extended to these more complicated structures.

Two simple examples of stratified populations are as follows:

1. A population of physicians is stratified by state of practice and specialty (e.g. cardiology or neurology). One such stratum is New York cardiologists.
2. A population of hospital discharged patients in the US is stratified by region, and size of hospital classified by bed size. A typical stratum could be hospitals in the South with 500 or more beds.

After we establish some basic groundwork on stratification, some actual surveys will be discussed.

Basic Foundations for Stratification

The planners of a sample survey usually start by having a set of analytic survey objectives, including domains of study and precision requirements for target estimators. Additionally, costs and administrative constraints are an integral part of the survey design process. Cochran [1, Section 5.1] discusses four principal reasons why planners consider a stratified design:

1. The population contains subpopulations or subdomains which are of primary interest to the survey planners. When distinct estimates of known precision are needed for these selected subdomains, it is advisable to treat each subpopulation as a "population" in its own right. Sample sizes within a designated subpopulation stratum may be increased to meet target precision levels.
2. It may be administratively convenient to stratify. An agency conducting a survey may have field offices which may be used to stratify a population. Each field office may be responsible for the survey administration of its part.
3. Distinct groups within a population may differ to such a degree that different sampling procedures are required. Also, since the population of study may be partitioned by multiple frames with different operational characteristics, a stratified sample may be the only workable option.
4. Stratification may improve the precision of sample estimators of the entire population. It may be possible to divide a heterogeneous population into subpopulations, each of which is internally homogeneous. Sampling variability within each stratum should be much smaller than sampling variability over the population as a whole. Precise estimates of the means of each stratum can be obtained by targeted sample sizes, and then the estimates combined to form an estimate for the entire population. With an appropriate allocation of sample, this estimator will be more precise than one created from the same size sample, but without stratification.

The gaining of precision through stratification, as outlined in reason 4 above, can be justified theoretically for many commonly used sampling methods. For simplicity, the mathematical theory presented here will focus upon simple random sample methods and linear estimators; for example, totals and means having a known base.

Suppose that a population of N elements has already been divided into L strata of known sizes N_h, $h = 1, 2, \ldots, L$, and that stratum h contains population elements Y_{hi}, $i = 1, 2, \ldots, N_h$. The true

stratum population means and **variances** are defined as $\overline{Y}_h = \sum_{i=1}^{N_h} Y_{ih}/N_h$ and $S_h^2 = \sum_{i=1}^{N_h}(Y_{hi} - \overline{Y}_h)^2/(N_h - 1)$, respectively, and the true total population mean and variance may be expressed as $\overline{Y} = \sum_{h=1}^{L}\sum_{i=1}^{N_h} Y_{hi}/N = \sum_{h=1}^{L}(N_h/N)\overline{Y}_h$, and $S^2 = \sum_{h=1}^{L}\sum_{i=1}^{N_h}(Y_{ih} - \overline{Y})^2/(N-1)$, respectively. Now, if a simple random sample (SRS) of size n is taken from the entire population, the typical estimator of $\overline{Y}$ is the sample mean, $\overline{y}_{\text{srs}} = \sum_{j=1}^{n} y_j/n$. For stratified random sampling over L strata, a random sample of size n_h is taken independently within each group. The sample stratum mean, $\overline{y}_h = \sum_{i=1}^{n_h} y_{hi}/n_h$, is calculated and weighted by relative stratum size to define the stratified estimator, $\overline{y}_{\text{str}} = \sum_{h=1}^{L}(N_h/N)\overline{y}_h$. Both estimators are unbiased for the true population mean – that is, $\text{E}(\overline{y}_{\text{srs}}) = \text{E}(\overline{y}_{\text{str}}) = \overline{Y}$ – and they have respective variances:

$$\text{var}(\overline{y}_{\text{srs}}) = \left(1 - \frac{n}{N}\right)\frac{S^2}{n} \quad \text{and}$$

$$\text{var}(\overline{y}_{\text{str}}) = \sum_{h=1}^{L}\left(\frac{N_h}{N}\right)^2 \frac{S_h^2}{n_h}\left(1 - \frac{n_h}{N_h}\right).$$

Note that for an estimator of population total, one just multiplies the above mean estimators by N and the variances by N^2.

The impact of stratification on survey costs and estimator precision depends upon how the sample of n units is allocated to the strata. If the unit cost of sampling varies by some naturally defined strata, few survey planners would consider an unstratified sample. Most surveys are conducted under the constraint of a fixed budget, and the survey planners must have some ability to control sample sizes by stratum costs. For example, the National Hospital Discharge Survey (NHDS), a survey of hospital procedures performed throughout the year, stratifies hospitals into those the records of which have been automated and are served by an abstract service and into those the records of which must be processed manually. An "automated-record" hospital costs considerably less to sample and process than a "manual-record" hospital. This topic of optimal sample allocations with respect to cost and precision requirements is discussed in greater detail in Sukhatme et al.[7, Chapter 4] (*see* **Stratified Sampling, Allocation in**).

For surveys in which sample unit costs are identical over strata, both stratified and nonstratified sampling can readily be compared for various allocations of a fixed total sample size n. First, under some mild conditions it can be shown that the optimal allocation of the total sample size n into L independent samples, n_h, is defined by

$$n_h = n\frac{N_h S_h}{\sum_{h=1}^{L} N_h S_h},$$

with S_h the stratum population **standard deviation**. This is referred to as the Neyman allocation. This is optimal in the sense that $\text{var}(\overline{y}_{\text{Neyman}}) \le \text{var}(\overline{y}_{\text{str}})$ for any other stratified sample allocation. Intuitively, the largest strata are the most important in estimating the population mean, and more sample should be allocated to the large strata. Also, the strata with the largest dispersions require more sample for precise estimation. The proportionality factor $N_h S_h$ can be can be thought of as a combined measure of these two intuitive concepts. In practice, a true Neyman allocation is rarely implemented, because the true S_h is usually unknown. Instead, survey planners use a variable that has a close relationship with the variable of interest. For example, in the NHDS discussed earlier, hospitals are stratified in part by geographic location, type of hospital, and bed size. Bed size is positively correlated with the number of discharges that a hospital produces and could be used to define a Neyman allocation.

Another commonly used stratified sampling method is proportional sampling, where $n_h = n(N_h/N)$. In practice, this method is easy to implement provided that the true sizes, N_h, of the strata are known. If the S_h do not deviate much by strata, then proportional sampling will be close to the Neyman optimal. If the strata sizes N_h are large, then the following relationships among the variances for Neyman, proportional, and unstratified SRS sampling can be established:

$$\text{var}(\overline{y}_{\text{srs}}) = \text{var}(\overline{y}_{\text{prop}}) + \frac{(1 - n/N)}{n} \times \sum_{i=1}^{L}\left(\frac{N_h}{N}\right)(\overline{Y}_h - \overline{Y})^2$$

with

$$\text{var}(\overline{y}_{\text{prop}}) = \left(1 - \frac{n}{N}\right)\left(\frac{1}{n}\right)\sum_{h=1}^{L}\left(\frac{N_h}{N}\right)S_h^2$$

and

$$\mathrm{var}(\overline{y}_{\mathrm{prop}}) = \mathrm{var}(\overline{y}_{\mathrm{Neyman}}) + \frac{1}{n}\sum_{i=1}^{L}\left(\frac{N_h}{N}\right)(\overline{S}_h - \overline{S})^2.$$

From the above two equations, one sees that the proportional allocation will provide a sampling variance at least as small as an unstratified simple random sample. The greatest sampling efficiencies occur when the true stratum means vary to a large degree. Neyman allocation will reduce the variance by a factor proportional to the variance of the stratum standard deviation. It should be noted that for a fixed proportion allocation on the same strata, both $\mathrm{var}(\overline{y}_{\mathrm{prop}}) \leq \mathrm{var}(\overline{y}_{\mathrm{srs}})$ and $\mathrm{var}(\overline{x}_{\mathrm{prop}}) \leq \mathrm{var}(\overline{x}_{\mathrm{srs}})$ for different characteristics y and x. This is an attractive property of stratified proportional sampling. For a Neyman allocation determined by a variable y, but also used for an other unrelated survey variable x, it is possible that $\mathrm{var}(\overline{x}_{\mathrm{Neyman}[y]}) \geq \mathrm{var}(\overline{x}_{\mathrm{srs}})$. Such a phenomenon may occur if $S_h(x)$ and $S_h(y)$ are negatively correlated. For example, in a population stratified by income level, a Neyman allocation targeted to estimate occupational work-loss days would probably be quite inefficient for estimating health insurance coverage for the unemployed. Thus while proportional sampling may not be optimal, it would be a safe strategy to use when several different variables are to be estimated using the same sample.

While stratified proportional sampling reduces the variance relative to unstratified SRS, Kish [3, Section 3.4] points out that, in practice, the relative gains may be only small or moderate. This is because survey planners do not have population variables available to define a highly efficient stratification. A special case of interest is the impact of stratification on estimating a population proportion, p. Here, the population variance is $p(1-p)$, and the stratum variance becomes $S_h^2 = p_h(1-p_h)$, with p_h the stratum proportion. The nature of this variance makes it somewhat insensitive to stratification if the resulting strata p_hs are in the central range of 0.20–0.80. However, for stratified cluster sampling, typical in major surveys, the efficiency gains for proportional sampling are greater than the element sampling discussed here.

If the strata themselves are of interest and comparisons are to be made among strata, then the individual stratum estimates, $\overline{y}_h$, and not the aggregate, $\overline{y}_{\mathrm{str}}$, are most important in meeting precision requirements. Equal allocation of sample to strata, $n_h = n/L$, could be used. In such cases, especially when the strata sizes, N_h, vary greatly in size, $\mathrm{var}(\overline{y}_{\mathrm{str}})$ may exceed $\mathrm{var}(\overline{y}_{\mathrm{srs}})$. For several computationally detailed examples of the stratified random sampling method, the reader is referred to Levy & Lemeshow [4].

The above discussion has assumed that a mean or total for an entire population is the target of estimation. Also important is the subdomain or subpopulation estimator. Frequently, subdomains dictate the main precision requirements of a survey. The estimation of the mean of a population subdomain is a special case of ratio estimation (*see* **Ratio and Regression Estimates**). Here, the **target population** parameter is

$$\overline{Y}_{\mathrm{D}} = \frac{\sum_{i=1}^{N} Y_i \delta_i}{\sum_{i=1}^{N} \delta_i},$$

where $\delta_i = 1$ if unit i is in subdomain D and 0 if not. A combined ratio estimator is $\overline{y}_{\mathrm{D,strc}} = (\overline{yd})_{\mathrm{str}}/\overline{d}_{\mathrm{str}}$, where the $(\overline{yd})_{\mathrm{str}}$ and $\overline{d}_{\mathrm{str}}$ are the stratified estimators of the numerator and denominator of $\overline{Y}_{\mathrm{D}}$. For this ratio estimator, the denominator may be random, and the **linearization method** may be used to derive approximate variance formulas.

Real Examples of Stratified Sampling

The following examples are taken from the **National Center for Health Statistics (NCHS)** family of surveys. They should be typical of the large-scale surveys conducted by government agencies to produce official statistics. The somewhat involved design structures of the NCHS surveys, as with most large-scale surveys, require some oversimplification to conceptualize the fundamentals. Furthermore, the design structures of NCHS surveys tend to change over time as objectives change. Most of the examples below should be considered as core design structures which will be somewhat modified for any specified year. The reader should refer to the NCHS references to get a more thorough description of any specific survey.

Example 1: National Maternal and Infant Health Survey (NMIHS)

One component of the NMIHS targets mothers who have recently given live birth or experienced fetal or infant death. Sample mothers are contacted by mail or telephone whenever possible. With this mode of data collection, certificates of live births, certificates of infant death, and official reports of fetal death are used as sampling frames. These frames are stratified and sampled as follows. Since birth and death records are collected and processed within a registration area, typically a state, these areas define an imposed administrative stratification. Mothers of low-**birthweight** infants and of black infants are specific targets of investigation. To meet these two study objectives, the live-birth certificates are partitioned by black and nonblack status and then cross classified by the infant's birthweight to form race–birthweight strata within each state. Simple random samples are taken within each stratum, but to meet precision goals for low-birthweight and/or black infants, these particular strata are oversampled, i.e. $n_B/n > N_B/N$, where B is any oversampled stratum.

Example 2: National Ambulatory Medical Care Survey (NAMCS)

For NAMCS, the target population consists of all patient visits to physicians engaged in office-based practice in a given year. The mode of data collection for this survey involves an experienced interviewer conducting face-to-face interviews with the sampled physicians. To keep costs manageable, a stratified multistage cluster sample is used. The primary sample units (PSUs) are a sample of "representative" counties (or equivalent territorial divisions) from a stratification of all counties in the US. Counties are stratified within four regions of the US by criteria involving the similarity of US Bureau of Census classifications (e.g. metropolitan status) and Decennial Census statistics available at the county level (e.g. county income or minority populations). PSUs are selected by **sampling with probability proportionate to size**. The size used for the NAMCS' PSUs has been the person population size, not the number of physicians. For cost considerations, the same sampled counties have served as sampled PSUs for other surveys. Since the sizes of the person population and physician population in a county are highly correlated, little efficiency is lost. Next, a sampling frame of licensed physicians taken from recent professional directories is created. This frame associates physicians with the counties and, furthermore, the physicians' specialty (e.g. family practice or neurology) is available on the frame. Ambulatory care should vary somewhat by the physicians' specialty, so within each sampled PSU the physicians are then substratified by specialty. Physicians are selected within specialty substrata by SRS, in such a way that over the first two sampling stages, any physician in the US has the same probability of being in the sample. This is called a self-weighting sample and may be expressed as follows.

If a physician b lives in PSU a then

$$\begin{aligned}\Pr(b \text{ is sampled}) &= \Pr(b \text{ sampled given PSU } a \text{ is sampled}) \Pr(\text{PSU } a \text{ is sampled}) \\ &= \left(\frac{n_{ah}}{N_{ah}}\right)\left(\frac{M_a}{M_s}\right) = \frac{1}{SI},\end{aligned}$$

where M_s is the size of the stratum containing PSU a, M_a is the size of county a, N_{ah} is the size of the specialty substratum h in PSU a, SI is a sampling interval determined to meet design objectives, and $n_{ah} = (N_{ah}/M_a)(M_s/SI)$ defines the sample size of physicians to be taken from substratum h in county a. Finally, a SRS sample of about 30 patient visits is sampled from each physician's practice. The size at this level is determined so not to burden the physicians.

Example 3: National Health Interview Survey (NHIS)

The NHIS, a major health survey sampling about 50 000 households and about 120 000 persons, is conducted annually over the US noninstitutionalized population. It targets numerous health variables on age–race/ethnic–sex domains for specified precision levels. The mode of data collection involves a face-to-face interview which requires a stratified multistage geographic cluster sample to be cost effective. The target population is not directly available as a sampling frame, but is covered for the most part by two distinct frames. An area sample frame consisting of small geographic areas with dwelling units covered by the most recent US Decennial Census includes most of the target population. To

keep the coverage current, a frame consisting of places where new residential housing has been constructed since the last Decennial Census is also created. The former frame contains Decennial Census social–economic–demographic information, but the latter frame contains only location. For the survey design implemented from 1995 to 2004, a survey objective is to make the NHIS more conducive to possible future dual frame surveys at the state level. This objective results in the population primary sampling units (PSUs), counties (or equivalents), being stratified within each state by metropolitan status and poverty status. Large states have more strata than small states. For national statistics, this stratification is not as efficient as one that would allow stratum geographic boundaries to cross state borders. Within each PSU, smaller geographic units, called segments, are classified into 20 race–ethnicity substrata by the density of black and Hispanic populations covered by the area frame, and into a substratum containing the new construction frame.

At the first stage of sampling, either one or two PSUs are selected from each stratum, with probability proportional to population size. The very large population PSUs – for example, New York City and Los Angeles – are self-representing; that is, they are in the sample with certainty. At the second stage, a SRS sample of segments is taken from each race–ethnic substratum within a sampled PSU. At the third stage, all black or Hispanic households are sampled within each segment, while a SRS of the complement households is taken. The second- and third-stage SRS sample sizes are defined in such a way as to obtain precise estimates for minority populations. The end result is that black and Hispanic samples are a much greater proportion of the sample than are their population proportions. This allows for precise estimation on small minority age–sex subdomains.

Example 4: National Health and Nutrition Examination Survey (NHANES)

The NHANES family of surveys assess the health of the noninstitutionalized population. They are much more in-depth than the NHIS in that they target about 30 000 sample subjects to be given a complete physical examination. This examination is conducted in a specially designed mobile examination center, and it takes 6 years of data collection. Operational constraints and costs dictate that only about 89 geographic sites in the US can be visited, each for a period of about one month to collect data. NHANES planners have the objectives of measuring hundreds of health related variables for 52 different age–sex–race/ethnic subdomains of the US population, with an emphasis on black and Mexican-American domains. A comparison of domain considerations dictates that each domain should have a sample size of 560 or more to meet the following precision requirements:

1. If D is a targeted domain, then $\mathrm{se}(\hat{p}_\mathrm{D})/\mathrm{E}(\hat{p}_\mathrm{D}) \leq 0.30$ whenever $\mathrm{E}(\hat{p}_\mathrm{D}) = 0.10$ (relative standard error requirement).
2. If D_1 and D_2 are two distinct targeted domains, then a test of hypotheses (*see* **Hypothesis Testing**) $\mathrm{H}_0 : \mathrm{E}(\hat{p}_{\mathrm{D}_1} - \hat{p}_{\mathrm{D}_2}) = 0.0$ vs. $\mathrm{H}_1 : |\mathrm{E}(\hat{p}_{\mathrm{D}_1} - \hat{p}_{\mathrm{D}_2})| \geq 0.10$ should have **power** at least 0.90 for a size 0.05 test.

A county is the primary sampling unit, just as in the NHIS. While age and sex define domains of interest, and one might expect health variables to differ on these domains, age and sex make poor stratification variables when aggregated at the county level. This is because counties vary little in their proportional age–sex composition. On the other hand, race–ethnic aggregates make good county stratifiers, since they vary greatly by county. NHANES used Decennial Census information on race/ethnicity along with income and metropolitan status to stratify the counties into 47 strata. Unlike the NHIS, the measure of size of a county is not the total population, but a composite measure that placed more weight on a county's black and Mexican-American components. One or two counties are sampled from each stratum, and then multiple stage sampling is used to obtain a sample of persons. The precision objectives for minority populations leads to the black, Mexican-American, and the white/other populations to have approximate sample proportions of 0.30, 0.30, and 0.40, respectively, while the population proportions are about 0.13, 0.07, and 0.80, respectively.

Defining Strata

The discussion so far has considered sampling methods while treating the strata as already given, but the construction of the strata themselves is also important. Some basic issues involve the selection

of stratification variables, the boundaries between strata, and the number of strata to use (see Särndal et al.[6, Chapter 12]). Most optimality results cannot be implemented in practice, due to limited population information, conflicting design objectives, cost considerations, and administrative restrictions. Frequently, survey planners consider several stratified sampling options with respect to cost and precision to determine a design that will perform well over a wide spectrum of target variables; the selected design may not be optimal for any given variable.

Some stratification boundary defining rules have been studied under theoretic conditions. The best known is the *cum* $\sqrt{f}$ *rule*. This rule states that if y is a continuous variable, and $f(y)$ is the density function of y with support $[A_L, A_U]$ then an approximate optimal stratification of the population into H units with boundaries $A_L = a_0 < a_1 < a_2 < \ldots < a_{H-1} < a_H = A_{\mathrm{U}}$, each to be sampled by the Neyman allocation, would result from creating the H strata in such a way that

$$\int_{a_{\mathrm{H}-1}}^{a_{\mathrm{H}}} [f_Y(y)]^{1/2}\,\mathrm{d}y = \frac{1}{H}\int_{A_{\mathrm{L}}}^{A_{\mathrm{U}}} [f_Y(y)]^{1/2}\,\mathrm{d}y.$$

That is, each stratum accounts for $1/H$ of the total integral of $\sqrt{f}$. In practice, a variable related to y would be used. Using a histogram approach, Cochran [1, Section 5.A.7] provides a computational example of this method.

For element sampling, it is suggested by Kish [3, Section 3.6I] and Cochran [1, Section 5.A.8] to keep the number of strata modest in size. This suggestion is based in part on some simple theoretic structures. Let y be a **linear regression** on x, with ρ the **correlation** between y and x in the unstratified population. If the population is partitioned into L strata defined by the variable x, using the optimal strata boundaries along with sample sizes of n/L in each stratum, then

$$\frac{\mathrm{var}(\overline{y}_{\mathrm{str}})}{\mathrm{var}(\overline{y}_{\mathrm{srs}})} \geq \left[\frac{\rho^2}{L^2} + (1-\rho^2)\right].$$

As L becomes large, the lower bound tends to $(1-\rho^2)$, and a point of little return in variance reduction can be established. For $\rho < 0.95$, little reduction occurs for more than six strata. This argument would assume that, overall, estimators rather than individual stratum estimators are important.

Stratification after Sampling

Frequently, variables well-suited for partitioning the population into strata do not exist before sampling. In this case, an estimation technique, called **poststratification** can be used. Here, the sampled data are stratified after sampling, and then an estimator for population mean or total is created as if the sample had come from a presample stratification. More precisely, in the case that a simple random sample of size n is taken from an unstratified population, the sample is first poststratified into H strata, with sample stratum means $\overline{y}_g$, for $g = 1, 2, \ldots, H$, and then a poststratified mean estimator is defined: $\overline{y}_{\mathrm{pstr}} = \sum_{g=1}^{H}(N_g/N)\overline{y}_g$, where N_g/N are the population totals of the poststratification classes (see [8, Section 11.6]).

While the functional forms of the stratified and poststratified mean appear identical, there are some important distinctions as to implementation and statistical properties. First, selected poststratification classes must have known population sizes (or independently known accurate estimates of size). For example, in large-scale surveys, age–race–sex classes are frequently used for poststratification, since the US Bureau of the Census produces very accurate national tabulations, which it updates quarterly. However, a poststratification on a health status variable would be difficult, since the true class totals could not be obtained. Second, the sample sizes, n_g, observed within the poststratification cells are themselves random variables. If these sample sizes are reasonably large, perhaps having $n_g > 20$ in each class, then this method is almost as precise as the proportional stratified sampling discussed earlier. This method can be extended to more complicated sampling schemes.

Other Stratification Issues

In many large-scale surveys, the process of creating multiple levels of stratification and simple random samples can become quite involved. Instead, a process called implicit stratification along with **systematic sampling** is used [5]. For example, for an official survey of a metropolitan area, the US Bureau of the Census may provide a large sampling frame which partitions the area into identified blocks along with each block's urban status (central city or not), percentage minority population, and **median** income.

This frame may be sort-ordered by these variables. This example is a three-layer implicit stratification. Next, a systematic sample, say 1 of every 50 blocks or sampling interval of 50, can be taken from the ordered frame to obtain the sample. This method is very easy to implement and has frequently been used to obtain the within PSU samples of many NCHS surveys. The expected systematic sample sizes are proportional to the total size within any sort level. For variance estimation purposes, coarse levels containing large samples are often treated as stratified proportional samples. This facilitates analysis using conventional software (*see* **Software for Sample Survey Data**).

Well-designed surveys plan a method to compute unbiased estimators of variance for the basic total and mean estimators. In large-scale multistage cluster samples, such as NAMCS or NHIS, some strata may have only one sampled cluster. In such cases, no unbiased estimator exists. For such cases, collapsed strata may be created for variance estimation (see [2, Section 8.6]). Original strata may be collapsed by combining strata with similar stratum characteristics. The sampled clusters within a collapsed stratum are treated as having been sampled with replacement (*see* **Sampling With and Without Replacement**).

V. PARSONS

Stroke

World Health Organization criteria define stroke in humans as a sudden onset of signs of focal or global disturbance of cerebral function lasting more than 24 hours unless interrupted by surgery or death, with no apparent nonvascular cause [39]. For example, stroke can be characterized by the sudden loss of the ability to use the right hand and arm, the loss of the capability to produce and comprehend speech, or the loss of ability to see to one side. The causes of stroke vary. The most common is the sudden occlusion of a brain artery by a blood clot (ischemic stroke). Another cause is bleeding from a brain artery into the brain itself (intracerebral hemorrhage) or into the fluid-filled space around or within the brain (subarachnoid hemorrhage). Stroke is a major cause of morbidity and mortality in the world. In the US and other industrialized countries stroke is the third most common cause of death [2]. Although mortality has been in an accelerated decline from 1965 to 1985, studies suggest the decline is primarily attributable to a decrease in **case–fatality** rates rather than a decrease in incidence [4, 40].

Of the 500 000 strokes that occur each year, only 100 000–150 000 are fatal [2]. For most patients who survive a stroke, there is wide variability in impairment of physical and neurological function. Symptoms are highly dependent on time from stroke onset. During the course of disease, symptoms usually worsen, then gradually improve, albeit usually not completely. The disability can be a personal disaster for the patient. Loss of independence or a prolonged period of nursing home care is a common outcome [30].

Historical Development

Until 1995 no treatment was available for stroke. Studies focused on describing the epidemiology of stroke and on **clinical trials** of interventions for primary or secondary stroke prevention. Studies of mechanisms and etiology initially were restricted to animal models. With the advent of safer methods of measuring cerebral blood flow and the development of noninvasive imaging techniques such as nuclear magnetic resonance imaging and positron-emission tomography, humans could be studied (*see* **Image Analysis and Tomography**). The intense pain that accompanies a myocardial infarction, bringing patients quickly to the hospital, is rarely present in patients with stroke. Patients attribute symptoms to "flu" or symptoms go unnoticed because observers believe the patient was "sleeping". Also, in previous years, when there was no available treatment, patients with strokes were a lower priority for transport by emergency medical systems. Thus, few patients have been available for study early in their disease. With the advent of a treatment for stroke that must be given early in the course of the stroke [33], and more education of the public about the signs and symptoms of stroke, there may be more patients available for study early in the course of their stroke. However, the introduction of effective therapeutic strategies presents the medical community with new challenges. Efficient detection of treatment effects among the diverse outcomes for patients with stroke is often difficult. Given the traditional focus on risk factors and secondary prevention where the outcome is presence or absence of stroke, and given the types of symptoms that characterize stroke, standard tools for evaluating different degrees of disability due to stroke have developed slowly.

Types of Study

Risk factors for stroke have been identified both retrospectively, using **case–control** methodology, and prospectively. Methods of preventing stroke, both initially in high-risk individuals and secondarily after an initial stroke, and approaches to stroke treatment have been studied using standard clinical trials methodology.

Landmark Studies

Prospective epidemiologic studies of stroke risk factors include the **Framingham Study** and Honolulu Heart Study that assessed stroke as an adjunct to cardiovascular disease, and studies in Japan, Sweden, Denmark, Norway, Finland, the Netherlands, and Australia. Whisnant et al. reference and discuss these epidemiologic studies in their report on a case–control study of stroke risk factors in Olmsted County, Minnesota [38]. Sacco [30] also provides a summary of some case–control studies of stroke risk

factors. Primary risk factors include age, gender, race/ethnicity, heredity, hypertension, diabetes mellitus, ischemic heart disease, transient ischemic attack, atrial fibrillation, mitral valve disease (other than prolapse), and current smoking (although not in Japan).

Landmark studies of stroke prevention included studies of both surgical and nonsurgical treatments. A major surgical trial was the Extracranial/Intracranial (EC/IC) Bypass Trial [10], notable because surgery was found to be no better than best medical care. Although the results of this trial generated great debate, the results were accepted by the medical community and the procedure is now rarely used in stroke prevention. Three other landmark primary stroke prevention trials of surgical procedures were the North American Symptomatic Carotid Endarterectomy Trial (NASCET) [25], European Carotid Surgery Trial (ECST) [12], and Asymptomatic Carotid Atherosclerosis Study (ACAS) [3]. In contrast to the EC/IC trial, these trials demonstrated the effectiveness of carotid endarterectomy in reducing the incidence of subsequent strokes for those with symptomatic and asymptomatic severe carotid artery stenosis (60–70%). Dyken [9] provides a summary of these and other landmark primary and secondary prevention studies through 1992, including the Physicians' Health Study [31]. The latter study, while a landmark for cardiovascular disease prevention, gave equivocal data on the usefulness of aspirin in preventing stroke, suggesting heart and brain are different in their response to treatment. A **meta-analysis of randomized trials** of cholesterol reduction provided another example of the potential difference between heart and brain. Based on their meta-analysis, Aitkins et al. concluded that lowering serum cholesterol did not reduce stroke morbidity or mortality in middle-aged men [1].

In the early 1990s several emergent stroke treatment trials were initiated. In 1995, the National Institute of Neurological Disorders and Stroke (NINDS) t-PA Stroke Treatment Trial investigators reported a beneficial effect for patients with acute ischemic strokes treated with tissue plasminogen activator (t-PA) within 180 minutes of stroke onset [33]. The genetically engineered drug, t-PA, was previously used to break up clots in patients with heart attacks. The success of t-PA opened the field of stroke to a plethora of new treatment trials aimed at salvaging brain function after an ischemic stroke. At the same time, new surgical procedures showed some promise in treating hemorrhagic stroke [22] and Nimodipine, a calcium channel blocker, was shown to be effective in treating subarachnoid hemorrhage [27].

Statistical Concepts, Problems, and Techniques

Outcome Measures

Standard statistical approaches for **prevention trials** and risk factor studies can be applied in stroke. For modeling recurrent stroke, Foulkes suggests that a linear **hazard rate** function may fit better than the more commonly used **proportional hazard** function or other parametric approaches [13] (*see* **Parametric Models in Survival Analysis**). For studies estimating incidence and mortality, the **biases** noted in many hospital or clinic-based studies pertain [11, 14, 32]. Stroke treatment trials present more of a challenge to statisticians. By contrast to cardiovascular trials, mortality is seldom considered the sole outcome for stroke treatment trials, since, as noted above, most patients survive. Of the outcome measures available in the late 1990s, there was no single accepted measurement for quantifying stroke-related disability or the course of stroke recovery. Many trials use the Barthel Index [21], a measure of functional status. Other common measures include the Rankin Scale [29] and the Glasgow Outcome Scale [17], more general summary measures than the Barthel Index, and outcomes such as the **National Institutes of Health** (NIH) Stroke Scale [6], the Canadian Neurological Scale [7], and the European Stroke Scale [16] that measure neurological function. The outcome measures are highly **correlated** but each scale or index gives slightly different information about the patient's disability [8, 24].

Quantification of infarct volume or brain function with methods such as computerized tomography or measures of cerebral blood flow has only duplicated with technology the immense complexity of the clinical assessment of neurological conditions. Measurements of infarct volume are intuitively simple, but in practice tediously difficult and, to date, of limited value compared with the relative ease of determining more clinically relevant functional outcomes.

Clinical interpretation of the numeric value of the scale score also presents challenges. For example, a

10-point difference in the **means** between two treatment groups for a scale such as the Barthel Index or NIH Stroke Scale is difficult for both patients and clinicians to interpret. Using scores as a continuum of numeric values requires that a value be placed on death, and scales such as the NIH Stroke Scale or Barthel Index do not provide such a value in their scoring system. Hallstrom describes one approach for stroke trials, based on developing a consensus among clinicians as to the score for death [15]. For scales measuring neurologic or physical disability, the overall summary score may have limited meaning as the scale is composed of multiple components, any one of which can represent a serious disability. To avoid interpretation of a continuous measure, some stroke trials require a specified degree of patient-specific improvement from baseline. In other trials, investigators dichotomize scales into favorable or unfavorable outcomes or into "cure" vs. "no cure", considering these outcomes more clinically meaningful [5, 33]. Categories or approaches to dichotomization should be chosen before starting the trial and they should represent clinically meaningful categories for the intervention being tested. A treatment such as t-PA that is expected to have severe side effects such as hemorrhage and potentially large benefits might be categorized differently than an intervention expected to have few expected side effects and moderate benefits. Dichotomization or categorization of scores allows deaths to be assigned to the category representing the worst outcome.

Methods of Analysis

The choice of the method of analysis is also an issue. A J-shaped or U-shaped distribution is typical for many outcome measures in stroke trials. Lesaffre et al. [20] give an example for the Barthel Index. Where there are equal sample sizes, skewness alone does not affect validity of the t-test (*see* **Student's *t* Statistics**) [23]. However, sample size calculations for the t-test and the **Wilcoxon–Mann–Whitney** nonparametric test suggest that a **binary** categorization of the data and analysis by **chi-square test** or other approaches such as **logistic regression** can reduce the required sample size (*see* **Sample Size Determination for Clinical Trials**) [35]. Logistic regression with multiple **ordered categories**, particularly when death is considered a category, should be considered cautiously in analyzing stroke-related data, as it is possible that underlying assumptions may be violated.

Global Tests

A global test provides a single test statistic for comparing groups that combines correlated information on multiple outcomes per individual. Global tests for continuous and **binary data** are described by O'Brien [26], Pocock et al. [28], Lefkopoulou et al. [18] and Legler et al. [19]. Global tests have application to stroke trials since, as noted previously, no single outcome measures all degrees of disability after stroke. Of interest is whether there is a preponderance of evidence that patients in the intervention group experience a better outcome than patients in the **control** group using multiple measures of disability. For dichotomized outcomes, we can calculate a Wald statistic (*see* **Likelihood**) using **generalized estimating equations (GEE)** with a log link to take correlations among multiple outcomes for a single individual into account. We can obtain an **odds ratio** and its **confidence limits** in addition to a ***P* value**. The odds ratio can be useful to clinicians in their interpretation of stroke trial data. The GEE approach also allows for inclusion of **covariates**, important for stroke trials where baseline covariates must be taken into account (*see* **Baseline Adjustment in Longitudinal Studies**). Tilley et al. [34] describe the use of global testing in the NINDS t-PA Stroke Trial [33].

The global approach differs from **Hotelling's T^2**, a statistic that tests whether there is a treatment association with multiple outcomes, despite the direction of the association across the outcomes, a question of little interest in stroke trials. The global approach to the analysis of stroke trial data also differs from the composite outcome often used for cardiovascular disease. In cardiovascular disease, we may consider a patient a treatment failure if the patient has a new myocardial infarction or dies or has severe angina or perhaps severe congestive heart failure requiring hospitalization. This is considered a composite outcome. For stroke trials we could construct a composite outcome by defining a category for failure on each scale of interest (Barthel, NIH Stroke Scale, Rankin, etc.). However, considering a patient a failure because of a failure on only one of multiple outcomes may set too stringent a criterion. Conversely, requiring a patient to have a favorable result on every outcome to be a success might be too

stringent. The **power** of a composite test as compared to the global test depends on the correlation among outcome measures, but is generally less than the power of the global test [18]. The power of the global test is greater than or equal to the power of any test of a single outcome included in the global test and power is greater than adjusting for multiple outcomes using a **Bonferroni** approach [28]. Thus the use of global tests in stroke trials can potentially reduce sample sizes, if the investigator is willing to have less power to detect differences in individual outcomes.

Anticipated Developments and Unresolved Problems

The primary unresolved problem in the study of stroke remains the definition of an outcome (*see* **Outcome Measures in Clinical Trials**). Given that t-PA has been shown to be effective for only a brief interval after stroke onset and has a risk of hemorrhage, many other treatments for stroke are now under investigation. These trials, even those that are not successful, will provide more information on stroke outcome measures and may lead to the development of new measures. There is also the potential for further development of existing outcome measures. Researchers using the SF-36 measure, which assesses health-related **quality of life** [37], have quantified scales that incorporate several dimensions of an outcome by calculating scores for each dimension measured by the scale rather than an overall score. As yet, such an approach to analyzing the Barthel Index or NIH Stroke Scale as a set of scores for different dimensions of disability has not been thoroughly evaluated. Also, as technology improves, as magnetic resonance imaging can be done more quickly and becomes more widely available, and as statistical methodology in this field develops, this technology may become more useful as an outcome measure or in identifying subgroups of stroke patients who could benefit from different types of therapies.

A potential analytic development relates to the measure of association in global testing. The use of the odds ratio as a measure of association in global testing has only partially solved the problem of clinical interpretation. **Relative risk** as a measure of association is sometimes preferred for clinical trials. Work is currently in progress to expand the work of Wacholder [36] to allow computation of relative risks rather than odds ratios when using global tests.

Another anticipated development will be the use of **Phase II trial** methodology in stroke. The Phase II approach in stroke is as yet untested and may identify potentially beneficial treatments more quickly for Phase III testing. Most stroke trials consider short-term outcomes (3–6 months after stroke) but have been using Phase III approaches to the design of pilot trials, adding to the time and cost of stroke research.

Because of the advent of a successful stroke treatment and the upsurge of interest in studying stroke, stroke will be a fertile area for biostatistical research.

Structural and Sampling Zeros

Structural and sampling zeros are cells with zero frequency in **contingency table** models formed by the cross-classification of categorical variables. Structural zeros arise because of the impossibility of observing a given combination of categorical factors comprising a contingency table. That is, structural zeros occur with probability equal to one. In contrast, sampling zeros occur with probability less than one, which is a function of table size, sample size, and the patterns of association between the factors pertaining to the table.

The focus on structural and sampling zeros relates closely to **loglinear models** and associated lack-of-fit statistics. The ensuing results extend in a straightforward manner with minor modifications to **logistic regression** models involving categorical covariates, as these models are derived from loglinear models [9]. We do not address logistic models with continuous covariates here, since the corresponding contingency tables are typically too complex to consider in terms of sampling zeros.

Structural Zeros

Many examples of structural zeros occur in biomedical studies. For example, in the cross classification of sex with cancer type, structural zeros occur for the following combinations: females and testicular or prostate cancer, and males and ovarian or uterine cancer.

The ease of accommodating structural zeros depends upon the method of analysis. Commonly used data analysis packages such as SAS (*see* **Software, Biostatistical**), generally offer two different ways of analyzing contingency table data: (1) chi-square and associated statistics (e.g. exact tests and measures of association) based upon cross-classification tables (e.g. PROC FREQ in SAS); and (2) model-based analyses (e.g. PROC LOGISTIC in SAS; and the `glm` function in S-PLUS). With the first approach, it is difficult if not impossible to accommodate structural zeros. In contrast, the modeling approaches provide much flexibility in this regard. If the data analyst wants to impose a structural zero, then he or she may take one of at least three approaches: (i) omit the corresponding cases from the analysis; (ii) assign weights of zero to these cases and one to the remaining cases; or (iii) fit unique parameters to the cases corresponding to the structural zero. Under all of these approaches, the data analyst should determine any **collinearity** among covariates resulting from omitting structural zero cases. One may deal with such collinearities as in any regression context; for example by removing one or more covariates from the model. Such adjustments allow the degrees of freedom for a particular model to be computed in a conventional way by packages such as SAS (e.g. PROC GENMOD and PROC LOGISTIC). These adjustments for structural zeros assume that **maximum likelihood** or weighted **least squares** methods are employed to fit the models of interest. Under another estimation approach, **iterative proportional fitting**, one sets initial table frequencies for structural zeros to zero at the start of the algorithm, such that final estimates for the corresponding cells are zero. Bishop et al. [4] address this issue, in addition to discussing different patterns of structural zeros and corresponding degrees of freedom computation and closed form parameter estimation.

Sampling Zeros

Factors influencing the likelihood of sampling zeros include the number and type of factors that constitute a contingency table, and/or the size and nature of the sample of observations contributing information to the table. For example, cross-classifying 100 patients by sex, age intervals, and a wide range of cancers is more likely to yield an observed zero count for a particular cell, such as breast cancer in young men, than cross-classifying 100 subjects according to sex and a binary cancer classification (e.g. lung cancer vs. no lung cancer). The size of the three-dimensional table, the rare occurrence of breast cancer in young men, and the limited sample size increase the probability of a sampling zero relative to the analogous probability in the two-dimensional table for lung cancer and gender. Increasing the size of the sample by a factor of ten would reduce the probability of sampling zeros in each case.

Accommodating sampling zeros in the analysis of contingency tables has been a topic of debate [2, 3, 5, 6, 9, 10]. The focus of this dialog has been on the computation of degrees of freedom for loglinear

models fitted to contingency tables under sampling zeros and the consequences for related chi-square statistics for lack of fit. The discussion by Haslett [9] of the different approaches for handling sampling zeros serves as the basis for the ensuing review.

The debate over sampling zeros has centered on the first of two ways in which sampling zeros impact degrees of freedom calculations: (1) by causing zeros in marginal tables; and (2) by causing pathologic sampling zeros [4], or what Haslett [9] calls "parity-based inestimability". The latter zeros will not be discussed further, as algorithms for detecting them do not appear to be available, and they impact only the highest-order interactions of saturated loglinear models, i.e. those models that yield expected frequencies equaling observed table frequencies.

A marginal table is formed by collapsing a multidimensional table down to a table representing the cross classification of fewer factors. This is achieved by summing over the categories or levels of the factors left out of the marginal table. For example, starting with the cross classification of three factors, sex, age, and cancer, one may form a marginal table for sex and cancer by summing the frequencies across all age categories for each sex–cancer combination.

Zero cells in marginal tables have two ramifications: (i) causing estimated cell frequencies to be zero, that is, fitted zero frequencies; and (ii) leading to the lack of existence of parameter estimates under a loglinear model, that is, to inestimable parameters [7] (*see* **Identifiability**). The two methods that account for sampling zeros differ in how they treat these two consequences of sampling zeros in the computation of degrees of freedom. The first method (method 1) subtracts the number of parameters in a given model, adjusted for inestimable parameters, from the number of zero cells in the table, adjusted for the number of fitted zero frequencies [2, 4, 5, 7]. The second method (method 2) adjusts only for inestimable parameters, ignoring fitted zero frequencies [9, 10]. Specifically, under this approach one subtracts the number of parameters of a given model, adjusted for inestimable parameters, from the adjusted number of parameters in the corresponding saturated model. Finally, a third point of view [3] advocates ignoring sampling zeros altogether in computing degrees of freedom, arguing that degrees of freedom should depend upon whether expected frequencies are zero (i.e. structural zeros) rather than whether estimated or observed frequencies are zero. This view is based upon the fact that parameter estimates always exist under certain models other than loglinear models. The focus of the debate on sampling zeros has been on the first two methods.

The distinction between methods 1 and 2 for adjusting degrees of freedom – that is, adjusting or not adjusting for fitted zero frequencies – relates to the method of fitting loglinear models. Typically, estimation procedures used for loglinear models are unconditional, in that they do not condition on the frequency counts in marginal tables, as opposed to conditional estimation approaches; for example, exact estimation procedures. Stirling [10] and Haslett [9] maintain that method 1 is appropriate for conditional estimation but not for unconditional estimation. That is, they assert that adjusting for fitted zero frequencies is necessary only if one is conditioning on marginal counts. Exact conditional tests based upon the **hypergeometric distribution** are not impacted by sampling zeros, as asymptotic distributions based upon degrees of freedom are not an issue for these tests.

Methods 1 and 2 may be extended to logistic regression models fitted conditionally (*see* **Logistic Regression, Conditional**) or unconditionally. Aston & Wilson [2] present method 1 calculations for a logistic model fitted conditionally to an example data set. Haslett [9] discusses the extension of method 2 to logistic models fitted unconditionally, while contrasting the two-degree-of-freedom methods in the context of conditional and unconditional likelihood estimation.

Parameter inestimability under loglinear models, which is a major factor in the debate about calculating degrees of freedom, is attributable to sampling zeros in marginal tables [1, 8]. To circumvent the problem of inestimable parameters due to marginal sampling zeros, some statistical packages (e.g. SAS PROC CATMOD and PROC FREQ) allow the user to add a small constant (e.g. 0.5) to every cell in a contingency table with sampling zeros. In general, this results in forcing estimates of association parameters closer to their null values (e.g. log **odds ratio** estimates are closer to zero). Agresti [1] suggests trying different constants that are very small (e.g. 10^{-8}) to assess the resulting sensitivity of parameter estimates and lack-of-fit statistics.

In addition to impacting the existence of parameter estimates and degrees of freedom of chi-square lack-of-fit statistics, sampling zeros have other effects. By diminishing expected cell frequencies, sampling zeros may affect the adequacy of chi-square approximations to the sampling distributions of lack-of-fit statistics. Agresti [1] provides a review of the literature on such effects of sparse tables in general. The bias of parameter estimates under the loglinear model may also be affected by sampling zeros, as this bias is a function of the size of the marginal table cells corresponding to the parameters of interest [8].

Structural Equation Models

Structural equation models refer to general statistical procedures for multiequation systems that include continuous latent variables ("factors" or "unmeasured variables"), multiple indicators of concepts, errors of measurement, errors in equations, and observed variables that are continuous, ordinal, dichotomous (**binary**), or **censored** (*see* **Measurement Scale**). One way to view these models is as an interrelated system of **regression** equations where some of the variables have multiple measures, and where measurement error is taken into account when estimating relationships (*see* **Errors in Variables**). From another perspective, these are **factor analysis** models in which some factor loadings are restricted to zero or other constants, and the researcher allows factors to affect each other, directly and indirectly. The most general form of the structural equation model encompasses **analysis of variance** (ANOVA), **analysis of covariance** (ANOCOVA), **multiple linear regression**, **multivariate multiple regression**, seemingly unrelated regressions, recursive and nonrecursive simultaneous equations, **path analysis**, **confirmatory factor analysis**, classical test theory (*see* **Psychometrics, Overview**), dichotomous and ordinal probit, tobit, and a variety of other procedures (*see* **Quantal Response Models**) as special cases. Occasionally, the term "structural equation model" refers to the simultaneous equation models of classical econometrics. Increasingly, though, it has come to refer to its more general form. *Covariance structure models, LISREL models, analysis of moment structures, and structural equations with latent or unobserved variables* are largely interchangeable terms for structural equation models.

Model and Notation

The structural equation models are represented in a variety of notations, but researchers most commonly use the one derived from Jöreskog [19, 20], Keesling [23], and Wiley [31]. It is called the **LISREL** notation, named after Jöreskog & Sörbom's [22] **software** package. The model has two primary components, a latent variable and a measurement model. The latent variable model is

$$\boldsymbol{\eta} = \boldsymbol{\alpha} + \mathbf{B}\boldsymbol{\eta} + \boldsymbol{\Gamma}\boldsymbol{\xi} + \boldsymbol{\zeta}, \tag{1}$$

where $\boldsymbol{\eta}$ is an $m \times 1$ vector of latent endogenous variables, $\boldsymbol{\xi}$ is an $n \times 1$ vector of latent exogenous variables, $\boldsymbol{\alpha}$ is an $m \times 1$ vector of intercept terms, $\mathbf{B}$ is an $m \times m$ matrix of coefficients that give the influence of the $\boldsymbol{\eta}$s on each other, $\boldsymbol{\Gamma}$ is an $m \times n$ matrix of coefficients for the effect of the $\boldsymbol{\xi}$ on $\boldsymbol{\eta}$, and $\boldsymbol{\zeta}$ is the $m \times 1$ vector of disturbances that contains the unexplained parts of the $\boldsymbol{\eta}$s. The term "endogenous" refers to variables that are influenced by other variables in the model. "Exogenous" describes variables that are determined outside of the system of equations.

The model assumes that $\mathrm{E}(\boldsymbol{\zeta}) = \mathbf{0}$, that $\mathrm{cov}(\boldsymbol{\xi}, \boldsymbol{\zeta}') = \mathbf{0}$, and that $(\mathbf{I} - \mathbf{B})$ is nonsingular. The **covariance matrix** of the latent exogenous variables is represented by an $n \times n$ matrix, $\boldsymbol{\Phi}$, and the $m \times m$ matrix $\boldsymbol{\Psi}$ is the covariance matrix of the equation disturbances, $\boldsymbol{\zeta}$. Implicit in (1) is a subscript to index the observations. Since the same model holds for all cases, the subscript is omitted to simplify the notation.

The traditional LISREL notation has two equations for the measurement model:

$$\mathbf{y}^* = \boldsymbol{\nu}_y + \boldsymbol{\Lambda}_y\boldsymbol{\eta} + \boldsymbol{\varepsilon}, \tag{2}$$

$$\mathbf{x}^* = \boldsymbol{\nu}_x + \boldsymbol{\Lambda}_x\boldsymbol{\xi} + \boldsymbol{\delta}, \tag{3}$$

where $\mathbf{y}^*$ is the $p \times 1$ vector of indicators of the latent variables in $\boldsymbol{\eta}$, $\boldsymbol{\nu}_y$ is the $p \times 1$ vector of intercept terms, $\boldsymbol{\Lambda}_y$ is the $p \times m$ **factor loading matrix** of coefficients giving the linear effect of $\boldsymbol{\eta}$ on $\mathbf{y}^*$, and $\boldsymbol{\varepsilon}$ is the $p \times 1$ vector of measurement errors or disturbances. The model assumes that $\mathrm{E}(\boldsymbol{\varepsilon}) = \mathbf{0}$ and that $\mathrm{cov}(\boldsymbol{\eta}, \boldsymbol{\varepsilon}') = \mathbf{0}$. The covariance matrix for $\boldsymbol{\varepsilon}$ is the $p \times p$ matrix, $\boldsymbol{\Theta}_\varepsilon$. Analogous definitions and assumptions hold for (3), with $\boldsymbol{\Theta}_\delta$ the $q \times q$ covariance matrix for errors in $\mathbf{x}^*$. In addition, we assume that $\boldsymbol{\varepsilon}$, $\boldsymbol{\delta}$, and $\boldsymbol{\zeta}$ are mutually uncorrelated (*see* **Correlation**). Here too the observation index is omitted, but is implicit. The disturbance or error term for each equation in the latent variable or measurement model typically has different variances for different equations but, for a single equation, the assumption is that the disturbance's variance is homoscedastic (*see* **Scedasticity**) and uncorrelated across observations.

Eqs. (1)– (3) make up the classical form of the LISREL model, in which it is assumed that

the latent and observed variables are continuous variables. More recently, Jöreskog & Sörbom [21], Muthén [26], and others have generalized the model by allowing **categorical** or censored observed variables. In this case, some of the variables in $\mathbf{y}^*$ and $\mathbf{x}^*$ are "latent indicators" that are only observable through categorical or censored observed variables. Here the model requires an additional set of equations to link the observed variables to their underlying continuous counterparts:

$$\mathbf{y} = f(\mathbf{y}^*, \boldsymbol{\tau}_y), \tag{4}$$

$$\mathbf{x} = f(\mathbf{x}^*, \boldsymbol{\tau}_x), \tag{5}$$

where $\mathbf{y}$ and $\mathbf{x}$ are the vectors of observed variables, some or all of which can be categorical or censored, and $\boldsymbol{\tau}_y$ and $\boldsymbol{\tau}_x$ are vectors that contain threshold parameters that determine the values taken by $\mathbf{y}$ and $\mathbf{x}$, respectively. For instance, suppose that y_1 is a four-category ordinal variable. In this case, we would have

$$y_1 = \begin{cases} 1, & \text{if } y_1^* \le \tau_{01}, \\ 2, & \text{if } \tau_{01} < y_1^* \le \tau_{11}, \\ 3, & \text{if } \tau_{11} < y_1^* \le \tau_{21}, \\ 4, & \text{if } \tau_{21} < y_1^*, \end{cases} \tag{6}$$

where τ_{01}, τ_{11}, and τ_{21} are the three thresholds that determine whether the ordinal y_1 variable falls in the 1, 2, 3, or 4 category. Alternately, if the y_4 variable is censored from below, we would have

$$y_4 = \begin{cases} 0, & \text{if } y_4^* \le 0, \\ y_4^*, & \text{if } 0 < y_4^*. \end{cases} \tag{7}$$

The single threshold point is zero and when y_4^* is above zero, y_4^* and the observed y_4 are the same. If the observed variables are continuous, we have no need for (4) and (5). But when we have noncontinuous observed variables, (4) and (5) are nonlinear, deterministic equations that relate the observed variables to their underlying continuous indicator.

Many of the more familiar statistical models are derivable from this general model. Table 1 illustrates how restrictions on the general model can lead to more familiar techniques. If, for instance, we assume a scalar, continuous dependent **response variable**, no measurement error in the dependent or **explanatory variables**, and only **dummy** explanatory variables, we are led to the restrictions shown in the first row that leads to **analysis of variance** (ANOVA). Keeping the same restrictions, except allowing continuous or dummy explanatory variables, leads to multiple regression. Probit regression has the same constraints

Table 1 Common statistical models as special cases of structural equation models (SEMs)

√, Present in model; – , absent from model.

as multiple regression, except that we have a dichotomous or ordinal dependent variable (*see* **Ordered Categorical Data**). Classical econometrics is a special case of the model that assumes perfect measurement and the absence of multiple indicators. From this perspective, structural equation models have less restrictive assumptions than many better known procedures. In addition, we can estimate many models that are not treated by the traditional procedures.

Steps in Modeling

An analysis that uses structural equation models has several components to it. These concern (i) model specification, (ii) the implied moment matrix, (iii) identification, (iv) estimation, (v) model–data fit assessment, and (vi) respecification. These are examined in the next six subsections.

Model Specification

The first step is to specify the hypothesized relations between all latent and observed variables. In other words, the researcher needs to describe the specific form that all the matrices in Table 1 take for the specific example of interest. Typically, not all of the matrices are required, so that the task is simplified. However, model specification requires the substantive expertise of the analyst to be able to formulate a set of restrictions that defines the model. A person who has little or no knowledge about the substantive area will not fare well with structural equation models (*see* **Model, Choice of**).

A path diagram for a hypothetical example, to illustrate model specification, is shown in Figure 1. A more detailed description of path diagrams is given in the article on **path analysis**, but in brief it provides a pictorial representation of the multiequation model that a researcher specifies. The ovals or circles enclose the latent variables, boxes signify observed variables, and the disturbances and error terms are not enclosed. The single-headed straight arrows indicate a linear impact of the variable at the base of the arrow on the variable at the head of the arrow. Curved two-headed arrows show linear covariances (correlations) between variables that are not explained within the model and they signify the covariances between exogenous variables or between disturbances/errors. To simplify it, the diagram does not include the

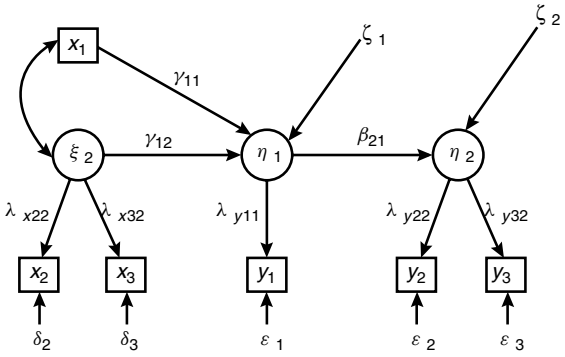

Figure 1 An hypothetical example of a structural equation model with three latent variables and six observed variables

regression constants that enter the equations for each endogenous variable.

An alternative to the path diagram is to represent the model specification using (1)–(3). In this specific example, (1) is

$$\begin{bmatrix}\eta_1\\ \eta_2\end{bmatrix} = \begin{bmatrix}\alpha_1\\ \alpha_2\end{bmatrix} + \begin{bmatrix}0 & 0\\ \beta_{21} & 0\end{bmatrix}\begin{bmatrix}\eta_1\\ \eta_2\end{bmatrix} + \begin{bmatrix}\gamma_{11} & \gamma_{12}\\ 0 & 0\end{bmatrix}\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} + \begin{bmatrix}\zeta_1\\ \zeta_2\end{bmatrix}, \quad (8)$$

(2) is

$$\begin{bmatrix}x_1\\ x_2\\ x_3\end{bmatrix} = \begin{bmatrix}0\\ \nu_{x2}\\ \nu_{x3}\end{bmatrix} + \begin{bmatrix}1 & 0\\ 0 & \lambda_{x22}\\ 0 & \lambda_{x32}\end{bmatrix}\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} + \begin{bmatrix}0\\ \delta_2\\ \delta_3\end{bmatrix}, \quad (9)$$

and (3) is

$$\begin{bmatrix}y_1\\ y_2\\ y_3\end{bmatrix} = \begin{bmatrix}\nu_{y_1}\\ \nu_{y_2}\\ \nu_{y_3}\end{bmatrix} + \begin{bmatrix}\lambda_{y11} & 0\\ 0 & \lambda_{y22}\\ 0 & \lambda_{y32}\end{bmatrix}\begin{bmatrix}\eta_1\\ \eta_2\end{bmatrix} + \begin{bmatrix}\varepsilon_1\\ \varepsilon_2\\ \varepsilon_3\end{bmatrix}. \quad (10)$$

The observed variables are continuous, so that (4) and (5) are $\mathbf{x} = \mathbf{x}^*$ and $\mathbf{y} = \mathbf{y}^*$. These relations are substituted into the above three equations. This also means that we will not need any threshold parameters ($\boldsymbol{\tau}_x, \boldsymbol{\tau}_y$) in the model. In addition, (9) shows that x_1 is perfectly measured (i.e., $x_1 = \xi_1$) and this explains the use of x_1 in place of ξ_1 in the path diagram in Figure 1. The covariance matrices of the exogenous variables and disturbances/errors are not represented in path diagrams. In the example, these

matrices are

$$\boldsymbol{\Phi} = \begin{bmatrix} \phi_{11} & \phi_{12} \\ \phi_{21} & \phi_{22} \end{bmatrix},$$

$$\boldsymbol{\Psi} = \begin{bmatrix} \psi_{11} & \psi_{12} \\ \psi_{21} & \psi_{22} \end{bmatrix}, \tag{11}$$

$$\boldsymbol{\Theta}_\delta = \begin{bmatrix} 0 & 0 & 0 \\ 0 & \Theta_{\delta 22} & 0 \\ 0 & 0 & \Theta_{\delta 33} \end{bmatrix},$$

$$\boldsymbol{\Theta}_\varepsilon = \begin{bmatrix} \Theta_{\varepsilon 11} & 0 & 0 \\ 0 & \Theta_{\varepsilon 22} & 0 \\ 0 & 0 & \Theta_{\varepsilon 33} \end{bmatrix}. \tag{12}$$

The zero in the (1,1) position of $\boldsymbol{\Theta}_\delta$ follows since x_1 contains no measurement error. If we had correlated errors of measurement specified, then some of the off-diagonal elements of $\boldsymbol{\Theta}_\delta$ or $\boldsymbol{\Theta}_\varepsilon$ would contain free parameters rather than zeros.

Implied Moment Matrix

Once a model is specified, it implies that the first and second **moments** (means, variances, and covariances) of the observed variables are functions of the model parameters. Few have examined the higher-order moments of the observed variables and their relation to the model parameters. Most structural equation models focus on the implied covariance matrix, $\boldsymbol{\Sigma}(\boldsymbol{\theta})$. The general expression for $\boldsymbol{\Sigma}(\boldsymbol{\theta})$ comes from the cov($\mathbf{z}^*$, $\mathbf{z}^{*\prime}$), where $\mathbf{z}^{*\prime}$ is [$\mathbf{y}^{*\prime}\mathbf{x}^{*\prime}$]. The linkage to the model parameters comes from substitution of (3) in for $\mathbf{x}^*$ and the reduced form equation in for $\mathbf{y}^*$,

$$\mathbf{y}^* = \boldsymbol{\nu}_y + \boldsymbol{\Lambda}_y(\mathbf{I} - \mathbf{B})^{-1}(\boldsymbol{\alpha} + \boldsymbol{\Gamma}\boldsymbol{\xi} + \boldsymbol{\zeta}) + \boldsymbol{\varepsilon}. \tag{13}$$

The reduced form of an equation results by solving the right-hand side of the equation, so that it contains only exogenous variables, disturbances, errors, and coefficient matrices. After these substitutions and taking the cov($\mathbf{z}^*$, $\mathbf{z}^{*\prime}$), the implied covariance matrix is

$$\boldsymbol{\Sigma}(\boldsymbol{\theta}) = \begin{bmatrix} \mathbf{C}(\boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Gamma}' + \boldsymbol{\Psi})\mathbf{C}' + \boldsymbol{\Theta}_\varepsilon & \mathbf{C}\boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Lambda}_x' \\ \boldsymbol{\Lambda}_x\boldsymbol{\Phi}\boldsymbol{\Gamma}\mathbf{C}' & \boldsymbol{\Lambda}_x\boldsymbol{\Phi}\boldsymbol{\Lambda}_x' + \boldsymbol{\Theta}_\delta \end{bmatrix}, \tag{14}$$

where $\mathbf{C} = \boldsymbol{\Lambda}_y(\mathbf{I} - \mathbf{B})^{-1}$ and $\boldsymbol{\theta}$ is the $t \times 1$ vector that contains all of the model parameters to be estimated in a given model. The upper left quadrant of $\boldsymbol{\Sigma}(\boldsymbol{\theta})$ is the implied covariance matrix for $\mathbf{y}^*$ (called $\boldsymbol{\Sigma}_{\mathbf{y}^*\mathbf{y}^*}(\boldsymbol{\theta})$), the lower right quadrant is the implied covariance matrix for $\mathbf{x}^*$ ($\boldsymbol{\Sigma}_{\mathbf{x}^*\mathbf{x}^*}(\boldsymbol{\theta})$), and the off-diagonal quadrants are the implied covariance matrices for $\mathbf{y}^*$ with $\mathbf{x}^*$($\boldsymbol{\Sigma}_{\mathbf{x}^*\mathbf{y}^*}(\boldsymbol{\theta})$).

The implied mean vector, $\boldsymbol{\mu}(\boldsymbol{\theta})$, is

$$\boldsymbol{\mu}(\boldsymbol{\theta}) = \begin{bmatrix} \boldsymbol{\nu}_y + \mathbf{C}(\boldsymbol{\alpha} + \boldsymbol{\Gamma}\boldsymbol{\kappa}) \\ \boldsymbol{\nu}_x + \boldsymbol{\Lambda}_x\boldsymbol{\kappa} \end{bmatrix}, \tag{15}$$

where $\boldsymbol{\kappa}$ equals the mean vector of $\boldsymbol{\xi}$ [E($\boldsymbol{\xi}$) = $\boldsymbol{\kappa}$]. These general expressions for the first and second implied moments apply to any specific model. For the model in Figure 1, the implied covariance matrix for $\mathbf{y}^*$ is

$$\boldsymbol{\Sigma}_{\mathbf{y}^*\mathbf{y}^*}(\boldsymbol{\theta}) = \begin{bmatrix} \lambda_{y11}^2\text{var}(\eta_1) + \Theta_{\varepsilon 11} & & \\ \lambda_{y11}\lambda_{y22} \times \beta_{21}\text{var}(\eta_1) & \lambda_{y22}^2\text{var}(\eta_2) + \Theta_{\varepsilon 22} & \\ \lambda_{y11}\lambda_{y32} \times \beta_{21}\text{var}(\eta_1) & \lambda_{y22}\lambda_{y32} \times \text{var}(\eta_2) & \lambda_{y32}^2\text{var}(\eta_2) + \Theta_{\varepsilon 33} \end{bmatrix}, \tag{16}$$

with

$$\boldsymbol{\Sigma}_{\mathbf{x}^*\mathbf{y}^*}(\boldsymbol{\theta}) = \begin{bmatrix} \lambda_{y11} \times \text{cov}(\xi_1, \eta_1) & \lambda_{y22}\beta_{21} \times \text{cov}(\xi_1, \eta_1) & \lambda_{y32}\beta_{21} \times \text{cov}(\xi_1, \eta_1) \\ \lambda_{x22}\lambda_{y11} \times \text{cov}(\xi_2, \eta_1) & \lambda_{x22}\lambda_{y22}\beta_{21} \times \text{cov}(\xi_2, \eta_1) & \lambda_{x22}\lambda_{y32}\beta_{21} \times \text{cov}(\xi_2, \eta_1) \\ \lambda_{x32}\lambda_{y11} \times \text{cov}(\xi_2, \eta_1) & \lambda_{x32}\lambda_{y22}\beta_{21} \times \text{cov}(\xi_2, \eta_1) & \lambda_{x32}\lambda_{y32}\beta_{21} \times \text{cov}(\xi_2, \eta_1) \end{bmatrix}, \tag{17}$$

and

$$\boldsymbol{\Sigma}_{\mathbf{x}^*\mathbf{x}^*}(\boldsymbol{\theta}) = \begin{bmatrix} \phi_{11} & & \\ \lambda_{x22}\phi_{21} & \lambda_{x22}^2\phi_{22} + \Theta_{\delta 22} & \\ \lambda_{x32}\phi_{21} & \lambda_{x32}\lambda_{x22}\phi_{22} & \lambda_{x22}^2\phi_{22} + \Theta_{\delta 33} \end{bmatrix}, \tag{18}$$

where

$$\text{var}(\eta_1) = \gamma_{11}^2\phi_{11} + 2(\gamma_{11}\gamma_{12}\phi_{12}) + \gamma_{12}^2\phi_{22} + \psi_{11},$$

$$\begin{aligned} \text{var}(\eta_2) &= \beta_{21}^2 \text{var}(\eta_1) + \psi_{22}, \\ \text{cov}(\eta_1, \xi_1) &= \gamma_{11}\phi_{11} + \gamma_{12}\phi_{12}, \\ \text{cov}(\eta_1, \xi_2) &= \gamma_{11}\phi_{12} + \gamma_{12}\phi_{22}. \end{aligned} \tag{19}$$

With these implied moment matrices we have a one-to-one relation between a mean, variance, or covariance of the observed variables and a function of the parameters in the model. For instance, in the model the variance of x_2 equals $\lambda_{x22}^2\phi_{22} + \Theta_{\delta 22}$. These connections are critical to the issues of model identification, estimation, and fit assessment.

Model Identification

Model identification concerns the question whether it is possible to determine uniquely the parameters of a model from the means, variances, and covariances of the observed variables (*see* **Identifiability**). The last section gave the relation between these moments and the model parameters. Identification concerns whether it is possible to uniquely solve for the model parameters in terms of the moments of the observed variables using these equations. To illustrate this point, consider a simple example with a single observed variable, x_1, that equals $\xi_1 + \delta_1$. Here $\boldsymbol{\Sigma}(\boldsymbol{\theta})$ has a single element, $\phi_{11} + \Theta_{\delta 11}$ and $\boldsymbol{\mu}(\boldsymbol{\theta})$ is κ_1, the mean of ξ_1. The only second moment of the observed variable is the population variance of x_1, and the single first moment element is the population mean of x_1, μ_{x1}. The mean of x_1 identifies κ_1, but the single variance for x_1 is insufficient to identify the two parameters, ϕ_{11} and $\Theta_{\delta 11}$. For any given value of the variance of x_1, an infinite set of values of ϕ_{11} and $\Theta_{\delta 11}$ would satisfy the equation for the implied variance. The model is underidentified. More generally, if in a model $\boldsymbol{\theta}_a$ and $\boldsymbol{\theta}_b$ are any two sets of values for $\boldsymbol{\theta}$ such that $\boldsymbol{\Sigma}(\boldsymbol{\theta}_a) = \boldsymbol{\Sigma}(\boldsymbol{\theta}_b)$ and $\boldsymbol{\mu}(\boldsymbol{\theta}_a) = \boldsymbol{\mu}(\boldsymbol{\theta}_b)$, then $\boldsymbol{\theta}_a = \boldsymbol{\theta}_b$ must be true if the model is identified.

A necessary but not sufficient condition for identifying a model is that the researcher must assign a scale to each latent variable that is measured with error. One way to do this is to choose an indicator for each latent variable and set the coefficient or factor loading for the indicator to one. The intercept for the same observed variable should be set to zero. With this scaling, the latent variable has a metric that is similar to that of the observed variable. In the model in Figure 1, for instance, we could set λ_{x11}, λ_{y11}, and λ_{y22} to 1, and set ν_{x11}, ν_{y11}, and ν_{y22} to zero to assign scales to ξ_1, η_1, and η_2. An alternate method to scale the latent variable is to set the variance of the latent variable to one and its mean to zero. This latter option is less desirable when analyzing panel data or when testing whether models are the same across different groups.

Establishing model identification in the general structural equation model can be difficult. Algebraic manipulation of the implied moment equations can sometimes establish that each model parameter has a unique solution in terms of the means, variances, or covariances of the observed variables. In complicated models, this becomes less feasible. In special cases, such as the classical econometric model or confirmatory factor analysis, there are rules of identification that are helpful or that researchers can combine to establish model identification (see, for example, Fisher [13]; Bollen [6, pp. 88–104, 238–254, 326–333]). Also widely used are empirical checks on model identification that are based on whether the information matrix of the model parameters from a **maximum likelihood** solution is nonsingular. Singularity suggests that the model is underidentified. In most cases the empirical tests of identification work well, but it is possible for them to fail (see, for example, Bollen [6, pp. 246–251]).

Estimation

The earliest developments of structural equation models assumed that $\mathbf{y}$ and $\mathbf{x}$ were continuous and multinormally distributed. The maximum likelihood estimator under this assumption is

$$\begin{aligned} F_{\text{ML}} = {} & \ln|\boldsymbol{\Sigma}(\boldsymbol{\theta})| + \text{tr}(\mathbf{S}\boldsymbol{\Sigma}^{-1}(\boldsymbol{\theta})) \\ & + (\bar{\mathbf{z}} - \boldsymbol{\mu}(\boldsymbol{\theta}))'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\theta})(\bar{\mathbf{z}} - \boldsymbol{\mu}(\boldsymbol{\theta})) \\ & - \ln(|\mathbf{S}|) - (p+q), \end{aligned}$$

where $\mathbf{S}$ is the sample covariance matrix of the observed variables and $\bar{\mathbf{z}}$ is the vector of sample means of the observed variables. Numerical minimization procedures find the $\hat{\boldsymbol{\theta}}$ that minimizes F_{ML}. The $\hat{\boldsymbol{\theta}}$ has the usual maximum likelihood estimator properties of being asymptotically **unbiased**, asymptotically **efficient**, **consistent**, asymptotically normal, and an asymptotic covariance matrix that is the inverse of the **information matrix** of $\hat{\boldsymbol{\theta}}$ (*see* **Large-sample Theory**).

Fortunately, the $\hat{\boldsymbol{\theta}}$ from F_{ML} retains many of its desirable properties under some conditions when $\mathbf{y}$

and $\mathbf{x}$ are not from multinormal distributions. For instance, if $\mathbf{x} = \boldsymbol{\xi}$ – that is, $\mathbf{x}$ is exogenous – then the usual properties hold assuming that the disturbances, $\boldsymbol{\zeta}$ and $\boldsymbol{\varepsilon}$, are from multinormal distributions. Even if $\mathbf{x}$ does not equal $\boldsymbol{\xi}$ and $\mathbf{y}$ and $\mathbf{x}$ are nonnormal, $\hat{\boldsymbol{\theta}}$ remains a consistent estimator. Corrections to the asymptotic standard errors from the usual maximum likelihood procedures also are available (see, for example, [9] and [28]). Furthermore, there are **robustness** conditions under which the usual maximum likelihood asymptotic **standard errors** and significance tests hold for observed variables from nonnormal distributions (see, for example, Sattora [27]).

Another class of estimators are explicitly designed to take account of nonnormality rather than relying on robustness conditions or correcting standard errors. For instance, Browne [9] proposed an asymptotically distribution free estimator (also called the weighted **least squares**) that applies to observed variables from distributions with finite eighth-order moments. Although the estimator appears to work well in moderately large samples with models that do not involve many parameters, the performance of this estimator has been disappointing in large models. An **instrumental variable** estimator, **two-stage least squares**, is a limited information estimator that also does not require observed variables from multinormal distributions. Hägglund [16] developed this estimator for factor analysis models with uncorrelated errors of measurement. Recent work proposed a two-stage least squares estimator for all the coefficients of both the measurement model and the latent variable model with or without correlated errors of measurement [7]. The two-stage least squares estimator has known asymptotic properties including standard errors that allow significance tests without assuming multivariate normality of the observed variables. The finite sample properties of the estimator are not well studied in latent variable models.

The estimation of parameters is more complicated when some of the endogenous observed variables are categorical. This would be the case if the indicators of a latent variable are ordinal, censored, or dichotomous variables, or in other situations in which the "dependent" variable of a relationship is noncontinuous. Analysts have proposed several approaches to incorporate such variables into a structural equation model, but they all share a similar strategy. It is assumed that all observed endogenous noncontinuous variables have underlying continuous variables that correspond to them. So, for example, we assume that underlying our five-point ordinal scale on self-reported health is a continuous variable of perceived health. The first step is the estimation of the correlation (covariance) matrix of the continuous variables that underlie the noncontinuous observed variables. The next step takes this matrix and analyzes it with the arbitrary distribution function (weighted least squares) estimator. Thus the main difference when endogenous categorical variables are part of the analysis is that we take the extra step of estimating what the correlation (covariance) matrix would look like if these variables were measured on continuous scales.

Model–Data Fit

Once the researcher estimates a model, attention turns to assessing its **goodness of fit**. Model fit assessments have two parts: (1) overall fit and (2) component fit. Overall fit refers to summary measures of how well the model as a whole corresponds to the data. The most widely used measure of overall fit is a test statistic (*see* **Hypothesis Testing**) that asymptotically approaches a **chi-square distribution** when the population covariance matrix equals the implied covariance matrix; that is, the null hypothesis is $\mathrm{H}_0 : \boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\theta})$. In the case of F_{ML} described above, the test statistic is $T = (N-1)F_{ML}$, evaluated at the final parameter estimates. The **degrees of freedom** equal $\frac{1}{2}(p+q)(p+q+3) - t$, where p and q are the number of y and x variables and t is the number of unrestricted parameters estimated. The first term gives the number of nonredundant elements in the covariance matrix of the observed variables and the number of sample means. If the distributional assumptions of the test are satisfied, a significant value of the test statistic suggests that the model is misspecified (*see* **Misspecification**). In large samples the **power** of the significance tests is sometimes so great that even trivial departures lead to rejection of H_0. In small samples, the power of the test might be too weak to detect problems.

In response to these difficulties a variety of other overall fit measures have arisen. The **residual** matrices, $\mathbf{S} - \boldsymbol{\Sigma}(\hat{\boldsymbol{\theta}})$ and $\bar{\mathbf{z}} - \boldsymbol{\mu}(\hat{\boldsymbol{\theta}})$, are two simple measures. These values show the departures of

the observed and the predicted covariance matrices and mean vectors of the observed variables. Standardization of the residuals that take account of the scaling of the observed variables or the standard errors of the residuals are sometimes employed. Numerous other overall fit measures appear in the literature. Most are normed to range approximately from 0 to 1, where the value of 1 represents an ideal fit. The fit indices are the subject of debate in the literature on structural equation models (e.g. Bollen & Long [8]).

A second type of fit assessment occurs for the components of the model rather than the overall fit of the model. These components of fit are ones that are familiar to researchers using regression techniques. Researchers examine such things as the signs and the significance of coefficients, variances, and covariances, and the R-squares for equations. They also check for "improper" solutions such as negative variances or correlations greater than one.

Respecification

It is not unusual to find that an initial model specification provides an inadequate match to the data. A common reaction is to attempt to improve the model. Once the researcher enters this more **exploratory** mode of analysis, the usual significance tests cannot be interpreted in the usual way. It is then important to seek to replicate the final model on an independent data set. The substantive expert of the research is the most valuable source for possible modifications of the initial model. It is not unusual for the analysts to have considered several plausible relationships that were excluded from the initial model. These modifications are natural ones to consider, if the initial model fit is poor.

Empirical methods that can help in respecification also are available. The residual covariance matrix and mean vector described above show poorly fit parts of the data. But care must be taken in using such residuals [10]. Other aids are Lagrangian multiplier (and Wald) test statistics, that estimate the decrease (increase) in the chi-square test statistic for the freeing up (restricting) one or more parameters at a time [2]. Too great a reliance on these empirical methods can lead to problems (e.g. MacCallum [25]), but when used in conjunction with substantive expertise, they can prove helpful.

Historical Origins

We can trace the ancestry of contemporary structural equation models to several sources: Sewall Wright's (1918 [32], 1921 [33], and 1925 [34]) **path analysis**, the factor analysis tradition in psychometrics, simultaneous equation work in econometrics, and the 1960s and early 1970s synthesis of these areas in sociometrics. Although contemporary structural equation models are distinct in many ways, Wright's path analysis is probably the closest relative. Path analysis begins with a model specified prior to estimation. It provides a method of testing the consistency of a model to the data and a method to trace the influences of variables through a system of equations. The path diagram invented by Wright in 1921 [33] is a pictorial representation of the model. It provides a simple way to represent the complex relations between a large number of latent or observed variables. These diagrams are standard in structural equation models. Wright also used these diagrams to distinguish the direct, indirect, and total effects of one variable on another. The direct effects are the influences of one variable on another that do not pass through any other variable. The indirect effect is an impact that is through at least one other variable, while the total effect is the sum of the direct and indirect effects of one variable on another. This decomposition of effects is still part of structural equation models, although researchers have elaborated the definitions to include reciprocal relations and the presence of latent variables and have debated their "causal" meaning (*see* **Causal Direction, Determination**).

Another lasting influence of Wright's path analysis is the practice of writing the variances and covariances between variables as functions of the model parameters (e.g. coefficients, variances, and covariances of exogenous variables and disturbances). Wright used these relations to explore issues of model identification and the estimation of the parameters in a path model. Through examples, he demonstrated how path analysis could incorporate latent variables (factors), reciprocal relations, and recursive relations into statistical models. See the entry on **path analysis** for further details.

Wright's [32] first application of path analysis, appearing in 1918, was a factor analysis of bone size measurements. Unknown to Wright, Spearman [29] had proposed factor analysis over a decade earlier to analyze whether a general intelligence factor

underlied individuals' performances on tests. Spearman's work launched the beginning of the factor analysis tradition in psychometrics. Factor analysts soon moved from single to multiple-factor solutions and developed various methods of "rotating factors" to improve interpretability (*see* **Rotation of Axes**). Psychometricians became the most experienced group in the analysis of latent variables measured with multiple indicators. Some applied factor analysis to test prior hypotheses about the dimensionality of measures. However, most researchers used factor analysis as a data reduction tool, in which the number of factors and the pattern of influences of the latent variables on the observed variables were determined by the statistical procedures rather than by being specified in advance.

A related but separate development in psychometrics was classical test theory [24]. It shared with factor analysis a concern with latent or true score variables, but each observed variable was a function of a true score and error rather than being possibly influenced by multiple factors. In addition, factor analysis conceives of each variable as having a specific variance that is distinct from the factors and separate from the pure random error. The true score from classical test theory would include specific variance as part of the true score, not a part of the residual term. Classical test theory developed distinct definitions and approaches to the **reliability** and **validity** of measures. And these concepts of reliability and validity still hold influence in contemporary structural equation modeling, although such models lead to far more general relations between variables than those included in classical test theory by allowing correlated errors of measurement and multiple latent variables to influence observed variables.

The contribution of econometrics to structural equation modeling comes largely from its work on *simultaneous equations*. These models focused on observed rather than latent random variables. They dealt with issues of identification and estimation of a system of equations [15]. Econometricians proposed general rules of identification for simultaneous equations [13] that systematized the study of this issue and greatly influenced the contemporary perspective on identification in the more general structural equation models. Similarly, econometricians' work on limited information (e.g. Theil [30] and Basmann [1]) and full information estimators [18] led to the more sophisticated estimators that are commonly applied to structural equation models.

In the 1960s and early 1970s, sociometrics set the stage for the cross fertilization of path analysis, factor analysis, and econometric models that eventually merged into the contemporary form of structural equation models. Blalock [4], for instance, demonstrated the power of path analysis and partial correlations in examining a researcher's model of hypothesized relationships. Duncan's [11] didactic paper on path analysis in 1966 had a tremendous impact on the spread of path analysis in sociology as well as in psychology and other disciplines. Duncan et al. [12] illustrated the synthesis of latent variable and simultaneous equation models using path analysis in a classic 1968 study of peer influence. In 1969, Heise [17] shed new light on the use of panel data to explore reliability and stability in the measurement of variables. A classic 1971 edited volume by Blalock [5] illustrates the early merging of these techniques and the diffusion of statistical approaches from one field to another.

Although separated by only a couple of years, a 1973 edited volume by Goldberger & Duncan [14] revealed the more sophisticated approach to structural equation models that now dominates the field. Included in the volume is the highly influential paper by Karl Jöreskog, where he presented an early version of the LISREL model. The papers marked a more general approach to model specification, the implied covariance matrix, identification, estimation, and testing that is typical of current research.

Structural equation models have diffused through most of the social sciences and have begun to appear in the biostatistics and public health literature. Numerous software packages to estimate structural equation models are available with LISREL [22] and EQS [3] being the two most widely used ones. Publications using structural equation models are common in sociology, marketing, psychology, and education, and the technical literature continues to grow. *Structural Equation Modeling* is a journal devoted to the technique, but other statistical journals also publish work in this area. SEMNET is a listserver devoted to structural equation models and to date has over 1400 subscribers. Structural equation models remains an active area of research and applications.

KENNETH A. BOLLEN

Structural Nested Failure Time Models

Structural nested failure time models (SNFTMs) are causal models for the effect of a time-dependent treatment or exposure on a survival time outcome in the presence of **time-dependent** confounding covariates [1, 10, 11, 15–17, 19, 20, 23, 31, 32] (*see* **Confounding**). The simplest SNFTMs map a subject's observed failure time T, observed treatment and confounder history, and an unknown parameter ψ_0 into the time U at which the subject would have failed if, possibly contrary to fact, treatment had been withheld. The causal parameter ψ_0 is identified if, as in a sequentially randomized experiment, the treatment at time t is randomly assigned (i.e. ignorable) conditional on past treatment and confounder history. The method of g-estimation provides computationally convenient and **robust** semiparametric estimators of ψ_0 when ψ_0 is identified [16, 26].

The usual approach to the estimation of the effect of a time-varying treatment on survival has been to model the **hazard** of failure at t as a function of past treatment history using a time-dependent **proportional hazards model**. In the next section, we show that the usual approach may be biased, whether or not one further adjusts for past confounder history in the analysis, when (i) there exists a time-dependent risk factor for, or predictor of, the event of interest that also predicts subsequent treatment, and (ii) past treatment history predicts subsequent risk factor level. The following two examples demonstrate conditions (i) and (ii) will be true in studies in which there is treatment by "indication" and/or a time-dependent covariate that is simultaneously a confounder and an intermediate variable on the causal pathway from treatment to failure.

The drug AZT, used in the treatment of **AIDS**, is a direct red blood cell toxin that is often withheld in anemic subjects, since the toxic effects of AZT can worsen the anemia. Furthermore, anemic patients are at increased risk of death. Thus in a study of the effect of AZT on survival of patients with AIDS, the time-dependent covariate anemia is both a risk factor for death and a predictor of subsequent treatment with AZT. Furthermore, as a red blood cell toxin, past AZT treatment is a risk factor for the development of anemia. In **occupational mortality** studies, unhealthy workers who terminate employment early are at an increased risk of death compared to other workers and receive no further exposure to the chemical agent under study. Therefore, the time-dependent covariate, employment status at time t, is an independent risk factor for death and a predictor of future exposure to the study agent. In addition, previous exposure to the study agent may lead to early termination of employment if the agent causes a disabling illness. Epidemiologists refer to covariates such as anemia or employment status in the above examples as *time-dependent confounders*.

This article is organized as follows. We first describe the fundamental assumption of no unmeasured confounders that, if true, allows us to test for and estimate causal effects from longitudinal data. In the next section we describe a valid α-level test, the g-test, of the **null hypothesis** of no causal effect of treatment on survival. We then describe the potential for bias and lack of robustness of alternative testing procedures. In the section "Deterministic Structural Nested Failure Time Models" we introduce the simplest SNFTMs – the deterministic SNFTMs. In the section "g-Estimation of ψ_0" we show that g-estimation of deterministic SNFTMs provides a unified approach to estimation of and testing for the effect of a time-dependent treatment. In the section "Sensitivity Analysis", we describe how the consequences of violations of our assumption of no unmeasured confounders can be explored through a sensitivity analysis. In these sections, we assume censoring is absent. In the following section we extend our methods to allow for censoring by end of follow-up, loss to follow-up, and competing risks. In the section "Inference Based on Instantaneous-Rate RPSNFTMs", we show that it is difficult to incorporate a priori biological knowledge as restrictions on the functional form of our deterministic SNFTMs. However, it is straightforward to incorporate biological knowledge if we adopt a more general class of causal models, the instantaneous-rate rank-preserving structural nested failure time models (RPSNFTMs), which model the effect of a final instantaneous blip of treatment on survival. The parameters of an instantaneous-rate RPSNFTM can be consistently estimated using g-estimation. Instantaneous-rate RPSNFTMs allow the magnitude of the treatment effect to depend on the measured factors but not on unmeasured factors. This restriction is often biologically implausible. We therefore

introduce, in the following section, the class of instantaneous-rate SNFTMs which allow the magnitude of the treatment effect to depend on both measured and unmeasured factors, and include the instantaneous-rate RPSNFTMs as a special case. It is of scientific and public health interest to estimate the survival curves that would be expected under various treatment regimes in order to determine the optimal regime with which to treat future patients. Hence, we consider estimation of regime-specific survival curves. Finally, we briefly describe an alternative nonnested structural failure time model that may sometimes have advantages in survival curve estimation.

Structural nested models for repeated measure and other nonfailure time outcomes (*see* **Longitudinal Data Analysis, Overview**) are considered in [15, 17, 18, 20], and [21]; they are not considered in this article.

Causal Inference from Observational Data

The Data

For pedagogic purposes we consider a study of the effect of AZT treatment on the survival of AIDS patients. Let T_i be a continuous variable recording the survival time for the ith study subject, $i = 1, \ldots, n$, with time measured from study enrollment. Let $A_i(t)$ record subject i's AZT dosage rate at t and $\mathbf{L}_i(t)$ record the value at t of a vector of various time-dependent and time-independent covariates such as CD4 lymphocyte count, presence of anemia, and gender. For any time-dependent random variable $Z_i(t)$, let $\overline{Z}_i(t^-) = \{Z_i(u); 0 \leq u < t\}$ be the history of the Z-process up to but not including time t and let $\overline{Z}_i(t)$ be the history of the process through t. Note that $Z_i(t)$ is defined only for $t \leq T_i$. For the time being, we assume there is no censoring. In the absence of censoring, the observable variables are then $\{T_i, \overline{A}_i(T_i), \overline{\mathbf{L}}_i(T_i)\}$, which we assume are independent and identically distributed, and henceforth suppress the i subscript denoting subject. Following [3, 13, 14], and [29], we shall also assume there exists a latent (possibly counterfactual) "baseline" failure time random variable U representing a subject's survival time had, possibly contrary to fact, AZT always been withheld.

The Fundamental Assumption of No Unmeasured Confounders

Our fundamental assumption of no unmeasured confounders is

$$U \perp\!\!\!\perp A(t) | \overline{\mathbf{L}}(t^-), \overline{A}(t^-), T \geq t, \qquad (1)$$

where $A \sqcup B|C$ means A is independent of B given C [4]. We will also refer to assumption (1) as the assumption that treatment $A(t)$ is sequentially ignorable or randomized given the past. Assumption (1) states that, conditional on AZT history and the history of all recorded covariates prior to t, increments in AZT dosage rate at t are independent of the baseline failure time random variable U. This assumption will be true if all risk factors for, i.e. predictors of, the baseline failure time U that are used by patients and physicians to determine the dosage of AZT at t are recorded in $\overline{\mathbf{L}}(t^-)$ and $\overline{A}(t^-)$. For example, since physicians tend to withhold AZT from anemic subjects, and in untreated subjects anemia is a predictor of survival, assumption (1) would be false if $\overline{\mathbf{L}}(t^-)$ does not contain anemia history. It is the primary goal of the epidemiologists conducting an observational study to collect data on a sufficient number of covariates to ensure that our assumption (1) will be at least approximately true.

Assumption (1) is the fundamental condition that will allow us to draw causal inferences from observational data (*see* **Causation**). It is precisely because (1) cannot be guaranteed to hold in an observational study and is not empirically testable that it is so very hazardous to draw causal inferences from observational data. Note that if, as in a sequentially randomized trial, at each time t, the dose of AZT was chosen at random by the flip of a coin, then (1) would be true even if the probability that the coin landed heads depended on past covariate and AZT history. It is because physical randomization guarantees (1) that most people accept that valid causal inferences can be obtained from a randomized trial (*see* **Randomization**). See [5, 13], and [29] for further discussion. In a later section we describe how the consequences of violations of (1) can be explored through sensitivity analysis.

For convenience, until a later section we shall assume that the treatment $A(t)$ received at time t is dichotomous, i.e. $A(t) = 1$ if on treatment at t and zero otherwise. Robins [16] and Robins

et al. [26] consider nondichotomous treatments. For $A(t)$ dichotomous, assumption (1) can be written

$$\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), U) = \lambda(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-)), \quad (2)$$

where, if $A(t)$ is an instantaneous-rate process, $\lambda_A(t|\overline{A}(t^-), \cdot) = \lim_{\delta t \to 0} \Pr[A(t+\delta t) \neq A(t^-)| \overline{A}(t^-), T \geq t, \cdot]/\delta t$ is the hazard of the treatment process jumping in the infinitesimal interval $[t, t+\delta t)$ given $\overline{A}(t^-)$ and $\cdot$. However, $\lambda_A(t|\overline{A}(t^-), \cdot) = \Pr\{A(t) \neq A(t^-)|\overline{A}(t^-), T \geq t, \cdot\}$ is a discrete hazard if $A(t)$ can only jump at nonrandom discrete times $t_1, t_2, \ldots$, as would be the case if the $A(t_k)$ recorded whether a subject was on AZT at weekly clinic visits. Owing to measure theoretic subtleties, (2) but not (1) is a mathematically precise statement of our assumption of no unmeasured confounders.

A g-Test of the Causal Null Hypothesis

The sharp causal null hypothesis of no treatment effect on survival is that each subject's observed and baseline lifetimes are the same. That is,

$$U = T \text{ w.p.1}, \quad (3a)$$

where w.p.1 stands for with probability 1. Given our assumption (2), the restriction on the distribution of the observables implied by (3a) is that the hazard of treatment jumps at t does not depend on the survival time T given past treatment and covariate history. That is,

$$\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), T) = \lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-)). \quad (3b)$$

Hence, if the A process is a instantaneous-rate process, then we can test (ii) by specifying a time-dependent **Cox** (proportional hazards) **regression model**

$$\lambda_0(t) \exp[\boldsymbol{\alpha}' \mathbf{W}(t)] \quad (4)$$

for $\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-))$, where $\mathbf{W}(t)$ is a known vector-valued function of $(\overline{A}(t^-), \overline{\mathbf{L}}(t^-))$, $\boldsymbol{\alpha}$ is an unknown parameter vector, and $\lambda_0(t)$ is an unspecified baseline hazard function. If the A process jumps only at fixed discrete times, we interpret (4) as a model for the **odds** $\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-))/\{1 - \lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-))\}$. If model (4) is correctly specified, an asymptotic α-level Cox **partial likelihood** score, Wald (*see* **Likelihood**), or **likelihood ratio test** of the hypothesis $\theta = 0$ in the extended model that adds a term θT to $\boldsymbol{\alpha}' \mathbf{W}(t)$ in (4) is an asymptotically α-level test (*see* **Level of a Test**) of the sharp null hypothesis (3a) under the assumption (2) of no unmeasured confounders. Robins [16] refers to such a test as a g-test. Note a g-test first models the hazard of the treatment process as a function of the survival time T and past treatment and covariate history, and then tests whether the coefficient θ of T is significant. In fact, we obtain an α-level test of (3b) by testing $\theta = 0$ in the extended model that adds the term $\theta Q(t)$ to $\boldsymbol{\alpha}' \mathbf{W}(t)$ in (4), where $Q(t) = q(t, \overline{A}(t^-), \overline{\mathbf{L}}(t^-), T)$ is a function chosen by the data analyst. The choice of $Q(t)$ effects the power but not the level of the g-test. The g-test is a generalization to time-dependent treatments and confounders of Rosenbaum's [27, 28] test for the effect of a single time-independent treatment.

Bias of Standard Methods

To understand why standard approaches that use Cox regression to model the hazard of failure as a function of past treatment history are biased whether or not one adjusts for past confounder history, we consider a group of AIDS patients who are alive at 10 months, dichotomized into those who developed anemia by 8 months and those who remain free of anemia at 8 months. A Cox regression analysis that estimates the rate ratio at 10 months attributable to AZT exposure in the interval 8–10 months without adjusting for or stratifying on anemia status can make AZT appear falsely beneficial, since anemic subjects are at a higher risk of dying at 10 months and are less likely to receive AZT therapy in months 8–10. That is, anemia status at 8 months is a confounder for the causal effect of AZT treatment received in the interval from 8 to 10 months.

However, because AZT causes anemia, even if both AZT and anemia have no causal effect on the survival of any subject, the above Cox regression analysis may continue to suggest falsely that AZT is beneficial even when we adjust for anemia at 8 months. To see why, for simplicity, suppose now that 300 subjects receive AZT by 4 months, and 300 subjects never receive AZT. In both groups of 300, suppose that, regardless of AZT treatment or treatment for anemia, 100 individuals are poor-prognosis subjects who are destined to die at 10 months, 100 are moderate-prognosis subjects destined to die at 20 months, and 100 are good-prognosis subjects destined

Table 1 A Hypothetical study

Anemia by 8 months				No anemia			
	Time to death (months)				Time to death (months)		
	10	20	30		10	20	30
No AZT	100[a]	0	0	No AZT	0	100[b]	100[c]
AZT by 4 months	100[a]	100[b]	0	AZT by 4 months	0	0	100[c]

[a]Poor-prognosis patients.
[b]Moderate-prognosis subjects.
[c]Good-prognosis subjects.

to die at 30 months. Suppose AZT causes anemia in moderate-prognosis patients. Specifically, all moderate-prognosis patients would develop anemia at 8 months if given AZT, whereas none would develop anemia without AZT. All poor-prognosis and no good-prognosis patients develop anemia regardless of AZT therapy. Under these assumptions, the data would be as shown in Table 1. Inspecting Table 1, we observe that, within the stratum defined by the presence of anemia at 8 months, the mortality rate at 10 months is less in those who received AZT than in those who did not. Similarly, in the stratum defined by the absence of anemia, the mortality rate at 20 months is less in those who received AZT than in those who did not. Thus, a Cox analysis that adjusts for (or stratifies on) past anemia history would falsely suggest that AZT has a beneficial effect on survival. This bias is attributable to the fact that in Table 1 AZT by 4 months is a risk factor for subsequent anemia, and that anemia is a noncausal risk factor for death, since the death rate at 10 months is greater in those with anemia than in those without anemia among subjects without AZT, and the death rate at both 10 and 20 months is greater in those with anemia than in those without anemia among subjects with AZT. Note, by construction of our example, anemia is not a causal risk factor for death; rather, it is a proxy for the unmeasured prognosis variable. Furthermore, anemia is not an intermediate variable on the causal pathway from AZT treatment to death since, by construction, there is no such causal pathway (*see* **Path Analysis**).

It follows that we must control for the confounder "anemia status at month 8" to estimate the causal effect of AZT in the interval (8,10). However, we must not control for the variable "anemia status at month 8" to estimate the causal effect of AZT therapy in the interval (0,8) on survival. If, however, we summarize AZT history over the interval (0,10) in terms of cumulative dosage, average dose intensity, or the time since the initiation of AZT therapy, these requirements cannot be met, since we lose the ability to separate out AZT in the interval (0,8) from AZT in the interval (8,10). However, the g-test of the previous subsection is specifically designed to control for confounding by variables affected by earlier treatment by never lumping treatment received at different times. Specifically, the g-test checks, at each time t, for association between treatment $A(t)$ received at t and the failure time T after adjusting for confounder and treatment history before t, but without adjusting for the "post-treatment" variables "covariate and treatment history subsequent to t". It is essential to the validity of the g-test that treatment history $\overline{A}(t^-)$ before t be adjusted for as a potential confounding factor for the effect of the treatment $A(t)$ received at t.

Formally, results in this section reflect the fact that the null hypothesis (3b) does not imply either that

$$\lambda_T(t|\overline{A}(t^-)) = \lambda_T(t) \tag{5}$$

or that

$$\lambda_T(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-)) = \lambda_T(t|\overline{\mathbf{L}}(t^-)), \tag{6}$$

where $\lambda_T(t|\cdot)$ is the hazard of failure at t given $\cdot$. However, Robins [12] proves that (3b) does imply (5) if either of the following are true:

$$\lambda_T(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-)) = \lambda_T(t|\overline{A}(t^-)) \tag{7}$$

or

$$\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-)) = \lambda_A[t|\overline{A}(t^-)]. \tag{8}$$

If (7) holds, we say $\mathbf{L}(t)$ is not an independent predictor of failure. If (8) holds, we say $\mathbf{L}(t)$ is not an independent predictor of subsequent treatment. If

either (7) or (8) holds, we say that the $\mathbf{L}(t)$ process is not a confounder for the effect of $A(t)$ on survival. In that case, we can test the sharp null hypothesis (3a) under assumption (2) by ignoring data on $\mathbf{L}(t)$ and testing (5) using a time-dependent Cox model for failure.

Computational Complexity and Nonrobustness of Tests Based on the g-Computation Algorithm

In this subsection, to avoid the need for product integral notation, we assume the covariate history $\overline{\mathbf{L}}(T)$ can jump only at fixed times $k = 0, 1, 2, \ldots$. This is no practical limitation, since, for example, we could take the time interval between the jump times k and $k+1$ to be 1 second. The g-computation algorithm formula $r(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ of Robins [13, 14] for the effect of a treatment regime $\overline{a} = \{a(u); 0 \le u < \infty\}$ on survival to time t conditional on $\overline{\mathbf{L}}(m^-) = \overline{\mathbf{l}}(m^-)$ and $\overline{A}(m^-) = \overline{a}(m^-)$ is

$$r(t, \overline{a}, \overline{\mathbf{l}}(m^-)) = \int \cdots \int \exp\left\{-\int_0^t \lambda_T(u|\overline{\mathbf{l}}(u^-), \overline{a}(u^-))\right\} \times \prod_{k=m}^{\mathrm{int(t)}} \mathrm{d}F[\mathbf{l}(k)|\overline{\mathbf{l}}(k^-), \overline{a}(k^-)], \qquad (9)$$

where $\mathrm{int}(t)$ is the greatest integer less than t, and $\lambda_T(u|\cdot)$ is the conditional hazard of failure at u given $\cdot$. Robins [13, 14] showed that under a sequential randomization assumption, $r(t, \overline{a}, \overline{\mathbf{l}}(0^-))$ is the probability of survival to t had, contrary to fact, all subjects followed treatment regime $\overline{a}$ until failure. Researchers studying causal models based on directed acyclic graphs [12, 30] have recently rediscovered that g-computation algorithm formula. In addition, Arjas & Eerola [2] and Klein et al. [7] have also considered estimation of causal effects using this formula.

The g-null theorem of Robins [13] states that (3b) is true if and only if, for all $(t, \overline{a}, \overline{\mathbf{l}}(m^-))$, $r(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ depends on $\overline{a}$ only through $\overline{a}(m^-)$. It follows that one can, in principle, test the null hypothesis (3a) under the assumption (2) of no unmeasured confounders by: fitting a Cox proportional hazards model for $\lambda_T(u|\overline{a}(u), \overline{\mathbf{l}}(u^-))$ depending on parameters θ and a parametric or semiparametric model for $f(\mathbf{l}(k)|\overline{\mathbf{l}}(k^-), \overline{a}(k^-))$ depending on parameters η, using the fitted model to construct an estimator $\hat{r}(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ of $r(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ for various choices of $t, \overline{a}, \overline{\mathbf{l}}(m^-)$ by evaluating the right-hand side of (9); deriving estimates of the standard errors of the $\hat{r}(t, \overline{a}, \overline{\mathbf{l}}(m^-))$; and finally constructing a test of the hypothesis that $r(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ only depends on $\overline{a}$ through $\overline{a}(m^-)$ using the estimates $\hat{r}(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ and their estimated standard errors.

The difficulty with this procedure is twofold. First, it is computationally extremely demanding since (i) the integral on the right-hand side of (9) cannot in general be evaluated analytically, and a **Monte Carlo** approximation must be used; and (ii) it is difficult to compute **delta-method** estimators for the standard error of $\hat{r}(t, \overline{a}, \overline{\mathbf{l}}(m^-))$, and **bootstrap** standard errors may be computationally too demanding because of (i). Secondly, there will in general be no simple function ψ of the parameters (θ, η) that takes a fixed value (say zero) if and only if $r(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ only depends on $\overline{a}(m^-)$. As discussed in [19], this fact implies that the tests based on the $\hat{r}(t, \overline{a}, \overline{\mathbf{l}}(m^-))$ will be exquisitely sensitive to inevitable model misspecification. In summary, we suggest the g-test described earlier be used to test the null hypothesis (3b).

Deterministic Structural Nested Failure Time Models

The g-test of the hypothesis $\theta = 0$ in the extension of model (4) is an asymptotic α-level test of the sharp null hypothesis (3a) if model (4) is correctly specified and if the assumption (2) of no unmeasured confounders is true. However, we also wish to estimate the size of the treatment effect when the causal null is false. To do so, we introduce g-estimation of structural nested failure time models which will provide a unified approach to estimation of and testing for the effect of a time-dependent treatment.

The simplest SNFTM is a deterministic transformation model which assumes the counterfactual failure time U is a known function $h(T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi_0)$ of the observed data $(T, \overline{A}(T), \overline{\mathbf{L}}(T))$ and an unknown parameter ψ_0; that is

$$U = H(\psi_0), \qquad (10a)$$

where

$$H(\psi) \equiv h(T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi). \qquad (10b)$$

A specific example of a deterministic SNFTM is the strong version of the **accelerated failure-time model** of Cox & Oakes [3] which assumes

$$h(T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi) = \int_0^T \exp\{\psi A(t)\}\,\mathrm{d}t. \quad (11)$$

Any deterministic SNFTM (11) satisfies the following:

$$\text{if } \overline{A}(T) \equiv 0, \text{ then } U = T; \quad (12a)$$

$$T \equiv U \text{ w.p.1 if and only if } \psi_0 = 0. \quad (12b)$$

Statement (12a) is a natural consistency assumption stating that if a subject is, in fact, untreated, then the observed failure time T equals the failure time U when treatment is withheld. Statement (12b) implies the null hypothesis $\psi_0 = 0$ corresponds to the causal null hypothesis (3a) that treatment has no effect. To understand the implications of (11) when $\psi_0 \neq 0$, consider a subject who is continuously treated. Then, by (10) and (11), $U = \mathrm{e}^{\psi_0} T$ so $T = \mathrm{e}^{-\psi_0} U$. That is, a subject's untreated survival time U is expanded or contracted by the factor $\mathrm{e}^{-\psi_0}$ by constant treatment. Hence, if $\psi_0 > 0$, treatment is harmful and lessens survival; if $\psi_0 < 0$, treatment is beneficial and increases survival. Robins et al. [26] referred to deterministic SNFTMs as rank-preserving structural failure time models.

g-Estimation of ψ_0

We now describe how to obtain consistent asymptotically normal point and **interval estimates** of the parameter ψ_0 consistent with the g-tests of introduced above in the sense that 95% **confidence intervals** for ψ_0 will fail to include zero if and only if the corresponding 0.05 level g-test rejects. As a simple example, consider the deterministic SNFTM (11) with ψ one-dimensional. We estimate ψ by a "grid search". First, we note that for each value of ψ, $H(\psi)$ can be computed by (11) from the observed data. Hence, under the reasonable biological assumption that $|\psi_0| < 3$, separately, for each of the 61 values of ψ in the set $\{-3, -2.9, \ldots, 0, \ldots, 2.9, 3\}$, we perform a Cox partial likelihood score test (g-test) of the hypothesis $\theta = 0$ in the extended model that adds a term $\theta Q(t, \psi)$ to $\boldsymbol{\alpha}'\mathbf{W}(t)$ in (4) with $Q(t, \psi) = q(t, \overline{A}(t^-), \overline{\mathbf{L}}(t^-), H(\psi))$ a function chosen by the data analyst. A valid 95% large-sample confidence interval for ψ_0 is the set of ψ for which the score test fails to reject at the 0.05 level provided our no-confounding assumption (2), our Cox model (4), and our deterministic SNFTM (10)–(11) are correct. Furthermore, the g-estimate $\hat{\psi}$ is a consistent asymptotically normal estimator of ψ_0, where $\hat{\psi}$ is defined to be the value of ψ for which the partial likelihood score test of $\theta = 0$ is precisely zero. The parameter ψ is treated as a fixed constant when calculating the score test. The choice of the function $q()$ affects the length but not the coverage rate of the interval. The optimal choice of the function $q^*()$ is given in [16]. The method of g-estimation can be extended to estimate the parameter, say, $\psi = (\psi_1, \psi_2)'$ of a multiparameter deterministic SNFTM such as

$$H(\boldsymbol{\psi}) = \int_0^T \exp\{\psi_1 A(t) + \psi_2 L^*(t) A(t)\}\,\mathrm{d}t. \quad (13)$$

In model (13), $L^*(t)$ represents a known function of the covariate history $\overline{\mathbf{L}}(t^-)$. If the true value ψ_{20} of ψ_2 is nonzero, then there is a treatment–covariate interaction in the sense that the magnitude of the effect of the time-dependent treatment $A(t)$ depends on a subject's time-dependent covariate history $\overline{\mathbf{L}}(t^-)$ through the function $L^*(t)$. A g-estimate of the parameter vector $\boldsymbol{\psi}$ of (13) is obtained by choosing $Q(t, \boldsymbol{\psi})$ to be a known vector-valued function of dim $\boldsymbol{\psi}$ chosen by the data analyst and $\boldsymbol{\theta}$ to be a (dim $\boldsymbol{\psi}$)-valued parameter with dim $\boldsymbol{\psi}$ the dimension of the vector $\boldsymbol{\psi}$.

Estimation with Instrumental Variables

Suppose $A(t) = (A_1(t), A_2(t))$, with $A_1(t)$ recording a physician's prescribed treatment and $A_2(t)$ recording the actual treatment at time t. One then might suppose that

$$A_1(t) \coprod U | \overline{\mathbf{L}}(t^-), \overline{A}(t^-), T > t \quad (14)$$

is true but (1) is false if one believed that a predictor of both U and actual treatment $A_2(t)$ had not been included in $\overline{\mathbf{L}}(t^-)$. Under assumption (14), g-estimation of the parameter ψ_0 of the deterministic SNFTM (10) can proceed as before, except we view model (4) as a model for the cause-specific hazard $\lambda_{A_1}(t | \overline{A}(t^-), \overline{\mathbf{L}}(t^-))$ for jumps in the $A_1(t)$ process, thus ignoring jumps in the actual treatment $A_2(t)$ process in our estimation procedure. In this setting,

$A_1(t)$ is often referred to as an **instrumental variable** process, especially when prescribed treatment $A_1(t)$ has no direct causal effect on survival except through the actual treatment process $A_2(t)$. A familiar example of an instrumental variable is when $A_1(0)$ is the randomization indicator for assignment to treatment arm in a randomized **clinical trial** in which there is possibly nonrandom noncompliance and $A_2(t)$ is the actual treatment dose. (In such a setting, $A_1(t)$ can be defined to be zero by convention for times $t \neq 0$.) Then the g-estimation method described above is the method for adjusting for nonrandom noncompliance in randomized clinical trials described in [17]. For alternative **rank** estimation procedures, see [11] and [25].

Sensitivity Analysis

In observational studies, our fundamental assumption (2) of no unmeasured confounders cannot be empirically tested from the data. Hence, it is important to conduct sensitivity analyses to determine how point and interval estimates for ψ_0 would change under increasingly severe violations of (2). Let η be a sensitivity parameter that we will vary (but not estimate) in our sensitivity analysis and consider the model

$$\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), U) = \lambda_0(t) \exp[\boldsymbol{\alpha}'\mathbf{W}(t) + \eta U]. \tag{15}$$

When $\eta = 0$, both the assumption (2) of no unmeasured confounders and our Cox model (4) are true. As $|\eta|$ increasingly deviates from zero, (2) is increasingly violated. Our goal, in a sensitivity analysis, is to obtain valid point and interval estimates for the causal parameter ψ_0 of our deterministic SNFTM under the assumption that (15) is correctly specified, with α an unknown parameter to be estimated but with η known. Specifically, a 95% confidence interval for ψ_0 under these assumptions is obtained as the set of ψ for which the score test of the hypothesis $\theta = 0$ fails to reject at the 0.05 level in model

$$\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), H(\psi)) = \lambda_0(t) \exp[\boldsymbol{\alpha}'\mathbf{W}(t) + \eta H(\psi) + \theta Q(t, \psi)], \tag{16}$$

when η and ψ are treated as fixed and known when maximizing the partial likelihood over α. The data analyst should then display point and interval estimates for ψ for a moderately large number of choices for the sensitivity parameter η.

Censoring

In this section we extend our results to allow for right-censoring. We handle censoring by administrative end of follow-up differently from censoring by **competing risks** or by loss to follow-up (*see* **Bias from Loss to Follow-up**).

Censoring by End of Follow-Up

We assume that there is a fixed known calendar date at which the follow-up of all subjects will end. We then define the potential censoring time C for a subject to be the difference between this end-of-follow-up date and the date at which the subject entered follow-up. Hence, the potential censoring time C is known for all subjects, even those who fail before the end-of-follow-up date. Because the potential censoring time C is known at start of follow-up ($t = 0$), we can and do regard C as a time-independent "pretreatment" covariate that is contained in $\overline{\mathbf{L}}(t^-)$ for each time $t \geq 0$. If, as we assume in this section, the only cause of censoring is by end of follow-up, the data available for data analysis for each subject are $\{X = \min(T, C), \overline{A}(X), \overline{\mathbf{L}}(X)\}$.

Since $H(\psi)$ can only be computed for uncensored individuals, it might seem natural when calculating g-estimates of ψ_0 to replace the now partially unobservable $H(\psi)$ by the new random variable $X^*(\psi)$ obtained by replacing T by X in (10b). Unfortunately, this approach fails since, if $\psi_0 \neq 0$, then $X^*(\psi_0)$ is not independent of $A(t)$ given $(\overline{A}(t^-), \overline{\mathbf{L}}(t^-), X \geq t)$ even under the assumption (2) of no unmeasured confounders. Thus, an alternative approach is necessary. The key to our approach is to define new variables $(X(t, \psi), \Delta(t, \psi))$ that (i) in contrast to both T and $H(\psi)$, but like $X^*(\psi)$, are observed for all subjects, including those censored, and (ii) like $H(\psi_0)$, but unlike $X^*(\psi_0)$, satisfy, for $t < C$,

$$\lambda_A[t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), X(t, \psi_0), \Delta(t, \psi_0)] = \lambda_A[t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-)] \tag{17}$$

under assumption (2) and model (10). We can then estimate ψ_0 by g-estimation as before, except with

$Q(t, \psi)$ now a function $q(t, \overline{\mathbf{L}}(t^-), \overline{A}(t^-), X(t, \psi), \Delta(t, \psi))$. Below, we define $X(t, \psi)$ and $\Delta(t, \psi)$ only for the deterministic SNFTM (11). Robins [17, Appendix 4] gives the appropriate definitions for arbitrary SNFTMs. Let

$$X(t, \psi) = \min\{H(\psi), C(t, \psi)\},$$
$$\Delta(t, \psi) = I\{X(t, \psi) < C(t, \psi)\},$$

where $C(t, \psi) \equiv C - t + \int_0^t \exp\{\psi A(t)\}\, dt$ if $\psi \geq 0$ and $C(t, \psi) = \int_0^t \exp\{\psi A(t)\}\, dt + (C - t)e^{\psi}$ if $\psi < 0$. Eq. (17) is satisfied since $X(t, \psi_0)$ and $\Delta(t, \psi_0)$ are only functions of $\overline{A}(t^-), H(\psi_0)$ and C. Also $X(t, \psi)$ and $\Delta(t, \psi)$ are observables, since one can calculate that $X(t, \psi)$ is the minimum of the two observables $X^*(\psi)$ and $C(t, \psi)$. When $\Delta(t, \psi) = 0$, we say an individual is ψ-censored. Note that when $\psi \neq 0$, some failures will be ψ-censored. In practice, if **efficiency** is not of overriding concern, then it is convenient to use a very simple function $Q(t, \psi)$ that produces reasonably efficient estimators of ψ_0. The indicator function $\Delta(t, \psi)$ has been found often to satisfy this criterion in a number of examples [32]. The efficient choice of $Q(t, \psi)$ is given in [17, Appendix 4]. The simple sensitivity analysis methodology of the previous section can be extended to the censored data setting by replacing ηU by $\eta X(\psi)$ in (15); however, better methodology should be developed.

Censoring by Competing Risks

In this section, we assume that in addition to censoring by end of follow-up C, there is additional censoring by loss to follow-up and/or competing risks. Let Q be the minimum of time to loss to follow-up or to a competing risk event. For ease of exposition, we no longer distinguish censoring by loss to follow-up from censoring by competing risks and simply refer to Q as time to censoring by competing risks. The data available are $X^* = \min(T, C, Q) = \min(X, Q), \tau = I(X^* \neq Q), \overline{A}(X^*), \overline{\mathbf{L}}(X^*)$ so that $\tau = 1$ if and only if a subject was either observed to fail or to reach end of follow-up without suffering a competing risk. To adjust for censoring by competing risks, we assume that we have recorded data on a sufficient number of potential confounding factors in $\overline{\mathbf{L}}(t^-)$ so that there are no unmeasured confounders for censoring due to competing risk. That is,

$$\lambda_Q[t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), X > t, X] = \lambda_Q[t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), X > t], \quad (18)$$

in which case we shall also say that censoring by Q is ignorable given the past. Here, $\lambda_Q(t|\cdot)$ is the hazard for the random variable Q given $\cdot$.

Given the ignorable censoring assumption (18), our next task is to estimate the probability $K(X)$ of a subject surviving to $X = \min(T, C)$ without suffering a competing risk, which will be used as an inverse weight in the weighted g-estimation procedure described below. To do so, we fit the Cox proportional hazard model

$$\lambda_{0Q}(t) \exp\{\boldsymbol{\alpha}^{*'} \mathbf{W}^*(t)\} \quad (19)$$

for the hazard $\lambda_Q(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-), X > t)$, where $\mathbf{W}^*(t)$ is a known vector-valued function of $\overline{A}(t^-)$ and $\overline{\mathbf{L}}(t^-), \boldsymbol{\alpha}^*$ is the vector of unknown parameters, and $\lambda_{0Q}(t)$ is an unspecified baseline hazard. We then estimate $K(X)$ by multiplying together the estimated conditional probabilities of not suffering a competing risk before X using the time-dependent Cox model version of the **Kaplan–Meier estimator** [6]. Specifically, at each time Q_j where any subject j suffered a competing risk, we compute the Cox baseline hazard estimator

$$\hat{\lambda}_Q(Q_j) = 1 \Big/ \sum_{i=1}^{n} \{\exp[\hat{\boldsymbol{\alpha}}^{*'} \mathbf{W}_i^*(Q_j)] I(X_i^* \geq Q_j)\}$$

of $\lambda_{0Q}(Q_j)$. We then estimate a subject's $K(X)$ by the Cox model version of the Kaplan–Meier estimator

$$\hat{K}(X) = \prod_{\{j; Q_j \leq X, \tau_j = 0\}} \{1 - \hat{\lambda}_Q(Q_j) \exp[\hat{\boldsymbol{\alpha}}^{*'} \mathbf{W}^*(Q_j)], \}$$

which is the product, over the competing risk times $Q_j < X$, of the subject's estimated conditional probabilities of not suffering a competing risk. Note that a subject's estimated probability $\hat{K}(X)$ depends on his/her treatment and covariate history through the covariate $\mathbf{W}^*(t)$.

Having estimated $\hat{K}(X)$ for each subject with $X = \min(T, C)$ observed, we then estimate ψ_0 by replacing, in our g-estimation procedure of the previous subsection, the function $Q(t, \psi)$ by $Q^*(t, \psi) \equiv$

$Q(t, \psi)/\hat{K}(X)$ for each person who did not suffer a competing risk ($\tau = 1$) and by $Q^*(t, \psi) = 0$ for each person who did ($\tau = 0$). For example, if we use the simple function $Q(t, \psi) = \Delta(t, \psi)$, then $Q^*(t, \psi) = \tau\Delta(t, \psi)/\hat{K}(X)$.

We now give an intuitive explanation of why the g-estimate $\hat{\psi}$ obtained by this method should be **consistent** for ψ_0. Given the correctness of our Cox model (19) and of our assumption of ignorable censoring by competing risks (18), the following will be true: for each person with X observed ($\tau = 1$) and an estimated cumulative probability of, say, $\hat{K}(X) = 0.25$ of avoiding censoring by competing risks, there would, on average, have been three other persons (i.e. **ghosts**) who were censored by competing risks before $X(\tau = 0)$, and who would have had a similar value of X and a similar covariate and treatment history up to X, had censoring by competing risks been prevented. We therefore assign this person with $\tau = 1$ and $\hat{K}(X) = 0.25$ a weight of 4 in the g-estimation procedure by multiplying her covariate $\Delta(t, \psi)$ by the factor 4; she needs to count not only for herself but also for the three other similar subjects for whom X could not be observed due to censoring by competing risks and thus had $Q^*(t, \psi)$ set to zero.

This argument can be formalized to prove that the "competing risk" g-estimator $\hat{\psi}$ is a CAN estimator of ψ_0. However, the previous method of obtaining confidence intervals and P values is no longer valid because the contributions to the Cox partial likelihood score of the extended Cox model (4) for the treatment process are no longer uncorrelated for two distinct reasons. First, $K(X)$ and, therefore, the time-dependent covariate $\tau Q(t, \psi)/K(X)$ at time t depend on a subject's treatment and covariate history beyond t, disrupting the "martingale" structure of the Cox partial likelihood score. Secondly, the probability $K(X)$ of avoiding a competing risk is replaced by the estimate $\hat{K}(X)$ which depends on all the data. However, if we fit the extended model (4) using a Cox proportional hazards program that computes the so-called "robust variance" [8], the resulting g-intervals and tests are guaranteed to be conservative, i.e. in large samples, nominal 95% confidence intervals are guaranteed to cover ψ_0 at least 95% of the time and 0.05 level g-tests are guaranteed to reject the null hypothesis $\psi_0 = 0$ when true no more than 5% of the time. If the conservative "robust variance" g-intervals are too long to distinguish important substantive alternatives, narrower intervals that cover ψ_0 95% of the time in large samples can be obtained using the formulas provided in Appendix 1.

Remarks. Often it is reasonable to assume that censoring by end of follow-up C is also ignorable. To incorporate this assumption, we redefine Q to be the minimum of time to loss to follow-up, competing risks, and end to follow-up and replace C by a constant c^* which is slightly less than the maximal follow-up time $\max\{C_i; i = 1, \ldots, n\}$ so that $K(c^*)$ is bounded away from zero w.p.1. Then g-estimation and testing can proceed as above.

Estimation of Direct Effects

Suppose now we wish to estimate the direct effect of AZT $A(t)$ on survival when another treatment, say aerosolized pentamidine (AP), is not taken. If a reasonably large fraction of the study population, say at least 30%, were untreated with AP until failure or censoring, a quite robust approach is to regard a subject as censored at the first time the subject is on AP therapy; redefine Q to be the minimum of time to censoring by competing risks, time to loss to follow-up, and time to being on AP therapy; and estimate ψ_0 using the methods of the previous subsection.

If only a small fraction of the study population avoided AP therapy, then one can redefine $A(t)$ to be the joint treatment AP and AZT taken at time t and specify a deterministic SNFTM (10) that has separate parameters for the AZT effect and for the AP effect as described in [16, Section A2.12]. An alternative, and preferred approach is to specify a direct effect structural nested model as described in [21]. Discussion of these latter models is beyond the scope of this article.

Inference Based on Instantaneous-Rate RPSNFTMs

Difficulties Incorporating a Priori Biological Knowledge with Deterministic SNFTMs

In our simple deterministic SNFTM (11), the scientific meaning of the parameter ψ_0 was relatively straightforward; $\exp(-\psi_0)$ was the factor by which continuous treatment extended life. More specifically, since $\partial T/\partial H(\psi_0) = \exp\{-\psi_0 A(T)\}$, Cox &

Oakes [3] suggest interpreting $\exp\{-\psi_0 A(t)\}$ as the relative rate at which real time is being used up compared to baseline time at real time t. Thus, if an individual has U years of baseline time to be used up if treatment is withheld, then the actual time T at which the U years of baseline time will have been used is determined by (11). One might hope that the physical interpretation of $\partial T/\partial H(\psi_0)$ as the relative rate at which real time is being used up compared to baseline time would serve in more complex settings to allow us to easily incorporate prior biological knowledge as specific functional form restrictions on our deterministic SNFTM models. However, the following example suggests that this is not the case.

Suppose, based on a priori biological understanding, it is known that any treatment received at time t would have no effect on survival unless the subject is destined to fail within the next 5 weeks without additional treatment. An example would be a setting in which (i) failure is death from an infectious disease, (ii) if death occurs, it always occurs within 5 weeks from the time of initial unrecorded subclinical infection, and (iii) $A(t)$ is a preventive antibiotic treatment at t which is of no benefit unless the study subject is already infected by t. The challenge then is how to incorporate such biological knowledge into the functional form of a deterministic SNFTM (10). We will see that it is difficult to succeed at this challenge if we try to incorporate the biological knowledge directly into a deterministic SNFTM. However, incorporating such biological knowledge is straightforward in a more general class of causal models, the instantaneous-rate (locally) RPSNFTMs which model the effect of a final instantaneous blip of treatment on survival. Since each instantaneous-rate RPSNFTM mathematically entails a unique deterministic SNFTM (10) as a solution to a particular differential equation, it follows that by solving this differential equation, we can determine the restrictions on the functional form of our deterministic SNFTM (10) implied by the restriction that only treatment received within 5 weeks of failure can affect failure.

Instantaneous-Rate RPSNFTMs

To describe instantaneous-rate RPSNFTMs, we shall require a number of additional definitions.

Definition. A treatment regime or plan $\overline{a} \equiv a(\cdot) \equiv \{a(t); 0 \le t < \infty\}$ is a continuous from the right with left-hand limits (cadlag) function on $[0, \infty)$ that is everywhere continuously differentiable except possibly on a countable set of discontinuity points, only finitely many of which are contained in any bounded interval.

Remark. If (i) $\overline{A}(T)$ is generated by a marked point process with hazard $\lambda_A(t|\overline{A}(t^-), \overline{\mathbf{L}}(t^-))$, and (ii) we define $A(t) \equiv 0$ if $t > T$, then, with probability 1, sample paths of the **stochastic process** $A(t)$ are treatment regimes with discontinuity set the fixed or random jump times for the process depending on whether the process can jump only at fixed discrete times or in continuous time.

We assume that $\overline{\mathbf{L}}(T)$ as well as $\overline{A}(T)$ have cadlag sample paths w.p.1. We define the set *Dis* to be the possibly random set of times at which $\overline{\mathbf{L}}(T)$ or $\overline{A}(T)$ are discontinuous.

Definition. Given $\overline{a}$, let $U_{\overline{a}}$ be the (possibly) counterfactual survival time that would be observed if subjects followed treatment regime $\overline{a}$ until failure.

Note that the baseline failure time U is $U_{\overline{a}}$ for the function $\overline{a}$ that is everywhere zero.

Definition. Given $\overline{a} \equiv a(\cdot)$, let $(\overline{a}(t), 0)$ be the regime that agrees with $\overline{a}$ for $u \le t$ and is zero for $u > t$. $U_{\overline{a}(t),0}$ is the survival time had regime $\overline{a}$ been followed through t and treatment withheld after t.

We assume $U_{\overline{a}}$ obeys the following natural consistency assumptions that essentially assert that the future cannot affect the past.

Consistency Assumption A. Given $\overline{a}$ and $t > u$, the following are equivalent: $U_{\overline{a}(u),0} > u, U_{\overline{a}} > u$, $U_{\overline{a}(t),0} > u$.

Consistency Assumption B. Given $\overline{a}$ and $\overline{a}^*$ such that $\overline{a}(u) = \overline{a}^*(u)$, $U_{\overline{a}(u),0} = U_{\overline{a}^*(u),0}$.

The following consistency assumption links the counterfactual variables $U_{\overline{a}}$ to the observable variables $(T, \overline{A}(T))$.

Consistency Assumption C.

$$T = U_{\overline{A}(T),0} \text{ w.p.1.} \tag{20}$$

The instantaneous-rate RPSNFTM studied in this section requires the assumption of local rank preservation. In the following definition, parts (i) and

(ii) are the substantive parts. Part (iii) contains technical assumptions used later.

Definition of Local Rank Preservation. There is local rank preservation w.p.1 if:

(i) $U_{\overline{a}(t),0}$ is continuous in t w.p.1 and

$$\lim_{\Delta t \downarrow 0}\{U_{\overline{A}(t+\Delta t),0} - U_{\overline{A}(t),0}\}/\Delta t = D(U_{\overline{A}(t),0}, t) \text{ whenever } U_{\overline{A}(t),0} > t, \quad (21)$$

where

$$D(u,t) \equiv d\{u, t, \overline{\mathbf{L}}(t), \overline{A}(t)\}$$

(ii) $d(u, t, \overline{\mathbf{L}}(t), \overline{A}(t)) = 0$ if $a(t) = 0$;

(iii) for $t \notin Dis$ on which $\overline{A}(T)$ or $\overline{\mathbf{L}}(T)$ is discontinuous, $D(u,t)$ is bounded and its partial derivatives with respect to u and t are bounded and uniformly continuous.

Eq. (21) states that if $U_{\overline{A}(t),0} > t$, then, for infinitesimal positive Δt,

$$U_{\overline{A}(t+\Delta t),0} - U_{\overline{A}(t),0} = D(U_{\overline{A}(t),0}, t)\Delta t. \quad (22)$$

Now recall that by $\overline{A}(t)$ cadlag w.p.1, $A(t)$ is constant in $[t, t+\Delta t)$ for Δt sufficiently small. The left-hand side of (22) is the additive increment in survival time attributable to a final blip of treatment $A(t)\Delta t$ in the interval $[t, t+\Delta t)$ administered at dose rate $A(t)$. Thus (22) states that the additional increment $D(U_{\overline{A}(t),0}, t)\Delta t$ is deterministic function of $\overline{\mathbf{L}}(t)$, $\overline{A}(t)$ and $U_{\overline{A}(t),0}$. Hence we will refer to $D(u,t)$ as the instantaneous blip function.

To help understand the meaning of the instantaneous blip function $D(u,t)$, consider the infectious disease example presented earlier; it follows from (22) that the restriction on the instantaneous blip function $D(u,t)$ implied by the biological knowledge that the treatment received $A(t)$ at time t is only harmful or beneficial to those destined to fail by $t+5$ if they receive no further treatment (i.e. to those with $U_{\overline{A}(t),0} - t < 5$) is that

$$D(u,t) = 0, \quad \text{if } u - t > 5. \quad (23)$$

We now define a instantaneous-rate RPSNFT model under the assumption of local rank preservation.

Definition. If the assumption of local rank preservation holds, then we say the data follow an instantaneous-rate RPSNFT $D(u,t,\psi)$ if $D(u,t) = D(u,t,\psi_0)$, where ψ_0 is an unknown parameter and $D(u,t,\psi) \equiv \mathrm{d}(u,t,\overline{\mathbf{L}}(t),\overline{A}(t),\psi)$ is a known continuously differentiable function of ψ satisfying (i) $D(u,t,0) = 0$, (ii) $D(u,t,\psi) = 0$ if $A(t) = 0$, and (iii) for each fixed value of ψ, assumption (iii) in the definition of local rank preservation holds.

We will now show that any instantaneous-rate RPSNFTM implies a unique deterministic SNFTM (10). We first show that the instantaneous-rate RPSNFTM

$$D(u,t,\psi) = 1 - \exp\{\psi A(t)\} \quad (24)$$

implies the deterministic SNFTM (11). Model (24) states that the effect of a final instantaneous brief bit of treatment $A(t)\Delta t$ is to add or subtract $[1 - \exp\{\psi_0 A(t)\}]\Delta t$ to a subject's lifetime, so that $\psi_0 = 0$ implies no effect of treatment on survival. The regularity conditions in assumption (iii) of the definition of local rank preservation and Theorem 2.3 of [9, Section 6] on the existence and uniqueness of solutions to differential equations guarantee that w.p.1 there exists a unique continuous solution $U(t) \equiv U_{\overline{A}(t),0}$ to the differential equation

$$\frac{\mathrm{d}U(t)}{\mathrm{d}t} = D\{U(t), t\} \quad (25)$$

satisfying consistency assumption C that $U(T) \equiv T$.

We now solve the differential equations (25) corresponding to model (24). Integrating $\mathrm{d}U(t)/\mathrm{d}t = 1 - \exp\{\psi_0 A(t)\}$, we obtain $U(t) = t - \int_0^t \exp\{\psi_0 A(u)\}\,\mathrm{d}u + c$. Imposing the initial conditions $U(T) = T$ of consistency assumption C, we obtain $c = \int_0^T \exp\{\psi_0 A(u)\}\,\mathrm{d}u$ so $U(t) = t + \int_t^T \exp\{\psi_0 A(u)\}\,\mathrm{d}u$. Hence $U \equiv U(0) = \int_0^T \exp\{\psi_0 A(u)\}\,\mathrm{d}u$, reproducing model (10)–(11) as promised. It is interesting to note that the additive effect $\{1 - \exp[\psi_0 A(t)]\}\Delta t$ of the treatment $A(t)\Delta t$ implies, by model (11), a multiplicative effect of constant unit treatment, i.e. $U_{\overline{a}\equiv 1} = \exp(-\psi_0)U$ where $\overline{a} \equiv 1$ is the regime that always gives unit treatment. The reason for this is a "compound interest effect" of continuous treatment: any additional increment of survival time due to treatment received at t is itself later subjected to treatment, adding a further increment to survival time, etc. Summing the resulting "infinite series" produces the multiplicative effect on survival time of constant treatment.

More generally, for any instantaneous-rate RPSNFTM $D(u,t,\psi)$, there exists a unique solution

$H(t, \psi)$ to the differential equation

$$\frac{\partial H(t, \psi)}{\partial t} = D(H(t, \psi), t, \psi) \qquad (26)$$

satisfying the initial condition $H(T, \psi) = T$. Note $H(t, \psi)$ is a function $h(t, T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi)$ of ψ and the data. If the RPSNFTM is correctly specified with true value ψ_0, then we have by the uniqueness of the solutions to (25) and (26) that $H(t, \psi_0) = U(t) \equiv U_{\overline{A}(t),0}$. In particular, abbreviating $H(0, \psi_0)$ to $H(\psi_0)$ and $h(0, T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi_0)$ to $h(T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi_0)$, we obtain the unique deterministic SNFTM $U = H(\psi_0)$ of (10).

It follows that a CAN g-estimator $\hat{\psi}$ of the parameter ψ_0 of the instantaneous-rate RPSNFTM can be obtained by g-estimation under the assumptions described earlier (including the assumption (1) of no unmeasured confounders).

Consider next the instantaneous-rate RPSNFTM

$$D(u, t, \psi) = I(u - t < 5)\{1 - \exp\{\psi A(t)\}\}, \quad (27)$$

which satisfies the assumption (23) that treatment at t only affects those destined to fail by $t + 5$ in the absence of further treatment. Integrating (25) with $D(u, t) = D(u, t, \psi_0)$ and imposing the initial condition $U(T) = T$, we obtain $U(t) = t - \int_t^T \exp\{\psi_0 A(u)\}\, du$ for $U(t) - t \leq 5$. For $U(t) - t > 5$, $U(t)$ solves $U(t) = \{U(t) - 5\} + \int_{U(t)-5}^{T} \exp\{\psi_0 A(u)\}\, du$, i.e. $\int_{U(t)-5}^{T} \exp\{\psi_0 A(u)\}\, du = 5$. It follows that $U \equiv U(0) = \int_0^T \exp\{\psi_0 A(u)\}\, du$ for $U < 5$ and U satisfies $\int_{U-5}^{T} \exp\{\psi_0 A(u)\}\, du = 5$ when $U > 5$. This implies that $\partial U/\partial T = \exp\{\psi_0 A(T)\}$ when $U < 5$ and $\partial U/\partial T = \exp[\psi_0\{A(T) - A(U - 5)\}]$ when $U \geq 5$. It follows that when $A(u)$ varies with time u, we do not have a closed-form expression for U or for $\partial U/\partial T$. Hence, for the corresponding deterministic SNFTM (10), we will not have a closed-form expression for the function $H(\psi) = h(T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi)$ or its derivative $\partial H(\psi)/\partial T$, although $H(\psi)$ is easily evaluated by numerical means. This "nonobvious" form of $\partial H(\psi_0)/\partial T = \partial U/\partial T$ justifies the remarks of the previous subsection.

Instantaneous-Rate SNFTMs

Biological Implausibility of Local Rank Preservation

Consider two subjects, say i and j, who have identical survival times and covariate and treatment histories $(T, \overline{A}(T), \overline{\mathbf{L}}(t))$. It follows from the uniqueness of the solution to the differential equation (25) that, under the assumption of local rank preservation, the two subjects would have identical survival times U if treatment had been withheld. This assumption is biologically implausible. To see why, again consider the infectious disease example of the previous section. Suppose $A(t)$ is the dose of treatment taken at t, treatment has a beneficial biological affect, subject i and j are both infected at time t, subject i fails to absorb his/her dose due to gastrointestinal difficulties, while subject j successfully absorbs his/her dose. Then we would expect $U_i = T_i = T_j > U_j$ since subject j but not subject i experiences the benefit of treatment. Dependence of the magnitude of the treatment effect on unmeasured factors such as bioabsorption and genetic endowment is the rule. In this section, we describe the general class of instantaneous-rate SNFTMs which allow the magnitude of the treatment effect to depend on unmeasured factors. Specifically, the class of instantaneous-rate SNFTMs does not require that U be a deterministic function of $\{T, \overline{A}(T), \overline{\mathbf{L}}(T)\}$, and contains the instantaneous-rate RPSNFTMs as a subclass. Furthermore, the parameter ψ of a instantaneous-rate SNFTM can be consistently estimated using the g-estimation procedures described previously.

We now define a new function that will allow us to relax the assumption of local rank preservation. Given continuously distributed failure time variates T_1 and T_2 with survivor functions $S_1(u)$ and $S_2(u)$, recall that the quantile-quantile function $v(u) = S_1^{-1}\{S_2(u)\}$ is the unique function $v(u)$ such that $v(T_2)$ has the same distribution $S_1(u)$ as T_1. We now let $U_{\overline{A}(t),0}$ and $U_{\overline{A}(t+h),0}$ play the roles of T_1 and T_2 where, by convention, $A(u) \equiv 0$ if $u > T$. Specifically, let $\mathcal{V}(u, t, h) \equiv v(u, t, h, \overline{\mathbf{L}}(t), \overline{A}(t))$ be the unique function such that $U_{\overline{A}(t+h),0}$ and $\mathcal{V}(U_{A(t),0}, t, h)$ have the same conditional distribution given $\overline{\mathbf{L}}(t)$, $\overline{A}(t)$, $T > t$. That is,

$$\Pr[U_{\overline{A}(t+h),0} > \mathcal{V}(u, t, h) | \overline{\mathbf{L}}(t), \overline{A}(t), T > t]$$
$$= \Pr[U_{\overline{A}(t),0} > u | \overline{\mathbf{L}}(t), \overline{A}(t), T > t].$$

Note $\mathcal{V}(u, t, 0) = u$. We now make a smoothness (differentiability) assumption.

Assumption (*). We assume that (i) $D(u, t) \equiv \lim_{h \downarrow 0}\{\mathcal{V}(u, t, h) - \mathcal{V}(u, t, 0)\}/h$ exists and is bounded for all (u, t) w.p.1 where the function $D(u, t) \equiv d(u, t, \overline{L}(t), \overline{A}(t))$ satisfies assumption (iii) in the definition of local rank preservation, and (ii), for $t > x$,

$$\Pr[U_{\overline{A}(t),0} > u | \overline{\mathbf{L}}(x), \overline{A}(x)] \text{ is continuous in } t. \quad (28)$$

We have reused the notation $D(u, t)$ in Assumption (*) because, under local rank preservation, $D(u, t)$ as just defined is equal to $D(u, t)$ as defined previously. Even without local rank preservation under Assumption (*), we can regard $D(u, t)\Delta t$ as the effect of a last blip of observed treatment $A(t)$ at t sustained for an instantaneous time Δt on quantiles of $U_{\overline{A}(t),0}$. That is, for infinitesimal positive Δt, if, conditional on $\overline{\mathbf{L}}(t)$, $\overline{A}(t), u$ is, say, the zth quantile of $U_{\overline{A}(t),0}$, then $u + D(u, t)\Delta t$ is the zth quantile of $U_{\overline{A}(t+\Delta t),0}$. As before, $D(u, t)$ may be discontinuous for $t \in$ Dis.

Remark. It is important to note that we no longer assume $U_{\overline{A}(t),0}$ is continuous in t. This is scientifically important since $U_{\overline{A}(t),0}$ will be discontinuous at t if $A(\cdot)$ is exposure to cigarette smoke and a single molecule of benzpyrene inhaled at time t initiates lung cancer. However, (28) remains reasonable since the probability of lung cancer being initiated in $[t, t + \Delta t)$ is small. However, (28) and thus Assumption (*) would be inappropriate if $A(t)$ recorded whether a subject received a mammogram or any other truly "point-source" exposure at time t, where $A(t)$ is a point source if exposure of $\{t; A(t) \neq 0\}$ is a finite set w.p.1. Models for the effect of point-source exposures, such as mammography, will not be further discussed in this chapter; the SNFTMs discussed in [16, Appendix 2] are appropriate.

It then follows from Theorem 2.3 of [9, Section 6] that there exists a unique continuous solution $\mathcal{H}(t) \equiv h(t, T, \overline{\mathbf{L}}(T), \overline{A}(T))$ to the differential equation $\mathrm{d}\mathcal{H}(t)/\mathrm{d}t = D(\mathcal{H}(t), t)$ satisfying $\mathcal{H}(T) = T$.

Under local rank preservation, we have seen that this unique solution $\mathcal{H}(t)$ is precisely $U(t) \equiv U_{\overline{A}(t),0}$. This will not be true in the absence of local rank preservation, since $U(t)$ will no longer satisfy (25). However, our main result is the following theorem which states that $\mathcal{H}(t)$ and $U(t)$ continue to have the same conditional distributions.

Theorem 1. $\mathcal{H}(t)$ and $U_{\overline{A}(t^-),0}$ have the same conditional distribution given $(\overline{\mathbf{L}}(t), \overline{A}(t), T > t)$. In particular, $\mathcal{H} \equiv \mathcal{H}(0)$ and U have the same marginal distributions.

As yet, Theorem 1 has only been proved in the special case where the jump times of the $\overline{A}(t)$ and $\overline{\mathbf{L}}(t)$ processes are fixed rather than random [22], although it is almost certain that Theorem 1 holds in general. The limitation to nonrandom jump times for the measured $\mathbf{L}$ and A processes is no limitation in practice, since we can suppose them to have been measured, say, every second rather than continuously, and then the theorem is true.

We say the data follow a instantaneous-rate SNDM if there is a function $D(u, t, \psi)$ satisfying $D(u, t) = D(u, t, \psi_0)$ with $D(u, t, \psi)$ satisfying the conditions previously described under the definition of a instantaneous-rate RPSNFTMs.

Again letting $H(t, \psi) \equiv h(t, T, \overline{A}(T), \overline{\mathbf{L}}(T), \psi)$ be the solution to the differential equation (26) and setting $H(\psi) \equiv H(0, \psi)$, it immediately follows by uniqueness that $\mathcal{H} = H(\psi_0)$. Hence, a CAN estimator $\hat{\psi}$ of the causal parameter ψ_0 of a instantaneous-rate SNFTM can be obtained by g-estimation if, as we assume, (2) holds with $U_{\overline{A}(t^-),0}$ replacing U. .

Estimating the Distribution of $U_{\overline{a}}$

Given an instantaneous-rate SNFTM $D(u, t, \psi)$, we have shown how to obtain a CAN estimator $\hat{\psi}$ of ψ_0 under the assumptions given above. However, we often wish to estimate the survival curves $S_{U_{\overline{a}}}(t)$ of $U_{\overline{a}}$ for various treatment regimes $\overline{a}$. Suppose censoring is absent. Then $\hat{S}_U(t) = n^{-1}\sum_i I\{H_i(\hat{\psi}) > t\}$ is a CAN estimator of $S_U(t)$. The main tool we shall use to estimate other $S_{U_{\overline{a}}}(t)$ is the blip-up function $B(u, t) \equiv b(u, t, \overline{\mathbf{L}}(t), \overline{A}(t))$ defined to be the unique continuous solution to $\mathrm{d}B(t)/\mathrm{d}t = D(B(t), t)$ through $(0, u)$.

Example

For model (24) with $D(u, t) = 1 - \exp\{\psi_0 A(t)\}$, we obtain upon integrating that $B(t) = t - \int_0^t \exp\{\psi_0$

$A(u)\}\,du + c$. By the initial condition $B(0) = u$, we obtain $c = u$, so

$$B(u,t) \equiv B(t) = u + t - \int_0^t \exp\{\psi_0 A(u)\}\,du. \tag{29}$$

In general, $B(u,t)$ is related to the blip-down function $\mathcal{H}(t)$ by $B(\mathcal{H},t) = \mathcal{H}(t)$ where $\mathcal{H} \equiv \mathcal{H}(0)$. For any covariate and treatment histories $\bar{\mathbf{l}}$ and $\bar{a}$ defined on $[0,\infty)$, define $b^*(u,\bar{\mathbf{l}},\bar{a})$ to be the solution t^* to $t^* = b(u,t^*,\bar{\mathbf{l}}(t^*),\bar{a}(t^*))$ if one exists and $b^*(u,\bar{\mathbf{l}},\bar{a}) \equiv \infty$ otherwise. Note $b^*(\mathcal{H},\overline{\mathbf{L}},\overline{A}) = T$, since $T = B(\mathcal{H},T)$, where $\mathbf{L}(u) \equiv A(u) \equiv 0$ if $u > T$.

Example

With $B(u,t)$ given by (29), $b^*(u,\bar{\mathbf{l}},\bar{a}) = b^*(u,\bar{a})$ is the unique solution to $u = \int_0^{b^*(u,\bar{a})} \exp\{\psi_0 a(u)\}\,du$.

If (i), as in model (24), $d(u,t,\bar{\mathbf{l}}(t),\bar{a}(t)) \equiv d(u,t,\bar{a}(t))$ does not depend on $\bar{\mathbf{l}}(t)$, i.e. there is no treatment–covariate interaction, so $b^*(u,\bar{\mathbf{l}},\bar{a}) = b^*(u,\bar{a})$, and (ii) there are no unmeasured confounders for each $U_{\bar{a}}$, i.e.

$$U_{\bar{a}} \perp\!\!\!\perp A(t) | \overline{\mathbf{L}}(t^-), \overline{A}(t^-), T > t, \tag{30}$$

then

$$S_{U_{\bar{a}}}(t) = \Pr\{b^*(U,\bar{a}) > t\}. \tag{31}$$

By Theorem 1, U can be replaced by $\mathcal{H}$ in (31). Robins [17, Appendix 1] discusses conditions weaker than (30) which imply (31). It now follows that given a CAN g-estimator $\hat{\psi}$ of ψ_0, $n^{-1}\sum_i I\{b^*(H_i(\hat{\psi}),\bar{a},\hat{\psi}) > t\}$ is a CAN estimator of $S_{U_{\bar{a}}}(t)$ where $b^*(u,\bar{a},\psi)$ is $b^*(u,\bar{a})$ under $\psi = \psi_0$.

Models for Cure

The fact that $b^*(u,\bar{a})$ can be infinite reflects the possibility of "cure" (*see* **Cure Models**). As an example, suppose U represents the time from diagnosis to death from pancreatic cancer in the absence of treatment. Suppose untreated pancreatic cancer is uniformly fatal so that U is finite w.p.1. Suppose, however, that $\Pr\{b^*(U,\bar{a}) = \infty\} = p \neq 0$. Then a fraction p of the population will be cured under treatment regime $\bar{a}$.

Consider the multiplicative blip model

$$D(u,t,\psi) = (u-t)\psi A(t). \tag{32}$$

By the formula for solutions to linear first-order differential equations [9, Chapter 6],

$$b(u,t,\bar{a}(t)) = \exp\left[\int_0^t \psi_0 a(x)\,dx\right]\left\{u - \int_0^t x\psi_0 a(x) \times \exp\left[-\int_0^x \psi_0 a(v)\,dv\right]dx\right\},$$

which simplifies, when $\bar{a}$ is the constant-dose regime a^*, to $\exp(\psi_0 a^* t)[u - (\psi_0 a^*)^{-1}] + t + (\psi_0 a^*)^{-1}$. Hence, $b^*(u,\bar{a}) = \ln\{-(\psi_0 a^*)^{-1}/[u - (\psi_0 a^*)^{-1}]\}/\{\psi_0 a^*\}$ if $u < (\psi_0 a^*)^{-1}$ and $b^*(u,\bar{a}) = \infty$ if $u > (\psi_0 a^*)^{-1}$. Thus, the probability of cure under $\bar{a}$ is the probability that U exceeds $1/\{\psi_0 a^*\}$. The intuition behind this result is that, according to model (32), $d(u,t,\bar{a}(t),\psi_0)$ exceeds 1 at $t = 0$ if and only if $u\psi_0 a^* > 1$. If $d(u,t,\bar{a}(t),\psi_0) > 1$, then a blip of treatment a^* at t sustained for duration Δt adds more than Δt years to a subject's survival time. If, as in our model when $u > (\psi_0 a^*)^{-1}$, the instantaneous blip function exceeds 1 for each time t, then the subject is cured.

If the failure time variable is death from all causes, we would want $b^*(u,\bar{\mathbf{l}},\bar{a})$ to be finite for all $u,\bar{\mathbf{l}}$, and $\bar{a}$ which is guaranteed by having $d(u,t,\bar{\mathbf{l}}(t),\bar{a}(t)) < 1-\sigma, \sigma > 0$, for all $u,t,\bar{a}(t),\bar{\mathbf{l}}(t)$. A natural parameterization of an instantaneous-rate SNFTM that essentially accomplishes this is $D(u,t;\psi) = 1 - \exp\{r(u,t,\overline{\mathbf{L}}(t),\overline{A}(t),\psi)\}$ for some function $r(\cdot)$ as in models (24) and (27).

Covariate–Treatment Interaction

If $d(u,t,\bar{\mathbf{l}}(t),\bar{a}(t))$ depends on $\bar{\mathbf{l}}(t)$, we can obtain independent draws from the distribution of $U_{\bar{a}}$ under assumption (30) when the covariate process $\mathbf{L}(t)$ only jumps at non random times, say 0,1,2, ... as follows.

Step 1. Draw U from its marginal distribution.
Step 2. Draw $\mathbf{L}(0)$ from $f\{\mathbf{l}(0)|U = u\}$.
Step 3. Set $m = 1$.
Step 4. If $b[U, m-1, \overline{\mathbf{L}}(m-1), \bar{a}(m-1)] \leq m$, set $U_{\bar{a}}$ to $b^*(U,\overline{\mathbf{L}},\bar{a})$ where $\mathbf{L}(t) = 0$ for $t > m$ and agrees with the drawn $\overline{\mathbf{L}}(m^-)$ up to time m. Otherwise, draw $\mathbf{L}(m)$ from $f[\mathbf{L}(m)|(\overline{\mathbf{L}}(m^-),\bar{a}(m^-),U,T > m]$,

increment m by 1, and return to the start of this step.

To carry out this algorithm in practice, we first obtain a g-estimate $\hat{\psi}$ of the parameter ψ_0 of an instantaneous-rate SNFTM; draw U from the empirical distribution $\hat{S}_U(t) = n^{-1}\sum_i I(H_i(\hat{\psi}) > t)$; replace the functions $b(\cdot)$ and $b^*(\cdot)$ by $b(\cdot, \hat{\psi})$ and $b^*(\cdot, \hat{\psi})$; and estimate the density $f[\bar{\mathbf{l}}(m)|\bar{\mathbf{l}}(m^-), \overline{a}(m^-), U, T > m]$ by specifying a parametric model $f[\mathbf{l}(m)|\bar{\mathbf{l}}(m^-), \overline{a}(m^-), U, T > m; \eta]$ and evaluating it at $\hat{\eta}$ which maximizes

$$\prod_{i=1}^{n}\prod_{m=0}^{\text{int}(T_i)} f[\mathbf{L}_i(m)|\overline{\mathbf{L}}_i(m^-), \overline{A}_i(m^-), H_i(\hat{\psi}), T_i > m; \eta].$$

A heuristic explanation of the above algorithm is as follows. If a stimulated subject with baseline time U manages to survive to time m under regime $\overline{a}$, we randomly draw $\mathbf{L}(m)$ and then use the blip-up function $b(u, t, \bar{\mathbf{l}}(t), \overline{a}(t))$ to determine whether the subject has survived to time $m+1$ or whether the subject has died at a time $U_{\overline{a}}$, determined by the function $b^*(u, \bar{\mathbf{l}}, \overline{a})$ in the interval $(m, m+1]$. This explanation is heuristic in that it implicitly but unnecessarily assumes local rank preservation. Robins et al.[26, Appendix 2] discusses how to generalize the results of this section to allow for censoring. A drawback of SNFTMs is that in the presence of a covariate–treatment interaction $S_{U_{\overline{a}}}(t)$ cannot be calculated without modeling the law of $\mathbf{L}(m)$ given $\{\overline{\mathbf{L}}(m^-), \overline{A}(m^-), U, T > m\}$. Estimation of the nonnested structural Cox proportional hazard models for $U_{\overline{a}}$ described in Appendix 2 can obviate this problem.

Appendix 1: Calculation of the Variance of the g-Test Statistic Numerator

We shall require some notation. Given a stochastic process $G(\cdot)$, let $U_A\{G(\cdot)\} = \int_0^X \mathrm{d}M_A(u)\{G(u) - \mathrm{E}[\exp[\boldsymbol{\alpha}'\mathbf{W}(u)]G(u)]/\mathrm{E}[\exp[\boldsymbol{\alpha}'\mathbf{W}(u)]\}$ where $\boldsymbol{\alpha}'\mathbf{W}(u)$ is from model (4), $\mathrm{d}M_A(u) = \mathrm{d}N_A(u) - \lambda_0(u)\exp[\boldsymbol{\alpha}'\mathbf{W}(u)]\,\mathrm{d}u$ and $N_A(u)$ counts the number of jumps in the $A(u)$ process through time u.

Now define $U_1 \equiv U_A\{\tau Q(\cdot, \psi_0)/K(X)\}$ and $\boldsymbol{U_2 \equiv U_A\{\mathbf{W}(\cdot)\}}$. Then define $V_1 \equiv \mathrm{E}[\{U_1 - \mathrm{E}[U_1U_2']\,\mathrm{E}[U_2^{\otimes 2}]^{-1}U_2\}^{\otimes 2}]$. V_1 is the "robust variance" of the g-test numerator (i.e. Cox partial likelihood score test numerator) of the hypothesis that $\theta = 0$ in the extended Cox model (4) when the true $K(X)$ is used.

Now define $V \equiv V_1 - V_{\text{corr}}$, where V_{corr} is the correction to the variance V_1 required when we replace $K(X)$ by its estimator $\hat{K}(X)$. Specifically, $V_{\text{corr}} = V_2 + V_3$, where $V_2 = \mathrm{E}[\int_0^\infty \mathrm{d}N_Q(u)\{\mathcal{L}^Q(u, J(u))\}^{\otimes 2}]$, $N_Q(u) = I[Q \le u, \tau = 0]$, $J(u) \equiv \int_0^X \mathrm{d}M_A(t)\,Q(t, \psi_0)/K(u)$ and, for any $G(u)$, $\mathcal{L}^Q\{u, G(u)\} \equiv \mathrm{E}[K(u)\ \{K(X)\}^{-1}\ \tau\ G(u)\ I(X^* > u)\exp[\boldsymbol{\alpha}^{*'}\mathbf{W}^*(u)]/\mathrm{E}[I(X^* > u)\exp[\boldsymbol{\alpha}^{*'}\mathbf{W}^*(u)]$ with $\boldsymbol{\alpha}^{*'}\mathbf{W}^*(u)$ from model (19).

$V_3 = V_{31}\{V_{32}\}^{-1}V_{31}'$, $V_{31} = \mathrm{E}[\int \mathrm{d}N_Q(u)\{\mathcal{L}^Q\{u, J(u)\mathbf{W}^*(u)\} - \mathcal{L}^Q(u, J(u))\mathcal{L}^Q(u, \mathbf{W}^*(u))\}]$ and V_{32} is the expected partial information matrix for $\boldsymbol{\alpha}^*$ from Cox model (19). Since V_{corr} is nonnegative definite, the robust variance V_1 is greater than or equal to the true variance V in the nonnegative definite sense. A consistent estimator $\hat{V}$ of V is obtained by substitution into the above formulas according to the following six steps.

1. Replace any expectation by a sample average over the n study subjects.
2. Replace $\boldsymbol{\alpha}$ and $\boldsymbol{\alpha}^*$ by their partial maximum likelihood estimates.
3. Replace ψ_0 by the value of ψ being tested in the g-test.
4. Replace $K(\cdot)$ by $\hat{K}(\cdot)$.
5. Replace $\mathrm{d}M_A(u)$ by $\mathrm{d}N_A(u) - \mathrm{d}\hat{\Lambda}_0(u)\exp[\hat{\boldsymbol{\alpha}}'\mathbf{W}(u)]$, where $\hat{\Lambda}_0(u)$ is the Cox cumulative hazard estimate from model (4).
6. Estimate V_{32} by the observed partial information matrix from the fit of model (19).

Now let $\hat{U}_1(\psi)$ be U_1 with the substitutions described in steps 1–6 above. The g-statistic numerator is precisely $\sum_{i=1}^n \hat{U}_{1i}(\psi)$. We then have the following theorem on which our inferences are based.

Theorem. Given that (2) and (18) and that models (4), (10), and (19) are correct, then, when $\psi = \psi_0$, $n^{-1/2}\sum_i \hat{U}_{1i}(\psi)$ is asymptotically normal with mean zero and asymptotic variance V that can be consistently estimated by $\hat{V}$.

The proof is analogous to that given in [17, pp. 284–285] using the methods developed in [24].

Appendix 2

A (nonnested) structural Cox proportional hazard model specifies

$$\lambda_{U_{\bar{a}}}(t) = \lambda(t)\exp[r\{t, \overline{a}(t^-), \beta_0\}] \qquad (33)$$

where $r(\cdot)$ is a known function and $\lambda(t)$ an unspecified baseline hazard. For simplicity, assume $A(t)$ is dichotomous. Then a consistent asymptotically normal estimator $\hat{\beta}$ of β_0 under assumptions (18) and (30) and models (4), (19), and (33) is the solution to the weighted Cox score equation for T

$$0 = \sum_i \int_0^\infty \left\{\frac{dN_{Ti}(u)}{\hat{\Omega}_i(u)}\right\} \times \left\{P_i(u,\beta) - \hat{\mathrm{E}}[P(u,\beta),\beta]/\hat{\mathrm{E}}[\mathbf{1}(u),\beta]\right\},$$

where (i) $N_T(u) = I[X^* \le u, X^* = T]$; (ii) $P(u,\beta) = p\left[u, \overline{A}(u^-), \beta\right]$ is a vector function of dimβ chosen by the analyst such as $\partial r\left(u, \overline{A}(u^-), \beta\right)/\partial\beta$; (iii) $\mathbf{1}(u) = 1$ is the identity; (iv) $\hat{\mathrm{E}}[J(u,\beta),\beta] = \sum_i I(X_i^* > u)\exp\left[r\left\{u, \overline{A}(u^-), \beta\right\}\right] J_i(u,\beta)/\hat{\Omega}_i(u)$; (v) $\hat{\Omega}_i(u) = \hat{K}_i(u)\hat{K}_{Ai}(u)$, $\hat{K}(u)$ as defined in the text; (vi) $\hat{K}_A(u) = \exp\left[-\int_0^u \hat{\lambda}_A\left[t|\overline{\mathbf{L}}(t^-), \overline{A}(t^-)\right]\mathrm{d}t\right] \prod_{\{t;t<\mu \text{ and } A(t)\neq A(t^-)\}} \hat{\lambda}_A\left(t|\overline{\mathbf{L}}(t^-), \overline{A}(t^-)\right)$, where $\hat{\lambda}_A\left[t|\overline{\mathbf{L}}(t^-), \overline{A}(t^-)\right] = \hat{\lambda}_0(u)\exp\left[\hat{\boldsymbol{\alpha}}'\mathbf{W}(u)\right]$ and $\hat{\lambda}_0(u)$ is now a kernel smoothed version of the Cox estimate of $\lambda_0(t)$ of model (4) as in [31]. $\hat{\beta}$ combined with the estimate $\hat{\lambda}(t) = \sum_i dN_{Ti}(t)/\left\{\hat{\Omega}_i(t)\hat{\mathrm{E}}\left[\mathbf{1}(t),\hat{\beta}\right]\right\}$ of $\lambda(t)$ produces an estimate of $\lambda_{U_{\bar{a}}}(t)$ and thus of $S_{U_{\bar{a}}}(t)$. In the above, we have assumed that Q is the minimum of time to loss to follow-up, competing risk, and end to follow-up as discussed in the remark in the section "Censoring by Competing Risks" above. Note that $\hat{K}_A(u)$ is a consistent estimate of probability that a subject would have his observed history $\overline{A}(u)$ through time u.

Structural Time Series Models

Structural time series models are set up in terms of components, such as trends, seasonals, and cycles, which have a direct interpretation. They can then be used not only for **forecasting** but also for providing a description of the main features of the series. Structural time series models have been used to tackle a wide range of problems; for example, the monograph by Harvey [8] includes applications in economics, meteorology, criminology, energy, and association football. Other illustrations are in the books by Durbin and Koopman [4], Jones [17] and Kitagawa, and Geisch [18].

The next section sets out the principal univariate structural time series models and describes their properties. The following section explains how to bring **explanatory variables** into a single equation model, thereby bringing together regression and time series techniques. Intervention analysis (*see* **Intervention Analysis in Time Series**) is treated as a special case. In a multivariate model several series are modeled jointly. Structural time series models extend naturally to this situation and are described in the section on multivariate models. Of particular interest is the fact that such models provide a framework within which to handle control groups.

The section on data irregularities explains how structural time series models can be adapted to handle problems such as **outliers**, missing observations and data not recorded at equally spaced intervals of time. In the final section we look at methods for handling non-Gaussian data such as counts, consisting of small integers, or qualitative variables, recorded as zeros or ones.

Univariate Structural Time Series Models

The basic idea of structural time series models is that they are set up as regression models in which the explanatory variables are functions of time, but with coefficients which change over time. Thus within a regression framework a simple trend would be modeled in terms of a constant and time with a random disturbance added on. That is,

$$y_t = \alpha + \beta t + \varepsilon_t, \quad t = 1, \ldots, T. \tag{1}$$

The model is straightforwardly estimated by ordinary least squares, but suffers from the disadvantage that the trend is deterministic. This is too restrictive in general and the necessary flexibility is introduced by letting the coefficients α and β evolve over time as **stochastic processes**. In this way the trend can adapt to underlying changes. The current, or filtered, estimate of the trend is obtained by putting the model in state space form and applying the Kalman filter. Related algorithms are used for making predictions and for smoothing, which means computing the best estimate of the trend at all points in the sample using the full set of observations. The extent to which the parameters are allowed to change is governed by *hyperparameters*. These can be estimated by maximum likelihood but, again, the key to this is the state space form and the Kalman filter. All these methods and algorithms are described in detail in Harvey [8], Durbin and Koopman [4], and Koopman. The *STAMP* package of Koopman et al. [21] carries out all the calculations and is set up so as to leave the user free to concentrate on choosing a suitable model. If desired, the weights implicitly assigned to observations in computing a trend, or indeed any component, may be obtained by using the algorithm set out in [20].

The model selection methodology for structural models is somewhat different to that used for autoregressive integrated moving average (ARIMA) models (*see* **ARMA and ARIMA Models**) in that there is less emphasis on looking at the correlograms of various transformations of the series in order to get an initial specification; see Box & Jenkins [3]. Instead the emphasis is on formulating the model in terms of components suggested by a knowledge of the application or an inspection of the graph. Once a model has been estimated, the same type of diagnostics tests as are used for ARIMA models can be performed on the residuals. In particular, the Box–Ljung statistic can be computed, with the number of relative hyperparameters subtracted from the number of residual autocorrelations to allow for the loss in degrees of freedom. Standard tests for nonnormality and heteroscedasticity can also be carried out, as can tests of predictive performance in a postsample period. The structural framework also allows tests for outliers and structural breaks to be performed; these are based on what Harvey & Koopman [11] call "auxiliary residuals". Plots of residuals can be augmented by graphs of the smoothed components. These can often be very informative since they enable the model builder to

check whether the movements in the components correspond to what might be expected on the basis of prior knowledge. Finally, it is shown by Andrews [1], among others, that the forecasting performance of structural time series models is as good as, and sometimes even better than, the performance of ARIMA models.

A Bayesian approach to structural time series modeling is described in West & Harrison [28]. Recent developments in Bayesian techniques, such as Markov chain Monte Carlo, are discussed in [4] and [6].

The principal univariate structural time series models are set out below. In the last subsection the formal relationship between structural and ARIMA models is discussed.

Local Level

The simplest structural time series model addresses a situation in which the underlying level of the series changes over time. This level is modeled by a random walk, on top of which is superimposed a random, or white noise (*see* **Noise and White Noise**) disturbance. The specification is therefore

$$\begin{aligned} y_t &= \mu_t + \varepsilon_t, \quad \varepsilon_t \sim \text{NID}\ (0, \sigma_\varepsilon^2), \quad t = 1, \ldots, T, \\ \mu_t &= \mu_{t-1} + \eta_t, \quad \eta_t \sim \text{NID}\ (0, \sigma_\eta^2), \end{aligned} \tag{2}$$

where NID denotes normally and independently distributed, and the two disturbances are mutually uncorrelated. An important practical feature of this model is that the estimator of the level, based on currently available information, is given by an exponentially weighted moving average (EWMA) of past observations, that is

$$\begin{aligned} \tilde{\mu}_T = \lambda[&y_T + (1-\lambda)y_{T-1} + (1-\lambda)^2 y_{T-2} \\ &+ (1-\lambda)^3 y_{T-3} + \cdots], \end{aligned} \tag{3}$$

where the "smoothing constant", λ, is a function of the *signal-to-noise ratio*, $q = \sigma_\eta^2/\sigma_\varepsilon^2$. Forecasts of future observations, however many steps ahead, are given by exactly the same expression. This was established by Muth [24]. For a pure random walk, q is infinite and $\lambda = 1$, leading to a forecast equal to the last observation. As q moves towards 0, λ also goes to zero and the forecast becomes the sample mean. That this happens is not apparent from the formula above, which is actually an approximation to the exact forecast function produced by the Kalman filter [8, Chapter 3]. The important point about the Kalman filter when applied to a nonstationary model like (2) is that it is initialized with what is called a diffuse *prior*. There has been considerable progress in the statistics literature recently on developing stable algorithms for this situation [19]. The estimation of q, the main hyperparameter in the model, can be carried out by maximum likelihood, which basically entails minimizing the sum of squares of the one-step-ahead prediction errors throughout the sample.

Within a medical context, μ_t might be thought of as the underlying state of a patient, while ε_t represents measurement error. A doctor wishing to monitor the state of the patient's health needs to have as good an estimate as possible of μ_t given the information which is currently available. If the model is correct, the Kalman filter delivers such an estimate, together with its root mean square error (RMSE). Hence a confidence interval can be constructed around the estimate, and the doctor can use this as a guide as to whether it is reasonable to suppose that the level of whatever is being monitored is acceptable see [12].

Local Linear Trend

The local linear trend model replaces the deterministic trend in (1) by a stochastic trend. The exact formulation is

$$\begin{aligned} y_t &= \mu_t + \varepsilon_t, & \varepsilon_t &\sim \text{NID}\ (0, \sigma_\varepsilon^2), \\ & & t &= 1, \ldots, T, \\ \mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t, & \eta_t &\sim \text{NID}\ (0, \sigma_\eta^2), \\ \beta_t &= \beta_{t-1} + \zeta_t, & \zeta_t &\sim \text{NID}\ (0, \sigma_\zeta^2), \end{aligned} \tag{4}$$

with the level and slope disturbances, η_t and ζ_t mutually uncorrelated and uncorrelated with ε_t. The extent to which the level, μ_t, and slope, β_t, change over time is governed by the relative hyperparameters, $q_\eta = \sigma_\eta^2/\sigma_\varepsilon^2$ and $q_\zeta = \sigma_\zeta^2/\sigma_\varepsilon^2$. The forecast function is a straight line starting from the estimates of the level and slope at the end of the sample. In the limiting case when both relative hyperparameters are zero, the deterministic trend model is obtained with $\alpha = \mu_0$. Other special cases of interest arise when $q_\zeta = 0$, in which case the trend is a random walk plus drift and $q_\eta = 0$, in which case the smoothed trend is related to a cubic spline (*see* **Spline Function**).

Stochastic Seasonality

Many series recorded quarterly or monthly are subject to seasonal variation. What are effectively seasonal effects also occur when observations are recorded within the day. Just as more flexibility needs to be given to a trend by allowing it to be stochastic, so a seasonal component needs to be allowed to change over time. Although the case for a stochastic seasonal component is arguably less compelling than the case for a stochastic trend, there are many reasons why changes in the seasonal pattern may take place.

If the seasonal component is deterministic, it should have the property that it sums to zero over the previous year; this ensures that it cannot be confounded with the trend. Adding a disturbance term to the sum of seasonal effects over the past year allows the seasonal pattern to evolve over time. This is a "dummy variable" form of stochastic seasonality,

$$\gamma_t = \gamma_{t-1} + \cdots + \gamma_{t-s+1} + \omega_t,$$
$$\omega_t \sim \text{NID}\ (0, \sigma_\omega^2). \tag{5}$$

An alternative way of capturing a deterministic seasonal pattern is by a set of sine and cosine functions. Allowing these to be stochastic leads to the "trigonometric form" of stochastic seasonality [8, Chapter 2]. It is better than the dummy variable stochastic seasonal model because it allows the seasonal pattern to evolve more smoothly; it can be shown that the sum of the seasonals over the past year follows a MA $(s-2)$ rather than white noise.

Seasonal effects are typically combined with trend and irregular components, usually after taking logarithms. This leads to the basic structural model (BSM),

$$y_t = \mu_t + \gamma_t + \varepsilon_t, \quad t = 1, \ldots, T, \tag{6}$$

where the stochastic trend component, μ_t, and the irregular component are defined as in the local linear trend model above; see, for example, [18]. This model has been widely applied and can be used as the basis for seasonal adjustment of time series.

Cycle

A deterministic cycle can be expressed as a sine–cosine wave, that is

$$\psi_t = \alpha \cos \lambda t + \beta \sin \lambda t, \quad t = 1, \ldots, T. \tag{7}$$

In the previous section it was pointed out that a seasonal pattern could be modeled by a set of stochastic cycles defined at the seasonal frequencies (*see* **Seasonal Time Series**). A somewhat different situation arises when we wish to model a cycle, which may be stochastic, and, unlike the seasonal cycles, may be stationary. The statistical specification of such a cycle, ψ_t, is as follows:

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \rho \begin{bmatrix} \cos \lambda_c & \sin \lambda_c \\ -\sin \lambda_c & \cos \lambda_c \end{bmatrix} \begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix} + \begin{bmatrix} \kappa_t \\ \kappa_t^* \end{bmatrix}, \quad t = 1, \ldots, T, \tag{8}$$

where λ_c is the frequency, in radians, in the range $0 \leq \lambda_c \leq \pi$, κ_t and κ_t^* are two mutually uncorrelated white noise disturbances with zero means and common variance σ_κ^2, and ρ is a *damping factor*, such that $0 < \rho \leq 1$. Note that the *period* is $2\pi/\lambda_c$. For some purposes it is useful to take the variance of ψ_t, rather than the variance of κ_t, as a hyperparameter. Then since $\sigma_\kappa^2 = (1-\rho^2)\sigma_\psi^2$, a deterministic, but stationary, cycle is obtained when $\rho = 1$. The **autocorrelation function** (ACF) of ψ_t is

$$\rho(\tau) = \rho^\tau \cos \lambda \tau, \quad \tau = 0, 1, 2, \ldots. \tag{9}$$

This is a cycle which damps down to zero as τ goes to infinity, except when $\rho = 1$. The spectrum has a peak around λ_c, denoting irregular, or pseudocyclical, behavior (*see* **Spectral Analysis**). The peak becomes sharper as ρ approaches one, and in the limiting case when ρ equals one it manifests itself as a jump in the spectral distribution function. A test that the cycle is deterministic is given in Harvey and Streibel [14].

Cyclical components of this type have proved useful in economics for modeling the business cycle; an extended class of cycles is presented in [15]. Cycles can be combined with other components, such as trend and seasonal, as well as with other cycles or perhaps autoregressive processes.

Reduced Form ARIMA Models

All the structural time series models described in the previous section are linear and hence there is a corresponding ARIMA model which gives identical predictions. Since the ARIMA model contains only a single disturbance, it is called the "reduced form".

The specification of the reduced form can be found very easily for the simpler models. Thus for the local

level, (2), taking first differences yields

$$\Delta y_t = \eta_t + \varepsilon_t - \varepsilon_{t-1}, \quad t = 2, \ldots, T. \tag{10}$$

The ACF has the same form as that of a first-order moving average process, and so the local level has an ARIMA (0, 1, 1) reduced form,

$$\Delta y_t = \xi_t + \theta \xi_{t-1}, \quad t = 2, \ldots, T. \tag{11}$$

Equating the first-order autocorrelations in the two models gives the following relationship between the structural and reduced form parameters:

$$\theta = \frac{[(q^2 + 4q)^{1/2} - 2 - q]}{2}. \tag{12}$$

Note that θ is constrained to be negative. In more complicated models, the constraints tend to be stronger.

The reduced form of the local linear trend model is ARIMA (0, 2, 2), while that of the BSM, given in (6), is shown by Maravall [22] to be quite close to that of the "airline" model of Box–Jenkins analysis, namely the seasonal ARIMA of order $(0, 1, 1) \times (0, 1, 1)_s$.

Explanatory Variables and Interventions

Observable explanatory variables may be added to the right-hand side of a structural time series model. Some or all of these variables may be under the control of the researcher, for example they may represent the levels of drugs administered.

To keep the discussion simple, we will assume that the only component, apart from the irregular, is a random walk as in (2), and that there is a single explanatory variable, x_t. Then

$$y_t = \mu_t + \delta x_t + \varepsilon_t, \quad t = 1, \ldots, T. \tag{13}$$

The rationale for such a model is that the explanatory variable does not capture all the underlying movements in the level of the series. If it did, q would be zero, μ_t would be constant, and we would be left with a classical regression model. At the other extreme, if σ_ε^2 were zero, the model could be treated as a regression in first differences. More generally,

$$\Delta y_t = \delta \Delta x_t + (\eta_t + \varepsilon_t - \varepsilon_{t-1}), \quad t = 1, \ldots, T, \tag{14}$$

and it should be clear from the discussion surrounding (11) that the disturbance in curly brackets is equivalent to a first-order moving average process. Thus the model in (13) is equivalent to a transfer function model in which the stochastic part has an ARIMA (0, 1, 1) specification. An example of such a specification can be found in [3, pp. 409–412] and in [16], where it is used to model the effect of pollution on respiratory diseases in children. The interpretation of the structural formulation is more direct and the route by which it is obtained is simpler.

The model can be generalized so as to allow for a lag in the response of y to a change in x. There is an enormous literature, particularly in econometrics, on how to put restrictions on the lag structure so as to obtain a more stable lag structure.

Intervention variables are dummy variables which are used to take account of outlying observations and structural breaks. These data irregularities are usually thought of as arising from a specific event, for example, a specific hot day in the case of outliers or a change in policy or treatment in the case of a structural break. Consider the local level model of (2) and suppose that there is a shift in the level due to an intervention at a known time $t = \tau$. The model is then

$$y_t = \mu_t + \lambda w_t + \varepsilon_t, \qquad \varepsilon_t \sim \text{NID}\ (0, \sigma_\varepsilon^2), \quad t = 1, \ldots, T, \tag{15}$$

where w_t takes the value zero for $t < \tau$ and is one thereafter. Other components and explanatory variables can be added to the right-hand side. An example of the use of intervention analysis in structural time series models can be found in [10] on the effect of the 1983 seat belt law in Great Britain.

Multivariate Models

In a multivariate time series model there are observations on a number of individuals or groups over a period of time, and the model tries to capture the correlations and interrelationships between these series (*see* **Multiple Time Series**).

As before, each series may depend on various time series components, both nonstationary and stationary, and observable explanatory variables, including intervention effects. For example, with N series,

$$y_{it} = \mu_{it} + \psi_{it} + x_{it}'\delta_i + \lambda_i w_{it} + \varepsilon_{it}, \quad i = 1, \ldots, N, \quad t = 1, \ldots, T. \tag{16}$$

This may represent a situation in which an experimental group is subject to some treatment, which varies over time and is measured by x_{it}, and a control group which is not subject to the treatment or has it at a different level. An intervention variable would be used for a treatment which is either on or off. The role of the time series components is to pick up changes which occur over time independently of the treatments. It may sometimes be reasonable to suppose that these effects are common to both groups.

The above framework can also be used for a situation where there are observations on a number of individuals over time. These individuals may be given different treatments or they may be subdivided into experimental and control groups. In economics, such cross sections of time series are known as "panel data", though in medicine, the term "**longitudinal data**" is more common [17].

The first subsection below generalizes the univariate structural time series models to multivariate series and explores their properties. It is then shown how such models can be used in connection with intervention analysis and control groups. The last subsection looks at longitudinal data.

Seemingly Unrelated Time Series Equations

In the seemingly unrelated time series equations (SUTSE) model, each series in an $N \times 1$ vector of observations, $\mathbf{y}_t = (y_{1t}, \ldots, y_{Nt})'$, is modeled as in a univariate structural time series model, but the disturbances in each of the components may be correlated across series. There are no dynamic interactions between the series in a SUTSE model. Such features can be introduced, for example by including a vector of components which follows a stationary vector autoregression (VAR). Explanatory variables can also be included in the models.

To understand the implications of SUTSE models we focus on the special case of a multivariate local level model,

$$\begin{aligned} \mathbf{y}_t &= \boldsymbol{\mu}_t + \boldsymbol{\varepsilon}_t, \quad \boldsymbol{\varepsilon}_t \sim \text{NID}\ (\mathbf{0}, \boldsymbol{\Sigma}_\varepsilon), \\ &\qquad\qquad t = 1, \ldots, T, \\ \boldsymbol{\mu}_t &= \boldsymbol{\mu}_{t-1} + \boldsymbol{\eta}_t, \quad \boldsymbol{\eta}_t \sim \text{NID}\ (\mathbf{0}, \boldsymbol{\Sigma}_\eta), \end{aligned} \tag{17}$$

where $\boldsymbol{\Sigma}_\varepsilon$ and $\boldsymbol{\Sigma}_\eta$ are the $(N \times N)$ covariance matrices, and $\boldsymbol{\eta}_t$ and $\boldsymbol{\varepsilon}_t$ are multivariate normal disturbances which are mutually uncorrelated in all time periods. The long-run connections between the series are captured by the covariances in the off-diagonal elements in $\boldsymbol{\Sigma}_\eta$, while the short-run correlations are in $\boldsymbol{\Sigma}_\varepsilon$. These long-run and short-run correlations may be completely different. In the special case when they are the same, the system is said to be homogeneous. Because $\boldsymbol{\Sigma}_\eta = q\boldsymbol{\Sigma}_\varepsilon$, where q is a positive scalar, the statistical treatment is simplified considerably [8, Chapter 8].

Common Factors

The form of a common factor model is similar to that of a SUTSE model except that some or all of the components are driven by disturbance vectors with covariance matrices which are less than full rank. Such models may be formulated in terms of common factors.

Consider the bivariate local level model,

$$\begin{aligned} y_{1t} &= \mu_t + \varepsilon_{1t}, \quad t = 1, \ldots, T, \\ y_{2t} &= \theta\mu_t + \overline{\mu} + \varepsilon_{2t}, \end{aligned} \tag{18}$$

where μ_t is a univariate random walk. The long-run components in the two series depend on the same underlying source, with the level in the second series being a linear function of the level in the first. If $\theta = 1$, the underlying levels remain a constant distance apart, while if $\overline{\mu} = 0$ they are identical. An important feature of this model is that the common nonstationary level can be removed by a certain linear combination of the two series. This property is known as cointegration in the econometrics literature [5]. In the present case it leads to the following relationship between y_{1t} and y_{2t}:

$$y_{2t} = \alpha y_{1t} + \overline{\mu} + \varepsilon_t, \quad t = 1, \ldots, T, \tag{19}$$

where $\alpha = \theta$ and $\varepsilon_t = \varepsilon_{2t} - \alpha\varepsilon_{1t}$.

When there are more than two series, there may be more than one common factor for each component, and these factors are not unique. A factor rotation may sometimes give components with an interesting interpretation.

Control Groups and Intervention Analysis

Suppose we wish to assess the effect of an intervention on a series. This can be done by a univariate model as described in the section on explanatory

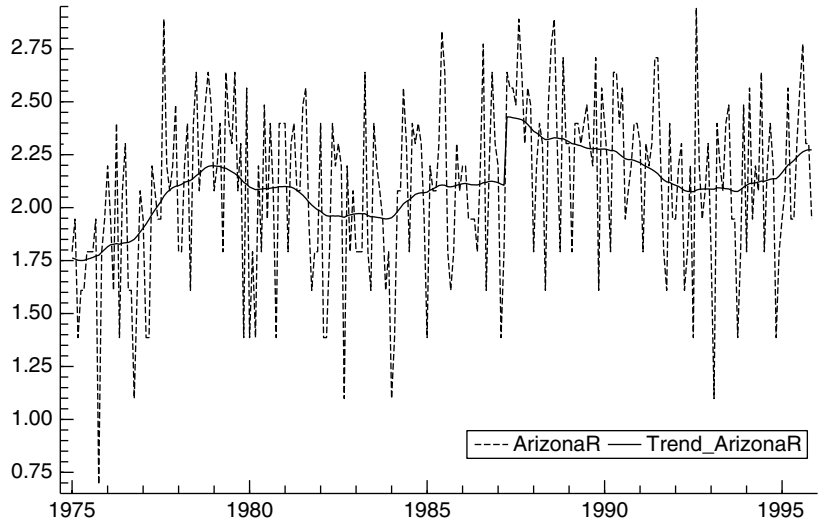

Figure 1 Monthly crashes on rural interstate highways in Arizona.

variables. However, if observations are available on another series correlated with the series of interest but unaffected by the intervention, it is possible to construct a bivariate model in which this second series acts as a control group.

Consider the following model:

$$y_{1t} = \mu_{1t} + \varepsilon_{1t}, \quad t = 1, \ldots, T,$$
$$y_{2t} = \mu_{2t} + \lambda w_t + \varepsilon_{2t}, \tag{20}$$

where the first series contains the observations on the control group. The higher the correlation between the two trends, the bigger the gain is likely to be. The most extreme case is when the two series are driven by a common level, so that they are cointegrated. The model is as in (18) except that the second equation becomes (21):

$$y_{2t} = \theta\mu_t + \overline{\mu} + \lambda w_t + \varepsilon_{2t}, \quad t = 1, \ldots, T, \tag{21}$$

and so (19) becomes

$$y_{2t} = \alpha y_{1t} + \overline{\mu} + \lambda w_t + \varepsilon_t, \quad t = 1, \ldots, T. \tag{22}$$

In contrast to (15), there is no stochastic level in (22). As a result the intervention effect can be estimated consistently and large gains can be expected when there are only a small number of observations after the intervention. For example, Harvey [9] shows that the standard error of the estimate of the parameter measuring the effect of the British seat belt law is more than halved when a control group is used. Another example, taken from [2, p. 22–4], concerns the relaxation of the speed limit on certain rural highways in the US in 1987. Figure 1 shows the random walk trend extracted from a model fitted to monthly data on crashes in rural Arizona, with the intervention in April of that year. A seasonal component was also included. The t-statistic on the intervention was 2.21, but a joint model with the series on crashes on urban highways, where the speed limit was not changed, increased the t-statistic to 2.41. The gain arose from the correlation of 0.81 in the level disturbances.

Longitudinal Data

When there are observations on a large number of individuals over time, the unrestricted SUTSE model becomes unmanageable. However, in such situations it is quite reasonable to suppose that, for each component, the correlation between the disturbances in any two individuals is the same. This restriction may be introduced by assuming that there is an effect common to all individuals and that the individual specific effects are mutually independent. Thus, in the local level model, with observable explanatory variables

$$y_{it} = \mu_t + \mu_{it}^* + \mathbf{x}_{it}'\boldsymbol{\beta} + \varepsilon_t + \varepsilon_{it}^*,$$
$$i = 1, \ldots, N, \quad t = 1, \ldots, T, \tag{23}$$

where μ_t is the common level driven by a disturbance with variance σ_η^2, μ_{it}^*, $i = 1, \ldots, N$, are the individual specific levels each driven by a disturbance with variance $\sigma_{\eta*}^2$, and ε_t and ε_{it}^* are the common and specific irregular disturbances with variances σ_ε^2 and $\sigma_{\varepsilon*}^2$, respectively; see [12], and [23].

Data Irregularities

It is not unusual for time series to suffer from data irregularities such as missing and irregularly spaced observations. A discrete time model can handle missing observations by using the state space form and letting the Kalman filter skip over the missing observations. Irregularly spaced observations pose a more fundamental problem and the solution is to set up a model in continuous time and then use the state space form to construct the relevant discrete time model; see [13] and [17]. For a local level this is very easy. Let δ_t be the time interval between the observation at time t and the observation at time $t-1$. The level is assumed to evolve as a Wiener process, or **Brownian motion**, and if the observations are equally spaced, that is $\delta_t = 1$, the corresponding discrete time model is just (2). With unequally spaced observations the only difference is that $\text{var}(\eta_t) = \delta_t \sigma_\eta^2$, where σ_η^2 is a parameter defined with respect to the continuous time white noise process driving the Wiener process. Handling this model within the state space framework presents no problem since, although the system is not time invariant, the way in which it varies with time depends on the δ_t's and so is known.

Outliers may also arise in time series. These are observations which appear to be inconsistent with a model which is appropriate for most of the data. The simplest kind of outlier is one which is identified as an incorrect measurement, in which case it may be handled by an intervention variable or treated as a missing observation; the second solution is preferable if there are a large number of such cases. A less extreme case arises if some observations are known to be more reliable than others. For example, suppose that the tth observation is constructed as the average of the values of n_t units. In this case it may be appropriate to let the variance of the measurement error, ε_t, be proportional to $1/n_t$. As with irregularly spaced observations, there is no problem in handling such a situation with the state space form. An example involving survey data is in Pfeffermann [25]. Finally, outliers might be handled by allowing the disturbance in the measurement equation to have a heavy-tailed distribution. This makes the model more robust. References to the techniques used for dealing with heavy-tailed distributions are given in the next section, but a specific example can be found in Dubin and Koopman K [4, p. 233–5].

Non-Gaussian Observations

Suppose it is felt that a **Poisson distribution** is suitable for a set of count data. In the **generalized linear model** framework, the mean is assumed to depend on a linear combination of explanatory variables which determine the mean of the distribution via an exponential link function. A deterministic time series model can be constructed by letting the explanatory variables be functions of time. However, for all the reasons given earlier this may not be satisfactory. The functions of time may therefore be given stochastic coefficients as in the models described earlier. However, because of the nonnormality of the observations, the Kalman filter is no longer appropriate. There is no simple analytic solution and a number of ways of designing suitable filtering and estimation procedures, based on simulation techniques such as importance sampling, have been suggested; see, for example, [4], and [26]. An alternative approach is to design transition equations such that the density of the mean, conditional on the information in the previous time period, is conjugate to the observation density so that there exists an exact analytic solution. This turns out to be possible for a number of observation distributions in the simplest situation when the level of the series is assumed to change, that is the analog of the Gaussian local level model of (2); see [7, 10], and [27].

The above techniques may also be applied to other distributions used for count data and to the **binomial distribution** as used for qualitative data.

Studentization

Suppose that $X_1, X_2, \ldots, X_n$ is a random sample from a normal population with mean μ and standard deviation σ, then $Z = \sqrt{n}(\overline{X} - \mu)/\sigma$ follows the standard normal distribution. Here, $\overline{X}$ is the mean of the sample. If, in Z, σ is replaced by the sample standard deviation $S = [\sum(X - \overline{X})^2/(n - 1)]^{1/2}$, then the random variable $T = \sqrt{n}(\overline{X} - \mu)/S$ follows a **Student's *t* distribution** with $n - 1$ df. The process of obtaining T is called *Studentization*, initiated by William Sealy **Gosset** (1876–1937, with the pseudonym "Student"). Since then, studentization has been extended to **studentized range**, studentized extreme deviate (*see* **Extreme Values**), studentized **residuals**, and others.

AUSTIN F.S. LEE

Studentized Range

Let $Y_{ij} \sim \mathrm{N}(\mu_i, \sigma^2)$, $j = 1, \ldots, n, i = 1, \ldots, k$, be independent observations in a (balanced) one-way layout with k treatments. Let $\overline{Y}_1, \ldots, \overline{Y}_k$ be the sample averages and let S^2 be the usual independent and unbiased estimator of σ^2 based on $\nu = k(n-1)$ df. Let W be the **range** of the $\overline{Y}_i$ and consider the *studentized range* Q,

$$Q = \frac{W}{S/\sqrt{n}}.$$

According to David [2]: "The beginning of interest in the studentized range is attributed by **Egon Pearson** [15] to a letter he received from 'Student' (**W.S. Gosset**) in 1932. Referring to the comparison of *selected* differences in variety means. . .". The test statistic for $\mathrm{H}_{ij} : \mu_i = \mu_j$ against a two-sided alternative is

$$|T_{ij}| = \frac{|\overline{Y}_i - \overline{Y}_j|}{S(2/n)^{1/2}},$$

but in view of a potential *selection effect*, Pearson and Gosset considered contrasting each $|T_{ij}|$ with upper α quantiles of

$$\max_{1 \le i < j \le k} |T_{ij}| = \sqrt{2}Q.$$

That constituted the basis for two different **multiple comparison** procedures (MCPs).

The Newman–Keuls (NK) Method

Newman [13] provided approximate tables of upper percentage points of Q using Pearson's [14] method for approximating the distribution of the range of a normal sample. Keuls [10] proposed a stepwise coherent MCP for testing all *subset homogeneity hypotheses* based on Newman's tables, and the method became known as "the NK method". The NK method rejects a given subset-homogeneity hypothesis (of means in a one-way layout, say) if, and only if, all tests of subset-homogeneity hypotheses which imply the given one end in rejection. Accordingly the NK method is a *stepdown* procedure starting with the overall homogeneity hypothesis, continuing testing all its subsets of size $k-1$ if, and only if, rejected, etc. The test of any given subset homogeneity hypothesis is an α-level studentized range test with means pertaining to the given subset, and a common pooled S^2 from all observation in the experiment. Hochberg & Tamhane [9] discuss various properties of the original NK procedure and some of its modifications that were proposed in order to turn it into a *familywise error-rate* (FWE) controlling MCP as well as other stepwise MCPs (e.g. Duncan's [4] method) which followed the NK method.

Tukey's *T*-Method

This is a **simultaneous confidence** estimation and testing MCP for all pairwise comparisons in a balanced one-way layout. With probability $1 - \alpha$ simultaneously for all $i \neq j$,

$$\mu_i - \mu_j \in \left[\overline{Y}_i - \overline{Y}_j \pm S Q_{k,\nu}^{(\alpha)}/\sqrt{n}\right],$$

where $Q_{k,\nu}^{(\alpha)}$ is the $1 - \alpha$ percentile of Q. Tukey [20] extended his method to all contrasts and to all linear combinations of the μ_i. The latter is based on percentiles of the (Studentized) augmented range defined as the maximum between the studentized maximum modulus $\sqrt{2}\max_{1 \le i \le k}\{|\overline{Y}_i - \mu_i|/(S/\sqrt{n})\}$ and Q. Tukey [20] also proposed other extensions of his original method. One of his suggestions involved the use of the critical points of the studentized range also for (all pairwise) comparisons in unbalanced designs. His suggestion was essentially repeated by Kramer [11], and has become known as the "Tukey–Kramer (TK) procedure". Tukey's original conjecture on the conservative nature of such a procedure in unbalanced **analysis of variance** (ANOVA) was proved by Hayter [7]. These and other extensions and comparisons between Tukey's method (as well as other single-step MCPs which stemmed from it) and the NK method (as well as other stepwise MCPs) are discussed in Hochberg & Tamhane [9].

The Internally Studentized Range

David [1] indicated that the term *studentized range* was also used in a different sense. "Let $X_1, \ldots, X_n$ be a random sample from a normal $\mathrm{N}(\mu, \sigma^2)$ population and let $X_{(1)} \le \cdots \le X_{(n)}$ be the corresponding

order statistics. Then $W = X_{(n)} - X_{(1)}$ is the sample range... Let $S^2 = \sum(X_i - \overline{X})^2/(n-1)$... we call... $Q = W/S$ the internally studentized range" (ISR). He refers to the first similar ratio discussed above as "the *externally* studentized range" (ESR). In the case of the ESR there is independence between W and S. In contrast, in the case of the ISR, W and S are associated. David [2] discusses the history of the ISR, including applications, approximations, and theoretical derivations of its distribution. He indicates that Snedecor [17] discussed several applications of the ISR "even before any appropriate theory was developed". Snedecor [17] considered applications of the ISR under the heading of "short cuts". He wrote: "... we introduce a topic of great utility in the common sense understanding of statistics...". He references earlier work by Tippett [19], who apparently "has given a mathematical statement of the problem, providing an extensive table..." but indicates that, "In Tippett's table the sample range is divided by the population standard deviation." Snedecor [17] studies the relation between W and S empirically in normal samples of different sizes, provides a table for the expected ratio Q, and discusses various applications, some of which are indicated in David [2].

David [2] indicates that the ISR was proposed as a test of normality [by David, H.A., Hartley, H.O. & Pearson, E.S., *Biometrika* **41** (1954) 482–493] and was found ("In empirical sampling studies") to possess "particularly good properties against symmetric, especially short-tailed (e.g. uniform) distributions but seems to have virtually no power with respect to asymmetry" (*see* **Normality, Tests of**). David [2] also discusses some distribution-free bounds on Q due to Thompson [18]. Interesting results on the power of the ESR as a test of the global null hypothesis in one-way layouts are discussed in David et al. [3].

Exact Distributions and Tables

According to David [2], "... definitive tables" for the cumulative distribution function (CDF) of the ESR are given by Harter [5] based on Hartley [6]. He also indicated that for larger values of ν one can use Pearson & Hartley's [16] percentage points of Q and that "A computing algorithm for upper tail CDF and percentage points of Q_ν is given by Lund & Lund [12]."

David [1] discusses how the distribution of the ISR was facilitated by the independence of Q and S in normal samples and indicates that this result can also be established based on Fisher, R.A., *Proceedings of the Royal Society of London, Series A* **130** (1931) 16–28 and Geary R.C. (1933), *Biometrika* **25**, 184–186. He also describes various numerical methods for approximating its percentage points.

YOSEF HOCHBERG

Student's *t* Distribution

The probability density function (pdf) of the Student's t distribution is given by

$$f(x) = \frac{\Gamma[(\nu+1)/2]}{(\pi\nu)^{1/2}\Gamma(\nu/2)}(1+x^2/\nu)^{-(\nu+1)/2},$$

where $-\infty < x < \infty$ and $\nu > 0$. The parameter ν is called the **degrees of freedom** (df) of the distribution. Suppose that Z is a standard normal random variable (*see* **Standard Normal Deviate**), Y is a **chi-square** random variable with ν df, and Z and Y are statistically independent (*see* **Random Variable**). Then the random variable T obtained by

$$T = \frac{Z}{(Y/\nu)^{1/2}}$$

has a t distribution with ν df.

The t distribution is symmetric around 0. If X is a random variable that follows the t distribution, then $\mathrm{E}(X) = 0$, $\mathrm{var}(X) = \nu/(\nu-2)$, **skewness** $= 0$, and **kurtosis** $= 6/(\nu-4)$. Furthermore, as ν increases, the t distribution approximates the standard normal distribution. The percentage points of t distributions have been tabulated and can be found in many statistical texts. The t distribution plays an important role in **confidence intervals** and **hypotheses tests**.

(*See also* **Student's *t* Statistics**)

AUSTIN F.S. LEE

Student's *t* Statistics

A Student's t statistic may arise from many **hypothesis testing** problems. In general the Student's t statistic utilizes a **Student's *t* distribution** to determine the critical value (*see* **Critical Region**) for rejecting or not rejecting the **null hypothesis**. The most common Student's t statistics are given below.

1. *One-sample t statistic*. Suppose that $X_1, X_2, \ldots, X_n$ is a **random sample** from a **normal** population with mean μ and variance σ^2. To test the null hypothesis that $\mu = \mu_0$, one constructs the t statistic by $T = \sqrt{n}(\overline{X} - \mu_0)/s$, where $\overline{X}$ is the mean of the sample and $s^2 = \Sigma(X_i - \overline{X})^2/(n-1)$, the sample variance. For a given level of significance (*see* **Level of a Test**), the one-sample t-test compares T with the critical value found from the Student's t distribution with $n-1$ **degrees of freedom** (df).
2. *Two-sample t statistic*. Suppose that $X_1, X_2, \ldots, X_n$ is a random sample from a normal population with mean μ_x and variance σ_x^2, and $Y_1, Y_2, \ldots, Y_m$ is another random sample from a normal population with mean μ_y and variance σ_y^2. Assume also that X_S and Y_S are independent samples and that $\sigma_x^2 = \sigma_y^2 = \sigma^2$. In testing the null hypothesis that $\mu_x = \mu_y$, the t statistic is calculated from

$$T = \frac{\overline{X} - \overline{Y}}{s_p \left(\frac{1}{n} + \frac{1}{m}\right)^{1/2}},$$

   where $\overline{X}$ and $\overline{Y}$ are the sample means of X_S and Y_S, respectively, and

$$s_p^2 = \frac{(n-1)s_x^2 + (m-1)s_y^2}{n+m-2}.$$

   Here, s_p^2 is a weighted average of the sample variances s_x^2 and s_y^2 of X_S and Y_S, respectively, and called the pooled estimate for σ^2. For a given level of significance, the two-sample t test compares T with the critical value found from the Student's t distribution with $n+m-2$ df. However, if the assumption of homogeneity in variance ($\sigma_x^2 = \sigma_y^2$) is violated, the actual probability of type I error (*see* **Hypothesis Testing**) may deviate largely from the given level of significance. In the statistical literature, this is referred to as the **Behrens–Fisher problem**. In this case, another test (for example Welch's approximate τ; *see* **Aspin–Welch Test**) is recommended.
3. *The t statistic for testing significance of the regression coefficient*. In **linear regression** analysis, the t statistic $T = b/\mathrm{se}(b)$ is computed for testing significance (i.e. being statistically different from zero) of the regression coefficient β, using its **least squares** estimate b.
4. *The t statistic for testing significance of the* **correlation** *coefficient*. In correlation analysis, one computes the t statistic $T = (n-2)^{1/2} r/(1-r^2)^{1/2}$ and compares it with the critical value from the Student's t distribution with $n-2$ df. Here, r is Pearson's product–moment correlation coefficient.

Different types of Student's t statistic arise from other hypothesis testing problems.

AUSTIN F.S. LEE

Study Population

The term *study population* is often used to refer to the population from which observations are drawn; that is, the sampled population (*see* **Target Population**). In other writings, it has been used to refer to the study sample [1].

SANDER GREENLAND

Subjective Probability

Subjective probability provides a language for organizing and expressing uncertainty, to articulate expert knowledge, and/or to serve as a meaningful framework for **Bayesian** statistical **inference**. Subjective probabilities refer directly to the strength of a person's beliefs regarding the propositions in question. The currently dominant frequentist view of probability, by contrast, claims that probabilities exist in the real world as physical properties, potential long-run frequencies. Under the frequentist notion, probabilities lack meaning as uncertainties, and their numerical values are typically unknown (although they can be subject to inference from statistical data).

Bruno de Finetti [1, 2] gave subjective probabilities an operational definition as personal prices for lottery tickets, in which $\$P(A)$ is interpreted as the person's price for a ticket that pays \$1 if A. To avoid being a potential sure loser, a person must choose his prices to have coherent values, i.e. values for which no set of hypothetical transactions exists at these prices that would combine to guarantee the person will suffer a net loss for every possible outcome. Such coherence is equivalent to numerical agreement with at least one probability measure, satisfying a finitely additive version of the usual probability axioms.

De Finetti's Fundamental Theorem of Probability enables a person to assert probability values sequentially for an open-ended sequence of propositions. Coherence is preserved at each step by restriction to an interval of available values whose endpoints are obtained by **linear programming**. Expert opinion can be articulated and quantified in probability form by this method (or by further restricting the choices to satisfy some parameterized subjective-probability model).

An equivalent alternative theory of subjective probabilities satisfying the mathematical axioms (together with subjective utilities) proceeds by axiomatizing, first, the person's preferences for lottery tickets and corresponding rewards. This approach by **L.J. Savage** [5] was inspired by ideas in Ramsey [4], and von Neumann & Morgenstern [3]. To emphasize the dependence of degree of belief on the believer, Savage used the term, "personal probability".

Conditional subjective probability was defined by de Finetti as the person's price, now, in a transaction that will be voided (with reimbursement) if the conditioning proposition turns out not to be true: $\$P(A|B)$ is the person's price for a ticket that pays 1 if A and reimburses $\$P(A|B)$ unless B. With transactions of this new type included, the requirement of coherence can be shown to be equivalent to the probability axioms *plus* the usual relationship between conditional and unconditional probability: $P(A|B) = P(A \text{ and } B)/P(B)$, if $P(B) > 0$. Thus, **conditional probability** has a natural interpretation as what the person thinks, now, that his/her opinion should be if and when B is learned. Unfortunately, there is no completely satisfactory coherence-type justification in the literature for the requirement that *after* B becomes known, the person's new opinion conforms to such previous conditional probabilities. There is no normative theory of temporal coherence.

Bayesian statistics, however, is based on the notion that inference should proceed by probability conditioning. Bayesian posterior probabilities, "posterior" to statistical data B, are conditional probabilities $P(A|B)$, which can be computed from the **"prior" probability** $P(A)$ and the statistical sampling probabilities of the data B, $P(B|A)$, $P(B|\text{Not}A)$, by use of **Bayes' theorem:** $P(A|B) = P(B|A)P(A)/[P(B|A)P(A) + P(B|\text{Not}A)P(\text{Not}A)]$. So, subjective probabilities can be of practical use as Bayesian prior or posterior probabilities, with the prior probabilities elicited from a subject-matter expert and the corresponding posterior probabilities obtained by Bayes' theorem.

Frequentist sampling probability can, itself, be viewed as a special limiting case of conditional subjective probability, namely probability expressing opinion of further future data conditional on a long sequence of observed data. According to de Finetti's Representation Theorem for **Exchangeability**, an infinite exchangeable random sequence is representable as a probability mixture of independent, identically distributed (iid) random sequences. The iid random sequences are mathematically the same as a statistical sampling model with unknown physical probabilities, and the mixing probabilities are interpretable as a corresponding prior distribution of the unknown probabilities. Hence, a person who has exchangeable uncertainties concerning an infinite sequence of observable experimental outcomes behaves as if he/she believed there to be a real-world

iid statistical model with unknown physical probabilities. Thus, frequentist probability can be subsumed within the theory of coherent subjective probability. (For a mathematically elementary treatment of the representation, see [6].)

Sufficiency

Sir R.A. Fisher introduced the concept of sufficiency in [3] and claimed in [4] that the "sufficient statistic" is equivalent, for all subsequent purposes of **estimation**, to the original data. More generally, the *sufficiency principle* states that any **inference** should be based on the **sufficient statistic**. This principle is widely accepted by statisticians.

Two related principles are the **likelihood** principle (*see* **Foundations of Probability**) and the **conditionality principle**. The likelihood function $L_X(\theta)$ is defined as $L_X(\theta) = P_\theta(X)$ [where $P_\theta(X)$ is the density function of the data X] and is regarded as a function of the parameter θ for final X. The *likelihood principle* states that a statistical procedure should depend only on $L_X(\theta)$. It further then states that if two different experiments with the same parameter result in proportional likelihoods for the data observed, then identical conclusions should be drawn in the two experiments.

In particular, the likelihood principle implies that conclusions should be based only on the data observed, and not on any data which might have been observed. Hence such considerations as **unbiasedness**, size (*see* **Level of a Test**), power, risk (*see* **Decision Theory**), and so on, which involve averaging over the sample space, may violate the likelihood principle. **Maximum likelihood** estimates and **Bayesian methods** based on posterior distributions, on the other hand, do satisfy the likelihood principle.

The *conditionality principle* states that if the experiment actually performed is chosen randomly and independently of θ from a collection of possible experiments, then the statistical conclusions should not depend on any experiment not performed.

A famous result of Birnbaum [2] shows that, for discrete distributions, the sufficiency principle plus the conditionality principle are equivalent to the likelihood principle. Berger & Wolpert [1] extend this result to general distributions and give an extensive discussion on these principles and many related ones. They, and many others, argue that the likelihood principle ought to be followed, and that the Bayesian approach is the most reasonable way of guaranteeing its implementation. Others, including eventually Birnbaum himself, have argued that the likelihood principle is not universally valid.

In practice, we commonly have less than complete faith in our statistical models and perform residual and other analyses intended to assess model reasonableness. Even if our model appears consistent with the data, it is almost certainly the case that "nearby" models exist which fit the data essentially as well and which may well have a different set of minimal sufficient statistics. The development of **robust** methods indicates the utility of extending a given model (for example, a normal location model) to a broader model (for example, ε-contamination models), where the relatively simple sufficient statistics of the original model (such as the sample mean) are no longer sufficient for the expanded model. In this case sufficiency may provide no reduction at all for the expanded model, and the sufficiency principle may provide little in the way of guidance.

A very large collection of commonly used statistical procedures, however, owe at least a part of their development and desirable properties to the sufficiency principle and the optimality properties of sufficient statistics.

WILLIAM E. STRAWDERMAN

Sufficient Statistic

A sufficient statistic is a statistic (i.e. a function of the data) such that the **conditional** distribution of the data given the sufficient statistic does not depend on any unknown parameters. If I know the value of a sufficient statistic, then I can, with the use of an auxiliary randomization using this conditional distribution, reproduce "data" which has the same (unconditional) distribution as the original data. In this sense the sufficient statistic contains all the **information** in the original data. The notion of **sufficiency** was introduced by R.A. Fisher in [5], and has played an important role in the development of statistical theory and practice.

A simple but concrete example should help to fix ideas. Suppose that we wish to estimate the probability θ that a particular medication will cure migraine headaches. We select two migraine patients randomly and treat them with the medication. Let $X_i = 1$ if the ith patient is cured and 0 if not, and let $T = X_1 + X_2$. If $T = 0$, then the data (X_1, X_2) is (0,0) with probability 1. Similarly, if $T = 2$, then $(X_1, X_2) = (1, 1)$. If $T = 1$, then the data is either (1,0) or (0,1) each with probability $\frac{1}{2}$ regardless of the value of θ. Hence T is a sufficient statistic.

If T is known, then we may reconstruct a set of "data" (X_1, X_2) with a distribution equal to the original data (X_1, X_2) as follows. If $T = 0$, then $(X_1^*, X_2^*) = (0, 0)$. If $T = 1$, then toss a fair coin and set $(X_1^*, X_2^*) = (1, 0)$ if the coin comes up heads and $(X_1^*, X_2^*) = (0, 1)$ if tails. If $T = 2$, then $(X_1^*, X_2^*) = (1, 1)$. The distribution of (X_1^*, X_2^*) is thus the same as that of (X_1, X_2).

Note that if $\delta(X_1, X_2)$ is any estimator of θ (*see* **Estimation**), then the "estimator" $\delta(X_1^*, X_2^*)$ has the same distribution as $\delta(X_1, X_2)$ regardless of the value of θ and hence the same bias, variance, **mean square error**, and so on. Since $\delta(X_1^*, X_2^*)$ is based only on knowledge of T (and an auxiliary toss of a fair coin), we see that knowledge of T "is equivalent, for all subsequent purposes of estimation, to the original data from which it was derived", as Fisher claims in [6].

It should be reasonably clear from the previous example that, in general, knowledge of a sufficient statistic allows the construction of a (random) set of data X^* with a distribution equivalent to the original data X. Hence given any estimator $\delta(X)$ one may construct a (randomized) procedure $\delta(X^*)$ with the same behavior (bias, variance, etc.) as $\delta(X)$. In addition, in many problems, a sufficient statistic may provide a dramatic reduction in the complexity of the data. For example, if in the above example we treated n patients instead of 2, then $T = \sum_{i=1}^{n} X_i$ (= total number of people cured) is a sufficient statistic. T is one-dimensional and takes on the values $0, 1, \ldots, n$. By contrast, the original data $(X_1, \ldots, X_n)$ is an n-dimensional vector and may take on any of 2^n different values. Hence the sufficient statistic is simpler in structure (dimension n vs. 2^n) and in the number of values it takes on (n vs. 2^n).

In what follows I give a somewhat more formal definition of sufficiency, discuss how to find sufficient statistics, give other results indicating that reduction by sufficiency results in no loss of information, and discuss some related notions and results.

Finding Sufficient Statistics

A statistical model consists of data X which takes values in the sample space $\mathcal{X}$ and has a probability distribution $P_\theta(x)$ depending on an unknown parameter θ which takes values in the parameter space Θ. Unless explicitly stated otherwise, we assume that both $\mathcal{X}$ and Θ are contained in Euclidean vector spaces of possibly different dimension. A statistic is a (measurable) function, $T(X)$ possibly vector valued, defined on $\mathcal{X}$, which does not depend on θ. A sufficient statistic is a statistic such that the conditional distribution of X given T does not depend on θ (with probability one).

A rigorous discussion of sufficiency requires measure theory because the required conditional distributions are not necessarily uniquely defined for all values of T. For a rigorous measure-theoretic treatment, see Halmos & Savage [8], Lehmann [10], Bahadur [1], or Hurzurbazar [9]. We assume throughout that X is either discrete or continuous with density $p_\theta(x)$.

In some cases, such as in the example in the introductory section, it is relatively easy to find the conditional distribution of X given a statistic T. In general, however, it is quite difficult. A basic tool for determining sufficiency is the factorization theorem due originally to Fisher [5] and made more rigorous by Neyman [15] and Halmos & Savage [8].

Theorem 1 (factorization theorem). A statistic T is sufficient if and only if $p_\theta(x) = k(x)g(T(x), \theta)$ for some functions g and h.

It follows immediately that if $S(X)$ is an invertible function of a sufficient statistic $T(X)$ then $S(X)$ is also sufficient.

Example 1

Let $X_1, X_2, \ldots, X_n$ be independent, $X_i \sim \mathrm{N}(\mu, \sigma^2)$. Then $X = (X_1, \ldots, X_n)$ and $\theta = (\mu, \sigma^2)$. If $T = (T_1, T_2) = \left(\sum X, \sum X^2\right)$, then T is sufficient, since

$$p_\theta(x) = (2\pi)^{-n/2}\sigma^{-n} \exp\left(\frac{T_1\mu}{\sigma^2} - \frac{T_2}{2\sigma^2} - \frac{n\mu^2}{2\sigma^2}\right).$$

Furthermore, $\overline{X} = T_1/n$ and

$$S^2 = \frac{\sum(X_i - \overline{X})^2}{n-1} = \frac{T_2 - T_1^2/n}{n-1};$$

the sample mean and variance also form a sufficient statistic since $(\overline{X}, S^2)$ is an invertible function of (T_1, T_2).

Minimal Sufficiency

In any model the data X itself clearly is a sufficient statistic. It is of interest to find the sufficient statistic which in some sense has the simplest structure. One way in which to formalize this idea is to define a *minimal sufficient statistic* as a sufficient statistic that is a function of every other sufficient statistic.

One way in which to find a minimal sufficient statistic, due to Lehmann & Scheffé [12], is the following. Define an equivalence relation on the sample space $\mathcal{X}$ by $x_1 \equiv x_2$ if $p_\theta(x_1) = h(x_1, x_2)p_\theta(x_2)$ for all θ, where h is not zero and does not depend on θ. Let $C_x = \{y \in \mathcal{X} : y \equiv x\}$ be the set of ys equivalent to x. Then C_x defines a partition of the sample space. Any statistic $T(x)$ which takes on different values on different sets of the partition but is constant on each such set is a minimal sufficient statistic.

In fact, any (sufficient) statistic $S(x)$ defines a partition where a generic member is $C_x = \{y : S(y) = S(x)\}$. The partition defined in the previous paragraph is unique and is called the minimal sufficient partition. The partition corresponding to any sufficient statistic is a refinement of the minimal sufficient partition in the sense that any set in the minimal sufficient partition is the union of (at least one) sets in the given partition.

Furthermore, two sufficient statistics are invertible functions of one another if and only if they generate the same partition. It follows that if T is minimal sufficient and S is an invertible function of T, then S is also minimal sufficient. See Lindgren [13] for an extended discussion.

Perhaps the most useful example of the Lehmann–Scheffé construction of a minimal sufficient statistic is the following

Theorem 2 (exponential family). Let $p_\theta(x) = c(\theta)h(x)\exp[\sum_1^k \eta_i(\theta)T_i(x)]$. If $\eta_1(\theta), \ldots, \eta_k(\theta)$ are linearly independent, then $[T_1(x), \ldots, T_k(x)]$ is minimal sufficient.

Example 2

For the setup of Example 1, it is easily seen that $T = \left(\sum X_i, \sum X_i^2\right)$ is minimal sufficient as is $(\overline{X}, S^2)$. Here $\theta = (\mu, \sigma^2)$, $\eta_1(\theta) = \mu/\sigma^2$, and $\eta_2(\theta) = -1/(2\sigma^2)$.

Many of the families of distributions of classical statistics, including the **binomial**, **Poisson**, and **gamma**, provide examples of so-called exponential families of distributions to which the above theorem applies. In these examples the dimension of the sufficient statistic T is equal to k, the number of components of $[\eta_1(\theta), \ldots, \eta_k(\theta)]$. Often, as in Example 2, this is also the dimension of θ, but not always. For example, if in Example 2 $\sigma^2 = \mu^2$, then the dimension of $\theta = \mu$ is 1 but $\eta_1(\theta) = 1/\mu$ and $\eta_2(\theta) = -1/2\mu^2$ are still linearly independent and hence $(\overline{X}, S^2)$ remain minimal sufficient.

Occasionally, minimal sufficiency provides very little reduction of the original data. For example if $X = (X_1, \ldots, X_n)$, where the X_i are independent and identically distributed with a **Cauchy** or double exponential distribution with unknown location parameter, then the **order statistics** $(X_{(1)}, \ldots, X_{(n)})$ are minimal sufficient.

Ancillary Statistics

The degree of reduction achieved by minimal sufficient statistics varies greatly from problem to problem. As we have just mentioned, the order statistics are minimal sufficient when the data is from a Cauchy

population with an unknown location. By contrast, if the population is normally distributed with an unknown location, it follows from Theorem 2 that the sample mean is minimal sufficient.

In the former case, the minimal sufficient statistic contains ancillary information in the sense that, for example, the distribution of the sample **range** (the maximum minus the minimum) is a function of the minimal sufficient statistic, but contains no information about the location θ. A statistic $V(X)$ the distribution of which does not depend on θ is said to be an **ancillary statistic**. Reduction by sufficiency seems most successful when the minimal sufficient statistic contains no ancillary information. This is closely related to the notion of a complete sufficient statistic, which we now discuss.

Complete Sufficient Statistics

$T(X)$ is a *complete sufficient statistic* if $\mathrm{E}_\theta f(T) = 0$ for all θ implies that $f(T) = 0$ for all T (actually, for almost all T). The following result of Basu (see for example, Lehmann [10]) implies that a complete sufficient statistic carries no ancillary information.

Theorem 3 (Basu). If T is a complete sufficient statistic, then any ancillary statistic V is independent of T.

It follows that if $f(T)$ is any function of a complete sufficient statistic T, then $f(T)$ is independent of T, and by completeness must be constant. Hence no nontrivial function of a complete sufficient statistic can be ancillary.

A complete sufficient statistic is minimal complete. A result which gives a complete sufficient statistic for many classical statistical models is the following.

Theorem 4 (completeness for exponential families). If in the exponential family setup of Theorem 2, the set $N = \{\eta = [\eta_1(\theta), \eta_2(\theta), \ldots, \eta_k(\theta)] : \theta \in \Theta\}$ contains an open set, then T is a complete sufficient statistic.

Hence $\overline{X}$ is a complete sufficient statistic for sampling from a normal population with unknown location (and known scale). Similarly, $(\overline{X}, S^2)$ is a complete sufficient statistic if both the location and scale are unknown.

If, however, we sample from a normal population with unknown mean, μ, and variance equal to μ^2, then $(\overline{X}, S^2)$ is minimal sufficient (by Theorem 2) but not complete since $\mathrm{E}(n\overline{X}^2/(n+1) - S^2) = 0$ for all μ. Here $[\eta_1(\theta)\eta_2(\theta)] = (1/\mu, -1/(2\mu^2))$ and N is a curve in two dimensions, which does not contain a two-dimensional open set.

It is not necessary that N contain an open set in order for T to be minimal sufficient. For example, Messig & Strawderman [14] show that a class of commonly used **quantal response models** are exponential family models with a complete sufficient statistic, but that the space N does not contain an open set.

Some Uses of Sufficiency

There are a variety of results in different contexts which allow us to find a statistical procedure based on a sufficient statistic which is as good as, or better than, a given procedure. We discuss some of these results in this section. We suppose throughout that we are given data X with distribution $p_\theta(x)$ and that $T(X)$ is a sufficient statistic.

Estimation

Suppose that we wish to estimate $\tau(\theta)$, a possibly vector valued function of θ, and that $\delta(x)$ is any estimator. Define $\delta^*(T) = \mathrm{E}[\delta(x)|T]$. Since T is sufficient, $\delta^*(T)$ does not depend on θ and hence is itself an estimator of $\tau(\theta)$. By elementary properties of conditional expectation $\mathrm{E}_\theta\delta(x) = \mathrm{E}_\theta\delta^*(T)$, and hence δ^* is unbiased for $\tau(\theta)$ if δ is. Furthermore, the variance of δ^* is at least as small as the variance of δ and is, in fact, strictly smaller for every θ if $\delta(x)$ is not itself a function of T (and the variance of δ is finite).

If, in addition, T is a complete sufficient statistic, δ^* is the unique estimator of minimum variance among all estimators with expectation equal to that of $\delta(x)$ for all θ. In particular, if $\delta(x)$ is unbiased for $\tau(\theta)$, then δ^* is the unique minimum variance estimator provided that an unbiased estimator with finite variance exists (*see* **Minimum Variance Unbiased (MVU) Estimator**; **Unbiasedness**).

The above results can be considerably broadened along the following lines. A loss function $L(\theta, a)$ measures the "loss" (*see* **Loss Function**) when we

estimate $\tau(\theta)$ by a and θ is the true value. The risk function of an estimator $\delta(x)$ is defined by $R(\theta, \delta) = \mathrm{E}_\theta L[\theta, \delta(x)]$. For example, a common loss is so-called squared error loss, $L(\theta) = [\tau(\theta) - a]^2$ [if $\tau(\theta)$ is one-dimensional]. In this case, the risk function $R(\theta, \delta) = \mathrm{E}_\theta[\delta(x) - \tau(\theta)]^2$ is mean square error. We may generalize the above results to the following theorems.

Theorem 5 (Rao–Blackwell). If $L(\theta, a)$ is a (strictly) convex function in a, then $R(\theta, \delta^*) \leq R(\theta, \delta)$ with (strict) inequality for all θ provided that δ is not a function of T and $R(\theta, \delta)$ is finite [16].

Theorem 6 (Lehmann–Scheffé). Let $L(\theta, a)$ be convex in a and let T be a complete sufficient statistic. If $\delta(x)$ is an unbiased estimator of $\tau(\theta)$ with finite risk, then δ^* uniformly minimizes the risk among all unbiased estimators.

Hypothesis Testing

Consider testing the hypothesis $\mathrm{H}_0 : \theta \in \Theta_0$ against $\mathrm{H}_a : \theta \in \Theta_0^c$. Let $\phi(x)$ be any *critical function* (or *test function*) defining the probability of inclusion in the **critical region** for an observation x, and let $\phi^*(T) = \mathrm{E}[\phi(x)|T]$ (*see* **Hypothesis Testing**). Then ϕ^* is also a critical function. Furthermore, $\mathrm{E}_\theta\phi = \mathrm{E}_\theta\phi^*$ and hence ϕ and ϕ^* have the same **power** function. If ϕ is unbiased, so is ϕ^*.

Completeness is particularly helpful in obtaining uniformly **most powerful** unbiased (UMPU) tests of and one- and two-sided hypotheses concerning a one-dimensional parameter in the presence of **nuisance parameters** (*see* **Alternative Hypothesis**).

Suppose, for example, that the statistical model is a $k + 1$ parameter ($\theta = (\mu, \gamma_1, \gamma_2, \ldots, \gamma_k)$) exponential family with density $p_\theta(x) = c(\mu, \gamma_1, \gamma_2, \ldots, \gamma_k)$ $h(x) \exp[\mu U(x) + \sum \gamma_i T_i(X)]$, and we wish to test a hypothesis about μ. To be specific, suppose that we wish to test $\mathrm{H}_0 : \mu \leq \mu_0$ against $\mathrm{H}_\mathrm{a} : \mu > \mu_0$. Here $(\gamma_1, \ldots, \gamma_k)$ are the nuisance parameters. The boundary between the null (H_0) and alternative (H_a) hypotheses is $\Theta_B = \{\theta = (\mu, \gamma_1, \ldots, \gamma_k) : \mu = \mu_0\}$. With θ restricted to Θ_B, X has a k parameter exponential family with complete sufficient statistic $T(X) = [T_1(X), T_2(X), \ldots, T_k(X)]$. Furthermore, the distribution of $U(X)$ conditional on $T(X)$ is a one-parameter exponential family with parameter μ. The uniformly most powerful test of H_0 against H_a based on this conditional distribution is easily found to be a one-sided test $\phi^*(U, T)$ based on U (conditional on T) with the property that $\mathrm{E}_{\mu_0}[\phi(U, T)|T] = \alpha$.

However, any unbiased size α test$^*\phi(x)$ must be such that $\mathrm{E}_\theta\phi(x) = \alpha$ for all $\theta \in \Theta_B$. Completeness of T for $\theta \in \Theta_B$ implies that $\mathrm{E}_{\mu_0}[\phi(x)|T] = \alpha$ for all T, or that ϕ has what is called *Neyman structure*. But as the above one-sided test is uniformly most powerful among all such tests, it is uniformly most powerful among all unbiased size α tests and is therefore UMPU. Similar arguments work for two-sided hypotheses about μ in this model. For a more detailed development, see Lehmann [11] and Ferguson [4].

It is important to remark that the one-dimensional parameter μ about which we wish to test a hypothesis may be any one-dimensional affine function of the so-called natural parameters. In this way UMPU tests may be found, for example, for the equality of two binomial or two Poisson parameters.

Likelihood Methods and Information

The function $g(T(X), \theta)$ in the factorization theorem (Theorem 1) may be taken to be the density of T. Thus, for example, the **maximum likelihood** estimator of θ will depend on X only through $T(X)$ and coincides with the maximum likelihood estimator obtained if only $T(X)$ is observed. Furthermore, the **likelihood ratio test** depends only on the sufficient statistic T and is the same as that for which only T is observed. It also follows from the factorization theorem that the Fisher information in a sufficient statistic T is equal to the Fisher information in the original sample X.

Bayesian Methods

Bayesian methods in statistics rely on treating the parameter θ as a random variable that has a **prior distribution** $\pi(\theta)$. The statistical model $p_\theta(x)$ is treated as the model of the distribution of x conditional on the value of the random variable θ. Statistical procedures are based on the posterior distribution, the conditional distribution of θ given the data X which is proportional to $p_\theta(x)\pi(\theta)$, the constant of proportionality depending on x.

If $T(X)$ is a sufficient statistic it follows from the factorization theorem that the conditional distribution of θ given x is the same as the conditional distribution of θ given $T(X)$. Hence Bayesian statistical methods will depend on X through the sufficient statistic T (in regular models). See, however, Blackwell & Ramanoorthi [2] for an example of a nonregular model in which the Bayesian notion of sufficiency does not coincide with the classical one.

Invariance

The important role of sufficiency in statistics is due to the fact that it allows a reduction in the complexity of the sample space without a loss of information. Invariance is another method of reduction which is often useful. Briefly, a statistical model is invariant under a group of invertible transformations, $g \in G$, of the sample space on to itself if, for each $g \in G$ and $\theta \in \Theta$, the distribution of gX is $P_{\theta'}$ for some $\theta' \in \Theta$. In many problems reduction by both sufficiency and invariance is helpful. In some of these problems, it makes a difference which method of reduction is applied first. As reduction by invariance typically involves some loss of information, Ferguson [4] suggests reducing first by sufficiency. For details about the relationship between sufficiency and invariance, see Hall et al. [7].

It often happens that a best invariant procedure (if one exists) may be calculated as a Bayes procedure relative to a particular invariant prior measure. It follows from the discussion in the previous subsection that in this case the best invariant procedure will be a function of the sufficient statistic T.

Concluding Comments

Virtually every textbook on mathematical statistics discusses sufficient statistics. Lindgren [13] is a particularly nice nonmeasure theory treatment, especially of minimal sufficiency and minimal sufficient partitions: see also Casella & Berger [3]. Ferguson [4] has a nonmeasure theory discussion of sufficiency in the context of **decision theory**. Lehmann [11] presents a nice measure theory treatment of the basic properties of sufficiency and remains the basic reference to hypothesis testing.

Summary Measures Analysis of Longitudinal Data

The method of summary measures is one of the most important and straightforward methods for the analysis of longitudinal data. If the measurements and observation times on the ith individual in a study are written as the vector $\mathbf{x}_i$, then a scalar-valued function f is chosen so that $s_i = f(\mathbf{x}_i)$ summarizes some essential feature of the response over time for that individual; the s_i are known as summary measures and some specific examples are given in the next section. Further analysis proceeds by applying standard univariate methods to the summary measures. The approach has been in use for many years [1, 3–6] and has been referred to by various names, including *response feature analysis* and *profile analysis*.

Choosing Summary Measures

The key step is the definition of the summary measure f. There are few restrictions on the type of summary that can be used, the main one being that the summary should make sense both in terms of the study and in the broader scientific context in which the study takes place. It is also advantageous if the summary can be specified before the data are collected, although this is not always possible. Some commonly used summaries include:

1. The rate at which an outcome changes (e.g. a growth rate), for which a suitable f may be the slope of a regression line (Figure 1(a)).
2. The general level of the response, which could be measured by the mean or median of all responses (Figure 1(b)); in many studies, especially in pharmacology, the area under the response curve is used.
3. Summaries defined in terms of the time axis, such as the time to the peak response or the time that a drug concentration stays above a therapeutic level: these can have particular clinical relevance (Figure 1(c)).

Although many summary measures will be closely related to one of the above types, any form of f that gives a valid numerical representation of a scientifically important aspect of the response is allowed. Indeed, there may be circumstances when the observation at a single time point is a suitable and comprehensible summary. However, such analyses must be distinguished from the flawed approach that analyzes separately all time points (*see* **Time-by-time Analysis of Longitudinal Data**).

Advantages of the Method

Three advantages of the method are: (i) the analysis avoids the need to consider the correlation structure of the whole response $\mathbf{x}_i$, and the different s_i can reasonably be assumed to be independent, so the statistical basis of the method is sounder than that of some methods in widespread use (*see* **Analysis of Variance for Longitudinal Data**); (ii) the final analysis of the s_i uses simple methods that are well known; and (iii) the analysis is readily interpreted because it is based on summaries that have been chosen for their relevance to the study.

Furthermore, determining what is a relevant summary measure forces the investigator to think carefully *and quantitatively* about the questions the study addresses; if this process occurs before data are collected, then it can lead to improvements in the design of the study, such as the proposed times at which outcomes will be recorded. It should also be noted that many summary measures will be correlated with the observed value at time zero, so if this is a legitimate covariate (as it would often be in, for example, a **clinical trial**), then using it in the analysis can lead to substantial gains in precision.

More than One Summary Measure

In many studies, more than one aspect of the response is of interest and, provided some care is taken, more than one summary can be defined in the analysis of a single study. Indeed, if a second summary measure, $t_i = g(\mathbf{x}_i)$, has been identified, then not only can the s_i and t_i be analyzed separately, but the relation between the summaries can be considered; often this will amount to no more than producing a scatterplot, but more formal methods might be adopted.

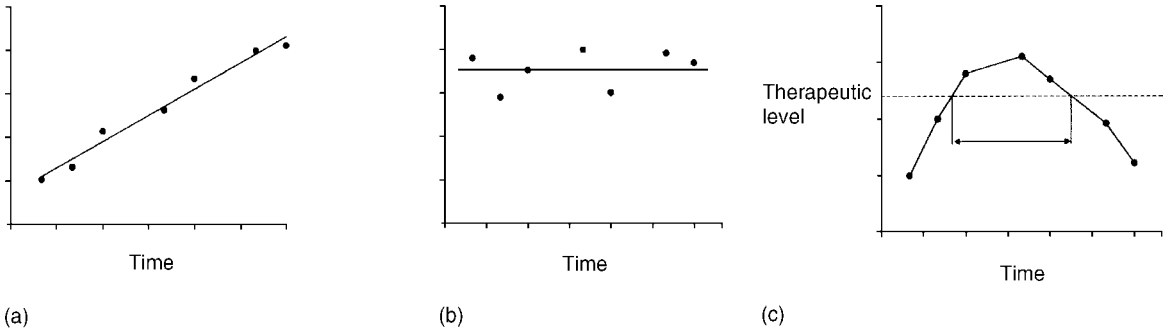

Figure 1 Examples of some common types of summary measure: (a) slope of regression line; (b) mean response; (c) time above a therapeutic level

Care must be taken to ensure that different summary measures address distinct features of the response. As with many aspects of this method, scientific judgment is as important as statistical expertise in deciding what constitutes "distinct features". The statistician should always be alert to the possibility that two apparently distinct summaries may measure the same thing. For example, in a study in which tumors of approximately the same size are transplanted into laboratory animals, the slope of the regression line of tumor size against time over the first 10 days may represent essentially the same information as the size of the tumor at the tenth day.

In practice, there are likely to be few studies in which the use of more than two or three summary measures will be helpful.

Missing Data and Irregular Time Points

In many instances, the definition of a summary measure is sufficiently flexible that missing values can easily be accommodated. Suppose measurements are anticipated on six occasions and the summary is their mean; then, if one of the measurements is missing, the summary is taken to be the mean of the remaining five observations. In practice, if the proportion of missing data points is small, then this type of device is likely to be satisfactory but there are two problems.

The first is that if the s_i are based on $\mathbf{x}_i$ that have widely differing structures then, even within apparently homogeneous groups, the s_i will not share a common distribution, contrary to the assumptions of most of the methods of analysis that are likely to be applied to the summaries. For example, means based on different numbers of observations, regression slopes based on differently located observations and maxima of sets of different sizes, will not share common distributions. Even in complete data sets, observations may be taken at different times on different individuals and this presents the same problems. The importance of this needs to be judged in each application, and will depend particularly on the relative sizes of sampling error and between-individual variation [2].

The second problem, potentially more serious, is the effect of *why* the observations are missing. If interest focuses on the maximum drug concentration and some adverse effect of high concentrations stops this being observed, for example by preventing attendance at the clinic, then it would be seriously misleading simply to use the maximum of the observations obtained. Of course, such problems occur throughout statistics but, because missing values present few computational difficulties for this technique, the analyst needs to be especially aware that this confers no special immunity from the potential dangers of missing data.

Disadvantages

The main problem with the method is that it might not be suitable for certain applications. In some instances, it may simply be impossible to identify a suitable summary measure. If there is interest in how changes over time in the response (for example, postoperative pain relief) relate to another variable (for example, plasma concentration of analgesic), then the method of summary measures has little to offer.

Superpopulation Models in Survey Sampling

A finite population is any collection of distinct entities (*units*) such as people, businesses, medical files, hospitals, or schools. Finite population sampling, sometimes called survey sampling, is concerned with selecting subsets (*samples*) of the units, observing features of the units, and then using the observations to make **inferences** about the entire population. For example, the population is "all short-stay hospitals in the United States," a sample of short-stay hospitals is selected, and for each hospital in the sample the number of patients discharged during a particular calendar year is measured. The goal might be to estimate the total number of discharges in the entire US (*see* **Estimation**).

Invariably, we bring a host of preconceptions and, possibly, hard relevant information (*auxiliary data*), to the study of the population. For example, we may know the number of beds in each of the hospitals in the population, and may strongly suspect that the number of discharges is related to number of beds.

A *superpopulation model* of a particular population is a probability model characterizing the population, formalizing our conceptions and knowledge of the population. Quantities of interest in the population are posited to be realizations of **random variables** with a particular joint probability distribution. For example, in the case of the hospital population, we might suppose

$$Y_i = \beta x_i + x_i^{1/2}\varepsilon_i, \quad i = 1, 2, \ldots, N, \qquad (1)$$

where, for the ith of the N hospitals constituting the population, Y_i is the to-be-realized number of patient discharges per year, x_i is the known number of beds, β is an unknown constant of proportionality, and ε_i is a **random error** with **mean** zero and constant **variance** σ^2, and is assumed to be independent across units. The inclusion of the $x_i^{1/2}$ factor in the error term is meant to capture the idea of greater variation in the larger hospitals.

Such models are invaluable aids in planning sample selection, in constructing estimators of quantities of interest, and in assaying the precision of estimates.

Surveys can be undertaken with *two* distinct sorts of estimation in mind [5, Chapter 7]. In the first sort, referred to most commonly as *analytic* or *inferential*, the aim is to understand the process underlying relations between variables in the population. In this context, the superpopulation model is understood to be an attempt to characterize the way the population (and possibly others like it) has come to be. In any case, the goal is to estimate the parameter(s) of the superpopulation model. Thus, by *definition*, a superpopulation model is necessary for analytic estimation. We might, in the hospital example, be interested in the law of proportionality between beds and discharges, i.e. in estimating the unknown parameter β. A characteristic of analytic inference is that even if the entire population were available, there would be uncertainty in the estimates of the model parameters.

The second, and in fact, more common, goal, is *descriptive*: the estimation of functions, like total, mean, or **quantiles**, of the population quantities themselves. Thus, in the hospital example, we might wish to estimate $T = \sum_{i=1}^{N} y_i$, the total number of discharges from the hospitals. Such quantities are sometimes referred to as "descriptive parameters". In distinction to the analytic case, if the whole population were known, there would remain no uncertainty about the value of the descriptive parameter.

Suppose, in the hospital example, that a sample s of size n is taken from the population P and yields y_i, $i \in s$. The plot in Figure 1 of sample discharges (y) against corresponding sample beds (x), appears to be in keeping with the superpopulation model (1). Then part of T is known, namely the realization of the total for sample units, $T_s = \sum_s Y_i$. The total on the remainder $r = P - s$, namely $T_r = \sum_r Y_i$, is unrealized and unknown, but the sample ys in combination

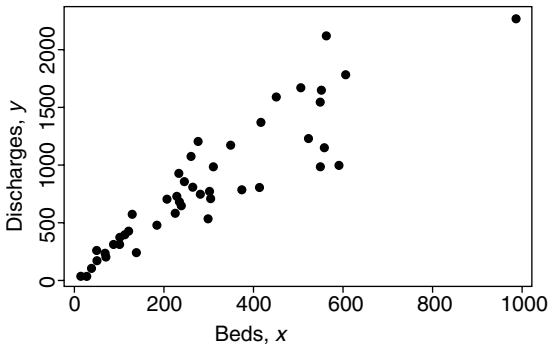

Figure 1 Number of patients discharged and number of beds in 50 short-stay hospitals

with the already known corresponding xs can be used to estimate the slope β. We might, for example, use the best linear **unbiased** estimator $\hat{\beta} = \sum_s Y_i / \sum_s x_i$, not for the sake of getting β itself (as in analysis), but as a means to estimating, or more precisely, predicting, $T_r = \sum_r Y_i$. The predictor $\hat{T}_r = \hat{\beta} \sum_r x_i$ can readily be shown to be *unbiased* for T_r, in the sense that $\mathrm{E}_M(\hat{T}_r - T_r) = \beta \sum_r x_i - \beta \sum_r x_i = 0$, where the **expectation** is with respect to the superpopulation model (1). Basically, one fills in the unknown ys by their predicted values under (1) based on the sample data, and uses these as surrogates to predict the unknown total T_r. Overall, one estimates the population total T by $\hat{T}_R = T_s + \hat{T}_r = \hat{\beta} \sum_P x_i$, which is well known as the *ratio estimator* (*see* **Ratio and Regression Estimates**) (note that if $s = P$, then $\hat{T} = T$). Then $\hat{T}$ will be the best linear unbiased predictor (BLUP) of T, under (1) (see Theorem 1 below).

(It should be noted in the above example, that no strictures were made about how to choose the sample s, other than that (implicitly) it not be in such a way as to make the *sample* pairs (x_i, Y_i) deviate from the model (1). In particular, no assumption was made about using a **random sampling** plan.)

This idea – of using a *superpopulation* model such as (1) to *predict* unknown characteristics of the *population* – has become known as the prediction, or model-based, approach, to survey sampling. The question arises: Can *every* population be characterized by a corresponding superpopulation model?

The presence of auxiliary data, such as number of beds, is *not* needed in order to posit a reasonable model. If a population is homogeneous (and that is all one knows), then a reasonable model is

$$Y_i = \mu + \varepsilon_i, \quad i = 1, 2, \ldots, N, \tag{2}$$

where, for the ith of the N units constituting the population, Y_i is the to-be-realized variate of interest, μ is an unknown constant, and ε_i, the random error, is assumed independent across units and has mean 0 and variance σ^2. It can be shown that $\hat{T} = N\overline{Y}_s$, where $\overline{Y}_s$ is the mean of sample Ys, is the BLUP under (2); see Theorem 1 below.

This particular estimator corresponds exactly to the classic *expansion estimator* for a total, that is unbiased with respect to the probability distribution of samples generated by a **simple random sample** (SRS) sampling scheme. It might be argued that this randomization distribution (of the sampler's activity in choosing the sample) is the adequate basis for choosing the expansion estimator and analyzing its properties. The method of inference that relies only on the random sampling plan for its probability distribution is known as *design-based* inference. To see that design-based inference is inadequate, consider the following thought experiment.

Suppose that one had an utterly heterogeneous population of items. For example, suppose that item 1 is a raisin, item 2 a 1957 Chevrolet, ..., item N a bit of dust. Suppose that the nature of any particular unit is unknown prior to sampling, and that one seeks the mean weight in grams of the items in the population. In this case, knowledge of any number of measurements of sampled items conveys no information regarding any of the nonsampled items. This will be the case whether or not the sample is constructed using SRS or any other probabilistic (or nonprobabilistic) scheme. Thus, we can make no inference from sample mean to population mean (or from any sample quantity to any population quantity) in this extreme sort of population. This is a reflection of the fact that neither the model (2), nor any other model, fits the population and can serve as an inferential bridge from sample to population.

(The software-ready reader might try the following simulation experiment intended to mimic to a degree the above thought experiment: generate a population of size $N = 1000$ having y-values α^i with $\alpha = 1.1$, $i = 1, 2, \ldots, N$; this population has mean $\overline{y} \approx (2.72)(10^{39})$. Suppose that the mode of generation of the population, and, in particular, the sequence number i of each unit and the constant α are unknown to you the sampler. Taking SRS samples of size $n = 100$, for each of the, say 1000, samples, calculate the sample mean $\overline{y}_s$, the SRS sample variance $v = n^{-1}(1 - n/N)(n-1)^{-1} \sum_s (y_i - \overline{y}_s)^2$, and the t-statistic $(\overline{y}_s - \overline{y})/v^{1/2}$ (*see* **Student's *t* Statistics**). Consider the distribution of the t-statistic. For adequate inference, the t statistic should lie between -2 and 2 in about 95% of runs.)

There has been much debate about the merits of model-based versus design-based inference. A key distinction between the two is that, given a sample, the model-based approach seeks to describe properties of estimators in the particular sample selected, in contrast to the design-based approach which calculates statistical properties by averaging across all the

samples that could have been selected using a specified sampling plan. Interesting additional reading can be found in [1, 9, 12, 14, 17, 23, 26].

The Need for Robustness to Model Failure

We suppose then, that, for inference from sample to population to be possible, there must be at least an implicit model of the population that the sampler can make explicit. But in making the model explicit, there are bound to be simplifications and even distortions. For example, in the model (1) adopted for the hospital population above, it was assumed implicitly that there was no curvature characterizing the relation between x and Y, that the variance went up as x rather than, say, x^2. Thus, if one is to make serious use of a superpopulation model in sampling inference, it is necessary to take into account the likelihood of deviations from the model, which may or may not be detectable from the sample data. It is necessary to "robustify" inferences against model failure (*see* **Robustness**).

One way to do this is to examine the effects, especially the **bias**, that arise if one model – the *working model* – is used as a basis for an estimator, and *another* model is correct. This idea goes back to the early stages of modern sampling: in his introduction of what effectively was a linear superpopulation model, Cochran [3] raised the question of the effect of having a quadratic model. The most serious work in this regard has been carried out by Royall and his colleagues [4, 15, 19, 20], who introduced the notion of *balanced samples* as a means of protecting against model failure of certain estimators.

To illustrate, let (1) be the working model, and suppose that if we had the population as a whole, we would recognize that the expected value of Y_i obeys

$$\mathrm{E}_M(Y_i) = \alpha + \beta x_i + \gamma x_i^2, \quad i = 1, 2, \ldots, N. \quad (3)$$

Then it is readily shown that the ratio estimator $\hat{T}_R = \hat{\beta} \sum_P x_i$, based on the working model (1) has a bias, given by

$$\mathrm{E}_M(\hat{T} - T) = N\alpha \left(\frac{\overline{x}}{\overline{x}_s} - 1 \right) + N\gamma \left(\frac{\overline{x}}{\overline{x}_s} \overline{x}_s^{(2)} - \overline{x}^{(2)} \right), \quad (4)$$

where $\overline{x}^{(2)} = N^{-1} \sum_P x_i^2$ and $\overline{x}_s^{(2)} = n^{-1} \sum_s x_i^2$. If the sample is selected to have the moments $\overline{x}_s$ and $\overline{x}_s^2$ equal to the corresponding population moments, then the bias (4) is *zero*. Such a sample is called *balanced*. Similarly, by balancing on moments up to the Jth order, the ratio estimator is protected against bias, if the underlying model is a polynomial of order J. Since smooth functions can be approximated by polynomials of high order, the implication is that, if the underlying model is unspecified but smooth, balanced sampling makes the ratio estimator bias-robust against a very wide range of underlying conditions.

This idea of balance can be generalized to a wide range of estimators (see [8, 15] and Theorem 2 below). Thus, for example, the best linear unbiased estimator $\hat{T}$ based on the superpopulation model

$$Y_i = \beta x_i + \gamma x_i^2 + x_i \varepsilon_i, \quad i = 1, 2, \ldots, N, \quad (5)$$

where ε_i is mean zero with constant variance, independent across units, will be bias-robust against high-order polynomials, if $\overline{x}_s^{(j-1)} = \overline{x}^{(j)}/\overline{x}$, for $j = 0, 2, \ldots, J$ – a sort of weighted balance with weights equal to x_i^{-1}; it will be more efficient than the ratio estimator if, as in the model (5), the variance of Y is proportional to x.

Balance is not a panacea; for example, it does not help if the goal is to estimate a distribution function $F(t) = N^{-1} \sum_P I(Y_i \le t)$ [where $I(A) = 1$, if A holds, and is *zero* otherwise]. In such cases, manipulation of the form of the estimator is necessary to protect against model **misspecification** [2, 7, 8].

Variance Estimation

Reduction or elimination of bias is not an end in itself. However, if the bias is low relative to the square root of the variance, then sound inference, in the form of valid **confidence intervals** or **hypothesis tests**, is achievable, if we can form **consistent** variance estimators. A major concern in model-based sampling is the construction of variance estimates that are unbiased for $v \equiv \mathrm{var}_M(\hat{T} - T)$, despite deviations of the working model, including its **variance component**, from the correct model.

The basic idea underlying a variety of variance estimators is as follows. Under the working model, we can write the estimation error, $\hat{T} - T$, as $\sum_s a_i Y_i - \sum_r Y_j$, where the as depend on the known values in the working model, so that, under a model with independent errors, $v = \sum_s a_i^2 \sigma_i^2 + \sum_r \sigma_j^2$, with

$\sigma_i^2 = \text{var}_M(Y_i)$. For example, in the case of the ratio estimator, $a_i = \sum_r x_i / \sum_s x_i$. Then the first term in v, i.e. the sum over the *sample* points, dominates if, as is typical, $N - n \gg n$, and the key idea is to replace the σ_i^2 by (usually slightly adjusted) squares of the residuals $r_i^2 = (Y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}})^2$, where $\mathbf{x}_i$ is a vector of auxiliaries and $\hat{\boldsymbol{\beta}}$ is an estimated parameter vector. These squared residuals are nearly unbiased for σ_i^2, even when the variance component of the working model is misstated. The second, relatively minor component, can be estimated by $[(N-n)/n]\sum_s r_i^2$ or in more sophisticated ways. The net result is a variance estimator $\hat{v} = \sum_s a_i^2 r_i^2 +$ (an estimate of $\sum_r \sigma_j^2$) that, if the working model of **expectation** is correct, is consistent for v as n, N grow to infinity and n/N goes to zero. In the case in which the working model is incorrect, but the sample is balanced, v will be conservative. The reader is referred to the literature for explicit alternatives to the unadjusted residuals, and for further details; see especially [4, 13, 16–18, 25].

The impact of model-based sampling has been very large. Although present theorists and practitioners are relatively few, many new ideas and considerations, for example, the development of "model-assisted" survey sampling, are traceable, in large measure to model-based inspiration; cf. the remarks of Särndal et al. [21, p. 535].

In the remainder of this article, we outline some theory for the **general linear model**, give a theorem on weighted balance, sketch results for the case in which errors in the model are correlated, useful for **cluster sampling**, and indicate other work in model-based sampling, not covered here.

Prediction Theory under the General Linear Model

The estimation problem can be formulated for a general linear model and the best linear unbiased predictor derived under that model. The finite population consists of N units, each of which has a value of a target variable y associated with it. In the prediction approach, the population vector $\mathbf{y} = (y_1, \ldots, y_N)'$ is treated as the realization of a random vector $\mathbf{Y} = (Y_1, \ldots, Y_N)'$. A common goal is to estimate a linear combination of the Ys, such as the total of all the Ys or their mean. A linear combination of the Ys is defined to be $\boldsymbol{\gamma}'\mathbf{Y}$, where $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_N)'$ is an N-vector of constants. If, for example, each $\gamma_i = 1$, then the prediction target is the total; if $\gamma_i = 1/N$, the target is the mean. Because the target Ys are modeled as random variables, any linear combination $\boldsymbol{\gamma}'\mathbf{Y}$ is a random sum, and our problem is one of prediction. The population vector of Ys, given a particular sample s, can be reordered so that the first n elements are those in the sample and partitioned as $\mathbf{Y} = (\mathbf{Y}_s', \mathbf{Y}_r')'$, where the subvectors $\mathbf{Y}_s$ and $\mathbf{Y}_r$ are $n \times 1$ and $(N-n) \times 1$. To proceed we need to define the terms "linear estimator" and "estimation error".

Definition 1. A *linear estimator* of $\theta = \boldsymbol{\gamma}'\mathbf{Y}$ is defined as $\hat{\theta} = \mathbf{g}_s'\mathbf{Y}_s$, where $\mathbf{g}_s = (g_1, \ldots, g_n)'$ is an n-vector of coefficients.

Definition 2. The *estimation error* of an estimator $\mathbf{g}_s'\mathbf{Y}_s$ is $\hat{\theta} - \theta = \mathbf{g}_s'\mathbf{Y}_s - \boldsymbol{\gamma}'\mathbf{Y}$.

We study this prediction problem under the general linear model:

$$\text{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}, \qquad \text{var}(\mathbf{Y}) = \mathbf{V}, \tag{6}$$

where $\mathbf{X}$ is an $N \times p$ matrix of auxiliaries, $\boldsymbol{\beta}$ is a $p \times 1$ vector of unknown parameters, and $\mathbf{V}$ is a positive definite **covariance matrix**. To compute some estimators generated from Theorem 1 below, it is necessary that all auxiliary values be known for each unit in the population, although for others summary population statistics like means are sufficient. If the population elements are rearranged so that the first n elements of $\mathbf{Y}$ are those in the sample, and the first n rows of $\mathbf{X}$ are for units in the sample, then $\mathbf{X}$ and $\mathbf{V}$ can be expressed as

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_s \\ \mathbf{X}_r \end{bmatrix}, \quad \mathbf{V} = \begin{bmatrix} \mathbf{V}_{ss} & \mathbf{V}_{sr} \\ \mathbf{V}_{rs} & \mathbf{V}_{rr} \end{bmatrix},$$

where $\mathbf{X}_s$ is $n \times p$, $\mathbf{X}_r$ is $(N-n) \times p$, $\mathbf{V}_{ss}$ is $n \times n$, $\mathbf{V}_{rr}$ is $(N-n) \times (N-n)$, $\mathbf{V}_{sr}$ is $n \times (N-n)$, and $\mathbf{V}_{rs} = \mathbf{V}_{sr}'$.

The auxiliaries being known for each unit in the population, implies that a **sampling frame** has been constructed that lists every unit that is in the survey universe. In a universe of hospitals, auxiliaries could include, in addition to the aforementioned number of beds, the number of patients admitted during a previous time period, or the type of hospital – general medical and surgical, psychiatric, rehabilitation, and so on. There are many practical situations, particularly in surveys of households, where a complete list

of every population unit is not available. Such cases may require **multistage sampling**, which is addressed in the section on clustered populations.

Given a model, we can also define unbiasedness and variance as they apply in the context of **prediction** theory.

Definition 3. The estimator $\hat{\theta}$ is *prediction unbiased* for θ under a model M if $\mathrm{E}_M(\hat{\theta} - \theta) = 0$.

Definition 4. The *error variance* or (equivalently *prediction variance*) of $\hat{\theta}$ under a model M is $\mathrm{E}_M(\hat{\theta} - \theta)^2$.

The general theorem [11], giving the BLUP of $\hat{\theta}$ under model (6) is an extension of a standard result in prediction theory [27]:

Theorem 1. Among linear, prediction unbiased estimators $\hat{\theta}$ of θ, the error variance is minimized by

$$\hat{\theta}_{\text{opt}} = \boldsymbol{\gamma}_s'\mathbf{Y}_s + \boldsymbol{\gamma}_r'\left[\mathbf{X}_r\hat{\boldsymbol{\beta}} + \mathbf{V}_{rs}\mathbf{V}_{ss}^{-1}(\mathbf{Y}_s - \mathbf{X}_s\hat{\boldsymbol{\beta}})\right], \tag{7}$$

where $\hat{\boldsymbol{\beta}} = (\mathbf{X}_s'\mathbf{V}_{ss}^{-1}\mathbf{X}_s)^{-1}\mathbf{X}_s'\mathbf{V}_{ss}^{-1}\mathbf{Y}_s$. The error variance of $\hat{\theta}$ is for $\mathbf{A}_s = \mathbf{X}_s'\mathbf{V}_{ss}^{-1}\mathbf{X}_s$

$$\begin{aligned}\mathrm{var}_M(\hat{\theta} - \theta) = {} & \boldsymbol{\gamma}_r'(\mathbf{V}_r - \mathbf{V}_{rs}\mathbf{V}_{ss}^{-1}\mathbf{V}_{sr})\boldsymbol{\gamma}_r \\ & + \boldsymbol{\gamma}_r'(\mathbf{X}_r - \mathbf{V}_{rs}\mathbf{V}_{ss}^{-1}\mathbf{X}_s)\mathbf{A}_s^{-1} \\ & \times (\mathbf{X}_r - \mathbf{V}_{rs}\mathbf{V}_{ss}^{-1}\mathbf{X}_s)'\boldsymbol{\gamma}_r. \end{aligned} \tag{8}$$

A feature of the BLUP, as noted earlier, is that it equals the weighted sum for the sample units, $\boldsymbol{\gamma}_s'\mathbf{Y}_s$ plus a predictor of the weighted sum for the nonsample units, $\boldsymbol{\gamma}_r'[\mathbf{X}_r\hat{\boldsymbol{\beta}} + \mathbf{V}_{rs}\mathbf{V}_{ss}^{-1}(\mathbf{Y}_s - \mathbf{X}_s\hat{\boldsymbol{\beta}})]$. When the sample and nonsample units are uncorrelated, $\mathbf{V}_{rs} = \mathbf{0}$, the BLUP simplifies to $\hat{\theta}_{\text{opt}} = \boldsymbol{\gamma}_s'\mathbf{Y}_s + \boldsymbol{\gamma}_r'\mathbf{X}_r\hat{\boldsymbol{\beta}}$. The assumption that $\mathbf{V}_{rs} = \mathbf{0}$ will often be reasonable in situations in which single-stage sampling is appropriate, such as institution or establishment sampling.

To appreciate the formulation of the problem as one of prediction, rather than estimation, it is instructive to look at the results for the optimum $\hat{\theta}$ if we minimize its variance, $\mathrm{var}_M(\hat{\theta}) = \mathbf{g}_s'\mathbf{V}_{ss}\mathbf{g}_s$ instead of the error variance $\mathrm{var}_M(\hat{\theta} - \theta)$. In that case, the **minimum variance estimator** is $\hat{\theta}^* = \boldsymbol{\gamma}'\mathbf{X}\hat{\boldsymbol{\beta}}$. In other words, the value for each unit in the population is estimated as its expected value from the estimated **regression** model. Contrast this to $\hat{\theta}_{\text{opt}}$, where the sum for the sample units, $\boldsymbol{\gamma}_s'$ is used directly, and the sum for the nonsample units is predicted by the estimated regression mean, $\boldsymbol{\gamma}_r'\mathbf{X}_r\hat{\boldsymbol{\beta}}$ plus an adjustment based on sample **residuals**, $\boldsymbol{\gamma}_r'\mathbf{V}_{rs}\mathbf{V}_{ss}^{-1}(\mathbf{Y}_s - \mathbf{X}_s\hat{\boldsymbol{\beta}})$.

Many commonly used estimators can be derived by applying Theorem 1 to particular models. In the examples below, the estimation target is the finite population total $T = \sum_{i=1}^{N} y_i$, implying that $\boldsymbol{\gamma} = \mathbf{1}_N$ is a vector of N ones. The model that leads to the ratio estimator, for example, is (1). The estimator itself is $\hat{T}_R = \hat{\beta}\sum_P x_i$ and its error variance under the model is

$$\mathrm{var}_M(\hat{T}_R - T) = \frac{N^2}{n}(1 - f)\frac{\overline{x}_r\overline{x}}{\overline{x}_s}\sigma^2, \tag{9}$$

where $\overline{x}_r$ is the mean of x for the nonsample units, $\overline{x}$ is the population mean, and $f = n/N$.

The linear regression estimator comes from the model $Y_i = \alpha + \beta x_i + \varepsilon_i$, with the ε_is being independent with mean 0 and variance σ^2. The BLUP is $\hat{T}_{LR} = N[\overline{Y}_s + b(\overline{x} - \overline{x}_s)]$, where $b = \sum_s(Y_i - \overline{Y}_s)(x_i - \overline{x}_s)/\sum_s(x_i - \overline{x}_s)^2$. The error variance is $\mathrm{var}_M(\hat{T}_{LR} - T) = N^2(1 - f)\sigma^2[1 + (\overline{x}_s - \overline{x})^2/\{(1 - f)c_s\}]$, where $c_s = \sum_s(x_i - \overline{x}_s)^2/n$.

Another common estimator is the stratified expansion estimator. A set of strata is a collection of mutually exclusive groups that covers the entire population (*see* **Stratified Sampling**). Strata might be regions of a country, for example. Suppose that h denotes a stratum and that the model is $Y_{hi} = \mu_h + \varepsilon_{hi}$, with the ε_{hi}s being independent with mean 0 and variance σ_h^2. The BLUP is $\hat{T}_{st} = \sum_h N_h\overline{Y}_{hs}$, where N_h is the number of population units in stratum h, $\overline{Y}_{hs} = \sum_{s_h} Y_{hi}/n_h$, s_h is the set of sample units in stratum h, and n_h is the number of sample units in the stratum. The error variance is $\mathrm{var}_M(\hat{T}_{st} - T) = \sum_h N_h^2(1 - f_h)\sigma_h^2/n_h$, where $f_h = n_h/N_h$.

A final example is the mean-of-ratios estimator, which flows from the model $Y_i = \beta x_i + x_i\varepsilon_i$. The BLUP is $\hat{T} = \sum_s Y_i + \hat{\beta}\sum_r x_i$, where $\hat{\beta} = \sum_s Y_i/(nx_i)$. The error variance is $\mathrm{var}_M(\hat{T} - T) = \sigma^2[(N - n)^2\overline{x}_r^2/n + \sum_r x_i^2]$. When the sampling fraction f is small, the BLUP is approximated by the mean-of-ratios estimator $\hat{T}_{MR} = N\overline{x}\sum_s Y_i/(nx_i)$.

Per Unit Weights

When constructing a database from a sample survey, it is often operationally convenient to have a "weight"

associated with each unit in the sample that is used to calculate linear estimates. The weights are intended to be applicable to possibly *several* variables of interest y.

Now for a single y variable, the $n \times 1$ optimal vector of coefficients in a linear estimator, implied by Theorem 1, is

$$\mathbf{g}_s = \mathbf{V}_{ss}^{-1}[\mathbf{V}_{sr} - \mathbf{X}_s\mathbf{A}_s^{-1}(\mathbf{X}_r' - \mathbf{X}_s'\mathbf{V}_{ss}^{-1}\mathbf{V}_{sr})]\boldsymbol{\gamma}_r + \boldsymbol{\gamma}_s.$$

Unit i would be assigned a weight equal to the ith component of the vector $\mathbf{g}_s$. The optimal weight depends, through the covariance structure, on the particular y variable being considered and on the way in which the population is split between the sample and nonsample units. Some examples follow.

For the expansion estimator $g_i = N/n$, for all $i \in s$. The ratio estimator has $g_i = N\overline{x}/(n\overline{x}_s)$. The linear regression estimator has $g_i = N[n^{-1} + (\overline{x} - \overline{x}_s)(x_i - \overline{x}_s)/\sum_{j\in s}(x_j - \overline{x}_s)^2]$. The weight for the stratified expansion estimator is $g_i = N_h/n_h$, for $i \in s_h$, and for the mean of ratios estimator is $g_i = N\overline{x}/(nx_i)$.

Notice that the coefficients a_i, in terms of which it is convenient to express the variance $v = \sum_s a_i^2\sigma_i^2 + \sum_r \sigma_j^2$ (discussed above for models with independent errors), are given by $a_i = g_i - 1$.

Although common survey practice is to use the same weight to make an estimate for different y variables, this would appear to be reasonable only when the ys follow the same general form of model. If one variable follows the expansion estimator model while another follows the regression estimator model, using the same weight for each is not generally sensible. However, in the case in which the sample is *balanced*, in the sense given in the next section, estimators of many forms can in effect be subsumed under one form, so that per unit weights are well-grounded.

It is worth noting that all of the examples that we have considered share a certain common structure. Let $\mathbf{1}_N$ and $\mathbf{1}_s$ be vectors of N and n ones. Suppose that $\mathbf{V}$ is diagonal and that the ith diagonal element can be expressed as $v_{ii} = \sigma^2 f(\mathbf{x}_i)$, with $f(\mathbf{x}_i) = \sum_{j=1}^{p} c_i x_{ij}$ a known function and $\mathbf{x}_i$ the vector of auxiliaries for unit i. In matrix terms, suppose that $\mathbf{V}\mathbf{1}_N = \mathbf{X}\mathbf{c}$ for a $p \times 1$ vector $\mathbf{c}$. The BLUP becomes $\hat{T} = \mathbf{1}_N'\mathbf{X}\hat{\boldsymbol{\beta}}$ (see Lemma 1 below). Note that this form of $\hat{T}$ is the same as would be obtained under the general linear model if we minimized $\mathrm{var}_M(\hat{T})$ rather than $\mathrm{var}_M(\hat{T} - T)$. Even if the variance condition $\mathbf{V}\mathbf{1}_N = \mathbf{X}\mathbf{c}$ does not hold, $\hat{T} = \mathbf{1}_N'\mathbf{X}\hat{\boldsymbol{\beta}}$ is still prediction unbiased under (6). The weight for the ith sample unit is then $g_i = N\overline{\mathbf{x}}[\sum_s \mathbf{x}_i\mathbf{x}_i'/f(\mathbf{x}_i)]^{-1}\mathbf{x}_i/f(\mathbf{x}_i)$, where $\overline{\mathbf{x}} = (\overline{x}_1, \ldots, \overline{x}_p)'$ is the vector of population means of the auxiliaries.

Weighted Balance and Robustness

Models that satisfy the variance condition $\mathbf{V}\mathbf{1}_N = \mathbf{X}\mathbf{c}$ play a key role in robustness and optimality. Let $M(\mathbf{X} : \mathbf{V})$ refer to the general linear model (not necessarily polynomial) with matrix $\mathbf{X}$ of auxiliary variables, and covariance matrix $\mathbf{V}$ given by (6). we first note the following.

Lemma 1 [15]. If $\mathbf{V}\mathbf{1}_N = \mathbf{X}\mathbf{c}$ for some vector $\mathbf{c}$, then the BLUP and its error variance are

$$\hat{T}(\mathbf{X} : \mathbf{V}) = \mathbf{1}_N'\mathbf{X}\hat{\boldsymbol{\beta}},$$
$$\mathrm{var}_M[\hat{T}(\mathbf{X} : \mathbf{V}) - T] = (\mathbf{1}_N'\mathbf{X}\mathbf{A}_s^{-1}\mathbf{X}'\mathbf{1}_N - \mathbf{1}_N'\mathbf{V}\mathbf{1}_N)\sigma^2. \tag{10}$$

Definition 5. The collection of samples that satisfy

$$\frac{1}{n}\mathbf{1}_s'\mathbf{W}_s^{-1/2}\mathbf{X}_s = \frac{\mathbf{1}_N'\mathbf{X}}{\mathbf{1}_N'\mathbf{W}^{1/2}\mathbf{1}_N} \tag{11}$$

will be denoted by $B(\mathbf{X} : \mathbf{W})$ and said to *balanced with respect to the weights root*$(\mathbf{W})$ or *root*$(\mathbf{W})$ *balanced*. Here $\mathbf{W}$ is an $N \times N$ matrix and $\mathbf{W}_s$ is the $n \times n$ submatrix for the sample units.

When $\mathbf{W} = \mathbf{I}$, $B(\mathbf{X} : \mathbf{I})$ is the set of samples that are balanced on the columns of $\mathbf{X}$, i.e. $\mathbf{1}_s'\mathbf{X}_s/n = \mathbf{1}_N'\mathbf{X}_N/N$. If the model for y is a polynomial in x, then $B(\mathbf{X} : \mathbf{I})$ is the set of samples satisfying $\overline{x}_s^{(j)} = \overline{x}^{(j)}$, the balance conditions introduced earlier.

Theorem 2 [15]. Under $M(\mathbf{X} : \mathbf{V})$, with $\mathbf{V}$ diagonal, if both $\mathbf{V}\mathbf{1}_N = \mathbf{X}\mathbf{c}$ and $\mathbf{V}^{1/2}\mathbf{1}_N = \mathbf{X}\mathbf{d}$, for some vectors $\mathbf{c}$, and $\mathbf{d}$, then

$$\mathrm{var}_M[\hat{T}(\mathbf{X} : \mathbf{V}) - T] \geq [n^{-1}(\mathbf{1}_N'\mathbf{V}^{1/2}\mathbf{1}_N)^2 - \mathbf{1}_N'\mathbf{V}\mathbf{1}_N]\sigma^2.$$

The bound is achieved if and only if $s \in B(\mathbf{X} : \mathbf{V})$, in which case

$$\hat{T}(\mathbf{X} : \mathbf{V}) = n^{-1}(\mathbf{1}_N'\mathbf{V}^{1/2}\mathbf{1}_N)(\mathbf{1}_s'\mathbf{V}_{ss}^{-1/2}\mathbf{Y}_s).$$

For a given variance structure $\mathbf{V}$, the theorem states that under mild conditions on the $\mathbf{X}$ matrix, the estimator $\hat{T}(\mathbf{X} : \mathbf{V})$ will have two important properties under root($\mathbf{V}$) balance: (i) it will be bias robust, since the best linear unbiased estimator for any *other* auxiliary matrix (satisfying the mild conditions) will equal $\hat{T}(\mathbf{X} : \mathbf{V})$; and (ii) it will be most efficient under $M(\mathbf{X} : \mathbf{V})$, since the variance is the smallest possible across samples.

By way of illustration, consider the case in which the variance is proportional to x. It has already been seen that the common ratio estimator, under standard balance, will be bias robust. Now consider the model $Y_i = \gamma_{1/2} x_i^{1/2} + \gamma x_i + x_i^{1/2}\varepsilon_i$. Call the best linear unbiased estimator based on this model $\hat{T}(\gamma_{1/2} x^{1/2} + \gamma x : x)$. The lower bound on its variance is

$$\left[\frac{\left(N\overline{x}^{(1/2)}\right)^2}{n} - \sum_{i=1}^{N} x_i\right]\sigma^2, \tag{12}$$

achieved in any sample balanced in the sense that $\overline{x}_s^{(1/2)} = \sum_{i=1}^{N} x_i / \sum_{i=1}^{N} x_i^{1/2}$. Bias protection against general polynomial models is obtained by balancing on additional powers:

$$\sum_s x_i^{j-1/2}/n = \sum_{i=1}^{N} x_i^j \Bigg/ \sum_{i=1}^{N} x_i^{1/2} \quad \text{for } j = 0, 1, 2, \ldots, J,$$

that is, under *root*(x) balance (of order J). In addition, by Theorem 2, $\hat{T}(\gamma_{1/2} x^{1/2} + \gamma x : x)$ has the minimum variance in every sample under the working model $Y = \gamma_{1/2} x_i^{1/2} + \gamma x_i + x_i^{1/2}\varepsilon_i$.

Note that (12) is less than the variance (9) of the ratio estimator under the balance condition $\overline{x}_s = \overline{x}$. The ratio estimator arises on the basis of a model with variance proportional to x, but is *not* bias robust under root(x) balance and does not yield the minimal variance, in contrast to $\hat{T}(\gamma_{1/2} x^{1/2} + \gamma x : x)$. When root($x$) balanced sampling is feasible, there can be no justification for *ever* using the ratio estimator, except when one is absolutely sure of a simple through the origin model.

A word on practical methods of achieving balanced samples is in order. Consider **sampling with probability proportionate to size** (*pps*), for which there are a variety of modes of implementation. If the variable according to which *pps* is carried out is $v_i^{1/2} = [\mathrm{var}_M(Y_i)]^{1/2}$, so that (for fixed sample size n) the inclusion probabilities are $\pi_i = n v_i^{1/2} / \sum_{i=1}^{N} v_i^{1/2}$, then the sample will be balanced *in (design) expectation*:

$$\mathrm{E}_{pps}\left(\frac{\sum_s v_i^{-1/2} x_{ji}}{n}\right) = \frac{\sum_{i=1}^{N} x_{ji}}{\sum_{i=1}^{N} v_i^{1/2}},$$

for $\mathbf{X} = (x_{ji})$.

This says that an appropriate *pps* scheme *aims* at balance. One reasonable approach to getting a balanced sample is to generate some (say 100) *pps* samples, and choose one among them that comes closest to meeting the criterion of balance. Herson [10] illustrated this type of restricted **randomization** when selecting simple random samples. There may be some trade-off between one column of $\mathbf{X}$ and another; in some cases, one may wish to go beyond the original set of samples.

It is to be noted that balance will not always be achievable. For example, in the case of root(x) balance, the expression (12) for the variance at balance implies that $n \leq [(\overline{x}^{(1/2)})^2/\overline{x}]N$, so that for large enough n balance is impossible. It can be shown that if the sample inclusion weights $\pi_i = n v_i^{1/2} / \sum_{i=1}^{N} v_i^{1/2}$ are less than *one* (so that the corresponding *pps* sampling is possible), then n is small enough for balance. Thus a general strategy for getting balance is first to weed out the units from the population for which π_i exceeds *one*, putting these into a separate certainty stratum, and balance on the remainder of the population.

Large Sample Normality

For any linear estimator $\hat{\theta} = \mathbf{g}_s' \mathbf{Y}_s$ of $\theta = \boldsymbol{\gamma}' \mathbf{Y}$, whether best linear unbiased or not, the estimation error $\hat{\theta} - \theta$ is a linear function of the elements of $\mathbf{Y}$. Thus, under a model for which $\hat{\theta}$ is prediction unbiased and the Ys are independent, the standardized error $(\hat{\theta} - \theta)/[\mathrm{var}_M(\hat{\theta} - \theta)]^{1/2}$ has an asymptotic standard **normal distribution** under some reasonable conditions [16]. When a **consistent** variance estimator $\hat{v}$ (see above) is substituted in the denominator of the standardized error, $(\hat{\theta} - \theta)/\sqrt{\hat{v}}$ will also be approximately normally distributed with mean 0 and variance 1 in large samples. An interval

of the form $\hat{\theta} \pm z_{\alpha/2}\sqrt{\hat{v}}$ will then have a confidence level of $(1-\alpha)\%$ asymptotically, with $z_{\alpha/2}$ being the $\alpha/2$-quantile from the standard normal distribution (*see* **Confidence Intervals and Sets**).

Clustered Populations

Many naturally occurring populations exhibit **clustering** in which units that are, in some sense, near each other have similar characteristics. Households in the same neighborhood may tend to have similar incomes, education levels of the heads of household, and amounts of expenditures on food and clothing. Business establishments in the same industry and geographic area will pay similar wages to a given occupation because of competition. This similarity among "nearby" units can express itself statistically as a **correlation** between the target variables for different units.

In clustered populations, the methods of data collection may also differ from the methods used in other populations. In a household survey, for example, a complete list of households to use for sampling is usually not available, especially if the population is large. In the US, for instance, there are nearly 100 million households. The households may be geographically dispersed so that fieldwork can be more economically done when sample units are clustered together to limit travel costs. A practical, and widely used, technique is to select the sample in stages, using, at each stage, sampling units for which a complete list is available. In the household example, geographic areas may be selected at the first stage. At the second stage, each first stage sample unit may be further subdivided and a sample of the subdivisions selected. A list of the households in each sample subdivision is then compiled and data collected from each. In a business population, establishments may be selected at the first stage, a list of occupations compiled in each sample establishment, and a sample of occupations then drawn from each list. Although occupations are the units ultimately sampled, a complete list of occupations for each establishment in the universe is unlikely to be available while a list of establishments often is. Selecting establishments at the first stage is also sensible because survey costs may depend on the number of sample establishments more than the number of sample occupations. Cooperation must be elicited at the establishment level; and the more establishments in the sample, the more the survey will cost.

An Intracluster Correlation Model for a Clustered Population

The population of units is divided into N clusters. Cluster i contains M_i units with the total number of units in the population being $M = \sum_{i=1}^{N} M_i$. We suppose that the clusters sizes M_i, and hence the population size M, are all known. Associated with unit j in cluster i is a random variable Y_{ij} the finite population total of which is $T = \sum_{i=1}^{N} \sum_{j=1}^{M_i} Y_{ij}$. One simple working model is

$$\begin{aligned} \mathrm{E}_M(Y_{ij}) &= \mu, \\ \mathrm{cov}_M(Y_{ij}, Y_{i'j'}) &= \begin{cases} \sigma_i^2, & i = i',\ j = j', \\ \sigma_i^2 \rho_i, & i = i',\ j \neq j', \\ 0, & \text{otherwise.} \end{cases} \end{aligned} \quad (13)$$

The model posits that units all have a common mean μ. Within cluster i, units have a common variance σ_i^2, which can be different from one cluster to another. Units in the same cluster also have a common correlation ρ_i. This type of model can also be combined with **stratification** to describe some populations better.

Elements are selected by a two-stage sampling scheme. First, a sample s of n clusters is chosen from the N. Denote the set of nonsample clusters by r. Then, from the M_i elements in sample cluster i, a sample s_i of size m_i is selected. The total number of units in the sample is $m = \sum_s m_i$. The population total is then naturally represented in three parts – the total for the observed elements, the total for unobserved elements in sample clusters, and the total for nonsample clusters:

$$T = \sum_{i \in s} \sum_{j \in s_i} Y_{ij} + \sum_{i \in s} \sum_{j \notin s_i} Y_{ij} + \sum_{i \notin s} \sum_{j=1}^{M_i} Y_{ij}. \quad (14)$$

The optimal estimator of T under model (13) is

$$\hat{T}_{\mathrm{BLU}} = \sum_{s} \sum_{s_i} Y_{ij} + \sum_{s} (M_i - m_i)\big[w_i \overline{Y}_{si} + (1 - w_i)\hat{\mu}\big] + \sum_{r} M_i \hat{\mu}, \quad (15)$$

where $w_i = m_i\rho_i/[1+(m_i-1)\rho_i]$, $\overline{Y}_{si} = \sum_{s_i} Y_{ij}/m_i$, and $\hat{\mu}$ is a weighted average of the sample means, $\hat{\mu} = \sum_s u_i \overline{Y}_{si}$, with weights

$$u_i = \frac{m_i \Big/ \left\{\sigma_i^2\,[1+(m_i-1)\rho_i]\right\}}{\sum\limits_s m_i \Big/ \left\{\sigma_i^2\,[1+(m_i-1)\rho_i]\right\}}.$$

Note that the estimator of the nonsample total for each sample cluster in the second term of $\hat{T}_{\mathrm{BLU}}$ is a kind of **composite estimator**.

Because the parameters σ_i^2 and ρ_i must be known or estimated in order to compute $\hat{T}_{\mathrm{BLU}}$, the practical use of this estimator is limited. For that reason, estimators of the form $\hat{T} = (N/n)\sum_{i\in s}\lambda_i\hat{T}_i$ are often used where $\hat{T}_i = M_i\overline{Y}_{si}$ and λ_i is a constant. Note that these will be unbiased under (13) if $(N/n)\sum_{i\in s}\lambda_i M_i = M$. The estimator $\hat{T}_p = (M/n)\sum_s \overline{Y}_{si}$ is in this class, for example (it is also the **Horvitz–Thompson estimator** under a plan in which clusters are selected with probabilities proportional to the cluster sizes M_i and an equal probability sample is selected within each cluster.)

Estimators can also be used for clustered populations that make use of a variety of auxiliary data, in cases in which $\mathrm{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ is appropriate. In many situations in which cluster models and multistage sampling are used, summary auxiliary data on a population may be available even though individual data for all units in the population may not. In a human population, for example, census counts of the number of persons by age, ethnic group, and sex may exist from a recent population census. If those variables are also related to the targets of a survey, regression estimation may be quite useful. The incidence and **prevalence** of some health conditions may depend on demographic characteristics, such as age, ethnic group, and sex, and on geographic place of residence, for instance. When $\mathrm{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, the predictors $\hat{T}_1 = \mathbf{1}_N'\mathbf{X}\hat{\boldsymbol{\beta}}$ and $\hat{T}_2 = \sum_s Y_i + \mathbf{1}_{N-n}'\mathbf{X}_r\hat{\boldsymbol{\beta}}$, with $\hat{\boldsymbol{\beta}} = (\mathbf{X}_s'\mathbf{X}_s)^{-1}\mathbf{X}_s'\mathbf{Y}_s$, are both prediction unbiased. In addition, the vectors $\mathbf{1}_N'\mathbf{X}$ and $\mathbf{1}_{N-n}'\mathbf{X}_r$ are the totals of the auxiliaries for the full population and the nonsample, respectively. If $\mathbf{Y}$ is set equal to $\mathbf{X}$, then $\hat{T}_1$ and $\hat{T}_2$ reproduce these totals – a feature sometimes known as **calibration** in finite population sampling [6] Although generally suboptimal, since they do not account for the covariance structure $\mathrm{var}(\mathbf{Y}) = \mathbf{V}$, $\hat{T}_1$ and $\hat{T}_2$ are practical choices because they do incorporate important auxiliary information and because $\mathbf{V}$ may be unknown and difficult to estimate.

Other Topics

Beyond what has been discussed here, superpopulation models have found many other areas of application in survey sampling. Much of biostatistical data on human populations is qualitative; for example, whether or not a person has a health condition, whether or not a certain medication is used, whether the average daily intake of calories is above a given level, and so on. Natural models for such variables include the **logistic** and other choices for **binary** responses that are often used in analysis of biostatistical data. These models can also be applied when estimating finite population totals [24]. Estimation of cumulative distribution functions and quantiles such as the **median** and first or third quartiles, may also be of interest in studies in which simple descriptive statistics alone do not suffice [2, 7, 8]. More complex, **multivariate analyses** of survey data also call for the use of superpopulation models [22]. A general reference on prediction-based survey sampling is [26].

Support Vector Machines

Introduction

Over the past 10 years, kernel methods such as Support Vector Machines and Gaussian Processes have become a staple for modern statistical estimation and machine learning. The groundwork for this field was laid in the second half of the twentieth century by Vapnik and Chervonenkis (geometrical formulation of an optimal separating hyperplane, capacity measures for margin classifiers), Mangasarian (linear separation by a convex function class), Aronszajn (Reproducing Kernel Hilbert Spaces), Aizerman, Braverman, and Rozonoér (nonlinearity via kernel feature spaces), Arsenin and Tikhonov (regularization and ill-posed problems), and Wahba (regularization in Reproducing Kernel Hilbert Spaces).

However, it took until the early 1990s when positive definite kernels became a popular and viable means of estimation. Firstly, this slow uptake was due to the lack of sufficiently powerful hardware, since kernel methods require the computation of the so-called kernel matrix, which requires quadratic storage in the number of data points (a computer of at least a few megabytes of memory is required to deal with 1000+ points). Secondly, many of the previously mentioned techniques lay dormant or existed independently and only recently the (in hindsight obvious) connections were made to turn this into a practical estimation tool. Nowadays, a variety of good reference books exist and anyone serious about dealing with kernel methods is recommended to consult one of the following works for further information [5, 12, 8, 15]. Below, we will summarize the main ideas of kernel method and support vector machines, building on the summary given in [13].

Learning from Data

One of the fundamental problems of learning theory (*see* **Machine Learning**) is the following: Suppose we are given two classes of objects. We are then faced with a new object, and we have to assign it to one of the two classes. This problem, referred to as *(binary)* **pattern recognition**, can be formalized as follows: we are given empirical data of m pairs

$$(x_1, y_1), \ldots, (x_m, y_m) \in \mathcal{X} \times \{\pm 1\}, \qquad (1)$$

and we want to estimate a *decision function* $f: \mathcal{X} \to \{\pm 1\}$. Here, $\mathcal{X}$ is some nonempty set from which the *patterns* x_i are taken, usually referred to as the *domain*; the y_i are called *labels* or *targets*. A good decision function will have the property that it *generalizes* to unseen data points, achieving a small value of the *risk*

$$R[f] = \int \frac{1}{2}|f(x) - y| \; \mathrm{d}P(x, y). \qquad (2)$$

(*see* **Decision Theory**). In other words, on average over an unknown distribution P that is assumed to generate both training and test data, we would like to have a small error. Here, the error is measured by means of the *zero–one loss function* $c(x, y, f(x)) := 1/2|f(x) - y|$. The loss is 0 if (x, y) is classified correctly, and 1 otherwise.

It should be emphasized that so far, the patterns could be just about anything, and we have made no assumptions on $\mathcal{X}$ other than it being a set endowed with a probability measure P (note that the labels y may, but need not, depend on x in a deterministic fashion). Moreover, (2) does not tell us how to *find* a function with a small risk. In fact, it does not even tell us how to *evaluate* the risk of a given function, since the probability measure P is assumed to be unknown.

We therefore introduce an additional type of structure, pertaining to what we are actually given – the training data. Loosely speaking, to generalize, we want to choose a fitted value $f(x)$ such that $(x, f(x))$ is in some sense similar to the training examples (1), for example, that $|y - f(x)|$ is small. To this end, we need notions of *similarity* in $\mathcal{X}$ and in $\{\pm 1\}$. Characterizing the similarity of the outputs $\{\pm 1\}$ is easy: in binary classification, only two situations can occur: two labels can either be identical or different. The choice of the similarity measure for the inputs, that is, x, on the other hand, is a deep question that lies at the core of the problem of machine learning.

One of the advantages of kernel methods is that the learning **algorithms** developed are quite independent of the choice of the similarity measure (*see* **Similarity, Dissimilarity, and Distance Measure**). This allows us to adapt the latter to the specific problems at hand without the need to reformulate the learning algorithm itself.

Kernels

Let us consider a symmetric similarity measure of the form

$$k: \mathcal{X} \times \mathcal{X} \to \mathbb{R}, \text{ where } (x, x') \mapsto k(x, x'),$$

that is, a function that, given two patterns x and x', returns a real number characterizing their similarity. The function k is often called a *kernel*.

Kernels as Similarity Measures

General similarity measures of this form are rather difficult to study. Let us therefore start from a particularly simple case, the *dot product* $\langle \mathbf{x}, \mathbf{x}' \rangle$, and generalize it subsequently.

The geometric interpretation of the canonical dot product is that it computes the cosine of the angle between the vectors $\mathbf{x}$ and $\mathbf{x}'$, provided they are normalized to length 1. Moreover, it allows computation of the *length* (or *norm*) of a vector $\mathbf{x}$ as

$$\|\mathbf{x}\| = \sqrt{\langle \mathbf{x}, \mathbf{x} \rangle}. \tag{3}$$

Being able to compute dot products amounts to being able to carry out all geometric constructions that can be formulated in terms of angles, lengths and distances. However, this is not really sufficiently general to deal with many interesting problems.

- First, we have deliberately not made the assumption that the patterns actually exist in a dot product space (they could be any kind of object). We therefore first need to represent the patterns as vectors in some dot product space $\mathcal{H}$, called the *feature space* using a map

$$\Phi: \mathcal{X} \to \mathcal{H} \text{ where } x \mapsto \mathbf{x} := \Phi(x). \tag{4}$$

  Note that we use a boldface $\mathbf{x}$ to denote the vectorial representation of x in the feature space.
- Second, even if the original patterns lie in a dot product space, we may still want to consider more general similarity measures obtained by applying the map (4).

Embedding the data into $\mathcal{H}$ via Φ has two main benefits. First, it allows us to deal with the patterns geometrically, and thus lets us study learning algorithms using linear algebra and analytic geometry. Second, it lets us define a similarity measure from the dot product in $\mathcal{H}$,

$$k(x, x') := \langle \mathbf{x}, \mathbf{x}' \rangle = \langle \Phi(x), \Phi(x') \rangle. \tag{5}$$

The freedom to choose the mapping Φ enables us to design a large variety of similarity measures and learning algorithms.

Examples of Kernels

So far, we have used the kernel notation as an abstract similarity measure. We now give some concrete examples of kernels, mainly for the case where the inputs x_i are already taken from a dot product space. The role of the kernel then is to implicitly change the representation of the data into another (usually higher dimensional) feature space. One of the most common kernels used is the polynomial one,

$$k(x, x') = \langle x, x' \rangle^d, \text{ where } d \in \mathbb{N}. \tag{6}$$

It corresponds to a feature space spanned by *all* products of order d of input variables, that is, all products of the form $[x]_{i_1} \cdots [x]_{i_d}$. Hence, the dimension of this space is $O(N^d)$, but since we are using the kernel to evaluate dot products, this does not affect us. Another popular choice is the Gaussian kernel

$$k(x, x') = \exp\left(-\frac{\|x - x'\|^2}{2\,\sigma^2}\right), \tag{7}$$

with a suitable width $\sigma > 0$.

Examples of more sophisticated kernels, defined not on dot product spaces but on discrete objects such as strings, are the string matching kernels proposed in [16] and [7].

In general, there are several ways of deciding whether a given function k qualifies as a valid kernel. One way is to appeal to *Mercer's theorem*. This classical result of functional analysis states that the kernel of a positive definite integral operator can be diagonalized in terms of an **eigenvector** expansion with nonnegative **eigenvalues**. From the expansion, the feature map Φ can explicitly be constructed. Another approach exploits the fact that k is the kernel of a *Reproducing Kernel Hilbert Space*; see [12] for references and details.

Support Vector Classifiers

Statistical Learning Theory shows that it is imperative to restrict the set of functions from which f is chosen to one that has a *capacity* suitable for the amount of available training data. It provides *bounds* on the test error, depending on both the empirical risk and the capacity of the function class. The minimization of these bounds leads to the principle of *structural risk minimization* [15].

Support Vector Machines (SVM) can be considered an approximate implementation of this principle, by trying to minimize a combination of the *training error* (or *empirical risk*),

$$R_{\mathrm{emp}}[f] = \frac{1}{m}\sum_{i=1}^{m}\frac{1}{2}|f(x_i) - y_i|, \tag{8}$$

and a capacity term derived for the class of hyperplanes in a dot product space $\mathcal{H}$ [15],

$$\langle \mathbf{w}, \mathbf{x}\rangle + b = 0 \text{ where } \mathbf{w} \in \mathcal{H}, b \in \mathbb{R}, \tag{9}$$

corresponding to decision functions

$$f(\mathbf{x}) = \mathrm{sgn}\,(\langle \mathbf{w}, \mathbf{x}\rangle + b). \tag{10}$$

Hard Margin Solution

Consider first problems, which are linearly separable. There exists a unique *optimal hyperplane* [15], distinguished by the maximum margin of separation between any training point and the hyperplane. It is the solution of

$$\underset{\mathbf{w}\in\mathcal{H}, b\in\mathbb{R}}{\text{maximize}}\ \min\{\|\mathbf{x} - \mathbf{x}_i\|\ |\mathbf{x} \in \mathcal{H}, \langle \mathbf{w}, \mathbf{x}\rangle + b = 0, i = 1, \ldots, m\}. \tag{11}$$

Moreover, the capacity of the class of separating hyperplanes can be shown to decrease with increasing margin. The latter is the basis of the *statistical* justification of the approach; in addition, it is *computationally* attractive, since we will show below that it can be constructed by solving a quadratic programming problem for which efficient algorithms exist.

As one can see from the example given in Figure 1, in order to construct the optimal hyperplane, we need to solve

$$\underset{\mathbf{w}\in\mathcal{H}, b\in\mathbb{R}}{\text{minimize}}\ \frac{1}{2}\|\mathbf{w}\|^2$$
$$\text{subject to } y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b) \geq 1 \text{ for all } i = 1, \ldots, m. \tag{12}$$

Note that the constraints ensure that $f(\mathbf{x}_i)$ will be $+1$ for $y_i = +1$, and -1 for $y_i = -1$. (One might argue that for this to be the case, we do not actually need the constraint "≥ 1". However, without it, it would not be meaningful to minimize the length of $\mathbf{w}$: to see this, imagine we wrote ">0" instead of "≥ 1." Now assume that the solution is $(\mathbf{w}, b)$. Let us rescale this solution by multiplication with some $0 < \lambda < 1$.

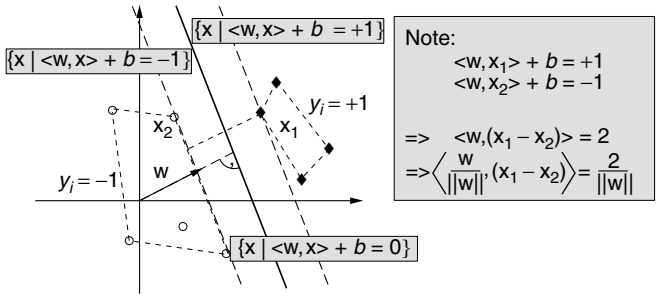

Figure 1 A binary classification toy problem: separate balls from diamonds. The *optimal hyperplane* is shown as a solid line. The problem being separable, there exists a weight vector $\mathbf{w}$ and a threshold b such that $y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b) > 0$ $(i = 1, \ldots, m)$. Rescaling $\mathbf{w}$ and b such that the point(s) closest to the hyperplane satisfy $|\langle \mathbf{w}, \mathbf{x}_i\rangle + b| = 1$, we obtain a *canonical* form $(\mathbf{w}, b)$ of the hyperplane, satisfying $y_i(\langle \mathbf{w}, \mathbf{x}_i\rangle + b) \geq 1$. Note that in this case, the *margin* (the distance of the closest point to the hyperplane) equals $1/\|\mathbf{w}\|$. This can be seen by considering two points $\mathbf{x}_1, \mathbf{x}_2$ on opposite sides of the margin, that is, $\langle \mathbf{w}, \mathbf{x}_1\rangle + b = 1$, $\langle \mathbf{w}, \mathbf{x}_2\rangle + b = -1$, and projecting them onto the hyperplane normal vector $\mathbf{w}/\|\mathbf{w}\|$ (from [12])

Since $\lambda > 0$, the constraints are still satisfied. Since $\lambda < 1$, however, the length of $\mathbf{w}$ has decreased. Hence $(\mathbf{w}, b)$ cannot be the minimizer of (12).)

The constrained **optimization** problem (12) is dealt with by introducing *Lagrange multipliers* $\alpha_i \geq 0$ ($\boldsymbol{\alpha} := (\alpha_1, \ldots, \alpha_m)$) and a *Lagrangian*

$$L(\mathbf{w}, b, \boldsymbol{\alpha}) = \frac{1}{2}\|\mathbf{w}\|^2 - \sum_{i=1}^{m} \alpha_i \left(y_i(\langle \mathbf{x}_i, \mathbf{w}\rangle + b) - 1\right). \tag{13}$$

L has a *saddle point* in $\mathbf{w}, b$, and $\boldsymbol{\alpha}$ at the optimal solution of the primal optimization problem. This means that it should be minimized with respect to the *primal variables* $\mathbf{w}$ and b and maximized with respect to the *dual variables* α_i. Furthermore, the product between constraints and Lagrange multipliers in L vanish at optimality, that is,

$$\alpha_i(y_i(\langle \mathbf{x}_i, \mathbf{w}\rangle + b) - 1) = 0 \text{ for all } i = 1, \ldots, m. \tag{14}$$

To minimize w.r.t. the primal variables, we require

$$\frac{\partial}{\partial b} L(\mathbf{w}, b, \boldsymbol{\alpha}) = -\sum_{i=1}^{m} \alpha_i y_i = 0 \tag{15}$$

$$\frac{\partial}{\partial \mathbf{w}} L(\mathbf{w}, b, \boldsymbol{\alpha}) = \mathbf{w} - \sum_{i=1}^{m} \alpha_i y_i \mathbf{x}_i = 0 \tag{16}$$

The solution thus has an expansion (16) in terms of a subset of the training patterns, namely those patterns with nonzero α_i, called *Support Vectors (SVs)*. Often, only few of the training examples actually end up being SVs.

By the *Karush–Kuhn–Tucker conditions* (14) known from optimization theory, the SVs lie on the margin (cf. Figure 1) – this can be exploited to compute b once the α_i have been found. All remaining training examples $(\mathbf{x}_j, y_j)$ are irrelevant: their constraint $y_j(\langle \mathbf{w}, \mathbf{x}_j \rangle + b) \geq 1$ could just as well be left out. In other words, the hyperplane is completely determined by the patterns closest to it.

By substituting (15) and (16) into the Lagrangian (13), one eliminates the primal variables $\mathbf{w}$ and b, arriving at the so-called *dual optimization problem*, which is the problem usually solved in practice:

$$\begin{aligned} \underset{\boldsymbol{\alpha} \in \mathbb{R}^m}{\text{maximize}} \; & \sum_{i=1}^{m} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{m} \alpha_i \alpha_j y_i y_j K_{ij} \\ \text{subject to } & \alpha_i \geq 0 \text{ for all } i = 1, \ldots, m \\ \text{and } & \sum_{i=1}^{m} \alpha_i y_i = 0. \end{aligned} \tag{17}$$

where $K_{ij} := \langle \mathbf{x}_i, \mathbf{x}_j \rangle$. Using (16), the decision function (10) can thus be written as

$$f(\mathbf{x}) = \operatorname{sgn}\left(\sum_{i=1}^{m} y_i \alpha_i \langle \mathbf{x}, \mathbf{x}_i \rangle + b\right), \tag{18}$$

where b is computed via (14); for details, see [5, 8, 12, 15].

The Kernel Trick

We now have all the tools to describe SVMs. Everything above was formulated in a dot product space, which we think of as the feature space $\mathcal{H}$ (see (4)). To express the formulae in terms of the input patterns in $\mathcal{X}$, we employ (5) and replace $\langle \mathbf{x}, \mathbf{x}' \rangle$ by $k(\mathbf{x}, \mathbf{x}')$ wherever it occurs. This substitution, which is sometimes referred to as the *kernel trick*, was used by Boser et al.. [3] to develop nonlinear SVMs. Now f can be rewritten as

$$f(x) = \operatorname{sgn}\left(\sum_{i=1}^{m} y_i \alpha_i k(x, x_i) + b\right). \tag{19}$$

Furthermore, in the quadratic program (17) the definition of K_{ij} becomes $K_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$. Figure 2 shows a toy example.

Soft Margin Solution

In practice, a separating hyperplane may not exist, for example, if a high noise level causes a large overlap of the classes. To accommodate this case, one introduces slack variables $\xi_i \geq 0$ for all $i = 1, \ldots, m$ in order to relax the constraints of (12) to

$$y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \geq 1 - \xi_i \text{ for all } i = 1, \ldots, m. \tag{20}$$

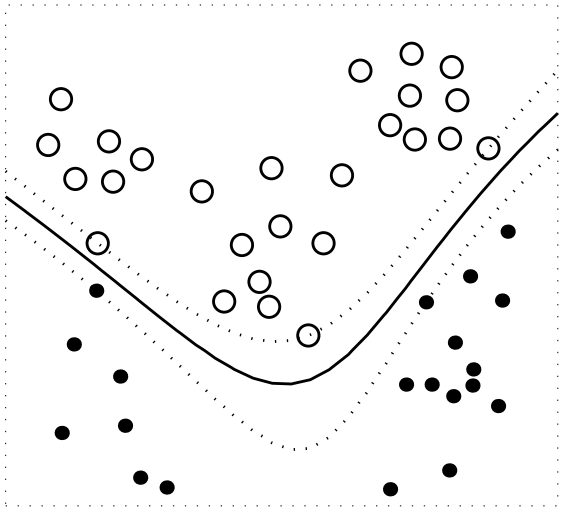

Figure 2 Example of an SV classifier found using a radial basis function kernel $k(x, x') = \exp(-\|x - x'\|^2)$. Circles and points are two classes of training examples; the middle line is the decision surface; the outer lines precisely meet the constraint of (12). Note that the SVs found by the algorithm (sitting on the dotted constraint lines) are not centers of clusters, but examples which are critical for the given classification task (from [13])

A classifier that generalizes well is then found by controlling both the classifier capacity (via $\|\mathbf{w}\|$) and the sum of the slacks $\sum_i \xi_i$. The latter can be shown to provide an upper bound on the number of training errors.

One possible realization of such a *soft margin* classifier is obtained by minimizing the objective function

$$\frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{m}\xi_i \tag{21}$$

subject to the constraints on ξ_i and (20), where the constant $C > 0$ determines the trade off between margin maximization and training error minimization. This again leads to the problem of maximizing (17), subject to modified constraints where the only difference from the separable case is an upper bound C on the Lagrange multipliers α_i.

Another realization uses the more natural ν-parameterization. In it, the parameter C is replaced by a parameter $\nu \in (0, 1]$, which can be shown to provide lower and upper bounds for the fraction of examples that will be SVs, and those that will have nonzero slack variables, respectively.

Its dual can be shown to consist in maximizing the quadratic part of (17), subject to

$$0 \le \alpha_i \le \frac{1}{\nu m}, \quad \sum_i \alpha_i y_i = 0, \text{ and } \sum_i \alpha_i = 1. \tag{22}$$

Discussion

Extensions

The applicability of the "kernel trick" extends significantly beyond the classification setting and in recent years a large number of kernel algorithms have been proposed to solve as diverse tasks as the estimation of the support (or, more generally, quantiles) of a distribution, of a **regression** function, or of a nonlinear manifold. Below, we give a brief overview of the most popular methods:

- Regression: Just as **classification** can be formulated as a quadratic optimization problem, so can regression. Here, the maximum margin condition is replaced by the requirement of finding the *flattest* function, which performs a regression within ε deviation from the observations.
- Principal Component Analysis: It can be extended to nonlinear settings by replacing PCA in input space by a feature space representation. The final algorithm consists of solving an eigenvector problem for the kernel matrix.
  Similar modifications can be carried out to obtain nonlinear versions of projection pursuit, for example, via *sparse kernel feature analysis*.
- Independent Component Analysis: Recently, an algorithm was suggested in [2] to find independent components via a modification of **canonical correlation** analysis. This is currently an active topic of research and it is likely to lead to novel criteria for factorizing distributions.
- Quantiles of a Distribution: In this problem, one attempts to find sets such that the probability of data occurring outside this set is controlled. This is done by ensuring that the set contains a certain fraction of the training data while at the same time keeping the set "simple" (where simplicity is determined by an SVM-style regularization term). This can be done

also for high-dimensional problems, and one can show that it can be cast as a classification problem with only one class. Kernel extensions exist.

- Estimation of Manifolds: Here one aims at finding smooth manifolds which approximate a dataset (i.e. manifolds for which the error incurred by projection of the data onto the manifold is small). Again, one can find optimization problems similar to the SV optimization problem (i.e. a regularization term plus a misprediction cost) and generate a kernel expansion.

These and many more kernel methods plus the corresponding references can be found in [12].

Implementations

An initial weakness of SVMs was that the size of the quadratic programming problem scaled with the number of SVs. This was due to the fact that in (17), the quadratic part contained at least all SVs – the common practice was to extract the SVs by going through the training data in chunks while regularly testing for the possibility that patterns initially not identified as SVs become SVs at a later stage. This procedure is referred to as *chunking*; note that without chunking, the size of the **matrix** in the quadratic part of the objective function would be $m \times m$, where m is the number of all training examples.

What happens if we have a high-noise problem? In this case, many of the slack variables ξ_i become nonzero, and all the corresponding examples become SVs. For this case, decomposition algorithms were proposed on the basis of the observation that not only can we leave out the non-SV examples (the x_i with $\alpha_i = 0$) from the current chunk, but also some of the SVs, especially those that hit the upper boundary ($\alpha_i = C$). The chunks are usually dealt with using quadratic optimizers. Several public domain SV packages and optimizers are listed on `http://www.kernel-machines.org`.

Empirical Results and Applications

Modern SVM implementations made it possible to train on some rather large problems. Success stories include the 60 000 example MNIST digit recognition benchmark (with record results), as well as problems in text categorization and **bioinformatics**, where two main areas of application are worth mentioning:

Firstly, there are classification and gene selection problems in DNA microarray analysis (*see* **Bioinformatics in Functional Genomics**). Given the high dimensionality of the data to begin with, the use of kernels is not advisable in this case. Instead, a linear classifier with a suitable penalty on the expansion coefficients favoring sparse expansions is found; see [4, 6] for further details and references. Finding suitable variable selection criteria is an active area of research (see e.g. [1], which points out substantial problems with the approach taken in [6], mainly due to improper testing). Reference [11] contains further empirical results on SVM performance.

Secondly, sequence analysis can often be cast into the form of a classification problem, requiring the design of custom tailored kernels for this purpose. Such research has led to excellent results (see [9, 7, 17, 16, 14, 10] and the references therein for further details).

Conclusion

During the last few years, SVMs and other kernel methods have rapidly advanced into the standard toolkit of techniques for machine learning and high-dimensional data analysis. This was probably due to a number of advantages compared to **neural networks**, such as the absence of spurious local minima in the optimization procedure, the fact that there are only few parameters to tune, enabling fast deployment in applications, the modularity in the design, where various kernels can be combined with a number of different learning algorithms, and the excellent performance on high-dimensional data.

Surgery

Surgeons have long been on the receiving end of criticism that they have a rather casual approach to the evaluation of new interventions. Pocock [18] discusses the problem from an objective perspective in the context of a discussion of the key role of **randomization**, but Horton [14] puts forward a more emotive argument in an editorial entitled "Surgical research or comic opera: questions but few answers". However, one approaches the issue, there is overwhelming evidence that few surgical procedures have been evaluated using randomized controlled trials [19] (*see* **Clinical Trials, Overview**), and the trials which have been conducted are often woefully inadequate methodologically [12, 17].

The history of surgery is littered with examples of procedures which were described and then widely adopted, only to be dropped when subjected to evaluation. The most recent example of a surgical "bandwagon" is laparoscopic surgery, and laparoscopic cholecystectomy in particular. This example is discussed in detail below.

What is unfair in much of the criticism of the scarcity of landmark trials in surgery is the implication that surgeons are unaware of the problem. Controlled trials in surgery are inherently more complex than drug trials, and numerous articles have been written by surgeons discussing the obstacles to performing trials in surgery. It has also been argued that the randomized clinical trial is not the only tool which can provide useful information on the efficacy of a surgical procedure, and surgical audit in particular is discussed later in this article.

The Necessity of Clinical Trials

Hierarchy of Evidence

Virtually all statisticians, and the large majority of clinicians, would agree that the randomized controlled trial is the **"gold standard"** for the evaluation of medical (and surgical!) interventions. However, it should be recognized that trials are not beyond criticism. In rather emotive terms, an editorial in the *Lancet* [1], which was discussing a proposed trial where one treatment arm involved hysterectomy, asked how we could convince a woman "that it is necessary to sacrifice her womb on the altar of science". The same article argues that trials are unnecessary in situations where "it stands to reason that the new procedure is indeed less risky". One could accept that argument if only there were not so many well-documented examples of procedures which were "obvious" advances until they were actually evaluated. One thinks, for example, of "gastric freezing", internal mammary artery ligation (see below), or extracranial–intracranial arterial anastomosis. This last procedure was widely practiced as a measure to reduce the risk of stroke, until a landmark trial demonstrated that the procedure was ineffective and possibly even harmful [8].

It is worth rehearsing the different sources of evidence on the efficacy of procedures, which were ranked by Chalmers [3] in terms of their credibility:

1. *Clinical impressions*. These should have no place in any scientific evaluation, but they do seem to be a basis for much of what is practiced in medicine.
2. *Case reports and uncontrolled case series*. Around 50% of the articles in leading surgical journals consist of **case series** [14], but their role in evaluation is severely limited. They are subject to **selection bias** and many other potential biases, including, even for surgery, a placebo effect. Their main role should be in refining procedures, and as an aid in screening potentially useful interventions prior to more formal evaluation.
3. *Case series with nonrandomized controls*. Such studies have more potential to provide useful information, but they are still prone to many sources of **bias**. For example, an experimental procedure might be introduced first with "low risk" patients, where the prognosis is atypically favorable. Alternatively, a new procedure, such as laparoscopic cholecystectomy, can be adopted so enthusiastically as to distort the indications for the procedure, so that on average a much fitter group of patients are undergoing the procedure. Comparing outcomes with historical controls then becomes a self-fulfilling prophesy because, of course, results improve when a more fit patient population is treated (*see* **Bias from Historical Controls**).
4. *Randomized controlled trial*. This is the only methodology which can control for the effects of potential biases in selection and evaluation. Any

new pharmacological agent needs to be tested to this level of rigor before it can be approved for marketing, but as yet there are no mechanisms which require "licensing" of surgical procedures.

Case Study – Internal Mammary Artery Ligation

The history of this procedure gives enormous insight into the role of trials in surgery, and also serves to highlight many of the associated problems. A very detailed history can be found in a chapter by Barsamian [2]. It was first proposed in the late nineteenth century that a heart which was receiving an inadequate blood supply via the coronary arteries could have the blood supply augmented through collateral circulation. Based on a number of animal studies and one anecdotal case report, a number of surgeons in the mid 1950s adopted an operation in which the internal mammary artery was ligated (tied off). This was used to treat patients with angina, on the principle that the operation ought to increase the blood supply to the heart. Many patients so treated experienced marked symptomatic improvement, and the operation grew in popularity. However, further animal studies failed to demonstrate any measurable effects on the blood supply, and in an uncontrolled study where 24 patients with angina were told in advance that the operation was experimental and with no physiological basis, it was reported that their response to the treatment was far less impressive. In all but four patients the anginal symptoms returned to their preoperative levels after a brief period of improvement. This suggested strongly that the response to the operation was determined by the patient's expectations, and this was reinforced by a report of two patients whose symptoms improved after an untied ligature was placed around the internal mammary arteries. When the ligatures were subsequently tied, the patients experienced no further improvement in their symptoms.

The issue was finally settled when almost simultaneously two controlled trials were reported. The studies were small (18 and 17 subjects, respectively), but they were randomized and well controlled. Indeed, the control procedure was a sham operation. All patients had their internal mammary arteries exposed, and then according to a random allocation the arteries were ligated or not, and the wound was closed. The results of both studies showed a clear improvement in symptoms in the control group and the ligated group, with no statistically significant difference between the response rates. In spite of the very small numbers, these two controlled trials led very quickly to the operation being abandoned.

This story has a number of profound implications. First, the studies showed unequivocally that surgery can have a placebo effect. This in turn throws severe doubts onto any procedure which is evaluated solely on the basis of an uncontrolled case series. Secondly, there are major ethical difficulties in surgical trials (*see* **Ethics of Randomized Trials**). There does not appear to be any other published clinical trial which has used sham operations as a control, and indeed by current standards of research ethics it is difficult to see that such a study would be regarded as ethical. Thirdly, it shows how quickly a new procedure can become popularized, based on a plausible argument for a mechanism and the most slender of anecdotal evidence.

Obstacles to Clinical Trials in Surgery

As previously mentioned, several authors have described various obstacles to performing clinical trials in surgery. Not all of these reasons are necessarily valid, but their perception as barriers has certainly dissuaded many surgeons from embarking on a clinical trial.

Blinding

The rationale for the controlled clinical trial is that it gives a mechanism which can control bias. The two key concepts which combine to achieve this are randomization and **blinding**. It is therefore a clear obstacle to surgical trials that rather obviously the operating surgeon cannot be blind to the procedure being undertaken! However, it is still possible to achieve the benefits of blinding provided (i) the allocation procedure is blinded in that the individual explaining the study to the patient, assessing the eligibility of the patient, and obtaining informed consent is unaware of the treatment which will be assigned should the patient be enrolled, and (ii) the individual assessing the response to treatment is also unaware of which treatment was allocated. There is no excuse for failing to blind the allocation procedure, and that, incidentally, is the main flaw in allocation schemes

based on apparently "random" mechanisms such as the final digit of a patient's hospital number, or the parity of the date of enrollment (*see* **Randomized Treatment Assignment**).

Blinding of the assessment of response to treatment will not always be straightforward, but ingenuity can help. Majeed et al. [16] describe a randomized comparison of a laparoscopic procedure with an open procedure, where the patients' "wounds" were dressed in an identical fashion, complete with masking bloodstains, irrespective of which procedure was performed. The impact of any loss of blinding on the assessment can also be minimized by the use of objective **outcome measures**, but even here care must be exercised. For example, in a trial of the management of severe head injuries, one might take death within seven days of injury as an end point. Death is a relatively objective end point, but in this context the precise time of death is essentially a function of when it is decided to begin the procedure for assessing brain stem death. It is conceivable that knowledge of the allocated treatment might induce a bias where deaths were delayed until after the 7-day threshold.

Consent

It can easily be seen that, in general, patients will often be unwilling to consent to a trial which involves a random choice between two surgical procedures, or between a surgical procedure and medical management. In a drug trial the effects will usually be reversible, and if a patient receives a drug which results in an undesirable side-effect, then the drug can be discontinued. Similarly, if the patient with a chronic condition is allocated to the drug which is subsequently found inferior, then at the end of the trial they can be switched to the preferred treatment. However, surgical procedures tend to be more permanent, and patients are very likely to have a preference for one or other treatment. For example, in a trial of breast-conserving surgery vs. mastectomy for early breast cancer, it is clear that some women would have a strong preference for mastectomy, to be sure that "all of the cancer is removed". Similarly, other women would have a strong preference for the less mutilating surgery because of concerns for their body image. Both opinions are perfectly valid, and it would be totally unethical to pressure a woman with a strong preference for either treatment to enter the trial. Thus, recruitment rates are likely to be slower than for trials of medical treatments.

It has been argued that the very procedure of seeking consent and implicitly or explicitly admitting uncertainty over what is the most appropriate treatment can undermine the patient's confidence in the surgeon. However, this is an argument which should be countered, since the patient–doctor relationship is totally dependent on each being truthful with the other.

One helpful approach to the problem of conducting a trial in the face of strong preferences for one or other treatment is to perform a patient preference trial, where patients with a clear preference for one type of treatment receive their preferred procedure, and patients with no preference are randomized. This results in a randomized trial together with a large body of supporting evidence which can help to place the randomized trial in context. A further solution which has been put forward is the randomized consent trial.

Surgical Skill

This is the area where surgical trials differ most obviously from drug trials. In general, a drug does not require any great skill to administer, and it is simple to standardize the administration to eliminate any potential effect of the physician. By contrast, surgeons will vary in their levels of skill, experience, and enthusiasm, and inevitably the effect of surgery will be **confounded** with the effect of the surgeon.

One aspect of this issue is the "learning curve", where one could argue that to give a fair assessment of an operation one should only recruit surgeons who are thoroughly familiar with the procedure. This needs to be balanced by an appreciation of how quickly an operation can become "standard practice" without any formal evaluation. If one waits until there are several surgeons fully trained and experienced in a new procedure, then the procedure could easily be so firmly established as to make a trial impractical, or even for a trial to be considered by some to be unethical. Chalmers [4] has argued that, to avoid this bandwagon effect, one should randomize from the very first patient.

A related problem is the question of how to compare two procedures where the surgeons participating in the trial are skilled in one procedure but inexperienced in the other. An extreme form of this

problem is when comparing procedures which would be performed by different specialists, say a conventional surgical procedure vs. a procedure performed by an interventional radiologist. Here, the only feasible design is to randomize the patients to the different specialities, meaning that the comparison of the procedures is completely confounded with the comparison of the individuals. This needs to be considered very carefully when discussing the generalizability of the results. For example, if one is comparing an "average" group of general surgeons with an atypical group of highly skilled and innovative radiologists, then the treatment comparison might be biased in favor of radiology and not generalize when the procedure becomes part of routine radiologic practice.

Technical Points

In addition to the "high-level" obstacles described above, there are several other technical difficulties which can arise in surgical trials. Many of these relate to the choice of an appropriate end point. For routine minor procedures the rate of serious complications will generally be low, but this means that without a very large sample size it would be possible to fail to detect a substantial and clinically relevant increase in the number of serious complications. This sample size issue is very relevant to the discussion of laparoscopic cholecystectomy which follows in the next section.

Another difficulty is in deciding when to assess outcome. In many procedures in surgical oncology the most relevant outcome measure is long-term survival, so there is a risk that a procedure might be obsolete even before it is fully evaluated. A more difficult question arises when the treatments compared attempt to strike different balances between short-term and long-term outcome. Typically, one might be comparing a major operation which has a high rate of early complications, but with the prospect of a long-term cure, against a more conservative procedure which might control local symptoms but compromise long-term prognosis. If such a study is analyzed too soon, then there will be a strong bias in favor of the treatment with the better short-term outcome, which might mask an important long-term benefit.

An extreme example of this problem is the assessment of a prophylactic operation such as carotid endarterectomy, where one operates on an individual thought at high risk of suffering a **stroke** in an attempt to reduce this risk. There is significant morbidity associated with the operation, and so the question is whether it is appropriate to accept the immediate risks of surgery in the hope of avoiding a stroke at some later date.

The example of carotid endarterectomy raises a further important issue, in that the problem is not to evaluate the procedure per se, but to identify patients where the procedure is indicated. There is good evidence that patients with severe stenosis (narrowing) of their internal carotid artery (70%–99% stenosis) do tend to benefit from the procedure, and those with mild stenosis (0%–29%) are more likely to be harmed than to benefit. The key statistical question is therefore not whether carotid endarterectomy is an effective treatment, but rather the problem is to estimate the threshold for percent stenosis above which the procedure is indicated. A refinement of this question would be to individualize this threshold to take account of each patient's constellation of risk factors. Preliminary results of a study of patients with moderate stenoses have been reported [9], but their analysis fails to address directly the question of estimating the threshold which determines whether the operation is indicated.

Case Study – Laparoscopic Cholecystectomy

Cholecystectomy, or removal of the gall bladder, is a very common surgical procedure. In the US, for example, approximately 500 000 such operations are performed annually. In the early 1980s a number of surgeons began experimenting with performing this operation laparoscopically rather than through a conventional incision, and by the early 1990s the laparoscopic approach had become so popular that several audits reported that over 80% of cholecystectomies were performed laparoscopically. The perceived advantages included less postoperative pain, a smaller scar, a shorter hospital stay, and a quicker return to normal activities. Indeed, the laparoscopic procedure is seen as such an advance over conventional surgery that the indications for cholecystectomy have been relaxed, and an increase of over 20% has been observed in the number of cholecystectomies performed.

In spite of the huge number of procedures performed worldwide, there is a remarkable dearth of scientifically secure data to evaluate the new approach. Cuschieri [6], one of the leading

proponents of laparoscopic surgery, has called the explosive growth in uptake of the new procedure "the greatest unaudited free-for-all in the history of surgery".

A recent review [7] identified 841 articles specifically on laparoscopic cholecystectomy published between January 1987 and October 1994. Of these 841 articles, only 15 were randomized trials, and of these, only three contained at least 50 patients in each group. Between 1994 and 1996 there have been over 1500 publications in English on laparoscopic surgery in general, but only 11 report randomized trials large enough to allow useful comparisons [15]. This is quite extraordinary given the number of procedures which are performed annually, and given that much of the debate over laparoscopic cholecystectomy centers around the risk of bile duct injury. This is a serious complication, but with an incidence of 1% or less. Clearly, to make a useful comparative statement about such a low complication rate would require a study of several thousand patients. However, it must be stressed that, for such a common procedure, which is generally performed to relieve symptoms in otherwise fit individuals, a complication rate of 1% is clinically important. Moreover, given the large number of procedures being undertaken, it would be eminently feasible to perform a trial based on several thousand individuals.

It is only now, ten years after the enthusiastic and widespread adoption of laparoscopic cholecystectomy, that a more balanced picture of the costs and benefits is beginning to emerge (*see* **Health Economics**). An influential randomized trial by Majeed et al. [16] used blinded assessment techniques to assess rates of recovery and length of hospital stay, and observed no difference between laparoscopic cholecystectomy and small-incision cholecystectomy. A number of audits have suggested that laparoscopic cholecystectomy is associated with approximately a twofold increase in bile duct injury and in other complications requiring readmission to hospital. Johnson [15] concludes his discussion of laparoscopic surgery by saying

> Laparoscopic surgery is not easier, quicker, cheaper, or safer; nor does it avoid general anesthetic. It may lead to a shorter initial hospital stay but readmissions for complications and other procedures have to be added. [...] Laparoscopic surgery [...] must be classified as an expensive luxury rather than a surgical revolution.

Surgical Audit

As discussed above, the randomized clinical trial should be regarded as the "gold standard" for the evaluation of surgical interventions. However, as also mentioned above, one of the most difficult variables to handle is the skill of the individual surgeon. In what has been an enormously influential paper, Fielding et al. [10] reported data from the Large-Bowel Cancer Project which showed dramatic differences between surgeons in the rate of breakdown of anastomoses (i.e. surgical joins of the bowel). In the summary of that paper it is stated

> The data in the current study show that the surgeon who has clinical responsibility for the care of the patient is probably the most important single factor influencing anastomotic integrity. Such a statement about surgical technique may be thought controversial, but there is a sixfold range of results (about 5–30%) that cannot be accounted for by any obvious differences in patient population.

If such results are indeed representative of surgery in general, then we could be straining at gnats when conducting trials looking for subtle differences between two variants of the same procedure, when the surgical outcome is largely determined by the responsible surgeon.

In certain unusual situations it might be feasible to conduct a randomized trial which compared different surgeons undertaking the same procedure, but the assessment of individual performance, which is termed "surgical audit", is generally undertaken less formally. There is a very large literature on surgical audit, and a review by Hayes & Murray [13] gives many of the key references. Surgical audit has many parallels with the equally controversial topic of school league tables (*see* **Quality of Care**), and a review of the statistical issues underlying both medical and school league tables is given by Goldstein & Spiegelhalter [11]. This paper brings out the idea of **multilevel modeling**, which is very relevant in a context where the data can have a clear hierarchical structure – with, say, data on individual patients, under the care of an individual consultant, working as part of a surgical team, within a hospital, within an administrative region (*see* **Hierarchical Models**).

The history of surgical audit goes back to at least the 1850s, when **Florence Nightingale** was working during the Crimean War. Throughout the first half of

the twentieth century surgical audit was developed in the US, very much from the point of view of regulation, and without notable success. An excellent review of these early historical developments is given by Wilkin & McColl [20]. There is also a long history of surgical audit in the UK, but always with more of an emphasis on education than on the "big stick". The Royal College of Surgeons of England now hosts a Surgical Epidemiology and Audit Unit, and provides a Comparative Audit Service.

The fundamental problem with all clinical audits is that one does not compare like with like. Differences in **case mix** confound direct comparisons of outcome, but this does not prevent such misleading data being sensationalized in the media. Many attempts have been made to build statistical models which can adjust for case mix, and hence give a better measure of "added value". The paper by Hayes & Murray [13] describes some of the better known scoring systems, and highlights some of their limitations. The POSSUM Score [5] is one scoring system which has been developed specifically for general surgery. It can be used either to identify patients whose outcome was unexpected, so that the case can be reviewed in detail, or else to compare the expected outcomes in a series of patients with the outcomes which were actually observed. POSSUM requires a large volume of data to be recorded, but it is claimed that the system can work in practice. One problem with the system is that the model is not well calibrated, and, in particular, the predicted risk of death cannot be below 1.08%, no matter how fit the patient or how trivial the operative procedure. Perhaps more seriously, some of the factors which are included in the model, such as blood loss, may actually reflect surgical competence. Thus one is assessing competence, adjusting for competence, which rather defeats the purpose!

No system for case mix adjustment is ever going to be perfect, but equally it seems likely that the demand for "league tables" will continue to grow. Certainly within the UK there is a growing requirement for purchasers of health care to be able to measure quality, and so further research into how best to adjust performance indicators for case mix needs to be a priority. Equally there is a pressing need to educate the consumers of "league tables" of their limitations, even after correction for case mix.

Surrogate Endpoints

The selection of the primary "outcome measures" or "endpoints" is a very important step in the design of **clinical trials** (*see* **Outcome Measures in Clinical Trials**). Typically, the primary goal of the clinical trial is to assess definitively a treatment's effect on these endpoints. Two major criteria should guide their selection. The endpoints should (i) be sensitive to treatment effects and (ii) be clinically relevant. Adequate attention is usually given to ensuring that the first criterion is satisfied. Unfortunately, ensuring that the endpoints also satisfy the criterion of clinical relevance is often improperly addressed. We focus on this second criterion and the corresponding controversial issues arising when surrogate endpoints are used as study outcomes.

The nature of clinical relevance depends on the stage of clinical experimentation. In **Phase II trials**, which provide a screening evaluation of treatment effect, the primary objective usually is to assess a treatment's *biological activity*. Relevant endpoints in such a trial in cancer patients might be measures of tumor shrinkage; in HIV-infected persons, measures of viral load or immune function; and in patients with cardiovascular disease, blood pressure or lipid levels. In contrast, in Phase III clinical trials, where the intent is to define the role of a therapy in standard clinical practice, the primary objective should be to assess the treatment's *clinical efficacy* through outcome measures that unequivocally reflect tangible benefit to the patient. In the treatment of patients with life-threatening diseases, such clinical efficacy measures include improvement in the duration of survival or in the **quality of life** (QOL).

Often, there is a sense of urgency in the evaluation of promising new interventions for patients having life-threatening diseases. When survival is the primary endpoint, clinical trials frequently require large sample sizes and very lengthy intervals of follow-up. The subjective nature of QOL outcome measures presents additional difficulties through the need to identify validated and widely accepted QOL instruments. To reduce the trial cost, size, and duration and to avoid complexities of QOL assessments, considerable attention has been given, in the design of definitive Phase III trials, to identifying surrogate or replacement endpoints for the true clinical efficacy endpoint. As defined by Temple [21],

> a surrogate endpoint of a clinical trial is a laboratory measurement or a physical sign used as a substitute for a clinically meaningful endpoint that measures directly how a patient feels, functions or survives. Changes induced by a therapy on a surrogate endpoint are expected to reflect changes in a clinically meaningful endpoint.

Measures of biological activity have been chosen frequently as surrogates because usually they are readily available early in a clinical trial and because often they are strongly correlated with clinical efficacy.

Unfortunately, treatment effects on the clinical efficacy endpoints may not be predicted reliably by the observed effects on surrogate endpoints, even when natural history data reveal that these surrogates are strongly correlated with the clinical efficacy outcomes. As indicated by Fleming & DeMets [9], there are several possible explanations for this failure.

> Even though a surrogate endpoint may be a correlate of disease progression, it might not involve the same pathophysiologic process that results in the clinical outcome. Even when it does, it is likely there are disease pathways causally related to the clinical outcome and yet unrelated to the surrogate endpoint. Of the disease pathways affecting the true clinical outcome, the intervention may only affect (i) the pathway mediated through the surrogate endpoint or (ii) the pathway(s) independent of the surrogate endpoint. Most importantly, the intervention might also affect the true clinical outcome by unintended mechanisms of action independent of the disease process. The intervention's effects mediated through intended mechanisms could be substantially offset by an array of mechanisms that are unintended, unanticipated and unrecognized.

The example of lipid-lowering agents clearly illustrates the existence and impact of these unintended mechanisms. In a comprehensive overview of 50 randomized trials (*see* **Meta-analysis of Clinical Trials**) of cholesterol-lowering agents by Gordon [12], an average reduction in cholesterol of 10% was achieved along with an intended 9% reduction in coronary heart disease (CHD) mortality. However, overall mortality was unchanged, due to an unintended 24% increase in non-CHD mortality.

Illustrations

Research across a broad array of clinical settings confirms that many powerful correlates of clinical

efficacy outcomes have been poor surrogates for true clinical efficacy [8, 9]. Anti-arrhythmic drugs effectively suppress ventricular arrhythmias after myocardial infarction (MI), yet lead to more than three-fold increases in death rate. Drugs improving cardiac output as treatment for congestive heart failure have increased mortality. The rate of vessel reperfusion has not predicted adequately the effect of thrombolytic therapies on mortality. Cholesterol-lowering interventions, such as diet, fibrates, hormones, resins, and lovastatin, have not lowered mortality rates. Antihypertensive calcium channel blockers reduce blood pressure, but now appear to increase the risk of myocardial infarction. Calcium antagonists reduce the risk of developing new angiographic lesions of atherosclerosis in patients with MI, yet increase the death rate. Sodium fluoride increases bone mineral density in postmenopausal women with osteoporosis, yet substantially increases the risk of bone fractures. In patients with retinitis pigmentosa, vitamin A provides a favorable slowing of decline on electroretinograms, yet has no effect on any direct measure of visual function. In addition to these **false positive** leads, surrogates can provide **false negative** leads as well. Gamma interferon fails to have a measurable effect on superoxide production and bacterial killing in children with chronic granulomatous disease, yet substantially reduces the rate of serious life-threatening infection.

Validation of Surrogates

Proper validation of a surrogate endpoint is a difficult task. Insights about validity can be provided by empiric evidence from an array of clinical trials documenting treatment effects on both surrogate and clinical efficacy endpoints, as well as by a thorough biological understanding of causal pathways in the disease process and of mechanisms of treatment effect (*see* **Causation**).

Prentice [19] provides a definition of a valid surrogate, and gives two sufficient conditions that jointly ensure this validity, thereby providing guidance for how one might approach using empiric evidence to assess validation. By his definition, a surrogate is valid if "a test of the null hypothesis of no relationship (of the surrogate endpoint) to the treatment groups must also be a valid test of the corresponding null hypotheses based on the true endpoint". Prentice's first condition to ensure this validity is the "correlate" requirement, i.e. a valid surrogate endpoint must be **correlated** with the true clinical endpoint. This condition usually holds since, in practice, potential surrogates are often selected by identifying measures that are strongly correlated with clinical efficacy endpoints. Prentice's very restrictive second condition requires the surrogate to capture fully the treatment's "net effect" on the clinical endpoint, where the net effect is the aggregate effect accounting for all mechanisms of action. The restrictiveness of this condition provides important insight into why correlates are rarely valid surrogates. In applications, extensive analyses have been performed to assess surrogacy of CD4 cell count, using data from several large clinical trials evaluating nucleoside analogs in HIV/AIDS patients. While these analyses show consistently that CD4 cell count is a correlate of the "progression to symptomatic AIDS or death" endpoint, thereby satisfying Prentice's first condition, CD4 has not been established as a valid surrogate endpoint, since the second condition of Prentice consistently fails to hold [3, 6, 14, 15, 22].

The validity of Prentice's restrictive second condition, requiring a surrogate to capture fully the net effect of an intervention on the clinical efficacy endpoint, has been explored by Freedman et al. [11] in an epidemiologic setting. Their methods involve estimating the proportion of the net treatment effect apparently captured by the marker, allowing assessment of the strength of evidence about whether this proportion is near unity. It should be recognized, however, that while particular interest often is in evaluating the effect of treatment on the disease process pathway(s) causally inducing the clinical events, it is not possible to determine the proportion, p, of that effect that is accounted for by effects on a surrogate endpoint [20]. To demonstrate how this nonidentifiability arises, DeGruttola et al. [7] consider a simple example in which the clinical efficacy endpoint is death and where, on the control regimen, the death rate induced by the causal pathways of the disease process is μ_h, while the death rate due to other causes is μ_o. They suppose further that the experimental intervention alters the death rate induced by the causal pathways of the disease process by the multiplicative factor r, to $r\mu_h$, but increases the death rate due to other causes (including those influenced by unintended mechanisms of the drug) by the multiplicative factor k, to $k\mu_o$. If it is assumed that

the treatment-induced change in the surrogate endpoint would only influence the death rate induced by the causal pathways of the disease process, then this change would alter the overall death rate by a multiplicative factor

$$r_{so} = \frac{(\mu_h + \mu_o) - p(1-r)\mu_h}{\mu_h + \mu_o}. \quad (1)$$

This parameter r_{so} can be measured using data on **control** patients from the study itself or natural history databases that allow modeling the association of death with surrogate endpoints. One can also measure the observed overall "net effect" of the intervention on death rate,

$$r_o = \frac{r\mu_h + k\mu_o}{\mu_h + \mu_o} \quad (2)$$

and, using (1) and (2), can compute the observed portion of the net effect accounted for by the treatment-induced change in the surrogate endpoint,

$$p_o = \frac{1 - r_{so}}{1 - r_o} = \frac{p(1-r)\mu_h}{(1-r)\mu_h + (1-k)\mu_o}. \quad (3)$$

By (3), $p_o = p$ if either $\mu_o = 0$ (i.e. death can only be caused by the causal pathways of the disease process) or $k = 1$ (i.e. the intervention has no effect on the other causes of death). However, in the more common setting where $\mu_o > 0$ and $k > 1$, even when $p \gg 1$, the observed proportion p_o approaches unity as k approaches $[1 + (\mu_h/\mu_o)(1-r)(1-p)]$. Thus, surrogate endpoints, which capture only a small fraction of the change in the death rate induced by treatment effects on the causal pathways of the disease process, may appear to capture an observed portion, p_o, near unity, simply due to unanticipated and unrecognized harmful effects of the intervention on the other causes of death.

To formulate estimators of p_o in epidemiologic data, Freedman et al. [11] used linear **logistic regression** models, while Choi et al. [3], O'Brien et al. [17] and DeGruttola et al. [7] used **proportional hazards** models to conduct similar analyses in the setting of **censored** failure time data. Specifically, these three sets of authors assume that the failure rate at time t in treatment group Z is

$$\lambda(t|Z) = \lambda_o(t)\exp(\beta Z), \quad (4)$$

where $Z = 0$ for control and $Z = 1$ for experimental treatment, β is an unknown constant, and $\lambda_o(t)$ is an arbitrary positive function. From (2) and (4), the "net treatment effect" is $r_o = e^{\beta}$. In turn, incorporating the effect of the surrogate $X(t)$ on the failure rate at time t, DeGruttola et al. [7] assume the model

$$\lambda[t|Z, X(t)] = \tilde{\lambda}_o(t)\exp(\beta_a Z)\exp[\alpha X(t)], \quad (5)$$

where β_a and α are unknown constants, and $\tilde{\lambda}_o$ is an arbitrary positive function that might differ from λ_o. Strictly speaking, models (4) and (5) cannot hold simultaneously; however, they may hold approximately when either α or $\int \tilde{\lambda}_o(t)$ is small. We will assume that the effects of model **misspecification** are negligible (see Lin et al. [16] for a rigorous discussion of this issue). By (4) and (5),

$$r_{so} = \exp(\beta - \beta_a).$$

Thus,

$$p_o = \frac{1 - \exp(\beta - \beta_a)}{1 - e^{\beta}}.$$

Freedman et al. [11] approximate p_o by

$$p_o^* = 1 - \frac{\beta_a}{\beta}.$$

The two quantities, p_o and p_o^*, are equivalent when $\beta_a = \beta$ or $\beta_a = 0$, and differ only slightly for intermediate values. Of course, as shown above, the quantities are equal to p only in very special cases. Note that while p, the proportion of the intended effect on causal pathways of the disease process captured by the surrogate, is always a proportion in the mathematical sense of lying in the interval [0, 1], p_o need not lie in the interval [0, 1]. When β_a and β differ in sign (a situation that arises when the surrogate captures all of the benefit so that only the harmful effect is reflected in β_a), p_o exceeds 1; when $\beta_a > \beta > 0$, p_o is negative.

The problems of interpretation of p_o and p_o^* are compounded by the high variability of their estimators [11]. Let $\hat{\beta}$ and $\hat{\beta}_a$ denote the estimates of β and β_a, obtained by the usual method of maximum **partial likelihood**. Then p_o^* is estimated by

$$\hat{p}_o^* = 1 - \frac{\hat{\beta}_a}{\hat{\beta}}.$$

Lin et al. [16] showed that, for large samples, $\hat{p}_{\mathrm{o}}^{*}$ is approximately normal with **mean** p_{o}^{*} and with **variance**

$$\sigma^2 = \frac{V_\beta}{\beta^2}\left\{\frac{V_{\beta_{\mathrm{a}}}}{V_\beta} + (1-p_{\mathrm{o}}^{*})^2 - 2(1-p_{\mathrm{o}}^{*})\frac{V_{\beta\beta_{\mathrm{a}}}}{V_\beta}\right\}, \tag{6}$$

where V_β and V_{β_a} are the variances of $\hat{\beta}$ and $\hat{\beta}_{\mathrm{a}}$, and $V_{\beta\beta_a}$ is their covariance.

Formula (6) indicates that the factors that determine the variance of $\hat{p}_{\mathrm{o}}^{*}$ include the coefficient of variation for β (i.e. the inverse of the unadjusted treatment effect relative to its **standard error**), the value of p_{o}^{*} itself, and the values of $V_{\beta_{\mathrm{a}}}$ and $V_{\beta\beta_{\mathrm{a}}}$ relative to V_β. For illustration, suppose α is small and the correlation between treatment and marker is low. Then $V_\beta \approx V_{\beta_{\mathrm{a}}} \approx V_{\beta\beta_{\mathrm{a}}}$, in which case

$$\sigma \approx |p_{\mathrm{o}}^{*}|\frac{\mathrm{se}(\hat{\beta})}{|\beta|}. \tag{7}$$

Suppose that we have a large unadjusted treatment effect which is four times its standard error, i.e. $\beta/\mathrm{se}(\hat{\beta}) = 4$. Then (7) implies that the mean width of the 95% **confidence interval** for p_{o}^{*} is equal to p_{o}^{*} itself. In practice, (7) tends to underestimate the true variability of $\hat{p}_{\mathrm{o}}^{*}$ because $V_{\beta_{\mathrm{a}}}$ is generally larger than V_β. The estimate $\hat{\beta}_{\mathrm{a}}$ becomes increasingly unstable as the correlation between treatment and marker increases. (An extreme scenario occurs when, in a placebo-controlled trial of a treatment, all treated and no untreated patients have a marker response.) Thus, an unadjusted treatment effect that is greater than four times its standard error is a necessary, though insufficient, condition for precise estimation of p_{o}^{*}. Similar observations are made by Freedman et al. [11].

Clinical studies with treatment effects that are many times their standard errors are unusual, because studies with large treatment effects tend to be stopped early, and because most studies do not compare treatments with greatly different degrees of efficacy. Thus, meta-analyses that combine evidence across studies usually would be required for statistical evaluation of the reliability of surrogate endpoints.

There are a number of ways to make use of data collected across studies. The first is simply to estimate p_{o}^{*} (and its associated variance) corresponding to a given surrogate for each individual study, and examine the consistency of these estimates. This may be especially useful when there have been a variety of treatments under study, with differing mechanisms of action and toxicity profiles. More formally, one could treat the true values of the p_{o}^{*} for each study as latent variables, and estimate their underlying distribution (or features of the distribution) across studies. In settings where p_{o}^{*} appears to be highly variable across studies, it might be of interest to assess whether such factors as class of drug or population under study explain this variability. While such efforts are not free from the problems of **identifiability** described earlier, values of p_{o}^{*} that are consistently near 1 for studies investigating different classes of treatments may provide more persuasive evidence about the validity of a surrogate than do results from individual studies. An alternative approach to using data across studies, proposed by Daniels & Hughes [5], uses **Bayesian methods** to construct prediction intervals for the true difference in clinical outcome associated with a given estimated treatment effect on the potential surrogate.

A factor that further complicates analyses of surrogacy, especially analyses across studies, is that marker values are generally not measured continuously or without error. **Measurement error** and the fact that marker values are available only at certain times – times that are often influenced by the disease under study – can result in **bias** in the estimation of α, and hence of β and p_{o}^{*}. Tsiatis et al. [22] explored methods for correcting for bias resulting from issues related to measurement.

Auxiliary Variables

Rather than serving as surrogates to replace clinical efficacy endpoints, response variables, such as the measures of biological activity discussed earlier, can be used to strengthen clinical efficacy analyses. Such variables, S, are then called *auxiliary*. Suppose one's interest is in the effect of treatment on time to a clinical endpoint, T. Suppose, furthermore, that the auxiliary information, S, is readily observed, whereas T is **censored** in a substantial fraction of the patients because they have relatively late clinical endpoints. If S and T are strongly correlated, one can expect that S will provide useful additional information about the timing of the clinical endpoint for those patients in which T is censored.

Three approaches have been proposed for using auxiliary variables, and are referred to as "variance

reduction", "augmented score" and "estimated likelihood". The variance reduction method, explored by Kosorok & Fleming [13], is applicable when S is a time-to-event endpoint and when the treatment relationship with S is described by a statistic X with zero mean, such that $\text{cor}(X, Y) \equiv \rho$ is positive, where Y is a standard statistic used to assess the effect of treatment on T. The statistic $Y - \rho X$ proposed by Kosorok & Fleming makes use of auxiliary information to provide a variance-reduced alternative to using Y.

The "augmented score" and "estimated likelihood" methods were explored by Fleming et al. [10]. Both approaches assume the proportional hazards model of (4) for the relationship between the covariate vector Z and the **hazard** function for the clinical outcome T. Denote the **cumulative hazard** for λ_o by Λ_0. Assume T_i and U_i are independent latent failure and censoring variables for the ith patient ($i = 1, \ldots, n$), and denote $X_i = \min\{T_i, U_i\}$ and $\delta_i = I_{\{X_i = T_i\}}$, where $I_{\{A\}}$ denotes an indicator for A.

To motivate the "augmented score" approach, recall that in the **semiparametric regression** setting where λ_o is unspecified, the Cox [4] maximum *partial likelihood* estimate of β is obtained by solving the score estimating equation:

$$\sum_{i=1}^{n} Z_i \hat{M}_i(X_i|\beta) = 0, \tag{8}$$

where, for any $t \geq 0$,

$$\hat{M}_i(t|\beta) = I_{\{T_i \leq t\}} - \exp(\beta' Z_i)\hat{\Lambda}_0(t \wedge T_i)$$

is the martingale residual (*see* **Counting Process Methods in Survival Analysis**) evaluated at β, and where $\hat{\Lambda}_0$ is the semiparametric Breslow [1] estimator of Λ_0 evaluated at β.

Censorship reduces the information available in (8) that is used for the estimation of β. Specifically, $\hat{M}_i(t|\beta)$ is only known over $t \in [0, X_i]$ rather than over $t \in [0, T_i]$ and, in (8), less information is available to formulate $\hat{\Lambda}_0$. Fortunately, the surrogate information, S_i, does allow recovery of some of this lost information. Suppose τ denotes some arbitrary large time. To recover some information over $(X_i, \tau]$ for a censored case (i.e. with $\delta_i = 0$), consider

$$e_{\hat{M}_i}(\beta) \equiv \text{E}[\hat{M}_i(\tau|\beta) - \hat{M}_i(X_i|\beta)|X_i, \delta_i = 0, S_i],$$

which essentially is the conditional expectation of the lost information over $(X_i, \tau]$, given available information on case i to X_i. Fleming et al. [10] formulate an estimator $\hat{e}_{\hat{M}_i}(\beta)$ in the special case in which S_i is a censored time-to-event endpoint, and propose estimation of β based on solving the "augmented score equation":

$$\sum_{i-1}^{n} Z_i \hat{M}_i(X_i|\beta) + \sum_{i=1}^{n} (1 - \delta_i) I_{\{X_i < \tau\}} Z_i \hat{e}_{\hat{M}_i}(\beta) = 0.$$

In the "estimated likelihood" approach, following Pepe's [18] semiparametric approach in which λ_o temporarily is assumed to be known and that involves **nonparametric** estimation of $P(S|T, Z)$ to obtain greater **robustness**, the corresponding estimated **likelihood** is

$$\hat{L}(\beta) = \prod_{\delta_i=1} P_\beta(T_i|Z_i) \prod_{\delta_i=0} P_\beta(T > X_i|Z_i) \times \prod_{\delta_i=0} \hat{P}_\beta(S_i|T > X_i, Z_i), \tag{9}$$

where S_i can be an arbitrary right-censored vector-valued process providing auxiliary information. The first two terms on the right-hand side of (9) represent the usual likelihood when the auxiliary information, S, is not taken into account. Under (4), these two terms reduce to the usual Cox partial likelihood when λ_o is considered to be unspecified and, in turn, is estimated by the piecewise linear approach presented in Breslow [2]. Turning to the third term in the estimated likelihood in (9), the amount of improvement provided by the estimated likelihood relative to the usual partial likelihood depends on the degree of dependence of $P_\beta(S_i|t, Z_i)$ on t.

Improvements in efficiency with these approaches using auxiliary information are likely to be small unless S and T are highly correlated and unless there is one pool of patients having longer-term follow-up and another pool of patients with auxiliary information but with relatively short-term follow-up on the clinical endpoint. In spite of these limitations, approaches using auxiliary information are of interest since they avoid the substantial risks for false positive or false negative conclusions that arise when surrogate endpoints are used to replace measures of clinical efficacy.

Conclusions

It would be rare to be able to establish rigorously the validity of a surrogate endpoint. False positive and false negative error rates in definitive trials evaluating intervention effects on clinical outcomes are required to be very low, typically in the range of 2.5% to 10%. Hence, to be a valid replacement endpoint, a surrogate must provide a very high level of accuracy in predicting the intervention's effect on the true clinical endpoint. Predictions having an accuracy of approximately 50%, such as was provided by the CD4 surrogate in the HIV setting (see Fleming [8]), are as uninformative as random tosses of a coin. The statistical methods for validation discussed in this article usually require meta-analyses since the sample sizes needed are much larger than those necessary for the typical phase III evaluation of interventions (*see* **Sample Size Determination for Clinical Trials**). Proper validation of surrogates also requires in-depth understanding of the causal pathways of the disease process, as well as the intervention's intended and unintended mechanisms of action. Such in-depth insights are rarely achievable.

Surrogate endpoints should be used in screening for promising new therapies through the evaluation of biological activity in preliminary Phase II trials. Results of such studies can guide decisions about whether the intervention is sufficiently promising to justify the conduct of large-scale and longer-term clinical trials. In these definitive Phase III trials, while information on surrogate endpoints can provide valuable additional insights about the intervention's mechanisms of action, the primary goal should be to obtain direct evidence about the intervention's effect on safety and clinical outcomes.

Surveillance of Diseases

Modern public health surveillance of disease has been defined by Langmuir [14] as "the continued watchfulness over the distribution and trends of incidence through the systematic collection, consolidation and evaluation of morbidity and mortality reports and other relevant data". It is now usual to add to this definition the final link of applying these data to prevention and control [26]. But this public health activity is not new. One of the earliest examples of population surveillance was that developed in the City of London in the sixteenth and seventeenth centuries to detect plague, so that the City Fathers could decide when to close theaters and limit the assembly of crowds, and the Royal Court could leave for the countryside [31]. Data on plague deaths were collected by parish clerks, summated each week and reported in the "Bills of Mortality". The system neatly illustrates the steps in surveillance, which are the systematic collection of data, analyses to produce statistics, interpretation to provide information–which is then reported fast enough so that action can be taken–followed by continuing surveillance to evaluate the success of the action.

The concept of surveillance is simple, but in practice there is a tendency for surveillance systems to drift from their original objectives and too easily lose their focus on public health action–"Reporting does not equal surveillance". It is therefore important that surveillance as a dynamic public health activity is distinguished from managing registries (*see* **Disease Registers**) and other health information systems such as registrations of births and deaths (*see* **Vital Statistics, Overview**), though these may be useful data sources for surveillance. It is also important to recognize that public health surveillance differs from epidemiologic research in a number of important ways [24] (Table 1). The need for ongoing reporting (which distinguishes surveillance from occasional **surveys**) to provide information for action requires that surveillance systems are simple in construction, place minimal demands on data providers, and report accurate, readily understood, and timely information. Systems have often degenerated because data requirements have not been agreed with data providers and have become overburdened with secondary objectives. Consequent failure to report in a timely way had led to the loss of credibility with data providers. Recent successful infectious disease surveillance systems have used electronic reporting to minimize the burden on data providers and provide high-quality, rapid reporting [11, 29].

Guidelines on the evaluation of surveillance systems have been proposed by the **Centers for Disease Control (CDC)** [13], although few national systems appear to have been audited as recommended. The criteria include:

1. a description of the *public health importance* of the health event, including incidence and **prevalence**, severity of disease as measured by mortality rates and **case fatality** rates, and preventability;
2. a description of *the system*, including the objectives, the population under surveillance, case definitions, a flowchart of data collection, details of data transfer, data analyses, and dissemination of information;
3. a measure of the *usefulness* of the surveillance system, including decisions and actions taken as a result of the information generated;
4. evaluation of *key attributes* of the system, including simplicity, flexibility, acceptability, **sensitivity, positive predictive value**, representativeness, and timeliness;
5. the *cost* of the system.

Surveillance Systems

Up until the 1960s, public health surveillance activities were developed mainly for infectious disease control (*see* **Communicable Diseases**). Since then surveillance has been applied to many diseases, including congenital malformations (*see* **Teratology**), injuries, occupational illness (*see* **Occupational Epidemiology**), and adverse drug reactions (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**), principally through the work of Langmuir at CDC [25]. Similar approaches have been taken to the surveillance of uptake of vaccines, and the surveillance of hazards, such as chemical accidents and the surveillance of behavioral risk factors [9]. Surveillance systems for chronic diseases have been less well developed [26]. Specific objectives of surveillance include:

1. early detection of changes in disease or risk factor prevalence and incidence to trigger rapid investigation and control;

Table 1 Distinctions between public health surveillance and epidemiologic research (adapted from Thacker & Berkelman [24])

	Surveillance	Epidemiologic research
Main purpose	Problem detection Problem description Trigger either investigation or intervention Suggest hypotheses	Hypothesis testing Problem description
Data collection		
Frequency	Ongoing	Time-limited
Methods	Normally routine systems study	Specially tailored for
Volume of data	Minimal	Considerable
Completeness of data	Often incomplete	Usually complete
Data analyses	Usually simple and descriptive	Often complex
Dissemination of information	Timely, regular, targeted to public health agencies	Not timely, sporadic, targeted to academics and clinical audience

2. measuring trends in disease, hazards, microbial agents, and risk factors to set priorities for interventions, and to evaluate disease-control programs;
3. to describe the basic epidemiology and natural history of disease in order to develop hypotheses about **causation**, which can be tested by separate research studies (*see* **Descriptive Epidemiology**).

Data Collection

Surveillance data may be sought actively or acquired passively by making use of routinely generated data such as death registrations (*see* **Death Certification**) or hospital admissions. A common weakness of surveillance systems is the lack of agreed case definitions. This applies to most laboratory reporting and notifiable diseases in the United Kingdom. In the United States, CDC have published surveillance case definitions for infectious diseases [30].

Statistical Analysis

Usually, the routine analysis of surveillance data is simply the presentation of **incidence rates** by time, place, and person, using graphs, histograms, and maps. However, more sophisticated methods are increasingly being used [23]. Particular statistical issues include the use of **time series** analysis to model epidemics (*see* **Epidemic Models, Stochastic**), the early recognition of unusual events in routine data against a variable baseline rate [4], **small area analysis** of **clustering**, adjustment for delays and incompleteness of reporting, the use of surveillance data to predict the course of epidemics (e.g. **AIDS**) (*see* **Projections: AIDS, Cancer, Smoking**).

Reporting

Timely reporting to those responsible for public health action is an essential part of a *bona fide* surveillance system. Timeliness is defined by the objectives of the surveillance. For infectious disease, timely reporting may need to be measured in hours, a target which can now be achieved globally through the Internet [7]. For chronic diseases, annual and quarterly reporting may be sufficient. Typically, surveillance reports appear either as specifically produced publications (e.g. *Communicable Disease Report, Office of National Statistics Monitor*, *Morbidity and Mortality Weekly Report*, and *Weekly Epidemiological Record*, or as electronic bulletins, such as EPINET [19]).

Infectious Diseases Surveillance

The best recent example of the power of surveillance is the case of AIDS. Following the first reports

Table 2 Statutorily notifiable diseases in England and Wales

Under the Public Health (Control of Disease) Act 1984	
Cholera	Relapsing fever
Food poisoning	Smallpox
Plague	Typhus
Under the Public Health (Infectious Diseases) Regulations 1988	
Acute encephalitis	Ophthalmia neonatorum
Acute poliomyelitis	Paratyphoid fever
Anthrax	Rabies
Diphtheria	Rubella
Dysentery (amoebic and bacillary)	Scarlet fever
Leprosy	Tetanus
Leptospirosis	Tuberculosis
Malaria	Typhoid fever
Measles	Viral hemorrhagic fever
Meningitis	Viral hepatitis
Meningococcal septicemia (without meningitis)	Whooping cough
Mumps	Yellow fever

Notes
"Viral hemorrhagic fever" means Argentine hemorrhagic fever (Junin), Bolivian hemorrhagic fever (Machupo), Chikungunya fever, Congo/Crimean hemorrhagic fever, Dengue fever, Ebola virus disease, hemorrhagic fever with renal syndrome (Hantaan), Kyasanur forest disease, Lassa fever, Marburg disease, Omsk hemorrhagic fever, and Rift valley disease.
There are minor differences in notifiable diseases in Scotland and Northern Ireland. Some diseases are notifiable locally; for example, psittacosis in Cambridge.
AIDS is *not* statutorily notifiable, but clinicians report cases voluntarily, in strict confidence, to the directors of the CDSC in England and Wales and of the SCIEH in Scotland. Advice about reporting is available from these centers and from genitourinary medicine physicians.

of a new clinical disease, surveillance based on a complex case definition quickly established the risk groups of AIDS and thereby the probable routes of transmission, so enabling preventive advice to be promulgated, even before the HIV virus was discovered. Subsequent surveillance using clinical reports of AIDS and laboratory reporting of HIV infection has been important in confirming the risk groups, reassuring the population about the absence of risk from casual contact and identifying localities of high incidence so that services can be targeted. Mathematical modeling using surveillance data has enabled prediction of the epidemic and has identified key transmission factors (e.g. number of sexual partners) in the maintenance of the disease [20].

Statutory Notification

In England and Wales, mandatory notification of infectious disease was introduced nationally in 1899. The current list of diseases is shown in Table 2. Notifications are made by registered medical practitioners. In England and Wales, weekly summaries of these data are now published in the Public Health Laboratory Service (PHLS) *Communicable Disease Report (CDR)*. The data are later corrected and published quarterly and annually by the **Office for National Statistics (ONS)**. The chief advantages of these data are that they are available quickly, and they relate to defined populations so that rates by age and sex can be calculated. The defects of the data are lack of case definitions and variable under-notification. Interestingly, the fee to medical practitioners to notify did not improve notification rates [18].

Laboratory Reporting of Microbiological Data

The PHLS developed laboratory reporting in the 1940s and 1950s [8]. Data are analyzed within a week of receipt by the Communicable Disease Surveillance Center to produce tables and line lists which are

used in compiling narrative reports for publication in the CDR. The recent introduction of CoSurv [11] has substantially replaced manual with electronic reporting. The main benefits of laboratory reports are that they are highly specific since they are based on laboratory-diagnosed infections and the fine typing of the infecting organisms [27], they often include clinical and epidemiologic details, and they allow for free-text comment. The reporting system is flexible, and unusual or new infections can be reported, even though they were not included in the original reporting instructions. However, the reports are limited to infections for which there is a suitable laboratory test.

General Practice Reporting of Clinical Data

The Royal College of General Practitioners (RCGP) set up a reporting system in 1966 based on first consultations to a limited number of volunteer practices [6]. In 1996 there were 367 participating general practitioners in 93 practices, serving a population of about 70 000 people; similar systems exist in Wales, Scotland, and the European countries [22]. They act primarily as early warning systems, particularly for influenza epidemics, providing data rapidly, and they have the advantages that the data are related to defined practice populations; they are useful for some common diseases which are not notifiable and for which laboratory tests are not usually performed, such as chicken pox.

Serological Surveillance

In 1990 in the UK, a serologic study to measure the spread of human immunodeficiency virus (HIV) infection in the population was begun; it has continued since and become a routine surveillance system [21]. Samples from sera collected for clinical purposes are unlinked from personal identifiers but remain linked to epidemiologic information (*see* **Record Linkage**); sera remaining unused are then tested for HIV infection.

Surveillance of Vaccine Preventable Diseases, Vaccine Uptake, and Vaccine Reactions

A comprehensive system of surveillance of vaccine-preventable diseases has been developed using the notification system, laboratory reporting, and regular serologic surveys of antibody levels in stored sera taken for other purposes [1]. Vaccine uptake is followed by the COVER [2] system in the UK, which uses the national child health system in which all children in the UK are registered by a health authority. Successive cohorts of children born within three-month periods are identified and their vaccination status at predefined target dates determined. Quarterly reports are published by the Communicable Disease Surveillance Centre and the comparative uptake rates are known by Districts within a few months. Health authorities have used the data to study and remedy reasons for low uptake. Surveillance of vaccine safety has used the Yellow Card Scheme, but record linkage of district health authority child health records and computerized hospital admissions records is a promising new method of postmarketing surveillance of vaccine safety [5]. Vaccine efficacy can also be the subject of surveillance if population rates of disease and the proportion of cases vaccinated (PCV) and the proportion of the population vaccinated (PPV) can be routinely measured [3]. Vaccine efficacy is calculated by the following expression:

$$1 - \frac{\text{PCV}}{1 - \text{PCV}} \times \frac{1 - \text{PPV}}{\text{PPV}}$$

(*see* **Vaccine Studies**).

Injury Surveillance

Particularly in Australia [10], hospital-based Emergency Room data have been used successfully to follow trends in injuries and identify etiologic risk factors. In the UK, injury surveillance currently relies on mortality data and hospital admissions, which will miss most common injuries such as fractures. Locally developed population-based schemes have illustrated the potential benefit of using Emergency Room databases [16]. In the US, systems have been developed to monitor spinal cord, firearm, and sports injuries [24].

Surveillance of Birth Defects

Following the thalidomide disaster, registries of congenital malformations were set up in several countries

for the early detection of malformations in order to investigate causes. However, incompleteness and inaccuracy of reports has reduced their potential effectiveness. Monitoring etiologically linked groups of malformations rather than single defects has been recommended [12]. In Europe, the European Registration of Congenital Anomalies (EUROCAT) concerted action project of the European Union collates standardized data from national and regional registries.

Occupational Illness and Injury Surveillance

In the United Kingdom, occupational illness and injuries are reportable by law under RIDDOR (the Reporting of Injuries Diseases and Dangerous Occurrences Regulations Act), which came into force on 1 April 1986. The Health and Safety Executive are the responsible agency who will investigate incidents and develop guidelines and regulations for prevention.

Pharmacosurveillance

In many countries voluntary reporting systems for adverse reactions to drugs and vaccines have been developed. In the UK, the Yellow Card Scheme is run by the Committee on Safety of Medicines. In the US, the **Food and Drug Administration** collects data from physicians and reports findings in the *FDA Drug Bulletin*. The **World Health Organization** has set up an international registry linked to national centers (*see* **Pharmacoepidemiology, Overview**).

Chronic Disease Surveillance

The use of mortality data for surveillance was the basis of the pioneering work of **William Farr**, who, as Compiler of Abstracts at the General Register Office from 1839 to 1879, used vital statistics to alert government and the public to health problems [15]. He developed a classification of diseases that eventually led to the **International Classification of Diseases**. The routine, timely analysis and reporting of cause and age-specific death rates continued today by the Office of National Statistics can legitimately be considered as chronic disease surveillance, as is illustrated by the London smog epidemic in 1952 [17]. Publication of the death registration totals for the week ending December 13 in London identified considerable **excess mortality**, leading to a government enquiry and eventually to the Clean Air Act. Another example is the identification of excess deaths during heat waves in the US, which has resulted in development of advice for prevention. In Russia and Eastern Europe, a sudden increase in death rates in men has been observed since 1991 [28], which highlights the utility of monitoring crude death rates in identifying chronic disease problems, and emphasizes the need for chronic disease surveillance.

Surveys, Health and Morbidity

One of the methods to assess features of health and morbidity in a population is to conduct a specific survey by means of which information on a **target population** is obtained by measuring a representative sample of that population. Besides measuring health, surveys can also be used to investigate related variables such as living conditions, housing demands, and participation in the labor force. A health survey includes measures of health characteristics, health-related behavior, and a variety of demographic and socioeconomic characteristics. If the target population for such a survey is all persons living in a certain country, the survey is usually referred to as a national health survey. If survey data are collected through face-to-face interviews, the survey is commonly referred to as a "health interview survey". Survey methodology can be used to assess the health of many different target populations, depending on the purpose of the survey. Examples of target populations are: population living in a country; population living in a certain area (e.g. a town); population of a specific age group (e.g. the elderly); population registered in a health service register (e.g. a register of a general practitioner); a specific occupational group (e.g. nurses), or the population belonging to an ethnic group. A health survey can also be limited to one single key subject such as pain, health expenditure, or dental health.

To assess information on the health and morbidity situation of such target populations, it is usually not practicable to measure every subject of that population. In most cases this is also not necessary – **probability samples** are usually sufficient to make reliable estimates for the target population. To gather information on the health and morbidity of the subjects in the sample, structured questionnaires and/or specific physical examinations are used. Most health surveys are carried out using only structured questionnaires administered by personal interview, telephone interview, or post. Surveys that consist of physical examinations (e.g. functional assessment of lungs) and/or laboratory measurements (e.g. of blood or urine) are usually called health examination surveys. It may be desirable to combine physical examinations with personal interview data in one survey because the collected data can be complementary, although the logistics of such a combined data collection are complex.

The health survey method is very popular, and applications are found in many countries as national health surveys, pain surveys, dental surveys, health expenditure surveys, and as health surveys for specific groups such as the elderly and ethnic minorities.

Survey data are used in national, regional, and local health statistics and information systems (*see* **Administrative Databases**; **Health Services Organization in the US**) and form an important base for planning, monitoring, and evaluating public health actions. One additional benefit of health surveys is that they can be used to explore the interrelationships between health, health-related behavior (*see* **Health Care Utilization and Behavior, Models of**), use of services (*see* **Health Care Utilization Data**), and social, economic, and demographic variables.

In comparison with the other sources of health and morbidity information and in particular in comparison with health service registers, the advantages of health surveys are:

1. extensive data on both health and morbidity and use of health services can be assessed
2. data on sociodemographic and other background variables, lifestyle, and many other possible determinants are assessed for the same individuals as the health and morbidity characteristics
3. subjective data such as perceived health and knowledge of health services, coping strategies, and opinions can be assessed
4. data can be collected on many subgroups in the population, including those not having contact with health services
5. they are relatively cheap and quick.

Disadvantages of health surveys compared with health service registrations include:

1. failure to contact everybody in the sample, and, therefore, the possible introduction of **bias**
2. questionable reliability for some topics assessed by self-reports
3. detailed medical information usually cannot be collected.

The design of a survey requires many decisions regarding the information that is needed, the instruments to be used (*see* **Questionnaire Design**),

sampling methods and other methodologic procedures. Survey design decisions should be directed by the desired quality of the data that are to be collected. The quality of the data is determined by the quality of the responses and the coverage of the target population. To establish an adequate insight into the health status of a population and its determinants and consequences, every detail of design of the survey should be considered in relation to the desired data quality. After designing a health survey, the implementation phase can start, and this also requires constant check-ups and management to warrant good quality. Protocols have to be carried out in detail, and adjusted when necessary. After data are collected, the coding of responses, building of data files, analysis, and reporting of the survey findings must be carried out.

Two important aspects in the design and implementation of a health survey are the kinds of information that are needed about the target population and the methodologic characteristics of the survey. Other important considerations include analysis and reporting of the data and the required survey management.

To illustrate these aspects the national health population survey will be used. A national health population survey is a general information source for those involved in health policy analysis and development. Health surveys are essential sources of information that cannot be collected routinely through registers (*see* **Disease Registers**), health records, or other available sources. National health and morbidity data are needed to provide a better foundation for decisions on priorities for public health policy action and for the effective allocation of resources.

A number of countries have experience with national health population surveys. However, the findings are usually applicable only in the country and for the population studied; international comparisons of this type of data pose problems due to differences in the methods and instruments used. Limited international comparability also may limit the use of data at the national level, since comparisons with other countries may be useful in providing insight into cultural, environmental, and economic factors associated with health problems. These limitations can be overcome not only by using comparable survey methods but also by using comparable methods of analysis and presentation. Efforts on harmonization of methods and instruments of national health interview surveys have been described in a joint **World Health Organization**/Statistics Netherlands publication, on which this article has partly been based [4]. Although the design and implementation of specific health surveys other than the general national health survey can have additional problems not covered in this article, most of the methodologic aspects described here should be considered by every health survey professional.

Kinds of Information Assessed by Health Surveys

The kinds of information assessed by health surveys are determined by their purpose. The classic health population survey includes questions on health and morbidity characteristics, use of health services (*see* **Health Services Research, Overview**), lifestyle characteristics, and sociodemographic characteristics. An overview of the most important characteristics can be found in Table 1. Health surveys can be extended with many other relevant subjects such as psychosocial factors, environmental characteristics (e.g. noise pollution), drugs use, accidents, and sexual behavior.

Detailed specification of the desired information can be seen as the first phase in designing a survey. What information is needed? At what level of detail is information needed? The choice of the content of the survey depends on many factors, including resources, actual health problems, and the need for specific information. Priorities have to be set in this phase because the length of the questionnaire must be limited to reduce both survey costs and respondent burden. After deciding on the content of the survey, specific instruments have to be chosen. In this context, the term "instrument" refers to a set of questions (or one question) which measure the characteristic of interest. The selection of instruments and the construction and wording of the questions is very important because this is the basis for the quality of the data. Ideally, instruments should:

1. Be as short as possible, i.e. the respondent burden should be kept as low as possible.
2. Collect information on characteristics that are not too rare in the target population (characteristics are only justified to be measured in a probability sample of the population if they are relevant for a sufficiently large proportion of that population. If not, other methods are preferable, such as

Table 1 Relevant characteristics measured in health surveys

Health and morbidity characteristics
Perceived health
Diseases
Disability, impairments, handicaps
Health complaints
Dental health
Mental health
Anthropometric characteristics
Height
Weight
Birthweight
Health services
General practitioner
Medical specialist
Hospital admission
Physiotherapist (and other paramedic professions)
Preventive services (e.g. participation in screening services such as cervical smear,
Mammography, and influenza vaccination)
Dentist
Maternity care (including information on pregnancy and delivery)
District nursing
General social work
Use of contraceptives
Medicine use
Alternative/complementary medicine (e.g. acupuncture and homeopathy)
Lifestyle
Smoking
Alcohol consumption
Physical activity
Food consumption
Breastfeeding
Psychosocial factors
Personality characteristics
Coping strategies
Social support
Sociodemographic characteristics
Age
Sex
Place of residence
Social class
Education
Work situation
Income
Economic position
Housing
Living arrangements
Health insurance

oversampling of subsets of the target population known to have a higher probability of possessing the characteristic, or previously identified by their response on a screening question in a larger scale survey).

3. Be simple to administer, and provide data that are easy to process (unnecessarily complex procedures should be avoided; otherwise errors may be introduced). Most of the time questions with fixed answer categories, so-called "closed questions", are preferable because "open-ended questions" require extensive efforts in the coding phase. The fixed responses should cover every possible answer to avoid the exclusion of important responses
4. Be reliable: the reliability refers to the reproducibility of the results.
5. Be valid: validity refers to the issue of whether the instrument really assesses the information that is meant to be assessed.

Adequate selection of instruments requires extensive knowledge about available instruments in each specific area. This knowledge is often obtained by consultation with experts and by extensive literature review. When available, adoption of standard questionnaire batteries should be considered. Construction and content of such standard instruments usually have been tested extensively. Additional advantages include the increased possibility of comparing the results with other data – an important consideration in the framework of international comparisons. Most countries have standard routines for questions on sociodemographic variables. Less standardization is found for the other domains in the likely content of a health survey.

Often, survey researchers use adaptations of sets of questions from existing instruments. Arguments for adapting the original instruments include their being too long or not entirely relevant for the specific setting. Modification of existing instruments and scales requires, as in the case of designing one's own questions, extensive pretesting and assessment of reliability and validity. Most of the time many revisions are necessary before the questionnaire is ready.

Careful attention has to be paid to the precise wording of the questions and the response categories. They should be simple to understand and should have a consistent meaning for all respondents. Use of introductory texts to the questions to prepare respondents for the questions following should be

chosen carefully because the context of the questions also affects response.

Additional requirements for the choice of instruments and the development of survey questionnaires are that they should not be biased by age or sex of the respondent, or by differences in culture, language, and socioeconomic status.

For most characteristics to be measured in health surveys, a large variety of instruments is available. Especially with respect to self-reported health, sometimes referred to as **"quality of life"** measures, an enormous literature has emerged. In general, the instruments that are selected for the health survey should be in correspondence with the latest developments in the field. Several handbooks with summaries of available instruments and evaluation of their quality (i.e. validity and reliability) are available [10]. However, there are often no internationally agreed standard instruments available. For national surveys that will be used in international comparisons this is a significant problem because the comparability becomes limited or impossible. Several efforts have been undertaken to reach international harmonization of methods and instruments in national health surveys.

A joint action of the World Health Organization Regional Office for Europe and Statistics Netherlands has led to the first step in harmonization of survey instruments on general health characteristics for the countries of Europe. These efforts were guided by the wish to have internationally comparable data for WHO's "Health for All" indicators [17]. A number of recommendations for common instruments which measure these indicators have been brought forward [4]. Some of these recommended instruments are presented here to give some examples of the possible content of a health survey. These illustrative examples of instruments deal with the first four domains of the content of a health survey as shown in Table 1: health and morbidity characteristics, anthropometric characteristics (*see* **Anthropometry**; **Growth and Development**), the use of health services, and lifestyle characteristics.

Health and Morbidity

The health and morbidity characteristics are part of the core characteristics measured in health surveys. The most important indicators are: subjective health assessment, disability, chronic conditions, and mental health.

Table 2 Perceived health

How is your health in general?
• Very good
• Good
• Fair
• Bad
• Very bad

Source: [4].

Subjective or *self-perceived health* is a principal health characteristic assessed by health surveys, an example question being shown in Table 2.

Even in its simplest form (see example) and despite its very general, seemingly subjective, character, perceived health is strongly associated with a number of health problems and the use of health services. It is also a strong predictor of survival in elderly people.

Many more extensive instruments measuring self-perceived health, or health-related quality of life measures, are available. These instruments usually distinguish several domains of interest, such as well-being, quality of life, life satisfaction, pain, functional disability, and handicap. Examples of such health instruments are: Nottingham Health Profile [8], the Sickness Impact Profile [3], and the MOS 36-item short-form health survey (SF36) [14]. Sometimes such instruments are referred to as generic health instruments to emphasize the distinction between them and the many disease-specific health instruments available.

These general health measures usually also have items to measure several kinds of disabilities, impairments, or handicaps. It is important to distinguish between temporary disability and long-term disability. *Temporary disability* refers to temporary restriction in an individual's level of functioning. Information on temporary disability is usually obtained by questions about days of restricted activity and bed-days. Measurement of the period of time, together with some notion of the severity of disability, can provide information on the time lost to ill-health in the society (see Table 3).

Because of changes in public health in relation to chronic diseases and the aging of the population, *long-term disability* has become an important concern to public health. It refers to long-term limitations in major daily activities. Especially for the

Table 3 Temporary disability

Think about the two weeks ending yesterday. Have you cut down on any of the things you usually do about the house, at work or in your free time because of illness of injury?
• Yes [ask questions (a) and (b)]
• No
(a) How many days was this in all during these two weeks, including Saturdays and Sundays? (01–14)
(b) On how many of these days were you in bed for all or most of the day? (00–14)

Source: [4].

elderly, in which morbidity is often characterized by multiple pathology, long-term disability is useful as an overall indicator of health problems associated with disease. Since the 1960s a large number of instruments have been developed for the assessment of long-term disability. In 1980 the International Classification of Impairments, Disabilities and Handicaps (ICIDH) [15] was introduced. This classification is a basic conceptual scheme, that has been used as a guide for the further development of instruments. Important domains of disability are: locomotion, self-care, continence, hearing, and vision. Self-care disabilities include problems with dressing, washing, feeding, and using the toilet. Instruments differ in their number of disability domains, the levels of severity, and the specification of details. In addition it can be important to distinguish between capability and performance: is it necessary to assess whether persons cannot or do not carry out an activity. Survey data on disabilities are also required to measure the *disability-free* **life expectancy** of a population [12].

Health surveys are also useful in providing data on the **prevalence** of diseases such as cancer, cardiovascular diseases, rheumatic disorders, respiratory disorders, and mental health disorders. These, often chronic, diseases are important because they are often accompanied by pain, suffering, inconvenience, and loss of physical capacity. They put pressure on health services and society in general, especially in the industrialized countries. Commonly used instruments for the assessment of the incidence and the prevalence of physical chronic conditions are still lacking. Most countries have their own list of diseases that are considered suitable for self-reporting. The available instruments show great variety in methodology, e.g. differences in the nature of the diseases, in the number of the diseases, and in the definition of severity and in the wording of the questions. Conditions like hypertension, asthma, bronchitis, thyroid disorders, diabetes, chronic skin condition, chronic heart disease, chronic cystitis, chronic dental problems, chronic back problems, arthritis, and stroke can be part of a general list of diseases measured in health surveys. For some specific disorders, such as cardiovascular diseases, internationally used survey instruments are available [13]. The wording of the questions must be based on the respondent's ability to understand the described condition. In some cases, the disease name or a popular synonym in the specific language is sufficient; in others, additional questions or lists of symptoms are necessary. For each condition measured in terms of diagnosis, respondents should be asked whether a health professional has made the diagnosis. Several methodological aspects on the survey assessment of diseases have been investigated. These include **reliability** and **validation** studies and the effects of construction of the instruments. For instance, using an "open" question such as "Do you suffer or did you last year suffer from a disease, and if as what disease(s)?" gives different results than asking the same question but showing a list of all diseases from which one can choose ("one-by-one method"). In addition, it has been shown that many diseases can be adequately assessed in a health survey. However, many methodologic problems are still to be tackled to reach internationally agreed survey instruments for many chronic diseases.

In designing or selecting an instrument to measure morbidity one should bear in mind that it is preferable to be able to summarize the results on disease prevalences into broad ICD-10 [16] categories (*see* **International Classification of Diseases (ICD)**).

In selecting diseases and the instruments to be used for population survey assessment, it is also important to distinguish between chronic mental conditions and chronic physical conditions. Of the more than 120 *mental* diagnoses that are now distinguished [2, 16], a selection of relevant disorders has to be made for inclusion in the health survey. On the basis of prevalence, severity, and duration, disorders like dementia, mental retardation, anxiety disorders, schizophrenia, and affective disorders are important for establishing public health policies. Because the knowledge of respondents about these diseases is

generally poor, instruments have to be based on a symptom approach. Such an approach is very time-consuming, as a large number of symptoms have to be checked to diagnose a mental disease. To reduce time and expense, a two-stage procedure should be considered: some screening questions followed by an extensive interview procedure. Apart from general mental health measures, such as the GHQ-12 [7], assessment of mental disorders can only be done in specialized surveys.

Anthropometric Characteristics

Data on *weight* and *height* are commonly assessed by health surveys, for instance to analyze problems related to obesity. Obesity is usually defined by the body mass index (BMI) or Quetelet's index – weight (in kilograms) divided by the square of height (in meters). Most respondents are able to state weight in kilograms and height in centimeters. Self-reported weight and height show small but systematic errors: height tends to be overstated and weight under reported. If precise information on the characteristics is necessary, actual weight and height instruments are needed.

Birthweight is a commonly used indicator for the nutritional and health status of the newborn. It is considered to be an important determinant of the survival of the infant and its ability to develop normally. A low birthweight is commonly defined as one less than 2500 g. Administrative records such as birth registration or maternity records are usually the main source for this information, but if linking of these external records to the survey questionnaires cannot be done, a question on birthweight should be included in the survey (see Table 4).

Table 4 Birthweight

1. Is the child twin or triplet?
   - Yes (multiple birth)
   - No
2. Was the child born before it was due?
   - Yes
   - No (go to question 4)
3. Was it less than one month before it was due or more than that?
   - less than one month
   - more than one month
4. How much did the child weight at birth? (record in grams)

Source: [4].

Health Services

Health surveys can be used to measure the level of use of health services. For health services for which good registers are available, it is sometimes seen that the health survey data on service use does not completely represent the total service use: on the basis of health surveys an underestimation of health services is sometimes seen. However, for many services there are no registers available, so the only tool to provide insight into service use is the health survey. In addition, the health survey allows the study of the relationships among the use of different health services and the relationships of measures of health, lifestyle, and sociodemographic characteristics to health services use. Another important advantage of a health survey is having data on the characteristics of nonusers of health services; for instance, to be able to investigate equality of access to health services. Also high users of health care can be of specific interest because it should be known to what extent the health care dependency is justified.

Beside the measurement of use of services and reasons for use, it can also be relevant to assess the knowledge of persons on specific health services or the availability of services – for instance, preventive services (*see* **Preventive Medicine**).

The actual measures to assess the different characteristics of health service use can be very different. It is, for instance, very important to evaluate the reference period (which should not be too long in order to prevent **recall bias**) and the definition of "use of" (or consultation). An example of questions on quantitative information regarding the consultation of a general practitioner (GP) is shown here as an illustration. With these questions the percentage of persons consulting in 1 year and the number of consultations in 1 year can be derived. Such questions can be followed by questions on reasons for consultation, where or how the consultation took place, whether there was a referral to a specialist, a hospital, or otherwise. In countries where there is no clear distinction between GPs and specialists, other questions should be used (e.g. using the term "medical doctor" instead of "GP"; see Table 5).

Table 5 Consultation of general practitioner

Introduction: "The following questions concern contacts with your GP. They relate to visits during surgery hours and house-calls, but also to telephone calls for other reasons than to make an appointment."

. . . . . .

1. How often have you consulted your GP during the past two weeks ending yesterday, so since . . . . . (date)?
   - . . . . . times (go to question 3)
   - no one single time (go to question 2)
2. When did you last consult your GP?
   - on . . . . . (date) or (if date not known) . . . . . weeks/months/years ago
   - never

   If last consultation <2 months ago go to question 3.
3. How often have you consulted your GP during the past 2 months, so since . . . . . (date)?
   - . . . . . times

Source: [4].

Lifestyle

To assess data on lifestyle and to study the relationship between lifestyle characteristics and health and morbidity, the health survey is an essential tool. For instance, studying the health effects of smoking, food consumption, and physical activity has expanded to specific scientific areas requiring specialized knowledge on measurements, analyses, and interpretation of these topics. For both food consumption [18] (*see* **Nutritional Exposure Measures**) and physical activity [1, 5], many instruments are available and evaluated in numerous review articles and handbooks. However, it has been difficult to agree on standard instruments internationally.

Smoking is seen as the major cause of lung cancer, ischemic heart disease, chronic bronchitis, and emphysema (*see* **Smoking and Health**). Health surveys are an important source of data on smoking behavior. They can supply information on proportions of daily smokers, occasional smokers, ex-smokers, and those who have never smoked. Other relevant parameters include number of cigarettes and other tobacco products used per day, total numbers of years smoking, whether a person has reduced smoking, how long ago a person stopped smoking, attempts to stop smoking, and opinions on the harmfulness of tobacco. The possibilities on measuring passive smoking, for instance by asking questions on exposure to tobacco smoke at work and at home, should also be considered (see Table 6).

Table 6 Illustration of a minimal set of health survey questions on smoking

1. Do you smoke?
   - Yes, daily
   - Yes, occasionally (go to question 3)
   - No (go to question 4)
2. How many cigarettes do you usually smoke on average each day?
   - Does not smoke cigarettes
   - Fewer than 20
   - 20 or more (heavy smoker)
3. Compared to two years ago would you say you now have reduced smoking?
   - Yes (end)
   - No (end)
4. Have you ever smoked?
   - Yes, daily
   - Yes, occasionally
   - No (end)
5. How long ago did you stop smoking?
   - Less than two years ago
   - Two years ago or more

Source: [4].

Questionnaire Construction

After selection of the necessary information and the choice of instruments, the health survey questionnaire has to be constructed.

The questions and instruments should be *ordered* in a logical way, determined by psychological and behavioral knowledge. In addition, the transitions from one set of questions to the other should be

clear, to indicate the content of the questions in a friendly but impersonal way. The actual introductory texts used to prepare and inform the respondent on the questions following should be carefully worded and standardized.

It is desirable to ask the respondents only those questions in the interview schedule that are *relevant* for them. For example, a man should not be asked about diseases that only affect women, and vice versa, and a college student should not be asked what profession he or she has. Besides the use of completely different questionnaires for different groups of respondents, special *routings* or questionnaire skip patterns are often used. Such routings are also necessary when in some sections of the questionnaire a procedure involving two or more stages is used. Complex routing of questions makes high demands on the design and layout of the questionnaire and increases the burden on the interviewer or, in the case of self-administered questionnaires, the respondent. The use of **computer-assisted interviews** for data collection in the field of health surveys has resolved many problems with complex routing, although it requires a heavy input of skilled resources in the preparatory phase.

During face-to-face interviews, *showcards*, that include the set of answers to a question, can be used. The showcard should be given to the respondent the moment the interviewer asks the specific question. This procedure can be used for two reasons:

1. to inform the respondent about the response possibilities, and
2. to encourage the respondent to give the correct rather than a socially desirable answer. This is facilitated when answers are precoded on the card, and the respondent needs only to reply with the appropriate code.

The extent to which answers have to rely on the *memory* of the respondent should be minimized, because recall from memory can be a source of bias. The magnitude of recall bias depends on the length of the recall period and the saliency of the events to be recalled.

Questionnaire length is least restricted in the face-to-face interview because people accept long interviews better than long self-administered questionnaires. Nevertheless, the length of a questionnaire is not unlimited because respondent burden should be as low as possible, i.e. to prevent reduction in motivation and tiredness. Interviews of 60–90 min are not uncommon. For telephone interviews (*see* **Telephone Sampling**) the duration is usually no longer than between 30 and 50 min, but is preferably shorter.

Mail questionnaires should not be longer than 12 pages; in general, most range between four and 12 pages. Longer questionnaires can be considered when the respondents are highly motivated. In general, respondents have to be rewarded for their participation; they have to be "pampered" and continuously motivated for their participation in a health survey. For self-administered questionnaires, the layout of the questions should be as attractive as possible. Easy to read type fonts, different colors, frames, "flowcharts", etc. should be used.

Health Examination Survey

The kind of information assessed by a health survey can be extended by information gathered by physical examinations. These examinations can be carried out by trained interviewers. Sometimes trained nurses, physicians, or laboratory personnel are necessary. Health examination surveys may include physical examinations (e.g. anthropometric measurements), functional assessment (e.g. ability tests and spirometry), laboratory tests on blood or urine samples (e.g. cholesterol level in blood), and the application of specific imaging techniques such as X-ray and MRI. Adding such measurements to a health survey requires extra effort in survey design, conduct, and analysis, and there will be increased respondent burden and extended duration of the survey.

Some examinations can be carried out by trained interviewers visiting respondents at home. Examples of such examinations are weight and height measures, blood pressure tests, and mobility tests. Other examinations require specific instruments that are not suitable for routine assessment at home, so specific arrangements have to be made. Respondents can be invited to visit a laboratory or clinic in order to be able to carry out the examinations. An alternative is the use of a mobile laboratory which can visit persons at home; the geographic spread of potential respondents should not be too large, otherwise such an approach would not be cost-effective.

Although the costs are very high, the general advantages of a health examination survey include the acquisition of objective medical data from

a **population-based study** sample, which can be important to assess population norms, and the possibilities to validate questionnaire-assessed data. An example of a study that combines a health interview and a health examination survey is the US National Health and Nutrition Examination survey [11].

Methodologic Considerations

There are many ways to design a health survey. The most important components of survey methodology are highlighted here. Methodologic aspects are broadly divided into those concerning the population and in those concerning data collection. All aspects of the survey process that may affect response quantity and quality should be taken into account. However, most decisions about survey design will depend on the resources available. Therefore an adequate balance between costs and quality will have to be pursued.

Survey Population

The definition of the *target population* depends on the purpose of the study and the practical possibilities of the available **sampling frames**. For a national health survey the sample should represent the general population. To get a representative sample for the target population concerned it is necessary to have a data file with all information of the subjects of the population, including information on how to locate them. The sample can be drawn by several methods, for example, by using:

1. address or postal files
2. electoral registers
3. population registers
4. telephone registers.

If available (and accessible as public records for sampling purposes), population registers should be used to obtain a representative sample. Data on name, age, sex, and address of all persons legally living in a country or a subarea are known within a population registry. An additional advantage of sample frames that include data on age and sex is the opportunity for **stratified sampling** – for example, **stratification** by age group and sex. Population registers seem to be nearly complete in some countries, but alterations such as changes of address may only be entered slowly, resulting in registers that are not fully up-to-date. The main limitation of the electoral register is that as a rule only those people are listed who are of legal voting age and who meet other voting requirements. Alternate sampling frames, e.g. address and telephone registers, have the disadvantage that not every person has the same chance of being selected. For those files the *sample unit* is the household living at the address or telephone number selected (*see* **Unit of Analysis**). When everybody in the household is interviewed, a maximum of, for example, four persons is often used to reduce "household" burden (*see* **Cluster Sampling**). Sometimes one person is interviewed on all health characteristics of the persons belonging to the household. If that is the case, the one who knows most about the health of the family is questioned. If a random choice of one person in the household is needed, then the selection can be decided by the one who is the first to have their birthday. If one person per household is invited to participate, those living in single households have a greater chance of being selected than those living in a household with more members. When there are unequal selection probabilities, the final responses have to be corrected by weighting procedures. Another disadvantage of address and telephone samples is the inclusion of inappropriate units, such as businesses, and the exclusion of certain subjects, such as the homeless. Those living in institutions such as nursing homes, homes for the handicapped, and prisons are also more difficult to reach due to sample frame limitations.

The actual sampling can have very different manifestations. A probability sample is to be preferred because precision of the sample estimates can be calculated. The strategy of generating a sample may involve several stages (*see* **Multistage Sampling**). For instance, when using address files for the sample and interviewers visiting subjects at home, first a sample of municipalities can be drawn before sampling the addresses. Such a strategy reduces the travel time of the interviewer.

The decision about *sample size* depends on many factors, including the required level of detail of the results; the finer the detail, the greater the sample size needed to provide estimates with acceptable confidence limits. This approach of calculating the necessary sample size (*see* **Sample Size Determination**) on the basis of sampling errors has two limitations.

First, most surveys are designed to make numerous estimates, and the necessary precision will vary. Secondly, in health surveys the sampling error is not the only or main source of error in a survey estimate. The decision will in most cases not depend on estimates for the total population but should depend on the estimates for the smallest subgroups of importance. The sample also depends on the expected percentage of individuals in the sample for which no data will be collected – the nonrespondents (*see* **Nonresponse**).

Nonresponse

There are several reasons why subjects eligible for the health survey are not measured (*see* **Missing Data in Epidemiologic Studies**). Groups of nonparticipating subjects include:

1. Subjects who cannot be reached – those who cannot be located because they have moved or have died. This number of nonresponders due to sample-frame defects should be determined to be able to calculate the *net response*.
2. Subjects who do not react, the not-at-homes or all those from whom no reaction is received. Efforts to reduce this group of nonresponse include increasing numbers of attempts to contact them by visits, reminders, and (multiple) telephone calls.
3. Subjects who refuse to participate. This is a difficult group because most of the time there is hardly any information on reasons for nonparticipation and so there is no possibility of tackling the question of **selection bias**. However, several approaches can be explored to get information on them, including the use of a small questionnaire with information or a preprinted refusal card with some additional questions on reasons for refusal and some additional information, e.g. perceived health and smoking habits.
4. Subjects who are unable to participate because they are too ill, do not speak the language of the interviewer, or whose reading and writing skills exclude them from filling in self-administered questionnaires. If specific subgroups are important for inclusion in the health survey, specific efforts are necessary to get information on such subjects, e.g. using proxy questioning.

Increasing *motivation for participation* is one of the most difficult and important aspects of a health survey. Traditionally, response figures for health surveys are high because health and morbidity belong to the most important aspects of life. Unfortunately, like other surveys, health surveys are experiencing reduced response rates in many countries.

General guidelines on increasing motivation for participation include (see, for example, [9]):

1. the topic should be of interest to potential respondents
2. the **confidentiality** of survey responses should be clear
3. advance contacts should be made
4. specific incentives should be used, e.g. gifts, money, or reporting back on the health status of the respondent
5. repeated visits, reminders, or telephone calls must be employed when appropriate (*see* **Callbacks and Mail-backs in Sample Surveys**)
6. use of trained interviewers, attractive questionnaires, etc.

Besides these points, the approach to the potential respondent is essential to their motivation. For interview surveys, an informative advance letter should be sent including information on the purpose of the study, why it is important, that confidentiality is assured, that it is approved by official institutions, how the person was sampled, and why it is important that they will participate. The advance notification should consist of an official letter, preferably signed by hand, to include the most important information, and an attractive and informative flyer about the research project and the participating institutions.

In spite of costly efforts to reduce nonresponse, not all eligible sample subjects will participate. When presenting results, the quality of the response group should be indicated by

1. response rate
2. estimates of nonresponse bias
3. corrections for nonresponse
4. describing to what extent the response population is representative of the target population.

In reporting on survey data, one of the key numbers readers look for is the *response rate*. In its most general form the response rate is the number of respondents divided by the number of people sampled, usually expressed as a percentage. If the denominator is reduced by those who could not be

reached for legitimate reasons, the response rate is usually higher. This *net response* figure is usually reported.

Although a low nonresponse is desirable it should always be considered whether it is likely or not that bias is introduced by the nonresponse, and what the possible size of that bias is. It is even possible that a survey with a 90% response rate is more biased than a survey with a 70% response rate. It depends on the selectivity of the response group with regard to the subject(s) of interest. "One usually does not know how biased nonresponse is, but it is seldom a good assumption that nonresponse is unbiased" [6].

Insight into nonresponse bias is only possible when there is information on the nonrespondents. In general a comparison of the response group and the nonresponse group on the basis of the sampling frame information is carried out. This information includes residence, and sometimes also age and sex. To correct for differences in these variables *weighting strategies* can be applied. In some cases, a *nonresponse study* has to be considered to measure nonresponse bias. This can be carried out by trying to contact (a random sample of) the nonresponders, using extreme extra efforts.

The main strategy to adjust for nonresponse is weighting adjustment. The response group is weighted in such a manner that the resulting response group has the same distribution of general sociodemographic characteristics as the sample or the target population. Evaluation of the *representativeness* of a response group depends on both the quality of the sample frame and the quality of the response group. One specific form of nonresponse is the item *nonresponse*, which refers to the part(s) of the questionnaires that are not answered or filled in by every respondent. This problem can be minimized by using the personal interview technique, but it is very common in self-administered questionnaires. Numerous missing data usually give big problems during analysis. Some methods of imputation are available and should be considered to reduce missing data (*see* **Missing Data**) [9].

Data Collection

An essential decision in the design of a health survey is the choice of the method of data collection, which could be either face-to-face interviews, telephone interviews, self-administered questionnaires, or a combination. Interviews can be conducted during visits to respondents at home, during the visits of respondents to a specific laboratory, or using the telephone. Self-administered questionnaires can be sent by post or can be an addition to an interview. The choice depends on the purpose of the study, sample frame, research topic, characteristics of the sample, and available resources.

Face-to-Face Interviews and Self-Completion

Personal interviews or face-to-face interviews carried out by trained interviewers who visit respondents at home and who ask questions and assess the answers by means of a structured questionnaire are generally considered to be the preferred mode of data collection (*see* **Interviewing Techniques**). Advantages include good response rates, and the questionnaires are usually filled in more completely than with other methods.

Furthermore, people will tolerate relatively long interviews much better than very long self-administered questionnaires, and the interviewers can have direct control of the quality of the response. For some topics, however, it may be useful to introduce some type of self-completion by the informant. Those measures are preferred when the questions refer to sensitive subjects, such as alcohol, drugs, contraception, sexual behavior, and/or when it is difficult to ensure privacy for an interview. One method is to introduce a self-administered questionnaire during the interview and to allow the informant time to complete it before carrying on with the interview. Another is to leave the questionnaire behind after the interview and collect it later.

Owing to some specific disadvantages of face-to-face interviews (*see* **Interviewer Bias**), the methodology of alternatives has gotten a lot of attention. These disadvantages include frequent long periods of fieldwork, high rates of "not at homes" because more persons in one household work and/or spend more leisure time outside the home, and high rates of persons who have moved. In addition, the safety of interviewers cannot be guaranteed in some areas. Furthermore, the alternatives – postal questionnaires and telephone interviews – are relatively cheap.

Postal and Telephone Surveys

Postal and telephone surveys are cheap alternatives for face-to-face interviews. Telephone surveys have

the advantages of use of interviewers, e.g. reduction of item nonresponse and control of data quality, but are limited to those persons who have a telephone, and there are measurement constraints: no visual aids or complex response categories can be used. For postal surveys, such visual aids and complex response categories can be used, and the response is the most anonymous of all data collection methods, which is preferred for sensitive topics. However, there is less control of data quality, and good reading and writing skills of the respondents are required.

Interviewers

The interviewer has the important task of tracking down the persons to be interviewed, taking care of their participation, and controlling the data quality. Considerable attention has to be paid to selection, training, and supervision.

Proxy Informants

In cases where a person acts as an informant for others, the term proxy informant is used. This is a useful approach if information on a household is needed and one person can provide all the answers. Proxy informants are usually essential for children and persons with mental or sensory disabilities, and also for the reduction of nonresponse where people are difficult to contact – for instance, married men and young single adults. In all these cases a spouse or significant other – partner or parent, or other family member (brother or sister) – can provide the necessary information. For some indicators the use of a proxy informant is not totally appropriate, such as for questions on feelings, opinions, and knowledge. Information on most other health survey assessed characteristics, such as obvious health problems and use of health services, can usually be provided adequately by proxies. Opinions on the role of proxy interviewing in relation to features such as alcohol intake and smoking differ substantially. On the one hand, it can be argued that proxy questioning may lead to increased, and possibly truer, estimates of consumption than self-reporting in areas where these habits are considered socially undesirable. On the other hand, proxies will not always know fully such habits of another person. Depending on the purpose of the survey and the cultural characteristics of the population to be investigated, the use of proxies can be considered, especially when it helps in reducing nonresponse. The philosophy of proxy use differs considerably by country. While in the UK proxy interviews are only accepted as a last resort, in France and the Netherlands they are used as a standard practice.

Specific Groups

The use of general methods can result in underrepresentation of some specific groups in the population. This can be due to the fact that they are more difficult to reach or because methods and instruments should be adapted to the specific abilities of specific groups. Problems can be caused by specific lifestyles or living situations, by language or cultural differences, and/or by their age. Groups that always have to be considered because general methodology can lead to an underrepresentation of them are the institutional population, children, elderly, homeless persons, and **ethnic groups**.

Because a lot of national surveys are based on address samples, it is usually the case that all nonprivate establishments are excluded. This means that people living in nursing homes, hospitals, prisons, hostels, and other places, such as some type of student and nurses' accommodation, the so-called *institutional population*, are excluded from the sample. Although they only make up a small proportion of the population, from a health point of view these people may be very different from people in private households, particularly regarding health problems such as dementia and long-term disability. To get national data, for instance, it can be recommended that the size of this part of the population has to be assessed adequately, and depending on the specific purpose of the study specific subsurveys should be considered. For *children* the most important source of information is the parents. Usually, separate questionnaires are necessary. If it is desirable to question children themselves, for instance with respect to topics like smoking and drinking, specific attention should be paid to a confidential environment and children should not be encouraged to exaggerate. Parental consent to interview children may be required or advisable.

Many countries have significant minorities in the population who may not be fluent in the main language. The use of questionnaires in different languages, interviewers with adequate knowledge of

alternative languages, or interpreters should be considered when the expected effect of excluding these groups is not marginal. There are some countries in which questionnaires in two main languages are essential, e.g. Canada and Belgium. In general there is some loss of standardization in questions when different languages are used – it is not always possible to find words or phrases with precisely the same meaning. In addition, the importance of health and health-related problems can differ between cultures, which may also hamper the comparability of data.

Collection Period

Many topics related to health, such as use of health services, accidents, and temporary disability are influenced by the period(s) in the year in which the fieldwork takes place. To rule out such seasonal effects, data collection should be spread evenly throughout the year, also including spreading evenly across weekdays. When analysis of trends is considered more important than average figures per year, an alternative is to collect data in the same period each year.

Frequency of Survey

Although a one-shot health survey can provide relevant data, some regularity – continuous or repeated – in assessment is usually relevant, especially to monitor changes in health status and health-related factors and to monitor effects of public health decisions.

If some regularity is needed, the costs and benefits of a continuous or regularly repeated survey, for instance every 3 years, should be carefully considered. For many health aspects, large differences are not likely to be observed from year to year. However, for any large-scale survey, the design and start-up costs will be great because large numbers of interviewers and other staff have to be recruited and trained. For this reason continuous surveys may be more cost-effective than repeated surveys. One option would be to have a continuous survey, with core questions asked each year and with a rotating element containing other items at regular intervals in turn. Additional advantages of such procedures are that new health topics can be added when necessary, and that the rotating elements can also include other national survey areas.

Data Processing and Presentation

After collection of the data they must be transformed into an appropriate form for analyses using computers. Relevant phases include deciding on the format of the data, data entry, data cleaning, weighting adjustment, and analysis of data to present the results (*see* **Data Management and Coordination**).

The format of the data in the computer refers to the way the data are organized: what kind of codes are necessary for the responses and what kind of variables should be used for what kind of questions? Information on each question is usually represented in at least one variable. A question with multiple responses can be represented by many variables.

After deciding how the data need to be organized, they should be entered into the computer. Because usually many respondents are questioned and a lot of information per respondent is assessed, the number of codes to be entered is very large. When data have to be entered by hand, specific software to assist the data entry should be used. When interviews are carried out using (laptop) computers, the data collection phase and data entry phase are the same. An alternative for data entry when written questionnaires are used is a method of computer optical scanning of the responses. These scanning procedures make specific demands for questionnaire layout. Data entry by hand can result in many errors, and with the use of computer-assisted personal interviewing such errors can be minimized.

The phase of data cleaning consists of checking the data file on inconsistencies and removing traceable errors. Three types of errors are usually distinguished: a range error (e.g. an age of 234), a consistency error (e.g. a person 6 years old and married), and a routing or skip pattern error.

Weighting adjustments may be needed to correct for unequal selection probabilities in the sample and to correct for nonresponse bias. This implies that not every respondent contributes equally to the results; the contribution depends on the specific subgroup to which the respondent belongs (most of the time based on characteristics such as age group, sex, household composition, marital status, and region).

To present the results adequately, different forms of data analysis are necessary. Many strategies are possible to make adequate tabulations of results and to analyze associations between the features assessed.

Survey Management and Logistics

The number of interviewers needed for conducting the fieldwork of a health survey largely depends on the content, the sample size, and the time period available. The usual face-to-face interview survey contains questions that can be handled by lay interviewers who have no medical skills. But when the survey includes physical examinations, these should often be left to appropriate staff (nurses, doctors, and laboratory personnel).

The number of full-time and/or part-time interviewers needed to perform an interview survey within a given period of time can be calculated when (i) the estimated duration of one interview (usually no longer than 30–45 min, to be tested in the pilot phase), (ii) the number of working days available for the fieldwork, and (iii) the net sample size are known. It should be kept in mind that interviewers may need a lot of time for traveling and other activities (phone calls, etc.) for making contacts with the respondents; time lost due to nonresponse should also be taken into account as far as possible.

For face-to-face interviews the administrative tools used to be "paper and pencil", but in recent years many of the larger survey organizations make use of laptop computers for conducting the fieldwork. Several software packages have been developed for managing the questionnaires in the laptops. The main advantages of using laptops in the field are that the actual entry of the data is done without extra effort by the interviewers (instead of afterwards at a central location by special staff) and above all that the number of administrative errors is reduced because the data can be checked and corrected interactively.

The number of scientific and administrative staff needed for an interview survey largely depends on the "history" of the survey, content and length, and the time available for preparations, analysis, and publication. A completely new survey needs more time in preparation than one that is more or less a repetition of an earlier effort. The number of organizations, ministries, and other institutes that have a say in the survey may also be an important factor of influence on the time needed for preparation and other activities. When a fairly large part of the questionnaire is not "standard" or "routine", the (scientific) staff time needed for developing and testing instruments for measuring a new topic is at least in the range of a few man-months. Once the questionnaire is ready, the scientific staff should also be involved in training the interviewers for the survey at hand (taking for granted that the interviewers have sufficient general experience).

Scientific staff should be available during the pilot phase of the fieldwork for answering the questions of interviewers and if necessary for adaptations to the questionnaire. During the fieldwork period, staff should be available for data entry and/or data checking and cleaning; preparations for the tabulations and further analyses may also be made during this period. In other words, preparations for analysis and publication should not wait until the fieldwork is completed, and staff for building the data file should be active from the very beginning. For timely reporting it is essential that a complete file becomes available shortly after conclusion of the fieldwork. Specialists in sampling and weighting – if not present in the scientific staff for the survey – should be hired at the time they are needed for the respective activities. Nowadays the technical equipment for the analysis of survey data, even if these consist of hundreds of variables and thousands of records, is no longer a problem: the storage capacity and speed of relatively cheap desktop computers is sufficient for timely and advanced analysis by means of software like SAS and/or SPSS (*see* **Software, Biostatistical**). But experienced scientific staff are needed to analyze the data and publish the results in a way that is practical and understandable for the users. In practice, the procedure may be that first the bare essentials are analyzed and published, followed by more profound analysis and publication at a later stage. Staff are also needed for making a well-documented micro data file – with sufficient protection of the privacy of respondents – for users who are willing and capable to make their own specific analysis of the data.

Finally, considerable workload may result from first and later publications of the results: questions coming from the users of the data need to be answered; additional requests for tabulation and analysis call for extra efforts that – even if additional costs are covered – need to be met by experienced staff. Although exact estimates cannot be given (all depend on the content, length, sample size, and "environment" of the survey), it is clear that any substantial health survey needs to be run by a more or less permanent staff, consisting of scientific, technical, and administrative members.

Survival Analysis, Overview

Survival analysis is the study of the distribution of life times, that is, the times from an initiating event (birth, start of treatment, employment in a given job) to some terminal event (death, relapse, disability pension). A distinguishing feature of survival data is the inevitable presence of incomplete observations, particularly when the terminal event for some individuals is not observed; instead, it is only known that this event is at least later than a given point in time: *right censoring* (*see* **Censored Data**).

The aims of this entry are to provide a brief historical sketch of the long development of survival analysis and to survey what we have found to be central issues in the current methodology of survival analysis. Necessarily, this entry is rich in cross-references to other entries that treat specific subjects in more detail. However, we have not attempted to include cross-references to *all* specific entries within survival analysis.

History

The Prehistory of Survival Analysis in Demography and Actuarial Science

Survival analysis is one of the oldest statistical disciplines with roots in **demography** and **actuarial** science in the seventeenth century; see [49, Chapter 2]; [51] for general accounts of the history of **vital statistics** and [22] for specific accounts of the work before 1750.

The basic **life-table** methodology in modern terminology amounts to the estimation of a survival function (one minus distribution function) from life times with **delayed entry** (or left **truncation**; see below) and right **censoring**. This was known before 1700, and explicit **parametric models** at least since the linear approximation of de Moivre [39] (see e.g. [22, p. 517]), later examples being due to Lambert [33, p. 483]:

$$\left(1-\frac{x}{96}\right)^2 - 0.6176\left(\exp\left(-\frac{x}{31.682}\right) - \exp\left(-\frac{x}{2.43114}\right)\right) \quad (1)$$

and the influential nineteenth-century proposals by Gompertz [19] and Makeham [37], who modeled the **hazard** function as bc^x and $a + bc^x$, respectively.

Motivated by the controversy over smallpox inoculation, D. Bernoulli [5] laid the foundation of the theory of **competing risks**; see [44] for a historical account. The calculation of **expected number of deaths** (how many deaths would there have been in a study population if a given standard set of death rates applied) also dates back to the eighteenth century; see [29] and the article on **Historical Controls in Survival Analysis**.

Among the important methodological advances in the nineteenth century was, in addition to the parametric survival analysis models mentioned above, the graphical simultaneous handling of calendar time and age in the **Lexis Diagram** [35, cf. 30].

Two very important themes of modern survival analysis may be traced to early twentieth century actuarial mathematics:

Multistate modeling in the particular case of disability insurance [41] and nonparametric estimation in continuous time of the survival function in the competing risk problem under delayed entry and right censoring [13].

At this time, survival analysis was not an integrated component of theoretical statistics. A characteristic scepticism about "the value of life-tables in statistical research" was voiced by Greenwood [20] in the *Journal of the Royal Statistical Society*, and Westergaard's [50] guest appearance in *Biometrika* on "Modern problems in vital statistics" had no reference to sampling variability. This despite the fact that these two authors were actually statistical pioneers in survival analysis: Westergaard [48] by deriving what we would call the standard error of the standardized mortality ratio (rederived by Yule [52]; see [29]) (*see* **Standardization Methods**); and Greenwood [21] with his famous expression for "the 'errors of sampling' of the survivorship tables", (see below).

The "Actuarial" life table and the Kaplan–Meier Estimator

In the mid-twentieth century, these well-established demographic and actuarial techniques were presented to the medical–statistical community in influential surveys such as those by Berkson and Gage [4] and Cutler and Ederer [13]. In this approach, time

is grouped into discrete units (e.g. one-year intervals), and the chain of survival frequencies from one interval to the next are multiplied together to form an estimate of the survival probability across several time periods. The difficulty is in the development of the necessary approximations due to the discrete grouping of the intrinsically continuous time and the possibly somewhat oblique observation fields in cohort studies and more complicated demographic situations. The penetrating study by Kaplan and Meier [28] (*see* **Kaplan–Meier Estimator**), the fascinating genesis of which was chronicled by Breslow [8], in principle, eliminated the need for these approximations in the common situation in medical statistics where all survival and censoring times are known precisely. Kaplan and Meier's tool (which they traced back to Böhmer [7]) was to shrink the observation intervals to include at most one observation per interval. Though overlooked by many later authors, Kaplan and Meier also formalized the age-old handling of **delayed entry** (actually also covered by Böhmer) through the necessary adjustment for the **risk set**, the set of individuals alive and under observation at a particular value of the relevant time variable.

Among the variations on the actuarial model, we will mention two.

Harris et al. [23] anticipated much recent work in, for example, **AIDS** survival studies in their generalization of the usual life-table estimator to the situation in which the death and censoring times are known only in large, irregular intervals (*see* **Grouped Survival Times**).

Ederer et al. [(14)] developed a "relative survival rate... as the ratio of the observed survival rate in a group of patients to the survival rate expected in a group similar to the patients ..." thereby connecting to the long tradition of comparing observed with expected; see, for example, [29] and the article on **Historical Controls in Survival Analysis**.

Parametric Survival Models

Parametric survival models were well-established in actuarial science and demography, but have never dominated medical uses of survival analysis. However, in the 1950s and 1960s important contributions to the statistical theory of survival analysis were based on simple parametric models. One example is the **maximum likelihood** approach by Boag [6] to a **cure model** assuming eternal life with probability c and **lognormally distributed** survival times otherwise. The **exponential distribution** was assumed by Littell [36], when he compared the "actuarial" and the maximum likelihood approach to the "T-year survival rate", by Armitage [3] in his comparative study of two-sample tests for **clinical trials** with **staggered entry**, and by Feigl and Zelen [16] in their model for (uncensored) lifetimes whose expectations were allowed to depend linearly on covariates, generalized to censored data by Zippin and Armitage [53].

Cox [11] revolutionized survival analysis by his **semiparametric regression** model for the hazard, depending arbitrarily ("nonparametrically") on time and parametrically on covariates (*see* **Cox Regression Model**). For details on the genesis of Cox's paper, see [42, 43].

Multistate Models

Traditional actuarial and demographical ways of modeling several life events simultaneously may be formalized within the probabilistic area of finite-state **Markov processes** in continuous time. An important and influential documentation of this was by Fix and Neyman [18], who studied recovery, relapse, and death (and censoring) in what is now commonly termed an illness–death model allowing for competing risks (*see* **Fix–Neyman Process**). Chiang [9], for example, in his 1968 monograph, extensively documented the relevant stochastic models (*see* **Stochastic Processes**), and Sverdrup [46], in an important paper, gave a systematic statistical study. These models have constant transition intensities, although subdivision of time into intervals allows grouped-time methodology of the actuarial life-table type, as carefully documented by Hoem [24].

Survival Analysis Concepts

The ideal basic independent nonnegative **random variables** $X_i, i = 1, \ldots, n$ are not always observed directly. For some individuals i, the available piece of information is a *right-censoring* time U_i, that is, a period elapsed in which the event of interest has not occurred (e.g. a patient has survived until U_i). Thus, a generic survival data sample includes $((\widetilde{X}_i, D_i), i = 1, \ldots, n)$ where $\widetilde{X}_i$ is the smaller of X_i and U_i and D_i is the indicator, $I(X_i \leq U_i)$, of not being censored.

Mathematically, the distribution of X_i may be described by the *survival function*

$$S_i(t) = \Pr(X_i > t). \tag{2}$$

If the **hazard function**

$$\alpha_i(t) = \lim_{\Delta t \to 0} \frac{\Pr(X_i \leq t + \Delta t \mid X_i > t)}{\Delta t} \tag{3}$$

exists, then

$$S_i(t) = \exp(-A_i(t)), \tag{4}$$

where

$$A_i(t) = \int_0^t \alpha_i(u)\, \mathrm{d}u \tag{5}$$

is the integrated hazard over $[0, t)$. If, more generally, the distribution of the X_i has discrete components, then $S_i(t)$ is given by the **product-integral** of the cumulative hazard measure. Owing to the dynamical nature of survival data, a characterization of the distribution via the hazard function is often convenient. (Note that $\alpha_i(t)\Delta t$ when $\Delta t > 0$ is *small* is approximately the conditional probability of i "dying" just after time t given "survival" till time t.) Also, $\alpha_i(t)$ is the basic quantity in the **counting process** approach to survival analysis (see e.g. [2], and the article on **Survival Distributions and Their Characteristics**).

Nonparametric Estimation and Testing

The simplest situation encountered in survival analysis is the nonparametric estimation of a survival distribution function based on a right-censored sample of observation times $(\widetilde{X}_1, \ldots, \widetilde{X}_n)$, where the true survival times $X_i, i = 1, \ldots, n$, are assumed to be independent and identically distributed with common survival distribution function $S(t)$, whereas as few assumptions as possible are usually made about the right-censoring times U_i except for the assumption of *independent censoring* (*see* **Censored Data**). The concept of independent censoring has the interpretation that the fact that an individual, i, is alive *and uncensored* at time t, say, should not provide more information on the survival time for that individual than $X_i > t$, that is, the right-censoring mechanism should not remove individuals from the study who are at a particularly high or a particularly low risk of dying. Under these assumptions, $S(t)$ is estimated by the *Kaplan–Meier estimator* [28]. This is given by

$$\widehat{S(t)} = \prod_{\widetilde{X}_i \leq t} \left[1 - \frac{D_i}{Y(\widetilde{X}_i)}\right], \tag{6}$$

where $Y(t) = \sum I(\widetilde{X}_i \geq t)$ is the number of individuals *at risk* just before time t. The Kaplan–Meier estimator is a **nonparametric maximum likelihood** estimator and, in large samples, $\widehat{S(t)}$ is approximately normally distributed with mean $S(t)$ and a variance that may be estimated by Greenwood's formula:

$$\widehat{\sigma^2(t)} = [\widehat{S(t)}]^2 \sum_{\widetilde{X}_i \leq t} \frac{D_i}{Y(\widetilde{X}_i)[Y(\widetilde{X}_i) - 1]}. \tag{7}$$

From this result, pointwise **confidence intervals** for $S(t)$ are easily constructed and, since one can also show weak **convergence** of the entire Kaplan–Meier curve $\{\sqrt{(n)}[\widehat{S(t)} - S(t)]; 0 \leq t \leq \tau\}, \tau \leq \infty$ to a mean zero Gaussian process (*see* **Brownian Motion and Diffusion Processes**), simultaneous confidence bands for $S(t)$ on $[0, \tau]$ can also be set up.

As an alternative to estimating the survival distribution function $S(t)$, the *cumulative hazard function* $A(t) = -\log S(t)$ may be studied. Thus, $A(t)$ may be estimated by the **Nelson–Aalen Estimator**

$$\widehat{A(t)} = \sum_{\widetilde{X}_i \leq t} \frac{D_i}{Y(\widetilde{X}_i)}. \tag{8}$$

The relation between the estimators $\widehat{S(t)}$ and $\widehat{A(t)}$ is given by the *product-integral* from which it follows that their large-sample properties are equivalent. Though the Kaplan–Meier estimator has the advantage that a survival *probability* is easier to interpret than a cumulative hazard function, the Nelson–Aalen estimator is easier to generalize to multistate situations beyond the survival data context. We shall return to this below. To give a nonparametric estimate of the hazard function $\alpha(t)$ itself requires some smoothing techniques to be applied (see **Smoothing Hazard Rates**).

Right censoring is not the only kind of data-incompleteness to be dealt with in survival analysis; in particular, *left truncation* (or **delayed entry**) where individuals may not all be followed from time 0 but maybe from a later entry time V_i conditionally on having survived until V_i, occurs frequently in, for example, epidemiological applications. Dealing with

left truncation only requires a redefinition of the *risk set* from the set $\{i: \widetilde{X}_i \geq t\}$ of individuals still alive and uncensored at time t to the set $\{i: V_i < t \leq \widetilde{X}_i\}$ of individuals with entry time $V_i < t$ and who are still alive and uncensored. With $Y(t)$ still denoting the size of the risk set at time t both (6), (7), and (8) are applicable though one should be aware of the fact that estimates of $S(t)$ and $A(t)$ may be ill-determined for small values of t due to the left truncation (*see* **Truncated Survival Times**).

When the survival time distributions in a number, k, of homogeneous groups have been estimated nonparametrically, it is often of interest to test the hypothesis H_0 of identical hazards in all groups. Thus, on the basis of censored survival data $((\widetilde{X}_{hi}, D_{hi}),\ i = 1, \ldots, n_h)$ for group $h, h = 1, \ldots, k$, the Nelson–Aalen estimates $\widehat{A_h(t)}$ have been computed, and based on the combined sample of size $n = \sum_h n_h$ with data $((\widetilde{X}_i, D_i), i = 1, \ldots, n)$, an estimate of the common cumulative hazard function $A(t)$ under H_0 may be obtained by a Nelson–Aalen estimator $\widehat{A(t)}$. As a general statistic for testing H_0, one may then use a k-vector of sums of weighted differences between the increments of $\widehat{A_h(t)}$ and $\widehat{A(t)}$:

$$Z_h = \sum_{i=1}^{n} K_h(\widetilde{X}_i)[\Delta\widehat{A_h}(\widetilde{X}_i) - \Delta\hat{A}(\widetilde{X}_i)]. \quad (9)$$

Here, $\Delta\widehat{A_h(t)} = 0$ if t is not among the observed survival times in the hth sample and $K_h(t)$ is 0 whenever $Y_h(t) = 0$, in fact all weight functions used in practice have the form $K_h(t) = Y_h(t)K(t)$. With this structure for the weight function, the covariance between Z_h and Z_j given by (9) is estimated by

$$\sigma_{hj} = \sum_{i=1}^{n} K^2(\widetilde{X}_i)\frac{Y_h(\widetilde{X}_i)}{Y(\widetilde{X}_i)}\left[\delta_{hj} - \frac{Y_j(\widetilde{X}_i)}{Y(\widetilde{X}_i)}\right]D_i, \quad (10)$$

and, letting $\mathbf{Z}$ be the k-vector $(Z_1, \ldots, Z_k)'$ and $\boldsymbol{\Sigma}$ the k by k matrix $(\sigma_{hj}, h, j = 1, \ldots, k)$ the test statistic $X^2 = \mathbf{Z}'\boldsymbol{\Sigma}^{-}\mathbf{Z}$ is asymptotically **chi-squared distributed** under H_0 with $k - 1$ **degrees of freedom** if all n_h tend to infinity at the same rate. Here, $\boldsymbol{\Sigma}^{-}$ is a generalized inverse for $\boldsymbol{\Sigma}$ (*see* **Matrix Algebra**).

Special choices for $K(t)$ correspond to test statistics with different properties for particular alternatives to H_0 (*see* **Linear Rank Tests in Survival Analysis**). An important such test statistic is the **logrank** test obtained for $K(t) = I(Y(t) > 0)$. For this test, which has particularly good power for **proportional hazards** alternatives, Z_h given by (9) reduces to $Z_h = O_h - E_h$ with O_h the total number of observed failures in group h and $E_h = \sum D_i Y_h(\widetilde{X}_i)/Y(\widetilde{X}_i)$ an "expected" number of failures in group h. For the two-sample case ($k = 2$), one may of course use the square root of X^2 as an asymptotically normal test statistic for the **null hypothesis**. For the case where the k groups are *ordered*, and where a *score* x_h (with $x_1 \leq \ldots \leq x_k$) is attached to group h, a *test for trend* is given by $T^2 = (\mathbf{x}'\mathbf{Z})^2/\mathbf{x}'\boldsymbol{\Sigma}\mathbf{x}$ with $\mathbf{x} = (x_1, \ldots, x_k)'$ and it is asymptotically chi-squared with 1 df.

The above **linear rank tests** have low **power** against certain important classes of alternatives such as "crossing hazards". Just as for uncensored data, this has motivated the development of test statistics of the **Kolmogorov–Smirnov and Cramèr–von Mises** types, based on maximal deviation or integrated squared deviation between estimated hazards, cumulative hazards or survival functions.

Parametric Inference

The nonparametric methods outlined in the previous section have become the standard approach to the analysis of simple homogeneous survival data without covariate information. However, parametric survival time distributions are sometimes used for inference, and we shall here give a brief review. Assume again that the true survival times $X_1, \ldots, X_n$ are independent and identically distributed with survival distribution function $S(t; \boldsymbol{\theta})$ and hazard function $\alpha(t; \boldsymbol{\theta})$ but that only a right-censored sample $(\widetilde{X}_i, D_i), i = 1, \ldots, n$, is observed. Under independent censoring, the likelihood function for the parameter $\boldsymbol{\theta}$ is

$$L(\boldsymbol{\theta}) = \prod_{i=1}^{n}(\alpha(\widetilde{X}_i; \boldsymbol{\theta}))^{D_i} S(\widetilde{X}_i; \boldsymbol{\theta}). \quad (11)$$

The function (11) may be analyzed using standard **large-sample theory**. Thus, standard tests, that is, Wald-, score-, and **likelihood ratio tests** are used as inferential tools (*see* **Chi-square Tests**). Two frequently used parametric survival models are the **Weibull distribution** with hazard function

$\alpha\rho(\alpha t)^{\rho-1}$, and the piecewise exponential distribution with $\alpha(t, \boldsymbol{\theta}) = \alpha_j$ for $t \in I_j$ with $I_j = [t_{j-1}, t_j)$, $0 = t_0 < t_j < \cdots < t_m = \infty$. Both of these distributions contain the very simplest model, the **exponential distribution** with a constant hazard function as null cases (*see* **Parametric Models in Survival Analysis**).

Comparison with Expected Survival

As a special case of the nonparametric tests discussed above, a *one-sample* situation may be studied. This may be relevant if one wants to compare the observed survival in the sample with the *expected survival* based on a standard life table. Thus, assume that a hazard function $\alpha^*(t)$ is given and that the hypothesis $H_0 : \alpha = \alpha^*$ is to be tested. One test statistic for H_0 is the one-sample *logrank test* $(O - E^*)/(E^*)^{1/2}$ where E^*, the "expected" number of deaths is given by $E^* = \sum[A^*(\widetilde{X}_i) - A^*(V_i)]$ (with A^* the cumulative hazard corresponding to α^*). In this case, $\widehat{\theta} = O/E^*$, the *standardized mortality ratio*, is the maximum likelihood estimate for the parameter θ in the model $\alpha(t) = \theta\alpha^*(t)$. Thus, the standardized mortality ratio arises from a **multiplicative model** involving the known population hazard $\alpha^*(t)$. Another classical tool for comparing with expected survival, the so-called *expected survival function*, arises from an *additive or excess* hazard model (*see* **Excess Mortality**; **Expected Number of Deaths**; **Historical Controls in Survival Analysis**).

The Cox Regression Model

In many applications of survival analysis, the interest focuses on how *covariates* may affect the outcome; in clinical trials, adjustment of treatment effects for effects of other **explanatory variables** may be crucial if the randomized groups are unbalanced with respect to important **prognostic factors**, and in epidemiological **cohort studies**, reliable effects of exposure may be obtained only if some adjustment is made for **confounding** variables. In these situations, a *regression model* is useful and the most important model for survival data is the **Cox** [11] *proportional hazards regression model*. In its simplest form, it states the hazard function for an individual, i, with covariates $\boldsymbol{Z}_i = (Z_{i1}, \ldots, Z_{ip})'$ to be

$$\alpha_i(t; \boldsymbol{Z}_i) = \alpha_0(t) \exp(\boldsymbol{\beta}' \boldsymbol{Z}_i), \tag{12}$$

where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ is a vector of unknown regression coefficients and $\alpha_0(t)$, the *baseline hazard*, is the hazard function for individuals with all covariates equal to 0. Thus, the baseline hazard describes the common shape of the survival time distributions for all individuals while the *relative risk* function $\exp(\boldsymbol{\beta}' \boldsymbol{Z}_i)$ gives the level of each individual's hazard. The interpretation of the parameter, β_j for a dichotomous $Z_{ij} \in \{0, 1\}$ is that $\exp(\beta_j)$ is the **relative risk** for individuals with $Z_{ij} = 1$ compared to those with $Z_{ij} = 0$ all other covariates being the same for the two individuals. Similar interpretations hold for parameters corresponding to covariates taking more than two values.

The model is **semiparametric** in the sense that the relative risk part is modeled parametrically while the baseline hazard is left unspecified. This semiparametric nature of the model led to a number of inference problems, which was discussed in the literature in the years following the publication of Cox's article in 1972. However, these problems were all resolved and estimation proceeds as follows. The regression coefficients $\boldsymbol{\beta}$ are estimated by maximizing the **Cox partial likelihood**

$$L(\boldsymbol{\beta}) = \prod_{i=1}^{n} \left[\frac{\exp(\boldsymbol{\beta}' \boldsymbol{Z}_i)}{\sum_{j \in R_i} \exp(\boldsymbol{\beta}' \boldsymbol{Z}_j)} \right]^{D_i}, \tag{13}$$

where $R_i = \{j : \widetilde{X}_j \geq \widetilde{X}_i\}$, the **risk set** at time $\widetilde{X}_i$, is the set of individuals still alive and uncensored at that time. Furthermore, the cumulative baseline hazard $A_0(t)$ is estimated by the *Breslow estimator*

$$\widehat{A_0(t)} = \sum_{\widetilde{X}_i \leq t} \frac{D_i}{\sum_{j \in R_i} \exp(\widehat{\boldsymbol{\beta}}' \boldsymbol{Z}_j)}, \tag{14}$$

which is the Nelson–Aalen estimator one would use if $\boldsymbol{\beta}$ were known and equal to the maximum partial likelihood estimate $\widehat{\boldsymbol{\beta}}$. The estimators based on (13) and (14) also have a nonparametric maximum likelihood interpretation. In large samples, $\widehat{\boldsymbol{\beta}}$ is approximately normally distributed with the proper mean and with a **covariance**, which is estimated by the **information matrix** based on (13). This means that approximate confidence intervals for the relative risk parameters of interest can be calculated and that the usual large-sample test statistics based on (13) are available. Also, the asymptotic distribution of the Breslow estimator is normal; however, this estimate

is most often used as a tool for estimating *survival probabilities* for individuals with given covariates, $\mathbf{Z}_0$. Such an estimate may be obtained by the product integral $\widehat{S(t;\mathbf{Z}_0)}$ of $\exp(\widehat{\boldsymbol{\beta}}'\mathbf{Z}_0)\widehat{A_0(t)}$. The *joint* asymptotic distribution of $\widehat{\boldsymbol{\beta}}$ and the Breslow estimator then yields an approximate normal distribution for $\widehat{S(t;\mathbf{Z}_0)}$ in large samples.

A number of useful extensions of this simple Cox model are available. Thus, in some cases, the covariates are **time-dependent**, for example, a covariate might indicate whether or not a given event had occurred by time t, or a time-dependent covariate might consist of repeated recordings of some measurement likely to affect the prognosis. In such cases, the regression coefficients $\boldsymbol{\beta}$ are estimated replacing $\exp(\boldsymbol{\beta}'\mathbf{Z}_j)$ in (13) by $\exp[\boldsymbol{\beta}'\mathbf{Z}_j(\widetilde{X}_i)]$.

Also, a simple extension of the Breslow estimator (14) applies in this case. However, the survival function can, in general, no longer be estimated in a simple way because of the extra randomness arising from the covariates, which is not modeled in the Cox model. This has the consequence that the estimates are more difficult to interpret when the model contains time-dependent covariates. To estimate the survival function in such cases, a joint model for the hazard and the time-dependent covariate is needed (*see* **Joint Modeling of Longitudinal and Event Time Data**).

Another extension of (12) is the *stratified* Cox model where individuals are grouped into a number, k of strata each of which has a separate baseline hazard (*see* **Stratification**). This model has important applications for checking the assumptions of (12). The model assumption of proportional hazards may also be *tested* in a number of ways, the simplest possibility being to add interaction terms of the form $Z_{ij}f(t)$ between Z_{ij} and time where $f(t)$ is some specified function. Also, various forms of *residuals* as for normal linear models may be used for **model checking** in (12) (*see* **Goodness of Fit in Survival Analysis**; **Residuals for Survival Analysis**). In (12), it is finally assumed that a quantitative covariate affects the hazard *log-linearly*. This assumption may also be checked in several ways and alternative models with other relative risk functions $r(\boldsymbol{\beta}'\mathbf{Z}_i)$ may be used. Special care is needed when covariates are measured with error (*see* **Measurement Error in Survival Analysis**).

Other Regression Models for Survival Data

Though the semiparametric Cox model is the regression model for survival data that is applied most frequently, other regression models, for example, *parametric* regression models also play important roles in practice. Examples include models with a multiplicative structure, that is, models like (12) but with a parametric specification, $\alpha_0(t) = \alpha_0(t;\boldsymbol{\theta})$, of the baseline hazard, and **accelerated failure-time models**.

A multiplicative model with important epidemiological applications is the **Poisson regression** model with a piecewise constant baseline hazard. In large data sets with categorical covariates, this model has the advantage that a sufficiency reduction to the number of failures and the amount of person-time at risk in each *cell* defined by the covariates and the division of time into intervals is possible. This is in contrast to the Cox regression model (12) where each individual data record is needed to compute (13). The substantial computing time required to maximize (13) in large samples has also led to modifications of this estimation procedure. Thus, in *nested case–control studies* the risk set R_i in the Cox partial likelihood is replaced by a random sample $\widetilde{R}_i$ of R_i (*see* **Case–Control Study, Nested**).

In the accelerated failure-time model, the focus is not on the hazard function but on the survival time itself much like in classical linear models. Thus, this model is given by $\log X_i = \alpha + \boldsymbol{\beta}'\mathbf{Z}_i + \varepsilon_i$, where the error terms are assumed to be independent and identically distributed with expectation 0. Examples include **normally distributed** ($\varepsilon_i, i = 1, \ldots, n$), and error terms with a **logistic** or an **extreme value** distribution, the latter giving rise to a regression model with **Weibull** distributed life times.

Finally, we shall mention some nonparametric hazard models. In Aalen's additive model, $\alpha_i(t) = \beta_0(t) + \boldsymbol{\beta}(t)'\mathbf{Z}_i(t)$ (*see* **Aalen's Additive Regression Model**), the regression functions $\beta_0(t), \ldots, \beta_p(t)$ are left completely unspecified and estimated nonparametrically much like the Nelson–Aalen estimator discussed above. This model provides an attractive alternative to the other regression models discussed in this section. There also exist more general and flexible models containing both this model and the Cox regression model as special cases (*see* **Additive–Multiplicative Intensity Models**).

Multistate Models

Models for survival data may be considered a special case of a *multistate model*, namely, a model with a transient state *alive* (0) and an absorbing state *dead* (1) and where the hazard rate is the force of transition from state 0 to state 1. Multistate models may conveniently be studied in the mathematical framework of *counting processes* with a notation that actually simplifies the notation of the previous sections and, furthermore, unifies the description of survival data and that of more general models like the competing risks model and the illness–death model to be discussed below. We first introduce the counting processes relevant for the study of censored survival data [1] Define, for $i = 1, \ldots, n$, the stochastic processes

$$N_i(t) = I(\widetilde{X}_i \leq t, D_i = 1) \tag{15}$$

and

$$Y_i(t) = I(\widetilde{X}_i \geq t). \tag{16}$$

Then (15) is a counting process counting 1 at time $\widetilde{X}_i$ if individual i is observed to die; otherwise $N_i(t) = 0$ throughout. The process (16) indicates whether i is still at risk just before time t. Models for the survival data are then introduced via the *intensity process*, $\lambda_i(t) = \alpha_i(t)Y_i(t)$ for $N_i(t)$, where $\alpha_i(t)$, as before, denotes the hazard function for the distribution of X_i. Letting $N = N_1 + \cdots + N_n$ and $Y = Y_1 + \cdots + Y_n$ the Nelson–Aalen estimator (8) is given by the stochastic integral

$$\widehat{A(t)} = \int_0^t \frac{J(u)}{Y(u)}\, \mathrm{d}N(u), \tag{17}$$

where $J(t) = I(Y(t) > 0)$. In this simple multistate model, the *transition probability* $P_{00}(0, t)$, that is, the conditional probability of being in state 0 by time t given state 0 at time 0 is simply the survival probability $S(t)$, which, as described above, may be estimated using the Kaplan–Meier estimator, which is the product-integral of (17). In fact, all the models and methods for survival data discussed above, which are based on the hazard function have immediate generalizations to models based on counting processes. Thus, both the nonparametric tests and the Cox regression model may be applied for counting process (multistate) models (*see* **Counting Process Methods in Survival Analysis**).

One important extension of the two-state model for survival data is the *competing risks* model with one transient alive state 0 and a number, k, of absorbing states corresponding to death from cause h, $h = 1, \ldots, k$. In this model, the basic parameters are the cause-specific hazard functions $\alpha_h(t)$, $h = 1, \ldots, k$, and the observations for individual i will consist of $(\widetilde{X}_i, D_{hi})$, $h = 1, \ldots, k$, where $D_{hi} = 1$ if individual i is observed to die from cause h, and $D_{hi} = 0$ otherwise. On the basis of these data, k counting processes for each i can be defined by $N_{hi}(t) = I(\widetilde{X}_i \leq t, D_{hi} = 1)$ and letting $N_h = N_{h1} + \cdots + N_{hn}$, the integrated cause-specific hazard $A_h(t)$ is estimated by the Nelson–Aalen estimator replacing N by N_h in (17). A useful synthesis of the cause-specific hazards is provided by the transition probabilities $P_{0h}(0, t)$ of being dead from cause h by time t. This is frequently called the *cumulative incidence function* for cause h and is given by

$$P_{0h}(s, t) = \int_s^t S(u)\alpha_h(u)\, \mathrm{d}u, \tag{18}$$

and hence it may be estimated by (18) by inserting the Kaplan–Meier estimate for $S(u)$ and the Nelson–Aalen estimate for the integrated cause-specific hazard. In fact, this **Aalen–Johansen estimator** of the matrix of transition probabilities is exactly the product-integral of the cause-specific hazards.

Another important multistate model is the *illness–death* or *disability* model with two transient states, say *healthy* (0) and *diseased* (1) and one absorbing state *dead* (2). If transitions both from 0 to 1 and from 1 to 0 are possible, the disease is *recurrent*, otherwise it is *chronic*. On the basis of such observed transitions between the three states, it is possible to define counting processes for individual i as $N_{hji}(t) =$ number of observed $h \to j$ transitions in the time interval $[0, t]$ for individual i and, furthermore, we may let $Y_{hi}(t) = I$ (i is in state h at time $t-$). With these definitions, we may set up and analyze models for the transition intensities $\alpha_{hji}(t)$ from state h to state j including nonparametric comparisons and Cox-type regression models. Furthermore, transition probabilities $P_{hj}(s, t)$ may be estimated by product-integration of the intensities.

Other Kinds of Incomplete Observation

A salient feature of survival data is *right censoring*, which has been referred to throughout in the present

overview. However, several other kinds of incomplete observation are important in survival analysis.

Often, particularly when the time variable of interest is age, individuals enter study after time 0. This is called *delayed entry* and may be handled by *left truncation* (conditioning) or *left filtering* ("viewing the observations through a filter"). There are also situations when only events (such as AIDS cases) that occur *before* a certain time are included (*right truncation*) (*see* **Truncated Survival Times**). The phenomenon of *left censoring*, though theoretically possible, is more rarely relevant in survival analysis.

When the event times are only known to lie in an interval, one may use the *grouped time* approach of classical *life tables* (*see* **Grouped Survival Times**; **Life Table**), or (if the intervals are not synchronous) techniques for **interval censoring** may be relevant.

A common framework (**coarsening at random**) was recently suggested for several of the above types of incomplete observation.

Multivariate Survival Analysis

For **multivariate survival**, the innocently looking problem of generalizing the Kaplan–Meier estimator to several dimensions has proved surprisingly intricate. A major challenge (in two dimensions) is how to efficiently use singly censored observations, where one component is observed and the other is right censored.

For regression analysis of multivariate survival times, two major approaches have been taken. One is to model the marginal distributions and use estimation techniques based on **generalized estimating equations** leaving the association structure unspecified (see **Marginal Models for Multivariate Survival Data**.) The other is to specify **random effects** models for survival data based on conditional independence (*see* **Frailty**.) An interesting combination between these two methods is provided by **copula** models in which the marginal distributions are combined via a so-called copula function thereby obtaining an explicit model for the association structure.

For the special case of repeated events, both the marginal approach and the conditional (frailty) approach have been used successfully (*see* **Repeated Events**).

Concluding Remarks

Survival analysis is a well-established discipline in statistical theory as well as in biostatistics. Most books on biostatistics contain chapters on the topic and most **software** packages include procedures for handling the basic survival techniques (*see* **Survival Analysis, Software**). Several books have appeared, among them the documentation of the actuarial and demographical know-how by Elandt–Johnson and Johnson [15]; the research monograph by Kalbfleisch and Prentice [27], the first edition of which for a decade maintained its position as main reference on the central theory; the comprehensive text by Lawless [34] covering also parametric models, and the concise text by Cox and Oakes [12], two central contributors to the recent theory. The counting process approach is covered by Fleming and Harrington [17] and by Andersen et al. [2]; see also [25]. Later, books intended primarily for the biostatistical user have appeared. These include [10, 31, 32, 38, 40]. Also, books dealing with special topics, like implementation in the **S-Plus** software [47], multivariate survival data [26], and the linear regression model [45] have appeared.

Survival Analysis, Software

Most, if not all, techniques for the analysis of time-to-event data (*see* **Survival Analysis, Overview**) requires specialized **software** (*see* **Software, Biostatistical**). For example, many of the estimators used with **censored data** do not have closed-form solutions and require iterative solutions to estimating equations (*see* **Estimating Functions**).

The specialized software for survival data may be in a stand-alone package such as *SURVIVAL* [16] or may be an integrated part of a more comprehensive package such as SAS or SPSS. Whatever the package, there are a minimal number of requirements that a program should have. The package should have the ability to handle right-censored data and to properly handle tied observations (*see* **Tied Survival Times**). Better packages should have the ability to handle other types of censoring such as left and interval censoring (*see* **Censored Data**). Some packages can also handle left truncated data (*see* **Truncated Survival Times**).

The types of analysis for survival data fall into four main areas. The first area is summary or univariate statistics. Here, most packages have routines to compute the Kaplan–Meier estimator (*see* **Kaplan–Meier Estimator**) for right-censored data and make summary plots.

The second area is **hypothesis testing**. Most packages have routines to compute the **logrank test** for right-censored data. More inclusive packages have routines for weighted logrank tests.

The third area is **semiparametric regression** modeling. Most packages have at least a routine to fit the Cox proportional hazards model (*see* **Cox Regression Model**; **Proportional Hazards, Overview**) with fixed time **covariates** to right-censored data. Some packages have routines for checking model assumptions (*see* **Model Checking**) of which a check of the proportional hazards assumption is most common (*see* **Goodness of Fit in Survival Analysis**). Most packages allow for **time-dependent covariates**.

The final area is **parametric models** for right-censored data (*see* **Survival Distributions and Their Characteristics**). Most packages have routines for at least the **Weibull** model. More complete packages have routines for the **lognormal** and log-logistic models. Many of these packages allow for regression analysis for right-censored data.

Several authors have compared the adequacy of statistical packages for survival data. These include surveys by Dain et al. [6], Goldstein et al. [9], and Harrell and Goldstein [10]. We refer the interested reader to these sources for a comparison of packages for the PC.

In the remainder of this article, we compare and contrast the abilities of five of the most common statistical packages in use. These are SAS (Version 8.2), S-PLUS (version 6.1.2), SPSS (Version 11), STATA (Version 7), and BMDP (New system 2.0). We have chosen these five packages since they are comprehensive packages that include a wide range of statistical routines. They are available for a number of platforms including the PC and UNIX systems. In our interaction with other biostatisticians, we have found that these are the packages that seem to be most popular. Contact information (many packages have contact sites outside the US as well) and worldwide web site address for these packages are listed below. Newest update information, new features and modules, user's manuals, and technical support information are often available on these web sites.

1. **BMDP**, SPSS Inc., 233 S. Wacker Drive, 11th Floor, Chicago, IL 60606, USA; (312) 651–3000; http://www.statsol.ie/bmdp/bmdp.htm.
2. **SAS**, SAS Institute Inc. 100 SAS Campus Drive, Cary, NC 27513-2414, USA; (919) 677–8000; http://www.sas.com.
3. **SPSS**, SPSS Inc., 233 S. Wacker Drive, 11th Floor, Chicago, IL 60606, USA; (312) 651–3000; http://www.spss.com.
4. **S-PLUS**, Insightful Corporation Global Headquarters, 1700 Westlake Avenue, North Suite 500, Seattle, WA 98109-3044, USA; (800) 569-0123; http://www.splus.com.
5. **STATA**, STATA Corporation, 4905 Lakeway Drive, College Station, Texas 77845, USA; (800)-782-8272; http://www.stata.com.

Summary of Univariate Statistics

Each of the five packages provides the Kaplan–Meier estimator for right-censored data. The packages all present estimates of the standard errors using Greenwood's formula. Each package provides

estimates of the **median survival** function based on the Kaplan–Meier estimator and confidence intervals for the median survival based on the Brookmeyer and Crowley procedure [4]. All these interval estimates of the median are based on the naïve confidence interval for the survival function except for the interval found in STATA that uses a log–log transformed confidence interval for the survival function. Each package provides estimates of the mean survival and its standard error; however, when the last observation is censored these estimates may differ. SAS estimates the restricted mean as the area under the Kaplan–Meier curve up to the last event, while each of the other packages estimates the area under the curve up to the largest on study time. STATA allows for an alternative estimator of the mean based on completing the tail of the Kaplan–Meier estimator by an exponential curve as suggested by Brown et al. [5].

Each of the packages has additional features that are not shared by all the other packages that we now summarize.

BMDP. BMDP allows right-censored data only. It allows the user to produce plots of the estimated survival function, log survival function and cumulative **cumulative hazard** function (i.e. $-\log\{\hat{S}(t)\}$). It provides estimates of the standard error of the median. BMDP does not give confidence intervals for the survival function. BMDP also computes life-table estimates of the survival function and **hazard rate** based on grouped survival data.

SAS. SAS also only handles right-censored data. It provides Kaplan–Meier estimator in the routine PROC LIFETEST and the **Nelson–Aalen estimator** of the cumulative hazard rate can be obtained in PROC PHREG. Naïve confidence intervals are constructed for the survival function based on the Kaplan–Meier estimator. Both the Kaplan–Meier and the Fleming–Harrington [8] estimators ($\exp\{-\hat{\Lambda}(t)\}$) of the survival function, where $\Lambda_{\widehat{(t)}}$ is the Nelson–Aalen estimator of the cumulative hazard function, can be put into a SAS data set from which a wide range of plots can be made. SAS also provides classical **life-table** estimates based on **grouped data**.

S-PLUS. S-PLUS is the most flexible of the packages. It has versions of the Kaplan–Meier estimator that handle right-, left-, and interval-censored data [18, 19]. For right-censored data it allows the user to select between three variance estimators [11] and three types of confidence intervals [2] (naïve, log, and log–log transformed). It also provides the Nelson–Aalen estimator of the hazard rate and Fleming–Harrington's estimator for the survival probability. It plots the estimated survival function and log survival function. Besides making default plots, a user can easily make custom plots using saved analysis results and S-PLUS's powerful graphical capability. However, it does not provide estimates based on classical life-table results.

SPSS. SPSS handles right-censored data only. It plots the estimated survival function. It does not provide confidence intervals for the survival function. SPSS does allow the user to perform a life-table analysis on grouped event time data.

STATA. STATA handles right-censored data. It is the only one of the five packages to allow the data to be left truncated. In fact, it allows for more complicated truncation where patients may move in and out of the **risk set**. It provides log–log-transformed pointwise confidence intervals for the survival probabilities. It also allows computation of the Nelson–Aalen's estimator for the cumulative hazard function and for confidence intervals based on this statistic. It does not provide classical life-table analysis.

Hypothesis Tests

Statistical hypothesis tests for the equality of $K \geq 2$ populations using survival data are typically based on the weighted logrank test (*see* **Linear Rank Tests in Survival Analysis**). This test is based on quadratic forms constructed from the statistics

$$Z_j = \sum_{t_i} W(t_i) \left\{ \mathrm{d}_{ij} - Y_j(t_i) \frac{\mathrm{d}_{\bullet i}}{Y_\bullet(t_i)} \right\}, \qquad (1)$$

where the sum is over the event times, t_i, in the combined sample, $Y_j(t_i)$ is the number at risk, and d_{ij} the number of events at time t_i in the jth sample. Here $Y_\bullet()$ and $\mathrm{d}_{\bullet i}$ are the total number at risk and number dead in all K groups.

The most common choices for the weight function are $W(t) = 1$, which leads to the **Mantel–Haenszel**

logrank test and $W(t) = Y(t)$, which gives the Breslow–Gehan [3] version of the **Wilcoxon test**. These weights are available in all five packages. Other weight functions that can be used are summarized in Table 1. Further details on these statistics can be found in Chapter 7 of [12].

In addition to these tests STATA, BMDP, and S-PLUS all have tests of trend that can be obtained using these weight functions. Stratified tests are directly available in BMDP and STATA. In SAS, the "STRATA" command in PROC LIFETEST is used to invoke weighted logrank tests to compare the survival over subgroups, but the package does not directly compute stratified tests.

Semiparametric Regression Modeling

All five packages have extensive routines for the Cox proportional hazards model. These routines all allow for stratified regression models with both fixed and user defined time-dependent covariates. They all allow for right-censored data. At a minimum the packages return estimates of the risk coefficients, standard errors of the risk coefficients, and Wald tests of significance of the risk coefficients. Each of the packages has the ability to produce estimates and plots of the predicted survival function for models with fixed covariates. All the packages have some type of **diagnostic** plots.

The packages do differ in what they can compute in a number of ways. Table 2 summarizes the differences between the packages.

From the table we see that BMDP and SPSS do not allow delayed entry or left truncation of the data. Both S-PLUS and STATA allow for individuals to enter and leave the risk set at multiple times. SAS also allows for discontinuous time at risk by using multiple records for individuals and the counting process form of input. While one can handle categorical variables in all models, only SPSS allows the user to specify variables as categorical so that the appropriate multiple degree of freedom test is performed.

Table 1 Additional weight functions available for logrank tests

Weight	BMDP	SAS	S-PLUS	SPSS	STATA
Peto–Peto–Prentice [15] $W(t) =$ Pooled Kaplan–Meier ($S_{\mathrm{KM}}(t)$)	YES	NO	YES	NO	YES
Tarone and Ware [17] $W(t) = Y(t)^{1/2}$	YES	NO	NO	YES	YES
Fleming–Harrington [7] $S(t)^p(1 - S(t))^q$	NO	NO	For $q = 0$ only	NO	YES

Table 2 Comparison of features related to the Cox model

	BMDP	SPSS	SAS	S-PLUS	STATA
Type of Data					
Left truncation	N	N	Y	Y	Y
Discontinuous time at risk	N	N	Y	Y	Y
Categorical variables	N	Y	N	N	N
Inference properties					
Choice of likelihood for ties	N	N	Y	Y	Y
Allows robust variances	N	N	Y	Y	Y
Allows general risk function	N	N	N	Y	Y
Stepwise model building	Y	Y	Y	N	N
Frailty modeling	N	N	N	Y	N
Penalized likelihood	N	N	N	Y	N
Residuals					
Cox–Snell	Y	Y	Y	Y	Y
Martingale	N	Y	Y	Y	Y
Deviance	N	N	Y	Y	Y
Schoenfeld residuals	N	Y	Y	Y	Y
Weighted Schoenfeld residuals	N	N	Y	N	Y
Score residuals (DfBeta)	N	Y	Y	Y	N

When there are ties in the data, there are a number of choices for the **partial likelihood** in the literature (see [12]) SAS, S-PLUS, and STATA allow the user to chose between these likelihoods. S-PLUS, SAS, and STATA allow for robust versions of the variance of the Cox model including sandwich estimators that correct for correlation between estimates (see [13]). S-PLUS allows the user to use a **penalized likelihood** approach to smooth estimators. They also use the penalized likelihood to deal with random effect or frailty models.

SAS, SPSS, and BMDP all have routines for forward, backward, and stepwise model building (*see* **Variable Selection**). With the exception of SPSS these packages do not treat categorical variables as factors and the results of these automated features are suspect at times. We recommend model building by hand, which can be done quite efficiently with any of the packages. Table 2 also list which **residuals** the packages have available (*see* **Residuals for Survival Analysis**). Definitions of these residuals can be found in Chapter 11 of [12].

Parametric Modeling

Parametric models are often used to analyze survival data. The **accelerated failure-time model** has been suggested as an alternative to the Cox model when one wants to adjust for covariates. All of the packages, except SPSS, are able to perform parametric regression analysis. Parametric survival data analysis depends on the chosen distribution and residuals can be used in model diagnosis. Available distribution functions and residual types vary among the four packages. Packages can handle different types

Table 3 Capabilities in parametric analysis among various packages

	BMDP	SAS	S-PLUS	STATA
Available distributions:				
Exponential	Yes	Yes	Yes	Yes
Gompertz	No	No	No	Yes
Generalized gamma	No	Yes	No	Yes
Log-logistic	Yes	Yes	Yes	Yes
Lognormal	Yes	Yes	Yes	Yes
Rayleigh	Yes	No	Yes	No
Weibull	Yes	Yes	Yes	Yes
Fitting model with no covariate	Yes	Yes	Yes	Yes
Data type:				
Left censoring	No	Yes	Yes	No
Right censoring	Yes	Yes	Yes	Yes
Interval censoring	No	Yes	Yes	No
Left truncation	No	No	Yes	Yes
Time-dependent covariate	No	No	No	Yes
Tests significance for individual covariate:				
Wald	Yes	Yes	Yes	Yes
Likelihood-ratio	Yes	No	No	No
Score	Yes	No	No	No
Stratified regression model	No	No	Yes	Yes
Type of residuals:				
Cox–Snell	Yes	Yes	No	Yes
Deviance	No	No	Yes	Yes
Df-beta	No	No	Yes	No
Likelihood displacement	No	No	Yes	No
Martingale type	No	No	No	Yes
Standardized	Yes	No	Yes	No
Multiplicative frailty model:				
Gamma frailty	No	No	No	Yes
Inverse-Gaussian frailty	No	No	No	Yes

of censored data. Table 3 shows the capabilities of each of the four packages.

Discussion

The five packages we have discussed have the ability to compute many of the statistics a practicing biostatistician needs to analyze survival data. Several of the packages (SAS, S-PLUS, and STATA) allow the user to program additional statistical methods. These programs can also take results from the built-in routines and perform further analysis on these results. S-PLUS has an extensive collection of routines for expected survival, which can be used to compare survival data to known mortality rates.

The completeness of the packages and the ability to add additional routines make S-PLUS, SAS, or STATA the best packages we have found to analyze survival data. However, the sophistication and personal preference of the user makes the choice between the packages difficult.

We close this article with a plea to the manufacturer of this software to consider adding important missing routines for survival data. These include statistical procedures for **competing risks**. In particular, routines for the cumulative incidence function, and routines for inference for the cumulative incidence function are needed. Also missing are routines for either **Aalen's** [1] or Lin and Ying's [14] **additive hazard regression model** or for other semiparametric alternatives to the Cox model.

Survival Distributions and Their Characteristics

Many applications in biostatistics involve the modeling of lifetime data. In these applications the outcome of interest is the time, T, until some event occurs. This event may be death, the appearance of a tumor, the development of some disease, recurrence of a disease, conception, cessation of smoking, and so forth. Here T is a nonnegative **random variable** from a homogeneous population (*see* **Survival Analysis, Overview**).

In this article we examine how the distribution of T can be characterized. Four functions characterize the distribution of T: the *survival function*, which is the probability of an individual surviving beyond time t; the **hazard** *rate*, which is approximately the chance an individual of age t experiences the event in the next instant in time; the *probability density (or mass) function*, which is the approximate unconditional probability of the event occurring at time t; and the *mean residual life* at time t, which is the mean time to the event of interest, given the event has not occurred at t. If we know any one of these four functions, then the other three can be uniquely determined. These functions are introduced for continuous, discrete and mixed random variables in the following sections and the interrelationships among the four functions are discussed.

The distribution of the time to an event can also be characterized by the aging properties of the distribution of T. Aging classes are based on certain properties of one of the four basic quantities that describe the distribution of T. These classes are defined and some basic properties of these classes are discussed in the final section.

The Survival Function

The basic quantity employed to describe time-to-event phenomena is the survival function. This function, also known as the survivor function or survivorship function, is the probability an individual survives beyond time t. It is defined as

$$S(t) = \Pr(T \geq t).$$

In the context of equipment or manufactured item failures, $S(t)$ is referred to as the *reliability function*. Note that the survival function is a nonincreasing function with a value of 1 at the origin and 0 as t approaches infinity.

If T is a continuous random variable, then $S(t)$ is a continuous monotone decreasing function and the survival function is the complement of the cumulative distribution function $F(t) = \Pr(T \leq t)$. That is, $S(t) = 1 - F(t)$. The survival function is the integral of the probability density function $f(t)$. That is,

$$S(t) = \Pr(T \geq t) = \int_t^\infty f(u)\,\mathrm{d}u.$$

Thus, we have the following relationship:

$$f(t) = -\frac{\mathrm{d}S(t)}{\mathrm{d}t}.$$

Note that $f(t)\Delta t$ may be thought of as the "approximate" probability of the event occurring at time t and that $f(x)$ is a nonnegative function with the area under $f(x)$ being equal to one.

Example

A common distribution used in many applications is the **Weibull distribution** with probability density function $f(t) = \lambda\alpha t^{\alpha-1}\exp(-\lambda t^\alpha), \lambda > 0, \alpha > 0$. The **exponential distribution** is a special case of the Weibull distribution when $\alpha = 1$. The survival function for the Weibull distribution is $S(t) = \exp(-\lambda t^\alpha), \lambda > 0, \alpha > 0$. Survival curves with a common median of 6.93 are exhibited in Figure 1 for $\lambda = 0.26328$, $\alpha = 0.5$; $\lambda = 0.1$, $\alpha = 1$; and $\lambda = 0.00208$, $\alpha = 3$.

When T is a discrete random variable then the survival function is a nonincreasing left-continuous step function. If T can take on values $t_0 < t_1 < t_2 < \ldots$ with probability mass function (pmf) $p(t_j) = \Pr(T = t_j)$, $j = 1, 2, \ldots$, then

$$S(t) = \Pr(X \geq t) = \sum_{j:t_j \geq t} p(t_j).$$

Note that the survival function and probability mass function are related by

$$p(t_j) = S(t_j) - S(t_{j+1}).$$

Here we have defined $S(t) = \Pr(T \geq t)$ as was the case in [3] and [5]. This definition was used to make later formulas for the discrete case simpler. Other

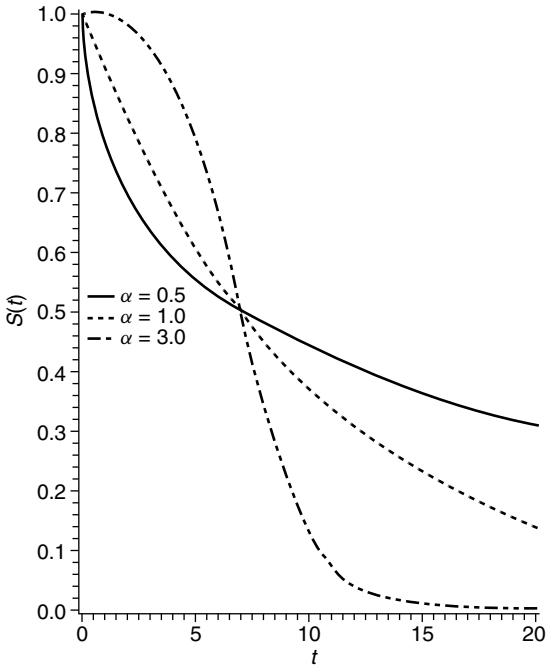

Figure 1 Comparison of Weibull survival functions

authors (see [4] and [6]) have defined $S(t) = \Pr(T > t)$, which makes the relationship $S(t) = 1 - F(t)$ hold for both the discrete and continuous case.

The Hazard Function

A basic quantity, foundational in survival analysis, is the hazard function. This function is also known as the conditional failure rate in reliability, the force of mortality in demography, the age-specific failure rate in epidemiology, the inverse of Mill's ratio in economics or simply as the hazard rate. The hazard rate is defined as

$$h(t) = \lim_{\Delta t \to 0} \frac{\Pr(t \le T < t + \Delta t | T \ge t)}{\Delta t}. \quad (1)$$

The hazard rate is a nonnegative function. It tells us how quickly individuals of a given age are experiencing the event of interest. The quantity $h(t)\Delta t$ is the approximate probability that an individual who has survived to age t will experience the event in the interval $(t, t + \Delta t)$.

This function is particularly useful in determining the appropriate failure distributions utilizing qualitative information about the mechanism of failure and for describing the way in which the chance of experiencing the event changes with time. There are many general shapes for the hazard rate. Some generic types of hazard rate are increasing, decreasing, constant, bathtub-shaped or hump-shaped. Models with increasing hazard rates arise when there is natural aging or wear-out. Decreasing hazard functions are much less common, but find occasional use when there is a likelihood of very early failure, as in certain types of electronic devices, or in patients experiencing certain types of transplant. Decreasing hazard rates often arise as models for heterogeneous populations where the hazard rates of members of the population are random (*see* **Frailty**). Most often a bathtub-shaped hazard is appropriate in populations followed from birth. Most population mortality data follow this type of hazard function: early in the process, deaths result primarily from infant diseases; then the death rate stabilizes; later, an increasing hazard rate sets in, due to the natural aging process. Finally, if the hazard rate is increasing early and eventually begins declining, then the hazard is termed 'hump-shaped'. This type of hazard rate is often used in modeling survival after successful surgery where there is an initial increase in risk due to infection, hemorrhaging, or other complications just after the procedure, followed by a steady decline in risk as the patient recovers.

If T is a continuous random variable, then

$$h(t) = \frac{f(t)}{S(t)} = -\frac{\mathrm{d}}{\mathrm{d}t} \ln[S(t)].$$

A related quantity is the cumulative hazard function, $H(t)$, defined by

$$H(t) = \int_0^t h(u)\,\mathrm{d}u = -\ln[S(t)].$$

Thus for continuous lifetimes we have the following relationship:

$$S(t) = \exp\{-H(t)\} = \exp\left\{-\int_0^t h(u)\,\mathrm{d}u\right\}.$$

The Weibull distribution is flexible enough to accommodate increasing ($\alpha > 1$), decreasing ($\alpha < 1$), and constant hazard rates ($\alpha = 1$). Figure 2 plots hazard rates, $h(x) = \alpha\lambda x^{\alpha-1}$, for the same Weibull

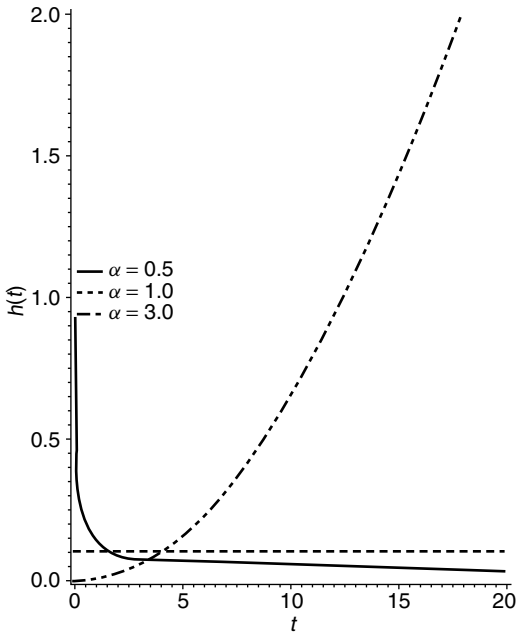

Figure 2 Comparison of Weibull hazard functions

distributions as in Figure 1. One can see that, though the three survival functions have the same basic shape, the three hazard functions are dramatically different.

When T is a discrete random variable, the hazard function is

$$h(t_j) = \Pr(T = t_j | T \geq t_j) = \frac{p(t_j)}{S(t_j)}, \quad j = 1, 2, \ldots.$$

Since $p(t_j) = S(t_j) - S(t_{j+1})$, we have

$$h(t_j) = 1 - \frac{S(t_{j+1})}{S(t_j)}, \quad j = 1, 2, \ldots,$$

so the survival function is related to the hazard function by

$$S(t) = \prod_{j:t_j<t} [1 - h(x_j)].$$

For discrete lifetimes the "cumulative hazard" function is defined by

$$H(t) = \sum_{j:t_j<t} h(t_j). \tag{2}$$

Notice that for this definition the relationship $S(t) = \exp[-H(t)]$ no longer holds true. Some authors [3] prefer to define the cumulative hazard for discrete lifetimes as

$$H(t) = \sum_{t_j<t} \ln[1 - h(t_j)]. \tag{3}$$

Note that for this definition the relationship for continuous lifetimes, $S(t) = \exp[-H(t)]$, will then be preserved for discrete lifetimes. If the $h(t_j)$ are small, (2) will be a first-order approximation to (3).

The hazard rate is a well-defined quantity for the case where T has both discrete and continuous components. In this case the hazard function defined by (1) will have a continuous part, $h_c(t)$ and a discrete part with mass h_j at time $t_1 < t_2 < \ldots$. The survival function in this case can be expressed as

$$S(t) = \exp\left\{-\int_0^t h_c(u)\,du\right\} \prod_{j:t_j<t} (1 - h_j).$$

For any survival function one can express the relationship between the hazard rate and the survival function by the using the notion of a product integral. For a function, $G()$, define the product integral of $1 - dG(u)$ over the range a to b by

$$P_a^b[1 - dG(u)] = \lim \prod_{k=1}^{r} \{1 - [G(u_k) - G(u_{k-1})]\},$$

where $a = u_1 < \cdots < u_r = b$ and the limit is taken as $r \to \infty$ and $u_k - u_{k-1} \to 0$. Here G is a function of locally bounded variation which is continuous from the right and has finite left-hand limits. If we define the cumulative hazard rate as

$$H(t) = \int_0^t h_c(u)\,du + \sum_{j:t_j<t} h_j,$$

then the survival function in the continuous, discrete or mixed case is given by

$$S(t) = P_0^t[1 - dH(u)].$$

Because of this property the product integral plays an important role in survival analytic techniques.

The Mean Residual Life Function

The fourth basic parameter of interest is the mean residual life (mrl) at time t. This parameter measures,

for individuals of age t, their expected remaining lifetime. It is defined as

$$\text{mrl}(t) = \text{E}(T - t | T \geq t).$$

It can be shown, using integration by parts or a partial summation formula, that the mean residual life is the area under the survival curve to the right of t divided by $S(t)$. Note that the mean life, $\mu = \text{mrl}(0)$, is the total area under the survival curve.

For a continuous random variable we have

$$\text{mrl}(t) = \frac{\int_t^\infty (u - t) f(t)\, \text{d}u}{S(t)} = \frac{\int_t^\infty S(u)\, \text{d}t}{S(t)}$$

and

$$\mu = \text{E}(T) = \int_0^\infty u f(u)\, \text{d}u = \int_0^\infty S(u)\, \text{d}u.$$

Also the variance of T is related to the survival function by

$$\text{var}(T) = 2 \int_0^\infty u S(u)\, \text{d}u - \left[\int_0^\infty S(u)\, \text{d}u \right]^2.$$

In some applications the median residual life, rather then the mean residual life, is of interest. To define this quantity recall that the $100p$th percentile (or pth **quantile**) of a random variable X with cumulative distribution function (survival function) $F(x)(S(x))$ is the value x_p such that

$$F(x_p) \geq p \quad \text{and} \quad S(x_p) \geq 1 - p.$$

The median lifetime is the 50th percentile, $x_{0.5}$, of the distribution of X. If X is a continuous random variable then the pth quantile is found by solving the equation $S(x_p) = 1 - p$. It follows that the median lifetime (mdrl), for a continuous random variable X, is the value $x_{0.5}$ such that

$$S(x_{0.5}) = 0.5.$$

The median residual life time of T at time t, mdrl(t), is defined as the median time to the event for an individual who has survived to time t. That is, mdrl(t) is the solution to the equation

$$\frac{S(\text{mdrl}(t))}{S(t)} = 0.5.$$

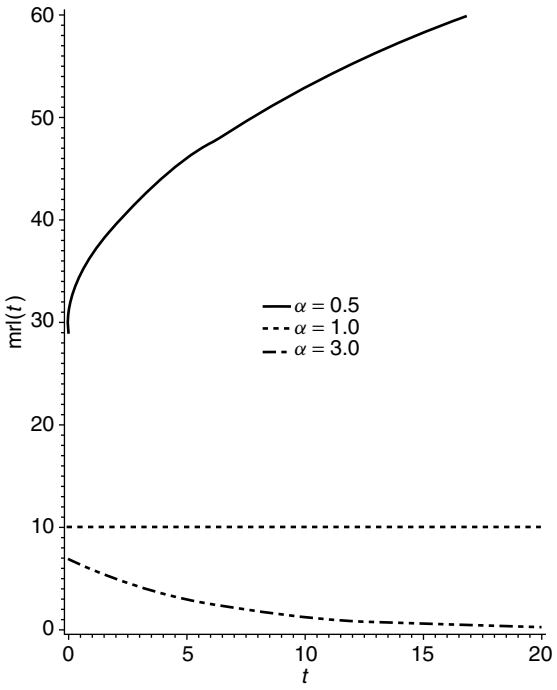

Figure 3 Comparison of Weibull mean residual life functions

The population median is simply the median residual life at time 0.

To illustrate these quantities consider the three Weibull distributions considered earlier. Figure 3 shows the mean residual life function for the Weibull models with $\alpha = 0.5$, 1.0 and 3.0. As the figure shows, the mean residual life is constant for the exponential distribution ($\alpha = 1$), decreasing for the case where $\alpha = 3$ and increasing for the case where $\alpha = 0.5$. Note that the trend in the mean residual life is reversed from the trend in the hazard rate in that when the hazard rate is increasing, reflecting aging, the mean residual life is decreasing. Figure 4 depicts the median residual life functions for the three Weibull models. The shapes of the functions are quite similar to those of the mean residual life functions.

Relationship Between Characterizations

Interrelationships between the characterizations discussed earlier, for a continuous lifetime T, may be

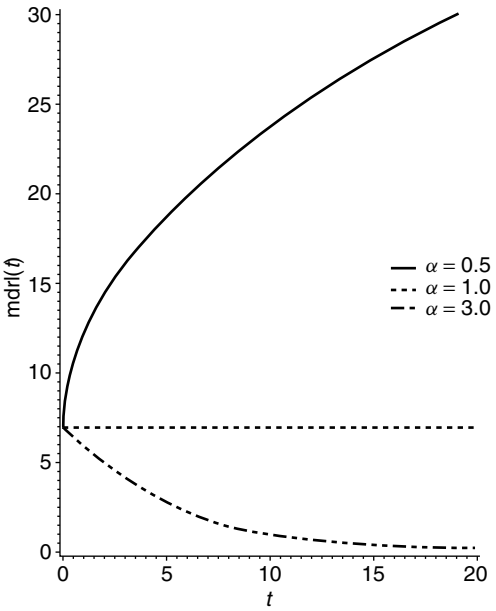

Figure 4 Comparison of Weibull median residual life functions

summarized as follows:

$$
\begin{aligned}
S(t) &= \int_t^\infty f(u)\,\mathrm{d}u \\
&= \exp\left\{-\int_0^t h(u)\,\mathrm{d}u\right\} \\
&= \exp\{-H(t)\} \\
&= \frac{\mathrm{mrl}(0)}{\mathrm{mrl}(t)}\exp\left\{-\int_0^t \frac{\mathrm{d}u}{\mathrm{mrl}(u)}\right\};
\end{aligned}
$$

$$
\begin{aligned}
f(t) &= -\frac{\mathrm{d}}{\mathrm{d}t}S(t) \\
&= h(t)S(t) \\
&= \left(\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{mrl}(t)+1\right)\left(\frac{\mathrm{mrl}(0)}{\mathrm{mrl}(t)^2}\right) \\
&\quad \times \exp\left\{-\int_0^t \frac{\mathrm{d}u}{\mathrm{mrl}(u)}\right\};
\end{aligned}
$$

$$
\begin{aligned}
h(t) &= -\frac{\mathrm{d}}{\mathrm{d}t}\ln[S(t)] \\
&= \frac{f(t)}{S(t)} \\
&= \frac{\left(\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{mrl}(t)+1\right)}{\mathrm{mrl}(t)};
\end{aligned}
$$

and

$$
\begin{aligned}
\mathrm{mrl}(t) &= \frac{\int_t^\infty S(u)\,\mathrm{d}u}{S(t)} \\
&= \frac{\int_t^\infty (u-t)f(u)\,\mathrm{d}u}{S(t)}.
\end{aligned}
$$

For a discrete random variable we have the following relationships:

$$
\begin{aligned}
S(t) &= \sum_{j:t_j \geq t} p(t_j) \\
&= \prod_{j:t_j < t} [1 - h(t_j)].
\end{aligned}
$$

If T is an integer-valued random variable with mean residual life at time k equal to $m_k, k = 0, 1, 2, \ldots,$ and m_0 is finite, then we have

$$
S(k) = \frac{1+m_0}{m_k}\prod_{j=0}^{k}\frac{m_j}{1+m_j}.
$$

Also, for any discrete survival function, we have

$$
\begin{aligned}
p(t_j) &= S(t_j) - S(t_{j+1}) \\
&= h(t_j)S(t_j), \quad j = 1, 2, \ldots; \\
h(t_j) &= \frac{p(t_j)}{S(t_j)};
\end{aligned}
$$

and

$$
\mathrm{mrl}(t) = \frac{[t_{k+1}-t]S(t_{k+1}) + \sum_{j:t_j \geq t_{k+1}} [t_{j+1}-t_j]S(t_{j+1})}{S(t)},
$$

$$
\text{for } t_k \leq t < t_{k+1}.
$$

Classes of Aging Distributions

An important characteristic of survival distribution is its aging properties (*see* **Aging Models**). There are a number of classes that have been suggested in the literature to categorize distributions based on their aging properties or their dual. The first aging class is

the class of increasing hazard rate (IHR) distributions and the dual class of decreasing hazard rate (DHR) distributions. A survival distribution is said to be in the IHR (DHR) class if and only if

$$\frac{S(t+x)}{S(t)} = S(x|t) \text{ is decreasing (increasing) in } t \text{ for all } x.$$

The definition says that T has the IHR aging property if the probability an individual of age t survives an additional period of time x is decreasing with time. If T is a continuous random variable then an equivalent definition of the IHR (DHR) class is that the hazard rate $h(t)$ is increasing (decreasing) for all t. Examples of distributions that fall in the IHR class are the Weibull distribution with $\alpha > 1$ and the gamma distribution with shape parameter greater than one.

A second, more general, aging class is the class of increasing (decreasing) hazard rate on the average, IHRA (DHRA), distributions. A distribution is said to fall in the IHRA (DHRA) class if and only if

$$-\left(\frac{1}{t}\right)\ln[S(t)] \text{ is increasing (decreasing) in } t. \quad (4)$$

The definition arises by declaring a distribution to be in the IHRA class when its cumulative hazard rate, $-\ln[S(t)]$ is increasing faster than the cumulative hazard rate of an exponential random variable, t. Since the exponential distribution reflects a model with no aging, this class is one of the distributions for which individuals are, on the average, aging. There are several equivalent definitions of a IHRA class. Since (4) implies that $S^{1/t}(t)$ is increasing in t we have that T is in the IHRA class if and only if $S(\theta t) \geq S^{\theta}(t)$. A second characterization of the IHRA class is that if T is in the IHRA class, then for any $\lambda > 0$ the quantity $S(t) - \exp(-\lambda t)$ has at most one change of sign, and if it does have a change in sign then it is from positive to negative. The class of IHRA distributions is larger than the class of IHR distributions in that every IHR distribution is an IHRA distribution but the converse is not true.

A third aging class is the class of decreasing (increasing) mean residual life, DMRL (IMRL), distributions. A distribution is said to be in the DMRL (IMRL) class if

$$\text{mrl}(t) = \frac{\int_t^{\infty} S(x)\,\mathrm{d}x}{S(t)} \text{ is decreasing (increasing) in } t.$$

This aging class, which includes all IHR models, is one where the mean remaining life of an individual of age t is becoming shorter as t increases.

A fourth aging class is the class of new better (worst) than used, NBU (NWU), distributions. Here a distribution is in the NBU (NWU) class if and only if

$$S(x+t) \leq (\geq) S(x)S(t), \quad \text{for any } x \text{ and } t.$$

An equivalent definition for the NBU class is

$$\frac{S(x+t)}{S(t)} = \Pr(T \geq x+t | T \geq t) \leq \Pr(T \geq x) = S(x).$$

From this second definition we see that T has an NBU distribution if the probability an individual of age t lives an additional x time units is smaller than the probability an individual of age 0 survives to age x. This aging class includes all the IHRA distributions.

A fifth aging class is the class of new better (worse) than used in expectation, NBUE (NWUE), distributions. A distribution is in the NBUE (NWUE) class if its mean, μ, is finite and

$$\int_t^{\infty} S(u)\,\mathrm{d}u \leq (\geq)\mu S(t), \quad \text{for all } t.$$

The NBUE class is one where the mean residual life of an individual of age t is less that the mean of an individual of age 0.

A final aging class is the class of harmonic new better (worse) than used in expectation, HNBUE (HNWUE), distributions. A distribution is said to be in the HNBUE (HNWUE) class if its mean is finite and

$$\int_t^{\infty} S(u)\,\mathrm{d}u \leq \mu \exp\left(\frac{-t}{\mu}\right).$$

An equivalent definition for the HNBUE class is

$$\left\{\frac{1}{t}\int_0^t \frac{\mathrm{d}x}{\text{mrl}(x)}\right\}^{-1} \leq \text{mrl}(0).$$

This means that for a HNBUE distribution the integral harmonic value of the residual life of an individual of age t is smaller than the same quantity for a newly born individual.

The aging classes are ordered as follows:

$$\text{IHR} \Longrightarrow \text{IHRA} \Longrightarrow \text{NBU} \Longrightarrow \text{NBUE} \Longrightarrow \text{HNBUE};$$

$$\text{IHR} \Longrightarrow \text{DMRL} \Longrightarrow \text{NBUE} \Longrightarrow \text{HNBUE};$$

$$\text{DHR} \Longrightarrow \text{DHRA} \Longrightarrow \text{NWU} \Longrightarrow \text{NWUE} \Longrightarrow \text{HNWUE};$$

$$\text{DHR} \Longrightarrow \text{IMRL} \Longrightarrow \text{NWUE} \Longrightarrow \text{HNWUE}.$$

Further discussion of these failure classes can be found in [1] and [2].

JOHN P. KLEIN

Synergy of Exposure Effects

Although environmental regulation of chemical exposures is typically based on laboratory studies in which animals are dosed to single agents, humans are invariably exposed to mixtures. People who drink may smoke as well. Cigarette smoke itself is an example of a mixture. Modeling and predicting the effects of combined exposures, or of exposures experienced in a particular temporal sequence, remain challenges to toxicologists and epidemiologists.

The effect associated with several exposures in combination sometimes far exceeds what would have been expected on the basis of their separate effects, a phenomenon known as "synergism" (or "synergy"). One example is the occurrence of lung cancer in relation to exposure to cigarette smoking and arsenic, where the risk in those exposed to both is high [6]. While the etiologic basis for this particular mutual enhancement of effect is not well understood, the demonstration of synergism of exposures can provide important insight into causal mechanisms and can suggest strategies for intervention. For example, mental retardation invariably ensues when a child has the metabolic disorder phenylketonuria and also consumes the amino acid phenylalanine in his or her diet; removal of dietary phenylalanine prevents the adverse effect. Negative synergism, known as "antagonism", can also arise, as when exposure to the polio virus follows exposure to the polio vaccine. Examples of more subtle forms of antagonism include scenarios where two different chemical exposures compete for the same population of receptor sites or when one interferes with the absorption or metabolism of the other.

While most would agree that epidemiologic synergism among exposures exists, defining it is problematic. Usually "synergism" is said to be present when the effect of exposure to a combination of factors exceeds the sum of the separate, factor-specific effects. We must then define what it means to "sum" effects. Such a definition would establish a model for independence, compared with which positive departures could be considered synergistic, and negative departures, antagonistic. Synergism and antagonism cannot be defined except in relation to some definition for independence of effect, except in rare scenarios where only one of the two factors has an effect when experienced without the other, and the effect of the combined exposures exceeds that of the one factor alone. The phenylketonuria example and the polio vaccine example were both of the latter, unambiguous type.

Most instances of mutual enhancement of effect are not of that simple, pure form, so a more general definition is needed. When the outcome of interest is **binary**, e.g. the occurrence of a particular disease, the exposure–response formulation often includes specification of a function to serve as a "link" between the risk of disease and the exposures. If the risk of disease, r, is first subjected to a "logit" **transformation**, by taking the logarithm of the "odds", $r/(1-r)$, then effect additivity on this inherently multiplicative scale is very different from additivity on the untransformed, "absolute", i.e. additive scale (*see* **Additive Model**). Thus, for example, if two factors each increase the risk of disease, and their combined effect can be correctly represented by a **logistic** model with no **interaction** ("product") term, then an additive formulation *would* require a positive interaction term. Conversely, the adequacy of an additive model for the combined effects would mean that a **multiplicative model** would require an interaction term. The distinction between this kind of statistical interaction, which corresponds simply to departure from additivity on some mathematically convenient scale, and biologic interaction, which corresponds to true biologic mutual enhancement of a causal mechanism, has long been appreciated by biostatisticians and epidemiologists [7, 16], who have searched for a formulation with biologic interpretability. The notion of synergism or "biologic interaction" can be defined as "the inter-dependent operation of two or more causes to produce disease" [15]. A related concept is that of independence of two factors (say, A and B) in a public health sense, which is said to occur "when the number of cases of disease that would occur in the population does not depend on the extent to which A and B occur together in the same individuals" [15].

While synergism or antagonism can involve causative factors or protective factors, the choice of null model can be different for the joint effect of protective factors [2, 23]; or for the joint effect of a protective and a causative factor. The discussion that follows will apply only to the combined effect

of causative factors, i.e. factors that each can increase the risk of the disease under study.

Rothman [14] proposes a conceptual framework for disease causality, where several "component" causes act together to form in their aggregate a "sufficient" cause, for which each component cause is necessary to its completion. (This conceptual model can be extended to continuous exposures by supposing that exceedence of a particular level of exposure is required for each sufficient cause in which the continuous exposure participates.) A single exposure may participate in (i.e. be a necessary component in) several different sufficient causes if there are several distinct pathways that involve it and can lead to the disease. If two exposures participate in the same sufficient cause, then that cause can only produce the disease when both are present, and such a pathway would imply synergism between the two exposures in a biologic sense [14] (*see* **Causation**).

For a single exposure, the difference between the incidence of the disease among those with the factor and among those without the factor can be interpreted as the **incidence rate** of completion for those sufficient causes that require that factor. By extension, the incidence rate for those with two factors, say A and B, minus those with neither is the sum of the incidence rate for completion of those sufficient causes involving A and not B and the incidence rate for completion of those sufficient causes involving B and not A, unless there exist one or more sufficient causes that require both A and B. In this way, the "causal pies" model proposed by Rothman leads naturally to the following model for independence based on incidence rates:

$$I_{AB} - I_{\overline{AB}} = I_{A\overline{B}} - I_{\overline{AB}} + I_{\overline{A}B} - I_{\overline{AB}}, \qquad (1)$$

where the overbar indicates the absence of the factor. This can be seen as additivity on the "risk difference" or absolute scale, and Rothman argues that absolute additivity is the only proper epidemiologic null model for "independent" effects. (Notice, however, that unless the lifetime risks are very small, model (1) does not imply the independence of A and B in the public health sense defined above: to the extent that A and B co-occur, the A-dependent and B-dependent pathways will compete for the same victims.) Such a model can easily be fitted to cohort data using standard statistical packages, such as SAS (the GENMOD procedure) and GLIM [19] (*see* **Software, Biostatistical**). The data are considered to provide evidence for synergism if the fit is significantly improved by inclusion of an interaction term, i.e. a nonzero γ, in the following model:

$$R[D|A,B \text{ status}] = \mu + \alpha(A \text{ present}) + \beta(B \text{ present}) + \gamma(\text{ both } A \text{ and } B \text{ present}),$$

where R denotes the incidence of the disease. For multilevel exposures, d_1 and d_2, to two exposures that now are not simply present or absent, the above zero-γ null formation generalizes to linearity in $f(d_1)$ and $g(d_2)$, for exposure-specific exposure–response functions $f(\cdot)$ and $g(\cdot)$.

It is instructive to think about what self-independence would mean for a single exposure. Exposure to 40 units of an exposure can be thought of as a combined exposure to two doses of 20 units each, or to 30 units, together with 10 units, and so on. For these separate exposures to combine independently, one can show that the exposure–response must be linear. Low-level alpha **radiation** provides an example where self-independence is plausible. Irreparable chromosomal damage at the cellular level caused by bombardment by a passing alpha particle is random, rare, and heritable, providing radiobiologists with a strong theoretical justification for a linear exposure–response.

Returning to the binary exposure scenario, when a **case–control** design is used to study the etiology of a rare disease, the incidence rates in (1) cannot be estimated. However, dividing through by the background incidence, and letting RR_{AB} denote the **relative risk** for the combined exposure, relative to the background risk, leads to the approximate relation:

$$RR_{AB} = RR_{A\overline{B}} + RR_{\overline{A}B} - 1.0, \qquad (2)$$

and thus independence can be assessed using case–control data. Wacholder & Weinberg [20] provide methods for evaluating the fit of the additive model to case–control data, under various designs.

We have thus far considered effects of two exposures on disease risk, presuming that the unexposed state is unambiguously defined, whereas Greenland & Poole [4] point out that the choice of coding of one level as "unexposed" can be arbitrary. One example is sex, where males could be considered unexposed (to

being female) or females could be considered unexposed (to being male). This raises the question as to how such factors should be incorporated in evaluations of synergistic effects. One can use algebra to show, however, that the above additivity criterion for independence is invariant under recoding of such a variable.

Under the usual understanding of the sufficient causes model, the disease invariably occurs once all components of a particular sufficient cause have been assembled, and in this sense Rothman's conceptual model is deterministic. Others have preferred to begin with a more stochastic conceptual approach and have nonetheless arrived at the same null model (1) for independence. In this way, divergent approaches to conceptualizing independence converge to a common mathematical formulation for the null model.

The stochastic approach has its roots in toxicology. Bliss [1] defines "independent joint action" between "poisons" as meaning that "the poisons or drugs act independently and have different modes of toxic action". Finney [3] provides mathematical rigor by specifying that "simple independent action" between two factors obtains if the outcomes are probabilistically independent. For one exposed to levels d_1 and d_2 of two different factors, the probability of avoiding the outcome (1 minus the risk) can be denoted $Q(d_1, d_2)$, so that the background "spontaneous" probability of nonoccurrence is $Q(0, 0)$. Probabilistic independence implies the following relationship:

$$Q(d_1, d_2) = \frac{Q(d_1, 0)Q(0, d_2)}{Q(0, 0)}. \qquad (3)$$

This reflects a scenario where the two causal mechanisms are completely separate and unrelated and where each of the exposure-dependent causal processes is independent of the background causal processes, i.e. those mechanisms that can produce the disease in the absence of either exposure.

Weinberg [23] describes a paradigm for this idealized model (3) in relation to two hunters, unaware of each other's presence, but shooting at the same ducks. To survive, a duck must stay clear of both. Under this independence scenario, the probability that the duck will survive some interval of time is the product of the probabilities that it escapes both hunters and also does not die of causes unrelated to being shot. This is the simplest probability-based notion of independence, corresponding to the situation where the exposures have completely separate biological modes of action.

This model, which can be written in **generalized linear model** form as additive in the log of the nonresponse, $\ln[Q(d_1, d_2)]$, has been applied to assessing synergism in animal experiments [21] and Korn & Liu [9] proposed a **Mantel–Haenszel**-type statistic for synergism based on follow-up with continuous failure times.

Mathematically, models (1) and (3) are equivalent. If one integrates risk over any fixed length of time, then the additive formulation (1) can be seen (replacing the factor A by the continuous d_1 and B by d_2) as equivalent to model (3), where the function $Q(d_1, d_2)$ is interpreted as the probability of survival without the disease over the specified follow-up interval for those with rates as given by (1). Conversely, the model given by (3) can be shown to imply model (1), because the negative of $\ln[Q(d_1, d_2)]$ converges in the limit, as the interval of time (hence the associated risk) becomes small, to the incidence rate associated with the combined exposure (d_1, d_2).

In the context of a rare disease, either formulation leads naturally to the case–control-based index for synergism proposed by Rothman [13]:

$$S = \frac{RR_{AB} - 1}{RR_{A\overline{B}} + RR_{\overline{A}B} - 2},$$

who also defines a synergism index for cohort data and provides **standard error** formulas for computing **confidence intervals**. Another index for synergism, resembling the usual interaction term in **analysis of variance**, provides a direct estimate for the **excess risk** associated with synergistic effects among those with both exposures: $T = R_{AB} - R_{\overline{A}B} - R_{A\overline{B}} + R_{\overline{A}\overline{B}}$ has certain advantages but can only be estimated in the context of a **cohort study** [7]. Wahrendorf et al. [21] propose a different index that can be used in cohort studies:

$$W = \frac{Q(A, B)Q(0, 0)}{A(\overline{A}B)Q(A, \overline{B})},$$

which, for a rare outcome, is approximately $\exp(-T)$, and should, in general, be one under independence. Weinberg [23] refers to W as a "health ratio" similar to a risk ratio (*see* **Relative Risk**), but interpretable

as the proportion *avoiding* the disease divided by the expected (based on independence) proportion avoiding disease, among those with both exposures. Simulations comparing W, T, and a third index, G, proposed by Korn & Liu [9], revealed that tests based on ln (W) had close-to-nominal size and relatively good **power** [12].

Statistics representing the fractional excess in the disease rate that is attributable to the synergistic effects of two factors have been developed, based on this model for independence. Hamilton [5] defines the "proportion of disease attributable to synergism" by taking the difference between the observed and expected risk among those with both divided by the overall risk and multiplying by the **prevalence** in the population of the combined exposure. Walker [22] later defines the "proportion of disease attributable to the combined effect of two factors" differently, by subtracting the expected from the observed rate of disease in those exposed to both factors and dividing by the observed rate. The difference between the indices proposed by Hamilton, and Walker, is that the Hamilton index divides by the overall population rate, while that of Walker divides by the disease rate among those with both exposures. Thus, the latter is more focused on etiology and the former on public health.

Darroch & Borkent [2] have recently revisited the question of how to assess the proportion of disease attributable to synergistic effects, within the context of a deterministic paradigm described by Hamilton [5]. They begin with the presumption that there are six types of people in the population: those who will get the disease regardless of their exposure to A and/or B; those who will *not* get the disease regardless of their exposure to A and/or B; those who will get the disease with A but will not with B or with neither; those who will get the disease with B but will not with A or with neither; those who will get the disease with A or with B but will not with neither; and those who will only get the disease in the presence of both A and B. Because only four parameters are estimable on the basis of relating the combined exposure to the observable risk of the disease, the fraction in the synergistic category, who would only get the disease with both exposures, cannot be directly estimated. Darroch & Borkent [2] propose an estimate based on maximum entropy, and illustrate its application to the problem of partitioning the cases of lung cancer among those exposed to both smoking and radiation into four parts: the fraction caused by smoking alone; the fraction caused by radiation alone; the fraction that would have developed even with neither exposure; and the fraction that developed as a result of the combined exposure. Extensions of this approach to multilevel exposures remain to be developed.

Both conceptualizations, the deterministic one championed by Rothman and Hamilton, and the probabilistic one preferred by toxicologists, are useful for clarifying our thinking about causality, but both have limitations. Suppose there are two distinct sufficient causes for the disease of interest, one requiring A and one requiring B. Koopman [8] points out that if they have a component cause in common, say C, then A and B will compete for the same pool of susceptibles, i.e. those with C, and this competition can produce apparent antagonism. This will be true even if we presume that the two sufficient causes are independent among those with C. Such shared causes may be common. Genetic factors, for example, can interact with exposures to produce disease; the existence of genetically based contributory causes, while usually unknown to the investigator, may be the rule rather than the exception.

Seen in the hunter paradigm for probabilistic independence, some ducks, depending on their size and coloring, are easier to see (hence to shoot) than others. Such variation among individuals in inherent susceptibility can produce apparent nonindependence, even when the causal processes (the two hunters) are truly functioning independently at the level of each individual at risk. Darroch & Borkent allow for the resulting inherent nonidentifiability of parameters within a deterministic conceptual framework by proposing a maximum entropy approach, while others [10, 23] compute upper and lower bounds for synergism indices that allow for covarying susceptibilities to A and to B across individuals in the population.

Whenever the epidemiologist begins with parameter relationships observed in the data and draws inferences regarding the likelihood that causal mechanisms for two different exposures are biologically linked, warning bells should sound: the same epidemiologic data can be consistent with very different underlying biologic scenarios, as discussed at length by Thompson [18]. Nevertheless, epidemiology can provide important clues regarding interdependent causal mechanisms.

A related set of issues not discussed here involves the epidemiologic identification of "initiator/promoter" relationships among pairs of exposures, where their temporal ordering can have an effect on risk [11] and [17] (*see* **Effect Modification**).

Systematic Error

Systematic error is the **bias** that results when a data-gathering process or method of analysis leads to results expected to deviate from the true quantity to be estimated. Unlike **random error**, systematic error is not ameliorated by increasing sample size, which only serves to obtain more precise **biased** estimates of the desired quantity (*see* **Random Error** for a simple example of systematic error.) Specific types of systematic errors in epidemiologic studies are discussed in several articles (*see* **Bias in Case–Control Studies**; **Bias in Cohort Studies**; **Bias in Observational Studies**; **Bias, Overview**; **Confounding**; **Validity and Generalizability in Epidemiologic Studies**).

MITCHELL H. GAIL

Systematic Sampling Methods

Systematic sampling is a simple and convenient sampling technique that is widely used in practice (*see* **Sampling Frames**). While it is attractive in its simplicity and ease of use, care should be taken in the application of this sampling technique. Depending on the structure of the study population, systematic sampling can be at best the optimal selection method, or at worst a method that provides no more information beyond the taking of a single observation at random.

Reviews of the literature of systematic sampling, as well as some applications of systematic sampling, may be found in Bellhouse [2], Buckland [4], Iachan [13], and Murthy & Rao [17]. Monographs with significant technical detail on systematic sampling have been written by Cochran [7], Levy & Lemeshow [15], Murthy [16], and Sukhatme et al. [20].

To take a systematic sample the population must first be sequentially ordered in some way. This ordering may have structure to it, such as houses on a street or an alphabetic list of names from a directory. Alternatively, there may be no structure, such as a frame listed in random order of the sampling units. A systematic sample is chosen by selecting an initial unit using a random start in the ordered population and then by selecting subsequent units at equal intervals from the random start. Since only one unit has been randomly selected, there is no estimate of variation that is **unbiased** with respect to the sampling design.

More formally, the study population may be defined over a fixed set of units labeled $u = 1, \ldots, N$, with measurement y_u attached to the unit labeled u. A systematic sample of size n is obtained by drawing a random integer r from $1, \ldots, N$, and sampling the set of units given by $s = \{r, r + k, r + 2k, \ldots, r + (n - 1)k\}$. The term k is called the sampling interval. For any j for which $r + jk > N$, then the unit selected is $r + jk - N$. The selection method reduces to the usual notion of systematic sampling when N/n is an integer and when k is chosen as N/n. This type of systematic sampling is equivalent to **cluster sampling** with the selection of a single cluster. When N/n is not an integer, the selection method is known as circular systematic sampling. The typical choices for k in this case are the greatest integer in N/n or the integer nearest N/n. Most classical and modern textbooks on sampling discuss systematic sampling from a finite population.

Applications of systematic sampling are wide ranging and include any population which can be put into a list. Systematic sampling is also useful when a **sampling frame** or list of the ultimate sampling units is not available. Kalton [14] has given several examples of this. His examples pertain to the use of systematic sampling for the sampling of human populations when they are mobile. These examples range from exit polls on election day in which every kth person leaving a polling station is interviewed to road traffic surveys in which every kth vehicle in a particular lane of traffic is sampled.

For any finite population, **means** and **variances** of sample statistics are calculated through the first- and second-order inclusion probabilities. These are respectively π_u, the probability that unit u is included in the sample, and π_{uv}, the probability the units u and v are both included in the sample. For systematic sampling, $\pi_u = n/N$. For the special case in which N/n is an integer, the joint inclusion probability $\pi_{uv} = n/N$ when $|u - v|$ is divisible by the sampling interval k, and is 0 otherwise.

Alternately, the population may be defined on a continuum with the measurement y_u attached to u, where u is in the interval $[0, N]$. The initial unit r is chosen from the interval $[0, k]$ and, as before, the set of sampled units is given by $s = \{r, r + k, r + 2k, \ldots, r + (n - 1)k\}$. It is not necessary that k be an integer in this case. Populations on a continuum are encountered in the stereologic examination of tissues. Sampling problems here are problems in geometric probability. Detailed descriptions of the theory and application of systematic sampling to **stereology** are given in Gundersen & Jensen [9] and Cruz-Orive [8]. An application of systematic sampling in this area is given in Pache et al. [18]. They describe techniques for the estimation of lung volume and the volume of other structures inside the lung, such as bronchi and arteries. Volume is estimated from serial sections of lung specimens using a CT scan. The serial sections are obtained through systematic sampling.

In descriptive surveys, the parameter that is usually of interest is the population mean $\overline{Y}$, which may be expressed as $\sum_{u=1}^{N} y_u/N$ for the finite population, or as $\int_0^N y_u \, du/N$ for the population defined on a

continuum. For either situation the estimator of $\overline{Y}$ is given by the sample mean for the systematic sample chosen by the random start r, $\overline{y}_r = \sum_{j=0}^{n-1} y_{r+jk}/n$. The variance of this estimator, denoted by V_{sys}, is given by $\sum_{r=1}^{N}(\overline{y}_r - \overline{Y})^2/N$ in the finite population framework. When N/n is an integer and when $k = N/n$, then V_{sys} reduces to the more common expression of the variance $\sum_{r=1}^{k}(\overline{y}_r - \overline{Y})^2/k$. The equivalent expression in the population defined on a continuum is $\int_0^k (\overline{y}_r - \overline{Y})^2 \, \mathrm{d}r/k$.

Often, there is structure to a population which can be modeled mathematically. In most situations with structure present, systematic sampling can be used to advantage in the sense of reducing the variance of the estimate of $\overline{Y}$ when compared with estimates obtained from other sampling designs. The assumed structure is usually modeled by assuming that the measurement y_u is an **random variable** and by making assumptions about the first- or second-order **moments** of this random variable. There are now two sources of random variation to consider, one due to the sample selection procedure and the other to assuming that y_u is a random variable. One generally accepted measure of the variation of an estimator in this case is to average the variance obtained under the sampling design over the distribution of the random variable assumed on the measurement y_u. For systematic sampling this may be denoted by $\mathrm{E}_m V_{\text{sys}}$, where E_m is the **expectation** with respect to the model assumption on y_u. This measure was first introduced by Cochran [6].

There are several examples of populations with models assumed on the first moment:

1. $E_m(y_u) = \mu$;
2. $E_m(y_u) = \alpha + \beta u$;
3. $E_m(y_u) = \alpha + \beta u + \gamma u^2$; and
4. $E_m(y_u) = \sum_{v=-\infty}^{\infty} c_v \exp(2\pi \mathrm{i} v u/p)$ where $\pi = 3.14159\ldots$, $\mathrm{i} = (-1)^{1/2}$, c_v are Fourier coefficients and p is a constant.

For each of these examples it is assumed that the ys are uncorrelated and that the second central moment is σ^2, a constant. Models 1, 2, and 3 describe constant, linear and quadratic trends in the measurement with respect to the label number. Model 4 is a model of periodic variation with period p. Under model 1, systematic sampling has the same efficiency as **simple random sampling** without replacement (*see* **Sampling With and Without Replacement**) or any other design with constant probability of inclusion for each of the sample units. Under models 2 and 3, systematic sampling is more efficient than simple random sampling but is less efficient than **stratification** (*see* **Stratified Sampling**). The efficiency of systematic sampling can be markedly improved under models 2 and 3 by changing the estimator. In particular, the new estimator is the sample mean plus a weight times the difference between the measurements with the largest and smallest labels. The resulting estimator, known as Yate's end corrections estimator, eliminates both α and β as components of the variance (*see* **Variance Components**). In the special case of $N = nk$, the end corrections estimator is given by $\overline{y}_r + (2r - k - 1)(y_r - y_{r+(n-1)k})/[2(n - 1)k]$. The estimator under circular systematic sampling is described in Cochran [7]. Under the model for periodic variation, given as model 4, the best and worst of situations can occur. When the sampling interval k coincides with the period p, then systematic sampling is equivalent to taking a simple random sample of one unit. When the sampling interval is the half period, or $k = p/2$, then the only component of variance is σ^2.

The most common model assumption for the second central moment is **autocorrelation**. The first moment is assumed to be as in model 1, with the second-order central moments given by $\mathrm{E}_m(y_{u+t} - \mu)(y_u - \mu) = \sigma^2 \rho(t)$ with $\rho(0) = 1$, where $\rho(t)$ is the autocorrelation function at lag t. When $\rho(t)$ is concave and decreasing in t, systematic sampling is more efficient than any other sampling scheme which has constant probability of inclusion for each of the sample units. Concave decreasing autocorrelation functions are obtained when the ys are modeled by an autoregressive process of any finite order such that the roots of the **characteristic** equations are real.

A simplifying assumption that is often made for systematic sampling is that the units are in random order. Then the sample that is obtained is treated as if it were from a simple random sample. More formally, the random ordering corresponds to the assumption that the set of finite population measurements $y_1, \ldots, y_N$ are a random permutation of a set of fixed numbers $z_1, \ldots, z_N$. Under this random permutation model, expressed in a linear model framework originally by Rao [19] (*see* **General Linear Model**), systematic sampling is equivalent in efficiency to any sampling design with constant inclusion probability.

As noted previously, since a single random start was used to obtain a systematic sample, there is no unbiased estimator of the variance of the sample mean. Here unbiasedness is meant to be with respect to the sampling design or method of sampling. In view of this, there are at least three ways to obtain an estimate of variability based on the single systematic sample:

1. Make a simplifying assumption. In particular assume random ordering of the units so that the sample obtained is equivalent to a simple random sample.
2. Assume a trend in the data and base the variance estimate on squared differences between successive observations in the sample.
3. Use the data to estimate the model parameters in $\mathrm{E}_m V_{\mathrm{sys}}$, and use this as the estimate of V_{sys}.

In the first case, the unbiased variance estimator from simple random sampling $(N-n)s^2/(Nn)$ may be used, where $s^2 = \sum_{j=0}^{n-1}(y_{r+jk} - \overline{y}_r)^2/(n-1)$ is the variance within the obtained systematic sample. If the random ordering assumption is correct then this estimator is unbiased for V_{sys}, where un-biasedness is observed with respect to the random permutation model. This estimator generally works well when there is no trend in the population or when the trend is weak. When a linear trend is present as in model 2, the variance is a function of β^2, where β is the slope in the linear trend function. The variance estimator suggested in the second case will also be a function of β^2. The estimator is then of the same form as in the first case, with s^2 replaced by $\sum_{j=0}^{n-2}(y_{r+jk+k} - y_{r+jk})^2/2(n-1)$. This variance estimator, which tends to work well under various types of trends, and other similar variance estimators, are described in Wolter [22]. If the third strategy is followed, it is necessary that the model assumption be correct. The variance estimator will work well under the correct model assumption but may not be **robust** to departures from the model.

If a design unbiased estimate of variance is of primary concern, then a change to the sampling design must be considered. One way to achieve an unbiased estimator while retaining some of the convenience of systematic sampling is take more than one random start, or repeated systematic samples. When $N = nk$ this is equivalent to cluster sampling with more than one cluster selected. Under autocorrelation and trend models, this method is less efficient than systematic sampling of equivalent sample size with a single random start. What is gained in unbiased variance estimation is lost in efficiency and in some convenience. If the units are in random order, then they are equally efficient so that convenience is the only issue. A second approach is to augment the single random start systematic sample with a small simple random sample. This retains most of the convenience of systematic sampling. However, the unbiased estimate of variance can be negative.

In many large-scale surveys with stratification and two or more stages of sampling (*see* **Multistage Sampling**) the primary sampling units, or the units at the first stage of sampling, are often chosen by **sampling with probability proportionate to the size** of the primary. There are several sampling methods which yield the inclusion probability for a unit proportional to some size variable. These are reviewed in Brewer & Hanif [3]. Among these methods, probability proportional to size (pps) systematic sampling is simple and convenient to execute. An application of pps systematic sampling to a large-scale survey is given in Chambless [5]. He describes a survey taken in and near Augsberg, Germany, as part of the World Health Organization's MONICA program (Monitoring Trends in Cardiovascular Diseases). The purpose of this international program was to study the relationship between risk factor levels, estimated by sample surveys, and the **incidence rates** for coronary heart disease, estimated from population registers. The design reported by Chambless for sampling outside of Augsberg was a pps systematic sample of administrative areas, where the size variable was population size, and then a stratified sample of individuals within the chosen areas. The stratification was done on age and sex. This design yields an approximate equal probability of selection for each individual in the population.

As in the equal probability case, the population units can be or can be put in random order. Randomized pps systematic sampling, as well as the nonrandomized version, has been used extensively for primary sample unit selection in the 1970s and 1980s for Canada's national monthly survey of employment and unemployment, the Canadian Labour Force Survey. Probability proportional to size systematic sampling was used in favor of other pps sampling methods because of the flexibility of its use in

sampling on successive occasions and because of the ease with which the sample can be expanded.

To describe the pps systematic sampling scheme, denote the size variable for unit u by x_u. Any pps sampling design will yield $\pi_u \propto x_u$ or $\pi_u = nx_u/X$, where $X = \sum_{u=1}^{N} x_u$ is the population total of the size variables. A pps systematic sample is chosen in the following way. Form the cumulative totals $T_u = \sum_{i=1}^{u} x_i$ for $u = 1, \ldots, N$. Draw a random integer r from $1, \ldots, X$, and obtain the set of integers given by $s = \{r, r + k, r + 2k, \ldots, r + (n - 1)k\}$. The sampling interval k is the integer nearest X/n. If for any $j, r + jk > X$, then the integer selected is $r + jk - X$. Unit u is selected for the sample if $T_{u-1} < r + jk \leq T_u$. The selection method reduces to systematic sampling with equal probability when $x_u = 1$ for all u. When X/n is an integer then, similar to the equal probability case, the selection procedure is equivalent to drawing the random start r from $1, \ldots, k$. Randomized pps systematic sampling is obtained when the N population units are in placed in random order prior to sample selection. As in the equal probability sampling case if the simplifying assumption of random ordering of the population units is made, or if random ordering is imposed, then relatively simple and valid variance estimates can be obtained.

The estimate of $\overline{Y}$ is given by the **Horvitz–Thompson estimator**, $\sum_{u \in s} y_u/(N\pi_u)$. For large population sizes and small sampling fractions (less than 5%), the variance of the estimate may be approximated by applying the appropriate formula for pps sampling with replacement. For other situations, the Yates–Grundy form of the estimate of variance may be used. This involves knowledge of the joint inclusion probability π_{uv}. For randomized pps systematic sampling Hartley & Rao [10] have provided, to order N^{-4}, an approximation to this inclusion probability. This approximation can be accurate for populations as small as $N = 10$. Hidiroglou & Gray [11] have provided Fortran code for the exact calculation of π_{uv} which is useful for small N.

Systematic sampling techniques have also been developed for sampling units with a spatial or two-dimensional ordering. Bellhouse [2] and Thompson [21] provide reviews of the theory of spatial sampling with some applications. Early applications of these techniques were in geography; a review is given in Holmes [12]. More recent applications have been in ecology and in other areas: for example, Bellhouse [1] applied two-dimensional systematic sampling techniques to the excavation of middens at Iroquoian Indian archeological sites.

D.R. BELLHOUSE

Target Population

The concept of a *target population* is an informal one, sometimes defined as "the population about which information is wanted" [1] or the "totality of elements which are under discussion and about which information is desired" [4]. Often, the word "population" refers to this concept; see, for example, Kendall & Stuart [3] or Freedman et al. [2]. The word "target" emphasizes, however, that this population is not necessarily the same as the one that we end up sampling. The latter population is sometimes called the *sampled population* [1, 4] or (in epidemiology) the *source population* [6]. Ideally, in **descriptive epidemiologic** studies, the two populations would be identical, but practical concerns usually lead to large discrepancies. For example, when a poll of the entire US population is desired but, for cost reasons, only a telephone survey of four cities is done, the sample population contains only persons who have a telephone and live in those cities, and is much smaller than the target (US) population.

In studies of causal effects (*see* **Causation**) it may be helpful or even essential for the sampled population to extend beyond or even exclude the target population. Consider a target population comprising five persons who were exposed to high asbestos levels during a job assignment, one of whom later developed mesothelioma (a very rare form of cancer). The question of whether this high rate of the disease was caused by the asbestos could not be approached by sampling the target. Only by comparison to a much larger reference experience (namely, the extensive prior data on the rate of mesothelioma in workers exposed and not exposed to asbestos) can we make any meaningful **inference** about the target. In settings such as this example, in which inferences about structural relations in the target are inferred from observations on other populations, it has been proposed to refer to the latter as *evidentiary populations* [5]. Such evidentiary populations are typically larger and sometimes more accurately measured than the target, although they may not be comparable to the target population in all important respects (*see* **Confounding**).

Issues of inferences from the sampled population to the target are sometimes classified as problems of generalizability or external validity. These issues are distinct from the issues that arise in making inferences about the sampled population from a sample (*see* **Validity and Generalizability in Epidemiologic Studies**).

SANDER GREENLAND

Teaching Medical Statistics to Statisticians

A degree in statistics does not usually prepare a graduate adequately for a career in biostatistics. Further training is needed in those aspects of statistics applicable to the health sciences, both in postgraduate degrees, and in continuing education courses for the statistician already working in a particular field (e.g. pharmaceuticals, public health, clinical medicine). In this account of teaching biostatistics, we do not intend to provide outline course contents. Rather, we bring forward a number of considerations that could help in course planning. The course planner then necessarily takes into account the assumed background knowledge of the student group, the time, physical and personnel resources available, and reasonable expectations of what the student will have acquired by the end of the course. The wide-ranging scope of this Encyclopedia makes it clear that no statistician can expect to be expert in every aspect of biostatistics. Those who plan and teach such courses must of necessity be selective.

Collaboration

Etymologically, the word biostatistics is a hybrid, its mixed parentage combining bio- (life; hence, care for health) with the statistician's art and sciences. Accordingly, instruction in biostatistics could well begin – and continue throughout – with an emphasis on the necessity of collaboration between the statistician and the health professional. Thus, it is important to recognize that even concepts which appear trivial (in the mathematical sense) to the statistician may be not only unfamiliar to, but often alien to the thought processes of, the health scientist, causing great difficulty in communication. Both teacher and pupil will benefit from an emphasis on the advantages of simplicity – in language, avoiding or explaining any jargon; and in the design, analysis and interpretation of studies. The student can be helped to develop consultancy skills by attending and contributing to consultations with health professionals who come to the teacher with real problems (see, for example, [2]) (*see* **Statistical Consulting**). Difficulties can also arise when an inappropriate statistical method has been used in a key publication in the client's area, which then spawns imitations. A common example is the use of repeated significance tests (*see* **Sequential Analysis**) at a series of time points in a **longitudinal study**, when one or more summary measures could well be more informative.

Other ways of improving understanding between the professions include organizing a "Meet the Clients" course, in which a number of established clinicians from various medical specialties, other carers, hospital laboratory staff, health care administrators, epidemiologists, pharmaceutical scientists, etc., present their own accounts of how biostatistics has impinged on their work. Discussions following such presentations can be both lively and rewarding to all concerned. Interdisciplinary understanding can also be enhanced by study of carefully selected publications from the health science literature, concentrating on the statistical methods that have been used or misused in the study design and analysis, and on the validity of the conclusions and the summary. The aims of these exercises are not only to develop constructive critical skills, but also to help to prepare the student for joint authorship with future collaborators. As medical teaching and practice is increasingly turning towards such critical appraisal of the literature to assist clinical decision making, statisticians should be aware of the important contribution of their discipline (see, for example, [1]) (*see* **Teaching Statistics to Medical Students**; **Teaching Statistics to Physicians**).

Examples from the literature can also be used to illustrate common pitfalls in the use of statistics – comparing the noncomparable (inappropriate choice of control subjects); not properly defining the denominator, or even ignoring it altogether, in the calculation of rates (*see* **Denominator Difficulties**); failing to adjust for **confounders** such as age and sex, by **standardization methods** or otherwise. Another pitfall common in health research is failure to recognize the long-established phenomenon of **regression to the mean**, which many find counterintuitive at first sight. If a patient is identified because her blood pressure reading is high, it seems strange that a subsequent reading is expected to be lower, even if no treatment has intervened. The same phenomenon will often explain why a treatment appears to produce better results in subjects with more severe disease, even when it is actually uniformly effective for all degrees of severity. These two apparent anomalies can be inspirational in

attracting bright young statisticians to this field of application – "there's more to biostatistics than meets the eye!".

How is Biostatistics Different?

What differentiates biostatistics from other applications of statistical methods? It is essentially the human context. We note three aspects: ethical issues, the failure of patients to behave as ideal "experimental units" and, in common with other biological rather than mechanical subjects, more difficulty in establishing **causation**.

Ethics

Human ethical implications arise both in research and in the implementation of health programs based on the interpretation of statistics. It is sometimes argued that ethical considerations are solely the responsibility of the health professional, and statisticians should be dispassionate and value-free in their contributions. In some instances the statistician is, however, very well placed to stand aside from the enthusiasms of a health researcher in the laboratory, the clinic or in the organization of health systems, and to see more clearly the ethical implications. These ethical issues are often important in: the design of a study (choice of subjects, sample size, likely effects of treatments, the concept of **randomization** of humans), the conduct of the study (in addition to the normal clinician–patient relationship, in most studies every patient is a volunteer and deserves to be treated as such), and the implications for the health of others of the results of the study, whether to individuals or to communities as part of a more general health program (*see* **Ethics of Randomized Trials**; **Medical Ethics and Statistics**).

Human Fallibility

Patients do not always behave as perfect experimental units. Some do not take their treatment as specified, often for very good reasons. This may occur during an experimental trial or subsequently after a successful trial when the treatment is made more generally available. Doctors may not be consistent, or even logical, when defining or making a diagnosis. Sources of variability, such as between or within observers or analytical methods, can often be identified, measured, and taken into account. Human biological variability may affect the precision of a diagnostic test (*see* **Diagnostic Tests, Evaluation of**). The dramatic effect of targeting **screening** to an at-risk population in which the **prevalence** of the disease is substantially greater than in the general community can be demonstrated as an application of **Bayes' Theorem**. The resulting increase in the **positive predictive value** of a screening test with a given **sensitivity** and **specificity** has important practical and financial implications. Cultural or educational background may affect a patient's response to a question. A biostatistician must be aware of these problems, and use personal or shared experience to take them into account in modeling the collection, analysis, and interpretation of the data.

Causation

Students will be aware that **association** does not necessarily imply causation, but the health professional expects the biostatistician to go further than that bald, and not particularly helpful, conclusion of an association. A number of accounts have been given on the topic; perhaps the most accessible is that given by **Bradford Hill**, one of the founders of twentieth century biostatistics. Drawing on, amongst other things, his literally vital contributions to establishing cigarette smoking as a cause of lung cancer (*see* **Smoking and Health**), he suggested a wide-ranging approach to establishing causation from **observational studies** on chronic diseases. Considerations include the strength of the association, consistency between studies in varied circumstances, specificity of the association, temporal consistency, **dose–response**, biological plausibility, coherence, experimental evidence, and analogy (*see* **Hill's Criteria for Causality**). The length of this list makes it clear that the biostatistician has responsibilities other than the purely mathematical. Health programs will seldom be mounted solely on the basis of statistical associations. A credible presentation of a causative link between a modifiable risk factor and a disease is necessary, and the statistician has important contributions to make to that presentation. Training should prepare the statistician for that role.

Study Types

At this stage, the epidemiologic approach to causality and the strength of evidence from various types of study may be of value in the course. In ascending order of strength of evidence for a causative link between a putative risk factor and a disease are: the **ecologic study**, the **cross-sectional study**, the **case–control study**, the **cohort study**, the randomized controlled trial (RCT) (*see* **Clinical Trials, Overview**), and the **meta-analysis of RCTs**. While the usual statistical methods of assessing and comparing **means** or proportions often conclude studies of all these types, other statistical questions arise in connection with each. Course designers may choose to structure courses on the study types, expanding on the statistical methods arising in each, or, more traditionally, to structure the course on statistical methods, giving the related study types as illustrations of their application. Whichever approach is used, examples of life-saving interventions that have been demonstrated by the various types of study design will be helpful.

We illustrate the former approach because it is a little unusual. It could be a more stimulating approach for the students, who will already be familiar with at least the theoretical aspects of **logistic regression** and perhaps **survival analysis**.

Observational Studies

While *ecologic studies* may be cited as evidence of coherence (countries or districts with higher per capita sales of cigarettes have higher death rates from disease X), they are more useful in a teaching context to illustrate the risks of **confounding** and the **ecologic fallacy**.

The *cross-sectional study* requires much attention to **questionnaire design**, use of focus groups, pilot studies, and methods of achieving adequate response rates, as well as the intricacies of sampling procedures and analyses which take account of the sampling details. No opportunity should be lost to draw attention to routinely collected statistics, national or regional (*see* **Vital Statistics, Overview**). It is all too easy for a study to produce a poor imitation on a small scale of a routine analysis, ignoring the accumulated experience of the official statisticians in data collection, coding, validation, analysis, interpretation, and limitations (*see* **Bias in Observational Studies**).

In a *case–control study* the main epidemiologic difficulty is to define the appropriate populations from which the **controls** should be selected. For example, selecting controls from hospital inpatients can lead to considerable bias. Other biases may arise in the diagnosis and coding of the disease outcome, or in the measurement of exposure to possible risk factors, which relies on recall or historical records collected for other purposes. The statistician needs to be trained to identify such biases before undertaking any analysis (*see* **Bias in Case–Control Studies**).

Case–control studies provide an ideal opportunity to introduce the concept of **odds ratios** and their interpretation as an approximation to **relative risk** for a rare disease. An example in which there is heterogeneity of the odds ratio across strata of another variable can be used to illustrate statistical **interaction**, or "**effect modification**" as it is more helpfully termed by epidemiologists. Furthermore, **logistic regression** is a way of obtaining an estimate of the approximate **relative risk** of the disease for those exposed to a particular risk factor, after adjusting for **confounding** variables. For the situation where the controls have been individually matched to the cases, **conditional logistic regression** can be demonstrated.

A *cohort study* may be affected by many of the same problems as case–control studies. In addition, attention should be drawn to the healthy worker effect in occupational cohorts (*see* **Bias in Cohort Studies**).

Randomized Trials

The *randomized controlled trial* has a central role in the evaluation of interventions in both clinical medicine and public health. Biostatisticians should have a thorough understanding of such trials, whether or not they are going to be directly involved in conducting trials. Historically, statisticians have contributed greatly to the development of valid trials, and it is good for a professional to know something of past achievements. Perhaps more importantly, the RCT introduces many apparently nonstatistical ideas that are essential to producing valid statistical analyses and interpretations. For example, **randomization** of subjects to treatments (*see* **Randomized Treatment Assignment**) raises important ethical questions including patient consent and what is meant by "informed" consent. Before randomization, however, a strict protocol (*see* **Clinical Trials Protocols**) is required to specify the population to be studied and to

whom the results will be applicable (*see* **Target Population**): diagnostic details, **eligibility and exclusion criteria**.

Careful **sample size** calculations are also important for both ethical and economic reasons. Simple randomization can be improved by techniques such as **blocking** and **stratification**, which should be taken into account in the analysis to increase **power**. If practical considerations lead to subjects being randomized in clusters (e.g. families, school classes, villages, etc.), failing to incorporate this in the analysis can produce seriously misleading conclusions (*see* **Group-randomization Designs**). Methods of **blinding** help to avoid the patient and the professional assessors of health status knowing which treatment each patient is receiving – human fallibility could introduce **biases**. Fallibility may also cause the patient not to receive the complete course of treatment as specified: analysis should almost always follow the "**intention-to-treat**" principle, which is sometimes not intuitive, particularly to the surgeon whose allocated patient dies before reaching the operating table.

Because RCTs often involve follow-up of subjects over time, **survival analysis** is often the most appropriate technique for evaluating the results. Many good medical data sets are available in the literature for demonstrating the calculation of an actuarial **life table** for grouped data or a **Kaplan–Meier** life table for individual survival data, discussing the underlying assumptions of these, illustrating the use of the **logrank test** to compare treatments, **Cox regression** to adjust for **confounders**, assessment of the **proportional hazards** assumption, and ways of dealing with violations of that assumption.

Meta-analysis is a powerful statistical method for combining the results of several RCTs. A single trial demonstrating the efficacy of a therapy is unlikely to lead to its adoption worldwide. Meta-analysis raises issues of heterogeneity and **fixed effects** vs. **random effects** models, which merit attention in this and other applications.

General Considerations

A mathematical statistics course may well omit methods relevant to biostatistics, from the very simple to the highly sophisticated. Students may be unfamiliar with, for example, the simplified formula for calculating the test statistic for a **2 × 2 table**, or with **McNemar's test** for paired proportions, which is merely an application of the **binomial distribution** with probability 1/2. There are also many practical uses of the **Poisson distribution**, ranging from the simple calculation of tail probabilities in the study of disease outbreaks, to modeling disease frequencies using **Poisson regression**. If students are given real data sets to analyze, they can learn some of the pragmatic aspects of biostatistical modeling, such as how the choice of model variables depends not only on statistical considerations, but also on biological plausibility, face validity, the "cost" of measuring a variable, confounding, and whether a risk factor is modifiable. The extent to which model assumptions may be violated can also be discussed. Students will benefit from becoming familiar with at least one of the major statistical computing packages (*see* **Software, Biostatistical**). In matching the assessment of a biostatistics course to its objectives, one needs to consider whether computers can be used, either in an open-book examination in a classroom equipped with computers, or in a take-home exam for which students have computer access.

It is clear from the above that it is appropriate to use a variety of teaching methods – lectures, seminars, computing practicals, tutorials, small-group exercises – to interest, stimulate, and extend the students. As they are mature students, the principles of adult teaching and learning should be employed. In particular, lectures are best used sparingly to motivate and expound concepts, rather than to give detail that can be better absorbed by reading, either before the lecture or afterwards.

Whatever is covered in a biostatistics course, it cannot be exhaustive, so it is important to teach and encourage students to continue their own education. They should be made aware of the resources available on the **Internet** for communicating with colleagues, finding relevant articles on unfamiliar topics, and keeping abreast of recent developments in the literature. The importance of maintaining contact by attending local meetings and conferences could also be emphasized.

We have deliberately avoided being prescriptive and giving an exhaustive list of topics to be included. Rather, we have tried to give the flavor of the process leading to decisions about course content. Those decisions will inevitably, and rightly, reflect the experience and research interests of the teachers.

DAVID NEWELL & JUDY SIMPSON

Teaching Statistics to Medical Students

It is difficult to pinpoint just when statistics was introduced into the medical curriculum, what medical school was the first to include lectures on statistics, and who was the first statistics lecturer to medical students. Clearly, the incorporation of statistics into the medical curriculum parallels publication of the early textbooks in medical statistics, with that by **Austin Bradford Hill** in 1937 being the first [13]. In the US, Colton [4] presented anecdotal material to indicate that at Johns Hopkins University, where the first US school of public health was established, there was clearly, by 1948, a course in biostatistics for medical students taught by **Margaret ("Maggie") Merrell**. Obviously, the initiation of the course dates several years earlier. Nevertheless, it is of interest to note that, in 1948, medical students at Johns Hopkins, a group that was almost exclusively male, received the required instruction in biostatistics from a female instructor who, moreover, was a professionally trained statistician and a nonphysician.

Perhaps the earliest published material on teaching statistics to medical students is an editorial written by Bradford Hill in 1947 for the *British Medical Journal* with the intriguing title, "Statistics in the Medical Curriculum?" [14]. Note the question mark in the title for which Hill comments:

> ... I should replace my querying title, "Statistics in the Medical Curriculum?", by "*What* Statistics in the Medical Curriculum?" (though I am well aware that some clinical teachers will prefer to read it as "*What!* Statistics in the Medical Curriculum?").

Hill enunciates what has become a common theme underlying the rationale for teaching statistics to medical students, namely,

> ... the medical worker, and his readers, must be at least on speaking terms with the elements of statistical reasoning and methods of analysis, and thus be able themselves to weigh numerical evidence justly in the balance.

His conclusion, which portends much discussion and debate that has appeared in the literature in the subsequent 50 years or so, is:

> Arithmetic guided by logic has been given as a fairly accurate definition of simple statistical methods, and it is that kind of teaching that would, it is my belief, be of real benefit to the medical student. It should introduce him not only to ... general viewpoints ... to be borne in mind in considering statistical evidence, but also teach him the appropriate methods of handling and presenting data, and familiarize him with the statistical concepts of variability, the ideas lying behind elementary tests of significance, simple means of measuring and interpreting associations, and so on ....

Thus, in addition to having written the first text in medical statistics, Bradford Hill is apparently among the first to state in print the rationale for teaching statistics to medical students as well as to propose the general content for such instruction.

In the US, an early publication on teaching statistics to medical students is the report in 1953 of a Committee of the Statistics Section of the **American Public Health Association** charged with consideration of the training in statistics needed by medical students, as well as that needed by public health students, including those who intended to specialize in medical and public health statistics [6]. With regard to training of medical students, the report included the findings of a questionnaire survey in 1952 sent to 90 medical schools in the US and Canada for which 82 replies (91%) were received. Of those replying, 82% indicated that instruction in biostatistics was a component of their undergraduate medical curriculum, with 46% stating that the course given was primarily one designated as biostatistics. (In the remaining schools that indicated they taught the subject, biostatistics was taught as a part of another course such as preventive medicine or scattered among several other courses such as pharmacology and physiology.) The predominant pattern was to teach biostatistics in the first two years as part of the basic science curriculum and to require the course of all medical students. Thus, by the mid-1950s, biostatistics instruction to medical students was well ensconced in the US and Canada and a clear pattern of the format and nature of such instruction was evident.

It is of interest to note the Committee's synthesis of areas of agreement among the Committee members, the respondents to the survey, and other medical school faculties whose opinions were solicited. The report states the "general agreement on a number of issues", as follows:

> It is desirable that all medical students receive statistical instruction. The important issues cannot

> well be discussed in a course of less than some 25–30 hours. The basic principles of the experimental method and of the statistical approach must be stressed, but there must also be an abundance of practical applications. The committee believes that the teaching should be done by a professional statistician (M.D., Ph.D. or other) well oriented with medical problems. People whose primary interest and concentration is in another field usually do not do the most efficient job of teaching statistics.

Subsequent to this report, findings of several other surveys of US and Canadian medical schools have been published – namely, surveys conducted in 1957 [16], in 1969–1970 and 1973–1974 [3], in 1986 [8], and most recently in 1993 (Looney, Grady & Steiner, personal communication). Most of the "issues of agreement" cited above in the 1952 survey prevail throughout the various surveys and remain areas of agreement today, except, perhaps, for the proposed 25–30 hours of class time for biostatistics. With the global trends of drastic reductions in formal lecture time, this amount of class time for biostatistics is most unrealistic in contemporary medical curricula in North America.

Another impetus in the US for the incorporation of biostatistics into the undergraduate medical curriculum has been the inclusion of questions in biostatistics on medical licensure examinations – namely, on the nationwide examinations administered by the US National Board of Medical Examiners that most US medical schools require their students to take. Traditionally, the bulk of the statistical questions appear on the Step 2 (formerly Part II) examination, the portion of the licensure examination usually taken at completion of the fourth year of medical school. At the time of the initial survey in 1952 of biostatistics instruction in US and Canadian medical schools, the biostatistics questions constituted 15% of the Preventive Medicine and Public Health component (one of six components) of the Part II examination. Undoubtedly, the inclusion of statistics questions on US medical licensing examinations offers some explanation for the proliferation of biostatistics instruction in US medical schools by the mid-1950s.

Parallel to the expansion of biostatistics instruction in medical schools in the 1950s and 1960s, additional textbooks in biostatistics began to appear and became the assigned texts for these courses. Those more commonly employed as course texts, in addition to Hill's pioneering text, were those by **Donald Mainland** published in 1952 [19], Huldah Bancroft published in 1957 [2], and Olive Jean Dunn published in 1964 [10]. In fact, by 1966, Hill's text appeared in its eighth edition.

In the US in 1969, a key event occurred – namely, the beginnings of the Subsection on Teaching of Statistics in the Health Sciences of the **American Statistical Association** (ASA). In early 1969 Anita Bahn sent a letter to several statisticians whom she knew and who had responsibility for teaching statistics to medical students. Her letter opened with the following paragraph:

> As a new teacher of biostatistics in a medical school, I have been faced with a number of problems in attempting to develop a meaningful learning experience. The rapidly changing horizon – new goals of medical schools and ways of doing things, core curricula, integrated National Board Examinations and other aspects – impinges on our teaching. It is challenging to keep one step ahead of the game.

She concluded by asking that those who shared her concerns meet informally that summer at the annual ASA meeting. The informal meeting was most successful, with keen interest indicated by virtually all who attended. Among the key next steps was the establishment of a Newsletter for which one of us (TC) served as the first editor. In the first Newsletter issued in Fall 1969, the rationale for this organization was stated as follows:

> Why is such a group needed and what are its objectives? Foremost is the need for communication among these educators to exchange information on how best to deal with the problem of student motivation, limited class time, integrated subjects, core curricula, changing medical school goals. There is much that we can learn from each other. One respondent stated that he never could understand why there has not been, heretofore, a mechanism for communication in such a sorely needed area.

Shortly after this meeting in 1969, the ASA was petitioned to form a Subsection (of the Section on Statistical Education) and thus this organization had its birth. Although the primary force behind its formation was statistics instruction to medical students, the target was more broadly defined as students in the Health Sciences, as reflected in the title. The Subsection's Newsletter continued and at each subsequent annual ASA meeting an invited papers session has appeared on the program where statistics instructors of students in the health sciences

could share their concerns, describe innovative course offerings and teaching techniques, and commiserate on their difficulties in reaching students as well as in preserving their courses intact under continued pressure from Curriculum Committees to reduce class time. In the 1990s the Subsection designation was removed and full Section status in ASA was established. Instruction of medical students remains as the key focus of the Section.

When the Subsection started, one of the major concerns of its members was the nature of the statistics questions on the National Board Examinations. Although statistics was indeed a required component of the examination, there was no professionally trained statistician responsible for determining the statistics questions that would appear on the examinations. On the preclinical examination (currently Step 1 and previously Part I), it was behavioral scientists who composed the statistics questions, and on the clinical examination (currently Step 2 and previously Part II) it was public health and preventive medicine specialists. Many of the questions that appeared on these examinations did not reflect adequately what the statistics instructors were teaching in their courses and, in several instances, the technical statistical basis of examination questions was incorrect. The Subsection lobbied successfully to place a professionally trained biostatistician, one of the founding members of the Subsection, on the National Board Test Committee responsible for creating and choosing the examination questions. By the 1970s, it was a biostatistician who composed and shared in the choice of statistics questions that would appear on the examination.

Another major effort in the early days of the Subsection was the formation of a Subcommittee to consider development of a core curriculum in biostatistics. The Committee did issue a report and its proposed core curriculum was published in 1975 [5].

In the UK, the embodiment of statistics into the medical curriculum proceeded at a considerably slower pace. Lowe [17] describes an inquiry he conducted in 1962 among the 27 undergraduate medical schools in the UK. He reports that there was some form of statistics instruction in 19 schools (70%), but that at most schools such instruction was voluntary (no examination was required) and in one school such instruction consisted of but a single hour's lecture. Despite Bradford Hill's editorial in 1947, it was not until the late 1960s that there was "official" recognition in the UK for inclusion of statistics in the medical curriculum, although as Lowe has indicated there were a substantial number of medical schools that did offer such instruction. This recognition occurred in 1968 with what has come to be known as the Todd Report [22]. With regard to statistics, this report by the Royal Commission on Medical Education states:

> Some knowledge of the principles of the statistical approach is now necessary so that doctors can make some judgement for themselves of the validity of the claims for medical advances made in journals and other communications. Instruction in statistics is a necessary part of the process of producing a graduate who can apply a scientific outlook to his future experience.

An interesting feature of the Todd Report is its Appendix, which reports the results of a survey of some 5000 students on their reactions to 18 specified courses in their curricula with regard to interest, usefulness, and difficulty. For statistics, which was offered in only some of the curricula among the schools surveyed, the report states that it

> . . . was considered dull (eighteenth and last in rank of interest), useless (seventeenth in the rank of helpfulness) and very difficult (first in degree of difficulty). This was true for all schools with the exception of Oxford where it was ranked of medium interest (ninth), of medium usefulness (ninth), and of great difficulty (first in degree of difficulty).

Consequently, by the 1970s statistics was well embodied into the medical curricula in the UK.

Over the past 25 years or so, the topic of teaching statistics to medical students has been of much concern to biostatisticians and other medical school faculties. In addition to the annual meetings of the Section on Teaching Statistics in the Health Sciences of ASA and their occasional published proceedings (the latest, at this writing, is [1]), there have been a number of symposia and workshops devoted to the topic. These include the following: a 1962 international symposium on Teaching of Statistics to Undergraduate Medical Students in Europe, organized by the **World Health Organization (WHO)**; a UK conference in 1971 organized by the Medical Section of the **Royal Statistical Society** and the Society for Social Medicine [15]; a 1978 Inter-regional Conference on Teaching Statistics

to Medical Undergraduates organized by WHO, the International Epidemiological Association (IEA), and the Government of Pakistan and that resulted in a publication entitled *The Successful Teaching of Statistics to Every Medical Student* [21]; and several conferences and workshops in the UK, a more recent one being that held in 1989 whose proceedings have been published in ***Statistics in Medicine*** [9]. The interested reader will find additional published commentaries and thoughts on this subject from the references in the above-cited publications. It is of interest to note as well that WHO and IEA had also sponsored publication in 1978 of a handbook entitled *Health Statistics: A Manual for Teachers of Medical Students* [18].

Where do we now stand with regard to teaching statistics to medical students, the contents of the courses taught, and the settings of these courses? At this writing, the most recent available information is the survey in 1993 of 125 US medical schools undertaken by Looney, Grady & Steiner (personal communication) and modeled after the previous US surveys. There were 100 responses (80%) among the 125 medical schools surveyed. Of those responding, 83% stated that their school offered such a course with 74% of those responding stating that it was a required course. Among 93% of schools that offered such a course, it occurred during the first 2 years (preclinical) and the median course length was 20 hours. Among responders who offered a course, 91% indicated provision of course notes to students, and 77% indicated use of a textbook. The three textbooks most frequently cited were those by Dawson-Saunders & Trapp [7], Morton, et al. [20], and Fletcher et al. [12]. Among the responders, 73% indicated that there was some integration of the biostatistics course with other subject matter in the curriculum. Among only 9% of the responders was there a sole instructor for the course who was a physician; in all other instances the instructor for the course had a Ph.D. or master's degree or was a nonphysician who shared with a physician major responsibility for the course. One trend noted in comparison with previous surveys is an increase in the proportion of biostatistics course directors who are full-time faculty members at their respective schools. This reflects the growing trend for US medical schools to recognize their need for and to recruit biostatisticians as full-time faculty members.

Surprisingly, with the computer revolution over the past decade, computers did not play an important role in the biostatistics courses. Only 27% of the respondents indicated use of computer-based tutorials and only 19% of respondents said they included instruction on the use of computers.

As with several of the previous surveys, the 1993 survey included questions on the topics covered in the various courses. Table 1 indicates responses to the topics covered, classified according to descriptive statistics and probability, inference, and epidemiology and clinical research (columns) and whether 75% or more of responses indicated coverage of the topic (top panel), 50%–74% indicated coverage (middle panel), or less than 50% indicated coverage (bottom panel). The survey investigators, in comparison with findings from the previous 1970 survey [3], note a shift in emphasis from more standard statistical topics to those considered more epidemiologic. There has likewise been a substantial increase compared with 1970 in coverage of **power** analysis. Undoubtedly, much of the shift in course content is commensurate with trends in the nature of the papers published in leading general medical journals such as *New England Journal of Medicine, Journal of the American Medical Association, Lancet*, and *British Medical Journal*, where there has been a substantial increase in publication of rather statistically sophisticated randomized **clinical trials** and epidemiologic **cohort studies** and **case–control studies**. Correspondingly, the issue of statistical power has received much more attention currently in the contemporary medical literature in research articles, letters to the editor, and editorials than it received at the times of the previous surveys.

It is of interest to compare the empirical results in Table 1 of what is taught in medical statistics courses in US medical schools with the topics designated as being covered currently in the Step 2 US Medical Licensing Examination [11]. Table 2 indicates the topics in Applied Biostatistics and Clinical Epidemiology that the 1997 examination covered. It is not surprising that there is considerable concordance between the topics listed in Tables 1 and 2.

Another item of interest in the 1993 survey is a solicitation of the respondent's perception of how the course was received by the students. This was compared with analogous data reported from Colton's survey in 1970 [3]. The 1993 survey investigators note that, compared with 1970, a considerably greater proportion of respondents perceived that the students had a very favorable or favorable opinion of

Table 1 Topics covered in biostatistics courses; 1993 survey of US and Canadian medical schools

Descriptive statistics and probability	Inference	Epidemiology and clinical research
Covered in 75% or more of the courses		
• Interpretation of tables and graphs • Frequency distribution • Descriptive statistics • Central tendency • Variability • Normal distribution • Probability	• Hypothesis testing • *P* values • Interpretation of confidence limits • Interpretation of the role of chance • *t* tests • Chi-square tests • Correlation	• Rates • Incidence and prevalence • Descriptive studies • Cross-sectional studies • Study design characteristics • Cohort studies • Case–control studies • Randomized clinical trials • Diagnostic tests
Covered in 50%–74% of the courses		
• Scales of measurement • Measurement issues	• Linear regression • Power analysis	• Adjusted rates
Covered in less than 50% of the courses		
• Construction of tables and graphs • Binomial distribution	• Analysis of variance • Multiple comparisons • Wilcoxon–Mann–Whitney test	• Stratified analysis

Table 2 Items in applied biostatistics and clinical epidemiology covered on the Step 2 US Medical Licensing Examination, 1997

1. Applications of concepts of measurement in medical practice (e.g. central tendency; variability, probability, and distribution; scales of measurement; disease frequency; case fatality, survival rate; relative risk, odds ratio, standardized morality rate; risk differences, attributable risk: sensitivity, specificity; positive and negative values; decision analysis).
2. Interpretation of the medical literature: study design (e.g. clinical trials, community intervention trials; cohort, case–control, cross-sectional case series; community surveys: subject eligibility and sampling; randomization, self-selection, systematic assignment; outcome assessment; validity; advantages and disadvantages of different designs; sample size).
3. Interpretation of the medical literature: statistical inference (e.g. hypothesis generation, hypothesis testing, and test statistics; statistical significance and type I error: statistical power and type II error; confidence intervals).

the course; correspondingly, a lesser proportion of respondents felt that the students' opinion of the course was neutral. Although one cannot exclude entirely the possibility of a shift over the past 20 years or so in the optimism among those who teach statistics to medical students, there is some indication that contemporary medical students are more favorably inclined to the subject and that they more readily perceive their need to understand these principles, regardless of whether or not they intend a career in medical research. Surely, one would like to think that the dismal survey results cited previously in the Appendix to the Todd Report in 1968 no longer apply to medical students in the late 1990s, both in the US and worldwide.

Finally, on a more personal note, one of us (TC) has had many years' experience in teaching statistics to medical students at several schools in the US and Canada. Sometimes it has been successful and other times it has been as disastrous as had been cited earlier in this article from the Todd Report [22]. Some view medical students as perhaps one of the toughest audiences one might have, particularly for a course in statistics. Colton [4] tried to articulate the difficulties in teaching statistics to medical students, at least those in North America, particularly in their preclinical years when such courses are almost always taught. We characterize the handicaps that the statistics instructor faces with medical students as their being the following: young, immature

and arrogant; highly competitive with one another; poorly motivated in *all* disciplines of public health; swamped by heavy demands of other courses; without any grasp or appreciation of the realities of clinical research; of considerably heterogeneous quantitative backgrounds; and a difficult group for whom to find good role models of practicing physicians as instructors. (We note that the latter has changed over time and there now is a more prevalent group of practicing physicians who are both appreciative of and knowledgeable in statistics.)

On the other hand, there are indeed some advantages to having medical students as one's audience. We characterize these advantages as their being the following: highly selected for academic performance; finely honed in knowing how to perform well in a course and to meet the instructors' demands; and that if the instructor reaches only a handful of students among a large class and can convey to them an appreciation for and enthusiasm with statistics, then the rewards and gratification are considerable.

THEODORE COLTON & STEPHEN W. LOONEY

Teaching Statistics to Physicians

There should be little disagreement over the proposition that a practicing physician requires a sound grasp of statistical concepts, and it is not surprising that medical statisticians have emphasized this [2, 4, 6]. It is, however, particularly encouraging that professional medical bodies such as the UK General Medical Council argue that the attributes of a practicing clinician should include [8]:

1. reasoning and judgement in the application of knowledge to the analysis and interpretation of data, in defining the nature of the problem, and in planning and implementing a strategy to resolve it, and
2. understanding of the contribution of research methods, and interpretation and application of others' research in the doctor's own specialty.

The very essence of clinical medicine is decision making under uncertainty. When a patient first presents, the physician needs to adopt a strategy that drives an investigation plan. This involves a sequence of decisions. Using any available prior information on the patient, together with the presenting symptoms and a knowledge of the epidemiology and etiology of disease, the doctor must decide what investigations are needed to confirm a working diagnosis, or to exclude an implausible but sinister diagnosis. Once the diagnosis is clarified, the attention turns to prognosis and treatment. Is the condition self-limiting, requiring at most symptomatic treatment, or is the prognosis so grim that only palliative treatment is appropriate? Is the condition such that it is appropriate to intervene in an attempt to improve the prognosis, and, if so, what evidence is there to support the use of different treatments for this individual? The likely side effects and cost implications need to be considered, and if treatment is initiated, whether further monitoring would be required. Would there be any obvious early signs that the treatment is not having the desired effect, and, if so, what modification to the treatment would be appropriate? On the other hand, if the problem does resolve, are there likely to be any long-term sequelae which mean that the patient should be monitored closely in future? At every step along this process, the physician needs to make decisions against a background of uncertainty, and such decisions should be informed by an understanding of statistical principles.

Much of what has been written about teaching statistics to physicians has focused on research, and in particular it has highlighted the many statistical failings that can be found in the medical literature [3, 10, 13]. This is hardly surprising, as most medical statisticians work with a highly selected group of academic clinicians who are actively involved in conducting research. However, I would argue that it is even more important that a practicing clinician should, for example, have a sound grasp of how the results of an investigation should update the prior probability of a particular diagnosis. This does not necessarily mean that every clinical decision should be based on a back-of-an-envelope application of **Bayes' Theorem**, but in selecting a test and interpreting its results a physician should at least be aware of the distinction between a highly **sensitive screening** test and a highly **specific** investigation which might precede a final decision to undertake a major operation (*see* **Decision Analysis in Diagnosis and Treatment Choice**).

What Statistics should be Taught?

In line with the suggestions of Leinster [9], I agree that we should be targeting three identifiable groups of physicians with quite different requirements in terms of statistical education. The first and by far the largest group consists of those practicing clinicians who are never likely to work in a research environment. The second group consists of the doctors who at some stage in their clinical training will take time out to work on research as part of their career development. Finally, there is the relatively small group of doctors who will remain within the academic environment and be active researchers throughout their careers. I shall refer to these three groups as "practitioners", "casual researchers", and "professional researchers", respectively.

Practitioners

These doctors require a core knowledge of statistics very much in line with the attributes set out by the General Medical Council and quoted above. Thus, these individuals should be aware of the

basic principles of problem formulation and strategies for problem solving, particularly in the context of diagnosis and **prognosis**. In addition, practitioners need to be sufficiently familiar with the "**scientific method**" to be able to use the research results of others to inform and guide their own clinical practice.

It is implicit in this that doctors should keep up to date with the literature in their specialty, by reading research reports and/or systematic reviews. Thus, any teaching should include an introduction to critical appraisal and the principles of **evidence-based medicine**.

Casual Researchers

The rather pejorative label that I have assigned to this group is not without just cause, as much that is wrong with medical research has its roots in the system which makes a curriculum vitae embellished with a number of token publications a prerequisite for career development. This argument is very well developed in an editorial by Altman entitled "The scandal of poor medical research" [1]. Altman argues that it is the system which should be changed. While heartily endorsing this view, I think that until such a change is achieved we have to accept that a very substantial volume of research is being undertaken by clinicians who are ill-equipped as researchers, and we must seek strategies for damage limitation.

For this group the priority should be to teach the principles of study design, and in particular the requirement to have a well defined question. Almost by definition, a well designed study that addresses a well defined question will generate data that can be presented and analyzed using a very limited set of statistical tools, and so this group does not need to be exposed to a large volume of methodological detail. However, they do need to be taught when it is appropriate to seek advice from a more experienced researcher, including perhaps a professional statistician.

Professional Researchers

One could argue that this group, which is small in number but highly influential, should be the priority for our teaching efforts [11]. Not only are these individuals active in conducting their own research, but they are responsible for training and supervising junior research workers. They are the individuals who edit journals and review submitted manuscripts (*see* **Statistical Review for Medical Journals**), and they also review grant applications. They therefore have great influence on what research is undertaken, and on how results are reported. These individuals not only require a sound grasp of research methodology, but also need to be aware of their own limitations, and should recognize the benefits of working closely with an experienced statistician from the outset of a research project.

When should Statistics be Taught?

Practitioners

The only practical mechanism for reaching all practitioners is to include statistics in the undergraduate medical curriculum (*see* **Teaching Statistics to Medical Students**). Dixon [6] has proposed a syllabus for such a core course based on current practice in UK medical schools, but this tends to emphasize techniques rather than "deep" understanding.

The situation with regard to teaching statistics in the UK medical schools is very well documented. Since 1980, there has been an annual meeting of the individuals responsible for this teaching, and a summary of each school's undergraduate and postgraduate teaching is compiled each year [5]. In what was an admittedly rather cynical exaggeration, Peters [12] described the situation with undergraduate teaching of medical statistics as "all get it, while few of them want it". At least part of the problem is that, in the majority of medical schools, the statistical teaching comes very early in the curriculum, while the students are concentrating on pre-clinical subjects and before they have been exposed to any clinical problems that would motivate the use of statistical methods. Current moves within the UK to change undergraduate medical courses to become more integrated, with clinical problems being discussed from the very outset, might help to make the relevance of our discipline more obvious to the students. Dunn & Everitt have recently published an introductory textbook [7] which presents medical statistics from this angle, and which should be a useful backup to teaching in a more integrated curriculum.

Researchers

By the time that clinicians are actively involved in research there is generally no problem with motivation, although often the cry for statistical help comes too late, when a poorly designed study is beyond salvage. These individuals should have the opportunity of attending a comprehensive course in research methodology at the outset of their research. As mentioned above, this would emphasize study design, and the importance of the formulation of the research question. A healthy dose of skepticism and the acquisition of skills in critical appraisal nurtured at this stage will be invaluable to their research, whether or not the individuals eventually become career researchers.

How should Statistics be Taught?

Undergraduate

Given the size of a typical undergraduate medical class, the usual practice is for much of the teaching of medical statistics to be based around formal lectures. The paper by Dixon [6] describes a typical undergraduate curriculum, but Appleton [4] suggests that a series of well chosen case studies might be more effective in demonstrating key concepts such as variability and bias. An alternate approach that is used in the University of Edinburgh Medical School is to use a self-tutoring work book. The work book is supplemented by a small number of formal lectures, and by small group tutorials [5].

With the introduction of more integrated medical courses, there is potential to make the relevance of statistics far more obvious. For example, if a basic practical class in physiology was based around the measurement of blood pressure and heart rate before and after exercise, then there would be great scope to incorporate a statistical component looking at issues such as observer variability (*see* **Observer Reliability and Agreement**), **bias**, graphical representation of data (*see* **Graphical Displays**), and **correlation** and **association**. Moreover, if experienced statisticians were involved more actively in teaching which was integrated with other medical disciplines, it would help to ensure that bad practices were not being promoted by teaching staff who were inexpert in statistics.

An issue to consider is the role of computers in teaching medical statistics. There are two aspects to this; namely, the use of computers as a tool for data handling and statistical analysis, and the use of computers to deliver teaching materials. I would see the former as a low priority for undergraduate courses, but computer-assisted learning might well have a role in teaching even very large classes. One commercial package, for example, is *Statistics for the Terrified* (Version 3, Radcliffe Medical Press Ltd, Abingdon, UK), which could be a complement to a series of lectures.

Postgraduate

Teaching at a postgraduate level can be much more flexible, as the numbers of students are more manageable. One format that I have used extensively is an introductory course with seven or eight two-hour sessions, each session consisting of a lecture followed by a practical exercise that reinforces the lecture material. Topics covered include statistics in the medical literature, looking at data, testing (*see* **Hypothesis Testing**) and **estimation**, study design, and case studies based on data provided by the students. The practical sessions have been computer-based, using the statistical package Minitab (*see* **Software, Biostatistical**). Such an approach is not without its problems, as it risks confusing the students with both the statistical concepts and the computing! However, an almost universal finding in our course assessment questionnaires is that the students find the interplay between the concepts and their practical outworking very helpful, reinforcing their understanding. It is also unrealistic to pretend that medical researchers do not have access to computers and statistical software, and so it is surely important to teach good practice such as using graphical presentations to explore the assumptions underlying a formal statistical analysis.

At this level, statistical education should be an ongoing activity rather than simply an initiation into the world of research. An introductory course can be followed up by more specialist courses that might be discipline-based (e.g. **clinical trials** in cardiology) or topic-based (e.g. systematic reviews; *see* **Meta-analysis of Clinical Trials**). As a further part of this continuing education, there is a healthy trend for medical journals to publish series of expository articles on statistical topics. The *British Journal of Cancer*, the

British Medical Journal, and the *Journal of the American Medical Association*, for example, all have a good track record in publishing statistical articles that are accessible to a general medical readership (*see* **Medical Journals, Statistical Articles in**). This not only has a direct educational effect, but such endorsement by leading journals also helps to highlight the key role of statistics in medical research.

Finally, I would also view my role as a statistical consultant as an educational opportunity (*see* **Statistical Consulting**). Whether seeing a client in a one-off advisory role, or working long-term as a full member of a multidisciplinary research group, there is ample opportunity to reinforce statistical principles.

Summary

It is clear that a knowledge of statistical techniques and the "scientific method" is crucial for both practicing clinicians and research workers. Yet there is ample evidence that as a profession we have frequently failed in our efforts to educate our clinical colleagues. Undergraduate students are confused and alienated, and published medical research continues to demonstrate a widespread and fundamental lack of understanding of key statistical principles. I have considered the situation in the UK, but the position is broadly similar in many other countries.

If we are to succeed in resolving some of these problems, then I believe that we need to focus on three areas. First, we should aim to equip all clinicians with the statistical skills necessary for day-to-day decision making, recognizing that most clinicians will only ever be consumers of medical research. Secondly, we should recognize that much research is being conducted by inexperienced research workers whose motivation is at least partly career development. This group needs to be taught primarily the principles of study design, and helped with the presentation and interpretation of their data. Thirdly, we should be committed to developing long-term working relationships with senior clinical colleagues, so that their statistical education can be extended and reinforced in the context of their own work.

GORDON D. MURRAY

Telephone Sampling

The use of the telephone for sample survey data collection requires the selection of samples of telephone numbers to identify sampling units for interviewing. The sampling techniques employed to make these selections are those used for many other problems where samples must be selected. However, several unique features of the **sampling frames**, the sets of materials useful for sample selection, have stimulated the development of sample designs specific to telephone surveys.

The available frames vary from one country to the next as telephone system characteristics vary. Since our own experience has been limited to telephone sampling frames available in the US, the discussion here concerns frames and sampling methods to select telephone households in the US. Frames and sampling methods in other countries will have similar features to those described here, although specific aspects of the frames and methods may require modification to improve the efficiency or other properties of survey operations.

Telephone sampling methods have largely developed and been applied in the context of household surveys. The methods can and have been adapted to other populations such as establishments. The present discussion is restricted, though, to sampling methods for household populations.

The presentation is divided into four major sections. Background on frames and basic telephone sampling methods are described in the next section. The following section addresses specific telephone sample designs, while the subsequent section presents estimators for the principal telephone sampling methods. The final section is a comparison of designs based on cost, **variance**, implementation, and **bias** considerations.

Frames and Basic Telephone Sampling Methods

The Telephone Household Population

Often the population of interest is broader than telephone households, seeking to include all households regardless of whether they have a telephone. To reduce the costs of data collection through the use of the telephone, investigators decide to compromise on the **target population**, defining a survey population of telephone households when in fact they seek to make inferences about all households. The disjuncture between target and survey population for many telephone surveys raises several important issues concerning noncoverage of households without telephones and the appropriateness of **inference** to a population other than the survey population.

Noncoverage of households without telephones can introduce **bias** into sample estimates. The bias depends both on the proportion of households that are not covered and the differences between telephone and nontelephone households on the characteristics of interest. Approximately 5% of US households do not have a telephone, and the percentage of persons who live in such households is even smaller. While the overall rate of noncoverage is small, and may be reassuring to some investigators, noncoverage varies substantially with a number of characteristics that may be related to variables being measured in a survey. For example, nontelephone households tend to have younger and more mobile populations and to be located in rural areas of the South of the US and in central cities. Noncoverage rates can rise to 15% or higher for some subpopulations, a level that is considered unacceptable to those who need to produce estimates for many small subgroups of the US population from the survey data.

The characteristics of nontelephone households have been examined in several reviews (see, for example, [15]). Nontelephone households tend to have higher rates of unemployment, have higher rates of smokers, and experience higher rates of crime victimization. Telephone surveys could produce biased estimates of employment, health, or social characteristics. Adjustments to telephone survey data to attempt to compensate for noncoverage may reduce the bias. The use of **poststratification**, or population control adjustments, for this purpose are discussed later.

Telephone Systems

Telephone systems vary from country to country, but there are features of the systems that are similar despite the variation. Telephone numbers are grouped into geographical areas. For example, in the US, telephone numbers consist of three parts: a three-digit area code, a three-digit prefix (or central office code), and a four-digit suffix. The area code and prefix

are established as part of an international system that extends across the US, Canada, Mexico, and the Caribbean. These numbers are not, of course, assigned at random across the entire geographic area covered by the phone system. Area codes are assigned to specific geographic regions that in the US do not, for the most part, cross state boundaries but otherwise do not correspond to political boundaries. Thus, there is a one-to-one correspondence between an area code and a geographic area. For instance, area code 313 is assigned to a region of southeast Michigan including a sizable portion of Detroit.

Prefixes are repeated across area codes, and within area codes are not generally geographically defined. However, prefixes are grouped into geographic areas called exchanges which are defined for the purposes of providing public service and maintaining the phone service. For example, the Ann Arbor exchange within the 313 area code is a geographic area roughly approximating the city of Ann Arbor and surrounding areas and is assigned more than 20 different prefixes. Households and businesses requesting a telephone service within the geographic area defined as the Ann Arbor exchange must be assigned a telephone number whose prefix is one of 20 serviced by the exchange. No other exchange within the same area code can use the prefixes assigned to the Ann Arbor exchange. There is little further geographic differentiation within most exchanges with respect to prefixes. Some exchanges with large numbers of prefixes will be divided into wire centers responsible for a subdivision of the area covered by the exchange and containing a subset of the prefixes assigned to the entire exchange.

The majority of the exchanges in the US are assigned only a single prefix. Exchanges have been until the recent past areas designated by public service commissions within which companies were able to obtain exclusive rights to provide a phone service. Service requirements are such that the land area covered by an exchange is limited, yet population density for a given exchange can vary enormously. Thus, some exchanges have very few customers, and enough numbers are available in a single prefix to assign to all customers. Other exchanges have large numbers of customers, and multiple prefixes are assigned to the exchange.

Suffixes are grouped in sets of 10 000. They are typically assigned by local telephone service personnel based on existing assignment patterns. There does not appear to be any particular system by which new customer requests for services are assigned suffixes within a prefix.

However, patterns of the assignment of suffixes within prefixes do emerge when the entire system is examined. In exchanges with multiple prefixes and larger numbers of customers, prefixes and suffixes are assigned haphazardly, depending on the availability of unassigned numbers within a prefix at the time of assignment. But in exchanges with a single prefix and a small number of customers, suffixes have been assigned in groupings to reduce the cost of assignment and to make telephone assignment easier. Older electromechanical switching equipment allowed smaller companies to assign all numbers in a single "1000-bank" of consecutive numbers all beginning with the same first digit of the four digit suffix. A company would only have to purchase a single bank of 1000 switches for its customers, thereby reducing costs. Telephone numbers in the more numerous single-prefix exchanges are thus effectively clustered, often at the 1000-bank level, as well as at the 100-bank level. Several telephone sampling methods described subsequently take advantage of this clustered assignment of numbers to improve the efficiency of identifying telephone numbers assigned to residential units.

Sampling Frames

There are four types of frame problems that arise in telephone sampling: listings on the frame that are not elements of the population (referred to as *blanks*); elements in the population for which there is no corresponding listing (*noncoverage*); listings on the frame which yield multiple elements in the population (*clustering*); and elements in the population which have two or more listings on the frame (*duplicates*). Each of these deficiencies can lead to bias in survey estimates or inefficiency in survey operations. Sampling statisticians develop selection procedures which try to reduce or eliminate bias due to these deficiencies. They also have been instrumental in finding selection procedures which reduce the inefficiencies associated with some of these deficiencies.

Three principal frames are used for telephone sampling: telephone numbers, directories, and commercial lists. The frame of telephone numbers can be created through a combination of a list of area

code and prefix combinations with randomly generated suffixes. The area code prefix combinations can be obtained for local studies from examination of local telephone directories, which are fairly up to date at the prefix level. For surveys covering larger areas than a local community, area code prefix combinations can be obtained in the US from Bell Core Research, Inc. The BCR frame is updated monthly and contains all area code and prefix combinations for the US, as well as for Canada, Mexico, and the Caribbean. The area codes and prefixes must be subset to the US to reduce the amount of screening of generated numbers for US telephone household surveys.

While the BCR frame affords virtually complete coverage of telephone households, it suffers from a substantial number of blank listings. Less than 25% of the generated numbers are assigned to residential units. It is operationally inefficient to use a simple **random digit dialing** scheme of area code, prefix, and randomly generated suffix. Other methods have been developed to take advantage of the inherent clustering of residential numbers in 1000 banks that increase the proportion of generated numbers assigned to residential units to more than 60%.

The BCR frame with randomly generated suffixes also has the disadvantage of duplicate listings. Households with more than one telephone number used for residential purposes are represented on the frame multiple times. **Probability sampling** methods require that the number of telephone numbers in a household be acquired and used to develop a compensatory weight for estimation.

Directories have been widely used as a frame for local studies. They are inexpensive to acquire for a local area, and simple list sampling methods can be used to select samples quickly, although not necessarily easily. Directory frames are difficult to assemble for wider geographic areas, with more than 5000 directories published across the US each year. Their popularity as a sampling frame is due to cost and convenience and to the lower proportion of blank listings in the directory compared to the telephone number frame: approximately 10%–15% of listings in a residential directory in the US are no longer residential.

On the other hand, directory frames suffer from noncoverage of the telephone household population due to unlisted numbers and changes in the telephone status of households. The percentage of telephone households which do not appear in directories exceeds 35% in the US, varying from low percentages (10%) in suburban and rural areas to more than 60% in some urban locations in the West such as Los Angeles. Survey designers generally do not ignore these high proportions of unlisted or out-of-date listings, and choose to use random digit dialing methods or other schemes that afford higher coverage.

Further, directories have higher levels of duplicate listings because subscribers can purchase additional listings. For example, a married couple at the same address with different surnames may choose for a small fee to appear in the directory under both names. The duplicate listing increases the chance of their telephone household being selected, which must, from a probability sampling point of view, be compensated through a weight for the household. Thus, a telephone directory has duplicate listings both because of multiple telephone numbers per household and multiple listings of the same telephone number in the directory.

Commercial firms now assemble electronic files in the US based on directories collected from across the country. Directory entries (name, address, and phone number) are either keyed or added to the file when an electronic format is available. Lists based on directories are supplemented by lists of automobile registrations obtained from approximately 30 states that release such data publicly. The combined file is subjected to processing to assign a zip code to each entry for the purposes of mailing. Several firms have taken advantage of the availability of telephone numbers in such files to create national directories and to draw and sell samples of telephone numbers from them. The commercial frames suffer from a small proportion of blank listings as well as the failure to cover unlisted numbers as well as duplicate listings described for directory frames.

Each of the three frames described here have generated different sampling methods that attempt to take advantage of strengths of the frame and reduce the impact of weaknesses in the frame. The methods are often classified as one of three types: simple list frame sampling methods suitable for directories; random digit dialing methods based on the telephone number frame; and list-assisted methods based on directories or commercial lists generating samples that include unlisted numbers as well. We do not discuss the sampling methods as applied to directories

here, but do examine the random digit dialing and list-assisted methods in the next section.

Telephone Sample Designs

All of the sampling designs discussed in this section assume the availability of a frame of telephone numbers which includes all possible telephone numbers in the target population. Very limited auxiliary information is available for the telephone numbers in the BCR frame: exchange name, geographic coordinates for the center of the exchange, and time zone. Importantly, though, the BCR frame does include new area code–prefix combinations approximately 3 months before they are added to the telephone system. Thus, in principle, the BCR-generated frame will provide complete coverage of the telephone household population but with little auxiliary information for the purposes of **stratification** or other design efficiencies.

The primary problem with commercial list frames is incomplete coverage of the telephone household population. Conversely, the primary problem with the BCR-generated frame is the inclusion of many telephone numbers which are not assigned to a household. The development of telephone sampling designs has been motivated almost entirely by a desire to develop an efficient methodology for sampling from the BCR frame.

Sample Designs Using the BCR Frame

The sample designs in this section document statistical sampling methodology for sampling residential households using only the BCR frame. Since approximately 95% of all residential households (and not only telephone households) can be linked to this frame, the researcher must give careful consideration to the question of how well the telephone population represents the target population with respect to the variables of primary interest.

Simple Random Digit Dialing (RDD). The simplest and most direct approach to utilizing the BCR frame is to select telephone numbers from the frame randomly, call the selected numbers and conduct the requisite interview for each number that is found to be connected to an in-scope household. Numbers are selected and called until the desired sample size, say n, of in-scope households is attained. As noted earlier, only about 20%–25% of the sample telephone numbers will be assigned to households, so the number of calls required, say n', will be considerably larger than n. The expected number of required calls is n/p, where p is the proportion of telephone numbers assigned to residential households. Thus, in order to account for the ineligible listing, the sample of telephone numbers from the BCR frame must be four to five times as large as the desired sample of n telephone households.

In general, the determination of the status of a telephone number is a costly matter, especially for telephone numbers not assigned to households. Frequently, a number must be dialed several times in order to determine its status. Since procedures must be specified for each type of dialing outcome, the use of the BCR list (or any list with a high proportion of spurious listing) will greatly increase the administrative and operational costs of telephone survey operations. This general subject is discussed in detail by Lepkowski [9]. For the purpose of constructing a simple cost model, let c_0 be the cost of determining the status of a number not assigned to an in-scope household, c_1 the cost of determining the status of a number assigned to an in-scope household, and c_2 the cost of conducting the survey interview. The total cost of the survey is then given by $C = n(c_1 + c_2) + (n' - n)c_0$ and the expected total cost of a simple random digit dialing survey is given by $\mathrm{E}(C) = n[(c_1 + c_2) + c_0(1 - p)/p]$. Obviously, for p in the neighborhood of 0.20–0.25, the component of expected cost due to unproductive calls, i.e. $nc_0(1 - p)/p$, will be a substantial proportion of total expected cost. The telephone designs described in the following sections were all motivated by a desire to reduce the proportion of cost due to unproductive calls.

The Mitofsky–Waksberg Design. The two-stage random digit dialing design proposed by Mitofsky [10] and more fully developed by Waksberg [17] has been so widely employed in telephone surveys that it has become nearly synonymous with RDD telephone surveys. The method capitalizes on the clustering of telephone numbers assigned to residential households within banks of consecutive telephone numbers. As noted above, only about 20%–25% of the numbers in the BCR frame are assigned to households; however, among banks of 100 consecutive numbers with at least one number assigned to a household,

over 60% of the numbers are assigned to residential households. Clearly, if the 100-banks with one or more residential numbers could be identified and if sampling were restricted to those banks, then the proportion of unproductive calls could be substantially reduced.

The Mitofsky–Waksberg technique starts by grouping the numbers in the BCR frame into 100-banks by using the area code, the three-digit prefix, and first two digits of the suffix to specify each bank. In the first stage 100-banks are selected at random, with replacement (*see* **Sampling With and Without Replacement**), and a telephone number within the bank is selected at random and dialed. If the selected number is found to be eligible, then the bank is retained for second-stage sampling. The process is continued until a specified sample of m 100-banks is attained. Within each retained 100-bank, telephone numbers are selected at random, without replacement, until a total of k eligible numbers (including the original number used to retain the 100-bank) have been identified.

Thus, the Mitofsky–Waksberg technique utilizes a two-stage design where 100-banks are selected – with probability proportional to number of eligible telephone numbers (*see* **Sampling With Probability Proportional to Size**) – in the first stage and a fixed-size sample of eligible households is selected in the second stage. Thus, the sample of $n = mk$ eligible households is selected with equal (but unknown) probability. The efficiency of the Mitofsky–Waksberg technique derives from the fact that the eligible telephone numbers are concentrated in a relatively small proportion of the 100-banks. Letting t be the proportion of 100-banks with no eligible numbers, then the total expected number of calls is $n[1 - t(k-1)/k]/p$ and the expected total cost is

$$\mathrm{E}(C) = n\left\{(c_1 + c_2) + \frac{c_0[1 - p - t(k-1)/k]}{p}\right\}.$$

Clearly both the expected number of calls and the expected cost decrease as k increases. Nationally, t is in the neighborhood of 0.65, so even modest values of k can lead to substantial cost savings.

Although the Mitofsky–Waksberg technique offers an elegant method to improve telephone survey efficiency, there are practical problems. The most obvious is that some 100-banks may have fewer than the requisite k eligible households, in which case all numbers in the bank will, of necessity, be called. Even then, compensatory weighting will be required. Another problem is that it is not always possible to determine accurately the eligibility status of a selected number. In the first stage this may lead to the incorrect inclusion or exclusion of 100-banks. In the second stage, some numbers may still be unresolved at the end of the survey period, so that fewer than k eligible households are identified for the bank. Another more subtle, problem is intrabank **correlation**, which is discussed in more detail in a later section.

The Potthoff Design. The design suggested by Potthoff [11] is similar to the Mitofsky–Waksberg design, except that eligibility is extended to a broader, larger class of telephone number which he termed *auspicious* numbers. Typically the auspicious numbers include not only the residential household numbers, but also ring-without-answer numbers and other results for which the residential status is unknown. This broader definition reduces the amount of screening needed for the first stage and the amount of replacement required at the second stage. Another innovative development by Potthoff [11, 12] specifies that $c \geq 2$ numbers be selected per bank in the first stage. Sampling in the second stage depends on the number of auspicious numbers observed in the first stage, but this is not discussed in detail here.

The Potthoff sampling design yields an equal probability sample of eligible numbers. Replacement is required for only a small number of selected prefix areas and it reduces ambiguities about the status of numbers dialed at the first stage. Also, as c increases, the chances of obtaining a bank that will be exhausted in the second stage are reduced.

Implementation of the Potthoff design requires knowledge about the proportion of auspicious numbers that are actually eligible numbers in order to determine the appropriate sample size. The administrative structure is more complex and the training requirements are increased for this procedure relative to the Mitofsky–Waksberg.

Sample Designs Utilizing Published Residential Telephone Numbers

As discussed in the first section, lists of published residential telephone numbers for the entire US are available from several vendors. Since 85%–90% of the telephone numbers on these lists are connected

to residential households, a straightforward random or systematic selection of numbers from such a list would be much more efficient than the designs used for sampling the BCR list. Unfortunately, the typical directory-based list only includes about 70% of the residential telephone households. Comparisons of telephone households with and without published numbers indicates that substantial bias may result if households without published numbers are omitted from the sampling frame [2]. The designs discussed in this section attempt to capitalize on the efficiency inherent in directory-based sampling while extending the coverage of the design to include the entire residential telephone population.

Designs Based on Plus Digit Dialing. Plus digit dialing is a directory-assisted procedure in which a sample of telephone numbers is selected from the directory and an integer is added to the suffix of the selected number. For instance, in plus-one dialing the integer "one" is added to the suffix of each number selected from the directory. The resulting sample of telephone numbers generally includes both listed and unlisted numbers; in addition, it yields a higher proportion of productive numbers than does the simple RDD design. Unfortunately this procedure has a number of theoretical problems. In general, the numbers in the target population have unequal and unknown probabilities of selection. In fact, some of the unlisted numbers may have a zero probability of selection unless the unlisted numbers are evenly mixed among the listed numbers. Such a mixing phenomena is, at best, difficult to verify. Generalizations of this design in which the last d digits (two or more) are replaced by a randomly generated d digit number have been suggested.

A closely related design, based on half-open intervals of telephone numbers, was suggested by Frankel & Frankel [5]. In numeric-order directories a cluster is defined to consist of a listed telephone number together with all numbers up to, but not including, the next listed number. A sample of clusters is selected from the directory by simply selecting a **simple random sample** of telephone numbers from the directory. This method achieves known, nonzero, probabilities of selection for all telephone households; however, the potentially large variation in cluster size can introduce formidable operational problems. Furthermore, this method is subject to estimation difficulties as cluster size and sample are both random variables. This basic design can be modified for use with alphabetical-order directories, but in this case the theoretical and operational problems are compounded by reporting error problems.

A Design Based on Two-Stage Sampling. A two-stage sampling design, utilizing a directory list, was proposed by Sudman [14]. This procedure, which was originally suggested by Stock [13], uses 1000-banks of telephone numbers (which are identified by the first six digits of the telephone number) as the first-stage sampling unit. The selection of 1000-banks is similar to the first-stage selection in the Mitofsky–Waksberg method except that the directory of listed numbers is used to select the first-stage sample. Thus, the probability of selection in the first stage is proportional to the number of listed numbers in the 1000-bank. In the second stage, numbers are selected until a predetermined fixed number of listed numbers are selected, and interviews are attempted for households with both listed and unlisted numbers. It should be noted that unlisted numbers in 1000-banks with no listed number have zero probability of selection, but in most cases this is not a serious problem. Of more concern is the fact that the determination of listing status often depends on a respondent report which can be in error; however, use of a directory in reverse telephone number order can eliminate this source of error.

Unlike the Mitofsky–Waksberg method, the Sudman procedure will produce unequal-size clusters of sample telephone households, although the variation in cluster size is usually not very large. Also, the potential for exhausted clusters exists, but with 1000 numbers (instead of 100 numbers, as in the Mitofsky–Waksberg method) this is of minor concern.

Designs Using Both the BCR Frame and Published Telephone Numbers

It should be noted that the designs discussed earlier require only the BCR frame, while those just discussed require only a published list of residential telephone numbers. The designs discussed in this Section require both. The basic idea behind these designs is to unite directly the desirable coverage properties of the BCR frame with the relatively high sampling efficiency of a frame of listed telephone numbers.

Dual Frame Designs. An RDD sample of n_B telephone households is selected from the BCR frame and simultaneously a sample of n_D telephone households is selected from the directory list frame. Letting n'_B and n'_D be the respective number of calls required to achieve the desired sample sizes, the cost of the dual frame design is given by

$$C = (n_B + n_D)(c_1 + c_2) + c_0(n'_B + n'_D - n_B - n_D).$$

The expected cost of a dual-frame survey is given by

$$E(C) = n\left\{c_1 + c_2 + c_0\left[\frac{\lambda(1-p_B)}{p_B} + \frac{(1-\lambda)(1-p_D)}{p_D}\right]\right\},$$

where $n = n_B + n_D$ is the total sample size, $\lambda = n_B/n$ is the proportion of the total sample allocated to the BCR frame, p_B is the proportion of telephone numbers in the BCR frame assigned to residential households, and p_D is the proportion of telephone numbers in the directory frame assigned to residential households. As p_B is in the neighborhood of 0.20–0.25 and p_D is usually in the neighborhood of 0.80–0.85, the expected cost (for a fixed total sample size n) will decrease as λ decreases.

There are several possible ways to combine the data from the two frames for estimation. In general, dual-frame estimators are more complicated than the estimators for the previously discussed designs. Groves & Lepkowski [6] provide a detailed discussion of the issue of dual-frame estimation and the problem of sample allocation to the two frames so as to attain the minimum cost for a specified **variance**.

To implement dual-frame methodology, the directory status (i.e. listed or unlisted) of each residential household from the BCR sample must be known. To avoid using potentially unreliable respondent reports regarding their listing status, numbers selected from the BCR frame can be matched to the directory list at the time of sample selection. If the directory frame contains addresses for the listed numbers, then it is possible to send advance letters for the purpose of improving response rates. In general, the dual-frame design requires a sophisticated administrative operation; also, costs may be increased by the need to match the BCD sample to the directory frame and by the use of a more complicated estimator. The benefits of a higher response rate should more than offset the costs of advance letters.

Directory-Based Stratification. For this design the directory list is used for the purpose of stratifying the BCR frame so as to improve sampling efficiency. In a typical application, the directory list is used to identify all 100-banks in the BCR frame with one or more directory listed telephone numbers. The BCR frame is then partitioned into two strata; one stratum contains all telephone numbers in 100-banks with one or more listed numbers and the other stratum contains all other numbers. The first stratum is often referred to as the high-density stratum, while the second is referred to as the residual stratum. Simple RDD samples are then selected from each stratum, with a much larger sample selected from the high-density stratum. The basic strategy behind this design is the same as for the Mitofsky–Waksberg method, i.e. telephone numbers for residential households tend to be highly clustered within 100-banks with listed numbers, so if banks containing such telephone numbers can be identified and sampled at a higher rate, then sampling efficiency can be greatly improved. Casady & Lepkowski [3] found that at the national level the proportion of the BCR frame assigned to the high-density stratum would be approximately 0.38 but it would contain about 95% of the numbers assigned to residential households. Thus, the proportion of numbers in the high-density stratum assigned to households is approximately 0.55, while the proportion of numbers assigned to households in the residual stratum is only about 0.02.

Assume that an RDD sample of n_1 telephone households is selected from the high-density stratum and that a sample of n_2 telephone households is selected from the residual stratum. Then, the cost for the stratified design is given by

$$C = (n_1 + n_2)(c_1 + c_2) + c_0(n'_1 + n'_2 - n_1 - n_2),$$

where n'_1 and n'_2 are the respective numbers of calls required to achieve the desired sample sizes. The expected cost of the stratified sample is

$$E(C) = n\left\{c_1 + c_2 + c_0\left[\frac{\gamma(1-p_1)}{p_1} + \frac{(1-\gamma)(1-p_2)}{p_2}\right]\right\},$$

where n is the total sample size, $\gamma = n_1/n$ is the proportion of the total sample allocated to the high-density stratum, p_1 is the proportion of telephone

numbers in the high-density stratum assigned to residential households, and p_2 is the proportion of telephone numbers in the residual stratum assigned to residential households. As p_1 is in the neighborhood of 0.55 and p_2 is usually in the neighborhood of 0.02, the expected cost (for a fixed total sample size n) will decrease as γ increases. The allocation of the sample to the strata to minimize the cost for a fixed variance (or minimize the variance for a fixed cost) is discussed in detail in [3].

The probability of selection is known, positive, and equal within a stratum, so the estimation of population totals is straightforward. The estimation of a population **mean** at the stratum level is also straightforward, but the estimation of the overall population mean requires that the total residential telephone population be estimated and then a ratio estimator (*see* **Ratio and Regression Estimates**) be used to estimate the population mean. A more detailed discussion of estimated means and variances is given later.

Under the relatively simple cost model given above, this design compares favorably with the Mitofsky–Waksberg design. In practice, directory-based stratification with simple RDD sampling within stratum has proven to have an advantage with respect to implementation and administration. There are two costs associated with this design that are not included in the simple model: the cost of the commercial list itself and the cost of stratifying the BCR frame. The cost of the commercial list will vary with vendor and with time, but for any large-scale, continuing survey operation this should be a relatively minor cost component. Both the costs cited above are fixed costs and can be amortized over multiple studies to reduce greatly the impact on any single study.

Directory-Based Truncation. This approach is really a special case of the preceding one in that no sample is allocated to the residual stratum, i.e. the BCR frame is truncated by removing the residual stratum. The greatly increased hit rate, together with the other advantages of the directory-based stratification design, make this an extremely attractive approach. The obvious disadvantage is that not all of the target population is accessible when the frame is truncated. In the example given above, approximately 5% of the telephone population will not be covered by the truncated frame. However, experience has indicated [1] that for many variables the out-of-scope population is very similar to the target population, so that very little bias results from truncation. As previously noted, approximately 5%–7% of the household population is not included in the telephone population, and any additional bias due to truncation of the BCR frame is probably minimal.

Estimation

The probability features of these designs must be taken into account in the computation of estimates from the samples. The basic principles of such estimation are described briefly here for means (and by implication, for proportions) and their sampling variances. In addition, poststratification, or population control adjustment, is in some cases applied to telephone survey data to attempt to adjust the telephone household sample to the distribution of all households.

Estimating Means

For the simple RDD design, let $\overline{Y}_{\mathrm{RDD}}$ be the simple mean of the n observations of the household variable y. Similarly, let $\overline{Y}_{\mathrm{MW}}$ be the simple mean of the mk observations under the Mitofsky–Waksberg design. Both $\overline{Y}_{\mathrm{RDD}}$ and $\overline{Y}_{\mathrm{MW}}$ are design-unbiased for the population mean μ; furthermore, $\mathrm{var}(\overline{Y}_{\mathrm{RDD}}) = \sigma^2/n$ and $\mathrm{var}(\overline{Y}_{\mathrm{MW}}) \cong (\sigma^2/mk)[1 + \rho(k-1)]$, where σ^2 is the population variance and ρ is the intra-100-bank correlation for the variable y.

The estimation of the population mean for the directory-based stratified designs is somewhat more complicated. Sampling within stratum is RDD, so $\overline{Y}_h$ (the simple mean of the n_h observations from the hth stratum) is unbiased for the stratum population mean μ_h. It follows that $Y'_{\mathrm{t}} = \sum_{h=1}^{H} N_h(n_h/n'_h)\overline{Y}_h$ is approximately unbiased for the population aggregate of the y values for telephone households and $N'_{\mathrm{t}} = \sum_{h=1}^{H} N_h(n_h/n'_h)$ is approximately unbiased for the total number of telephone households, say N_{t}. Thus, the ratio estimator, $\overline{Y}_{\mathrm{Strat}} = Y'_{\mathrm{t}}/N'_{\mathrm{t}}$, is approximately unbiased for the population mean and

$$\mathrm{var}(\overline{Y}_{\mathrm{Strat}}) \cong \sum_{h=1}^{H} \frac{z_h^2\sigma_h^2[1 + (1-p_h)\lambda_h]}{n_h},$$

where p_h is the proportion of telephone numbers in the hth stratum assigned to residential households, z_h

is the proportion of the telephone household population included in the hth stratum and $\lambda_h = (\mu_h - \mu)^2/\sigma_h^2$.

Several other statistical issues should be kept in mind when utilizing telephone designs:

1. In general, ratio estimators are required for estimating subclass means, in which case the relatively simple variance expressions above are not applicable.
2. The designs above yield samples of households, not persons. If persons are selected within households then additional weighting and more complex estimators are required.
3. To have unbiased estimators, the weights of households with multiple telephones must be adjusted to account for their higher probability of selection.
4. The estimators above are based on the use of random digit dialing to achieve fixed sample size. This requires that the status of all numbers selected be determined, which, in turn, requires careful record keeping and close supervision. Because fixed sample sizes are required for each retained 100-bank, the Mitofsky–Waksberg method is more complex and thus the need for tight control is even more important.

Estimating Sampling Variance

For the purpose of estimating $\text{var}(\overline{Y}_{\text{RDD}})$, we let Y_i be the value of the variable y for the ith household selected. An unbiased estimator for $\text{var}(\overline{Y}_{\text{RDD}})$ is given by $\widehat{\text{var}}(\overline{Y}_{\text{RDD}}) = \hat{\sigma}^2/n$, where

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^{n}(Y_i - \overline{Y}_{\text{RDD}})^2}{n-1}.$$

For the Mitofsky–Waksberg sampling we let Y_{ij} be the value of the variable y for the jth selected household in the ith retained 100-bank. An unbiased estimator for $\text{var}(\overline{Y}_{\text{MW}})$ is given by

$$\widehat{\text{var}}(\overline{Y}_{\text{MW}}) = \frac{1}{m}\frac{\sum_{i=1}^{m}(\overline{Y}_i - \overline{Y}_{\text{MW}})^2}{m-1},$$

where

$$\overline{Y}_i = \frac{\sum_{j=1}^{k} Y_{ij}}{k}.$$

For the stratified design we let Y_{hi} be the value of the variable y for the ith household selected in the hth stratum. Applying the **linearization** technique to the ratio estimator $\overline{Y}_{\text{Strat}}$ yields the variance estimator

$$\widehat{\text{var}}(\overline{Y}_{\text{Strat}}) = \sum_{h=1}^{H} \frac{\hat{z}_h^2\hat{\sigma}_h^2[1 + (1-\hat{p}_h)\hat{\lambda}_h]}{n_h},$$

where

$$\hat{p}_h = \frac{n_h}{n_h'},$$

$$\hat{z_h} = \frac{N_h\hat{p}_h}{N_t'},$$

$$\hat{\sigma}_h^2 = \frac{\sum_{i=1}^{n_h}(Y_{hi} - \overline{Y}_h)^2}{n_h - 1},$$

and

$$\hat{\lambda}_h = \frac{(\overline{Y}_h - \overline{Y}_{\text{Strat}})^2}{\hat{\sigma}_h^2}.$$

Although results are not given in detail, the linearization technique can also be used to derive estimators for the variance of the ratio estimators required for subclass means.

Poststratification

In traditional sampling theory, poststratification arises when the variables to be used to create strata are not available at the time of selection. That is, one may be interested in partitioning the population into G poststrata using variables collected during the survey. As under proportionately allocated stratified sampling, improvements in precision are possible with suitable modification to variance estimation. Poststratification requires that for each sample element the poststrata be known and that poststratum weights, say W_g, are available for each poststratum. The poststratum weights must come from an outside source such as a **census**, census projections, or administrative records. For example, poststrata based on age and

gender may be created for the respondents if suitable population counts or proportions W_g can be found for age and gender groups in the population. In telephone sampling, poststratification often adjusts not to the population residing in telephone households, but rather to the population residing in all households. This form of poststratification is applied to obtain estimates that have, in a certain sense, been adjusted to the distribution of the population in all households and not just telephone households.

In summary, poststratification is applied as follows:

1. Sort the sample into G poststrata based on some observed characteristic(s).
2. Obtain sample weights W_g for the population, typically from an outside source such as a larger survey, census or census projection data, or administrative records.
3. Compute the means $\overline{Y}_g$ for the characteristic of interest separately for each poststratum and compute the overall mean $\overline{Y}_{\text{ps}} = \sum_{g=1}^{G} W_g \overline{Y}_g$.
4. For variance estimators, use

$$\widehat{\text{var}}(\overline{Y}_{\text{ps}}) \cong \frac{1}{n}\left[\sum_{g=1}^{G} W_g S_g^2 + \sum_{g=1}^{G} W_g(1-W_g)\frac{S_g^2}{N_g}\right]$$

or, alternatively,

$$\widehat{\text{var}}(\overline{Y}_{\text{ps}}) \cong \frac{1}{n}\sum_{g=1}^{G} W_g S_g^2\left[1+\frac{1-W_g}{N_g}\right],$$

where S_g^2 is an estimator for the within-poststratum element variance, and N_g is the population size for poststratum g. The form of the estimators S_g^2 will depend on the sample design.

In almost all practical situations the poststratified estimate $\overline{Y}_{\text{ps}}$ will have smaller variances than the estimated mean without the poststratification.

Poststratification is also often referred to as population-control adjustment. Generally, poststratified weights are applied at the element level, and weighted estimates computed using the poststratified weights are "adjusted" to the outside distribution represented by the W_g. In the case of the RDD design the effects of this adjustment can be seen more clearly if we reexpress the poststratified estimate of the mean as follows. Let r denote the number of respondents in the sample and r_g denote the number of respondents in the gth poststratum. In addition, let Y_{gi} denote the value of characteristic Y for the ith respondent in the gth poststratum. Then the poststratified mean can be written in terms of element weights w_{gi} as follows:

$$\begin{aligned}
\overline{Y}_{\text{ps}} &= \sum_{g=1}^{G} W_g \overline{Y}_g = \frac{\sum_{g=1}^{G} N_g \overline{Y}_g}{N} \\
&= \frac{\sum_{g=1}^{G}\left(\frac{r}{N}\right)\left(\frac{N_g}{r_g}\right)\sum_{i=1}^{r_g} Y_{gi}}{\sum_{g=1}^{G}\left(\frac{r}{N}\right)N_g} \\
&= \frac{\sum_{g=1}^{G}\sum_{i=1}^{r_g} w_{gi} Y_{gi}}{\sum_{g=1}^{G}\frac{N_g/N}{1/r}} \\
&= \frac{\sum_{g=1}^{G}\sum_{i=1}^{r_g} w_{gi} Y_{gi}}{\sum_{g=1}^{G}\sum_{i=1}^{r_g}\left(\frac{1}{r_g}\right)\frac{N_g/N}{1/r}} = \frac{\sum_{g=1}^{G}\sum_{i=1}^{r_g} w_{gi} Y_{gi}}{\sum_{g=1}^{G}\sum_{i=1}^{r_g} w_{gi}}.
\end{aligned}$$

That is, the weight w_{gi} is the ratio of the proportion in the population in the gth poststratum to the proportion in the sample in the gth stratum: $w_{gi} = (N_g/N)/(r_g/r)$. Thus, poststratification of a telephone household sample of respondents to a distribution based on all households provides a simultaneous adjustment for nonresponse and noncoverage of the households without telephones.

There are several features of poststratification for telephone samples that are important to observe. Typically, the W_g are census or other related data for all households, not just telephone households. Secondly, while the poststratification adjustment may be viewed as an adjustment for both **nonresponse** and noncoverage (*see* **Nonsampling Errors**) it is

often applied in practice after some form of nonresponse compensation through weighting. Thirdly, it may not be possible to obtain population weights W_g across a full cross-classification of characteristics for the population, but marginal distributions may be available. Raking ratio adjustment procedures can be used to generate a complete distribution of the cross-classification based on the marginal distributions. For example, population weights may be available for age and education, but not their cross-classification. Raking ratio estimation can be used to generate the cross-classification based on a "main effects" model for age and education. The raked cross-classification weights for the population are then applied to the respondent distribution to generate element-level weights as indicated above.

Comparison of Designs

Cost–Variance Tradeoffs

The cost function, together with the variance of the estimator of the population mean given before, can be used to determine the size of the within-100-bank sample size k that will minimize that expected cost for a fixed variance (or minimize the variance for a fixed cost) for the Mitofsky–Waksberg design. An explicit expression for the optimal value of k can be found in [17]. Similarly, the cost function, together with the variance of the estimator of the population mean given before, can be used to determine the sample allocation to the strata that will minimize the expected cost for a fixed variance (or minimize the variance for a fixed cost) for directory-based stratification. Explicit expressions for sample allocation can be found in [3].

Using generally accepted values of cost factors and population parameters for the simple cost models and the variance expressions cited above, Casady & Lepkowski concluded that both the Mitofsky–Waksberg design and directory-based stratification offer considerable improvement over the simple RDD design. They also concluded that on the basis of the simple cost model alone there was little difference in efficiency between the two approaches; however, if the possibility of additional bias could be tolerated, then the truncated design was by far the most efficient.

Implementation Considerations for Telephone Samples

There are a host of features of the telephone system that affect the implementation of the designs described in the preceding section. We discuss here several of the more important ones briefly.

The identification of the residential status of each telephone number generated in RDD or list-assisted samples is not always an easy process. Numbers that are answered must be checked for residential use, and those used for mixed residential and business purposes must be suitably classified (usually any residential use is sufficient to classify a number as residential). Some numbers are readily identified as nonresidential because they are not in service, and a recording clearly indicates that status. Many numbers that are not in service are not connected to a recording to indicate their status, but are connected to a "ringing machine". Thus, interviewers screening telephone numbers to determine residential status cannot distinguish residential numbers where no one is at home from numbers not currently in service.

This latter problem of numbers that repeatedly ring without answer is an important consideration in the implementation of some designs. It is difficult to manage the ring-without-answer numbers in two-stage RDD designs that require the replacement of nonresidential numbers, particularly in time-limited survey data collection periods. Many survey organizations treat ring-without-answer numbers that have been called at varying times of day and days of the week as nonresidential. If the nonresidential classification is made late in the study period, then the replacement number has a relatively short period during which it can be called. Replacements often do not get the same variation in time of day and day of week calling that can be applied to original numbers. Thus, many survey organizations now prefer sampling procedures that give them a fixed sample of telephone numbers rather than one that may generate new telephone numbers late in the survey period.

At the end of the study period, ring-without-answer numbers that have been called repeatedly must be classified as residential or not in order to close out the study. If a number has been called at a variety of times and days, then it may be arbitrarily classified as nonresidential. It thus does

not count against the response rate for the survey because it has been classified as nonsample. On the other hand, ring-without-answer numbers that have not been called enough times are typically classified as residential and nonresponding, leading to a conservative calculation of the response rate.

To overcome these difficulties, and to reduce the costs of screening telephone numbers for residential status, automated screening systems have been developed to identify at a minimum telephone numbers that are connected to recordings indicating whether they are in service. The typical recording is preceded by a "tri-tone" without any ringing of a telephone number. Proprietary hardware and software has been developed which dials telephone numbers and detects the tri-tone recording. Numbers with a tri-tone recording are dropped from further sampling. Numbers without the tri-tone will often have a "ring splash" in which the telephone will ring momentarily while the hardware disconnects the call.

Surveys that are statewide or national in scope have geographic boundaries for the population that correspond to area code boundaries. Sample numbers generated within the sample area codes will be assigned to residences within the target geographic area. Many surveys target geographically defined populations whose boundaries do not match area code and exchange boundaries. In these cases, one may redefine the population, limiting it to that residing in specified exchanges, or one may select a sample from a set of exchanges that covers the entire geographic area but includes areas outside the target. Telephone numbers must then be screened not only for residential status but also for location of residence, based on respondent self-reporting. The classification of ring-without-answer numbers is even more problematic in these screening surveys.

Identification of duplicates in each of the frames also typically involves a respondent self-report. Responding households are asked if they have more than one telephone number assigned to the household, and, if so, the number of such numbers assigned. This self-reported number of telephone numbers through which a household may be reached is subsequently used to generate a weight for estimation. Many survey organizations also check for wrong connections and operator misdialing. Misdialed numbers are discarded, as are wrong connections, to avoid further complications in the weighting process for duplicate listings of a household.

Social science and health surveys (*see* **Surveys, Health and Morbidity**) also frequently select a single eligible person in a household for more interviewing. For example, on a survey involving marital satisfaction, a single adult will be selected to avoid contamination of responses among adults who converse about the content of the survey between interviews. Respondent selection must be done at an early stage in the interview. The procedure for objective respondent selection described by Kish [7] has been widely used in telephone surveys for this purpose, but it leads to an undesirable consequence – increased nonresponse rates. Households are reluctant to participate in a survey when the first questions are designed to obtain a roster of eligible persons living in the household. Alternative methods include a procedure described by Troldahl & Carter [16] and the nearest-birthday method (see [8] for a description). These latter procedures have been shown to be biased, but they continue to be used because they are easy to apply and avoid concerns about increased nonresponse rates.

Finally, answering machines and cellular telephones are posing increasing problems for telephone sampling operations. Answering machines do allow, for the most part, ready identification of residential units. Messages can be left asking that the household call a toll-free number, and calling of households with answering machines can be scheduled at a variety of times of day and days of week to try to reach the household at a time when a person will answer the phone. Cellular telephones pose a different problem. Are such telephone numbers residential or business? Further, the subscriber incurs a charge when they receive such calls. Cellular telephone numbers may be mixed in with other numbers with the same prefix, making identification difficult. Yet they are more readily answered than telephones at a residence. In addition, a well-trained interviewer can make arrangements to call a household at another number, thus reducing the cost to the telephone subscriber.

Bias

A critical issue in the use of the truncated frame is the magnitude of the bias introduced by dropping the low-density stratum. Various studies have shown that an average of less than 5% of the US household population are in the low-density stratum

[1, 4]. Thus it is likely that the additional coverage bias will not be substantial for many characteristics of the total population. Connor & Heeringa [4] show that the coverage bias associated with the truncated frame is negligible for economic attitude measurements. Brick et al. [1] show that the coverage bias for the sociodemographic measure is also small, although for some characteristics and for some subgroups of the population, the additional coverage bias may be large enough to be of concern. Generally, though, the empirical investigations have confirmed the speculation that the additional coverage bias associate with the truncated frame can be safely ignored.

Choice Among Alternative Designs

As indicated previously, the choice among alternative designs is largely based on a consideration of cost and error properties of each design. Typically, three basic cost factors are considered: the cost of generating the sample of telephone numbers, the cost of screening the sample, and the "convenience" of working with the sampling procedure in implementation (a cost consideration that is often difficult to quantify). On the error side, there are two principal concerns: coverage of the telephone household population and sampling variance.

If we examine three main competitors on these characteristics, we can see why organizations are today making particular choices among alternative designs. For example, it is inexpensive to generate telephone numbers in the Mitofsky–Waksberg two-stage RDD sample design. Screening is efficient in the second stage since nearly 65% of the telephone numbers are residential. The Mitofsky–Waksberg design presents a number of difficulties in implementation, including replacement of nonresidential numbers and exhausted clusters. These can be substantial inconveniences for some survey operations, and alternative methods that avoid these problems have substantial attraction. On the error side, the Mitofsky–Waksberg design does provide complete coverage of the telephone household population. Sampling variances are larger than for element sample designs because of the cluster sample selection and well-known increases in variance due to within-cluster homogeneity among sample elements. That is, design effects for Mitofsky–Waksberg samples are greater than one.

The stratified design has a somewhat different set of characteristics. The sample-generation costs can be high. The listed stratum sample can be purchased from a commercial sampling firm at a reasonably low cost per sample number, but the unlisted stratum sample requires further stratification of numbers and two-stage RDD samples drawn from each unlisted stratum. Screening costs are also higher than for the Mitofsky–Waksberg design since approximately 50% of the sample telephone numbers in the listed stratum are residential, and an even lower percentage are residential in the unlisted stratum. Given that different sampling methods are used across strata, sample selection is less convenient for the stratified design than for the Mitofsky–Waksberg design. However, the stratified design does eliminate the need to replace numbers in the listed stratum, and there will be no exhausted clusters in that stratum either. In terms of error, the stratified design does cover the entire telephone household population. Sampling variances will be smaller for the stratified design than for the Mitofsky–Waksberg design because it is element sampling, and some improvements in precision due to stratification can be expected.

The truncated design has the disadvantage relative to the Mitofsky–Waksberg and stratified designs of noncoverage of telephone households in 100-banks with no listed numbers. The level of noncoverage is low, and empirical investigations have shown that the difference for many characteristics between the covered and noncovered populations is small. Samples drawn using the truncated design are inexpensive when obtained from commercial sampling firms. The screening costs of the truncated design are intermediate to those of the Mitofsky–Waksberg and the stratified designs since approximately 50% of the generated telephone numbers will be residential. The truncated design is the most convenient among the three designs considered here since no replacement numbers are needed, and the sample is drawn only from the listed stratum; no two-stage sampling is needed for the unlisted stratum. The sampling variances of estimates should be the smallest for the truncated design since it is a stratified element sample with no cluster sampling.

The sampling practitioner is faced with a choice between designs which provide complete coverage but a number of inconveniences in selection and a design with less complete coverage but a number

of conveniences in selection. Given the empirical evidence on the size of the bias due to the non-coverage of telephone households in 100-banks without listed numbers, current practice favors the latter truncated design. That is, practitioners are choosing truncated sampling methods for telephone surveys based on a classic, although informal, cost–error tradeoff.

Teratology

Aristotle used *terata* to mean monsters, which he interpreted as the result of forces upsetting **reproduction** from its normal natural development. Thus teratology (derived from Greek *terata*, meaning monster/prodigy, + logy) became the term used in medicine and biology for the study of monstrosities and abnormal forms in man, animals, or plants as described by Warkany [17].

This article is restricted to the occurrence of these abnormal births in man. Literature on birth defects in laboratory animals exposed to pharmaceutical substances in the search for new treatments is described by Shepard [14] and Schardein [13].

The first use of the term, teratology, is generally attributed to Isidore Geoffroy Saint-Hilaire of Paris, son of Etienne, a distinguished teratologist. Teratology encompasses what are now known to be genetically inherited conditions, developmental conditions, e.g. Down syndrome, which are not inherited by any Mendelian (*see* **Mendel's Laws**) or other mechanisms, and the common birth defects or congenital malformations whose etiology is largely unknown. This very heterogeneous collection of defects affecting the newborn and children comes within the health services remit of the medical or clinical geneticist.

Historical Development

Historically, abnormal births were viewed with a mixture of curiosity and superstition and were generally regarded as a portent of ill luck. The Chaldeans used their occurrence to predict the future, as documented on clay tablets in the Royal Library of Nineveh in the reign of Ashurbanipal, King of Assyria in 700 BC. Likewise, the Romans used monstrous births for divination and also developed the concept of maternal impression whereby mental modification of expectant mothers was thought to influence their offspring. The Spartans passed a law requiring pregnant women to look at statues of Castor and Pollux so that their babies might be born perfect and strong. An ancient Egyptian anencephalic mummy was found in a sepulchre used for animals, monkeys, and sacred ibises, in the catacombs of Hermopolis. In Paris it was unwrapped by Etienne Saint-Hilaire and his assistants who found it not to be a monkey but an eighth month of gestation human fetus with anencephalus. The specimen joined the collection of the King of Prussia in Berlin. During bombing of that city in World War II the museum was hit, the collection destroyed, and this specimen disappeared.

From the time of the Renaissance onwards collections of descriptions of abnormal births were published including a text by the famous French surgeon, Ambroise Paré, an eight-volume treatise in Italian by Taruffi, German texts by Förster and Ahfeld, and Ballantyne's works in English together with the journal *Teratologia* which he set up and edited. By the beginning of this century a large number of birth defects were known, statistical methods of measuring the degree of likeness between relatives by **correlation** (co-relation) analysis had been discovered by **Galton** and the study of Mendelian and other types of inheritance was under way. From the 1950s onwards studies were made of early abortions, human cells and chromosomes, and birth defect registers (*see* **Disease Registers**) and monitoring systems (*see* **Surveillance of Diseases**) were set up.

Types of Study

Teratological investigations in humans can be classified as **descriptive epidemiological** studies, **analytic epidemiological** studies, and case reports (*see* **Case Series, Case Reports**). Descriptive epidemiological studies describe the frequency (usually the **prevalence** at birth) of congenital anomalies in a particular community and how this frequency varies by geographic area, year and month of birth, or with characteristics of person such as socioeconomic status, maternal age, and parity. This type of study usually is based on information available from existing sources such as birth certificates, **death certificates**, or hospital records.

Broadly classified, analytic epidemiologic studies include case–control and cohort studies, and clinical trials. In **case–control studies** in the field of teratology, a group of index cases (births/fetuses with anomalies, other adverse reproductive outcomes such as miscarriages) is identified and information is sought about prior exposures, often during a reference period such as periconception. A **control** series is identified on whom similar information is obtained. The purpose of the control series is to

provide information on the distribution of exposure in the population at risk of the adverse reproductive outcome under consideration. Information on the distribution of exposure is compared between cases and controls, and a measure of association, the **odds ratio**, may be calculated which closely approximates the **relative risk**. Important issues in evaluating the validity of data from case–control studies include the appropriateness of the control group or control groups chosen, and the similarity in the degree of accuracy of the data on exposures for cases and controls.

In a **cohort study** as applied to teratology, a group of women is classified in terms of exposure status at some defined point in time prior to the occurrence of the outcome of interest and are followed up to determine reproductive outcome. Exposure status may refer to the fact of exposure vs. nonexposure, e.g. work with video display units during pregnancy or with the husband or partner working in a specific occupation during pregnancy, or it may relate to degree of exposure, for example the reported intake of specific dietary factors per week. The frequency of adverse reproductive outcomes is compared between the groups, and on this basis the relative risk associated with the exposure may be calculated. Fewer cohort studies than case–control studies have been carried out because, for comparable statistical **power**, substantially greater numbers of subjects need to be studied. Another potentially important problem of cohort studies in this context is that ascertainment may be influenced by knowledge of the exposure status of the mother of the infant being examined. Studies of familial aggregation may be classified as a special type of cohort study in which the "exposure" is having an affected relative. Special techniques of analysis have been applied in some of these studies, such as **segregation analysis** and **linkage analysis**.

Another special type of cohort study is the **clinical trial**. In trials, assignment to exposure is determined by the investigator. The randomized control trial is the definitive method of evaluating interventions. If the trial is of adequate size, then the **randomization** ensures comparability of the group assigned to receive the intervention and the control group for potentially **confounding** factors, both known and unknown. A further refinement is to make both the woman receiving the intervention and those responsible for her care and that of the child unaware of whether or not she has received the intervention. This minimizes the chance that the women will change their behavior in a way that is related to the intervention and also the possible effect of knowledge of exposure status on the ascertainment of reproductive outcome (*see* **Blinding or Masking**). The only randomized trials carried out to date in the field of teratology have related to vitamin supplementation during the periconceptional period. **Nonrandomized trials** have been carried out regarding the possible preventive effect of multivitamin supplementation against recurrent NTDs and orofacial clefts.

In teratology, the number of analytic epidemiologic studies carried out is small compared with the fields of cancer or heart disease in adults.

Classification and Frequency

Classification and how this relates to morphology is fundamental to any understanding of teratology. However, this subject is complex. Unlike plant taxonomy, no Linnaeus has appeared to embrace the whole field of diverse birth defects and classify them according to any universally agreed order. The modern-day equivalents of the collections of the last century are McKusick's catalog [10] and the *Birth Defects Encyclopedia* [2]. The former is mainly concerned with genetically inherited conditions although it does include a large number of birth defects and associated syndromes. Other useful reference sources are those made by the March of Dimes Birth Defects Foundation in the US and the International Clearinghouse for Birth Defects Monitoring Systems [8].

The usual definition of an **incidence rate** is the number of occurrences of a disease that manifest in a unit of time in a known population of individuals at risk. This definition is not easy to apply to congenital anomalies, as it implies a process occurring regularly over the period of time chosen. In embryonic development, the frequency of an event in one week is unlikely to be the same as in the next week. It is more natural to think of prevalence, that is the proportion of living embryos with the condition, at a point in time or at the time of an event, such as birth. Prevalence is more simple because the denominator changes rapidly as a result of pregnancy loss, and because many congenital anomalies represent not so much something that occurs, but something that does not occur, such as fusion of the palatal shelves (cleft palate) or neural tube closure (NTDs). If it were possible to obtain complete information, then the

progress over time of a cohort of embryos could be followed, documenting depletion as a result of miscarriage and the events relating to organogenesis in the survivors.

The **cumulative incidence rate** is the total frequency of an event in a cohort of at-risk subjects up to a relevant time. There are theoretical and practical problems of estimating both the numerator and the denominator of this incidence rate. Theoretical problems concern the manifestation of anomalies throughout development. There is evidence that the mammalian embryo is capable of regeneration and of repairing itself. If these findings were applicable to man, then an apparently normal child may have shown defects at an early stage of intrauterine development, leading to underestimation of cumulative incidence. The practical problems of estimating incidence rates include pregnancy termination, undetected abortion, and problems of ascertainment. Antenatal diagnosis with selective termination of pregnancy has had a substantial impact on the numbers of births with certain types of congenital anomalies diagnosed at the time of delivery. Only the cases from pregnancies which went to term are eligible to be notified to the national birth defects monitoring scheme. Failure to include fetuses from terminated pregnancies may greatly distort the epidemiologic information, so it is now accepted practice to include fetuses with anomalies detected by antenatal diagnosis with subsequent termination of pregnancy in the estimation of the "prevalence at birth" of congenital anomalies.

Landmark Studies

Frequency and Types of Birth Defects

One of the first studies to address this lack of information about the frequency and types of birth defects throughout the world was that by the **World Health Organization** (WHO) in 1958 and later discussed at an informal meeting at Ann Arbor, Michigan, in April 1959. Stevenson and colleagues conducted a WHO supported prospective study of births in 24 centers in 16 countries and described the occurrence and types of birth defects found in stillborn and liveborn infants [16]. Outcomes relating to 421 781 pregnancies were traced based on 416 695 single births, 5022 sets of twins, 63 sets of triplets, and one set of quadruplets. A 400 page book containing basic tables for each center was published. The group recognized biases in the data, particularly in the centers which recorded hospital births only. This research demonstrated the large impact of NTDs on fetal wastage and a **correlation** between these defects and dizygous twinning (*see* **Zygosity Determination**). Consanguinity between parents increased stillbirth rates and early **infant mortality** rates, these being highest where parents are most closely related.

Vitamin A Deficiency

Why do birth defects occur? For the majority and wide spectrum of abnormalities observed, environmental factors have been identified in only a few instances. Hale observed a Duroc–Jersey sow, who received a ration deficient in vitamin A, at the Texas Agricultural Experimental Station. She gave birth on March 29, 1932, to 11 pigs, all of which were born without eyeballs [7]. Ten were alive at birth, one lived 4 days, one lived 3 hours, while all the others died within 5 minutes after birth. He postulated that the abnormalities were caused by vitamin A deficiency. The study marked the beginning of experimental teratology and led to many future studies using animal models for the experimental investigation of birth defects. The pharmaceutical industry built on this work extensively to investigate nutritional imbalances, drugs, chemicals, irradiation, and many other postulated teratogenic substances. Some 60 years later the Chief Medical Officer of the UK issued a warning that women who were pregnant or might become pregnant must not take excessive quantities of vitamin A. While this message relates to overprovision rather than underprovision, the origin of this work goes back to Hale's key paper.

German Measles

In the first 6 months of 1941 in Sydney, Australia, there were an unusual number of cases of congenital cataract. Gregg, an ophthalmologist, personally saw 13 cases [6]. He noted that as well as these babies being born with bilateral cataract, they were of small size, ill-nourished, and difficult to feed. Many had congenital heart defects. There were a few with monocular cataract which in two-thirds of cases was associated with microphthalmia. Close questioning of the mothers revealed that they had German measles

during early pregnancy. There had been a widespread and severe epidemic in Australia in 1940. Altogether 78 children with congenital cataract were ascertained and of these 68 were associated with a definite history of maternal rubella infection.

Thalidomide

At a meeting of the German Paediatric Society at Kassel in October, 1960, Kosenow and Pfeiffer presented photographs and X-rays of two infants with aplasia of the extremities and various other defects. Within a few months another doctor, Wiedemann, reported similar cases. At the Paediatric Society meeting on November 18, 1961, Lenz suggested that the drug, thalidomide, might be the cause, as it appeared in 17 out of the 20 maternal records that he had investigated [9]. The manufacturers withdrew thalidomide (trade names Contergan, Distaval, Softenon) and all other preparations containing this substance from the market on November 25, 1961. However, the damage was done. Some 129 cases were studied by Lenz at the University of Hamburg. Another 203 cases were reported to him by letter from the rest of West Germany and also isolated cases from Belgium, Brazil, England, Egypt, Israel, Sweden, Switzerland, and a few cases from the US. The much more strict enforcement of food and drugs legislation in the US (*see* **Drug Approval and Regulation**) ensured that many fewer births were affected in North America than in Europe.

Thalidomide is a derivative of glutamic acid, discovered in Germany, and first marketed in 1956. It was well tolerated, considered safe, and used as an analgesic, sedative, and hypnotic agent. By the time of the papers by Lenz & Knapp in 1962 [9], at least 2000 children with drug-induced abnormalities had been born in West Germany. Worldwide it is thought at least 8000 children had been affected by thalidomide.

Identification of the Relationship between Diet and Neural Tube Defects (NTDs) as a Paradigm of Teratological Investigation

Several features of the descriptive epidemiology of NTDs led to a dietary hypothesis for their etiology. Details are contained in [5]. There was an increased prevalence at birth of NTDs in the offspring of women of lower socioeconomic status compared with the offspring of other women. In the British Isles, and some other areas, the highest rates of anencephalus were amongst babies conceived in the spring and early summer, possibly linked to a lack of fresh vegetables in the winter. Body stores of certain nutrients are low in the spring. Improved all-year availability of various nutrients might in part explain the recent changes in seasonal pattern. It was known from the 1950s that therapeutic abortions could be induced by giving a folic acid antagonist 4-aminopteroylglutamic acid taken orally. This was interpreted to indicate that folic acid deficiency could induce abortion and possibly malformations.

A Case–Control Study

In western Australia, Bower & Stanley, using notifications to the local malformation registry in the period 1982–84 ascertained 77 infants with NTDs [1]. They were compared with two control groups each matched by date of last menstrual period: a group of 77 infants with other malformations registered in the same way, and a group of 154 normal infants. A telephone interview was conducted to obtain details of demographic and other factors. A three-part questionnaire was mailed to each mother, comprising a section on food frequencies (*see* **Nutritional Exposure Measures**) during the period from 9 months before to 9 months after the last menstrual period, a section on illness and drugs taken for nausea in pregnancy, cooking methods, changes in diet and other factors over the same period, and a 24-hour dietary record to be completed on a specified day after receipt. These data were used to assess the daily dietary intake of folate, including that provided by supplementation, and intakes of a number of other nutrients. Participation rates were very high: 93% for mothers of cases, 88% for mothers of infants with other malformations, and 84% for mothers of normal infants. A statistically significant association of reduced NTD risks with increased reported intake of total folate was observed.

A Cohort Study

Milunsky et al. [12] reported a cohort study based on information collected on women undergoing prenatal testing by maternal serum α-fetoprotein screening or amniocentesis in Massachusetts. Information on diet in the first 8 weeks of pregnancy was obtained using

a food frequency questionnaire, and on vitamin supplementation in the 3 months before and 3 months after conception, was collected by telephone interview. A total of 22 715 study subjects was available for analysis, of whom 49 had an infant with a neural tube defect. There was a statistically significant protective effect of taking multivitamins at least once a week before conception and during the first trimester, with a relative risk of 0.36 (95% **confidence interval** 0.15–0.83). The effect was almost entirely restricted to preparations containing folic acid. The relative risk associated with folic acid supplementation in the first 6 weeks of pregnancy was 0.29 (95% confidence interval 0.15–0.55). Amongst women who did not use supplements containing folic acid, the relative risk of NTDs associated with a dietary intake of more than 100 micrograms daily was 0.42 (95% confidence interval 0.16–1.15).

A Nonrandomized Clinical Trial

Smithells and colleagues carried out a multicenter nonrandomized prospective trial of periconceptional multivitamin supplementation in the prevention of NTDs [15]. They selected mothers who already had had one affected offspring. The oral tablets taken (Pregnavite Forte-F, made by Bencard) consisted of a mixture of folic acid, numerous vitamins, and a mineral supplement containing iron, calcium, and phosphorus. There were three groups. The fully supplemented group of 185 mothers, who took one tablet three times a day for at least 28 days prior to conception until the date of the second missed period, produced 178 infants or fetuses, of whom one (0.6%) had an NTD. This compared with 13 births with an NTD (5.0%) out of 260 infants or fetuses of unsupplemented mothers; a significant difference (relative risk 0.12, $p < 0.01$). There was also a third group of partially supplemented mothers defined as those conceiving within 28 days of beginning supplementation or commencing supplementation after conception but known to have missed tablets for more than one day. These results produced immediate and widespread interest.

An early and sustained criticism was why a randomized design had not been used. Smithells et al. eventually stated that they originally intended to use a double-blind randomized design (*see* **Blinding or Masking**; **Clinical Trials, Overview**) but that this protocol was rejected by three separate hospital research ethics committees. Owing to the absence of **randomization**, women therefore selected themselves into the supplemented and nonsupplemented groups (*see* **Selection Bias**). There were other criticisms. There was no true placebo group; which preparation might be effective, multivitamin or folic acid, was not clear.

A Randomized Clinical Trial

The debate for and against the need and ethical justification for a larger and valid randomized trial of folic acid supplementation continued (*see* **Ethics of Randomized Trials**). By September 1982 the UK Government had approved funding for 3 years and asked the Medical Research Council to carry out such a study.

The MRC vitamin study [11] was a randomized double-blind **prevention trial** with a **factorial design** conducted at 33 centers in seven countries to determine whether supplementation with folic acid or a mixture of seven other vitamins (A, D, B1, B2, B6, C, and nicotinamide) around the time of conception can prevent NTDs (anencephalus, spina bifida, encephalocele). Some 1817 women who had at least one previous affected pregnancy with an NTD were allocated at random to one of four groups (see Table 1).

Some 1195 had a completed pregnancy in which the status of the fetus or infant was ascertained with respect to having or not having an NTD. A known abnormality occurred in 27: six in the folic acid groups and 21 in the other two groups. This is a 72% protective effect (relative risk 0.28, 95% confidence interval 0.12–0.71). No significant protection effect was found with respect to the

Table 1 The 2×2 factorial design used in the UK Medical Research Council randomized trial of folic acid and other dietary supplementation in high-risk pregnancies

Group		Folic acid	
		Yes	No
Multivitamins	No	A	C
	Yes	B	D

Note: all women had a previous offspring with NTD and all received minerals supplement.

other vitamins (relative risk 0.80, 95% confidence interval 0.32–1.72). Of the centers, 17 were in the UK, seven were in Hungary, three in Australia, three in Canada, and one each in Israel, Moscow, USSR, and Lyon, France. The randomization was carried out by the Clinical Trials Service Unit at Oxford. Women took one capsule a day from the date of randomization until 12 weeks of pregnancy, estimated from the first day of the last menstrual period. The folic acid capsules contained 4 mg of the substance. The multivitamin groups contained various amounts of the various vitamins. The control substance consisting of minerals contained dried ferrous sulfate and calcium phosphate. There was an independent data monitoring committee (*see* **Data Monitoring Committees**) which reviewed progress every 6 months. The trial was double-blind with neither patients nor their medical attendants knowing which regime had been allocated.

There was a 2×2 factorial design:

A Folic acid and minerals.
B Folic acid, minerals and other vitamins.
C Minerals only.
D Minerals and other vitamins.

In this design the effect of folic acid is determined by comparing groups A and B together vs. groups C and D together. The effect of multivitamins is determined by comparing groups B and D together vs. groups A and C together. If it is thought that there might be a synergistic action between folic acid and multivitamins then only group B would benefit. This factorial design with 2000 participants would give a statistical power of 80% to detect a reduction in recurrence from 4% to 2% using a one-sided significance level of 0.05 (*see* **Alternative Hypothesis**). This degree of difference is similar to that observed by Smithells et al., who reported a reduction of recurrence risk from 4.7% to 0.7%. About one woman was being recruited each working day and it was thought that the trial would continue until around 1993. However, in April 1991 the data monitoring committee recommended that the trial be stopped. The results of the trial had been kept under review and assessed by **sequential analysis** for which the cumulative difference between the number of NTDs occurring in the folic acid and nonfolic acid groups was plotted against the total number of NTDs occurring in the study.

By April 12, 1991, results showed that this difference had passed the preset lower boundary in the sequential analysis. At this point 1817 women had been randomized and findings were known on 1195 informative pregnancies. The findings were very clear and showed a significant beneficial effect specific to folic acid supplementation. This important trial was based on measuring the reduction in recurrence risk. Roughly, only 5% of mothers who produce offspring with NTDs have previously had at least one affected birth. The great majority, about 95% of mothers who produce NTD births have only one such occurrence.

This key question of whether a periconceptional vitamin supplementation with folic acid or multivitamins would prevent the first occurrence of NTDs in a similar fashion was studied by Czeizel & Dudás in Hungary and reported in 1992 [3]. They randomized women in two groups. Some 2104 women received the folic acid and vitamin supplement and 2052 women received a trace element supplement which contained copper, manganese, zinc, and vitamin C. Birth defects were significantly more prevalent in the group receiving the trace element supplement compared with the folic acid and vitamin supplement group (22.9 per 1000 and 13.3 per 1000 births, respectively; $P = 0.02$).

The mechanism whereby folic acid supplementation in the periconceptional period reduced the occurrence and recurrence risk of NTDs has not been determined. It is clear that supplementation does not act to correct a simple nutritional deficiency, because most pregnant women carrying an affected fetus have levels of folate above the deficient range. Therefore, the possibility that an abnormality in folate metabolism is responsible for a large proportion of NTDs is being investigated. Functional variants in some of the enzymes involved in folate metabolism can be identified by demonstrating differences in the genes encoding them. Three studies have suggested that homozygosity (*see* **Heterozygosity**) for the V677T mutation in the gene coding for 5,10-methylenetetrahydrofolate reductase (MTHFR), which results in a thermolabile variant of the MTHFR enzyme, is a risk factor for spina bifida.

Particular Statistical Concepts, Problems, and Techniques

It is useful to compare progress in teratology with research in another field such as cancer. In the latter,

descriptive studies have led to case–control studies of each of the common cancers, possible treatments have been identified and tested using clinical trials. In teratology these developments have not happened. There is the difficulty of direct observation, and the major problem of assessing exposure. However, compared with cancer, the interval between exposure and outcome in a fetus or newborn is relatively short and new cohorts of births are formed by the natural process of conception, gestation, and birth.

Another key problem relates to the frequency of birth defects. For example a case–control study would need at least 750 cases and a similar number of controls to detect an exposure factor which changed the incidence of any of the most common birth defects, e.g. NTDs, by a factor of 50% (*see* **Sample Size Determination**). In turn this would require a population of around 750 000 births corresponding to a total population of at least 50 million persons. This corresponds to an entire year of births in France or England and Wales and at least 2 years of births in Australia or Canada. In the MRC trial of folic acid we have noted that this required collaboration between 33 centers drawn from 14 countries. It follows that there is a great need for international collaboration.

Fundamental problems exist relating to classification (*see* **Classification, Overview**). The debate is summarized by the phrase "lumpers and splitters". Birth defects rarely, if ever, occur as an all or nothing phenomenon. Taxonomy is crucial. Further difficulties arise due to the observation of more than one defect occurring in the same individual and the large number of complex syndromes that have now been described. A systematic study of each of the major common birth defects using rigorous case–control studies has not yet been completed. Once the selection of subjects for study has been made there may be errors and **bias** in observations (*see* **Measurement Error in Epidemiologic Studies**). One of the most difficult to assess is logical and not statistical, and relates to the definition of affected individuals. Errors of measurement may occur. Bias is common, most frequently due to incomplete ascertainment.

Solutions to These Problems

Classification problems may be clarified by new and better observations and techniques. Detailed biochemical studies and possible genetic defects have been identified using DNA methods (*see* **DNA Sequences**) in the case of NTDs. The human genome project will undoubtedly provide a great deal of knowledge relating to teratology. Progress could be made by extending existing malformation registers. These should contain more accurate observations, preferably verified by experienced clinicians, more complete ascertainment of birth defects in a defined community, and in due course larger data sets. Analysis specifically of cases with malformations of more than one system may have greater statistical power to detect associations with putative teratogens if the exposure of interest is primarily associated with a pattern of multiple defects of unknown cause rather than with isolated defects.

Monitoring

Several surveillance systems for births with malformations were established after the thalidomide tragedy of 1961. Tests for statistically significant increases in observed numbers of cases as compared with baseline expected numbers are made on a monthly basis in England and Wales and Norway, on a 1, 2, 3, 6 and 12 monthly basis in Atlanta, and on a quarterly basis in the Birth Defects Monitoring Program in the US. Many of the surveillance schemes participate in the International Clearinghouse for Birth Defects Monitoring Systems. Most of these are based solely on malformations recorded in the neonatal period. There are also systems in which malformations are recorded irrespective of the age at detection. In Europe, a number of this type are included in the EUROCAT Project, a concerted action project on registration of congenital abnormalities and twins (*see* **Twin Registers**) in the European Community.

The statistical methods used have been of the following types: (i) **graphical display** of frequencies; (ii) chi-square linear trend analysis (*see* **Trend Test for Counts and Proportions**); (iii) comparison of observed numbers of cases of specific types of congenital anomalies with the numbers expected according to the **Poisson distribution**; (iv) "self-reinforcing" techniques, notably the cumulative sum ("cusum") technique and the sets method; and (v) scan analysis (*see* **Scan Statistics for Disease Surveillance**). Some comparisons of these techniques have been carried out. In applications with small denominator populations, the Poisson technique was

found to be inefficient compared with the sets method and the cusum technique. In applications with larger denominator populations, the cusum technique is somewhat more efficient than the Poisson and sets techniques. In **simulation** analysis for four specific groups of malformations, the cusum technique showed greater **sensitivity**, **specificity**, and accuracy than the sets method. One obvious limitation of these techniques, which applies to certain types of malformations only, is the difficulty of obtaining data on terminations of pregnancy in which fetuses with certain types of anomalies have been detected by antenatal diagnosis. The size of the population surveyed is a crucial issue in view of the fact that most teratogens identified to date have had a low prevalence of exposure, and the background rate of specific anomalies is low.

Clustering in Time and Space

The recognition and investigation of clusters of congenital anomalies, and particularly the assessment of whether the occurrence of **clustering** or a particular cluster is purely a chance phenomenon, leads to considerable methodological and practical difficulties. The available studies can be classified into one of three groups based on the motivation for the investigation: (i) studies carried out to test if clustering exists within a predefined population of births, in the absence of specific spontaneous reporting of clusters or a specific hypothesis concerning an environmental agent; (ii) studies carried out when the existence of the cluster has been suspected and spontaneously reported, usually either by clinicians or local inhabitants; and (iii) studies initiated because of concern about specific environmental exposures. In the 1970s, recognition of the problems of investigating spatial clustering led to investigation being focused more on the identification of time space clustering using the methods of Ederer et al. [4]. All of these approaches have been used in investigations of neural tube defects; no clear-cut evidence of clustering was found in any study.

Anticipated Developments and Unresolved Problems

Progress in teratology, as in other fields, requires accurate and perceptive observation which in turn relates to the power and sophistication of techniques and instruments available at the time. It is likely that this will be revolutionized by the new work in genome research, the identification of chromosomal differences between mothers of affected and nonaffected offspring, and in due course by the detection of how these differences are manifest via biochemical pathways or other means. The definition and identification of clusters of birth defects is unresolved and continues to be of concern. Such outbreaks are notified from time to time usually accompanied by requests for investigation. These are difficult, expensive and time-consuming and the majority so far have rarely led to finding any new cause.

The etiology of most types of congenital anomalies remains unknown. For many types of anomaly there is an elevated recurrence risk, probably due to a combination of genetic and environmental factors (*see* **Gene-environment Interaction**). Advances in molecular genetics have made it possible to **genotype** large numbers of individuals by polymerase chain reaction (PCR) techniques. This greatly simplifies the investigation of genotype–environment interaction. For example, research has identified an increased risk of orofacial clefts among individuals with the uncommon allele for transforming growth factor alpha (TGFα).

Progress is being made at finding reasons why some rare defects occur, but this has had a small effect to date on the overall burden of the common teratological defects (*see* **Burden of Disease**), which remain a major public health problem.

Textbooks in Clinical Trials

Introduction

As the number of drug, biologic, and device **clinical trials** increases at an ever-expanding rate, the number of texts discussing clinical trials seems to grow just as quickly. And just as there are a wide variety of clinical trials and aspects of clinical trials (e.g. protocol, design, monitoring, data management, regulatory, statistical analysis, and reporting results), so are there numerous texts covering these different types and aspects. Further, within each clinical trial aspect (e.g. statistical analysis), there are still a wide variety of texts. For example, some statistical texts may give an overview on how to apply standard statistical techniques to clinical trials data, while others may focus on specific topics such as analyzing **crossover** trials, **Bayesian methods** or **generalized estimating equation** (GEE) techniques. Overall, in order for anyone working with or interested in clinical trials to choose a reference text best suited to one's needs, one must first decide what one's needs are in this field. Is one new to the clinical trials field and thus interested in getting a general overview of clinical trials? Is one interested in regulatory aspects? (*see* **Drug Approval and Regulation**; Data management) Is one an entry-level **statistician in a pharmaceutical company** and wants to learn how standard statistical techniques are used to analyze clinical trials data? Is one a veteran of statistical analysis of clinical trials, but wants to learn more about a specific specialized topic?

In addition to the large amount of choices an individual has in choosing appropriate clinical trials texts, another consequence of the clinical trials boom is that more and more academic institutions are offering courses or entire programs in clinical trials. The variation in these courses mimics the variation in the types and aspects of clinical trials. There is not necessarily one course that could be considered a standard clinical trials course. As with texts, some courses may focus on introduction, conduct, ethics, components, and/or design of a clinical trial; other courses may focus on analysis. Within the different types of courses, there is not necessarily a standard syllabus that could be developed. For example, analysis courses have the following (not necessarily exhaustive) list of topics from which to choose, all of which could not be covered in a standard one semester course: Statisticians role in data management; **randomization**; **power** and **sample size** calculations; reporting results; NDA/PLA/PMA writing; application of the more common statistical techniques (**ANOVA**, **ANCOVA**, **Chi-Square**, **Mantel–Haenszel** Statistics, **Logistic Regression**, **Survival Analysis**, Repeated Measures (*see* **Longitudinal Data Analysis, Overview**)) to clinical trials; handling treatment-by-center and **treatment-by-covariate interactions**; **confounding**; the application of more complex yet now widely used statistical techniques of mixed models, GEE techniques, and **missing data** techniques (especially for dropouts); interim analyses (*see* **Data and Safety Monitoring**), group sequential methods, and **data safety monitoring boards**; crossover trials; noninferiority trials (*see* **Equivalence Trials**); analysis of safety data; **intent-to-treat** versus per-protocol analysis; **multiplicity** (multiple endpoints; multiple treatment groups; multiple looks at the data); and Bayesian methods.

Clearly, as it would not be possible for a course to cover these topics in one or even two semesters, the organizers and instructors of clinical trials courses have the not-too-easy task of first choosing the appropriate topics to cover in one course or in a set of courses, followed by the task of choosing the appropriate text to use as a reference or as a textbook. Given the wide variety of texts and courses, an instructor may have a difficult time finding a book that would be a one-to-one correspondence with the topics he or she desires to cover in a given course.

In general, whether you are a student, clinical trials professional, or an instructor, choosing references or course textbooks can be overwhelming, even after deciding upon a specific learning objective. In this article, we hope to offer guidance on appropriate textbooks or references for those interested in (a) an introduction or overview of the design and components of clinical trials; and (b) statistical analysis of clinical trial data. What follows is not a critical review of texts, since the number of texts is too numerous for such handling here. However, if this author knows of a review that does exist in journals, it is noted. Rather, what follows is a brief description of various texts discussing clinical trials and the audience for which the text is meant. Also presented is this author's judgment on whether each text might be more useful as a textbook or a reference for a clinical trial statistics course or for a clinical

trial introduction/overview/design course. Note that, again, this article focuses on various texts giving an introduction or overview of clinical trials, and on those texts focusing on analysis. The numerous other texts focusing on issues such as regulatory aspects or data management, or focusing on clinical trials in certain indications (e.g. **AIDS**, cancer) are not included here. Also, given the ever-increasing advances in the conduct and analysis of clinical trials, the concentration of this article is on clinical trials texts that have been developed or updated within approximately the last 10 years (however, a discussion of some of the books generally considered as "classics" by the statistical and clinical trial community that do not necessarily satisfy the time criterion is also given).

Discussion of Clinical Trials Texts

Table 1 gives an outline of several available clinical trials text focusing on (a) an introduction or general overviews of clinical trials, or (b) the general statistical analysis. Any text not included here must *not* be considered a reflection on the quality of the omitted text, but is rather due to the fact that the book was published after to the finalization of this report (i.e. through beginning of 2004), is not focused on design or general statistics in clinical trials in this author's opinion, was not published within approximately the last 10 years, or, despite efforts, is an oversight of the author. The table is sorted by the year of publication, with the more recent texts being listed first. Included in this table for each text is the title, author, year of publication and publisher. Also included for each text is an assessment of the level of the text (either graduate level or undergraduate level), highlights of the text's contents, this author's assessment of whether the text is more useful as a reference or textbook, the type of course where the text is most useful (categorized into two classes: introduction/overview/design, or statistics), and references for a detailed review of text, if a review is available. Note that for virtually all texts listed below, the intended audience includes both statistical and clinical researchers, where "clinical researcher" includes any nonstatistician involved in clinical trials, such as investigators and clinical trial monitors.

Note that any text listed in the table as a possibility for being used as a textbook in a clinical trials course does not necessarily imply the text has practice problems and exercises. Rather, it indicates that, in this author's (and only this author's) opinion, the text covers a relatively wide range of topics in detail, yielding sufficient quantity and quality material on which a course could be based. Unless otherwise noted, texts indicated as possible use in a clinical trial statistics course are most useful if the student has already had a one-year elementary statistics or biostatistics course. Texts indicated as possible use in as introduction/overview/ design of clinical trials often do not necessarily require such a prerequisite (nor do they usually require a medical background).

In addition to the texts listed in the table, there are numerous texts that focus on a specific statistical aspect of clinical trials (e.g. sample size; crossover designs; group sequential methods; sample size). Many of these texts are excellent references, or could be considered as textbooks for courses designed in such a specific topic, and are listed below:

Sample Size Calculation
Sample Size Calculation in Clinical Research by Chow S-C, Shao, J, Wang H (2003).
Publisher: Marcel-Dekker (This is a complete overview of sample size calculation methods for a wide variety of clinical trial scenarios; includes a discussion of sample size re-estimation in interim analyses).

Randomization
Randomization in Clinical Trials: Theory and Practice by Rosenberger WF, Lachin JM (2002).
Publisher: Wiley.

Safety
Drug Safety Evaluation by Gad SC (2002).
Publisher: Wiley.
Drug Safety Assessment in Clinical Trials by G.S. Gilbert (1993).
Publisher: Marcel-Dekker.
Review in: Biometrics (1994); 50:1231–1232;
JRSS-A (1994), 157:503.

Cross-over Trials
Design and Analysis of Cross-Over Trials, Second Edition by Kenward MG and Jones B (2003).
Publisher: Chapman & Hall/CRF.
Review in: Statistics in Medicine (1990); 9:1007;
Biometrics (1991); 47:787;
JASA (1991); 86:232.

Discussion

Whether one wants to learn more about statistical issues in clinical trials, is a clinical trials professional, or is planning or teaching a course in the design or analysis of clinical trials, the number and type of texts from which to choose is tremendous. The number of books will only increase in the future, as theory and technology further develop. Before choosing the text (or texts), the reader needs to first determine his or her objectives (not necessarily an easy task itself). After that determination, it is hoped that the above discussion and the Table 1 provide a useful guidance to those wishing to find an appropriate reference or textbook.

JOSEPH M. MASSARO

Thiele, Thorvald Nicolai

Born: 24 December, 1838, Copenhagen, Denmark.
Died: 26 September, 1910, Copenhagen, Denmark.

T.N. Thiele trained as an astronomer at the University of Copenhagen and held the position of Professor of Astronomy there from 1875 to his retirement in 1907. He worked out the **actuarial** basis for the new life insurance company Hafnia which was founded in 1872 and had Thiele as its mathematical director until 1901. Along with these activities, Thiele made deeply original contributions to mathematical statistics, described by Hald [2–4], Lauritzen [5–7] and Edwards [1].

Thiele contributed to the theory of **skew** distributions, particularly in his study of what is often called the Gram–Charlier type A distribution, and he invented cumulants (*see* **Characteristic Function**), calling them semi-invariants, and developed a theory for them, with the proposal to use empirical cumulants as estimators. He contributed importantly to linear models (*see* **General Linear Model**), using what was then a modern algebraic definition of the canonical form of the linear hypothesis and emphasizing the role of the **residuals** in **model checking**. The special cases of one- and two-way **analysis of variance** were considered separately.

In **time series**, Thiele studied a fascinating model consisting of a sum of a **regression** component, a **Brownian motion** and a white noise, as we should call it now. Along the way, he gave an attractive geometric construction and explanation of what we now call the **Kalman filter**. Lauritzen [5, 6] applied this model to the temporal development of hormone levels during pregnancy.

In estimating a **binomial** probability, Thiele made explicit use of the idea of **likelihood** using the specific Danish term "Rimelighed", which has a similar relation to "Sandsynlighed" (probability) as that of the corresponding English terms. Finally, Thiele contributed to the theory of **grouped** observations.

For a more detailed account, see [7].

Tied Survival Times

Tied survival, or failure, times frequently occur in survival studies. Although theoretically a lifetime is a continuous variable, in practice it is often measured to a degree of fineness due to measurement limitations on the way failure times are recorded, and the expense of more accurate measurements may outweigh the value of added information. If the number of ties are substantial, discrete failure time models may need to be considered. Therefore, discrete failure time methods or grouped data techniques such as life tables should be used. However, if there are only a few ties, then the regular procedures in handling continuous data may be used with some adjustment for tied observations. In the literature, adjustment for ties has been proposed and studied for various statistical procedures in survival analysis (see [1, 6, 7, 8, 9], and [10]). Here, we only discuss adjustment for ties for some common statistical procedures.

Consider the method of handling ties in the **Kaplan–Meier** or product-limit (PL) estimator of the survival function. If only one individual fails (no ties are present) at time t, then the factor for the single death in the PL estimator is $[1 - 1/Y(t)]$, where $Y(t)$ counts the number of individuals at risk at time $t-$. For tied uncensored observations, suppose d failures occur at time t. Split the times of the d failures infinitesimally so that the factor for the d failures in the PL estimator is

$$\left[1 - \frac{1}{Y(t)}\right]\left[1 - \frac{1}{Y(t)-1}\right]\cdots \times \left[1 - \frac{1}{Y(t)-d+1}\right] = 1 - \frac{d}{Y(t)}.$$

If censored and uncensored observations are tied at time t, then consider the uncensored individuals as having failed just before the censored observations.

In the k-sample test, the weighted **logrank test** statistic is

$$Z_h(t) = \int_0^t K(s)\, \mathrm{d}N_h(s) - \int_0^t K(s)\frac{Y_h(s)}{Y_\cdot(s)}\, \mathrm{d}N_\cdot(s)$$

for $h = 1, 2, \ldots, k-1$, where K is the weight function, $N_h(s)$ and $Y_h(s)$ are the number of failures during time period $[0, s]$ and number of individuals at risk prior to time s for the hth sample, respectively, and $N_\cdot = \sum_h N_h$, $Y_\cdot = \sum_h Y_h$. The covariance of $[Z_h(t), Z_j(t)]$ may be estimated consistently by

$$\hat{\sigma}_{hj} = \int_0^t K^2(s)\frac{Y_h(s)}{Y_\cdot(s)}\left[\delta_{hj} - \frac{Y_j(s)}{Y_\cdot(s)}\right]\mathrm{d}N_\cdot(s),$$

where δ_{hj} is a Kronecker delta, i.e. $\delta_{hl} = 1$ if $h = l$, and 0 otherwise. In the presence of tied observations, the covariance of $[Z_h(t), Z_j(t)]$ needs to be adjusted to

$$\hat{\hat{\sigma}}_{hj} = \int_0^t K^2(s)\frac{Y_h(s)}{Y_\cdot(s)}\left[\delta_{hj} - \frac{Y_j(s)}{Y_\cdot(s)}\right] \times \frac{Y_\cdot(s) - \Delta N_\cdot(s)}{Y_\cdot(s) - 1}\,\mathrm{d}N_\cdot(s).$$

Clearly, when there are no tied observations, $\hat{\sigma}_{hj}$ and $\hat{\hat{\sigma}}_{hj}$ coincide.

Cox's **partial likelihood** has been commonly used to estimate the coefficients, $\boldsymbol{\beta}$, in **Cox's (proportional hazards) regression model**. Let $t_1 < t_2 < \cdots < t_k$ be the k ordered event times. Let the set $\mathcal{D}_i$ consist of the d_i individuals who failed at time t_i and $\mathcal{R}_i$ be the **risk set** prior to t_i. Denote $\mathbf{s}_i = \sum_{l\in\mathcal{D}_i}\mathbf{z}_l$, where $\mathbf{z}_l$ is the covariate vector for individual l. If there are ties among event times, then the following adjusted partial likelihoods have been proposed:

1. Breslow [2] suggests a partial likelihood of

$$L_1(\boldsymbol{\beta}) = \prod_{i=1}^{k}\frac{\exp(\boldsymbol{\beta}'\mathbf{s}_i)}{\left[\sum_{l\in\mathcal{R}_i}\exp(\boldsymbol{\beta}'\mathbf{z}_l)\right]^{d_i}}.$$

2. Efron [5] proposed an alternative partial likelihood of

$$L_2(\boldsymbol{\beta}) = \prod_{i=1}^{k}\left(\exp(\boldsymbol{\beta}'\mathbf{s}_i) \Big/ \prod_{j=1}^{d_i}\left[\sum_{l\in\mathcal{R}_i}\exp(\boldsymbol{\beta}'\mathbf{z}_l) - \frac{j-1}{d_i}\sum_{l\in\mathcal{D}_i}\exp(\boldsymbol{\beta}'\mathbf{z}_l)\right]\right).$$

3. The third partial likelihood due to Cox [3] is based on a discrete-time hazard rate model. The

discrete logistic likelihood is

$$L_3(\boldsymbol{\beta}) = \prod_{i=1}^{k} \frac{\exp(\boldsymbol{\beta}'\mathbf{s_i})}{\sum_{\mathbf{q}\in\mathcal{Q}_\mathbf{i}} \exp(\boldsymbol{\beta}'\mathbf{s_q^*})},$$

where $\mathcal{Q}_i$ is the set of all subsets of d_i individuals who could be selected from the risk set $\mathcal{R}_i$ and $\mathbf{s}_q^* = \sum_{j=1}^{d_i} \mathbf{z}_{q_j}$ (*see* **Logistic Regression**).

4. The fourth alternative partial likelihood is (see [4])

$$L_4(\boldsymbol{\beta}) = \prod_{i=1}^{k} \left(\int_0^\infty \prod_{j=1}^{d_i} \left\{ 1 - \exp\left[-\left(\exp(\boldsymbol{\beta}'\mathbf{z_j}) \Big/ \sum_{l\varepsilon\mathcal{R}_i^*} \exp(\boldsymbol{\beta}'\mathbf{z}_l) \right) t \right] \right\} \times \exp(-t)\, \mathrm{d}t \right),$$

where $\mathcal{R}_i^* = \mathcal{R}_i \backslash \mathcal{D}_i$ is the set of individuals whose event or censored times exceed t_i or whose censored times are equal to t_i. It is often called exact likelihood.

Note that, when the number of ties is small, Breslow's and Efron's likelihoods are quite close. Of course, if no ties occur at the event times, all four likelihood functions reduce to the regular Cox partial likelihood.

MEI-JIE ZHANG

Time Lag Effect

The term *time lag effect* refers to the delay between the time of an intervention or exposure onset, such as the date on which a person begins smoking cigarettes, and the subsequent development of a health outcome, such as the diagnosis of lung cancer. A variety of such time lag effects are described in the article, **Latent Period**. To design and to analyze **prevention trials** efficiently, one must account for the sometimes considerable time lag between the onset of intervention and subsequent beneficial health effects.

MITCHELL H. GAIL

Time Origin, Choice of

In **survival analysis** and more general event history analysis there is often more than one relevant origin for the time to the event(s) under consideration. This problem is sometimes discussed under the somewhat unsatisfactory name "choice of time scale" – it is the *origin*, not the scale (which could be hours, years, decades, etc.), which is under debate.

Here, I briefly mention some subject matter issues as well as some technical statistical points regarding the choice of time origin. To the former I append some brief remarks on the rare occasions where alternative time *scales*, literally speaking, are relevant.

Subject-Matter Issues in Choosing Time Origin

A fundamental discussion in many epidemiologic studies of incidence and mortality, as well as the derived concepts of **prevalence** (*see* **Incidence–Prevalence Relationships**), is the **age–period–cohort** problem (also briefly mentioned in the article on the **Lexis Diagram**). In its basic version, this issue regards the decomposition of the effect on certain rates (**incidence**, mortality, lethality) of calendar time t, age a, and "cohort", i.e. time of birth $t - a$. It has been well known for many years in sociology as well as epidemiology that there are only two identifiable linear effects here (see the above entries for references; *see* **Bayesian Methods**; **Identifiability**).

Regarding *clinical* contexts, **hazards** of relapse, death, or other endpoints, often depend both on *age* and certain *duration* variables, such as time since disease onset, since primary treatment, or since onset of remission (*see* **Duration Dependence**).

In *clinical trials with staggered entry*, the substantively interesting time origin is usually duration on trial, but since the trial takes place in "real" (calendar) time, this time variable can rarely be ignored in design and analysis (*see* **Interim Analysis of Censored Data**; **Staggered Entry**).

In the examples given so far, only the time origin was under debate, and the fact that the several "time scales" all run parallel and equally fast means that apparently multivariate time representations such as the Lexis diagram may fool the uninitiated observer (see [4] and [2, Chapters 6, 31] for further discussion and the technical consequences for statistical modeling). However, in certain clinical contexts the *cumulative time on* (intermittent) *treatment* may be of central substantive interest, sometimes as a proxy for the *cumulative dose*, which may itself in some cases be treated as a time variable. Such general situations are covered in the brief discussion by Farewell & Cox [3], although their particular example concerns the choice of time origin. The considerable body of literature on **multivariate survival analysis** seems to be surprisingly modest in its discussion of classes of practical situations where the several time variables are not constrained to move in parallel [i.e. in the direction given by the vector $(1, 1, \ldots, 1)$].

Technical Statistical Issues in Choosing the Time Origin

The **semiparametric** idea in the **Cox regression model** is to fix attention on one time variable (that is, one definition of time origin) which is modeled "nonparametrically" in the *underlying* intensity, relegating other time variables to the parametric part of the model as **time-dependent covariates**. It is then useful (though surprisingly sparsely discussed in the literature, except for [2, Chapter 31]) to put some detailed thought into choosing the "underlying" time variable, usually as that for which (i) the variation in the **hazard** is unknown or is expected to be dramatic and (ii) a parametric description is less important. Other time variables yielding less dramatic variation in the hazard or requiring parametric description for interpretation purposes can more usefully be modeled in the parametric part. In many clinical studies it will be wise to choose *duration since entry on study* as the underlying variable and *age* as a time-dependent covariate. (Note that using the techniques of **delayed entry**, it is perfectly possible to choose freely.)

In the piecewise constant intensity models (often termed "**Poisson regression**", *see* **Grouped Survival Times**) all time "scales" enter symmetrically and the above complications disappear.

Arjas (*see* **Real Time Approach in Survival Analysis**) has advocated that one should always use parametric models with "real", i.e. calendar, time as time variables, and let the statistical modeling handle other time origins of interest.

A different set of problems concerns the technical analysis of **semi-Markov processes** (see [1, Examples X.1.7-8] for a survey). Here the basic problem is that, if *duration in a state* is taken as the basic time variable, then some desirable martingale properties are lost, necessitating more complicated mathematical derivation of asymptotic statistical properties.

NIELS KEIDING

Time Series Regression

Time series regression is concerned with the situation in which the dependent and independent variables are measured over time. Examples might include mortality from sudden infant death syndrome (SIDS) and environmental temperature [2], or hospital admissions and air pollution [7]. An alternative is **transfer function modeling** [1] but the advantage of regression is that the method is flexible and the interpretation familiar and straightforward.

The potential for **confounding** in time series regression is very high – many variables either simply increase or decrease over time, and so will be correlated over time [8] (*see* **Correlation**). In addition many epidemiological variables are seasonal, and this variation would be present even if the factors were not causally related. It is important that seasonality and trends are properly accounted for (*see* **Seasonal Time Series**). Simply because the outcome variable is seasonal, it is impossible to ascribe causality because of seasonality of the predictor variable. For example, SIDS is higher in winter than in summer, but this does not imply that temperature is a causal factor; there are many other factors that might affect the result, such as reduced daylight, or the presence of viruses. However, if an unexpectedly cold winter is associated with an increase in SIDS, or very cold days are consistently followed after a short time by rises in the daily SIDS rate, then causality may possibly be inferred.

Often when confounding factors are correctly accounted for, the **serial correlation** of the residuals disappears; they appear serially correlated because of the association with a time-dependent predictor variable, and so conditional on this variable the residuals are independent. This is particularly likely for mortality data where, except in epidemics, the individual deaths are unrelated. Thus, one can often use conventional regression methods followed by a check for the serial correlation of the residuals and need only proceed further if there is clear evidence of a lack of independence. For further details of parametric and semiparametric approaches to modeling confounders, see [7].

Effect of Correlated Residuals on Least Squares Estimates

If the inclusion of known or potential confounders fails to remove the serial correlation of the residuals, then it is known that ordinary least squares does not provide valid estimates of the standard errors of the parameters

For a continuous outcome, suppose the model is

$$y_t = \boldsymbol{\beta}' \mathbf{x}_t + v_t, \quad t = 1, \ldots, n, \tag{1}$$

where $v_t = \varepsilon_t - \alpha v_{t-1}$, y_t is the dependent variable measured at time t, $\mathbf{x}_t$ is a vector of the predictor variables, $\boldsymbol{\beta}$ is a vector of regression coefficients and the ε_t are assumed independent normally distributed variables with mean zero and variance σ^2. Thus, we assume that v_t is generated by an AR(1) process with parameter α (*see* **ARMA and ARIMA Models**). If we also assume that $\mathbf{x}_t$ is generated by an AR(1) process with parameter γ, then it is possible to show [4] that using ordinary least squares to estimate $\boldsymbol{\beta}$, the ratio of the estimated variance to the true variance, is approximately $(1 - \alpha\gamma)/(1 + \alpha\gamma)$. Since, in general, $\mathbf{x}_t$ and v_t are likely to be positively correlated, the effect of ignoring serial correlation is to provide artificially low estimates of the standard error of the regression coefficients and thus to imply significance more often than the significance level would suggest, under the null hypothesis of no association.

Estimation using Correlated Residuals

Given the above model, and assuming α is known, a method of generalized least squares, known as the *Cochrane–Orcutt procedure*, can be employed [3].

Write $y_t^* = y_t - \alpha y_{t-1}$ and $\mathbf{x}_t^* = x_t - \alpha \mathbf{x}_{t-1}$. We can then obtain an estimate of $\boldsymbol{\beta}$ using ordinary least squares on y_t^* and $\mathbf{x}_t^*$. However, since α will not usually be known, it can be estimated from the ordinary least squares residuals e_t by

$$a = \frac{\sum_{t=2}^{n} e_t e_{t-1}}{\sum_{t=2}^{n} e_{t-1}^2}. \tag{2}$$

This leads to an iterative procedure in which we can construct a new set of transformed variables and thus a new set of regression estimates and so on until convergence. The iterative Cochrane–Orcutt procedure can be interpreted as a stepwise algorithm for computing maximum likelihood estimators of α and $\boldsymbol{\beta}$, where the initial observation y_1 is regarded as fixed [4]. If the residuals are assumed to be normally distributed, then full maximum likelihood methods are available, which estimate α and $\boldsymbol{\beta}$ simultaneously and this can be generalized to higher order autoregressive models and fitted using, say, PROC AUTOREG in the computer package SAS [6] (*see* **Software, Biostatistical**). However, caution is advised in using this method when the autocorrelations are high, and it is worth making the point that an autoregressive error model "should not be used as a nostrum for models that simply do not fit" [6, p. 192].

Regression with Counts

Many epidemiological series consist of counts, and require **Poisson regression** rather than ordinary linear regression. Zeger [9] described a method similar to the Cochrane–Orcutt method to allow for serial correlation, and using **generalized estimating equations** to estimate the parameters.

Essentially we assume a model of the form $\mathrm{E}(Y_t) = \mu_t$, where $\mu_t = \exp(\eta_t)$ and $\eta_t = \boldsymbol{\beta}'\mathbf{x}_t$ (a **loglinear model**). A latent process $\boldsymbol{\varepsilon}$, where $\boldsymbol{\varepsilon}' = (\varepsilon_1, \ldots, \varepsilon_n)$, is assumed to generate the autocorrelation. However, conditional on $\boldsymbol{\varepsilon}$, we suppose that Y_t is a sequence of *independent* counts such that $\mathrm{E}(Y_t|\boldsymbol{\varepsilon}) = \mathrm{var}(Y_t|\boldsymbol{\varepsilon}) = \varepsilon_t\mu_t$. This type of model is likely to be found in practice since the reason for the counts being serially correlated is their mutual dependence on another, possibly unmeasured, variable. The covariance matrix is assumed to be of the form $\sigma^2\mathbf{D}^{1/2}\mathbf{R}(\alpha)\mathbf{D}^{1/2}$, where $\mathbf{D} = \mathrm{diag}(\mu_t + \sigma^2\mu_t^2)$, $\mathbf{R}(\alpha)$ is an autocorrelation matrix generated by an autoregressive model, and σ^2 is the variance of the latent process. The order of $\mathbf{R}(\alpha)$ is determined from the data and may be greater than one. Details of implementation are given in [2] and [8]. Further details of this type of model and others is given in [5].

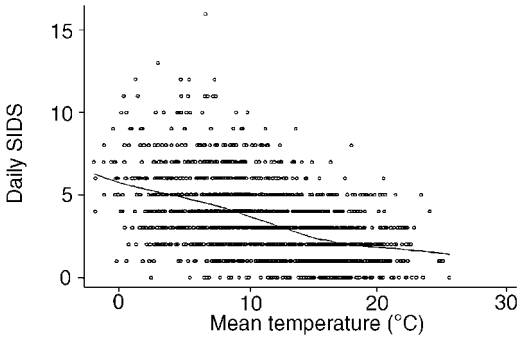

Figure 1 Daily sudden infant deaths (SIDS) in England and Wales from 1979 to 1983, with the mean temperature in London averaged over the period from two to five days earlier, with the lowess smoother plot

Example

Campbell [2] analyzed the dependence of daily deaths from SIDS in England and Wales from 1979 to 1983 on mean daily environmental temperature measured in London. A plot of the daily deaths against the temperature averaged over the period two to five days prior to the event is given in Figure 1, together with a lowess smoother plot with a bandwidth of 0.5. It can be seen that there appears to be a uniform decline in deaths with increasing temperature.

The predictor variables in the model were trend, annual and six month cycle sine and cosine terms, a weekend dummy variable, and the temperature averaged over the period two to five days prior to the event. The coefficient associated with mean temperature was -0.041 (se 0.005). We interpret this as saying that a $1\,^{\circ}\mathrm{C}$ drop in temperature is associated with a rise in SIDS by about 4%. Further investigations demonstrated that the relationship was approximately linear.

Often in practice, after controlling for seasonality and trend, the magnitude of the serial correlation is low, and estimates of the regression parameters will be little changed by incorporating serial correlation [6]. Thus, using Poisson regression on the SIDS data, having fitted annual and six-month sine and cosine terms and trend, the coefficient associated with mean temperature is -0.043 (se 0.005), which is very close to the Zeger estimate.

If the mean value for the counts is high, then methods assuming normality can be used and for this the standard software referred to earlier is available.

Time Series Similarity Measures

Introduction

Time series is the simplest form of temporal data. A time series is a sequence of real numbers collected regularly in time, where each number represents a value. Time series data come up in a variety of domains, including stock market analysis, environmental data, telecommunications data, medical data, and financial data. Therefore, time series account for a large fraction of the data stored in commercial **databases**.

One interesting problem with time series data is finding whether different time series display similar behavior. More formally, we need to define a distance (or equivalently a similarity) function between two time series (*see* **Similarity, Dissimilarity, and Distance Measure**). Such a distance function can be used to cluster a set of time series in order to discover general patterns, or to classify a new time series. Different notions of *distance* between time series have been proposed in **data mining** research. The problem is hard because the similarity model should allow for imprecise matches, be efficient to compute, and allow the design of efficient indexing structures that can be used to find the most similar time series to a query [6].

Time Series Similarity

Generally, time series similarity models can be described in the following framework:

Time Series Similarity Functions

Let $X = (x_1, \ldots, x_n)$ and $Y = (y_1, \ldots, y_n)$ be two time series with n values. Let F_1 and F_2 be functions $F_i : R^n \to R^k$, for $k \leq n$, and D be a function $D : R^k \times R^k \to [0, 1]$. Then the distance of the two time series is a function $D(F_1(X), F_2(Y))$. The design of the functions F_1, F_2, D determine the characteristics of the distance function.

Setting the Function D

The simplest form for D is the p-norm distance between two k-dimensional vectors:

$$D(X, Y) = \left(\sum_{1 \leq i \leq k} |x_i - y_i|^p \right)^{\frac{1}{p}}. \qquad (1)$$

Usually, p is either two (Euclidean distance) or one (Manhattan distance). Such a function is easy to compute, allows efficient approximation, and also allows the design of efficient indexing techniques. The main disadvantage is that it does not allow shifting of the time series in time.

Figure 1 shows how to compute the Euclidean distance of two time series (in this case, the time series have been derived from electrocardiograms). The ith value of one sequence is matched to the i-th value of the other sequence. This can result in a large error if the two sequences are out of phase.

Reference [3] introduces the technique of *dynamic time warping* to time series similarity. Dynamic time warping is an extensively used technique in speech recognition, and allows acceleration–deceleration of signals along the time dimension. We are allowed to extend each sequence by repeating elements, thus creating X', Y'. The dynamic time warping distance, $DTW(X, Y)$, is defined as:

$$DTW(X, Y) = \min_{\forall X', Y' \text{ such that } |X'| = |Y'|} L_1(X', Y') \qquad (2)$$

Figure 2 demonstrates the use of the dynamic time warping technique. All values of each time series are matched with at least one value of the other time series. However, we are allowed to extend each time series by repeating some values.

A straightforward quadratic algorithm uses a bottom-up **dynamic programming** approach, where the smaller subproblems $DTW((X_1, \ldots, X_i), (Y_1, \ldots, Y_j))$ are solved first, which are then used to solve the larger subproblems, until finally $DTW(X, Y)$ is computed.

A different technique is to find the longest common subsequence ($LCSS$) of X and Y, and set $D(X, Y) = n - LCSS(X, Y)$ [4]. The $LCSS$ shows how well the two sequences can match one another if we are allowed to stretch them but we cannot rearrange the sequence of values. It can also be computed by a bottom-up dynamic programming algorithm:

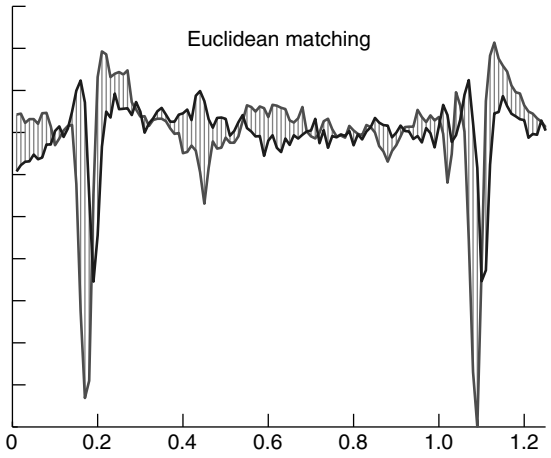

Figure 1 Using the Euclidean distance measure: the i-th value of time series X is matched to the ith value of the time series Y

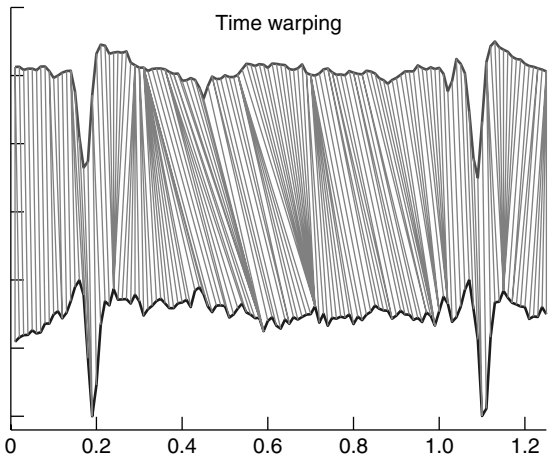

Figure 2 Using the dynamic time warping distance measure: a given value in each of the two time series can be matched to one or more consecutive values in the other time series. In the figure, the two time series have been separated vertically to make the matching clear

Given sequences $(x_1, \ldots, x_i)$, $(y_1, \ldots, y_j)$,
if $x_i = y_j$, then $LCSS((x_1, \ldots x_i), (y_1, \ldots, y_j)) =$
$\quad 1 + LCSS((x_1, \ldots, x_{i-1}), (y_1, \ldots, y_{j-1}))$
else $LCSS((x_1, \ldots x_i), (y_1, \ldots, y_j)) =$
$\quad \max(LCSS((x_1, \ldots, x_i), (y_1, \ldots, y_{j-1})),$
$\qquad LCSS((x_1, \ldots, x_{i-1}), (y_1, \ldots, y_j)))$.

Since the values are real numbers, we typically allow approximate matching. Figure 3 gives an example. The *LCSS* model allows shifting of the time series in time. One disadvantage of the *LCSS* model is that the triangle inequality does not hold, and therefore it is not formally a metric.

Setting F_1, F_2

There are many diverse proposals for what the functions F_1 and F_2 can be. They can be broken down into three main categories. However, techniques from different categories can be composed.

The first category is normalization functions: Let $\mu(X)$ and $\sigma(X)$ be the mean and variance of sequence X. The sequence X is replaced by the normalized sequence X', where

$$x'_i = \frac{x_i - \mu(X)}{\sigma(X)}. \tag{3}$$

Other similar transformations include moving averages for smoothening the time series [9, 15].

In the second case, the functions F_1 and F_2 are a specific transformation that is applied to the time series. A time series is represented as a point in n-dimensional space, and the transformation maps it to a point in a k-dimensional space ($k \leq n$). Such dimensionality-reduction techniques generally approximate the Euclidean distance of the original time series in the new space. The

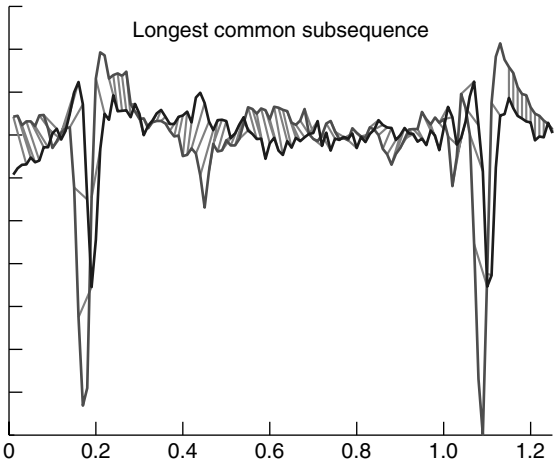

Figure 3 Using the longest common subsequence distance measure: Only similar values in the two time series are matched. Dissimilar values in one or both time series are dropped. The fraction of matched values determines the similarity of the time series

advantage of using a dimensionality reduction technique is that the distance computation is faster, and indexing structures are generally more efficient when used in lower dimensionality objects. Dimensionality reduction techniques that have been proposed include: the singular value decomposition (SVD) [12] (*see* **Matrix Computations**), the Fourier transform [1] (*see* **Fast Fourier Transform (FFT)**), the **Wavelet** decomposition [5], random projection techniques [10], FastMap [7], and Linear partitioning [13]. These techniques have specific strengths and weaknesses, making some of them better suited for specific applications and settings.

Another alternative is to define a family of functions $\mathcal{F}$, such that $F_1, F_2 \in \mathcal{F}$. The objective is to find those F_1, F_2 in $\mathcal{F}$ that minimize the distance. The distance between two time series X, Y is then

$$\text{argmin}_{F_1, F_2 \in \mathcal{F}} D(F_1(X), F_2(Y)).$$

The family of functions $\mathcal{F}$ can be global scaling, local scaling, global scaling, and different baselines.

This technique has generally been used with the *LCSS* notion of similarity. In [2], the authors develop a similarity measure that uses *LCSS*-like similarity with local scaling functions.

A simpler approach is to try and incorporate a single global scaling function with the *LCSS* similarity measure. In [4], an *LCSS*-like similarity measure is described that derives a global scaling and translation function that is independent of outliers in the data. The basic idea is that two sequences X and Y are similar if there exist constants a and b and long common subsequences X' and Y' such that Y' is approximately equal to $aX' + b$. The scale + translation linear function (i.e. the constants a and b) is derived from the subsequences, and not from the original sequences. Thus, outliers cannot taint the scale + translation function.

Probabilistic and Generative Methods

A different class of approaches to time series similarity is the class of *probabilistic and generative similarity measures*. Such measures have been studied in [8, 14]. Given a sequence X, the basic idea is to construct a probabilistic generative model M_X, that is, a probability distribution on waveforms. Once a model M_X has been constructed for a sequence X, we can compute similarity as follows. Given a new sequence pattern Y, similarity is measured by computing $p(Y|M_X)$, that is, the likelihood that M_X generates Y.

An alternate approach was undertaken by [11], who describe a general similarity framework involving a transformation rules language. Each rule in the transformation language takes an input sequence and produces an output sequence, at a cost that is associated with the rule. The similarity of sequence X to sequence Y is the minimum cost of transforming X to Y by applying a sequence of such rules. The actual rules language is application specific.

DIMITRIOS GUNOPULOS

Time Series

A time series consists of values of a variable recorded, usually at regular intervals, over a long period of time. Such data arise frequently in medical investigations; for example, weekly admissions into a hospital, monthly mortality rates for a particular disease and daily concentrations of a pollutant. The observations in such a series are usually denoted by $x_1, x_2, \ldots, x_n$, where n is the length of the series. Such data usually require special methods for their analysis because of the presence of **serial correlation**. In a series of hourly blood pressure readings, for example, a "high" reading at 1 p.m. is likely to have a certain inertia and to remain relatively high at 2 p.m. Neighboring observations in a time series will frequently be positively correlated, with this correlation declining as the time interval between observations increases. The existence of a possibly complex pattern of dependency between the observations in a time series implies that methods of analysis that assume that the observations are independent will not be appropriate.

Preliminary Analysis of Time Series

Many time series can be considered to be a mixture of the following four components:

1. A trend or long-term movement.
2. Fluctuations about the trend of greater or lesser regularity.
3. A deterministic cycle; for example, a pronounced **seasonal** component.
4. A residual, irregular or random effect.

Part of the analysis of a time series might aim to provide a description of regular or systematic variation; for example, by identifying periodic effects or cycles (*see* **Circadian Variation**). Additionally, it might be hoped to develop models for the series that allow inferences about the mechanisms generating the series and also open the possibility of making predictions about the future value of the series, i.e. **forecasting**. An essential *first* step, however, when considering *any* time series is simply to plot the observations against time. Figure 1, for example, shows a plot of the number of deaths per quarter from ischemic heart disease for males in the UK, from 1967 to 1991. Figure 2 shows the reported cases of chicken pox in New York in the years 1928–1972.

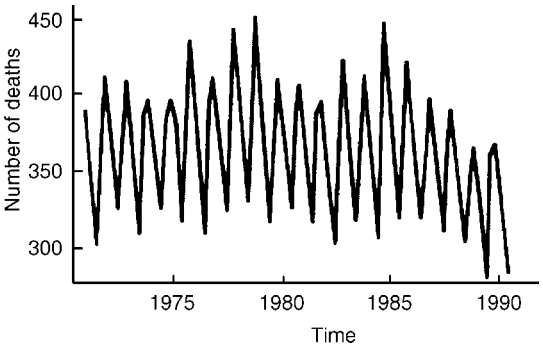

Figure 1 Number of deaths per quarter from ischemic heart disease for males in the UK – 1967–1991

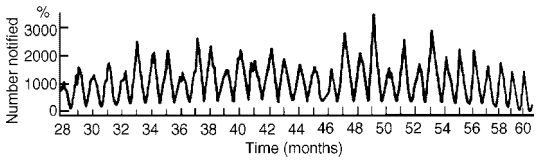

Figure 2 Reported cases of chicken pox in New York – 1928–1972

Simple plots such as those shown in Figures 1 and 2 are often valuable in highlighting qualitative features of a time series; for example, a trend, seasonality, or **outliers**, although such patterns are frequently obscured by "noise", making them less easy to detect without some formal analysis.

The simplest hypothesis that might be entertained about a time series is that it is random, i.e. a *white noise series* (*see* **Noise and White Noise**). A number of tests of randomness are available and are described in [2] (*see* **Cox's Test of Randomness**). In general, however, such tests are not applied to the original series, since, in most instances, this will clearly be nonrandom, but to the residuals arising after fitting some model or other to the series.

Stationarity

Stationarity signifies that the probability structure of a time series does not change with time. In particular, a stationary series has a constant mean and variance and a covariance structure that depends only on the difference between two time points. Many time series

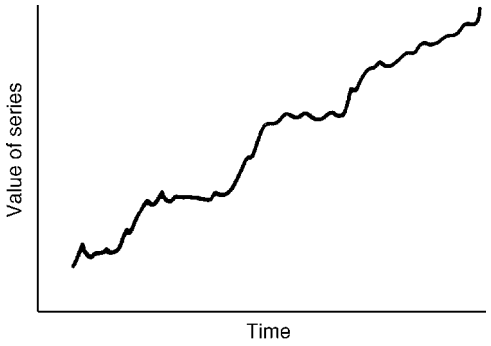

Figure 3 Time series with a trend

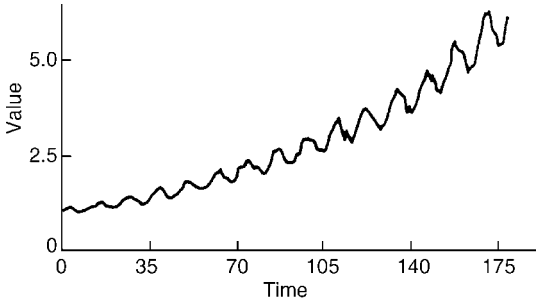

Figure 4 Time series in which variance is changing

encountered in medical studies are *not* stationary for a variety of reasons, the most common of which is the presence of a trend – see, for example, Figure 3. This feature of a series needs to be described and estimated in some way so that it can be removed before the series is analyzed further. One possibility is the use of some form of **moving average**. Another is to transform to a series of first differences,

$$z_t = x_t - x_{t-1}. \tag{1}$$

In some circumstances it might be more appropriate to take some simple **transformation** of the original series before attempting to remove any trends. If, for example, it is found that the variance is related to the mean, then a variance-stabilizing transformation would be needed. Such a series is shown in Figure 4.

Analyzing Time Series

Modern methods for the analysis for time series can be divided roughly into two classes – *frequency domain methods* and *time domain methods*.

Frequency Domain Methods

The primary aim of frequency domain methods for the analysis of time series is to identify oscillations of major importance, in the sense of explaining a large proportion of the variance in an observed series. Methods in this class are derived from the early ideas of Fourier analysis in which a series of observations is represented as a superposition of independently varying cosine and sine curves (*see* **Fast Fourier Transform (FFT)**). A typical sine wave, for example, has the form

$$x_t = A\sin(2\pi f t + \phi), \tag{2}$$

where the constant A is called the *amplitude*, f the *frequency*, and ϕ the *phase*. The curve is *periodic* with a period, $T = 1/f$. This simply means that the plot of x_t against t is the same at $t + 1/f, t + 2/f, \ldots$, etc. as at t. An example of a sine wave is shown in Figure 5.

An early tool for the analysis of time series data that used the idea of Fourier decomposition was the *Schuster periodogram* [4]. The time series observations are expressed as a sum of cosine curves of the form:

$$x_t = A_0 + \sum_{k=1}^{(n-1)/2} A_k \cos(2\pi f_k t + \phi_k). \tag{3}$$

The amplitude, A_k, and phases, ϕ_k, can be calculated from the data, with A_k indicating the importance of oscillations of period $1/f_k$ in the observed series. The periodogram is simply a plot of nA_k^2 against k. If the original series contains a well-defined cyclic component, then the periodogram can be expected to have a sharp peak at the appropriate value of k. In practice, however, such a peak is often masked because the great variability in the A_k values makes

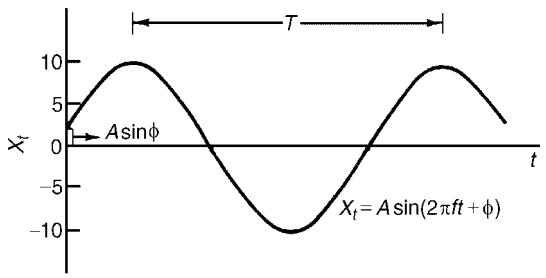

Figure 5 Sine wave

the plot extremely irregular. In other cases, apparent peaks may appear, even in the absence of genuine cycles, because one or more local maxima will seem substantially larger than neighboring values.

Most current frequency domain analyses are less concerned with the discovery of exact periodicities and more concerned with assessing how the variance of a series is distributed amongst oscillations of different frequencies by estimating the *spectrum* of the series (*see* **Spectral Analysis**). Such an approach has been most widely applied in the medical field in the analysis of EEG signals – see [1].

Time Domain Methods

The techniques used for the analysis of time series in the time domain are based on direct modeling of the lagged relationships between a series and its past. An important initial step in the search for an appropriate model for a time series is an examination of the dependence structure of the series via the *correlogram* (*see* **Autocorrelation Function**), which is a plot of the lagged correlations of a series against lag size.

The models most commonly used for time series data are those known as ARMA – autoregressive moving-average models or ARIMA – autoregressive integrated moving-average models (*see* **ARMA and ARIMA Models**). The parameters in such models can be estimated by likelihood methods. Examples of situations in which such models are of importance are:

1. Epidemiologists are often faced with assessing the relationship between a target or output series, such as the daily number of patients coming to a clinic, and explanatory or input series, such as the daily concentration of a pollutant.
2. Questions about changes in time series are frequently of great importance in medicine. An investigator might, for example, be interested in assessing how the pattern of morbidity in a population changes after an environmental accident, or in measuring the effectiveness of a campaign to make teenagers aware of the dangers of AIDS.
3. Accurate forecasts of the future values of a time series may be of great value in many areas of medicine. Public health organizations, for example, need to know what frequencies of diseases might be expected in coming years in order to plan how to allocate often limited resources.

Summary

The analysis of time series is a large and complex area. The main techniques are spectral analysis and ARMA or ARIMA models. All the main software packages have facilities for implementing both forms of analysis (*see* **Software, Biostatistical**). The **S-PLUS** package has facilities for more extensive and exotic analyses. A further software package, STAMP, developed by Koopman et al. [3], is useful for the analysis of time series using regression models in which the explanatory variables are functions of time, but with coefficients that change over time (*see* **Structural Time Series Models**).

BRIAN S. EVERITT

Time to Pregnancy

The time from initiating attempts to become pregnant until conception occurs (*time-to-pregnancy* or TTP) is gaining importance as a measure of natural fecundity [9]. This article highlights some special features in modeling and design for this special application of **survival analysis** methods.

Models for Time-to-pregnancy (TTP) Data

Statistical models for time-to-pregnancy (TTP) data belong to the general area of survival analysis. Often, the focus is on menstrual cycle as the time unit, which makes time intrinsically discrete and has motivated most authors' use of **discrete-time survival models**. However, the actual measurement is often not made in cycles but rather in months, either as a surrogate for menstrual cycles or because months are considered to be of interest in themselves, and then there would seem to be no harm in using continuous time survival models.

The statistical models need to be able to accommodate known heterogeneity between couples in the form of **covariates**, and one will often also want to incorporate residual random heterogeneity.

Let $t = 1, 2, \ldots$ be the number of menstrual cycles since "initiation", that is, since attempts at getting pregnant started, and let x_t be a vector of covariates at time t. The task is to model the discrete **hazard rate**

$$\lambda(t|x_t) = P(T = t|T \geq t, x_t), \tag{1}$$

which is the probability of becoming pregnant at cycle t, given that this did not happen before t, and given the covariates.

An early influential model by Weinberg and Gladen [10] assumed

$$\log(\lambda(t|x_t)) = x_t'\beta, \tag{2}$$

where log is natural logarithm and

$$x_t'\beta = x_{1t}\beta_1 + \cdots + x_{kt}\beta_k. \tag{3}$$

The model has the disadvantage that when β varies across $(-\infty, \infty)$, $\lambda(t|x_t)$ is not restricted to the range [0,1] of a probability. This problem was avoided by Scheike and Jensen [6] who postulated

$$\log(-\log(1 - \lambda(t|x_t))) = x_t'\beta \tag{4}$$

in line with current practice in discrete-time survival models [2]. This model may be interpreted as a grouped-time version of the **Cox regression model**.

Weinberg and Gladen incorporated *unobserved heterogeneity* in a model with no covariates by assuming that the hazard for each given couple was constant over time: $\lambda(t) = r$, and that r follows a **beta distribution** across the population. The resulting marginal hazard in the population is

$$\lambda(t) = \frac{1}{\alpha + \mu(t-1)} \tag{5}$$

with parameters α and μ given by the beta distribution. Weinberg and Gladen extended this model to accommodate covariates by postulating

$$\lambda(t) = \frac{1}{\alpha + \mu(t-1)} + x_t'\beta, \tag{6}$$

although the interpretation of a mixture across the population is then lost; indeed, the parameter β has no interpretation at the individual level, only marginally for the population (*see* **Marginal Models**).

In contrast, Scheike and Jensen [6] extended their model to incorporate a random effect R_i for couple i by assuming

$$\log(-\log(\lambda(t|R_i, x_{it}))) = R_i + x_{it}'\beta. \tag{7}$$

In this model, the individual interpretation of β is conserved. Scheike et al. [7] discussed generalizations of this model to allow several times to pregnancy per couple and connected to the current discussion of **frailty** models and **multivariate survival analysis**, including an important discussion of the interpretations of conditional versus marginal parameterizations. Ecochard and Clayton [1] generalized to a three-parameter distribution, while assuming constant baseline, and also allowed several pregnancies per couple.

Sampling Designs

The two most common and obvious designs are a **cohort** (follow-up) **study** where couples are followed forward in time from when they start attempting to become pregnant, or a **retrospective study** of pregnant women where couples are interviewed about when they started their attempt to become pregnant. A variation of the cohort study is the *historically*

prospective design where a general sample (usually of women) from the population is asked to recall their reproductive history. Below, we discuss these designs as well as the possibilities of using **cross-sectional** samples, referring to Weinberg and Wilcox [11] for a broader epidemiological discussion.

Prospective Sampling

In principle, the cohort approach leads to standard right-**censored** survival data, where the couples who have not conceived at the end of follow-up are counted as *right-censored*. Note that couples recruited into a prospective study at a known time t after initiation will have to be counted with **delayed entry** (left **truncation**) at t. In practice, prospective studies are not very common, usually rather small, and often marred by considerable self-selection problems (*see* **Selection Bias**). A particular difficulty with assessing the effect of calendar time is whether to score it at initiation, at conception (which creates difficulties at least for the censored couples), or as current calendar time along the way. The historically prospective study suffers from recall bias and also mixes experience over a long calendar time period.

Retrospective Sampling

Large TTP surveys are often retrospective, data being gathered from pregnant women. There are obvious weaknesses with these, primarily the biased sampling based on fecundity, particularly, the nonpresence of the sterile or nonfecund couples, but also under representation of the subfecund. Juul et al. [4] demonstrated how a true age-decreasing fecundity in a heterogeneous population can be made to look age-increasing by naive analysis of a retrospective sample.

However, even beyond these unavoidable difficulties, the correct analysis of retrospective TTP data is more intricate than often realized, particularly when the focus is on revealing the dramatic trends in initiation intensity, which must be behind the observed secular trends in birth rates. As an example, in a common design, the data are gathered from interviews in a fixed time window. It is then clear that if calendar time is related to initiation, long TTPs will be over represented in the early phase, short TTPs in the late phase, with intricate patterns of left and right truncations [6]. As pointed out by Jensen et al. [3], dramatic artificial temporal trends in fecundity may be generated by disregarding the effects of these truncations. These phenomena were defined away by a tacit (hardly tenable) assumption of stationarity in the classical work of Weinberg and Gladen [10], as made explicit in Weinberg et al. [8, p. 679]. Incorporation of several TTPs per couple in a retrospective design is possible through careful **likelihood** constructions; see [7] for details.

Current Durations in a Cross-sectional Sample

A simple procedure would be to ask a cross-sectional sample of a population (or subpopulation) of women whether they are currently attempting to get pregnant and if so, for how long have they attempted to do so. With this design, it would seem reasonably realistic to minimize selection bias: there is no a priori exclusion of sterile couples as in retrospective sampling and minimal self-selection in contrast to most prospective studies. This design was briefly mentioned by Weinberg and Gladen [10] and studied in some detail by Keiding et al. [5].

It may be useful to summarize the distributions involved in these three main sampling designs, as follows.

For each attempt at becoming pregnant, let T be the time to pregnancy, U the time to discontinuation without pregnancy (for reasons such as death of the woman, disappearance of partner, couple gives up trying; in some cases, the start of fertility treatment should perhaps be included), and V the time to discontinuation of follow-up since the start of the attempt. We are interested in the distribution of T. In a *prospective* design, the problem reduces to standard survival analysis with T as the time to endpoint and $\min(U, V) = U \wedge V$ the time to censoring. In the *retrospective* design (based on pregnant women), we have a complete sample from the **conditional** distribution of $T|T < U$. (Note that this situation is different from right truncation of T by U, which corresponds to observing the conditional distribution of $(T, U)|T < U$).

In the *current-duration* design, let $X = T \wedge U$ be the waiting time until termination for whatever reason, successful or not, with probability

density $f(x)$, survival function $S(x) = \int_x^\infty f(a)\,\mathrm{d}a$, and expectation $\mu_X = \int_0^\infty xf(x)\,\mathrm{d}x = \int_0^\infty S(x)\,\mathrm{d}x$, which we shall assume finite. Cross-sectional sampling takes place at some fixed time t_0, and assume that initiations happen according to a **Poisson process** in calendar time t with intensity $\beta(t)$. In the time-homogeneous situation, $\beta(t) = \beta$, which should suffice in most situations where only short calendar intervals are considered for each "cross-section", the observed experienced waiting time at t_0 ("current duration"), $Y = X \wedge V = T \wedge U \wedge V$ will be distributed as a backward recurrence time in a **renewal process** in equilibrium with renewal distribution $f(x)$, that is, the *density* of Y is

$$g(y) = \frac{S(y)}{\mu_X}. \tag{8}$$

Note in particular that $0 < g(0) < \infty$. Thus, Y has a *decreasing density* proportional to the *survival function* of X.

Time Trade-off Technique

Decisions on medical treatments and the setting of health programs involve both technical and value judgments. An important one, for example, is evaluating tradeoffs between **quality of life** and length of life or between different domains of quality of life. In recent years the concept of **utility** has been introduced into medical decision making (*see* **Decision Analysis in Diagnosis and Treatment Choice**) to help estimate the preferences that individuals attach to the consequences of various courses of action. This information is useful for decisions at the patient level (i.e. clinical decision making) and the program level (i.e. the best way of using available health care resources or economic evaluation of health care programs; *see* **Program Evaluation**).
